Heritable thrombophilias are a group of conditions characterized by an increased risk for vascular thrombosis. The mechanism of stillbirth is thought to be similar to that of APS: placental thrombosis and infarction. The most common are the factor V Leiden mutation and the G20210A mutation in the promoter of the prothrombin gene. Many retrospective case series have shown an increased risk of fetal death in women with these conditions as well as in those with deficiencies in the anticoagulant proteins antithrombin III, protein C, and protein S. The association between thrombophilias and fetal death after 10 weeks gestation is much stronger than the association between thrombophilias and recurrent early pregnancy loss (which is questionable). However, it is important to recognize that thrombophilias are extremely common in normal individuals, and most women with thrombophilias have normal pregnancies. In fact, two large prospective studies in unselected populations showed no association between the factor V Leiden and any adverse obstetric outcome, including fetal death. Thus, thrombophilias should be considered to be a risk factor as opposed to an etiology of fetal death. Women with thrombophilias and no prior obstetric complications should be reassured that they are at low risk for pregnancy complications. It is biologically plausible that thrombophilia may contribute to fetal death in cases with histologic and clinical evidence of placental insufficiency (placental infarction, IUGR, etc.). However, a positive test

for thrombophilia may be an incidental finding if there is a stillbirth in a normally grown fetus with a normal placenta.

Figure 23.5 Third-trimester fetal death with acalvarium. On sonogram, there was suspicion of possible neural tube defect. However, autopsy demonstrated amniotic band syndrome (*arrow* points to amniotic band). (Reprinted with permission from Silver RM. Fetal death. *Obstet Gynecol* 2007;109:153–167.)

Obstetric Conditions

Placental Abnormalities

Numerous placental abnormalities have been associated with stillbirth. Amniotic band syndrome is an uncommon condition wherein there is a disruption in the amnion early in gestation. This may cause severe deformation/amputation in the fetus that can be fatal (Fig. 23.5). Other placental conditions linked to fetal death include umbilical cord thrombosis and villamentous cord insertion as well as vasa previa (see Fetal–maternal Hemorrhage).

Fetal–maternal Hemorrhage

Fetal–maternal hemorrhage (FMH) is one of the most common causes of fetal death. It is reported in 5% to 14% of stillbirths. Small amounts of FMH are common in normal pregnancies, especially at delivery. Thus, FMH is most likely to contribute to stillbirth in cases of massive hemorrhage accompanied by evidence of fetal anemia and hypoxia on autopsy. Fetal blood in the maternal circulation is most commonly diagnosed with the Kleihauer-Betke stain. Many other tests may be used to assess for FMH, including flow cytometry, which may be more accurate than the Kleihauer-Betke test. It is important to note that FMH may occur in the absence of clinically apparent maternal bleeding. Since FMH occurs after many normal deliveries, it is best to test for it prior to delivery. However,

the amount usually is small, and testing should still be done after delivery in cases of stillbirth if it was not obtained prior.

Vasa previa refers to a fetal vessel that traverses the fetal membranes over or near the endocervical os. A tear in this vessel may lead to fetal exsanguination, and blood may pass through the vagina rather than enter the maternal circulation. Laboratory tests are of little clinical use, as the condition requires urgent or emergent delivery. In cases of stillbirth, the diagnosis is made with pathologic evaluation of the placenta and membranes.

Multiple Gestations

Multiple gestations dramatically increase the risk for fetal death. It is estimated that 10% of fetal deaths occur in multiple gestations. This is substantial, considering that only 3% of pregnancies are multiple gestations. Multiple gestations with monochorionic placentation are at risk for twin–twin transfusion syndrome (Fig. 23.6), umbilical cord entanglement in monoamniotic cases, and twin reverse arterial perfusion sequence. All have high fetal mortality rates. More commonly, multiple gestations are at risk for obstetric complications such as preterm labor, preterm premature rupture of membranes, preeclampsia, IUGR, abruption, and previa, all of which contribute to fetal death. The rising rate of multiple gestations due to the increased use of assisted reproductive technology may further elevate the proportion of fetal deaths from this condition.

Cord Accidents

Perhaps no other single etiology is purported to be the cause of stillbirth as often as umbilical cord accidents. This

is especially true for cases near term and is thought to be due to cord compression with cessation of blood flow to the fetus in the setting of a nuchal or “true knot” in the umbilical cord. Unfortunately, it is impossible to confidently attribute a fetal death to a cord accident simply based on the presence of a nuchal cord. Indeed, cord entanglement occurs in about 30% of uncomplicated pregnancies. Even true knots in the cord usually result in live births. Accordingly, stillbirth should not be considered to be due to cord accident simply based on the finding of a nuchal or true knot in the cord. Convincing evidence for a cord accident as the cause of stillbirth includes histologic demonstration of cord occlusion and/or fetal hypoxia as well as the exclusion of other etiologies.

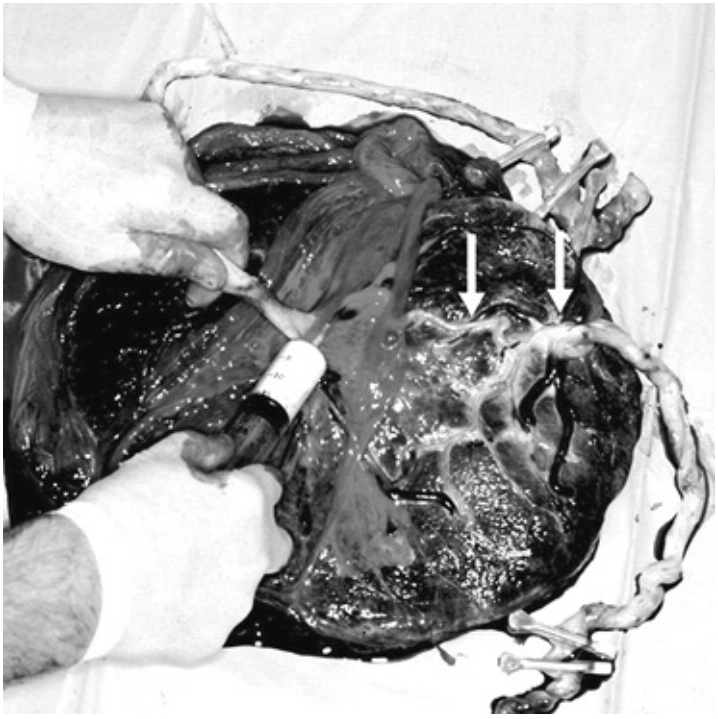

Figure 23.6 Placenta demonstrating arterial to venous anastamoses after injection of milk in a pregnancy complicated by twin–twin transfusion syndrome. (Reprinted with permission from Silver RM. Fetal death. *Obstet Gynecol* 2007;109:153–167.)

Other Obstetric Disorders

Several other obstetric disorders are associated with an increased risk of fetal death. These include cervical insufficiency, preeclampsia, abruption, preterm labor, preterm premature rupture of membranes, and placenta previa. Fetal death often occurs during the intrapartum period, although antepartum death also may occur. These obstetric disorders are discussed at length elsewhere in this text.

Other Conditions

A small percentage of stillbirths are due to a variety of other disorders. Red blood cell alloimmunization continues to cause fetal death, although modern management with the use of Rh D immune globulin and intrauterine transfusion has dramatically reduced the risk. Uterine malformations, especially uterine septums, are associated with pregnancy loss. They should be considered in cases of early preterm premature rupture of membranes or preterm labor, cervical insufficiency, and recurrent fetal death. Finally, maternal trauma through car accidents or violence causes some cases of stillbirth. The risk is greatest in teenagers.

Unexplained Causes

Although the proportion varies depending on the classification system used and whether or not risk factors are accepted as causes, many cases of stillbirth remain unexplained. A

large proportion of these are due to inadequate attempts to investigate possible etiologies. However, even in cohorts using extensive evaluations of possible causes, a reason for many stillbirths is never found. This is most common in term stillbirths compared with those occurring in the second trimester. Many of these cases have IUGR.

Management

The diagnosis of fetal death usually is straightforward. It is accomplished with real-time ultrasound documenting the presence of a fetus and the absence of a fetal heart pulsation. Women may perceive decreased or absent fetal movement or other symptoms such as bleeding or cramping. However, fetal death often is asymptomatic and may be a surprise to the patient.

On diagnosis of fetal death, most women prefer to deliver the fetus. However, there is no medical urgency to accomplish delivery, and the procedure may be delayed until the patient feels emotionally ready to proceed. Some women prefer to have a period of mourning or grief with their families prior to an induction of labor. Accordingly, most women should be offered a choice as to when she wishes to proceed with delivery.

Historically, there has been concern about the possibility of maternal coagulopathy and intrauterine infection in cases of expectant management. These conditions are rare in current practice, and the precise risks are unknown, in part because of the infrequency of prolonged expectant care. It is thought that most women will labor within 2 weeks of fetal death, but the latency period may be longer. Although of unproven utility, a reasonable approach is to perform serial assessment of temperature, abdominal pain, malodorous vaginal discharge, bleeding, and labor in women undergoing expectant management with stillbirth. These symptoms should be reported immediately. The benefits of serial determination of white cell count and measures of coagulation status are uncertain.

Delivery may be accomplished medically or surgically, although dilation and evacuation procedures usually are not performed after 20 to 24 weeks gestation in most centers. If possible, the patient should choose the method for delivery based on her preference. Advantages of labor induction include delivery of an intact fetus and the experience of labor. Surgical evacuation of the uterus is quick and allows for the use of a general anesthetic. Dilation and evacuation in the second trimester is as safe as labor induction if the surgeon is trained in the procedure. However, the procedure becomes more difficult with advancing gestation, and few providers are trained in the technique beyond 20 to 24 weeks gestation.

Most inductions of labor in cases of fetal death are accomplished with misoprostol. In past years, prostaglandin E_2 (PGE_2) was used for labor induction. Although effective, PGE_2 is associated with a higher rate of side effects such as fever, nausea, emesis, and diarrhea than those associated with misoprostol. Dosing of misoprostol depends on uterine size, and several protocols are in current use. The author's approach, if the uterus is less than 28 weeks gestation, is to place 200 mcg of misoprostol in the posterior fornix every 4 hours until delivery of the fetus and the placenta. Dosing of 400 mcg per vagina up to every 2 hours is safe but does not achieve delivery faster than 200 mcg every 4 hours. The drug

may be given orally as a lozenge (200 to 400 mcg) every 2 to 4 hours. This may take longer to achieve delivery than when misoprostol is administered vaginally. If the uterus is greater than 28 weeks size, the aforementioned doses may increase the risk for uterine rupture. Instead, the author gives an initial dose of 25 mcg in the posterior fornix, followed by 25 to 50 mcg every 4 hours. If the uterus is greater than 28-week size, the oral dose is 25 mcg every 4 hours. In women with prior uterine scars and a uterus greater than 26-week size, prostaglandins should be avoided due to the risk for uterine rupture. Alternatively, low-dose oxytocin may serve as an effective cervical ripening agent. Misoprostol has been safely used for medical induction in cases of uterine size <26 weeks gestation. However, rupture still may occur. This risk must be balanced against the risk of hysterotomy (often using a classical uterine incision) in cases of fetal death. Patients with significant cardiac, pulmonary, or renal disease and glaucoma should not be given PGE_2.

There is an increased risk of retained placenta in cases of fetal death in the second trimester, especially prior to 20 weeks gestation. The use of misoprostol has been reported to reduce the rate of retained placenta compared with PGE_2 and oxytocin. Also, being patient with the delivery of the placenta and avoiding pulling on the cord or manual manipulation can reduce the risk. It may be necessary to use additional doses of misoprostol (scheduled as noted previously) between delivery of the fetus and placenta. The author does not advise the use of an absolute time limit for the delivery of the placenta as long as there is not clinically significant hemorrhage. It is unusual for the delivery of the placenta to take more than 2 hours with this “hands-off” approach.

Helping families with bereavement is a major part of stillbirth care. Patients should be encouraged to keep mementos such as pictures, hand and footprints, and plaster casts and to hold the infant. It may be helpful to facilitate visits with clergy, support groups, and psychologists. A standard bereavement protocol is useful, especially for delivery suites that rarely care for stillbirths. It is important for clinicians to overcome their own discomfort and concerns regarding liability and to directly and openly discuss the case with families. Recovery on postpartum units should be avoided, and in most cases, 12 hours of observation is adequate prior to discharge.

Evaluation

The optimal “workup” of potential causes of stillbirth is uncertain and based on “expert opinion” rather than medical evidence. Investigation into potential etiologies of fetal death is influenced by cost and the preferences and desires of the family. It makes sense to test for the most common conditions as well as those with a meaningful recurrence risk, especially those amenable to treatment. However, there also is value in diagnosing sporadic conditions. This provides reassurance, facilitates emotional closure, and allows families to avoid unnecessary tests and interventions. The workup also should be guided based on clues provided by the clinical course or initial investigation.

Some families will be resistant to some or all of the evaluation into causes of fetal death. They may feel that it will not “bring their child back,” and there may be emotional or cultural issues with autopsy. It is very important to counsel patients regarding the potential

benefits of a stillbirth evaluation and to work with them in a supportive fashion regarding their particular concerns. A major potential benefit of finding a cause of death is emotional closure or healing. Many parents inappropriately blame themselves, and most desire an explanation for what happened. Even if a cause is not found, it is the author's impression that the act of trying to find one is of emotional benefit. Also, a majority of families will attempt to become pregnant again after suffering a fetal death. For these patients, determining a recurrence risk as well as potential strategies for improving subsequent outcomes is of major interest. This only can be accomplished by determining the cause of death.

The single most valuable test is perinatal autopsy. This procedure can provide insight into virtually every potential etiology of fetal death. Several studies have illustrated the value of perinatal autopsy. For example, new information that altered counseling or the recurrence risk has been found in up to 50% of cases. It is important to work with families to identify their fears and concerns regarding autopsy. In many cases, they have misconceptions about autopsy, or it is possible to modify the autopsy to address their needs. Some hospitals do not provide perinatal autopsy due to a lack of trained providers. It varies among communities, but often tertiary care centers are willing to perform perinatal autopsies on transported fetuses. If autopsy is declined, partial autopsy, x-ray, or postmortem magnetic resonance imaging (MRI) may provide important information regarding potential causes of death.

If feasible, fetal karyotype is advised in all cases of fetal death. However, fetal cells may not grow in culture, especially if there is a long interval between fetal death and delivery. Leukocytes from fetal blood are the preferred tissue for karyotype. If blood is unavailable, as is often the case, cells that can survive under low oxygen tension such as chorionic plate (placenta) and fascia latta may provide viable cells. Placental or fetal tissue intended for chromosome analysis should not be placed in formalin. Alternatively, amniocentesis (done prior to delivery) has been reported to increase the chances of successful cell culture. CGH allows for the evaluation of fetal chromosomes without the need for actively dividing cells. The technique is becoming increasingly available and can provide information in cases of cell culture failure. If expense is a concern for the family, autopsy or careful external examination by a clinician with appropriate training can determine the risk for abnormal karyotype. The risk is low (probably <2%) if there are no abnormalities and fetal growth is normal.

Placental evaluation by a trained pathologist also can provide valuable data about most causes of stillbirth. It is

---

advised in all cases of fetal death. Testing for FMH, typically with a Kleihauer-Betke stain (other methods are used in some laboratories), is advised since FMH is common and the test is inexpensive. Indirect Coombs testing to exclude red cell alloimmunization also is recommended. Toxicology screen (typically with maternal urine) is useful in some populations. However, screening for asymptomatic thyroid disease or diabetes is of unproven efficacy and is not advised outside of research protocols. In cases of loss due to preterm premature rupture of membranes or preterm labor, as well as recurrent pregnancy loss, uterine imaging should be considered.

Optimal testing for fetal infection remains controversial. Screening for syphilis is recommended, although the yield may be low depending on the population tested. Parvovirus serology also is advised. However, most other testing for infectious causes of stillbirth is of questionable utility. Autopsy and histologic evaluation of the placenta are the best modalities for determining if fetal death is due to infection. If histology is suspicious for infection, the pathologist may choose to culture fetal tissues. However, routine cultures of the placenta or fetus are of uncertain benefit and not recommended. Testing for TORCH titers (serology for toxoplasmosis, rubella, CMV, and herpes simplex virus) often is recommended but is probably of little value in the absence of histologic evidence of these organisms.

Screening for APS and heritable thrombophilias also is controversial. Testing makes good sense in the setting of a maternal or strong family history of thrombosis or SLE or if there is clear evidence of placental insufficiency (IUGR, placental infarction, oligohydramnios, preeclampsia, etc.). However, the yield is low in healthy women with normally grown infants and normal placentas. In addition, many women will have positive tests for heritable thrombophilias that may be unrelated to their stillbirth. Screening for APS should be accomplished with a lupus anticoagulant screen and testing for anticardiolipin antibodies. The most common thrombophilias that are associated with fetal death are the factor V Leiden mutation and the G20210A prothrombin gene mutation. Protein S, protein C, and antithrombin III deficiencies are rare in the absence of a personal or family history of thrombosis. Testing for deficiencies in these proteins is best accomplished in the nonpregnant state. Hyperhomocysteinemia and associated mutations such as the methylenetetrahydrofolatereductase mutation (MTHFR) is not advised, as their association with fetal death is controversial and they are very common in healthy people.

Table 23.4 lists a recommended evaluation for causes of stillbirth. The importance of a clinical history and evaluation cannot be overemphasized. In many cases, clinical features of the case help to target appropriate conditions. This is especially helpful when considering whether to test for uncommon conditions or if resources are limited. If possible, the clinician should work as a team with the pathologist (and possibly a geneticist) to in order to optimize the workup for each case.

TABLE 23.4 Recommended Evaluation for Stillbirth

Recommended in most cases:
Perinatal autopsy
Placental evaluation
Karyotype
Antibody screen[a]
Serologic test for syphilis[b]
Screen for FMH (Kliehauer-Betke or other)

Urine toxicology screen
Parvovirus serology
Recommended if clinical suspicion:
Lupus anticoagulant screen[c]
Anticardiolipin antibodies[c]
Factor V Leiden mutation[c]
Prothrombin G20210A mutation[c]
Screen for protein C, protein S, and antithrombin III deficiency[d]
Uterine imaging study[e]
Not recommended at present:
TSH
Glycohemoglobin
TORCH titers
Placental cultures
Testing for other thrombophilias

FMH, fetal–maternal hemorrhage; TSH, thyroid-stimulating hormone; TORCH, serology for toxoplasmosis, rubella, cytomegalovirus, and herpes simplex virus.

[a]Negative first-trimester screen does not require repeat testing.

[b]Repeat testing in cases of negative first-trimester screen if high-risk population.

[c]Test in cases of thrombosis, placental insufficiency, and recurrent fetal death.

[d]These thrombophilias are rare in the absence of personal or family history of thrombosis.

[e]Test in cases of unexplained recurrent loss, preterm premature rupture of the membranes, and preterm labor.

Management of Subsequent Pregnancies

The recurrence risk for fetal death is uncertain, and reliable data are lacking. One population-based study reported a stillbirth rate of 22.7 per 1,000 women with prior stillbirth compared with those without (odds ratio 4.7; 95% CI 1.2 to 5.7). The risk of recurrent stillbirth was higher in non-Hispanic blacks than whites. It is likely that the

recurrence risk can be stratified by whether or not there is an underlying medical, obstetric, or genetic condition that contributed to the pregnancy loss. For example, women with diabetes, APS, or who along with their partners are carriers of a lethal single gene mutation are at increased risk for recurrent fetal death. In contrast, sporadic conditions such

as most viral infections or a de novo nondysjunctional genetic abnormality have minimal recurrence risk. Also, the obstetric history influences recurrence risk. Women with prior live births are less likely to have recurrent stillbirths, while those with recurrent fetal death are at increased risk.

Appropriate medical care may improve obstetric outcome in subsequent pregnancies in cases associated with underlying medical conditions such as diabetes, hypertension, SLE, and APS or in women with red cell alloimmunization. When possible, modifiable risk factors such as obesity, smoking, and the use of seat belts should be addressed. Some genetic conditions may lend themselves to preimplantation genetic diagnosis. Heritable thrombophilias deserve special comment. It is biologically plausible and attractive to posit that thromboprophylaxis in women with these conditions may reduce the risk of fetal death in women with prior stillbirth. This is the case with APS. However, there is only one well designed study showing efficacy in women with heritable thrombophilias, and the vast majority of women with thrombophilias have normal pregnancies. Thus, thromboprophylaxis of women with thrombophilias with the intention of preventing fetal death should be considered experimental.

In most cases, there will not be an identified underlying condition that may benefit from intervention. In such cases, antepartum testing such as the use of nonstress tests often is advised in subsequent pregnancies. It may be useful after stillbirths characterized by placental insufficiency such as IUGR and preeclampsia. Even if there is no medical benefit from antepartum testing, there often is emotional benefit in reassuring parents that their fetus is “OK.” Testing typically is initiated at 32 weeks gestation. Doppler velocimetry, biophysical profile, amniotic fluid volume assessment, and serial sonography to assess growth may be used instead of or along with nonstress tests. In addition to recurrent stillbirth, women with prior stillbirth also are at increased risk for obstetric complications characterized by placental insufficiency such as fetal growth restriction, abruption, and preeclampsia. The increased risk for these conditions is another theoretical justification for antepartum testing.

Another intervention of unproven medical benefit in women with prior stillbirth is induction of labor. As with antepartum testing, there is considerable emotional benefit for many families from labor induction, despite a lack of proven medical efficacy in reducing the risk of stillbirth. Some authorities advocate delivery 2 weeks prior to the timing in gestation of the previous stillbirth. However, this strategy is of unproven benefit, and it is important to avoid iatrogenic prematurity. Instead, induction in the setting of prior stillbirth (excluding medical conditions such as diabetes) should be considered elective and offered at term with a favorable cervix.

Summary Points

- Pregnancy loss is common, affecting over 30% of conceptions.
- Most losses are first-trimester miscarriages.
- Although definitions vary, losses after 20 completed weeks gestation usually are referred to as stillbirths.
- The rate of stillbirth in the United States has decreased by about one third since the 1950s.
- The current rate of stillbirth in the United States is about 6.0 to 6.5 per 1,000 live births.
- Stillbirth accounts for about 50% of perinatal mortality (stillbirth plus infant deaths).
- There are several classification systems for stillbirth. None is considered to be a "gold standard," although the Wigglesworth scheme is most commonly used throughout the world.
- Causes of stillbirth should be distinguished from risk factors for stillbirth. Risk factors are present in many live births and do not always lead to fetal death.
- Maternal risk factors for stillbirth include black race, advanced maternal age, obesity, medical disorders, and thrombophilias.
- Black race is associated with about a fourfold increase in the risk of stillbirth.
- Medical disorders commonly associated with stillbirth include diabetes, hypertension, APS, and cholestasis of pregnancy. The risk is decreased with appropriate medical care. Any severe maternal illness may increase the risk for stillbirth.
- Heritable thrombophilias such as the factor V Leiden mutation and the G20210A prothrombin gene mutation have been associated with a modest increased risk of stillbirth in retrospective studies. However, these conditions are common, and the vast majority of women with thrombophilias have uncomplicated live births.
- Smoking increases the risk of stillbirth by approximately 1.5-fold. The risk decreases to baseline in women who stop smoking after the first trimester of pregnancy.
- Other exposures that may increase the risk of stillbirth include cocaine and, possibly, alcohol.
- Chromosomal abnormalities have been reported in 6% to 12% of stillbirths.
- Chromosomal abnormality is more likely if there are fetal abnormalities or if the fetus is SGA.
- The most common chromosomal abnormalities in stillbirths are monosomy X, trisomy 21, trisomy 18, and trisomy 13.

- Single gene mutations including autosomal recessive conditions such as glycogen storage diseases and hemoglobinopathies and X-linked conditions in male fetuses may cause stillbirth.
- Some stillbirths are probably due to genetic abnormalities that are not identified by karyotype.
- Infections are associated with 10% to 25% of stillbirths.
- Bacterial infections cause a higher proportion of infections in the second trimester than at term in developed countries. However, the proportion of stillbirth due to bacterial infection stays constant through term in developing countries.
- Most bacterial infections associated with stillbirth are organisms that ascend from the lower genital tract such as group B streptococcus, *E. coli*, and the organisms responsible for bacterial vaginosis.
- Rarely, bacteria such as *L. monocytogenes* may reach the fetus via a hematogenous route.
- Other organisms such as *T. pallidum* or *Toxoplasma gondii* also may cause fetal death.
- Numerous viruses such as parvovirus B19, CMV, and coxsackie virus have been associated with fetal death.
- SGA fetus is a major risk factor for stillbirth.
- FMH has been reported in 5% to 14% of stillbirths.
- Multiple gestations account for 10% of stillbirths yet only 3% of pregnancies in the United States.
- Placental abnormalities including amniotic band syndrome, vasa previa, and umbilical cord thrombosis are rare but important causes of stillbirth.
- Many stillbirths are attributed to cord accidents. However, nuchal and body cords and even true knots often are found in live births. Thus, ideally the demonstration of cord occlusion, fetal hypoxia, and the exclusion of other causes of fetal death should be accomplished before attributing cord accident as a cause of stillbirth.
- The optimal workup for potential causes of stillbirth is uncertain.
- Fetal autopsy is the single most informative test for determining the cause of stillbirth.
- If families are uncomfortable with autopsy, working through their concerns, considering partial autopsy, and postmortem MRI are useful options.
- Placental examination provides information about most potential etiologies of stillbirth, is uniformly advised, and is rarely refused by

families.

- Karyotype should be offered in all cases of stillbirth. Cells most likely to grow are chorionic plate, fascia latta, tendons, and skin from the nape of the neck. Amniocentesis should be considered due to a high rate of cell culture failure in cases of stillbirth.
- If cost is an issue, the chances of abnormal karyotype are low if there are no external dysmorphic features and the fetus is normally grown for gestational age.
- Kliehauer-Betke or another test to assess FMH is advised. Testing is still worthwhile after delivery since only cases of massive hemorrhage would be considered to potentially cause stillbirth.
- Other tests that are recommended for routine assessment of stillbirth include an antibody screen, serologic testing for syphilis, a urine toxicology screen, and parvovirus serology.
- Tests that should be considered if there is clinical suspicion of a condition include lupus anticoagulant, anticardiolipin antibodies, factor V Leiden mutation, prothrombin G20210A mutation, protein C, protein S, and antithrombin II deficiency as well as uterine imaging.
- Tests that currently are not recommended include thyroid-stimulating hormone (TSH), glycohemoglobin, TORCH titers, placental cultures, or testing for mutations associated with hyperhomocysteinemia.
- Bereavement should be facilitated with the development of a standard protocol.
- Families should be counseled regarding risks in subsequent pregnancies, including stillbirth and other obstetric complications.
- Although of unproven efficacy, antenatal surveillance and elective delivery after fetal maturity is achieved may provide emotional benefit.

Complications of Labor

Donald J. Dudley

From 1970 to 2005, the cesarean delivery rate in the United States increased from 5% to 30%. The four primary indications for cesarean delivery include dystocia, elective repeat cesarean delivery, fetal distress, and abnormal fetal presentation. *Dystocia*, translated, means “difficult birth” and includes all abnormalities that may occur in women during labor. An expanded definition advanced by Bowes is that dystocia is “any complication or circumstance that interferes with the progress of labor and vaginal delivery that endangers mother or fetus.” Most authorities agree that the number of cesarean deliveries remains excessively high. One reason for the continued high rate of cesarean delivery is a poor understanding of the labor process and the lack of an organized approach to the management of labor. This fundamental lack of understanding often leads to unnecessary induction of labor, which has an a priori risk of cesarean delivery of at least 25%, or to inadequate augmentation of abnormal labor. With fewer inductions of labor and improved management of labor, a decline in the cesarean delivery rate can be expected.

Efforts at reducing the cesarean delivery rate have more recently focused on the categories of dystocia and repeat cesarean section. Obviously, the best method to decrease the incidence of repeat cesarean deliveries is to decrease the incidence of cesarean delivery initially. Hence, new efforts are being directed at the diagnosis and management of labor abnormalities in term pregnancies. The purpose of this chapter is to review these labor abnormalities and management options.

Keys to the Management of Normal Labor

The normal labor process is reviewed in Chapter 2. The key points in the management of labor emphasized in this chapter are summarized in Table 24.1. Normal labor progresses in a predictable fashion after the diagnosis of labor is made. However, diagnosing labor is more difficult than might be expected. If the diagnosis of labor is made in error, all subsequent actions are not appropriate, as an induction of labor is being performed and different management is required. Labor in its simplest terms is defined as cervical change effected by regular, painful uterine contractions. In the nulliparous woman in her first labor, cervical change usually is manifest by cervical effacement, or thinning, followed by cervical dilation (Fig. 24.1). Conversely, in the multiparous woman, the initial stage of labor often is characterized by cervical dilation followed by effacement.

The normal labor curve is shown in Figure 24.2. This curve was developed by Emanuel Friedman based on the observation of several thousand laboring women. The first stage of labor is divided into the acceleration phase, active phase, and deceleration phase. The acceleration phase occurs when the active phase of labor starts. The cervix usually is effaced and <4 cm dilated. In the active phase, a minimum of 1 cm of dilation per hour can be anticipated (Table 24.2). The deceleration phase likely is an aberration of the mathematic analysis of Friedman's original data and as such is likely not a physiologic event. In the second stage of labor, from complete dilation until delivery, again one can anticipate the laboring woman gaining a minimum of 1 cm of station of the fetal head in relation to the maternal pelvis per hour. Cervical examinations should be performed periodically to confirm that progress is being made. Early in their training, residents should be encouraged and allowed to perform examinations hourly so that full educational opportunities are gained. More experienced obstetricians often will perform examinations every 2 to 3 hours, depending on the presentation of the patient. After each examination, the progress in labor should be documented graphically on some form of a labor curve and a plan formulated with regard to future examinations and potential interventions. Other terms for a labor curve include *partogram*, *labor graph*, and *parturograph*.

TABLE 24.1 Keys to the Management of Labor

Labor progress is predictable.
Diagnosis of labor is critical.
Labor in nulliparas is different from labor in multiparas.
Labor progress should be graphically followed.
Cardinal movements of labor should occur.
Prompt intervention is needed if labor does not progress appropriately.
Medical therapy with oxytocin is effective.
Clinical judgment must be made regarding the role of cesarean delivery.

Nulliparous women and multiparous women behave fundamentally differently in labor. Figure 24.3 is an example of a labor curve showing the difference in labor patterns expected between nulliparas and multiparas. In the simplest terms, labor is the force of uterine contractions overcoming the resistance of the female reproductive tract, including the lower uterine segment, cervix, vagina, and perineum. In nulliparous women, more uterine force is required to overcome resistance in the reproductive tract, and the uterus tends to be less effective in maintaining effective uterine contractions. In multiparous women, less uterine force is required, and the tissues of the reproductive outlet, having been stretched by the previous delivery, have less resistance. As a result, the myometrium of the multipara usually maintains effective contractile activity. Thus, nulliparous women

are more likely to develop labor abnormalities that require intervention. Multiparous women usually labor quickly and meet all expected milestones without the need for significant intervention.

In addition to graphically depicting labor progress, the practitioner should pay close attention to the *cardinal movements of labor* (Table 24.3). This term refers to the changes that occur in the flexion and position of the fetal head throughout labor. The cardinal movements of labor usually occur in the following sequence: engagement of the fetal head, descent of the fetal head, flexion of the fetal head, internal rotation (assumption of an occiput anterior [OA] position), extension (as the fetal head progresses through the birth canal and crowns at the perineum), external rotation (or restitution to the transverse position), and then shoulder rotation after the head has delivered. Abnormalities in the cardinal movements of labor may be reflected by abnormal fetal head position and other specific abnormalities discussed below.

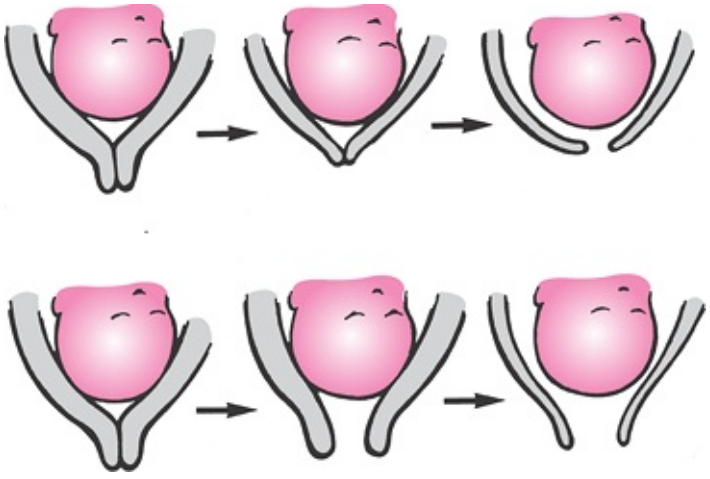

Figure 24.1 Cervical effacement and dilation: nulliparas versus multiparas. The upper portion of the figure depicts the cervical changes in early labor of the nulliparous woman. Note that cervical effacement precedes significant dilation. The lower portion depicts the cervical changes of the multiparous woman in early labor. Significant cervical dilation may precede achievement of complete cervical effacement.

If labor is progressing appropriately, then a noninterventional approach is indicated, providing for maternal comfort and encouragement. However, if these landmarks are not achieved by the patient, then timely intervention is recommended. Thus, the next important key in the management of labor is prompt intervention when labor progress is inadequate. The longer labor continues in a dysfunctional pattern, the less likely the underlying problem can be corrected with medical therapy. Prompt medical therapy for desultory labor is another important key to success in the management of labor.

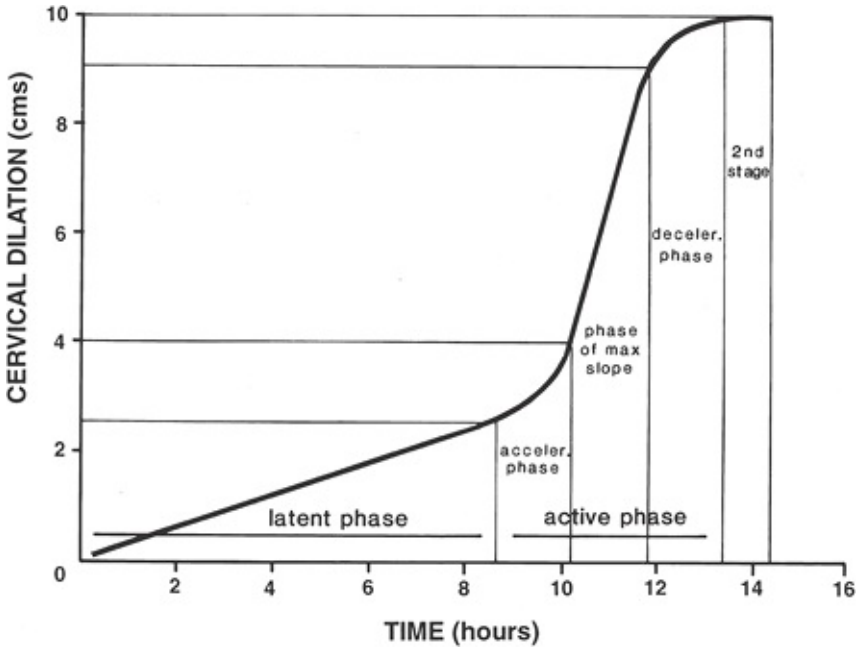

Figure 24.2 The Friedman labor curve. Note the different phases of the first stage of labor, including the latent phase, acceleration phase, active phase, and deceleration phase. (Adapted from Friedman EA. *Labor: clinical evaluation and management*, 2nd ed. New York: Appleton, 1978, with permission.)

TABLE 24.2 Expected Length of Different Phases of Labor

Phase of Labor	Average Duration (hours)	Maximum Slope (centimeters per hour)	Upper Limit of Normal
Nulliparous labor			
Latent phase	8.60	—	>20 h
Active phase	4.90	1.2 or less	—
Second stage	0.95	1.0 or less	None[a]
Multiparous labor			

Latent phase	5.30	—	>14 h
Active phase	2.20	1.5 or less	—
Second stage	0.24	2.0 or less	None[a]

[a]There is no limit to the length of the second stage as long as progress is being made and there is no fetal distress.

Ineffective uterine contractions lead to increased tissue acid content in the myometrium, which further contributes to poor contractility. In one study, the pH of myometrial capillary blood obtained at the time of cesarean delivery from women with dysfunctional labor was lower than in women having cesarean for other indications. This also was associated with higher capillary lactate and lower oxygen saturation.

Normal labor is characterized by coordinated uterine contractions, cervical dilation, gain in station of the fetal head, and normal progress in the cardinal movements of labor. With careful attention to achieving these milestones of normal labor, a successful vaginal delivery is likely. However, if the parturient does not achieve these milestones, prompt intervention is more likely to increase the chances for vaginal delivery. Although an aggressive approach with regard to diagnosing labor abnormalities may enhance maternal and fetal outcome, the last important key to the successful management of labor is to use clinical judgment on when to abandon medical therapy in favor of surgical intervention. If the judgment is made that continuing medical therapy may dangerously compromise either mother or fetus, then prompt surgical delivery (cesarean or operative vaginal delivery) should be considered.

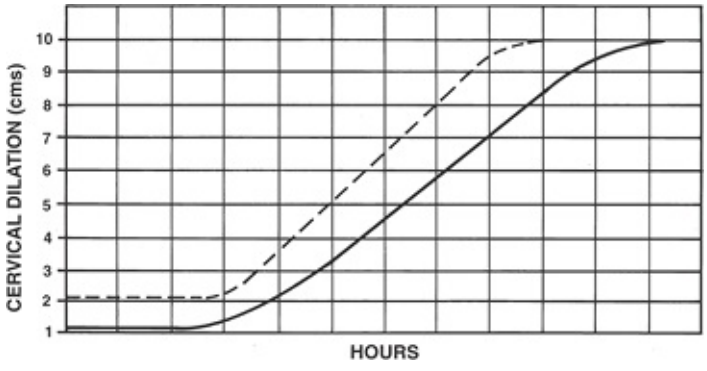

Figure 24.3 Labor curve of nulliparas versus multiparas. Note that different labor

slopes are expected between nulliparous (*solid line*) and multiparous women (*dotted line*).

Epidemiology of Dystocia

The precise incidence of dystocia is difficult to determine and varies with different populations and different labor and delivery units based on local practice patterns. According to the National Center for Health Statistics, 28% of women who delivered in the United States in the year 2000 were diagnosed with labor abnormalities, with a primary cesarean delivery rate of 16.1%. The rate of primary cesarean delivery in 2004 increased to 20.6% of all deliveries in the United States. Dystocia is more common in nulliparous women than in multiparous women and is more common in the first stage of labor than in the second stage of labor. Labor abnormalities occur in approximately 25% to 30% of nulliparous women and in 10% to 15% of multiparous women. Dystocia occurs in the second stage of labor in about 5% to 10% of nulliparous women and is relatively rare in multiparas (<2%).

Abnormal labor is a common indication for cesarean delivery. According to the National Center of Health Statistics, in the United States in 2005, 30.2% of pregnancies were delivered by cesarean. In 1990, the overall rate was 23.6%, with 7.1% for the indication of "failure to progress" or dystocia and 8.5% for a repeat procedure. Other indications included abnormal presentation (2.6%), fetal distress (2.3%), and other problems (3.2%). Improved management of labor with a decrease in the number of cesarean deliveries for dystocia (and then having less need for repeat procedures) should be the goal of every labor and delivery unit in the United States. One contributing

factor to the cesarean delivery rate is the number of inductions. In 2004, the rate of inductions was 21.4% compared with a rate of 9.5% in 1990. Clearly, the induction rate has increased dramatically, with no proven benefit to perinatal outcome. While there have been many proposed targets for the overall rate of cesarean delivery and inductions, none

of these figures is based on scientific evidence.

In 2000, the American College of Obstetricians and Gynecologists (ACOG) published a monograph reporting on the efforts of a special task force charged with focusing on cesarean delivery in the United States. The primary conclusion of this task force was that efforts to reduce the cesarean delivery rate in the United States should focus on two benchmarks. First, there should be a focus on nulliparous women at term (37 weeks gestation or greater) with singleton fetuses in cephalic presentation. In 1996, the cesarean delivery rate for this group was 17.9%, and the Task Force concluded that efforts to achieve a reduction to the 25th percentile, or 15.5%, in this group of women were reasonable and could be accomplished. Second, the Task Force recommended that efforts be made to increase the percentage of women who are attempting vaginal birth after cesarean (VBAC). Of multiparas at 37 weeks gestation or greater with singleton fetuses and vertex presentations with prior low transverse cesarean incisions, 30.3% attempted VBAC in 1996. The Task Force recommended that a primary goal at the 75th percentile for this year, or 37%, would be reasonable. However, in 2004, the rate of attempted VBAC declined to 9.2%. Unless there is a dramatic change in the delivery of obstetric care in the United States, the rate of VBAC attempts likely will continue to decline. Clearly, efforts to address the cesarean delivery rate in the United States have been found to be a daunting challenge.

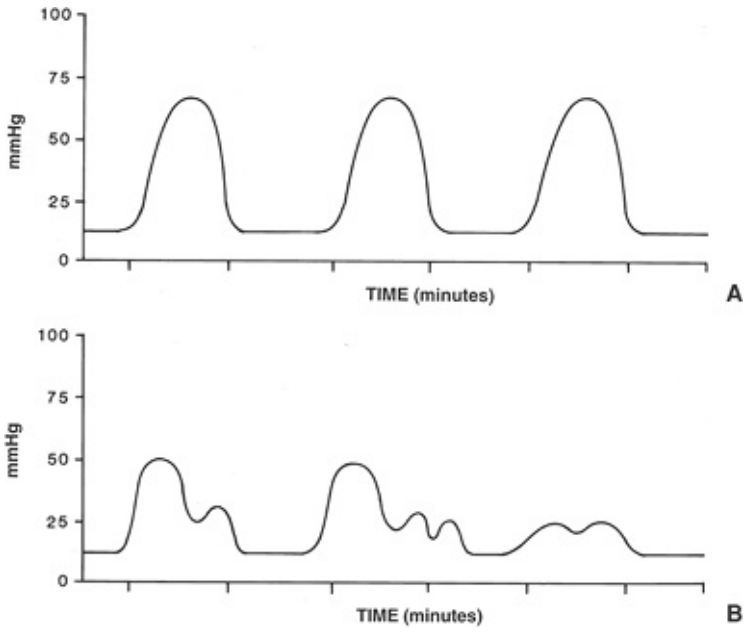

Figure 24.4 Uterine contractions patterns. Uterine contractions can be depicted using tocodynometry (external monitoring) or direct uterine pressures (using IUPCs). **A:** The contraction pattern of a normal labor. Significant pressure is obtained with contractions every 2 to 3 minutes. **B:** Uterine contraction patterns typical of primary dysfunctional labor. Contractions achieve varying degrees of pressure and often are combined (coupling).

Etiology of Dystocia

Traditionally, the causes of abnormal labor have been attributed to the “powers” (uterine contractility), the “passage” (maternal pelvimetry), and/or the “passenger” (position and size of the fetus). In more scientific terms, these represent a primary dysfunctional labor, cephalopelvic or fetopelvic disproportion, abnormal fetal head position, and asynclitism. This section evaluates each of these potential causes of dystocia. The generic term *failure to progress* often is used as a diagnosis to justify cesarean delivery and is more appropriately used as a sign of an underlying problem and does not represent a diagnosis. Hence, “failure to progress” is not sufficient to describe the labor problem and should not be used.

Primary Dysfunctional Labor

Primary dysfunctional labor refers to inadequate uterine contractility to maintain appropriate progress in labor. In general, an adequate uterine contraction pattern is one in which there are four to five concerted synchronous contractions every 10 minutes (Fig. 24.4). However, some women contract less frequently and continue to progress adequately in labor such that no intervention or treatment is required. Unlike the cardiac conduction system, the uterus has no defined nervous system for the conduction of electric signals to stimulate muscle contractions. The readiness of the uterus for labor is heralded by the occurrence and widespread distribution of gap junctions throughout the myometrium. Gap junctions allow for the rapid transmission of calcium fluxes through the uterine musculature and, hence, the occurrence of global uterine contractions. The uterus commonly has focal contractions throughout pregnancy (Braxton Hicks contractions), which are not of

---

sufficient strength or duration to effect cervical change and therefore do not constitute labor.

Smooth muscle cells of the uterus are not randomly distributed but are arranged in a specific fashion such that maximal force can be generated to effect vaginal delivery. In women with uterine embryologic abnormalities such as uterus didelphys and bicornuate uterus, labor is not often successful in achieving vaginal delivery, as global, concerted uterine contractions cannot occur because of the abnormal arrangement of uterine smooth muscle cells. Similar problems may be noted in women exposed to diethylstilbestrol (DES) in utero with uterine anomalies characteristic of this teratogen (e.g., T-shaped uterus).

In the structurally normal uterus, contractions begin to occur less randomly days to weeks before the initiation of labor. Moreover, there is a distinct diurnal variation of uterine contractility such that in most women, uterine contractions occur more frequently and labor most often commences at night. These rhythmic variations may be the result of hormonal patterns in which specific and predictable changes in different hormones (e.g., corticotropin-releasing hormone, cortisol, progesterone, estradiol) allow for more frequent and stronger uterine contractions until the final signal for labor. While the precise nature of this signal in women is not known, cortisol appears to play a key role in the initiation of parturition.

As the normal uterus approaches term and the labor commences, different foci for the

initiation of a uterine contraction may be present (Fig. 24.5). This phenomenon often leads to the clinical scenario in which some contractions are quite hard and lengthy whereas other contractions are mild and of short duration. Women will have mild contractions interspersed with firmer, more painful contractions because of the lack of a dominant "pacemaker" in the uterine musculature. While the uterus does not have a sophisticated electrical conduction system, cellular communication through gap junction formation allows for specific foci in the uterine smooth muscle from which contractions commence. Eventually, as labor progresses, one of these foci of uterine contractility predominates over other foci, resulting in more concerted and painful uterine contractions. As this occurs, true labor commences with effacement and dilation, and this change is reflected in the uterine tocodynometry patterns (Fig. 24.4). In a primary dysfunctional labor, uterine activity shifts from the concerted global contractions to more focal and less efficient contractions by allowing the reemergence of other pacemaker foci (Fig. 24.5). Medical therapy with oxytocin often is effective at correcting the underlying pathophysiology and restoring the pattern of global and concerted uterine contractions.

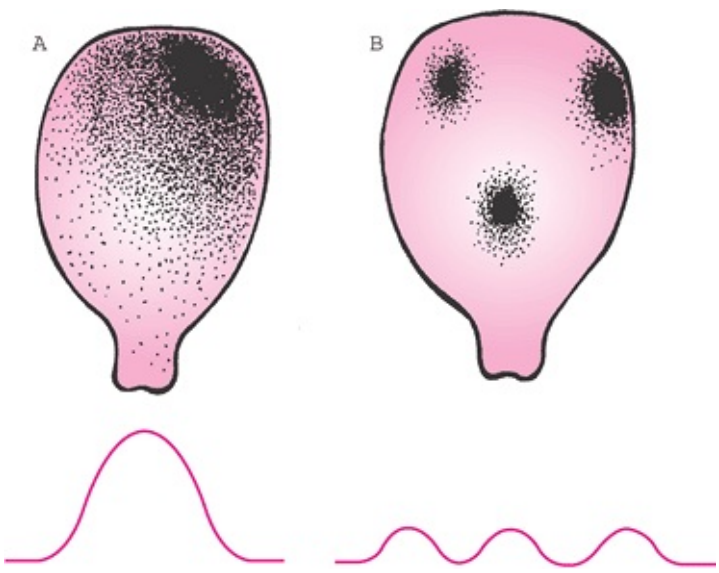

Figure 24.5 Uterine pacemakers and contractions. **A:** Normal uterine contraction pattern associated with a single dominant pacemaker focus. **B:** A uterus with three separate pacemakers, all firing sequentially. Note that the uterine pressures achieved in this situation are less than those shown with a single dominant pacemaker.

Although usually quite effective, oxytocin therapy may be of little benefit if the woman has intrauterine infection complicating labor. If the parturient has clinical signs of intrauterine infection, then labor progress often is desultory and not remedied with oxytocin augmentation, leading to a cesarean delivery rate of approximately 30% to 35% in these cases. Clinical signs of intrauterine infection include maternal fever (>38°C), fetal tachycardia (baseline fetal heart rate of >160 beats per minute), elevated maternal white cell count, uterine tenderness when the uterus is relaxed, and foul-smelling vaginal discharge. With the diagnosis of intrauterine infection, broad-spectrum antimicrobial agents should be administered and uterine activity stimulated with oxytocin if labor is not

progressing adequately. Because oxytocin often does not work well in this scenario, the obstetrician should be prepared to move to cesarean delivery if oxytocin is ineffective in order to avoid neonatal infectious morbidity.

Cephalopelvic Disproportion

True cephalopelvic disproportion (CPD), or fetopelvic disproportion, commonly is diagnosed on the labor and delivery suite, although some authorities believe that CPD occurs in as few as 1 in 250 pregnancies. CPD occurs when the fetal birth weight or the fetal head is of sufficient size or orientation to preclude entry into the maternal pelvic inlet. This diagnosis often is made in retrospect after the birth weight is known and the positioning of the fetal head has been determined at the time of cesarean delivery. However, in the United States, the term *cephalopelvic disproportion* is used to describe almost any unsuccessful attempt at vaginal delivery. Further, the diagnosis of CPD often is used when labor progress is not sufficient and medical therapy is not successful or even not attempted. These cases often reflect inadequate use of oxytocin and are not problems with large fetal size or a small maternal pelvis. CPD is an important diagnosis because it has prognostic information for subsequent pregnancies when VBAC is considered. In women with a prior diagnosis of CPD, success rates of VBAC are only 50%. Additionally, these women should be managed differently during the VBAC, with prompt repeat cesarean if labor does not progress appropriately.

Another important contribution to the fetopelvic relationship is the size of the fetus. Pregnancies with macrosomic fetuses (>4,000 g birth weight) have a greater risk of cesarean delivery for dystocia as a result of true CPD. In a study by Turner and colleagues, fetal macrosomia was associated with longer first and second stages of labor, a greater need for oxytocin therapy, and a greater risk for cesarean delivery for CPD refractory to oxytocin. In their patient population, the overall incidence of cesarean delivery of 5.2%, but if birth weight was between 4,000 and 4,500 g, the incidence of cesarean delivery was 13.8%. Also, forceps delivery was employed in 31.8% of infants with a birth weight between 4,000 and 4,500 g, whereas forceps were used in 13.6% of deliveries overall.

Unfortunately, there are no good predictors of fetal weight to guide management. Sonographic estimates of fetal weight at term are notoriously spurious and can miscalculate birth weight by up to 20%. The obstetrician employing Leopold maneuvers to estimate fetal weight by palpation of the maternal abdomen can only estimate small, average, or large fetal size. Hence, it is not advisable to induce labor or perform a cesarean delivery for presumed macrosomia unless the obstetrician judges that a dangerous situation exists for vaginal delivery (e.g., high risk of shoulder dystocia). Numerous studies of induction of labor for presumed macrosomia consistently show an increase in the cesarean delivery rate with no decrease in neonatal morbidity or shoulder dystocia.

When the diagnosis of a labor abnormality is made, clinical pelvimetry should be performed to assess the dimensions of the maternal pelvis (Fig. 24.6). Only in the rare cases in which the maternal pelvis is markedly small or if there is clear CPD should

cesarean delivery be performed without the prior use of oxytocin. For example, labor through a platypelloid pelvis with a normal term-sized fetus is rarely successful because of the markedly shortened anterior–posterior diameter that characterizes this pelvic architecture. After assessment of the pelvic type, approximations of the fetal size should be undertaken. Unless the fetus appears to be markedly macrosomic (>4,500 g), medical therapy with oxytocin should be instituted.

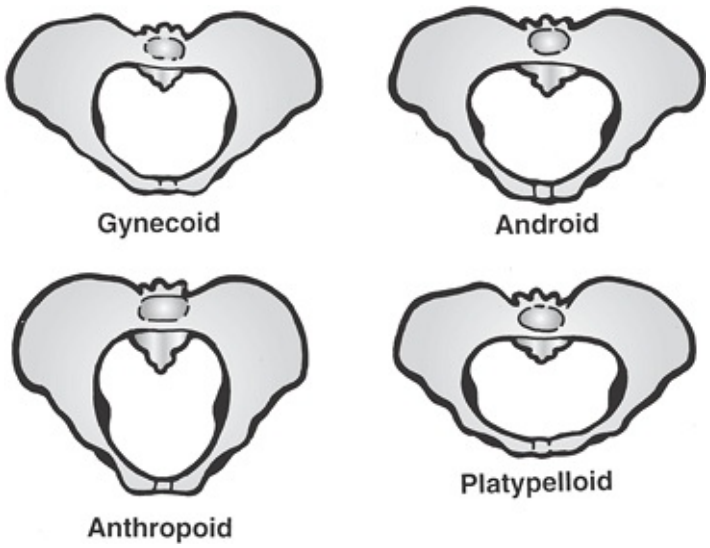

Figure 24.6 Pelvic types. There are four primary pelvic types: gynecoid, android, anthropoid, and platypelloid. Women may have a mixed pelvic type with features suggestive of different pelvic types that do not fit conveniently into one of these four types.

Abnormal Position of the Fetal Head

Abnormal positions of the fetal head include occiput posterior (OP), deep transverse arrest, and deflexion abnormalities such as face and brow presentations and reflect fundamental abnormalities in the cardinal movements of labor. Different positions of the fetal head are depicted in Figure 24.7. An OP position is unfavorable for successful vaginal delivery, particularly if the parturient has an android pelvic structure, as the long diameter of the fetal head negotiates the maternal pelvis at a relatively high station, leading to poor descent. The OP position may occur in up to 10% of women in labor and can be corrected with oxytocin therapy. According to Cheng and associates, associated factors for OP position include epidural use, amniotomy, African American race, nulliparity, and birth weight >4,000 g. Operative vaginal delivery, either via a Scanzoni maneuver or via a straight OP application with traction, is another option for delivery. A Scanzoni maneuver involves rotating the OP fetus to an OA position with forceps and then completing the delivery with forceps from the OA position. A Scanzoni maneuver is associated with a higher incidence of maternal trauma (third- and fourth-degree lacerations of the perineum and sulcus tears of the vagina) and fetal

trauma. Hence, such deliveries should be performed only by obstetricians skilled in these techniques and thus have largely fallen into disfavor. Moreover, delivery of the OP fetus via forceps should probably be attempted only if the fetal head has attained at least a +2 station. At higher stations, cesarean delivery may be the safest alternative. The prudent obstetrician will realize that assigning station in a labor characterized by an OP position is more difficult than in an OA position and often leads to the impression of a lower station than actually is present. Care should be taken to accurately assess the biparietal diameter in relationship to the maternal ischial spines.

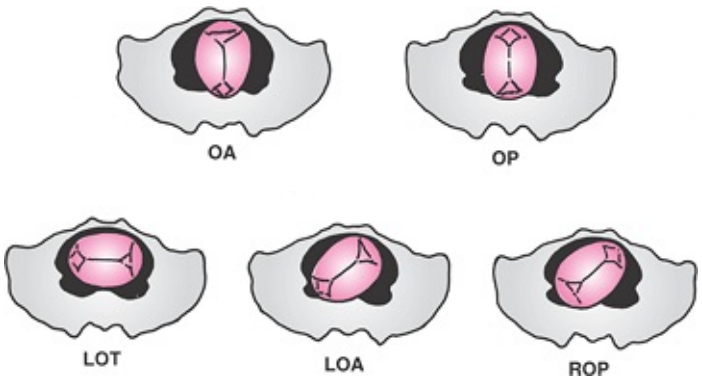

Figure 24.7 Position of the fetal head. The sutures of the fetal head should be palpated, and the fetal head position should be recorded to ensure that the normal cardinal movements of labor are being followed. The fetal occiput, with the maternal position, are the reference points. Hence, *OA* refers to the occiput anterior position; *OP*, occiput posterior; *LOT*, left occiput transverse; *LOA*, left occiput anterior; *ROP*, right occiput posterior. Any fetal position can occur and should be noted on the labor curve.

A deep transverse arrest occurs in the second stage, where the fetus maintains an OT position at a low pelvic station. Deep transverse arrests often are associated with abnormal maternal pelvic architecture and may not be easily delivered via forceps. Kielland. forceps were designed to address the problem of the deep transverse arrest. Vacuum delivery probably should be avoided in this circumstance, as excessive traction of the fetus with a deep transverse arrest can result in significant birth trauma. Cesarean delivery is the most prudent option if the fetal station is not sufficiently low for operative vaginal delivery or if excessive traction is required to effect delivery. Operative vaginal delivery for a deep transverse arrest should be performed only by obstetricians skilled in the use of forceps for this problem.

Deflexion abnormalities also cause dystocia. The classic forms of deflexion abnormalities include brow and face presentations. Typically, a brow presentation is characterized by the long axis of the fetal head negotiating the short axis of the midpelvis, precluding vaginal delivery. A fetus in the brow presentation may spontaneously convert to a vertex or face presentation. Whereas fetuses with a brow presentation that do not convert rarely deliver

vaginally (except in women with generously sized midpelvic dimensions with a small fetus), face presentations often will deliver vaginally if the mentum, or chin, is positioned anteriorly (mentum anterior). Although these extreme flexion abnormalities usually are easily diagnosed and are relatively rare, other mild flexion abnormalities may not be so readily evident. Flexion abnormalities may be suspected in a prolonged or protracted labor that is unresponsive to oxytocin. Unfortunately, there are no safe and accepted means to correct flexion abnormalities of the fetal head.

Often, abnormal fetal position may occur as the result of the maternal pelvic type (Fig. 24.6). For example, android pelvic types often lead to deep transverse arrest or OP position because of the progressive narrowing of the pelvis. Women with an anthropoid pelvis tend to have fetal positions persistently OA or OP, thus interfering with the normal cardinal movements of labor. Finally, women with a true platypelloid pelvis have transverse arrests, assuming that the fetal head negotiates the shortened pelvic inlet. Because many women have mixed pelvic types, careful clinical pelvimetry may provide valuable information in the management of dystocia.

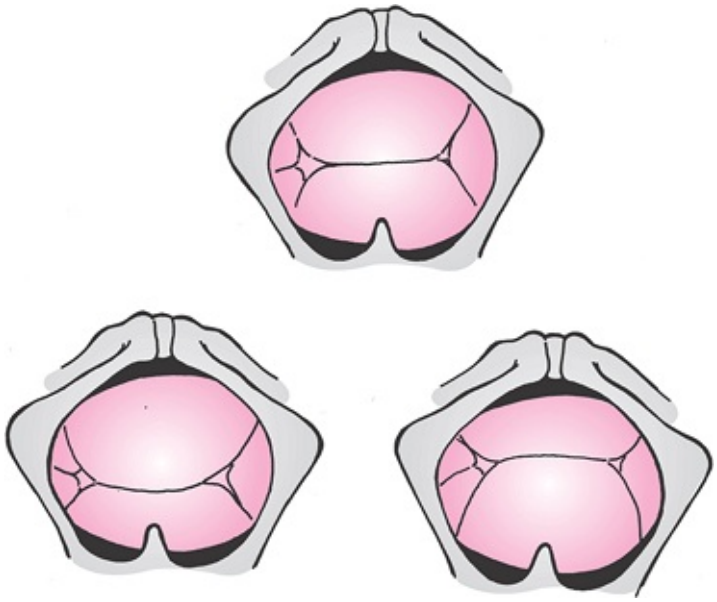

Figure 24.8 Synclitism. The term *synclitism* refers to the relative orientation of the fetal sagittal suture with the maternal bony pelvis. **A:** Normal synclitism of a fetus in left OT position, with the sagittal suture equidistant between the anterior and posterior segments of the maternal pelvis. **B:** Posterior asynclitism, where the sagittal suture is closer to the posterior bony pelvis and more of the right parietal bone is palpated. **C:** Anterior asynclitism in which the sagittal suture is more anteriorly located, and the left parietal bone is more readily evident.

Asynclitism

When asynclitism of the fetal head occurs, the sagittal suture of the head is either deviated posteriorly or anteriorly in relation to the maternal outlet (Fig. 24.8). As with

other abnormal positioning of the fetal head, a larger diameter of the fetal head is expected to negotiate the bony pelvis of the mother. In these situations, the second stage of labor often is prolonged and arrest of descent is common, leading to an increased need for operative vaginal delivery. An important aspect of performing operative vaginal delivery involves correction of the asynclitism of the fetal head. This correction often can be accomplished with forceps that have a sliding lock or via vacuum extraction of the fetus, where the precise attitude and positioning of the fetus is of less importance.

Fetal Abnormalities

Specific fetal abnormalities may contribute to the etiology of dystocia. Fetuses with neuromuscular disease, and particularly those who have suffered an in utero demise, may have flexion abnormalities. Also, fetal conditions such as hydrocephalus, hydrops fetalis, and tumors of the head or sacrum can lead to mechanical obstruction of the birth canal and hence cause dystocia, which usually is not remedied except by cesarean delivery.

Specific Labor Abnormalities

Only if the progress of labor is closely monitored can labor abnormalities be diagnosed. Moreover, the timely diagnosis of these labor abnormalities, with prompt medical therapy, should improve the chances of achieving a vaginal delivery. These labor abnormalities can be classified as either arrest disorders (Fig. 24.9) or protraction disorders (Fig. 24.10). Table 24.2 provides commonly used parameters for abnormal labor.

Prolonged Latent Phase

A prolonged latent phase (Fig. 24.9A) occurs when regular painful uterine contractions are present for an extended period of time without entering the active phase of labor. Although a prolonged latent phase generally is not classified as an arrest disorder, some authorities believe that the latent phase is an example of a primary dysfunctional labor. In nulliparous women, the definition of a prolonged latent phase is a period of uterine activity without cervical change for more than 20 hours, and in multiparas this time period is 14 hours. The cervix may be dilated up to 4 cm and be completely effaced. The precise etiology is not clear but likely reflects ineffective uterine contractions without a dominant myometrial pacemaker. The management of a prolonged latent phase is controversial, and there are two commonly used approaches. Some obstetricians believe that a prolonged latent phase reflects an underlying labor abnormality that should be managed aggressively

---

with amniotomy and oxytocin. The other approach is to provide supportive measures including intravenous hydration and narcotic pain relief. Studies comparing these approaches have not shown either to be a clearly superior choice, so either treatment plan is acceptable as long as the patient understands the plan and risks. The more aggressive approach in some cases may be an induction of labor with the attendant higher risk of cesarean delivery, whereas the more conservative approach runs of the risk of prolonging a potentially dysfunctional labor. Both options are acceptable and deciding which course to

take requires obstetric judgment and a motivated, informed patient.

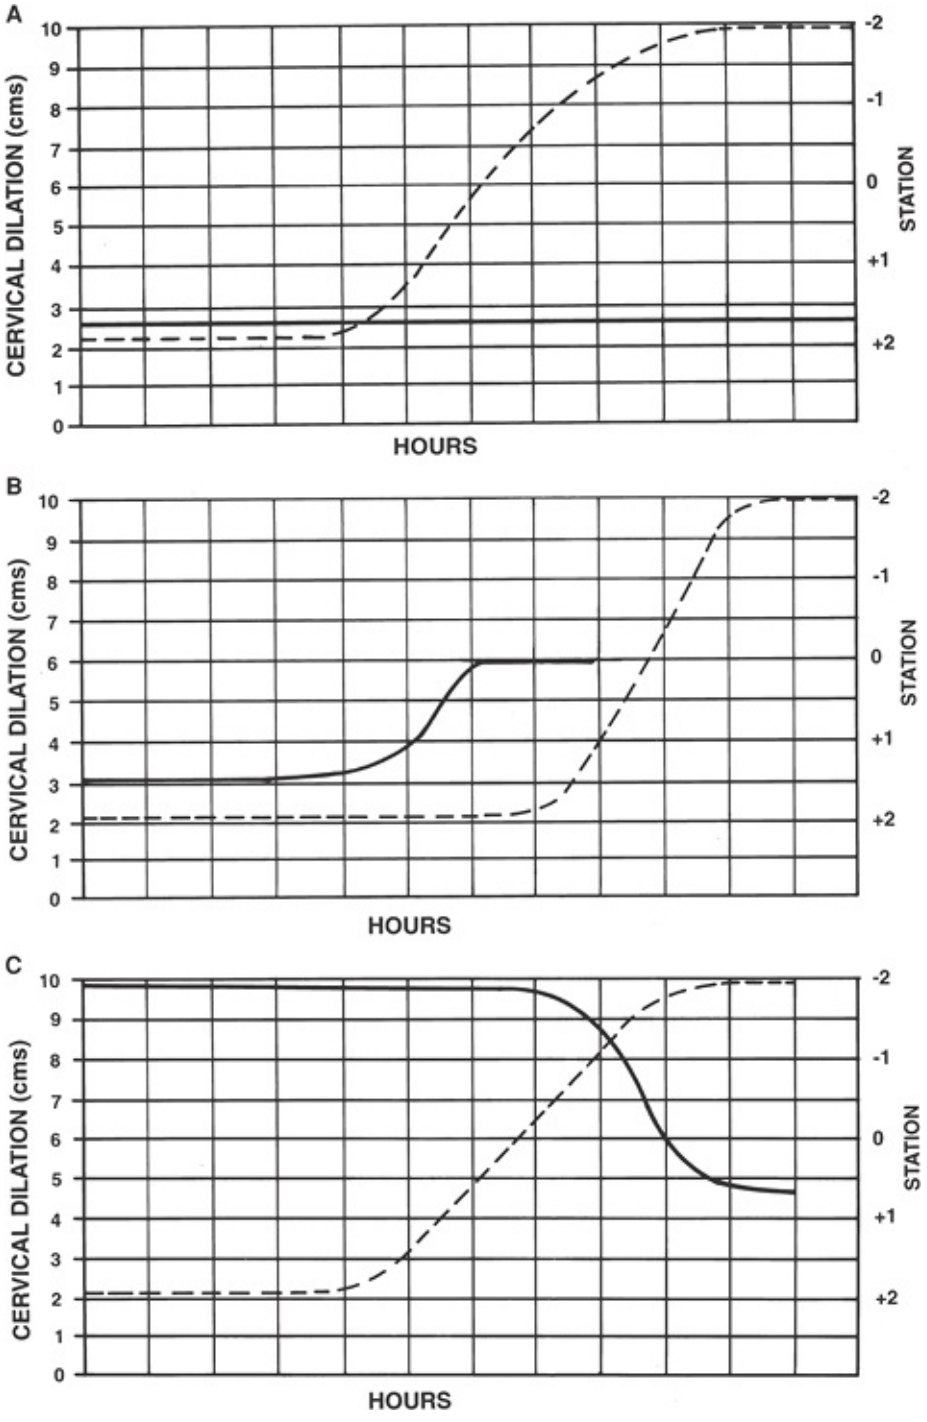

Figure 24.9 Arrest disorders. **A:** Prolonged latent phase. Although it might be said that a prolonged latent phase is not strictly an arrest disorder, it reflects an abnormality in the normal progress of labor in which the change into the active phase is arrested. **B:** Arrest of dilation, in which the cervix achieves 6 cm of dilation but then does not change for 2 hours. **C:** Arrest of descent. The fetal head moves from a –2 station to a 0 to –1 station but then makes no further progress.

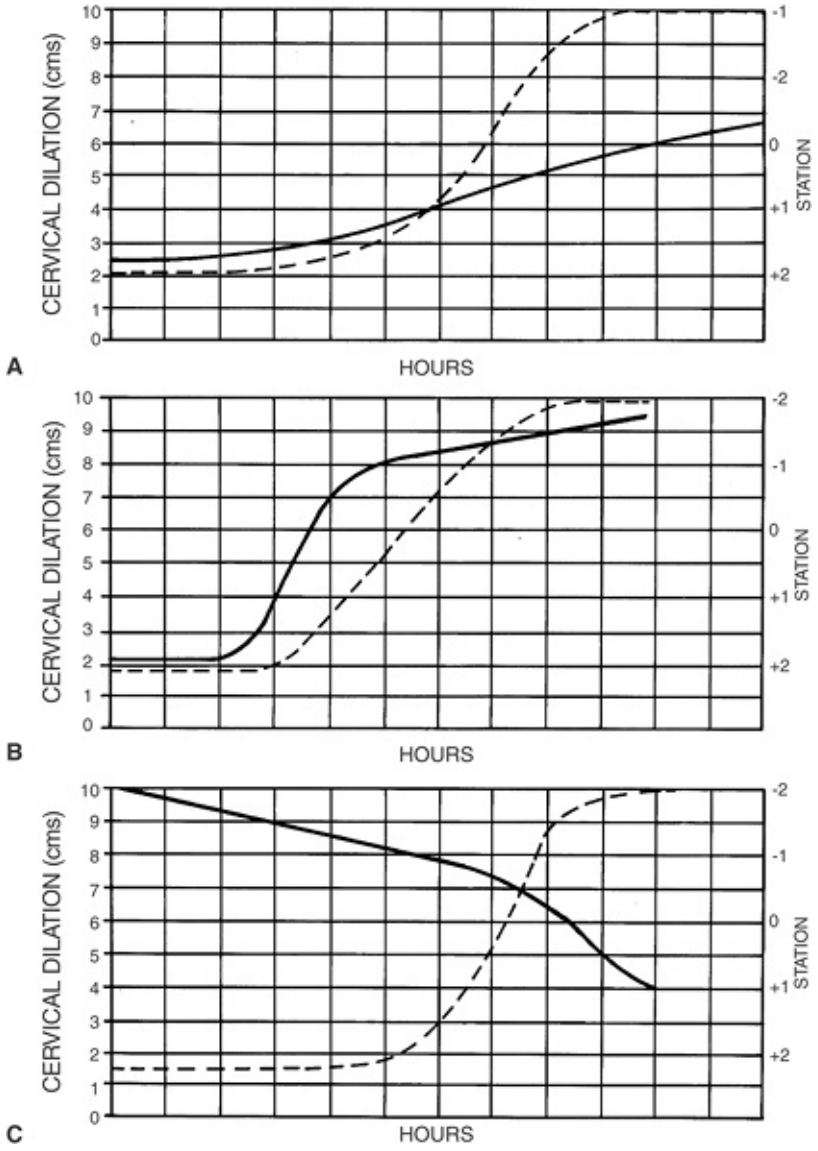

Figure 24.10 Protraction disorders. These examples of protraction disorders are exaggerated to depict each abnormality. In each case, these abnormalities should be detected early and appropriate therapy instituted. **A:** Protracted active phase. Note that the average slope is much less than 1.5 cm per hour. **B:** Protracted active phase that could be confused as a prolonged deceleration phase. **C:** Prolonged and neglected second stage. Intervention should occur sooner than indicated on this partogram.

Arrest of Dilation

An arrest of dilation occurs when there is no cervical change after 2 hours in the active phase of labor (Fig. 24.9B). In most cases, arrest of dilation occurs as a result of ineffective uterine contractions. Uterine contractions may become dysfunctional and lose their synchronous rhythmic nature. Figure 24.4 shows an example of the loss of a dominant myometrial pacemaker with the expression of two pacemakers firing independently and without coordinated uterine contractions. In any case, prompt medical therapy with oxytocin usually corrects the underlying problem. In those rare cases where CPD is evident on evaluation of the patient, prompt cesarean delivery is indicated and oxytocin

administration should be avoided.

Arrest of Descent

After complete dilation is achieved, the primary goal of the second stage of labor is to gain station of the fetal head through the maternal pelvis with eventual delivery. If the patient does not gain station of 1 cm after an hour of adequate pushing efforts, an arrest of descent is diagnosed (Fig. 24.9C). The cause of this arrest disorder may be one or a combination of several underlying abnormalities, including inadequate uterine contractions, CPD, abnormal fetal position, and asynclitism. If an arrest of descent is diagnosed, the obstetrician has several options including the use of oxytocin, operative vaginal delivery, or cesarean

---

delivery. The choices for therapy should be guided by the fetal status, station of the fetal head, maternal status, and operator experience.

Protracted Active Phase

When cervical change continues with adequate uterine contractions in the active phase of labor but over a longer time period than anticipated, then a prolonged active phase is the diagnosis (Fig. 24.10A). In nulliparous patients, cervical change is <1.2 cm per hour, whereas in multiparous patients cervical change is occurring at <1.5 cm per hour. A prolonged active phase may be the result of inadequate uterine contractility, but often both the timing and strength of uterine contractions appear to be normal, and cervix dilation occurs slowly despite oxytocin therapy. The underlying problem may be true CPD or an undiagnosed flexion abnormality. Oxytocin therapy often is not successful in accelerating labor, and an arrest of dilation or descent may be inevitable regardless of the therapies employed. If a protracted active phase leads to an arrest of labor despite oxytocin therapy, cesarean delivery is the best therapeutic course.

Prolonged Second Stage

An exaggerated example of a prolonged second stage is shown in Figure 24.10B. A prolonged second stage is diagnosed when the fetal head descends <1 cm per hour. A second stage lasting longer than 2 hours traditionally has been considered abnormal and an indication for operative vaginal delivery or cesarean delivery. However, more contemporary management allows for more flexibility in the management of the second stage of labor. If the fetus is tolerating the stresses of the second stage well and some gain in station is being made, then there is no indication for terminating the second stage solely on the basis of time in the second stage. Because epidural analgesia may increase the length of the second stage, there is no reason for intervention on the obstetrician's part if the fetal heart rate tracing is acceptable and the mother is comfortable. However, maternal exhaustion often will occur with the need for operative intervention. As with the other labor abnormalities, an attentive obstetrician with a plan of management for any contingency should improve both maternal and fetal outcome in abnormal second stages of labor.

In summary, several specific labor abnormalities may occur and can be diagnosed easily.

With a rational plan of management, the need for cesarean delivery can be avoided and salutary maternal and fetal outcomes accomplished. Thus, “failure to progress” is not sufficient for a diagnosis. For example, a woman may have “arrest of dilation” followed by treatment with oxytocin. If this is unsuccessful, then she may require cesarean delivery for “arrest of dilation refractory to oxytocin therapy.” Addressing labor abnormalities in more specific terms enables more rational treatment strategies to be utilized in the current and future pregnancies, regardless of the outcome.

Epidural Analgesia and Labor Progress

The impact of epidural analgesia on the occurrence of dystocia and the cesarean delivery rate has been controversial. Epidural analgesia is an excellent form of pain relief for the laboring woman, and in some labor and delivery units, the majority of laboring women opt for this therapy (Chapter 3). Epidural analgesia is a vital part of the obstetrician and anesthesiologist's armament to provide pain relief during labor, and both the ACOG and the American Society of Anesthesiologists endorse the use of epidural analgesia for pain management in labor.

However, epidural analgesia may have contributed significantly to the cesarean delivery epidemic of the past 2 decades. A meta-analysis in 1994 by Morton and colleagues regarding epidural use in the laboring woman cites an increase risk of 10% for cesarean delivery. Recent studies have supported this finding. In 2000, Traynor and coworkers reported that epidural analgesia was associated with a fourfold increased risk for cesarean delivery (12.2% in women with epidural vs. 3.3% in women without epidural) and that the risk for cesarean delivery increased progressively with higher station, less dilation, and less effacement at the time of catheter placement. Similarly, in 2000, Sizer and associates found that epidural analgesia was associated with an increased incidence of OP presentation, leading to a threefold increase in the risk for cesarean delivery (13.7% for OA presentation and 41.7% for OP presentation) and for operative vaginal delivery (24.4% for OA presentation and 43.7% for OP presentation).

Conversely, other studies contradict these reports and note that epidural use was not associated with an increase in the incidence of OP presentations. In 1998, Clark and colleagues published a prospective randomized trial comparing epidural analgesia with intravenous opioids for pain relief. The cesarean delivery rates were no different in the two groups (13.6% in the opioid group and 9.6% in the epidural group). Imprey and associates, in a retrospective review of 1,000 nulliparas, found that an increase in the epidural use from 10.0% to 57.0% over the course of 7 years did not result in an increase in the cesarean delivery rate of 3.8% to 5.0%. Zhang and coworkers, in a summary of studies regarding the use of epidural analgesia and labor outcome, concluded that clinical trials of epidural use of low-dose bupivacaine did not increase the risk of cesarean delivery.

A more recent prospective randomized study by Wong and colleagues compared application of intrathecal narcotic epidural analgesia with systemic narcotics early (<4 cm cervical dilation) and late (≥4 cm cervical dilation) in women with spontaneous labor. They found no difference in the cesarean delivery rate between groups and as well found that women

with intrathecal narcotic epidural analgesics had better pain relief and shorter labors. An analysis by the Cochran Collaboration summarized several studies regarding the risk of operative vaginal delivery and cesarean delivery in women who received epidural analgesia. They reported a significantly increased risk for operative vaginal delivery (Fig. 24.11) but no difference in the rates of cesarean delivery in women with epidural or nonepidural analgesia (Fig. 24.12). Notably, however, observational studies do indicate an increased risk for cesarean and instrumental deliveries, suggesting that selection bias may skew these results. These studies depict the exceptional difficulty of studying this clinical issue, given the complexity of the labor process and the multitude of factors that may impact on labor outcomes.

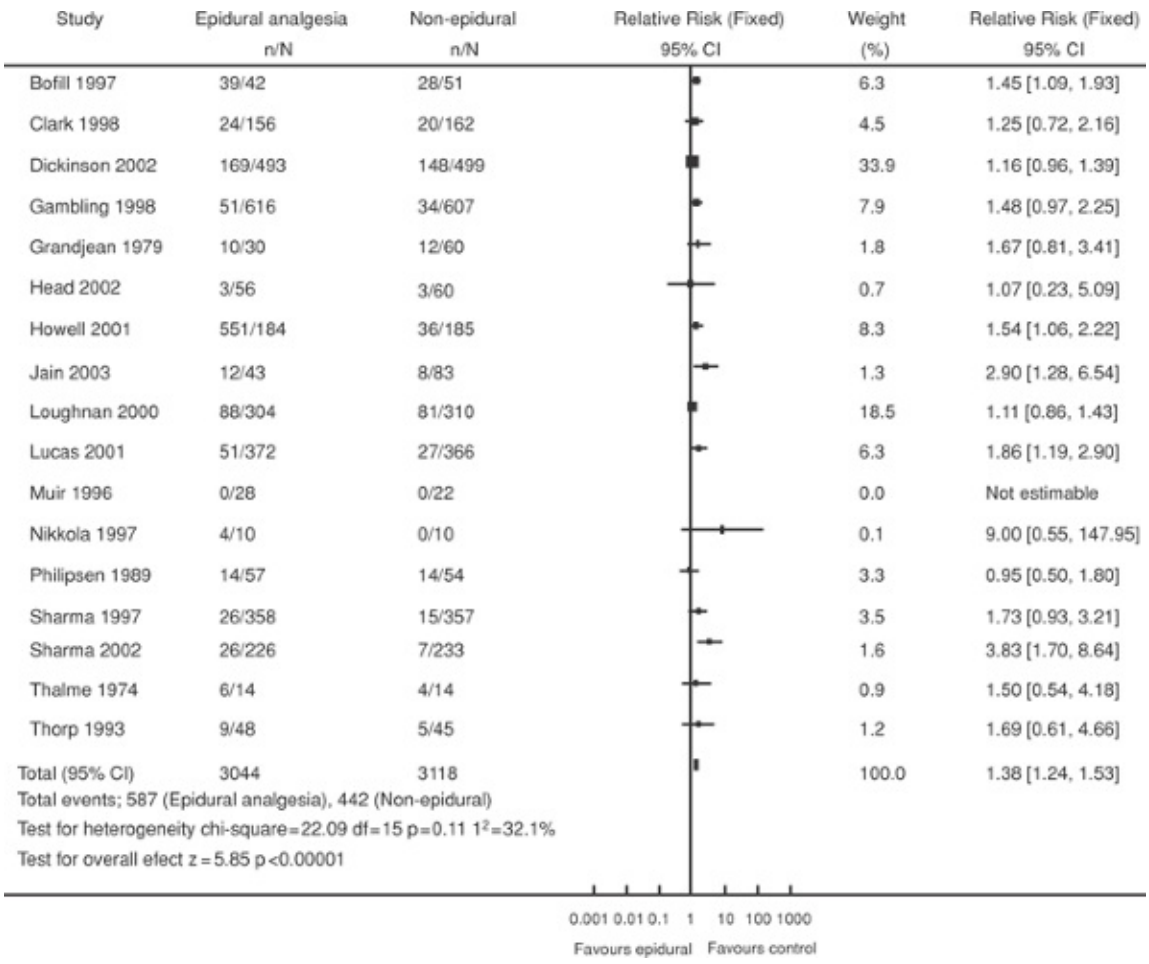

Figure 24.11 Epidural versus nonepidural analgesia: operative vaginal delivery. Women who have epidural analgesia have an increased risk for operative vaginal delivery (forceps or vacuum extraction) when comparative studies are combined. (From Anim-Somuah M, Smyth R, Howell C. Epidural vs. non-epidural or no analgesia in labour. *Cochrane Database Syst Rev* 2007; issue 2, with permission.)

The key to rational use of epidural analgesia is the approximation of fetal station and cervical dilation. In a 1999 study, Hold and associates reported that the strongest risk factor for cesarean delivery with epidural analgesia was station at the time of epidural placement. The higher the station at the time of epidural, particulary if -1 or higher, the

greater the risk for cesarean delivery. A subsequent study by Le Ray and coworkers showed that this increased risk may be due to a higher rate of OP and occiput transverse (OT) fetal head positions in women who receive epidural analgesia at less cervical dilation and a higher fetal station. Based on these studies, the obstetrician can be reassured that even early application of epidural analgesia is safe and, while there continues to be some controversy, not associated with an increased risk of cesarean delivery in most populations. Importantly, women in labor should not be denied epidural analgesia when clinically reasonable and safe.

Options for the Management of Dystocia

Once dystocia is diagnosed and a specific abnormality identified, the obstetrician has a number of therapeutic

options that can lead to vaginal delivery rather than immediate cesarean delivery. Oxytocin should be administered first unless there is a clear contraindication to this medication, as this is an effective and safe therapy in experienced hands and can correct most labor abnormalities.

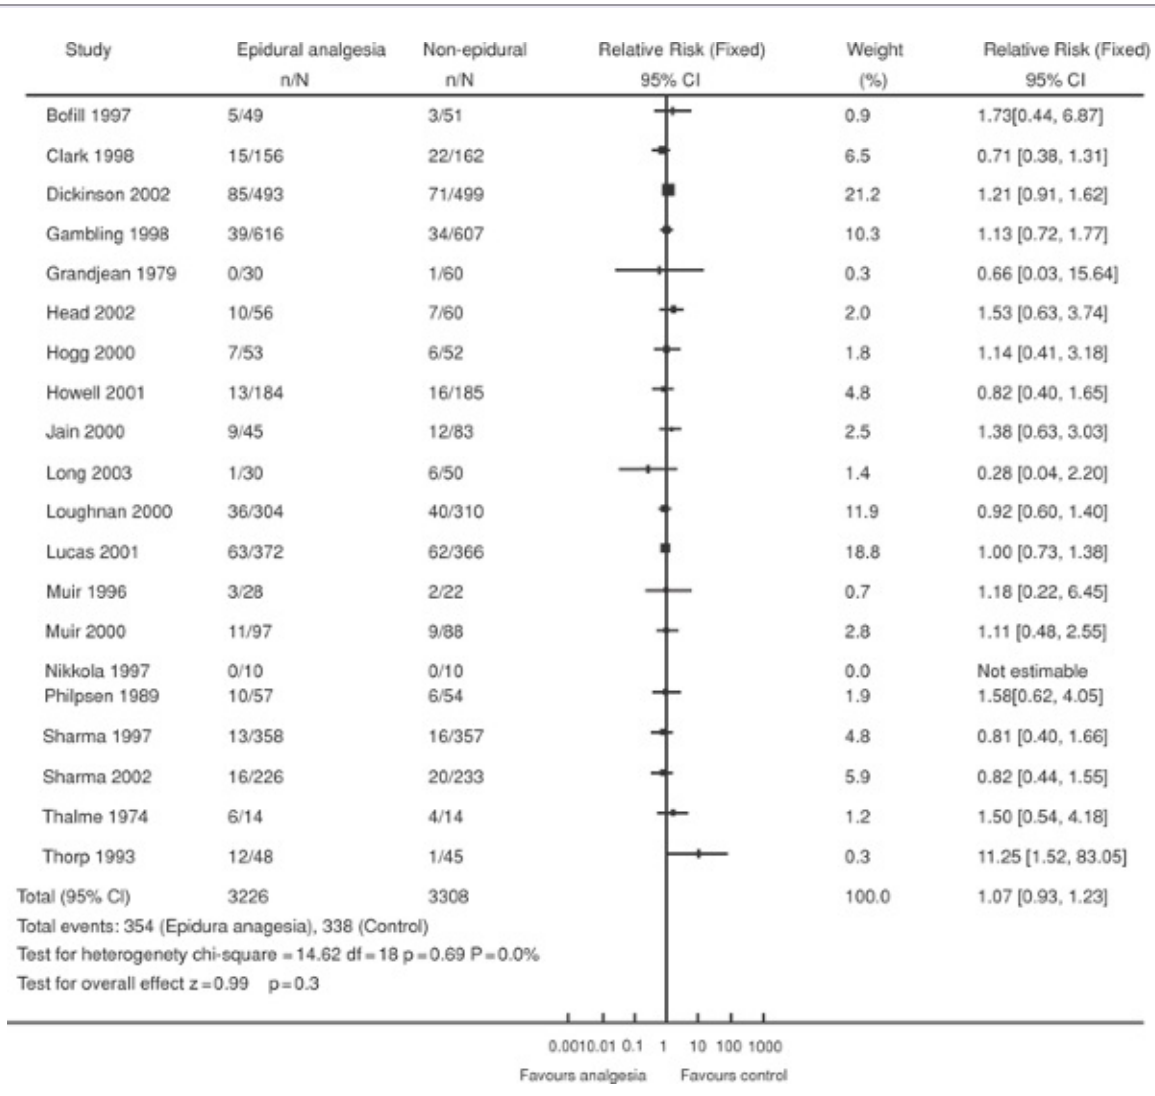

Figure 24.12 Epidural versus nonepidural analgesia: cesarean delivery. Women who have epidural analgesia do not have an increased risk for cesarean delivery when

comparative studies are combined. (From Anim-Somuah M, Smyth R, Howell C. Epidural vs. non-epidural or no analgesia in labour. *Cochrane Database Syst Rev* 2007; issue 2, with permission.)

Mapping the Progress of Labor

A key adjunct to the management of labor is the use of some form of a labor curve. Various types of labor curves have been developed, and no one is better than any other. Several reports have shown that the graphical analysis of labor progress improves maternal and fetal outcomes while lowering cesarean delivery rates, including sites in underdeveloped countries. Many labor and delivery units utilize the concept of “alert” and “action” lines (Fig. 24.13). In this type of partogram (or labor curve), crossing an alert line merely means that labor progress is slowing, while crossing the action line indicates that a specific action must be taken. Mapping labor progress allows for the timely diagnosis of dysfunctional labor and the prompt institution of medical therapy. Therefore, most contemporary labor and delivery suites have incorporated the use of labor curves into the routine management of laboring women.

Amniotomy

Artificial rupture of membranes has been used in the management of slow or desultory labor for decades. This intervention has been deplored by some obstetricians as needless intervention and recommended by others as a useful adjunct. Retrospective studies with relatively small sample sizes suggested that amniotomy could speed normal labor and stimulate abnormal labor to again meet normal

milestones. However, recent large-scale prospective randomized studies do not support the routine use of amniotomy in the management of dystocia (Fig. 24.14). Although normal labor is accelerated modestly, particularly in multiparous women, patients in whom amniotomy was routinely used did not have lower rates of cesarean delivery. Additionally, there is a modest increase in the rate of intrauterine infection in women who underwent amniotomy early in the course of labor (e.g., <4 cm dilation). Rupture of the membranes also is associated with variable decelerations of the fetal heart rate as a result of umbilical cord constriction. In some cases, this problem can be remedied via amnioinfusion of warm saline into the uterine cavity via an intrauterine pressure catheter (IUPC). An IUPC is placed in the situation of using one measure to improve outcome (amniotomy), which only leads to further interventions that otherwise could have been avoided.

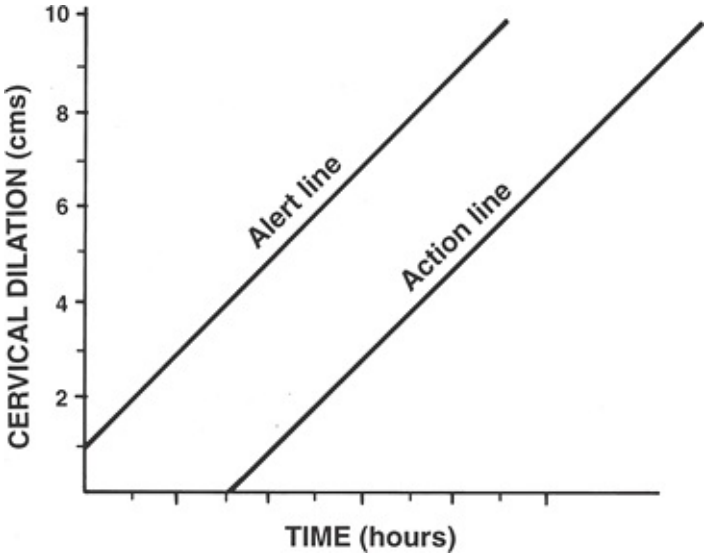

Figure 24.13 Action and alert lines in the management of labor, depicted graphically. This type of labor curve has been used successfully to manage labor in many different settings. With this curve, slowing of the labor curve is first marked by an alert that labor is not progressing normally. Then, with further lack of progress, the action line is crossed, mandating that some form of action (medical or surgical therapy) be instituted. (Adapted from Philpott PH, Castle WM. Cervicographs in the management of labor in primigravidae: II. The action line and treatment of abnormal labor. *J Obstet Gynecol Br Commw* 1972;79:599–602, with permission.)

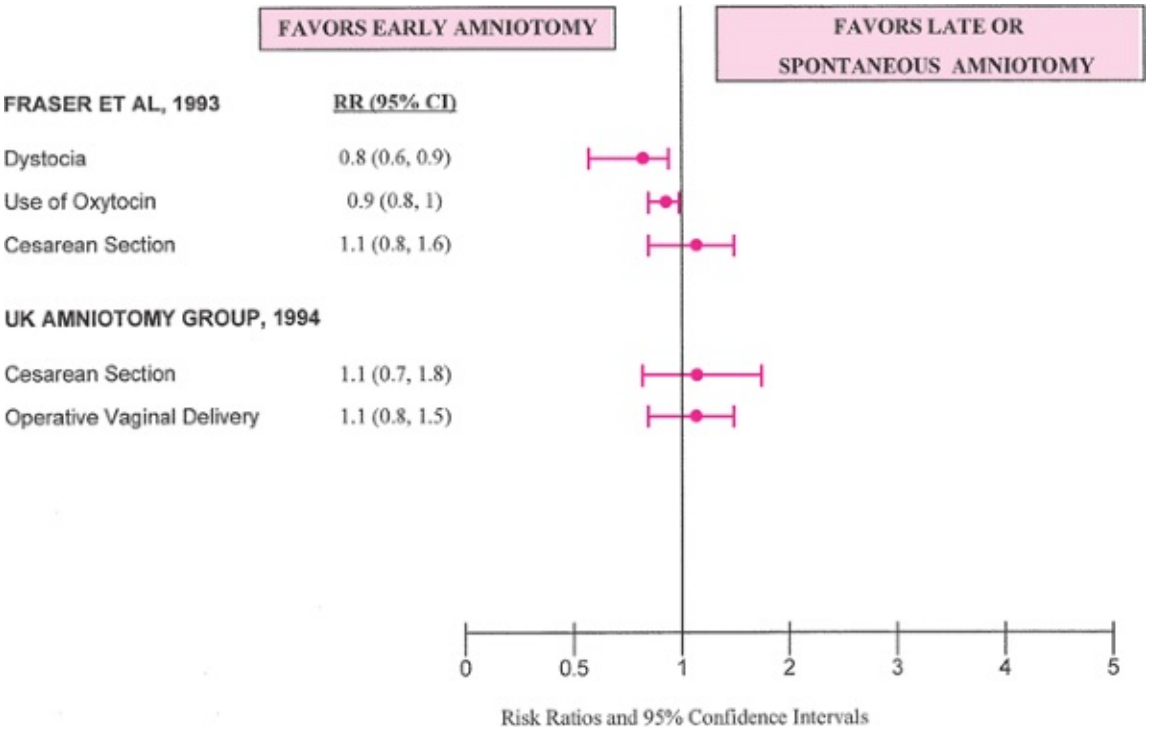

Figure 24.14 Odds ratio of the effect of amniotomy on labor dystocia. Amniotomy has little effect on the course of labor, the incidence of dystocia, or the incidence of cesarean delivery. (RR, relative risk; CI, confidence interval.)

Conversely, there are reasonable indications for amniotomy. Amniotomy is an excellent method for labor induction if the cervix is favorable and the fetal head is well applied to the cervix. The judicious use of amniotomy after 5 cm does accelerate labor in the multiparous woman but less so in the nullipara. Also, oxytocin tends to work more efficiently if the membranes have been ruptured. Disruption of the membranes is required for internal monitoring of the fetal heart rate tracing or of uterine activity. Rupturing of the membranes will detect meconium staining of the amniotic fluid and alert the obstetrician and pediatrician to be prepared for a potentially high-risk circumstance regarding care of the newborn and the prevention of meconium aspiration.

Thus, amniotomy can be a useful adjunct in the management of labor but only if used wisely and in appropriate circumstances. As long as the parturient is making adequate progress in labor and the fetal heart rate tracing is normal,

there is no indication for amniotomy. Cervical examinations should be minimized after the membranes have been ruptured to decrease the chance of infection, because the number of cervical examinations correlates well with the risk of intrauterine infection.

Intrauterine Pressure Catheters

An IUPC can be introduced into the amniotic cavity to help determine the strength of uterine contractions. Application of the catheter requires that the fetal membranes are ruptured, either by spontaneous or artificial means.

Many different quantitative approaches to uterine contractility have been proposed using IUPC technology. For example, the Montevideo unit is the average intensity of the uterine contractions multiplied by the number of contractions over a 10-minute period (expressed as mm Hg/10 minutes). A total of 200 Montevideo units is often used to indicate that there is adequate uterine contractility to effect labor progress. Past studies have suggested that if this level of uterine activity was achieved and no labor progress resulted, then one could state that an adequate trial of labor had been completed and justify cesarean delivery. Other studies have found that IUPCs increase the rate of intrauterine infection with no definable benefit. No study to date has shown that the use of IUPC technology improves maternal or perinatal outcome. Therefore, there is no compelling reason to use IUPCs in the management of labor. Perhaps their best application is in assisting nursing personnel with the use of oxytocin so that the precise timing of uterine contractions can be determined.

Oxytocin

Oxytocin is a nine-amino acid peptide (Fig. 24.15) that normally is produced in the hypothalamus and secreted by the posterior pituitary in a spurting or pulsatile fashion. During normal pregnancy, serum oxytocin concentrations increase slightly throughout gestation, and there is only modest increase in total serum concentrations before labor. However, with labor, plasma levels increase significantly and then peak in the second

stage. Expression of oxytocin receptors increase in the deciduas and myometrium in the weeks preceding the onset of labor and increase sharply just before labor. Oxytocin receptors are expressed primarily in decidua, myometrium, and breast tissue. Myometrial sensitivity to oxytocin parallels expression of oxytocin receptors such that responsiveness begins at about 20 weeks gestation and then dramatically increases at about 30 weeks gestation. Oxytocin is cleared from peripheral blood by the liver and kidney and also is significantly metabolized by oxytocinase, an enzyme produced in abundant quantities by the placenta and gestational tissues.

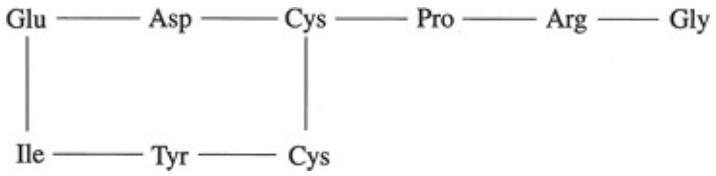

Figure 24.15 The amino acid structure of oxytocin. Oxytocin is a nine-amino acid peptide with two disulfide bonds. (*Glu*, glutamic acid; *Asp*, aspartic acid; *Cys*, cysteine; *Pro*, proline; *Arg*, arginine; *Gly*, glycine; *Ile*, isoleucine; *Tyr*, tyrosine.)

Oxytocin may be administered intravenously, subcutaneously, intramuscularly, and buccally. With intravenous administration, there is a concentration-dependent increase in its serum levels but with wide individual variation in responsiveness to the drug. Intravenous administration of oxytocin has effects only on tissues expressing receptors and thus has an excellent therapeutic index. Oxytocin administration results in an increase in the frequency, duration, and strength of uterine contractions. The myometrial response to oxytocin is highly variable, and uterine hyperstimulation may occur at any dose of administered oxytocin, depending on the patient. Uterine hyperstimulation necessitating discontinuation of the drug or a decrease in the dose being used is the most common side effect of the medication. The only known side effects of oxytocin not related to uterine activity include disturbances in water homeostasis and electrolytes. Oxytocin has approximately 1% the antidiuretic effect of vasopressin, and these side effects usually are seen only at high concentrations of oxytocin infusion (e.g., 40 to 50 total units administered). Also, intravenous boluses of oxytocin can lead to hypotension and tachycardia as a result of a paradoxical relaxation of vascular smooth muscle.

From the first clinically described use of oxytocin in the 1940s, there has been controversy as to the best and most appropriate regimen for oxytocin use. Table 24.4 summarizes some different acceptable oxytocin protocols that currently are in use. Historically, early regimens of oxytocin administration were highly individualized by physician preference,

ranging from relatively low doses to extremely high doses. For example, Seitchik and Castillo found that the most important determinant of the maximum oxytocin dose and the frequency of hyperstimulation was dose incrementation interval. Those patients who received lower-dose increments (every 30 to 40 minutes) by 1.0 mU per minute

had lower oxytocin doses and less hyperstimulation with good outcomes.

TABLE 24.4 Acceptable Oxytocin Protocols

Starting Oxytocin Dose	Incremental Dose Increase	Timing of Incremental Dose Increase	Source
1 mU/min	1 mU/min	40 min	Seitchik and Castillo
4 mU/min	4 mU/min	15–20 min	Houston, Texas
6 mU/min	6 mU/min	15–20 min	AMOL protocol

AMOL, active management of labor.

However, recent studies have shown that low-dose protocols may result in higher cesarean delivery rates when compared with higher-dose oxytocin protocols. Satin and associates utilized two different methods of oxytocin administration. In one 5-month period, they used a low-dose regimen in 1,251 women where the starting dose of 1 mU per minute was increased by 1 mU per minute every 20 minutes until 8 mU per minute was reached, and then the incremental increase was by 2 mU per minute every 20 minutes up to a maximum of 20 mU per minute. For the next 5-month period (1,537 women), they studied the higher-dose regimen advocated by O'Driscoll, in which the starting dose of 6 mU per minute was increased by 6 mU per minute every 20 minutes up to a maximum of 42 mU per minute. Among those patients being augmented, the average maximum oxytocin dose was greater in the high-dose protocol (14.7 mU per minute vs. 6.6 mU per minute), as was the incidence of uterine hyperstimulation (52% vs. 39%). Notably, there was a significant decrease in the cesarean section rate for dystocia (9% vs. 12%), the use of forceps (12% vs. 16%), rates of neonatal sepsis (8% vs. 12%), and a shorter time from admission to delivery (10.1 hours vs. 13.4 hours).

In a following study, Satin and associates compared two incremental dosing intervals of high-dose oxytocin, comparing a 20-minute dosing interval versus a 40-minute dosing interval. In those women receiving oxytocin for labor augmentation, 603 were in the 20-minute interval group and 564 were in the 40-minute interval group. The results of this study showed that the maximum oxytocin dose, the time from admission to delivery, and the incidence of uterine hyperstimulation were similar in each group. However, women receiving incremental increases in oxytocin at 20-minute intervals had a significantly lower cesarean section rate for dystocia (8% vs. 12%).

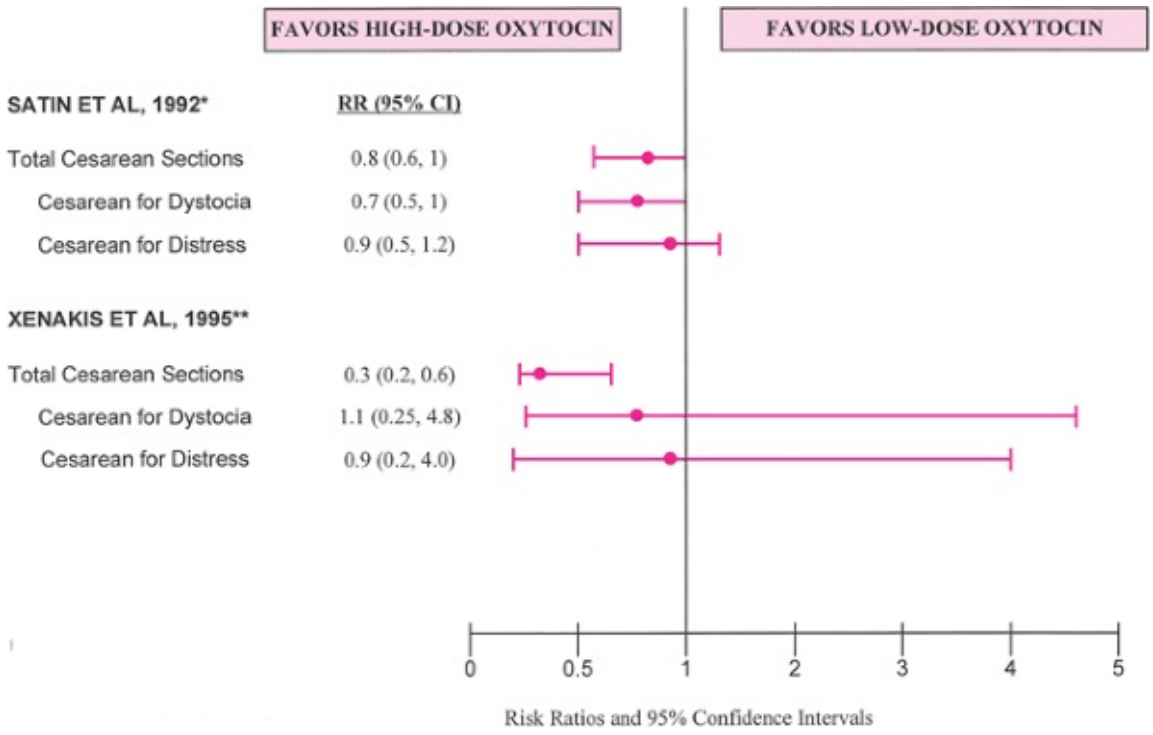

Figure 24.16 Odds ratio of low-dose oxytocin versus high-dose oxytocin. High-dose oxytocin results in lower overall cesarean delivery rates. (RR, relative risk; CI confidence interval.)

A randomized study by Xenakis and coworkers compared the low-dose protocol of Seitchik to a higher-dose protocol in which oxytocin was commenced at 4 mU per minute and increased by 4 mU per minute every 15 minutes. They found a significantly greater number of cesarean deliveries in women receiving the lower-dose regimen (25.7% vs. 10.4%). There were no differences in maternal or neonatal outcome or in the incidence of hyperstimulation. The average maximal dose of oxytocin in the high-dose regimen was only 9 mU per minute, suggesting that achieving a more rapid response with higher doses does not require excessive amounts of oxytocin and that prompt correction of the labor abnormality is critical for success.

In a more recent analysis of studies comparing epidural analgesia with opioid analgesia by Kotaska and colleagues, the authors concluded that prompt diagnosis of dystocia with a higher dose of oxytocin augmentation was associated with lower cesarean delivery rates

when compared with low-dose oxytocin protocols. These studies suggest that a higher dose of oxytocin will stimulate a higher proportion of patients earlier, resulting in more timely correction of dysfunctional labor and a lower risk for cesarean delivery (Fig. 24.16). There are numerous factors that can

account for the wide variation in responsiveness to oxytocin infusions, including differences in oxytocin receptor expression, differences in oxytocin plasma concentrations, and differences in oxytocinase concentrations and activity.

An important unanswered question relates to the safest maximum dose of oxytocin. While some authorities advocate a maximal dose of 42 mU per minute, there are few data on which to base this recommendation. In a prospective randomized double-masked trial of oxytocin dosage in labor induction and augmentation by Merrill and Zlatnik, two different doses were used. A low-dose regimen of 1.5 mU per minute increasing by 1.5 mU per minute every 30 minutes was compared with a higher-dose regimen of 4.5 mU per minute increasing by 4.5 mU per minute every 30 minutes. Higher-dose oxytocin was associated with a significant shortening of labor but with no significant differences in cesarean delivery rates. The highest oxytocin dose administered was 117 mU per minute, and there were no differences in neonatal outcomes. Hence, no solid recommendations based on data can be made regarding the maximal safe dose of oxytocin.

Regardless of the choice of protocols, clinical judgment should be used when oxytocin therapy is prescribed. There should be no evidence of fetopelvic disproportion based on clinical pelvimetry and estimated fetal weight. If the pelvis is not adequate or the fetus is large, then the dysfunctional labor may be a sign that vaginal delivery is not safe, and cesarean delivery would be the more appropriate therapy. Additionally, oxytocin should not be used in women with prior classical cesarean section scars, because the risk of uterine rupture is high (5% to 10%). Care should be utilized when women with prior low transverse cesarean sections are being augmented with oxytocin. Although the studies regarding the use of oxytocin and the risk of scar dehiscence are mixed, one should know the total dose given and follow the course of labor carefully. Oxytocin is an extremely effective drug when used appropriately but can be dangerous for mother and fetus if used inappropriately. Therefore, clinical judgment is required whenever oxytocin is utilized in the management of dystocia.

Obstetrical Patience

Recently, traditional management of labor has been challenged by some new concepts based on scientific data rather than expert opinion. Both of these new ideas rely on the obstetrician's patience and willingness to allow time for the patient to progress at a somewhat slower rate than has previously felt to be acceptable. In this regard, both concepts are based on the use of fetal monitoring to ensure that the fetus is tolerating labor well.

Traditionally, an arrest of the active phase of labor with oxytocin augmentation for >2 hours was an indication for cesarean delivery. However, studies by Rouse and coworkers question this 2-hour time limit. In their initial study, they found that extending the time

period of active phase arrest while on oxytocin from 2 hours to 4 hours was both safe and effective. In their original cohort of 542 normal women presenting with arrest of term labor, 126 demonstrated no labor progress after 2 hours of oxytocin augmentation. However, 101 of these 126 delivered vaginally, decreasing the overall cesarean delivery from 26% (if the 2-hour limit was used) to 8% for the entire study. In those women with presumed adequate labor on the basis of Montevideo units, 32 of 52 delivered vaginally simply by waiting for 4 hours rather than moving to cesarean after 2 hours. These women did have a higher incidence of intrauterine infection but without increased neonatal morbidity.

In a following study, Rouse coworkers studied 501 women with a similar protocol. Of these women, 38 had sustained adequate labor for 2 hours based on Montevideo units and no progress in labor. By merely waiting another 2 hours, 23 (or 61%) delivered vaginally and avoided an otherwise indicated cesarean delivery based on traditional criteria. Again, there were no adverse neonatal effects of continuing oxytocin for 4 hours, and there was a higher incidence of intrauterine infection in those women who labored further. As well, they found that achievement and maintenance of 200 Montevideo units, the value traditionally noted to represent “adequate” labor, was not predictive of delivery route.

While patient numbers are as yet insufficient to change traditional recommendations on the management of labor arrest, these studies, if confirmed, strongly suggest that allowing more time for oxytocin augmentation is reasonable, effective, and safe. A key issue again is that one management plan should not necessarily apply to all women in labor, as there is considerable individual variation in labor progress and responsiveness to oxytocin.

Different strategies managing the second stage have been reported. These studies have compared two groups of women in the second stage, in which one group of women was encouraged to push promptly with the diagnosis of complete dilation while the other group was encouraged to rest for 1 to 2 hours (or more) before starting pushing efforts. In the Canadian study by Fraser and associates, nulliparous women in the delayed pushing group were encouraged to wait at least 2 or more hours prior to pushing. Over 900 women were enrolled in each group. When compared with the early pushing group, women who delayed pushing had a lower incidence of “difficult delivery” (17.8% vs. 22.5%). Difficult delivery was defined as the need for midpelvic delivery, low-pelvic delivery with rotation, any manual rotational delivery, or second-stage cesarean delivery. The primary difference was in the incidence of midpelvic delivery (9.3% vs. 13.0%), while cesarean delivery rates were similar (5.0% vs. 5.7%). Maternal morbidity and neonatal outcomes were similar between the two groups.

The other study of delayed pushing, by Hansen and colleagues, also was a randomized prospective trial comparing immediate versus delayed pushing efforts in over 250 women. In those women randomized to delayed pushing,

---

nulliparas were rested for 120 minutes while multiparas rested for 60 minutes. The investigators found that there were no statistically significant differences in instrumental delivery rate, neonatal outcome, and rates of perineal injury. Women who rested had a longer second stage of labor but decreased total time pushing, fewer decelerations, and

less fatigue. Only three cesarean deliveries were performed, and all were in the control group. The authors concluded that delayed pushing, up to 4.9 hours, was safe and may be useful in selected patients.

The studies described in this section underscore the value of obstetrical patience. While there are average times in labor and in the second stage, these studies show that traditional and arbitrary time limits may be extended safely in selected patients, with improved maternal outcomes and continued good neonatal outcomes.

Operative Vaginal Delivery

Operative vaginal delivery should be performed only if the following criteria are met: complete cervical dilation, engagement of the fetal head filling the hollow of the sacrum, known position of the fetal head, and sufficient operator experience. Forceps- or vacuum-assisted vaginal delivery should be performed only on behalf of the mother or fetus and not for the convenience of the obstetrician. Although operative vaginal delivery has been shown to be safe in experienced hands, the rate of operative vaginal delivery in the United States continues to decline. According to the National Center for Health Statistics, the rate of operative vaginal delivery declined from 9.4% of all deliveries in 1996 to 5.2% of all deliveries in 2004.

In the context of dystocia, the primary reason for moving to assisted vaginal delivery is an arrest of descent of the fetal head. This arrest may be due to inadequate uterine contractions, insufficient maternal pushing efforts, abnormal position of the fetal head (OP or deep transverse arrest), or asynclitism of the fetal head. In these situations, the mother often has pushed for 2 hours or more and may be unable to continue with effective pushing efforts because of exhaustion.

Use of the appropriate forceps or the indications for vacuum extraction are dependent on the experience of the obstetrician. Experienced obstetricians who are skilled in the use of forceps have the judgment to use the appropriate instruments and traction for a successful and safe vaginal delivery. Less experienced providers may find vacuum extraction more successful, but vacuum-assisted delivery still requires judgment and skill for a safe delivery. Even with vacuum extraction, prudent use in specific situations will decrease the incidence of maternal and fetal complications. An all too common occurrence is the inappropriate use of operative vaginal delivery with adverse obstetric and neonatal outcome, usually due to inappropriate application on the fetal vertex at a higher than expected station. In experienced hands, there are no differences in neonatal outcome in infants delivered by normal vaginal delivery or by outlet forceps.

Cesarean Delivery

If all the previously mentioned measures are not successful, then cesarean delivery likely is needed to obtain a good maternal and neonatal outcome. Although cesarean delivery should not be considered before all options are entertained, similarly there should not be hesitation to operate if a successful vaginal delivery is not possible without potential serious risk or harm to the fetus and neonate. Delay in moving to cesarean delivery when

indicated can potentially lead to adverse maternal and neonatal outcomes such as postpartum hemorrhage, uterine rupture, and birth injury. Cesarean section is discussed in detail in Chapter 27.

Active Management of Labor

Since the mid 1960s, an organized approach known as the active management of labor (AMOL) has been developed and advocated by the obstetric staff at the National Maternity Hospital in Dublin, Ireland. Initially conceived by Kieran O'Driscoll, this approach has been modified over the years. The advocates of AMOL cite a continuing low cesarean delivery rate (approximately 18%) with excellent outcomes for mother and infant. The primary goal of AMOL is to prevent prolonged labor. Women are guaranteed that they will either be delivered, or close to delivery, within 12 hours of admission to the labor and delivery unit. The style and content of this labor management have generated much controversy and misunderstanding in the United States. For example, many obstetricians believe that the active part of AMOL is aggressive intervention in the laboring women or high oxytocin doses, but actually it refers to the fact that an obstetrician (usually the head of the department) reviews the labor progress of each patient to ensure that optimal outcomes are achieved.

Basic Concepts of Active Management of Labor

Table 24.5 lists the primary components of the AMOL. Perhaps the hallmark feature of AMOL is that no patients are admitted to the labor and delivery unit unless the diagnosis of labor has been made, with labor being defined as painful, regular uterine contractions with complete cervical effacement, regardless of cervical dilation. The average dilation of the cervix at the time of admission is 2 to 3 cm. AMOL applies only to the nulliparous patient, as multiparous women who have had previous vaginal delivery usually do not have prolonged labor and have a higher risk of uterine rupture with oxytocin administration. After the diagnosis of labor has been made, amniotomy is performed at the time of admission, regardless of cervical dilation. The

diagnosis of labor is key. If this diagnosis is incorrect, then an induction of labor is being initiated with the attendant increased risk for cesarean delivery.

TABLE 24.5 Key Concepts of Active Management of Labor

Comprehensive prenatal education
Admission only after labor is diagnosed
Strict criteria for the diagnosis of labor
Delivery with 12 h of admission
One-on-one nursing care
Immediate amniotomy at admission (if membranes still intact)

Frequent cervical examinations to ensure progress in labor
Prompt intervention if labor progress not confirmed
High-dose oxytocin protocols
Epidural analgesia is available
Midpelvic and rotational forceps not used
Continuous internal audit
“Active” involvement of attending obstetrician

On admission, a nurse–midwife or student midwife is assigned to the patient, who stays with only this patient throughout her entire labor. There are no provisions for change of nursing shifts. Also, these patients receive detailed instructions on expectations during labor in prenatal birthing classes. One-on-one nursing care, with a clear vision of the ensuing labor, alleviates maternal anxiety and is perhaps the most distinguishing feature of AMOL over other styles of labor management that are practiced in the United States.

Cervical examinations to corroborate labor progress are performed by the midwives every 1 to 2 hours. If the patient does not make adequate progress in labor, oxytocin administration is promptly initiated at 6 mU per minute and increased by 6 mU per minute every 15 minutes until seven to eight contractions occur every 15 minutes (Table 24.4). During labor, the patient is never left unattended by the midwife assigned to her care, and uterine activity is palpated by the midwife. The midwife will then perform the delivery with the head midwife in attendance. The attending obstetrician is asked to intervene only when there is need for an obstetric operation, such as episiotomy, forceps delivery, or cesarean delivery. Midforceps delivery and rotational forceps are not performed.

TABLE 24.6 Cesarean Delivery Incidence in Randomized Studi Active Management of Labor

Study	Total Number of Patients	Traditional n	Traditional n (%) CS	AMOL n	AMOL n (%) CS
Lopez-Zeno et al.	705	354	50 (14.1)	351	37 (10.5)
Frigoletto et al.	1,263[a]	585	66 (11.3)	678	62 (9.2)

Rogers et al.	405	205	24 (11.7)	200	15 (7.5)
Total	2,373	1,144	140 (12.2)	1,229	114 (9.3)

CS, cesarean section; AMOL, active management of labor; NS, nonsignificant.
[a]This value includes only those women eligible for the study proto
[b]Simple chi-square analysis.

With AMOL at the National Maternity Hospital, cesarean delivery rates for dystocia are <10%. Oxytocin is used in 50% to 60% of nulliparas and in only 10% to 15% of multiparas (who are not managed with this program). Delivery occurs in <12 hours in 98% of women. Cerebral palsy rates approximate that of the United States, or about 2 per 1,000 births, and birth trauma is a rare occurrence. Epidural analgesia is allowed and does not impact significantly on the cesarean delivery rate. Clearly, AMOL is well suited to the population served at the National Maternity Hospital.

Lessons from Active Management of Labor

There have been three prospective randomized trials of AMOL in the United States (Table 24.6). Lopez-Zeno and coworkers found a significant decrease in the cesarean delivery rate in nulliparous patients in the AMOL arm of the studies, from 14.1% to 10.5%. Frigoletto and colleagues randomized over 1,200 nulliparous women to AMOL or traditional management and found no decrease in the cesarean delivery rate but were able to show a modest decrease in the duration of labor in the AMOL arm. In the third study, Rogers and associates also found no significant decrease in cesarean delivery rate but confirmed a decrease in the length of labor. These discrepancies may be because AMOL might not significantly reduce the cesarean delivery rate if the baseline rate is 11% or less. In other nonrandomized studies, AMOL has been shown to decrease the primary cesarean delivery rate by 25% to 50%, and a recent meta-analysis by Glantz and McNanley showed that the risk of cesarean delivery for dystocia was decreased on average by 34%. In an analysis of these three randomized trials, AMOL resulted in a lower risk for cesarean delivery (Table 24.6; Fig. 24.17) and a greater incidence of delivery within 12 hours of delivery (Fig. 24.18). A prospective randomized study performed at the National Maternity

Hospital in New Zealand by Saldler and colleagues found that the cesarean delivery rate was similar in their conventionally managed and actively managed women (9.4% vs. 9.7%) but that women in the AMOL had shorter labors and a lower relative risk for prolonged labor.

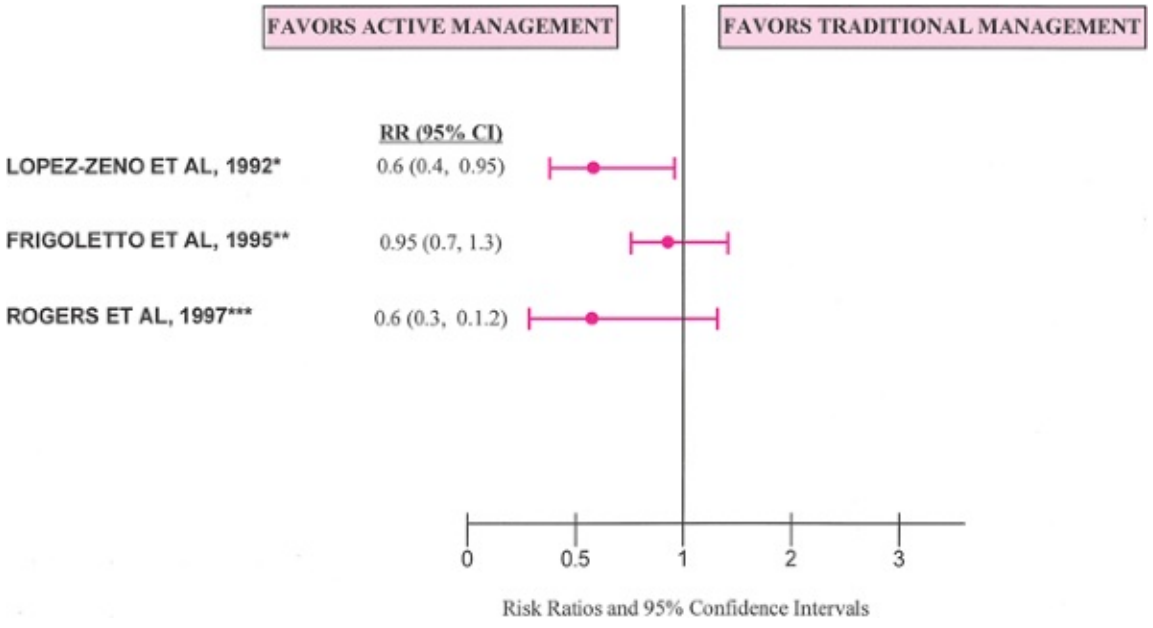

Figure 24.17 Odds ratio of the effect of active AMOL on cesarean delivery rate. AMOL is associated with a lower risk of cesarean delivery in one study but with equivocal results in two studies. (RR, relative risk; CI, confidence interval.)

Many lessons can be derived from the AMOL protocol. First, AMOL is a regimented integrated approach to the management of labor in all nulliparous women admitted to the hospital. In many ways, this philosophy runs counter to the concept of individualizing patient care according to her specific situation. However, application of protocols in some situations, as in clinical practice guidelines, leads to more standardized application of appropriate therapies with concomitant improved outcomes. Whereas much has been made of the use of early amniotomy and the relatively high doses of oxytocin employed in AMOL protocols, a recent detailed analysis by Thorton and Lilford indicates that the most important component of AMOL in achieving a low cesarean birth rate is one-on-one nursing. And perhaps the most important aspect of nursing care in this setting is the alleviation of maternal anxiety and the prompt diagnosis and treatment of dystocia.

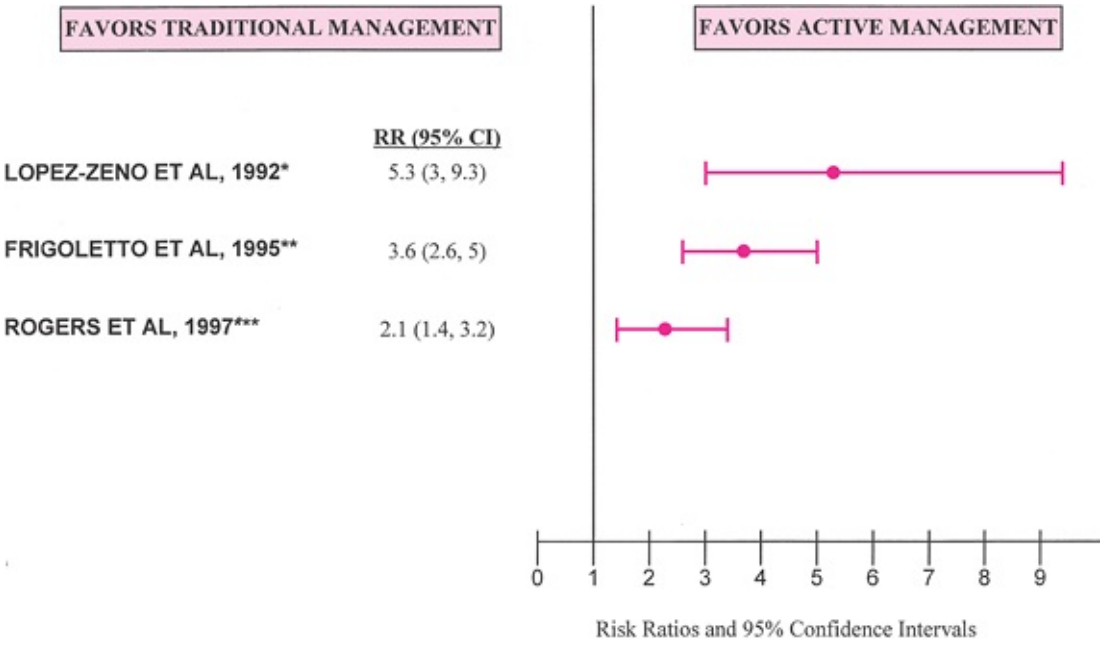

Figure 24.18 Odds ratio of the effect of AMOL on delivery within 12 hours. AMOL is associated with delivery within 12 hours of presentation to the labor and delivery units in each study depicted. (RR, relative risk; CI, confidence interval.)

AMOL is an excellent example of how an organized approach to labor management can lead to improved outcomes. Although AMOL cannot be adopted in its entirety in all labor and delivery units in the United States, the principles of AMOL can be adapted in many situations. First, normal women at term with uterine contractions should be admitted only when they are in active labor. Obviously, there are exceptions to this concept, but premature admission with interventions usually implies that an induction of labor is being performed for no clear indication. Second, dysfunctional labor should be promptly diagnosed and treated with appropriate medical therapy. Third, efforts to alleviate maternal anxiety through prenatal education and attentive sympathetic caregivers should be maximized. Unfortunately, labor and delivery units in the United States would find it impossible to provide one-on-one nursing care throughout labor with the current staffing policies of most units. However, more personal interactions with all caregivers, from nurses to obstetricians, should be encouraged. And last, there is little delay in making the decision to move to cesarean delivery, improving both maternal and neonatal outcomes. Although critics of AMOL cite perceived excessive intervention (based on the use and doses of oxytocin), proponents of AMOL counter that a cesarean delivery rate of 20% to 25% versus <10% is the greater intervention.

Summary Points

- Dystocia is common, particularly in the nulliparous patient, and is a common indication for cesarean delivery.
- Early amniotomy does not improve labor outcomes. However, amniotomy after 5 cm of dilation can shorten the time of labor but

at the expense of a modest increase in infectious morbidity.

- Early application of epidural analgesia can contribute to labor abnormalities, particularly in the second stage, and lead to an increased need for operative vaginal delivery but not an increased rate of cesarean delivery.
- AMOL protocols can decrease the cesarean delivery rate in some populations.
- Oxytocin protocols using higher doses (3 to 6 mU per minute and increasing concentrations every 15 to 20 minutes) decrease the need for cesarean delivery for dystocia with adequate safety for mother and fetus.
- All authorities agree that the primary goal in managing women in labor is to obtain healthy babies with minimal maternal morbidity. However, the methods used to achieve these goals elicit a great deal of controversy among obstetricians. Nevertheless, following the principles of labor management as outlined in this chapter should ensure good maternal and fetal outcomes.

Complications of Delivery

Larry C. Gilstrap
Edward R. Yeomans

Introduction

Although there are many potential complications associated with delivery of the newborn, postpartum hemorrhage is probably the most common cause of maternal mortality from both vaginal and operative abdominal delivery. Amniotic fluid embolism, on the other hand, is a rare complication of delivery but is associated with significant morbidity and a very high mortality rate when it does occur.

Postpartum Hemorrhage

Hemorrhage is one of the four leading causes of maternal death in women delivering after 20 weeks gestation. Thromboembolism, hypertensive disorders, and infection are the three other major causes of mortality. These latter complications are addressed elsewhere in this text.

The exact incidence of postpartum hemorrhage is unknown because there is no uniformly accepted definition for postpartum hemorrhage. However, it is of paramount importance that clinicians caring for pregnant women be both knowledgeable and skilled in the management of this potentially life-threatening complication.

Definitions

The classic definition of *postpartum hemorrhage* is a blood loss of 500 mL or more during the first 24 hours after delivery. Considering that the average blood loss following an uncomplicated vaginal delivery is approximately 500 mL, it is obvious that this classical definition is not helpful from a clinical standpoint. First and foremost, it has been well established that the blood volume in a normal, uncomplicated pregnant woman is increased by approximately 1,500 to 1,000 ml of plasma and 500 mL of red blood cells. Second, in a classic study almost half a century ago, it was shown that red blood cells equivalent to 445 mL of blood loss occurred with uncomplicated vaginal delivery, and red cell loss equivalent to over 1,000 mL blood loss occurred with cesarean delivery (over 1,500 mL loss for cesarean hysterectomy) (Table 25.1). Thus, the vast majority of pregnant

women losing a liter of blood would not suffer any ill effects and should not be classified (or coded) as postpartum hemorrhage. An exception to the latter is a woman with severe preeclampsia whose blood volume may expand little, if at all. A blood loss of 1,000 mL in this patient may be sufficient to require blood transfusion.

Other definitions of postpartum hemorrhage have included a significant drop in hemoglobin or hematocrit or a specific percentage of blood volume lost. A major problem with utilizing a change in hematocrit in this way is that the level of hematocrit most often depends on the degree of vasoconstriction (as seen in severe preeclampsia) and the volume of fluid administered during labor and delivery, including "preloading" prior to regional anesthesia. Moreover, the major problem with utilizing a percentage of blood volume lost in defining hemorrhage is not knowing with any degree of accuracy what the initial blood volume is in a given woman. At best, it can only be estimated in a given woman from her height and weight. Accurate estimation of blood loss at the time of delivery also is difficult. Finally, ≥10% blood loss, while potentially significant or serious in a nonpregnant woman, is probably of little significance in a normal pregnant woman who has expanded her blood volume by some 40% to 50%.

TABLE 25.1 Blood Loss following Vaginal Delivery, Cesarean Delivery, and Cesarean Delivery Plus Total Hysterectomy[a]

Delivery	Average Red Blood Cell Loss	Equivalent Blood Loss
Vaginal (n = 75)	190 cc	445 cc
Cesarean delivery (n = 40)	340 cc	1,200 cc
Cesarean plus hysterectomy (n = 35)	560 cc	1,570 cc

[a]Utilizing radio-chromium labeled red blood cells. Adapted from Pritchard JA, Baldwin RM, Dickey JC, et al. Blood volume changes in pregnancy and the puerperium, 2. Red blood cell loss and changes in apparent blood volume during and following vaginal delivery, cesarean section, and cesarean section plus total hysterectomy. *Am J Obstet Gynecol* 1962;84:1271.

The authors of this chapter have suggested in previous writings that the “diagnosis of postpartum hemorrhage is based primarily on clinical judgment.” It would seem reasonable to define postpartum hemorrhage or at least significant hemorrhage as that amount of blood loss that produces signs and symptoms of hemodynamic instability or bleeding to a degree that will result in hemodynamic changes if left untreated.

Postpartum hemorrhage also is classified as early or late hemorrhage. The former is hemorrhage that occurs within the first 24 hours following delivery (i.e., “early” hemorrhage), while the latter is defined as hemorrhage occurring after 24 hours and up to 6 weeks postpartum (i.e., “late” hemorrhage). This classification of early versus late is useful when considering the various etiologies of hemorrhage.

Incidence

It should be obvious from the above that in the absence of a universally accepted definition, the incidence of postpartum hemorrhage is difficult to ascertain. In the classic study previously mentioned regarding average blood loss at delivery, it was reported that approximately 5% of women will lose >1,000 mL from vaginal delivery. Importantly, 5% is similar to the incidence of postpartum hemorrhage reported by others.

Etiology

Postpartum hemorrhage is caused by uterine atony, genital tract lacerations, retained products of conception, or defective coagulation. In any given case, more than one cause may be found. Uterine atony is by far the most common cause of bleeding postpartum. Once the placenta is delivered, cessation of bleeding is dependent on adequate myometrial contractility to constrict blood vessels supplying the implantation site. A flaccid, atonic uterus cannot achieve the necessary vasoconstriction. With uterine blood flow of approximately 600 mL per minute, life-threatening hemorrhage can occur rapidly. In many but not all cases, uterine atony is predictable based on certain risk factors, which are summarized in Table 25.2. Occasionally, especially when the placenta is implanted in the lower uterine segment, there may be brisk bleeding despite a well-contracted fundus. This will be discussed in the section on Medical Management.

TABLE 25.2 Common Causes of Uterine Atony

- Overdistention—multifetal gestation, macrosomia, hydramnios
- Grand multiparity
- Protracted labor
- Precipitous labor and delivery
- Intra-amniotic infection
- Prolonged induction of labor

- Use of halogenated anesthetic agents

The second most common cause of postpartum hemorrhage is genital tract laceration, which can occur anywhere from the fundus to the introitus and should be strongly suspected when bright red bleeding occurs despite a firm, well-contracted uterus. Manual exploration of the uterine cavity along with careful examination of the cervix, vagina, and introitus should allow the clinician to identify the source of bleeding and take corrective action. An appreciable amount of bleeding can occur from the site of an episiotomy, particularly if it was performed early in the delivery process.

Retained products of conception, placental fragments, accessory lobes, or membranes may cause ongoing bleeding. Inspection of the delivered placenta and membranes may increase suspicion that tissue remains in the uterus. Routine manual exploration of the uterus is not indicated, however, and this procedure should be performed only if the bleeding is excessive.

Finally, coagulopathy can occur de novo or may aggravate one of the previously mentioned causes. Placental abruption with a dead fetus is the most common cause of coagulapathy in obstetrics. Other causes are listed in Table 25.3. Dilutional coagulopathy may result when excessive

blood loss is replaced by a combination of crystalloid and packed red blood cells, without clotting factors or platelets.

TABLE 25.3 Conditions Associated with Coagulopathy during Pregnancy

- Placental abruption
- Sepsis/shock
- “Dilutional” coagulopathy
- Fetal death
- Amniotic fluid embolism
- HELLP syndrome
- Anticoagulant therapy

HELLP, hemolysis, elevated liver enzymes, low platelet count.

TABLE 25.4 General Principles in the Management of Postpartum Hemorrhage

- Establish etiology
- Call for assistance
- Notification of blood bank for emergency need for packed red blood cells, platelets, and other clotting factors
- Establish venous access (preferably two large-bore intravenous lines)
- Replace blood volume
- Correction of coagulopathy
- Monitor pulse, blood pressure, and urine output (Foley catheter)

Medical Management

Medical management pertains primarily to the treatment of uterine atony and/or associated coagulopathy (Table 25.4). Many clinicians utilize a prophylactic infusion of oxytocin consisting of 10 to 20 U of oxytocin in 1,000 mL of Ringer's lactate or saline administered at 10 to 20 mL per minute to prevent uterine atony. Others prefer a 5 to 10 U intravenous bolus of oxytocin either in lieu of or in combination with a dilute oxytocin infusion. In an earlier study, it was reported that an intravenous bolus of 10 U was associated with a marked, transient fall in blood pressure; a decrease in systemic vascular resistance; and an increase in heart rate. In a more recent randomized controlled study, bolus oxytocin was reported to be efficacious and was not associated with adverse hemodynamic effects. However, the present authors prefer to utilize dilute oxytocin as opposed to a bolus regimen because of the unknown effects in the rare patient with undiagnosed heart disease or in the patient who presents with significant blood loss or in hemorrhagic shock. Moreover, the dilute regimen has been shown to be efficacious for prevention of uterine atony.

Another drug that may prove useful for the treatment of postpartum hemorrhage secondary to uterine atony is the ergot derivative methylergonovine. The usual dose is 0.2 mg given intramuscularly. This agent should not be utilized in women who are hypertensive or who have preeclampsia, as it might cause dangerous levels of hypertension. Moreover, this drug should not be administered intravenously for the same reasons.

Prostaglandin derivatives are probably the most commonly used agents following an ineffective response to oxytocin. A popular prostaglandin derivative for postpartum hemorrhage is carboprost tromethamine (Hemabate), which is 15-methyl prostaglandin $F_{2\alpha}$. This drug has been approved by the Food and Drug Administration (FDA) for the treatment of uterine atony, and the recommended dose is 0.25 mg (250 mcg) given intramuscularly.

This can be repeated at 15- to 90-minute intervals for a maximum of eight doses. This medication should be avoided in asthmatic women, and commonly reported side effects include nausea and vomiting, diarrhea, fever, tachycardia, and hypertension. A serious side effect of acute arterial oxygen desaturation has been reported with this medication. This side effect obviously could have detrimental effects on pregnant women with significant cardiovascular or pulmonary disease.

Other prostaglandins have also been utilized for postpartum hemorrhage from uterine atony. For example, prostaglandin E_2 or dinoprostone (Prostin E_2) and the prostaglandin E_1 analog misoprostol (Cytotec) have been reported to be effective. Dinoprostone has been utilized as either a vaginal or rectal suppository in 20 mg doses every 2 hours. Misoprostol has been used rectally in a dose of 800 to 1,000 µg.

Recently, recombinant factor VIIa has been reported to be effective in controlling refractory, life-threatening hemorrhage. Although there are no large series, factor VIIa appeared to be both efficacious and safe in individual case reports. In one review of 17 cases, 12 of the women had hysterectomies. Therapy with this factor is *expensive*, and the optimal dosing regimen is unclear. Moreover, one potential life-threatening adverse event that has been reported with this therapy is thromboembolism. Given the current level of available information, it would seem prudent to reserve therapy with recombinant factor VIIa to women with severe hemorrhage in whom other more commonly used protocols have failed.

Attention to blood volume replacement should begin with crystalloid followed by packed red blood cells as needed to maintain a urine output of 25 to 30 mL or more per hour and the hematocrit at or near 30%. This strategy has been referred to as the “30–30 rule” and is of proven effectiveness to prevent or treat hemodynamic instability. Transfusion of other clotting factors such as fibrinogen (fresh frozen plasma) or platelets should be considered in the woman with active bleeding and a coagulopathy. However, in the absence of a coagulopathy, there is little evidence to support the prophylactic use of fresh frozen plasma in women requiring multiple transfusions or packed erythrocytes.

Uterine Packing

Uterine packing has been advocated by some clinicians prior to resorting to hysterectomy for severe, refractory bleeding. The major concerns regarding uterine packing have centered around the potential for concealed hemorrhage and for infection. Most of the recent reports regarding the successful treatment of postpartum hemorrhage are 30 to 50 years or more old. However, in a report of nine women in 1993, the successful control of hemorrhage was accomplished by utilizing a special packing instrument called a Torpin packer. This instrument used a plunger

---

device to tightly place 4-inch-wide gauze into the uterine cavity. It is the authors' opinion that packing should be used primarily as a temporizing method to allow time for adequate blood volume replacement prior to laparotomy. If packing is utilized as a “last resort” prior to surgical intervention, the patient must be closely monitored to detect continued bleeding or significant concealed hemorrhage. Consideration also should be given to the

use of prophylactic antibiotics while the uterine pack is in place.

Closely related to uterine packing but perhaps more effective is the use of one of a variety of intrauterine balloon devices. The assumption is that a balloon would exert more uniform pressure than gauze on the walls of the uterine cavity and serve to diminish hemorrhage in that manner. The Sengstaken-Blakemore tube, used for esophageal varices, has been reported to be effective, but more promising is the Bakri balloon, which has a capacity of 500 mL and a separate port to facilitate evaluation of ongoing bleeding. A Rusch urological balloon, with up to a 500 mL capacity, also has been used. The accumulated experience with these different devices is minimal, and the same caveats offered previously for gauze packing apply.

Surgical Management

There are several surgical techniques that can be utilized for the treatment of postpartum hemorrhage (Table 25.5). Some of these techniques require both anatomical knowledge and surgical skill. If a clinician lacks this knowledge and experience, he or she should seek the help of a surgeon with these skills such as a gynecologic oncologist or vascular specialist. Many clinicians and their patients would be better served if a hysterectomy was performed in lieu of attempting hypogastric artery ligation without experienced help.

Most clinicians, however, can easily perform one of several techniques of uterine compression sutures. Uterine artery ligation, although not so successful for severe hemorrhage, also can generally be performed safely by trained obstetrician–gynecologists.

Uterine Compression Sutures

Several different types of uterine compression sutures have been described in the literature. Although the authors are unaware of any randomized controlled trial comparing one technique with another, each of these techniques is relatively easy to perform and is associated with few serious side effects. As well, all would appear to offer a relatively safe alternative to either hysterectomy or hypogastric artery ligation. In addition, future fertility may be preserved with the use of compression sutures.

TABLE 25.5 Surgical Techniques for the Management of Postpartum Hemorrhage

- Uterine compression sutures
- Uterine artery ligation
- Internal iliac (“hypogastric”) artery ligation
- Hysterectomy (supracervical or total)

B-Lynch Technique

The B-Lynch suture was first described in five women in 1997. In a review of the technique along with other uterine compression suture techniques, it has been reported that out of a 1,000 procedures performed, the failure rate was less than 1%. Very simply, the technique involves placing an absorbable suture in the lower uterine segment and then looping the suture over the fundus. The suture is then passed transversely through the lower uterine segment on the posterior surface of the uterus to the opposite side. The suture is then looped back over the uterine fundus (opposite side of the first loop) and then passed through the lower uterine segment on the anterior suture. Tying off the suture anteriorly results in vertical uterine compression (Fig. 25.1).

Other Uterine Compression Techniques

A modification of the B-Lynch suture utilizes a vertical compression suture technique (with and without a horizontal compression suture at the cervicoisthmic junction). This technique consists primarily of placing two vertical compression sutures on each side of the fundus. Each suture is started by passing it through the lower uterine segment from anterior to posterior and tying the two ends over the uterine fundus. Utilizing a “three-throw technique” to prevent slippage as bimanual compression of the uterus is carried out by an assistant has been suggested. This suture is repeated on the opposite side (Fig. 25.2). The reported advantage of this suture is that it is quicker than the B-Lynch and does not require a lower uterine transverse incision. The authors also recommend two horizontal compression sutures (passing anterior and posterior through the uterus and tied anteriorly) when significant lower uterine segment bleeding is encountered—one on each side. Alternatively, a technique placing multiple sutures to oppose the anterior and posterior uterine walls has been described.

Finally, another published technique utilizes multiple, interrupted horizontal compression sutures that do not pass through both the anterior and posterior uterine walls. These sutures are placed first on the anterior and then on the posterior wall, if necessary. When tied, the uterus often gives the appearance of a contracted uterus. In the authors' personal experience, this technique has only failed 3 times in over 20 procedures. A schematic of this technique is summarized in Figure 25.3.

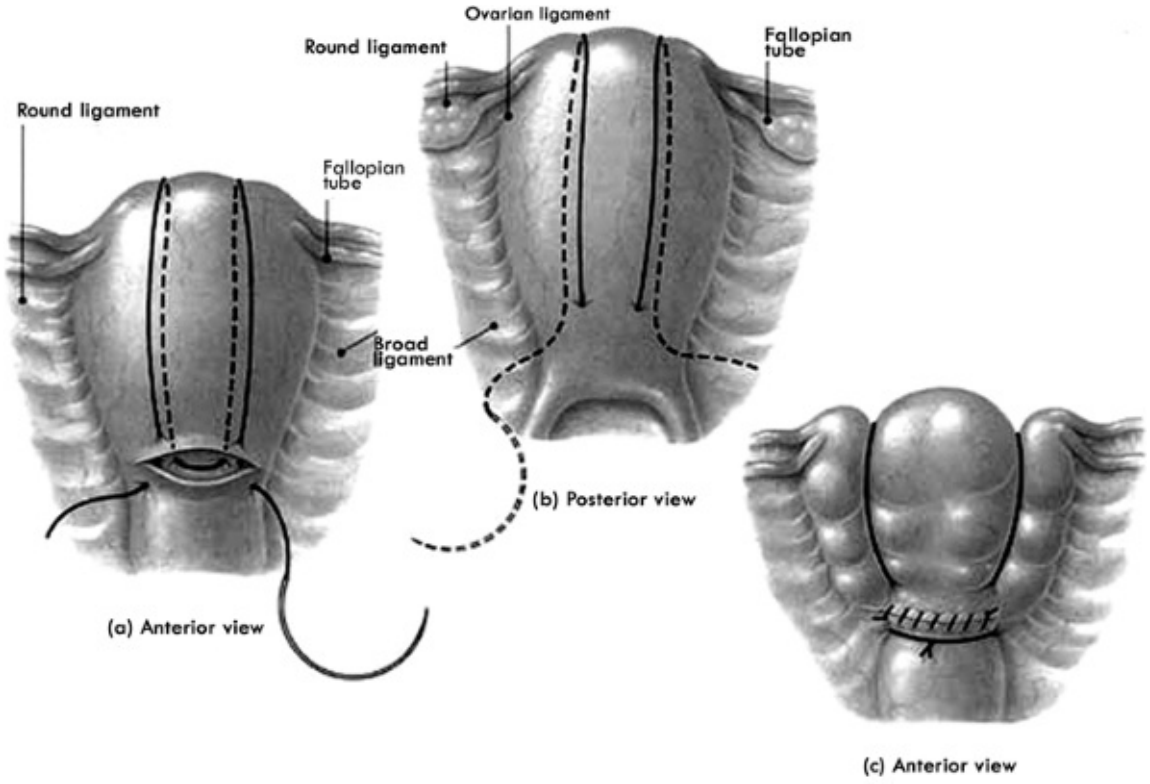

Figure 25.1 The B-Lynch suture, front and back view and knot. (Reproduced with permission from Allam MS, B-Lynch C. The B-Lynch and other uterine compression uterine suture techniques. *Int J Gynaecol Obstet* 2005;89:238.)

Uterine Artery Ligation

Although this technique is unlikely to be beneficial in the presence of severe, life-threatening hemorrhage, it might prove useful in women with lesser degrees of hemorrhage. Moreover, it is relatively easy to perform, and the reported incidence of complications is ≤1%. Unlike the technically more difficult internal iliac (“hypogastric”) artery ligation, it can be performed by most obstetricians. The technique consists of placing a no. 1 absorbable suture 2 to 3 cm medial to the uterine vessels through the myometrium and then through an avascular space in the broad ligament. To avoid injury to the ureter, it is important not to go too far lateral in the avascular space. Following the correct placement of the suture, it is then firmly tied. Some clinicians recommend placement of a second suture ligature at the uterine–ovarian ligament and uterine junction to prevent collateral flow from the ovarian artery. In one series of over 200 women (most of whom had uterine atony), uterine artery ligation was beneficial in 95% of the cases.

Internal Iliac (Hypogastric) Artery Ligation

The technique for performing an internal iliac artery (also known as the "hypogastric artery" by many obstetricians) requires a high degree of surgical skill. Thus, this procedure often requires the assistance of either a gynecologic oncologist or a vascular surgeon.

The anterior division of the internal iliac artery carries the major blood supply to the uterus and pelvis, and this technique would appear to work primarily by converting an arterial system to one that resembles a venous system. It has been reported that this technique will decrease the pulse pressure by up to 85%, allowing for hemostasis and clot

formation. It has been estimated that bilateral internal iliac artery ligation will be successful in avoiding hysterectomy in approximately 50% (range 20% to 60%) of women with severe postpartum hemorrhage secondary to uterine atony or placenta accreta.

Significantly more complications may occur with this surgical technique for control of hemorrhage. For example, in one series, both ureteral injury and cardiac arrest from blood loss occurred in women who required hysterectomy because of failure of the bilateral hypogastric artery ligation procedure to control hemorrhage. This increase in complications appears to be related to the delay in hysterectomy and in performing the hysterectomy itself. These two complications were much less when primary hysterectomy was carried out for hemorrhage without attempting an internal iliac artery ligation.

The technique consists first of entering the retroperitoneal space between the round and infundibulopelvic ligaments. The ureter should always be identified before attempting ligation, and it is best retracted medially. The external iliac artery is easiest to locate and trace proximally to the bifurcation of the common iliac artery. The internal iliac artery can then easily be identified. The areolar tissue can be dissected free from the artery for a distance of 2 to 3 cm from the bifurcation. A right angle clamp is then passed just beneath the artery, taking great care to avoid the contiguous internal iliac vein, regardless of whether this clamp is being passed from lateral to medial or vice versa. A nonabsorbable suture is used as a ligature, and the vessel is firmly ligated but not divided.

The major complications of this procedure include ureteral ligation or injury, hemorrhage from injury to the large iliac veins, and inadvertent ligation of the external iliac vein. Great care must be taken to assure that the external iliac artery is not incorrectly identified as the internal branch and ligated. This is a catastrophic complication that could lead to loss of the lower extremity.

Given the technical difficulty in performing internal iliac artery ligation; the lack of experience of many obstetricians; the high failure rate (50% or greater); and the major, life-threatening complications that can accompany the procedure, it may be best to perform a hysterectomy when other techniques have failed (such as uterine compression sutures).

Hysterectomy

Emergency hysterectomy is generally preferred after failure of other medical or surgical procedures to control life-threatening hemorrhage. In the authors' experience, the major morbidity associated with this procedure results from “procrastination” and delay in making a decision to take this final step when necessary. Although every reasonable effort should be made to preserve a patient's fertility, especially if this is her first pregnancy or if she is desirous of future children, undue delay or hesitation in the presence of life-threatening hemorrhage should not be at the expense of the mother's life.

In one series of 70 cases of emergency hysterectomy for obstetric hemorrhage, the authors report significant

---

maternal morbidity associated with the procedure. Others have reported similar findings

(Table 25.6). Blood transfusions and surgical infection appear to be among the most common reported morbidities.

TABLE 25.6 Maternal Morbidity Associated with Emergency Postpartum Hemorrhage

- Blood transfusions
- Shock/cardiac arrest
- Bladder/ureteral injury
- Febrile morbidity
- Wound infection
- Death

The indications for emergency hysterectomy are summarized in Table 25.7. Uterine atony and placenta accreta are the two most common indications for peripartum hysterectomy. With the increase in the cesarean delivery rate in this country, it seems reasonable to conclude that placenta accreta will soon, if it is not already, be the number one reason for hysterectomy. In fact, it is the number one reason in some series.

Pelvic Pack

There are several reports in the literature regarding use of a “pressure pack” for controlling pelvic bleeding following a hysterectomy. The authors have constructed such packs from Mayo stand covers and plastic bags (i.e., an organ transplant bag) filled with gauze. The pressure pack is placed in the pelvis with the “neck” of the pack being brought down through the vaginal cuff. Traction is placed on this portion of the pack. These packs may be especially useful and even lifesaving in cases of hemorrhage associated with coagulopathy or in cases of placenta accreta. Such packs have been reported to be successful in controlling hemorrhage in up to 80% of cases.

Arterial Embolization

Arterial embolization procedures may prove of benefit in the woman with persistent moderate postpartum bleeding. It has been utilized in the past for the treatment of vulvar, vaginal wall, and pelvic hematomas that are expanding. On the other hand, embolization techniques may not adequately stop or control bleeding that is excessive or in the woman with unstable vital signs secondary to hemorrhage.

TABLE 25.7 Indications for Emergency Peripartum Hysterectomy

- Uterine atony
- Placenta accreta
- Placenta previa
- Uterine laceration
- Uterine rupture
- Uterine leiomyomata

In one review of the literature, it was reported that arterial embolization was effective in controlling postpartum hemorrhage in 95% of cases. This is similar to reports by others. Complications from this procedure appear to be low and include fever, ischemia, uterine necrosis, nerve injury, and perforation of a major vessel. In a long-term follow-up of 28 women who underwent an embolization procedure for postpartum hemorrhage, those who were desirous of future pregnancies were able to achieve pregnancy and have uncomplicated courses.

The embolization procedure consists of a percutaneous transcatheter technique. Utilizing contrast material, active bleeding sites often can be identified for embolization. In the case of uterine atony, the anterior division of the internal iliac artery can be embolized. A variety of material has been utilized for embolization such as metal coils, Gelfoam, and polyvinyl alcohol particles.

Late or Secondary Postpartum Hemorrhage

Late or secondary postpartum hemorrhage is defined as hemorrhage occurring greater than 24 hours after delivery up until 6 weeks postpartum. The causes of late postpartum hemorrhage are summarized in Table 25.8. The treatment is essentially the same as for early postpartum hemorrhage and begins with medical therapy with oxytocin and prostaglandins. Because many of these women are infected, antibiotics also may prove beneficial. Although arterial embolization may be necessary, other surgical procedures (especially hysterectomy) are rarely indicated.

In one series of 132 women with late hemorrhage, the majority presented during the second postpartum week. The only risk factors identified were early postpartum hemorrhage and manual removal of the placenta. Two thirds of the women required surgical evacuation, and one required a hysterectomy for uterine perforation. Interestingly, pre-evacuation ultrasound was not especially useful, and only one third of those undergoing surgical evacuation had retained placental tissue.

- Retained placental fragments
- Subinvolution of the placental site
- Inherited or acquired coagulopathy

Amniotic Fluid Embolism

Fortunately, amniotic fluid embolism is rare, but when it does occur, it often is a catastrophic and fatal complication of pregnancy. In recent reviews of maternal mortality, it frequently is listed as one of the major causes of mortality in modern obstetrics. Much of the information published on this complication comes from case reports and small series. Because of the life-threatening nature of amniotic fluid embolism, there have been at least two large registries established to study this rare complication of pregnancy. One such registry is the United States National Registry, and the other is the United Kingdom Amniotic Fluid Embolism Register. Much of the outcome data presented in this chapter come from these two registries.

Incidence and Risk Factors

Even though amniotic fluid embolism is one of the leading causes of maternal mortality, its exact incidence is not known. There has been significant variation in reports of both the incidence and mortality associated with this catastrophic complication. However, in one study utilizing a computerized database from over 300 hospitals in California, the authors calculated a “population frequency” of amniotic fluid embolism of approximately 1 per 20,500 deliveries. They also reported a maternal mortality rate of approximately 26%, which was lower than that previously reported in the literature. For example, analysis of the National Registry revealed a maternal mortality of 61%, with only 39% of the fetuses surviving. Data from the United Kingdom Register revealed a mortality rate as high as 37%. There could be many reasons for the differences in incidence and mortality in various series (including registries) such as the criteria utilized for diagnosis and reporting bias (either only severe cases or only milder surviving cases reported). It also is difficult to confirm the diagnosis in surviving patients. Almost as important as maternal mortality is the significant risk of neurologic impairment in both the mother and the fetus. For example, in the National Registry report, a significant percentage of the women who had

experienced cardiac arrest and recovered had some degree of neurologic impairment. The same was true for the newborns.

There is considerable controversy regarding the association of the induction or augmentation of labor and amniotic fluid embolism. The same is true for other "potential" risk factors. In one relatively recent retrospective cohort study, induction of labor was associated with an almost doubling of the risk of amniotic fluid embolism. In contrast, no association was found with either oxytocin use or prolonged labor and amniotic fluid embolism. Other risk factors commonly reported to be associated with this complication are summarized in Table 25.9. It is important to note that many women who experience an amniotic fluid embolus do not have any of the known or reported risk factors.

TABLE 25.9 Possible or Reported Risk Factors Associated with Amniotic Fluid Embolism[a]

- Tumultuous labor (placenta abruption)
- Prolonged labor
- Induction/augmentation of labor
- Trauma
- Cesarean delivery
- Multiparity
- Advanced maternal age
- Operative vaginal delivery
- Hydramnios
- Uterine rupture
- Multifetal gestation
- Male fetal sex
- Eclampsia
- Allergy history

[a]Many women with amniotic fluid embolism have no identifiable risk factor.

Diagnosis

The diagnosis of amniotic fluid embolism is primarily clinical, based on a high degree of suspicion. An example of the "classical presentation" of a woman with an amniotic fluid embolus is one who is in advanced labor and suddenly complains of difficulty breathing, becomes hypotensive, gasps for air, and develops seizures (Table 25.10). The fetal heart rate tracing reveals fetal bradycardia, and the patient is noted to be oozing from her

intravenous site. An oxygen saturation monitor will reveal a marked decrease in oxygen saturation consistent with hypoxia. This may soon be followed by circulatory collapse and cardiopulmonary arrest. A similar picture may develop at the time of cesarean

delivery or in the immediate postpartum period. However, the signs and symptoms of this life-threatening complication may vary significantly, with some women manifesting only the coagulopathy with only mild or no level of hypoxia. The classic presentation is quite similar to a severe anaphylactic reaction, and some have suggested renaming this catastrophic syndrome the “anaphylactoid syndrome of pregnancy.” Although amniotic fluid embolism does indeed share some of the features of an anaphylactic reaction, the exact pathophysiologic mechanism is still unclear.

TABLE 25.10 Classical Signs and Symptoms of Amniotic Fluid Embolism in Some Women[a]

- Onset in late labor or within 30 min postpartum
- Acute onset of shortness of breath or gasping for air
- Sudden hypotension
- Hypoxia and or oxygen desaturation
- Diffuse coagulopathy
- Ominous fetal heart rate pattern (profound bradycardia and loss of variability)
- Seizures
- Cardiopulmonary arrest
- Death

[a]Clinical presentation is variable, and women may manifest some or all of these signs or symptoms.

From a laboratory standpoint, there are few tests that can be utilized to confirm the diagnosis of amniotic fluid embolism. In the presence of an overt coagulopathy, the serum fibrinogen level often will be quite low and the fibrin degradation products elevated. The platelet count also may be decreased but generally not much below 100,000 unless late in the process. An arterial blood gas will often reveal a decreased Po_2.

A chest radiograph is not particularly helpful. However, one test that might prove helpful is the recovery of squamous cells or fetal debris from the pulmonary circulation either from a pulmonary catheter or at the time of autopsy. Although not always present, it is considered by some clinicians to be confirmatory for the diagnosis of this syndrome. In analysis of the National Registry, fetal cells and debris were found in three fourths of the women at time

of autopsy and in one half of the antepartum specimens obtained from a pulmonary artery catheter. Unfortunately, even this finding is suspect, especially in the absence of a clinical picture suggestive of this syndrome.

Management

The mainstay of management of amniotic fluid embolism is care consisting of oxygenation, circulatory support (while being cognizant of the risk of pulmonary edema), and correction of the coagulopathy. There is no convincing evidence that utilization of an invasive pulmonary artery catheter is of any benefit in the management of amniotic fluid embolism, and such catheters are associated with significant risk, especially in the presence of a coagulopathy. Recently, recombinant factor VIIa has been used successfully in the management of disseminated intravascular coagulation from amniotic fluid embolism. Patients also may require fresh frozen plasma or cryoprecipitate to replenish fibrinogen as well as platelets. In the event of a cardiopulmonary arrest during labor, the clinical dilemma of perimortem cesarean delivery arises. There is considerable controversy regarding the timing of perimortem cesarean delivery, but many clinicians recommend considering this option within 5 minutes of initiating resuscitation. An even more difficult clinical dilemma is whether to initiate cesarean delivery in a woman who is not hemodynamically stable and whose fetus is manifesting severe bradycardia. Cesarean delivery in this latter scenario may be beneficial to the fetus but puts the mother at increased risk.

Recommendations

Hemorrhage is the most feared complication in obstetrics. Clinicians must constantly be on the alert for the development of excessive bleeding and follow an algorithm for management that has its primary objective preservation of the life of the woman and, hopefully, her reproductive capability as well.

Summary Points

- Hemorrhage is one of the four leading causes of maternal mortality.
- The average blood loss from an uncomplicated vaginal delivery is 500 mL, and for cesarean delivery it averages 1,000 mL.
- Although there is no universally accepted definition for postpartum hemorrhage, it would seem reasonable to define "clinically significant" postpartum hemorrhage as blood loss that produces signs and symptoms of hemodynamic instability.
- Postpartum hemorrhage may be due to uterine atony (the most common cause), genital tract lacerations, retained products of conception, or defection coagulation.
- Medical management pertains primarily to the treatment of uterine atony and/or associated coagulopathy.
- Blood volume replacement should begin with crystalloid followed by

packed red blood cells to maintain a urine output of 25 to 30 mL or more per hour and the hematocrit at or near 30% (the so-called "30–30 rule").
- Uterine packing should be used primarily as a temporizing method to allow time for adequate volume replacement prior to laparotomy.
- Surgical techniques for the management of postpartum hemorrhage include uterine compression sutures, uterine artery ligation, internal iliac artery ligation, and hysterectomy.
- Amniotic fluid embolism is a rare but often catastrophic and fatal complication of pregnancy.
- The mainstay of management of amniotic fluid embolism is care consisting of oxygenation, circulatory support, and correction of the coagulopathy.

Operative Vaginal Delivery

James A. Bofill
James N. Martin Jr.

Most likely, there has always been a desire of obstetric attendants to safely grasp the fetal head in order to accelerate delivery of the infant and shorten a woman's difficult labor. The story of the use of obstetric instruments to facilitate delivery—either forceps or vacuum devices—is both colorful and unique within the history of medicine. Properly used obstetric forceps may have saved more lives, both infant and maternal, than any other instrument devised by physicians. The heyday of obstetrical forceps use was in the early 20th century, when nearly half of deliveries were accomplished by their means. Obstetricians of that time considered that the obstetric forceps, with liberal use of episiotomy, protected the maternal genital tract and prevented more extensive injury. Similarly, the forceps were considered to provide the fetus, especially the preterm fetus, with a “helmet” that prevented rapid changes in cranial pressure during delivery. These notions have been discarded by the rigors of modern clinical studies. Early in the 21st century, the practice of operative vaginal delivery is considered by some obstetricians to be anachronistic, a “dying” art and not something to be mastered or practiced.

The total rate of operative vaginal delivery in 2004, the last year for which complete data are available, was only 5.2% in the United States. Obstetric forceps were used in 1.1% of deliveries, and 4.1% were delivered via the vacuum extractor (Fig. 26.1). Since 1989, there has been an 80% decrease in the frequency of operative forceps use, steadily falling over 15 years from 5.5% in 1989 to 1.1% in 2004. During this time, the frequency of vacuum extractor procedures peaked in 1997 at 6.2%, thereafter decreasing by one third to a level of 4.1% in 2004.

There are several possible causes that relate to diminishing operative vaginal delivery usage in the United States. Certainly, the crisis of litigation in the field of obstetrics is one cause. Yeomans and Hankins perceive a vicious cycle whereby (a) concern about litigation lessens usage and reduces teaching about obstetric forceps and vacuum in obstetrics and gynecology (OBGYN) residency training programs; (b) physician training and confidence with operative vaginal delivery is diminished; (c) usage of operative vaginal delivery decreases further, increasing the probability of poor clinical outcomes when used; and (d) poor clinical outcomes often lead to litigation in our society.

Utilization of operative vaginal delivery was very important to physicians during times when cesarean delivery was considered to present a significant health risk to an obstetric patient or its low frequency of use was considered to be a quality assurance barometer—both concerns were a driving force in minimizing abdominal delivery while encouraging vaginal delivery. Currently, there is a paradigm shift away from the former line of reasoning—cesarean delivery has become a very safe procedure, and a physician's personal cesarean delivery rate is rarely used today as a reflector of quality care. Hence, the rate of operative vaginal delivery in the United States has been declining as the frequency of primary and repeat cesarean delivery has been climbing—from 20.7% in 1996 to a record high of 29.1% in 2004. During the same time interval, trial of labor to accomplish vaginal birth after cesarean (VBAC) has decreased 67%. Not only has cesarean delivery become the most common surgical procedure in modern medicine, it has for the first time to any significant degree been considered appropriate for elective reasons when traditional obstetric indicators are absent.

Nevertheless, teaching and clinical experience with some types of operative vaginal delivery are considered an integral part of contemporary residency training in obstetrics. Although very challenging instrumental deliveries are

seldom undertaken when cesarean delivery is the better option, most physicians continue to learn outlet and low-forceps operations with some rotation as well as the proper techniques for vacuum extraction.

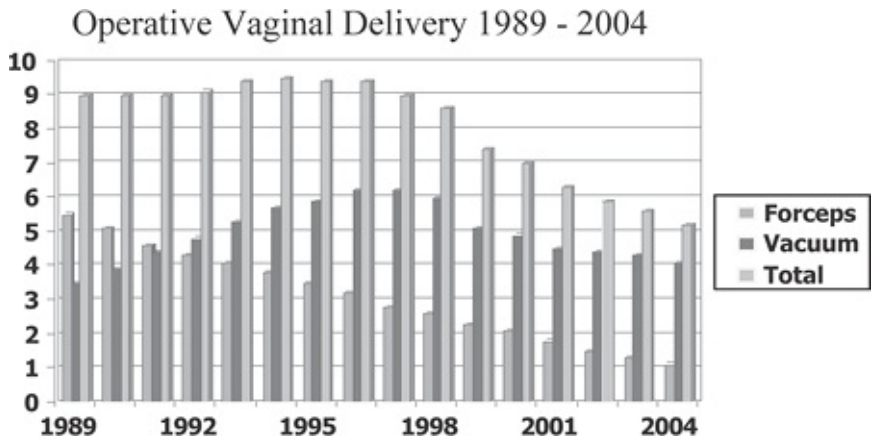

Figure 26.1 Trends in forceps and vacuum delivery from 1989 to 2004.

Delivery with the Vacuum Extractor

The vacuum extractor has a history nearly as colorful as the obstetric forceps. Its early development and use have been described previously. Since inception and the earliest stages of development, the vacuum extractor has been considered an easier instrument to use than the obstetric forceps. For example, Arnott in 1829 considered that the vacuum extractor was “a substitute for steel forceps in the hands of men who are deficient in manual dexterity, whether from inexperience or natural ineptitude.” This, of course, is

inaccurate in today's practice. The history of the forceps and vacuum extractor are intertwined, a fact that is best personified by James Young Simpson of Scotland, who performed the first well-documented series of successful vacuum deliveries and also designed the popular obstetric forceps that bear his name. Simpson's report was met with skepticism and caution. The vacuum instrument was essentially discarded, probably due to lack of appropriate materials for the construction of a durable device.

The modern era of vacuum extraction began in 1954, when Malmstrom introduced a metal cup that he termed the *vacuum extractor*. The original Malmstrom vacuum extractor consisted of a mushroom-shaped stainless steel cup with a smooth, inverted lip and an outside diameter of 60 mm. Unlike current obstetric practice, smaller Malmstrom devices were also commonly placed prior to full cervical dilatation late in the first stage of labor in order to overcome dystocia and hopefully accelerate delivery. The vacuum extractor was considered to be a simpler instrument as well as one that required less anesthesia than the obstetric forceps.

Vacuum-assisted vaginal delivery did not become popular in the United States in part due the entrenched place of obstetric forceps and reports of fetal complications with vacuum delivery. The vacuum device often was associated with scalp abrasions, and the edematous area of the scalp raised by the device (the chignon) was cosmetically unpleasant. Several reports of life-threatening neonatal complications after vacuum extraction were published. Many of these patients may not have been appropriate candidates for vacuum delivery. Nevertheless, these reports of poor neonatal outcomes led to refinements in technique. Wider's group refined the vacuum procedure in the 1960s and limited the instrument's use to the second stage of labor. To minimize neonatal morbidity, it was recommended that vacuum application to the fetal head should not exceed 15 minutes. Using the Bird modification of the Malmstrom device and comparing vacuum with forceps and cesarean delivery, Greis and colleagues demonstrated that neither perinatal mortality nor serious neonatal injury were more likely with vacuum extraction when the procedure time was limited to 15 minutes and/or two sudden disengagements (“pop-offs”). Preferential use of vacuum over forceps was reported for managing challenging deliveries. In that retrospective study, it was noted that 60% of vacuum cases were initiated in the midpelvis compared with only 9% of forceps deliveries. Malpositioning of the fetal head as occiput posterior (OP) or occiput transverse (OT) was seen in 81% of vacuum cases as compared with only 9% of forceps cases.

The utilization of the vacuum for operative vaginal delivery has surpassed the forceps in the United States, which traditionally has been considered a “forceps nation.” Findings from surveys undertaken in the mid 1990s revealed that vacuum delivery techniques were taught in most U.S. OBGYN residency training programs and frequently were practiced by U.S. obstetricians. Another survey found that residency program directors expected their OBGYN residents to be proficient with forceps and vacuum extraction for outlet and low-pelvic deliveries (with or without rotation). However, very challenging operative vaginal deliveries today probably reside more often in the vacuum domain since only 38% of the residency program directors expected their graduates to be proficient with midforceps procedures, while 69% expected proficiency with midpelvic vacuum extractions.

The age of the obstetrician is clearly important and relevant to choice of instrument for operative vaginal delivery. Recently trained obstetricians more commonly choose vacuum extraction over forceps, especially for the challenging case. Geography plays a role as well, since data from the National Center for Health Statistics and the National Hospital Discharge Survey demonstrated that the frequency of vacuum extractor use surpassed that of the forceps in the western United States in 1988, in the Northeast in 1990, and in the Midwest in 1991. Forceps procedures continued to outpace vacuum procedures in the southern United States during the study period until there was near parity between the two instruments in 1994, which was the last year of the study.

With increasing use of operative vacuum delivery, there also was a significant increase in the number of reported neonatal complications. On May 21, 1998, the U.S. Food and Drug Administration (FDA) distributed a public health advisory entitled *Need for Caution When using Vacuum-Assisted Delivery Devices*. The advisory included reports of 12 neonatal deaths and 9 serious injuries that were received during the preceding 4 years (about 5 events per year) in newborns for whom vacuum devices were used to accomplish delivery. The FDA was concerned that some health care professionals who were using vacuum devices for delivery might not be fully aware of the possibility of life-threatening neonatal complications such as subgaleal hematoma or intracranial hemorrhage. The FDA's main points were as follows:

- The vacuum extractor should be used only when a specific indication exists.
- The operator should be versed in its use and aware of indications, contraindications, and precautions.
- The operator should follow manufacturer recommendations regarding cup placement, vacuum strength, cumulative duration of applications, and number of extraction attempts.
- Rocking movements or torque should not be applied to the device, and only steady traction in the axis line of the birth canal should be used.
- Neonatal staff should be educated about the specific complications that can occur in association with the use of vacuum devices to accomplish delivery.
- Adverse events and complications associated with vacuum-assisting devices should be reported to the FDA under the auspices of the Safe Medical Devices Act of 1990.

The American College of Obstetricians and Gynecologists (ACOG) responded to the release of the FDA advisory with a committee opinion, which noted that an average of 228,354 vacuum deliveries occurred annually during the period of time covered by the FDA advisory —the equivalent of one adverse event for every 45,455 vacuum deliveries. Despite the infrequent occurrence of fetal injury, the ACOG committee recommended that all clinicians using vacuum devices for delivery should be familiar with the indications for the use of these devices and be properly educated in their use. This committee strongly recommended the continued use of vacuum-assisted vaginal delivery devices in appropriate clinical settings. In the first 6 months following release of the FDA advisory,

Ross and colleagues observed a 22-fold increase in the reporting of adverse events associated with vacuum delivery, including 10 neonatal deaths, 30 life-threatening events, 12 nonlife-threatening events, and 3 equipment failures. The increase in reports was ascribed to better compliance with reporting, increased awareness of the potential for fetal injury with vacuum extraction, and increased use of the vacuum device.

In response to four neonatal deaths secondary to subgaleal hemorrhage, the Health Protection Branch of Canada issued their own warning on February 23, 1999. The recommendations issued were directly in line with those of the FDA.

Types of Vacuum Extractors: Stainless Steel Devices

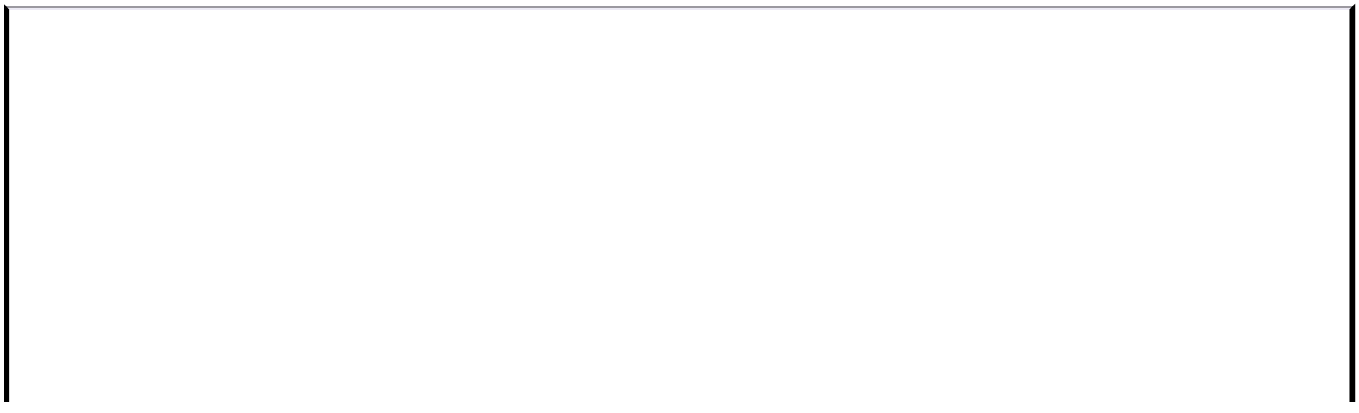
Stainless steel devices are mentioned primarily for their historical significance and because they have served as prototypes for plastic devices in use today. Early in 2000, the labor and delivery unit utilized by the authors attempted to buy new Malmstrom and Bird cups in order to teach our OBGYN residents the proper use of these devices. However, the European manufacturers declined to sell these devices to buyers in the United States. Their stated reservation was due to U.S. product liability laws and their wish to avoid any potential medicolegal entanglements.

The Malmstrom vacuum extractor (Fig. 26.2) is a shallow, mushroom-shaped stainless steel cup, with two

---

vacuum hoses, a traction chain and attached metallic disk, a traction handle, and a vacuum source. The center of the cup has a metallic suction port through which the traction chain passes. The traction chain is attached to the cup by a metallic disk that is inserted within the cup to prevent the fetal scalp from being pulled into the vacuum port. The margin of the metallic disk is scalloped at regular intervals such that the vacuum may be developed beyond the underside of the disk and onto the fetal scalp. The Malmstrom vacuum extractor can be assembled in seconds. After its use the device is easily disassembled, and the components are washed, autoclaved, and packaged for future use.

The Malmstrom cup has an inverted lip such that the diameter of the opening is smaller than the internal diameter of the cup. When the cup is placed on the fetal scalp and vacuum is established, a small artificial caput forms, termed the *chignon*. When the fetal scalp fills the internal dimensions of the cup, the scalp underlies the opening of the cup in a “key-in-lock” fashion. This allows a considerable traction force to be applied before cup detachment occurs.



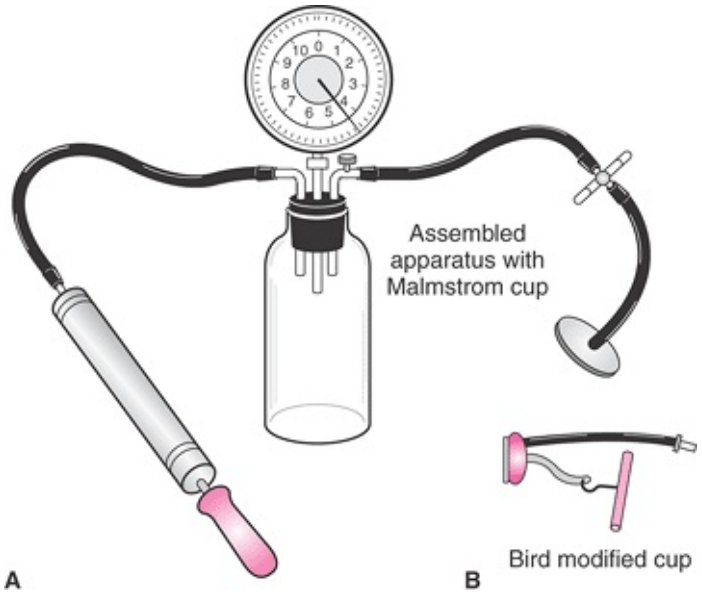


Figure 26.2 The original Malmstrom device with the bicycle-style pump.

The utility of the Malmstrom cup is limited by a combined vacuum port and traction apparatus in the dome of the cup, which makes appropriate application somewhat difficult in positions of the fetal head other than occiput anterior (OA). In 1969, Bird developed two modifications (anterior and posterior) of the Malmstrom cup to increase the versatility of the vacuum extractor for proper placement with difficult positioning of the fetal head. Bird separated the vacuum port and the traction apparatus (Fig. 26.2). The traction chain remained anchored to the center of the cup, while the vacuum port was attached eccentrically to the dome of the anterior cup. The vacuum port was attached laterally for the posterior cup. With these modifications, the vacuum tubing exited in the same plane as the cup, a change which enabled the physician to better maneuver the cup into its proper location within the maternal pelvis. In even later versions of the Bird cups, the central traction chain was replaced by a nylon cord anchored to the edges of the cup and to a traction bar for physician convenience.

Types of Vacuum Extractors: Soft-Cup Devices

There are several types of plastic or silicone vacuum cups currently in use in the United States (Fig. 26.3). The cups are separated into three groups, depending on the shape of the vacuum cup: funnel, bell, or mushroom. Of these, the funnel-shaped cups are the least used. The prototype for this vacuum extractor was based on the original Kobayashi silastic cup, introduced in 1973. The diameter of this device (65 mm) is the largest of any of the commercially available cups, and therefore its size obviates the need for a chignon to form in order to achieve appropriate traction. This device also has a vacuum release valve on the stem, which allows the operator to reduce vacuum pressure between contractions, if desired. Variations on the original Kobayashi design are available from several vendors. A much lower rate of neonatal scalp trauma was reported with the Kobayashi cup in contrast to experiences with stainless steel cups, a finding that was corroborated by five randomized studies of the silastic cup versus the stainless steel cups. Although the

Kobayashi vacuum extractor was noted to effect delivery in less time than stainless steel devices, a higher failure rate occurred, especially when the fetal head was in the OP presentation.

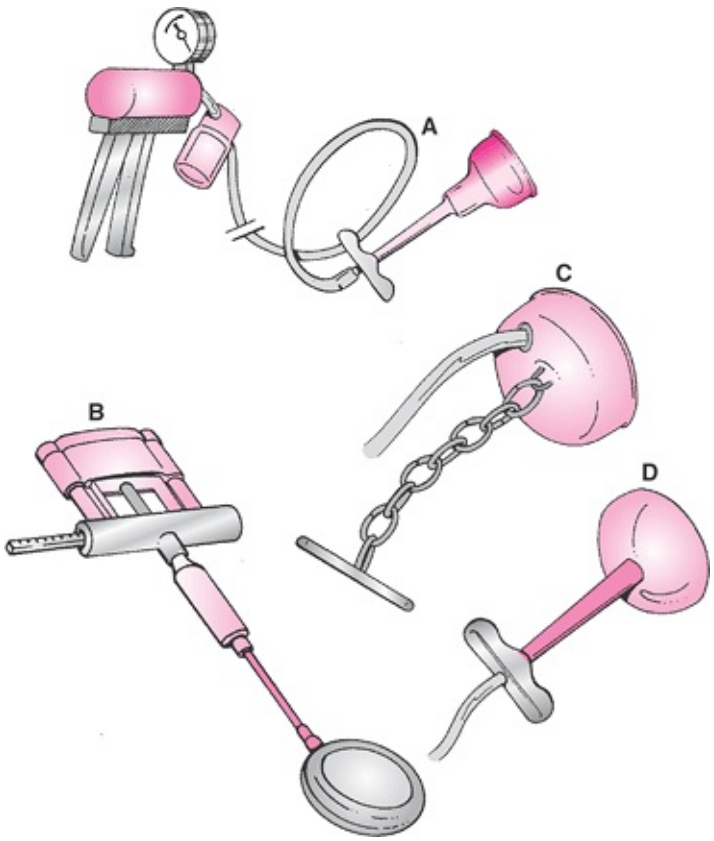

Figure 26.3 Vacuum extractor cup designs. **A:** Typical bell-shaped cup with a hand pump. **B:** Disposable plastic version of the Bird cup with combined pump and traction bar. **C:** Bird OA cup.**D:** Typical disposable mushroom-shaped cup.

Bell-shaped vacuum cups are widely available from several vendors in the United States. One example is the Mityvac device (Cooper Surgical, Trumbull, CT), which was compared with a silastic funnel-shaped cup and Tucker-McLane forceps in a prospective, randomized study of 118 delivered patients by Dell in 1985. Trauma to the maternal genital tract trauma was noted in 48.9% of the women delivered by forceps as compared with 36.1% and 21.6% of the women delivered by the silastic and bell-shaped cups, respectively. This represented a statistically significant reduction in maternal genital tract trauma with use of the bell-shaped vacuum device. Success rates using the bell-shaped cup (89.2%) versus forceps (93.3%) were not significantly different. However, there was a significantly higher rate of cephalohematoma formation in the neonates delivered with vacuum devices (funnel-shaped cup, 13.9%; bell-shaped cup, 16.2%) than with forceps (2%). Caput and scalp discoloration was more apparent with the bell-shaped cup than with the funnel-shaped cup. With regard to the utility of the soft-cup vacuum devices, Dell's group concluded that “the dramatic usefulness of these instruments to quickly deliver multiparas whose infants experienced fetal distress in late labor was far more impressive than their

performance as outlet instruments in nulliparas."

The first generation of mushroom-shaped cups represented an apparent attempt to produce a plastic version of the Malmstrom stainless steel cup. Several vendors offer disposable mushroom-shaped vacuum cup devices made of semirigid plastic; one of the more popular devices has been the M-cup (Mityvac). The efficacy of this cup was tested prospectively against the obstetric forceps in a large randomized clinical trial by Bofill in 1996. Both devices were comparably effective as tools to accomplish vaginal delivery, but deliveries with the M-cup were accomplished in less time and with less maternal genital tract trauma. As with nearly all other studies of vacuum and forceps, the clinical diagnosis of neonatal cephalohematoma was made significantly more often after vacuum delivery.

The first generation of mushroom-shaped vacuum cups faced the same problems as the original Malmstrom stainless steel device—limited maneuverability. They were, however, more easily maneuvered than funnel- or bell-shaped cups within the maternal introitus because the traction stem could be bent at a 90-degree angle with respect to the cup. Nevertheless, the combined and centrally located vacuum port and traction stem limited the ability of the physician to place the vacuum cup on the median flexing point, especially in cases of difficult positioning of the fetal head such as OP or OT positions or in the presence of significant asynclitism. Past experience with improvements to the stainless steel cups afforded a design solution to this shortcoming as a plastic equivalent of the Bird posterior cup. In 2001, Vacca tested the OmniCup (Clinical Innovations Inc., Murray, UT) and found that it was quite useful for both nonrotational and rotational vacuum-assisted vaginal deliveries (Fig. 26.3). Vacca was able to achieve a median flexing application in 90% of applications, which resulted in "autorotation" in 32 of 33 cases in which rotation was expected.

Vacuum Pressure and Traction Forces

The disposable plastic or silicone vacuum cups currently in use in the United States are marketed with a pistol grip hand pump that is connected to the cup by vacuum tubing (Fig. 26.3). A filter in the vacuum tubing prevents the suctioning of liquids or other debris into the pump. While it is possible to sterilize this pump, it is most commonly managed by a nurse or other attendant while the physician attends to the delivery. More recent versions of the mushroom vacuum cup are marketed with a disposable vacuum pump attached to the cup by a slender vacuum tube with an internal chain. This pump also contains a traction bar with a vacuum gauge and a vacuum release button. This allows the physician to better control the appropriate timing of vacuum pressure and traction.

The recommended operating vacuum pressures for the majority of cups, whether stainless steel or plastic, is from 0.6 kg/cm^2 to 0.8 kg/cm^2 (about 500 to 600 mm Hg). The original stainless steel devices used a device that resembled a bicycle hand pump to achieve the required vacuum strength. The vacuum tubing was attached to a stoppered vacuum bottle that had ports for the vacuum pump and a vacuum gauge (Fig. 26.2). Alternatively, a portable electric vacuum pump or the hospital's wall suction system could be used to generate vacuum pressure. These systems are used rarely, if at all, in the United States for vacuum-assisted delivery.

Newer vacuum devices permit the rapid achievement of required vacuum pressure as a single step over several seconds, much faster than the slow and stepwise increase in pressure required with the original Malmstrom device. There is no difference between the final recommended vacuum pressure to achieve for plastic or silicone cups compared with the original stainless steel cups. With steel, the vacuum pressure is slowly brought to 600 mm Hg and is maintained at that level until delivery is accomplished—there is no reduction between uterine contractions and traction efforts. However, with the plastic cups, some authorities have recommended that the level of vacuum pressure should be reduced from 600 mm Hg during traction and contractions to 100 mm Hg during rest. The rationale for this recommended reduction in vacuum pressure is to expose the fetal scalp to the least amount of time at high vacuum pressures. A randomized trial of the intermittent versus continuous techniques of vacuum pressures during delivery with a mushroom-shaped cup failed to demonstrate any difference in neonatal outcomes. Regardless of the technique, however, the longer a vacuum cup resides on the fetal scalp, the greater is the likelihood of cephalohematoma formation and other cosmetic scalp lesions.

Vacuum Extraction Delivery: Recommended Practice

The following list summarizes the recommended steps for use of a mushroom-shaped cup to accomplish vacuum-assisted vaginal delivery, analogous to the check-offs that a pilot undertakes while readying a plane for flight:

- **CHECK—Specify the Indication:** An indication should exist for the procedure.
- **CHECK—Get Informed Consent:** Obtain either verbally or as a written document.
- **CHECK—Gestational Age ≥34 Weeks:** The pregnancy is at term or near term—in the authors' practice, vacuum delivery generally is not used at a gestational age <34 weeks.

- **CHECK—Cervix Dilation and Effacement:** The cervix is fully dilated and the fetal head is well engaged, preferably deeply engaged for low-pelvic or outlet-pelvic delivery.
- **CHECK—Fetal Head Position:** The correct position of the fetal head should be determined.
- **CHECK—Contraindications Absent:** Face, brow, or breech presentations are strict contraindications to vacuum use for delivery.
- **CHECK—Test Vacuum:** The vacuum apparatus is tested against the clinician's gloved hand to assure achievement of adequate but not excessive vacuum pressure.
- **Correct Cup Application:** The vacuum cup is applied to the median flexing point of the fetal head (Fig. 26.4).
- **Partial Vacuum Pressure:** Vacuum pressure initially is raised to approximately 100 mm Hg so that the clinician can palpate around the cup rim to be assured that no maternal tissue is trapped under the cup.
- **Time the Procedure:** The procedure is timed from cup placement to completion of newborn delivery.

- **Full Vacuum Pressure:** Vacuum pressure is increased to 600 mm Hg, with subsequent initiation of traction concurrent with uterine contraction and maternal expulsive efforts—vacuum pressures higher than 600 mm Hg are not recommended.
- **Correct Traction:** Traction is undertaken in the direction of the pelvic axis and perpendicular to the cup.
- **Descent with Traction Rule:** The physician should be certain that traction produces descent of the fetal skull as well as that of the fetal scalp.
- **Traction—Not Torsion:** Intentional torsion of the cup is never applied to produce rotation of the fetal head; direct traction can lead to spontaneous rotation of the fetal head with descent ("autorotation").
- **STOP—Three Pop-Offs:** The procedure should be terminated if there are three pop-offs.
- **STOP—Fetal Scalp Trauma:** The procedure should be terminated if there is evidence of fetal scalp trauma after a pop-off.

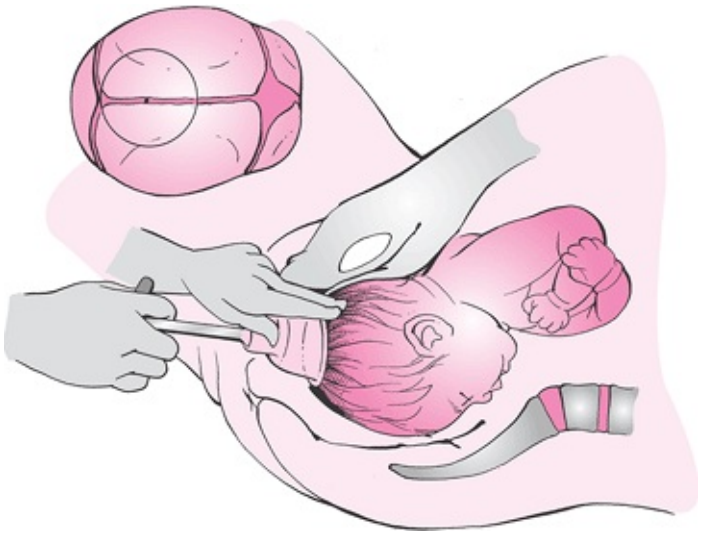

Figure 26.4 The median-flexing application.

- **STOP—20 Minutes:** The procedure should be terminated if delivery has not occurred within 20 minutes.
- **STOP—No Descent:** The procedure should be abandoned if there is no descent with correct application and appropriate traction (without waiting for three pop-offs or 20 minutes).
- **NEWBORN—Inspect the Scalp:** After delivery, the scalp should be inspected for trauma and position of the chignon.
- **NEWBORN—Communicate Vacuum Use:** Nursery personnel should be alerted that the delivery was accomplished via vacuum.
- **Document:** The procedure should be documented thoroughly in the medical record.

The indications for vacuum-assisted delivery are nearly identical to those for obstetric forceps. The most common indications include a prolonged second stage of labor or nonreassuring fetal status. Other indications include maternal exhaustion and maternal illnesses in which maternal expulsive efforts should be limited. The indication for vacuum delivery should be included in the delivery note portion of the medical record.

It is important for the physician to perform a careful assessment of the fetal head with regard to the size and position of the caput succedaneum and the amount of molding. Severe molding of the fetal head may indicate cephalopelvic disproportion. The method of Stewart is used to describe the amount of molding by examination of the parietal bones (Fig. 26.5). Safe and successful vacuum-assisted delivery is contingent on an appropriate application of the cup onto the fetal head. It is very important that the cup be placed on the median flexing point, as defined by Vacca (Fig. 26.4). To achieve the correct median flexing application, the center of a 60-mm cup should be placed 3 cm from the posterior fontanelle and symmetrically astride the sagittal suture. In this application, one edge of the cup will encroach on the posterior fontanelle, while the opposite edge will be about 3 cm from the anterior fontanelle. The median flexing point is located at the emergence of the mentovertical diameter and is about 3 cm anterior to the posterior fontanelle and in the midline (Fig. 26.6). The fetal head is considered to be optimally flexed when the mentovertical diameter points in the direction of the pelvic axis. The center of the vacuum cup should be placed over the median flexing point so that it is symmetrically astride the sagittal suture. Correct application of the vacuum cup as described is important because traction in the direction of the pelvic axis will maintain flexion of the fetal head and minimize or eliminate any asynclitism. Thus, the maternal pelvis is presented with the most favorable diameter of the fetal head, and atraumatic delivery is optimized.

There are several potential consequences of suboptimal cup placement. Asymmetric placement of the vacuum cup astride the sagittal suture (a paramedian application) will produce asynclitism when traction is applied. If the center of the cup is placed too far anteriorly, subsequent traction will produce deflexion of the fetal head (deflexing application). If the placement of the cup is both paramedian and deflexing, successful and safe delivery is unlikely.

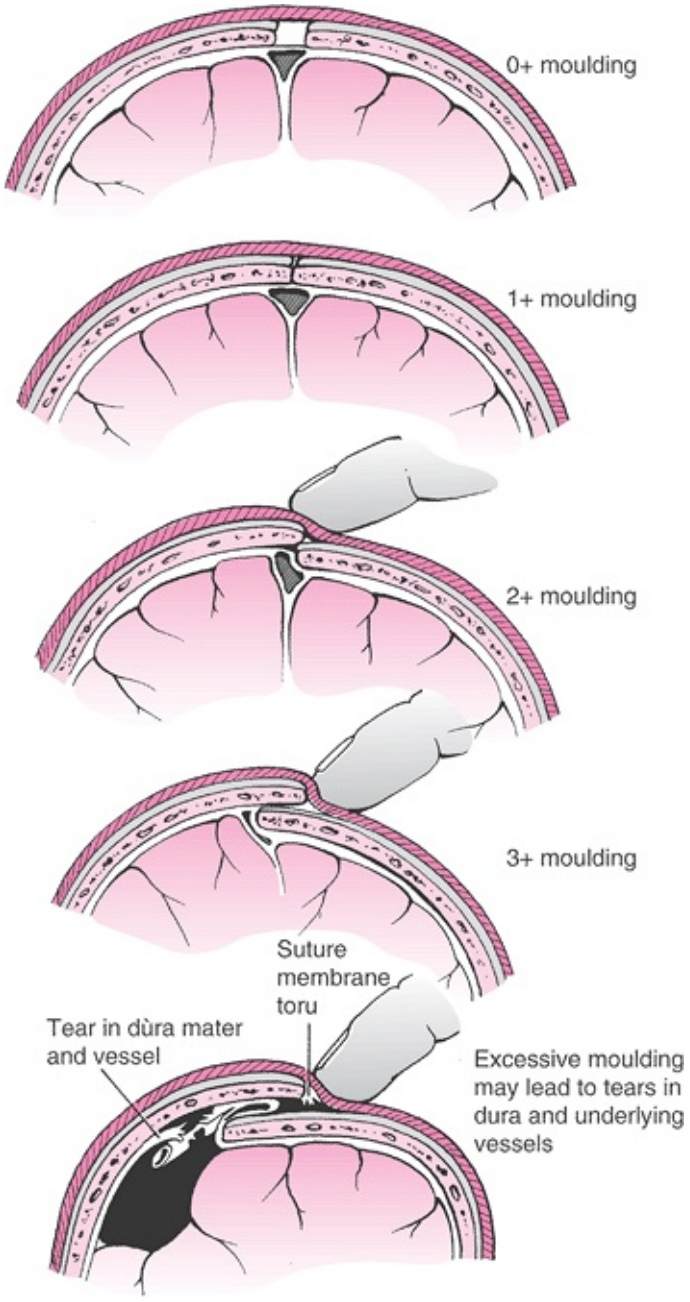

Figure 26.5 The Stewart method for estimation of the degree of molding of the fetal head.

The least resistance to delivery of the fetal head occurs when the direction of vacuum traction is parallel with the pelvic axis. Traction should be perpendicular to the vacuum cup. Angular (off-center) traction commonly produces lift at the far edge of the cup, which can lead to disconnects or “pop-offs.” If traction at an angle cannot be avoided secondary to asynclitism or deflection of the fetal head, the physician may be able to compensate for this off-center traction by using the thumb or index finger of the nontraction hand to apply counterpressure on the far side of the cup. This is the so-called three-finger grip, which also assures that descent of the fetal skull occurs with vacuum traction and maternal expulsive efforts.

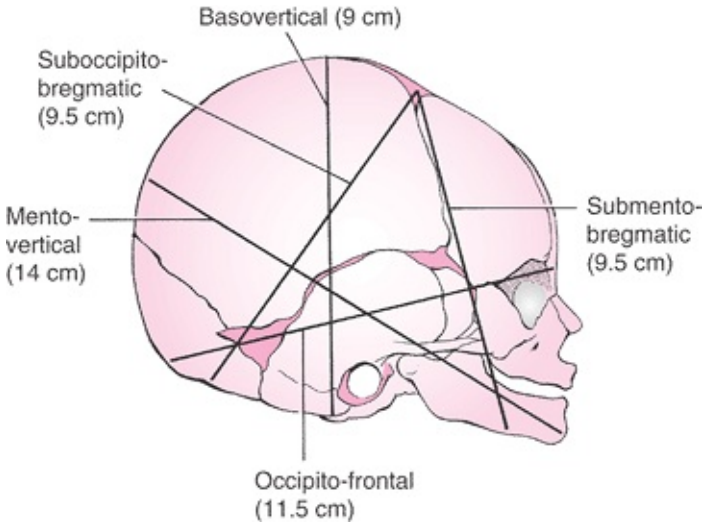

Figure 26.6 Diameters of the fetal head.

Physicians should never apply torsion to the vacuum cup when it is used to deliver an infant from an OP or OT presentation, as this can result in fetal scalp injury. Straight axis traction of a properly placed cup will often produce rotation to the OA position when the fetal head encounters resistance from the maternal levator musculature in a pelvis of adequate size for vaginal delivery. This is termed *autorotation*, a phenomenon that is commonly seen as the fetal head descends in both spontaneous as well as vacuum-assisted delivery. Vacuum traction should be applied only in concert with maternal expulsive efforts.

The physician should be willing to abandon an attempt at vacuum-assisted delivery if it does not go well and complications are noted. If fetal scalp trauma is observed with the vacuum cup, the cup should be removed and delivery accomplished otherwise. As the length of time a vacuum cup is on the fetal head increases, so does the potential for development of a cosmetic scalp lesion and cephalohematoma. Manufacturers of vacuum delivery devices frequently recommend that the fetal scalp be subjected to no more than 10 minutes at high vacuum pressures. Because recording of the cumulative time that the fetal scalp has been at high vacuum pressures is a cumbersome and frequently inaccurate procedure, we recommend that the length of time that a cup spends on the fetal scalp be limited to 20 minutes. It is the authors' opinion that if a vacuum cup pops off three times, it is wise to terminate any further attempt at vacuum delivery. Pop-offs may indicate the presence of a nonmedian or deflexing cup application, angular traction, or cephalopelvic disproportion. Perhaps the most important tenet of vacuum delivery is that if a proper application and adequate traction does not produce descent of the fetal head, the procedure should be terminated without waiting for three pop-offs or for 20 minutes to elapse. These deliveries are an excellent exercise in physician judgment and discretion.

After each vacuum delivery, it is recommended that the fetal scalp be examined to assess the position of cup placement and to document scalp trauma. Nursery physicians should be informed that the infant was delivered by vacuum so that attention can be focused on the

fetal scalp after delivery. Documentation of the vacuum delivery is of obvious importance, with a detailed written, dictated, or recorded-by-computer entry in the medical record. Details of importance to record include the indication(s) for the procedure, the instrument used, the station and position of the fetal head at the time the cup was applied, identification of the vacuum procedure as midpelvic or low or outlet in type, the number of pop-offs, and the length of time the cup was on the fetal head. Caput, molding, asynclitism, and autorotation, if encountered or noted during delivery, are documented as well. The type of analgesia provided and any maternal or fetal trauma also should be documented.

Unsuccessful Vacuum Delivery

Any physician who performs a substantial number of vacuum-assisted deliveries will occasionally need to abandon a vacuum procedure for one or more of reasons noted previously. In this situation, the physician has three options to consider. First, spontaneous delivery may be possible if there are good maternal expulsive efforts and the fetal head is on the pelvic floor. Second, cesarean delivery is clearly indicated if the fetal head is in the midpelvis or at low pelvic station with suspicion of cephalopelvic disproportion. Third, obstetric forceps can be used to accomplish vaginal delivery after a failed vacuum attempt, especially if the fetal head is deep within the pelvis. These “sequential operative vaginal deliveries” (vacuum first and then forceps or forceps first and then vacuum) are controversial. Some physicians consider initial use of a midpelvic vacuum extractor to be appropriate in order to convert what would have been a difficult midforceps procedure into a much easier low- or outlet-forceps procedure.

Small studies by two groups of investigators were unable to demonstrate any additional neonatal complications associated with “sequential” operative vaginal deliveries. The frequency of this sequential operative vaginal delivery ranged from 4% to 27% in nine studies of vacuum and forceps deliveries. However, a population-based study of fetal intracranial hemorrhage demonstrated that the risk of fetal intracranial hemorrhage clearly was increased after the sequential use of instruments as compared with spontaneous delivery, cesarean delivery, or the single use of either forceps or vacuum.

Another large study of the sequential use of instruments was produced by Gardella. In this study, the sequential use of instruments was associated with significantly higher rates of neonatal intracranial hemorrhage, brachial plexus injury, facial nerve injury, neonatal seizures, and depressed 5-minute Apgar scores. Thus, the sequential use of instruments for operative vaginal delivery is not recommended except in dire circumstances.

Neonatal Injury—Vacuum Extraction

The prevalence of neonatal scalp injury with vacuum delivery is difficult to ascertain from the literature because uniformity in reporting is lacking. A 1979 summary of outcomes with the Malmstrom vacuum extractor observed that neonatal scalp abrasions or lacerations ranged widely, from 0.8% to 37.6% (mean 12.6%). The relatively frequent occurrence of neonatal scalp injury in part led to the development of the soft plastic cups for vacuum extractors in order to accomplish a more gentle delivery. Most scalp abrasions or

lacerations are noted in place(s) where the fetal scalp is pulled under the rigid rims of the stainless steel cups or the mushroom-shaped plastic cups. However, the funnel- and bell-shaped cups mold themselves to the fetal scalp, create less artificial caput, and are associated with lesser degrees of superficial scalp injury. Many investigators have observed a lower prevalence of fetal scalp trauma with the soft cups as opposed to the stainless steel devices. Using logistic regression analysis, Teng and Sayre examined how neonatal scalp trauma occurred during a trial using the M-cup vacuum device. Independent predictors of neonatal scalp trauma included duration of the procedure (>10 minutes), duration of the second stage of labor, and a paramedian cup application. It is difficult, if not impossible, to compare the incidence of scalp trauma in studies of forceps and vacuum deliveries.

Cephalohematoma

A cephalohematoma is a self-limited injury that is caused by the rupture and bleeding of an emissary vein into the potential space just beneath the periosteum of the neonatal parietal bone (Fig. 26.7). The periosteum of the

parietal bone is firmly attached at the periphery, and only a limited amount of fetal blood can collect in this potential space. Cephalohematomas are diagnosed more commonly after vacuum extraction as opposed to forceps delivery. They typically resolve spontaneously over the course of a few days without long-term sequelae, although neonatal hyperbilirubinemia can develop. Most often, a cephalohematoma will not cross the suture lines of the skull, but edematous scalp can render the examination difficult and make the diagnosis challenging. Illustrative of this is the ultrasound confirmation of only three cephalohematomas in 12 neonates thought to have the condition. The other 9 infants had edematous scalps and not cephalohematomas.

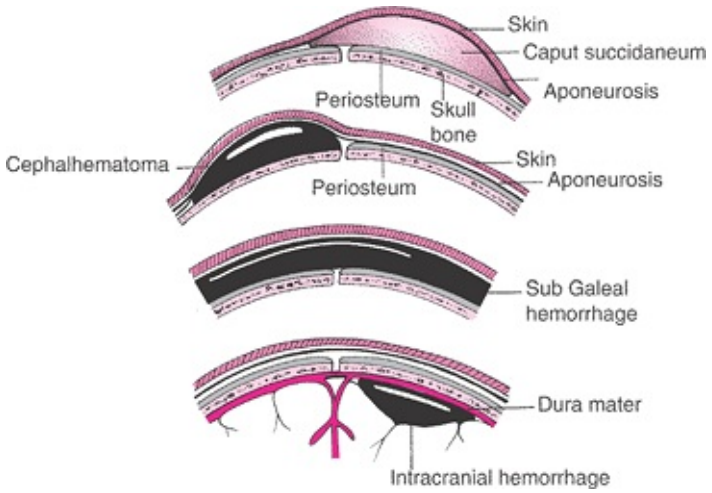

Figure 26.7 Normal caput, cephalohematoma, subgaleal (subaponeurotic) hemorrhage, and intracranial hemorrhage.

Factors associated with cephalohematoma formation were studied in a Mississippi series of

322 vacuum extraction procedures performed with the semirigid mushroom-shaped cup. The rate of cephalohematoma formation in this study was 11%. Significant contributors to the diagnosis of neonatal cephalohematoma included the duration of the vacuum procedure and the amount of asynclitism at the time of cup placement. Asynclitism easily leads to a paramedian cup application that is productive of the chignon over one parietal bone more so than the other, which enhances the possibility of a false diagnosis of cephalohematoma.

Subgaleal (Subaponeurotic) Hemorrhage

A much more serious and potentially fatal complication of vacuum extraction is a subgaleal (subaponeurotic) hemorrhage, in which a scalp vessel ruptures distal to the level of the periosteum where blood can accumulate in the layer of loose connective tissue known as the subgaleal or subaponeurotic space (Fig. 26.7). This potential space is very large and extends from the orbital ridges anteriorly, to the nape of the neck posteriorly, and to the zygomatic arches laterally. This space can easily accommodate the entire blood volume of a term newborn, even if filled only to a 1 cm depth. The most common physical finding with a subgaleal hemorrhage is a fluctuant mass that extends over the cranial sutures and fontanelles. This usually is accompanied by edema and bruising that extends posteriorly into the neck and laterally around the ears. The fluctuant mass can reach the upper eyelids and the root of the nose. The infant will commonly have evidence of hypovolemic shock. Shock may manifest hours after delivery or even later in the nursery. Subgaleal hemorrhage also has been associated with midforceps delivery, leading at least one investigator to conclude that instrumental delivery is the principal predisposing factor for this lesion. The incidence of subgaleal hemorrhage is estimated to occur in 4 of 10,000 spontaneous vaginal deliveries and in 59 of 10,000 vacuum-assisted deliveries.

The 1998 FDA public health advisory primarily was directed at alerting all physicians who practice vacuum-assisted vaginal delivery to be very aware of subgaleal hemorrhage as a potential complication. Advising nursery personnel that a vacuum-assisted vaginal delivery has been performed also is key to facilitating the early diagnosis of a subgaleal hemorrhage.

Intracranial Hemorrhage

Although intracranial hemorrhage in the term infant often is associated with traumatic operative vaginal delivery, it can occur after spontaneous delivery as well and have profound neonatal consequences (Fig. 26.7). In 1990, Hannigan and coworkers reported three cases of tentorial hemorrhage that were associated with soft-cup vacuum extraction deliveries. They reasoned that vacuum delivery could produce vertical stress in the occipitofrontal diameter, thereby causing tentorial venous hemorrhage. Nine other cases of tentorial subdural hemorrhage in term newborns were reported by another group, with five cases following delivery using the vacuum extractor. Seven of the nine infants were neurologically normal at 13 months of age. One infant delivered by vacuum extraction required a ventriculoperitoneal shunt for progressive hydrocephalus.

Vacuum extraction typically is avoided in the fetus that is very preterm because of the

increased risk for intracranial hemorrhage at earlier gestational ages. There is no evidence-based gestational age threshold on which to base practice, but most clinicians avoid vacuum extraction altogether at <34 weeks gestation. Two small retrospective studies have been published that were unable to demonstrate an increased risk of intracranial hemorrhage in preterm infants delivered via the vacuum. Finally, Towner and colleagues utilized a population-based study to show that the rates of intracranial hemorrhage are not statistically significantly different for vacuum-assisted delivery, forceps delivery, and for cesarean delivery performed during labor. However, those deliveries accomplished by the sequential use of instruments (vacuum, then forceps) were associated with a significantly higher rates of intracranial hemorrhage.

Retinal Hemorrhage

Neonatal retinal hemorrhage after vaginal delivery is quite common. In 1974, Ehlers and colleagues noted neonatal retinal hemorrhage in 28% of newborns following spontaneous delivery, 38% with forceps delivery, and 64% after delivery with the Malmstrom vacuum extractor. Others reported the incidence of moderate to severe retinal hemorrhages in infants delivered with the soft plastic bell-shaped cup to be 18% with spontaneous deliveries, 13% with forceps, 28% with vacuum, and 50% in infants delivered using sequential forms of operative vaginal delivery. Multiple logistic regression analysis has been used as well to identify the factors associated with moderate to severe retinal hemorrhage. These have included vacuum delivery of low–birth-weight infants, short second stages of labor, fetal acidemia, and the sequential use of vacuum-then-forceps

---

for delivery. Neonates delivered by vacuum extraction typically will have higher rates of retinal hemorrhage. Neonatal retinal hemorrhages have not been demonstrated to have long-lasting effects. Following a 5-year period of study, children delivered by random assignment either to vacuum or forceps extraction demonstrated no difference in visual problems.

Delivery with Obstetric Forceps

In modern-day obstetric practice, it is not uncommon for an educated and well-read patient to present for her first prenatal care visit with a birth plan that specifically excludes any form of operative vaginal delivery, especially one that might include obstetric forceps. The use of obstetric forceps has always engendered controversy. Points of view tend to cycle, to some extent in relation to the age of the obstetrician and the era during which he or she trained.

Most historians credit the 17th century Chamberlen family as the first well-known purveyors of the use of these instruments that were designed to deliver a living infant. Because the Chamberlens were engaged in an effort to monopolize the midwifery practice of London, family members attempted to keep their instruments secret from their patients and other physicians alike. For some time, these instruments had limited use in the hands of a skilled few, but this ended when a family member in difficult financial straits sold the secret to the Dutch medical community. The reader interested in the convoluted story of

the forceps and the generations of the Chamberlen family can easily find a more complete history. With more widespread use of obstetric forceps, particularly by unskilled providers, there was a predictable increase in poor maternal and neonatal outcomes. By the end of the 18th century, the use of obstetric forceps had declined greatly.

The well-known impetus for the rebirth and more frequent use of the obstetric forceps was the “triple obstetric tragedy.” In 1817, after a very protracted second stage of labor, Princess Charlotte delivered without assistance a stillborn who would have been the future king of England. The obstetric management of labor characterized by nonintervention became a contentious topic, as it was considered to account for the poor outcome of the pregnancy. Some considered that the judicious use of forceps could have shortened the labor since the fetal head was reportedly on the perineum for 10 hours. Not only was the infant stillborn, but the princess also died of a postpartum hemorrhage. The triple obstetric tragedy was completed when the royal obstetrician took his own life some weeks after this debacle.

This tragedy and the development of obstetric anesthesia in the mid 19th century helped to initiate an era of liberalized obstetric forceps use. In the first issue of the *American Journal of Obstetrics and Gynecology*, DeLee discussed his views on the prophylactic use of these instruments. By the 1940s, the rate of obstetric forceps deliveries in the United States approached 70%, but soon thereafter the trend began to reverse for several reasons, including the introduction of the vacuum extractor and expanding, liberal, and increasingly safe use of cesarean delivery. Thus, in recent decades, all but the simplest of obstetric forceps have disappeared from the armamentarium of the recently trained obstetrician. The rate of forceps deliveries in the United States in 2004 was just over 1%.

Types of Obstetrical Forceps

Hundreds of obstetric forceps have been developed for utilization in this country and elsewhere in the world—there are many choices (Fig. 26.8). Most obstetricians, however, comfortably and competently use no more than three or four different types of instruments in their practices.

Anatomy of the Forceps

Obstetric forceps are a paired instrument, fashioned of two branches that articulate with one another by a lock. The branches (left and right) are side specific and named according to the side of the maternal pelvis into which it will be applied. Before using any obstetric forceps, the obstetrician should be certain that the two branches of the pair constitute a matched set that is symmetrical when articulated. Application techniques are described below.

The classical forceps have two branches that are each constructed of a handle, shank, lock, and blade. The blade is curved and is the widened portion of the instrument that will be applied to and will cradle the fetal head within the maternal pelvis. The blade is named as if it were a shoe, with the tip being the toe and the portion of the blade at the base of the shank being the heel. The shanks connect the blades to the handle, and the instrument is

articulated via a locking mechanism that is located at the juncture of the handle and the shanks.

Modern forceps have a handle with finger grips or lateral flanges that facilitate traction efforts. The Bill axis-traction device can be attached to the flange of numerous classical instruments, such as the Simpson or Elliot forceps, and is designed to help the physician apply traction in the appropriate vector. On some instruments, the handles are quite small (Laufe divergent forceps), while others are very large (Salinas forceps). The handles of the classic Elliot forceps have a wheel and screw mechanism at the base, which permits adjustment of the distance between the branches, ostensibly to limit fetal head compression.

The shank connects the blade to the handle of the forcep, arranged structurally to be parallel (Simpson forceps), overlapping (Tucker-McLane or Elliot forceps), or divergent (Laufe forceps). Shanks vary in length, some being quite short in forceps designed to facilitate outlet delivery (Laufe forceps), while others are much longer in forceps designed for use with midpelvic operations (Kielland

and Bailey-Williamson forceps). Most instruments have straight shanks, but an exception is the Piper forceps with curved shanks, which is designed for placement on the after-coming head during a breech vaginal delivery.

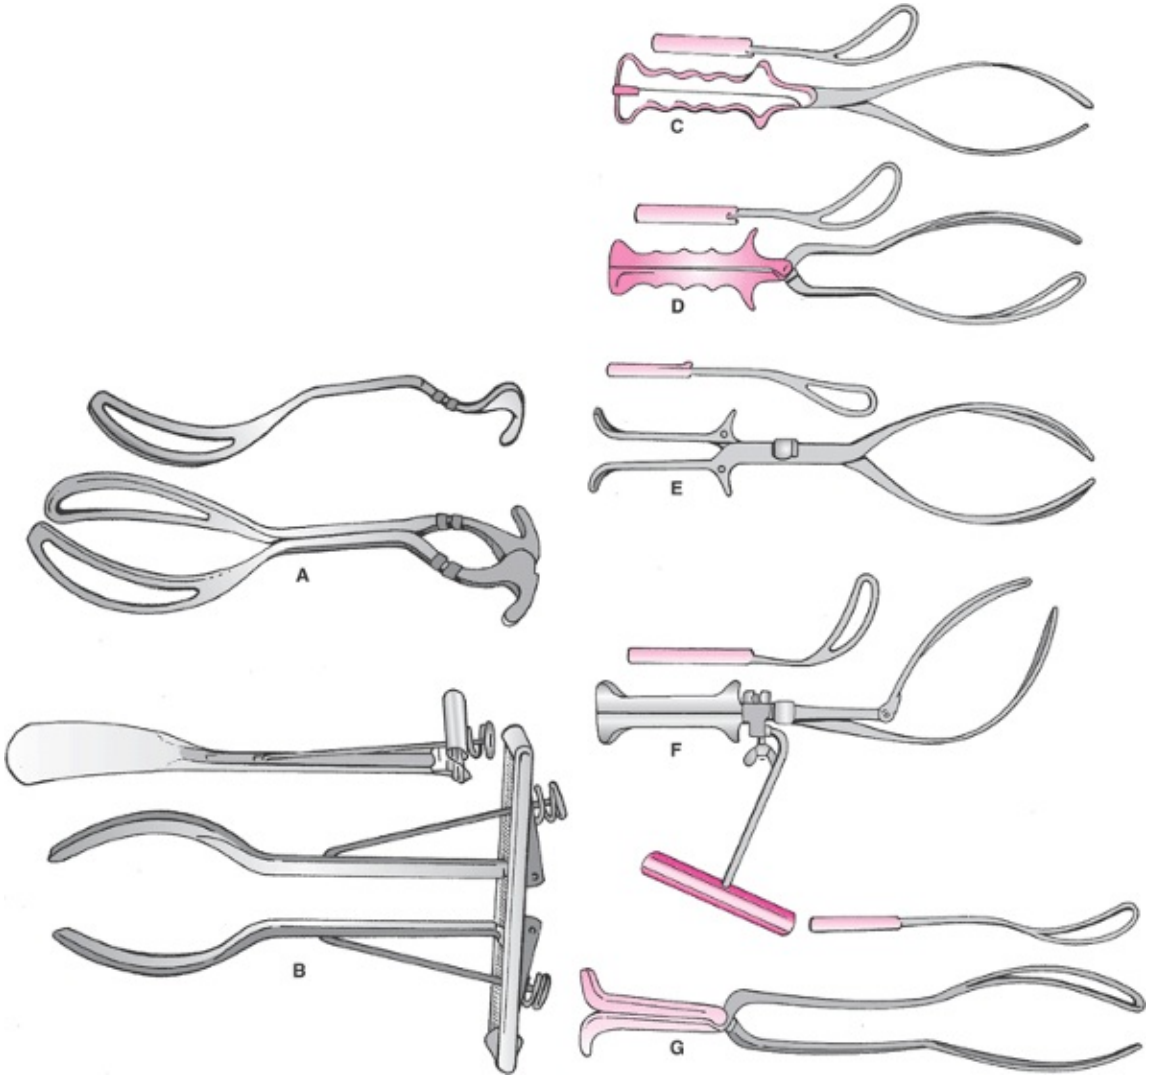

Figure 26.8 Common types of obstetric forceps. **A:** Laufe divergent forceps. **B:** Salinas forceps. **C:** Elliot forceps. **D:** Simpson forceps. **E:** Kielland forceps. **F:** Barton forceps with a traction bar.**G:** Piper after-coming head forceps.

The lock (Fig. 26.9) usually is found at the juncture of the shank and the handle on obstetric forceps, often incorporated into the left branch. The two most common locks are the English lock and the sliding lock. The English lock is formed by the mating of a tongue and slot mechanism located at the juncture of the shanks and handles on classical instruments such as Simpson, Tucker-McLane, and Elliot forceps. The English lock is easily articulated and secure because it allows locking of the blades only at this one point. The sliding lock, seen in the special rotational forceps known as Kiellands, actually is a misnomer because the branches are not fixed or locked together when articulated. Forceps with a sliding lock can be very useful in the correction of asynclitism of the fetal head.

Another type of lock is the pivot lock, as used in Laufe divergent forceps and short Piper forceps. This pivot lock is incorporated into the finger-grip handles. Thus, when traction is applied, the blades and shanks will actually diverge and shift any pressure on the fetal head to the maternal pelvic sidewalls. Salinas forceps, used commonly in Mexico, have a mechanism whereby the lock and the handle are one and the same. Forceps using a French lock in which a

wing-nut affixes the handles have very limited use currently in the United States.

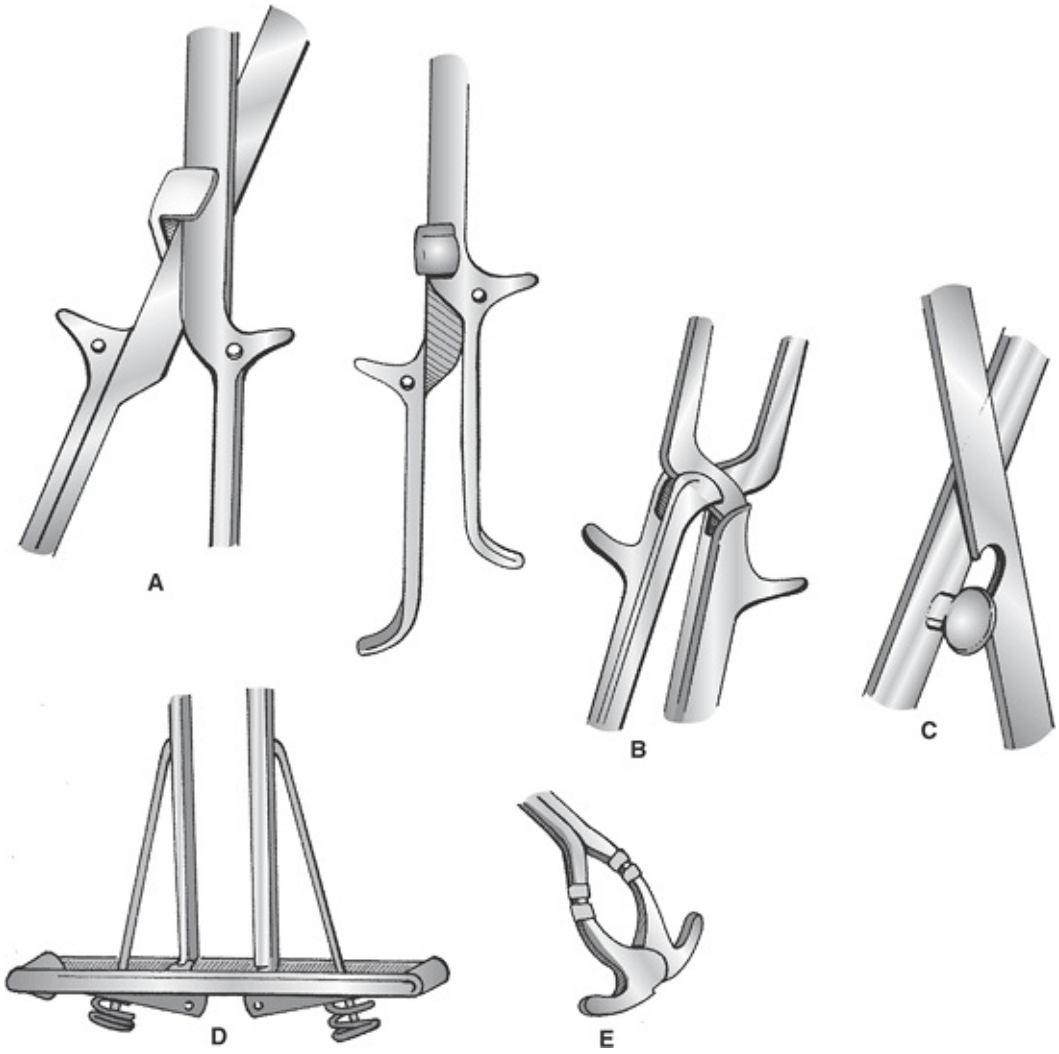

Figure 26.9 Types of locks.**A:** Sliding lock of the Kielland forceps. **B:** English lock of many types of forceps. **C:** French lock of the Tarnier forceps (historical interest only). **D:** Lock/handle of the Salinas forceps. **E:** Pivot lock of the Laufe divergent forceps.

Although some obstetricians refer to a single branch of the forceps as a *blade*, that term should be used only for the distal portion of the forceps that grasps the fetal head. Blades can be fenestrated (Simpson and Elliot forceps), pseudofenestrated (Luikart-Simpson forceps), or solid (Tucker-McLane and Salinas forceps). Forceps with fenestrated blades are superb for traction purposes but are considered more likely to cause maternal tissue damage during rotation than instrumental delivery using solid blades. Solid blades are considered to be superior for rotation with less risk of maternal injury during this maneuver, but they are not optimal as traction devices since slippage from the fetal head can occur.

Forceps blades have two right angle curvatures. The curve that will cradle the fetal head is called the *cephalic curve* and is designed to fit closely around the fetal head. This curvature has a diameter of no less than 7.5 cm at its greatest expanse. The other curvature is termed the *pelvic curvature* and is concave upward to approximate the maternal pelvic curve. If a set of classical forceps (Simpson, Elliot, or Tucker-McLane forceps) are placed on a level surface, the tips of the blades are clearly seen to be

approximately 3 inches above the level of the handles. Forcep blades, which are best suited for traction of a molded fetal head, are elongated and associated with a very shallow cephalic curvature (Simpson forceps). In contrast, forceps to facilitate delivery of a fetus with an unmolded head are those with a shorter blade and a more rounded cephalic curvature (Tucker McLane or Elliot forceps).

Some specialized forceps, such as the Kielland forceps, have almost no pelvic curvature, which renders them an excellent choice for rotation of the fetal head from an OT position. Major rotation (>90 degrees) of the fetal head using classical forceps with a significant pelvic curvature mandates that the handles of the forceps circumscribe a wide arc so that the toe of the blade will circumscribe a small arc and remain in the center of the pelvis. This type of procedure likely is rare in current obstetric practice in the United States.

Relevant Maternal Anatomy

Clinical assessment of the maternal pelvis is receiving less and less emphasis in current obstetric practice. Probably the best test of the cephalopelvic relationship in a patient is her conduct of labor. On occasion, careful and accurately

undertaken clinical pelvimetry will demonstrate obvious abnormalities in a patient that possibly prevent a difficult labor due to obvious cephalopelvic disproportion.

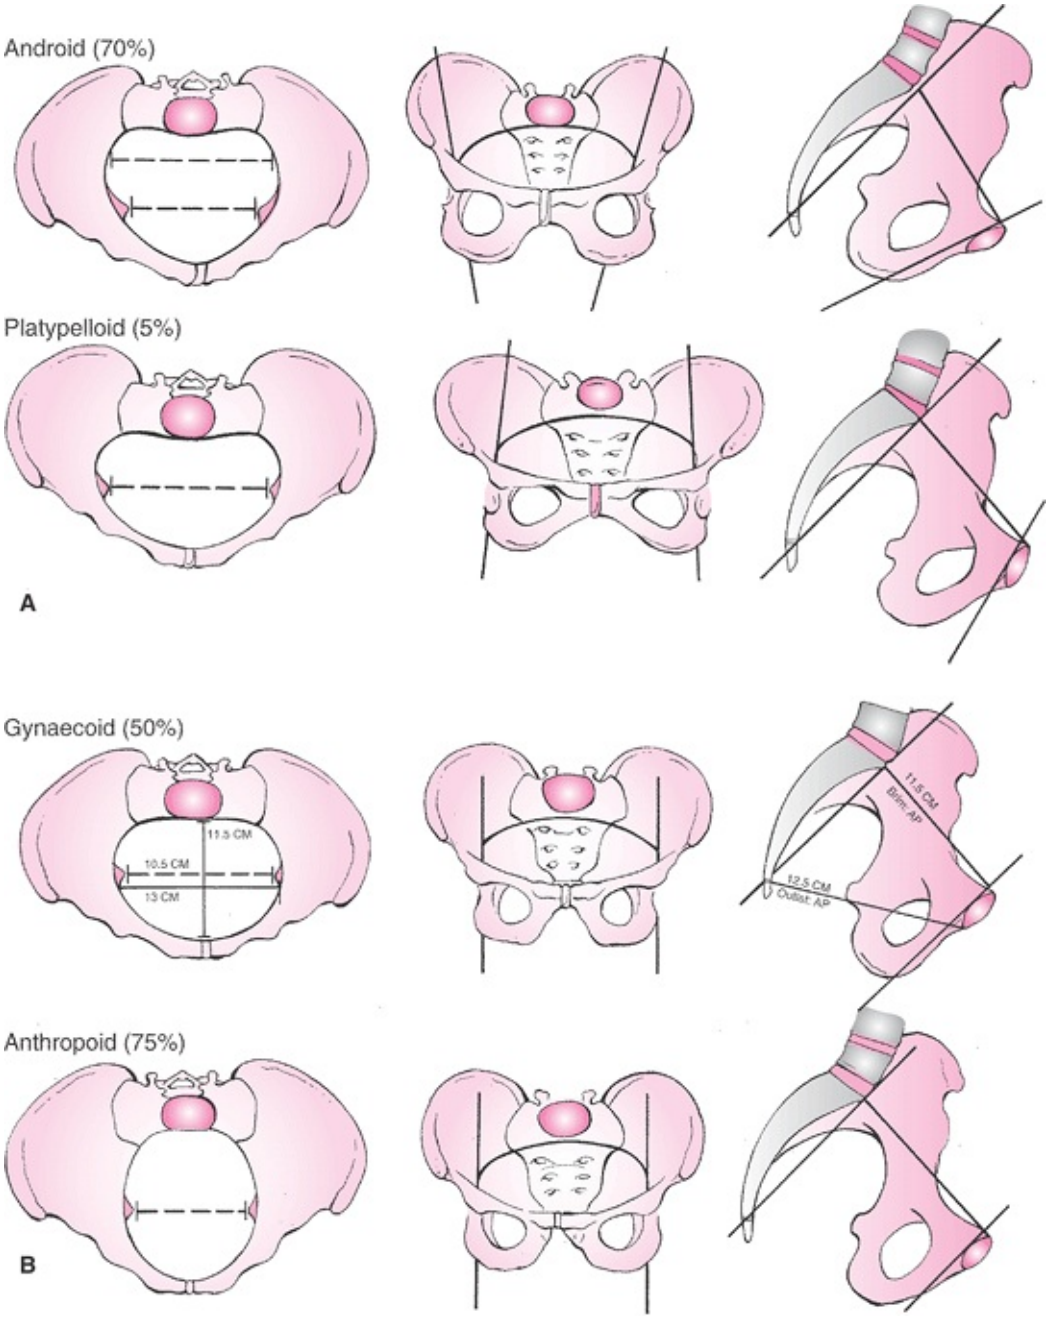

Figure 26.10 The pure types of maternal pelves and the convergence and divergence of their sidewalls.

Knowledge that the female pelvis has different configurations is important (Fig. 26.10). Four basic shapes of the maternal pelvis are described in the 1933 Caldwell-Moloy classification, although subsequent study demonstrated that intermediate types of pelvic shapes are more common than the pure versions. Table 26.1 lists the important measurements of the maternal pelvis. Clinical knowledge of the type and relative dimensions of a given pelvis form the basis of any decision to perform a forceps delivery. Familiarity with the type of pelvis in a laboring patient will enable the obstetrician to better understand the mechanism of labor and also foster a more intelligent management of her labor.

TABLE 26.1 Diameters of the Maternal Pelvis

Region of the Pelvis	Measurement (Centimeters)
Brim (Inlet)	
AP	11.5
Transverse	13.0
Midpelvis	
AP	12.0
Transverse	10.5
Outlet	
AP	12.5
Transverse	11.0

AP, anteroposterior.

Clinical Pelvimetry

The pelvis usually is assessed in terms of the inlet, midpelvis, and outlet (Table 26.1).

Pelvic Inlet

The pelvic inlet is best evaluated well before labor and engagement of the fetal head occurs with occupancy of the midpelvis and the posterior inlet. The examiner first assesses the anteroposterior (AP) diameter of the inlet by measuring the diagonal conjugate; namely, the distance from the undersurface of the symphysis pubis to the sacral promontory. Often, this causes discomfort for the patient being examined secondary to significant exerted pressure. The obstetric conjugate (the narrowest AP diameter of the inlet) is estimated by subtracting 2 cm from the diagonal conjugate measurement. The transverse diameter of the inlet cannot be measured directly by the obstetrician—a sense

of the shape and the extent of the circumference of the inlet can be gained by palpating laterally along the pelvic brim. If more than two thirds of the brim can be easily palpated, and especially if the posterior portions of the brim can be felt, it is likely that the patient has a contracted inlet.

Midpelvis

The midpelvis is evaluated by palpating the shape of the sacrum (curved or straight) and the width of the sacrosciatic notch. Additionally, the shape and prominence of the ischial spines and the distance between them is very important. A contracted midpelvis typically has a flat and forward projecting sacrum, prominent ischial spines, and a narrow interspinous distance. The sacrospinous ligament is short and is less than two fingerbreadths long.

Pelvic Outlet

The pelvic outlet is evaluated sequentially by (a) estimating the distance between the ischial tuberosities (usually about 10 cm), (b) palpating the coccyx to determine its orientation (not into the pelvis) and mobility, (c) assessing the subpubic angle to be greater than 90 degrees, (d) checking to ascertain that the retropubic angle is either flattened (platypelloid pelvis) or sharply angulated (android pelvis), and (e) the convergence or divergence of the pelvic sidewalls is assessed (Fig. 26.10).

Clinical assessment of a patient's labor and her pelvis is mandatory (ideally with documentation) prior to an operative vaginal delivery. To denote that a pelvis is “adequate” is vague and open to question in cases of a less than optimal outcome. The art of intrapartum care demands that clinical pelvimetry be combined with fetal information such as head position, attitude, molding, caput, asynclitism, presence of meconium, parameters to construct a labor curve describing descent and dilatation, and fetal heart rate response with contractions or pushing.

Fetal Information Relative to Clinical Pelvimetry

Fetal Lie

The fetal lie describes the relationship of the long axis of the fetal body to the long axis of the maternal body. The fetal lie typically is described as a longitudinal lie (with a pure cephalic or breech presentations), oblique lie (with one fetal pole, the head or the breech, in the maternal iliac fossa), or a transverse lie (with the long axis of the fetal body at a 90-degree angle to that of the long axis of the maternal body).

Fetal Presentation

Fetal presentation is determined according to the lowermost portion of the fetus that encounters the pelvic inlet. Most commonly, it is either cephalic, breech, or a shoulder presentation. Less common are footling breech and funic (cord) presentations.

Fetal Engagement

In a cephalic presentation, engagement is considered to occur when the largest part of the fetal head enters the pelvic inlet and/or when the leading edge of the fetal skull has reached the level of the ischial spines.

Fetal Attitude

In a cephalic presentation, the attitude refers to the degree of flexion of the fetal head, ranging from fully flexed (vertex presentation) to fully extended (face presentation). Midway between these two is the neutral position of the fetal head, the so-called “military” or sincipital presentation.

Fetal Station

The station of the fetal presenting part (fetal skull in a cephalic presentation, fetal sacrum in a complete breech presentation) describes its relationship in centimeters above, below, or exactly at the level (zero station) of the ischial spines within the maternal pelvis. Distance in centimeters of the presenting part above the ischial spines are considered as negative numbers, while those more deeply engaged (beyond the ischial spines) are positive numbers.

Fetal Position

The fetal position is defined by the relationship of the fetal presenting part to the maternal pelvis. The position of the fetal occiput (in a cephalic presentation) or the fetal sacrum (in a breech presentation) is described in relation to the maternal pelvis as left or right as well as anterior or posterior. Examples are “left occiput anterior” and “right sacrum posterior.”

Fetal Molding

Molding describes the degree of abutment or overlapping of the fetal skull plates as the fetal head progresses through

---

the maternal pelvis. Generally, the occipital and frontal bones will slide under the parietal bones during labor. The extent of this overlapping of cranial bones can be clinically quantified (Fig. 26.5).

American College of Obstetricians and Gynecologists' Classification of Station

In 1988, forceps operations were redefined by the ACOG with a classification system that emphasizes the station of the fetal head for stratification of the procedure. The leading part of the fetal skull is now described in numbers of centimeters above (0 to -5) or below the ischial spines (0 to +5). Minor degrees of rotation (<45 degrees) are acceptable and do not remove a forceps operation from the outlet category. The previously used 1965

classification system divided the pelvis into thirds above or below the ischial spines. With this old system, even minor degrees of rotation when performed at the outlet were categorized too many times as “midpelvic” operations. One group of investigators compared the 1965 and 1988 classification systems by using the same large cohort of forceps deliveries, validating the new classification scheme and clearly demonstrating that the risks of operative vaginal delivery can be appropriately stratified. The 1988 ACOG classification is noted in Table 26.2.

TABLE 26.2 Type of Procedure and Classification of Vacuum or Forceps Delivery according to Station and Rotation

Outlet forceps/Vacuum

- Scalp is visible at the introitus without separating the labia.
- Fetal skull has reached the pelvic floor.
- Sagittal suture is in the AP diameter or right or left OA or OP position.
- Fetal head is out or on the perineum.
- Rotation does not exceed 45 degrees

Low forceps/Vacuum

- Leading point of fetal skull is at station ≥+2 cm and not on the pelvic floor.
- Rotation is ≤45 degrees.
- Rotation is >45 degrees.

Midforceps/Vacuum

- Station is >2cm but fetal head is engaged.
- Rotation is ≤45 degrees.
- Rotation is >45 degrees.

High forceps/Vacuum

- Not included in 1988 classification

AP, anteroposterior; OP, occiput posterior.

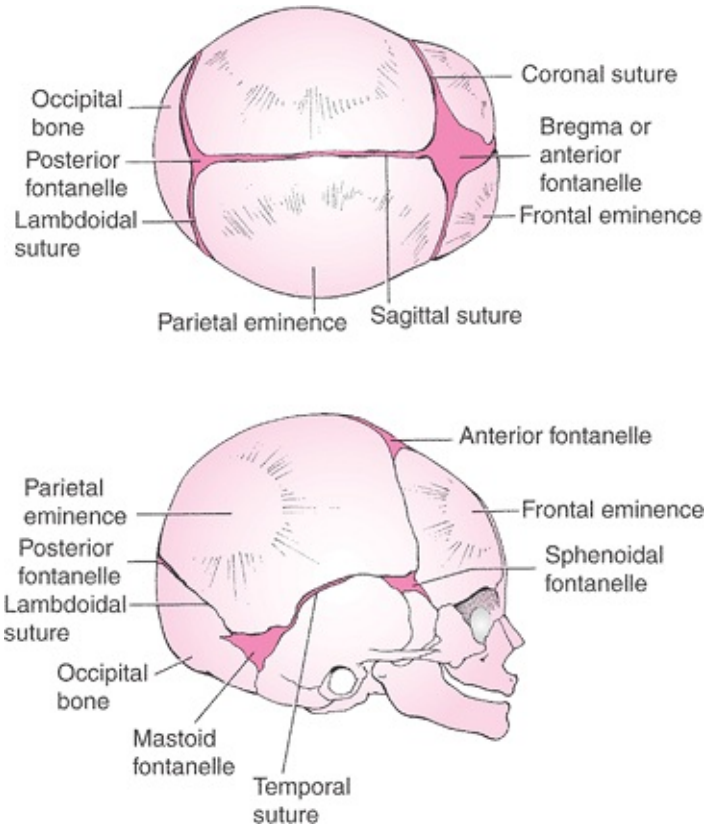

Figure 26.11 Bony anatomy, sutures, and fontanelles of the human fetal skull.

Applied Fetal Cephalic Anatomy

Knowledge of term fetal skull anatomy is essential to excellent labor and delivery patient management, especially if the physician is performing forceps or vacuum extractor deliveries. Different positions of the fetal head will present the pelvis with different diameters that significantly impact the success rate of delivery. Figures 26.6 and 26.11 demonstrate important anatomic landmarks and depict the relevant diameters of the fetal skull. Tables 26.3 and 26.4 demonstrate the diameters and circumferences of the fetal head that are required to negotiate the maternal pelvis in specific fetal head positions.

A number of terms are applied to swellings seen on the neonate's head. Caput succedaneum is seen in nearly all spontaneous deliveries and does not pose a risk to the neonate. Similarly, molding is seen to some extent in nearly all term vaginal deliveries and is considered normal. Figure 26.7 illustrates several examples of these normal lesions. In contrast, a cephalohematoma does involve a small subperiosteal bleed, and a subgaleal (subaponeurotic) hemorrhage can be a life-threatening condition for the newborn. The latter two conditions are most closely linked to vacuum delivery and were discussed in that section.

Caput Succedaneum and Molding

Commonly referred to as caput, caput succedaneum denotes scalp edema, which is a

serous effusion between the aponeurosis and the periosteum that typically overlies the leading part of the skull. This is considered normal and develops in response to cervical pressure on the scalp, which interferes with its venous and lymphatic drainage during labor. There are varying degrees of caput; the edema usually will disappear within hours after birth.

TABLE 26.3 Diameters of the Fetal Head

Diameter	Measurement (Centimeters)
Suboccipital–Bregmatic Nape of neck to center of bregma	9.5
Submental–Bregmatic Below chin to center of bregma	9.5
Mentum–Vertical Point of chin to above posterior fontanelle	14.0
Basal–Vertical Base of skull to most distant point of vertex	9.0
Occipital–Frontal Root of nose to occipital protuberance	11.5
Biparietal Between the two parietal eminences	9.5
Bitemporal Greatest distance between two halves of coronal suture	8.5

Molding is a normal deformation of the fetal head that occurs during labor. Some occipitoparietal molding is normally detected during the second stage of labor, but

excessive molding (particularly parietoparietal molding) is abnormal during the first stage of labor. Molding can be described by using the method of Stewart (Fig. 26.5) as follows:

0+ = suture easily felt between the two bones

1+ = no suture felt, but the bones can be separated easily with minimal digital pressure

2+ = overlap of bones, but they can be separated with digital pressure

3+ = overlap of bones that cannot be separated with digital pressure.

TABLE 26.4 Circumferences of Fetal Head in Specific Positions

Circumference	Measurement (Centimeters)
Suboccipital–Bregmatic × Biparietal	28.0
Well-flexed vertex	
Occipital–Frontal × Biparietal	33.0
Deflexed vertex, OP position	
Mentum–Vertical × Biparietal	35.5
Brow presentation	

OP, occiput posterior.

Accurately Determining Fetal Head Position

Precise knowledge of the position of the fetal head is essential in order to safely perform a forceps or vacuum delivery. The obstetrician should be able to delineate the positions of the fontanelles and fetal cranial bones and, and using this information, plan and perform the procedure. The true position of the fetal head can sometimes be difficult to determine, as caput succedaneum, molding, asynclitism, and maternal and fetal soft tissue edema can all combine to obfuscate the true fetal head position. Ascertainment of fetal head position is an important skill and practice for residents in training as well as in trained providers.

The authors stress to their house officers that it should become a routine practice during a vaginal examination in any laboring patient. In unusually difficult cases, translabial or transabdominal ultrasound can be used to ascertain the position of the fetal head. Neither forceps nor vacuum delivery should be attempted if the position of the fetal head cannot be ascertained.

Abdominal Examination Prior to Operative Vaginal Delivery

Examination of the maternal abdomen should be included in the assessment prior to vaginal examination and any attempt at operative vaginal delivery. This evaluation will help in a number of ways. First, an experienced clinician's estimated fetal weight is probably as accurate as an ultrasound estimate. Second, it will reveal the fetal lie and give an idea of the position of the fetal spine. If the fetal back is not palpated laterally, there is an increased chance that the fetus is lying in an OP or OT position. Often, this knowledge will allow the obstetrician to understand an otherwise confusing vaginal examination. Finally, the amount of fetal head palpated above the pelvis brim can be assessed (Fig. 26.12). Although infrequently used in the United States, the Crichton method provides the examiner with an assessment of the level of the fetal head clinically in terms of “fifths of the fetal head palpable above the maternal pubic symphysis” and should be used only after ascertainment of an OA position. This measurement relies on the mean term fetal head diameter (basovertical) of 9 to 10 cm and the width of the obstetrician's finger being about 2 cm. No more than two fingerbreadths of the fetal skull should be palpable above the symphysis when the fetal skull is at zero station (the level of the ischial spines). If three fingerbreadths are palpable above the maternal symphysis, then the fetal head should not be considered engaged even if a portion of the fetal skull is palpable below the level of the ischial spines. Of course, an unengaged fetal head should preclude any attempt at operative vaginal delivery. In 1993, Knight and colleagues demonstrated that their abdominal assessment of engagement was superior and correctly predicted successful vaginal delivery as opposed to their vaginal assessment.

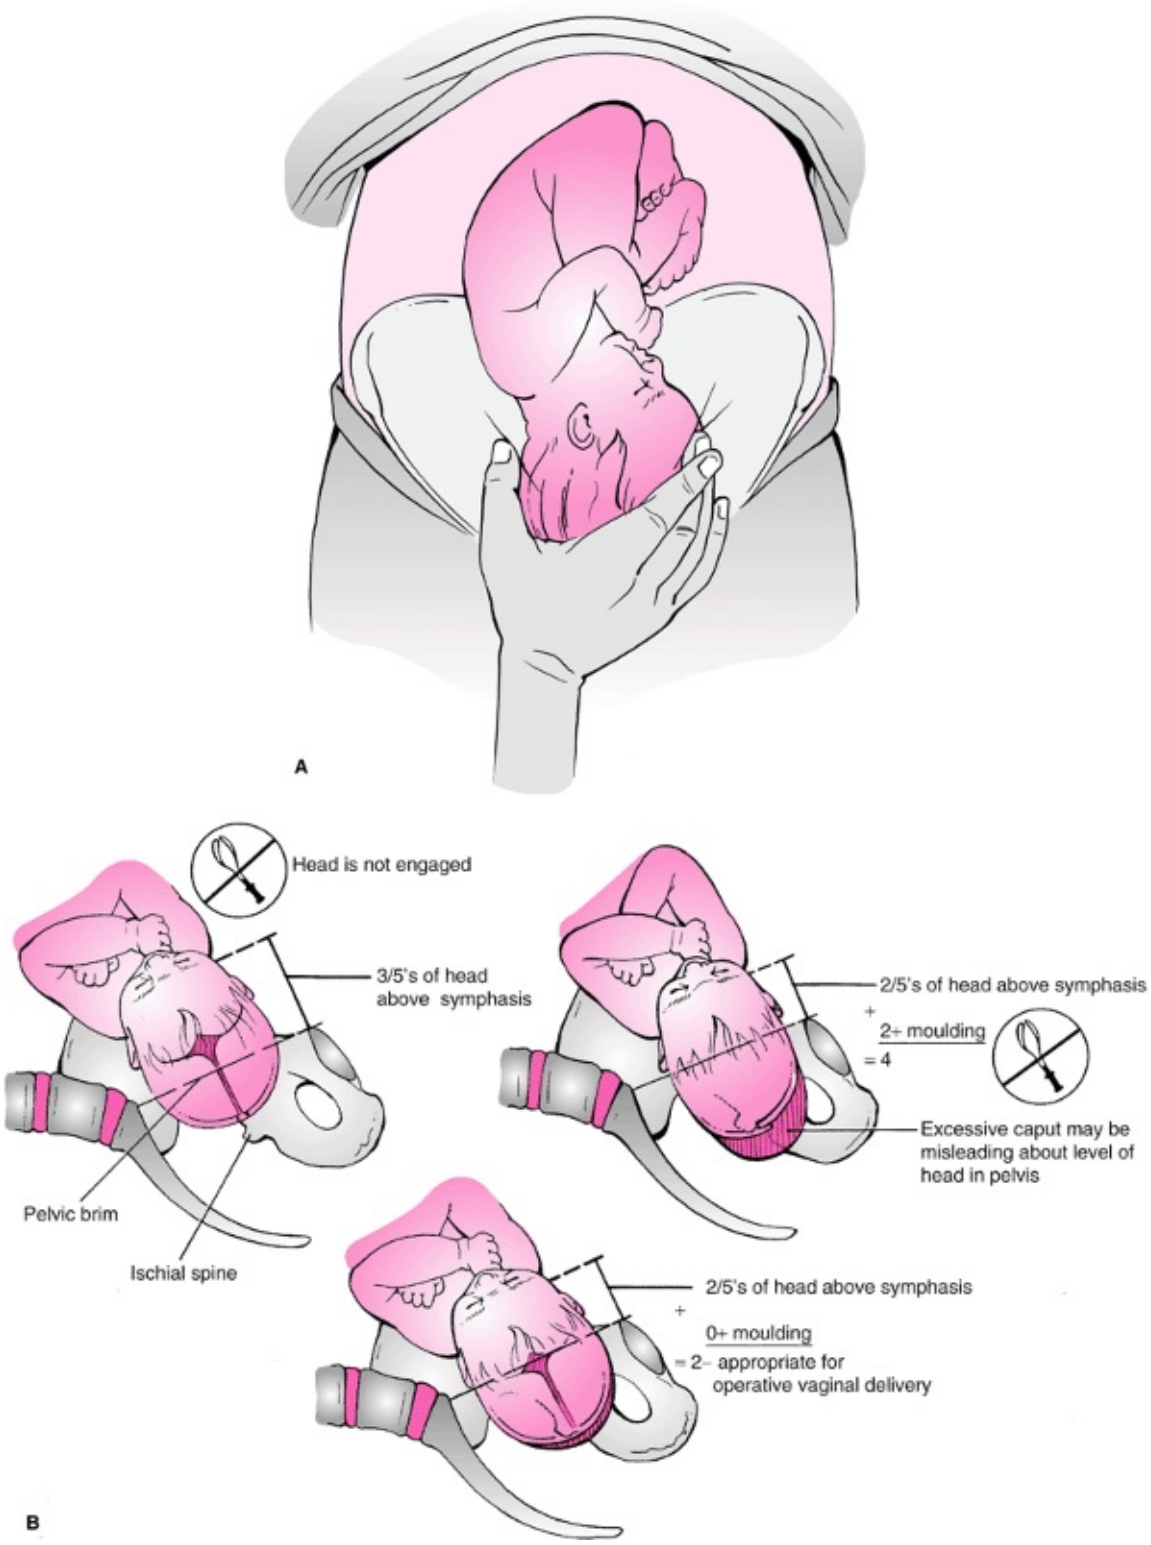

Figure 26.12 Abdominal palpation and the determination of the amount of the fetal head palpable above the pelvic brim.

Indications for Operative Vaginal Delivery

Indications for operative vaginal delivery vary according to regional, national, and international practice. No indication is absolute. However, for obstetric practice generally in the United States, the ACOG has summarized these indications as follows:

- *Prolonged second stage of labor.*

  In nulliparous women, a prolonged second stage of labor has been defined as lack of continuing progress for 2 hours without regional anesthesia or 3 hours with regional anesthesia.

- *Suspicion of immediate or potential fetal compromise.*

  Most obstetricians would rather use the term *nonreassuring fetal status* or *fetal compromise* with additional descriptive terminology instead of the formerly used but vague term *fetal distress.*

- *Shortening the second stage of labor for maternal benefit.*

  A common clinical scenario is *maternal exhaustion*, which is a poorly defined term. However, women with ocular, neuromuscular, cerebrovascular, or cardiovascular diseases in which vigorous or prolonged expulsive efforts are to be avoided are included in this group.

Contraindications to Operative Vaginal Delivery

There are several obvious contraindications to operative vaginal delivery with forceps or vacuum and several more subtle ones. In today's practice, neither forceps nor vacuum should be considered if there is an unengaged fetal head or if there is obvious cephalopelvic disproportion. An operative vaginal delivery should not be attempted in a patient who does not consent or is unable to cooperate with the obstetrician. It also is not attempted if it is known that the fetus has a known bleeding diathesis such as hemophilia, alloimmune thrombocytopenia, or a disease of osseous fragility such as osteogenesis imperfecta.

Choice of Instrument: Obstetric Forceps

Within the scope of current obstetric practice are a number of types of forceps that fall into one of two categories: the classical forceps and the specialized forceps. Resident physicians training in hospital systems within the United States typically are introduced to the art of forceps deliveries by using classical forceps such as the Simpson, Elliot, or Tucker-McLane instruments. These instruments are well suited for low- and outlet-forceps deliveries without the requirement for major rotations. Specialized forceps such as the Kielland (Fig. 26.8) forceps were designed and are utilized for specific requirements such as deliveries that require major rotational maneuvers or correction of asynclitism. Another example of a specialized forceps are the Piper forceps, which are designed to assist delivery of the after-coming head in a breech vaginal birth (Fig. 26.8). The Salinas forceps is a unique instrument that has been imported from Mexico and has two identically shaped, nonfenestrated blades with minimal pelvic curvature (Fig. 26.8). The lock of the Salinas forceps (Fig. 26.9) actually is part of the handle, which is used for traction. The convergent blades are maintained in place by maternal tissue, and the forceps produce no independent compression of the fetal head. The lack of pelvic curvature allows the instrument to be used for the purposes of rotation. The operator holds the locked handle of the forceps in

both hands and applies gentle traction to produce delivery. The blades will slip off if excessive force is applied.

The choice of forceps typically will depend on the clinical situation, the training of the obstetrician, and the instruments available. For instance, a nulliparous patient with a prolonged second stage of labor with a molded fetal head but without a requirement for rotation is a candidate for forceps with an elongated cephalic curve that will allow significant traction such as the Simpson forceps. On the other hand, if a low pelvic forceps delivery with some rotation is required in a multiparous patient with an unmolded fetal head, the physician may use the Tucker-McLane instrument, whose more rounded cephalic curvature and nonfenestrated blades will allow for a better fit for the fetal head and safer rotation, respectively. Some obstetricians would rather use a nonfenestrated instrument when there is significant maternal genital tract edema in order to minimize the likelihood of a laceration; some would choose an instrument with overlapping instead of parallel shanks for a patient with a narrow introitus. Obstetricians in the United States who continue to perform major rotational forceps maneuvers usually will reach for the Kielland forceps, whose sliding lock also will allow for the correction of asynclitism; in Mexico, the choice likely would be the Salinas forceps in similar circumstances. The Barton forceps have been abandoned for rotational maneuvers.

Positioning of the Patient

Typically, the patient is placed in the modified lithotomy position prior to undertaking an operative vaginal delivery. The maternal legs should be abducted, but there should not be excessive tension placed on the adductor muscles or on the soft tissues of the perineum. The patient's hips should not be overly flexed. The patient should not lie flat on her back—she should have at least a 30-degree upward tilt relative to the floor. To prevent pressure or stretching of any nerves, the patient should be maintained in this position only as long as is required for operative vaginal delivery and repair of any lacerations. The patient's hands typically are placed on handles that are near her hips on

each side of the delivery table so that she can brace herself during any expulsive efforts.

Analgesia/Anesthesia Considerations

More effective anesthesia is required to undertake a forceps delivery than a vacuum-assisted delivery. The gold standard for anesthesia is a functioning epidural or spinal block. If the patient does not already have a regional anesthetic in place at the time of delivery, a pudendal block using 1% lidocaine will usually suffice for a low- or outlet-forceps procedure. Additional anesthetic can be infiltrated into the tissues of the perineum.

Prerequisites for Operative Vaginal Delivery

Prior to any operative vaginal delivery, the patient and spouse/support person/family member(s) should be counseled regarding the rationale for undertaking the procedure. It is important that the physician remain calm and project a sense of confidence, maturity, and composure. Either verbal or written informed consent should be obtained. With

understanding and acceptance, the patient is likely to be less apprehensive and more cooperative. Ideally, the process taken for informed consent should be recorded in the physician's chart notes just before or just after the delivery is undertaken.

The prerequisites for an operative vaginal delivery should be systematically checked off mentally by the physician. The cervix should be fully dilated and the membranes ruptured. The pelvic architecture and capacity should be evaluated if this was not done earlier during labor. If the fetal head is in an OA position, there should be no more than two fingerbreadths of the fetal head palpable above the maternal symphysis to indicate engagement (preferably deep engagement) of the presenting part. The position of the fetal head should be verified and the amount of caput, molding, and asynclitism should be known. The maternal urinary bladder should be empty. Anesthesia should be adequate. Proper patient positioning in the modified lithotomy position should be ascertained with care to prevent hyperflexion and avoid pressure points. The forceps should be examined to verify that they are from a matched set and appear symmetric. Since the position of the fetal head is known, the forceps are held in front of the perineum in the position that they are expected to assume after appropriate application. This practice is termed *ghosting* and is vitally important for young obstetricians in training. In this environment, an experienced obstetrician should be at hand in a supervisory role to perform the procedure if needed.

Application of Forceps

The importance of the correct placement of the forceps into the vaginal canal and application to the fetal head cannot be overemphasized. It is best to introduce the forceps between contractions, when the patient is calm and resting. The application of the forceps blades should be gentle, smooth, and with minimal pressure. With correct insertion and positioning, gravity usually is sufficient to allow the forceps branch to fall into place. During residency training, it is recommended that the obstetrician learns to apply the forceps by using only the index finger, middle finger, and thumb to grasp the handle (Fig. 26.13) so that excessive force cannot be exerted. The blade should be positioned by using the thumb, index, and middle fingers placed on the edges. Minimal force should be required, and if there is resistance, the blade should be removed and reapplied. In this way, maternal and fetal injury will be minimized. A lubricant such as betadine soap or K-Y jelly placed on the blade may reduce friction and facilitate placement. Sudden vaginal bleeding after or during forceps placement suggests that the vaginal sidewall has been traumatized, for which immediate assessment is warranted.

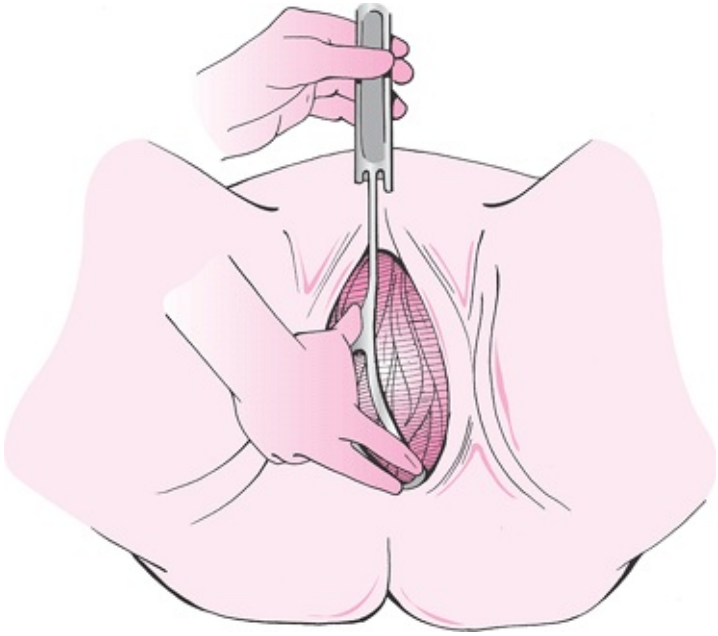

Figure 26.13 Gentle grasp of the handle and proper positioning of the right hand for the direct application of classical forceps for outlet or low-pelvic delivery.

Direct Placement of the Forceps

Direct placement of the obstetric forceps predominates, as most forceps operations performed with classical instruments will use this method. Most skilled operators will insert the posterior branch first in order to prevent loss of station of the fetal head. When there is a right OA position of the fetal head, the right or posterior branch will be placed first. With the fetal head in a left OP position or with a position that is directly OP, the left branch (i.e., the blade that lies on the maternal left) usually is placed first, by convention. The operator holds the handle above

the level of the lock, and the blade is introduced into the vagina in the approximate position that it will ultimately lie. The right middle finger is used to support the edge of the blade at the introitus, and the right index finger is used to gently apply the upper border of the blade around the fetal head. Some operators will place the fingers or hand into the vagina to “protect” the vaginal sidewall, but this is not required and is frequently not possible in the nulliparous patient. Once the left blade is correctly positioned, minimal force with the left hand will be required to slide it further into the vagina and into its correct final position. The index and middle fingers of the right hand will slide along the upper and lower borders of the blade as it enters the vagina, gently guiding and adjusting its position. When correctly placed, the left branch should be in the approximate position that was expected earlier by ghosting, snugly maintained by the pressure between the fetal head and maternal vaginal sidewall. If the anticipated shank and handle positions are judged to be incorrect, any attempt to place the right branch and forcing the branches together is absolutely contraindicated, as this may result in maternal and/or fetal injury. If the correct placement of the left branch cannot be obtained by gentle manipulation of the

middle and index fingers of the operator's hand, then the branch should be removed by reversing the movements used for its insertion.

Following placement of the left branch of the forceps, a “mirror image” procedure will introduce the right branch of forceps into the vagina. The handle of the right branch is then held with the right index finger, middle finger, and thumb, and the right branch is placed into the vagina in the approximate position that is expected according to the earlier ghosting application. The right branch should be above the left for appropriate locking. The left middle finger is used to support the edge of the blade at the introitus, and the left index finger is used to apply slight pressure onto the fetal head. Once the right blade is correctly inserted, a minimal force with the right hand is required to slide it farther into the vagina and into its correct final position. The index and middle fingers of the left hand will slide along the upper and lower borders of the blade as it enters the vagina, gently guiding and adjusting its position to complement that of the left branch. Force should not be used to lock the instrument. The shank and handle positions should be the same as that expected from the ghosting application. Once both branches of the forceps are placed, the fetal head position and the application of the forceps should be reviewed carefully prior to any traction efforts.

Wandering Placement Technique

The wandering placement technique is used less commonly than the direct technique because it is usually performed as part of a major rotational forceps maneuver. A common clinical scenario for wandering placement is encountered with OT positioning of the fetal head. For rotation of the fetal head, the most common forceps utilized is the Kielland forceps. As noted previously, most obstetricians in the United States have ceased performing major forceps rotational maneuvers. When undertaken with Kielland forceps, a rotational maneuver usually is initiated by either the “inversion” application or the wandering application. The inversion application is mentioned only for historical reasons, as it is no longer recommended secondary to a high incidence of trauma to the lower uterine segment and urinary bladder. Instead, a wandering placement method is typically utilized for Kielland forceps rotation. After ghosting, the left branch is inserted first, especially with a left OT positioning of the fetal head. The Keilland forceps have “buttons” on the handles (Fig. 26.9), and when the forceps are applied correctly, these buttons should be oriented toward the fetal occiput.

The operator holds the handle above the level of the lock, and the vertically held blade is introduced into the vagina with the toe of the blade at the posterior fourchette. The right index and middle fingers are used to support the edge of the blade at the introitus and to apply slight pressure onto the fetal head. Once the left blade is placed correctly, only minimal pressure is required to slide it farther into the vagina, because gravity and the weight of the handle are sufficient. The handle will move in an arc from the vertical to a horizontal position. To move the blade to the correct position with a left OT fetal head position, the right index and middle fingers gently guide the blade and “wander” it into a posterior position by using successive small finger movements (Fig. 26.14). The position of this branch is then compared with the expected ghosting application. After correct

placement of the left (posterior) branch, an assistant may hold the branch in position while the right branch is placed. Holding the right branch with the right index finger, middle finger, and thumb, the right blade is placed into the vagina in the same way as was the left branch. Again, only minimum pressure with the right hand will cause the blade to slide into the vagina, after which the left index and middle fingers gently guide the blade laterally. Repetitive finger movements help to “wander” the blade into an anterior position in the same way as was done with the left blade. The right branch should be maintained above the left branch to enable correct locking. Force should not be used to lock the instrument—the final shank and handle position should be the same as that expected from the ghosting application.

Checking the Position of the Blades

In any forceps operation, after the blades are introduced, their positioning should be examined. The blades are appropriately positioned when they are against the sides of the fetal head in the spaces between the orbits and the ears (Fig. 26.15). This typically is called the biparietal or bimalar application. The toe of the blade should extend just beyond the malar eminences in order

---

to allow even pressure distribution and to concentrate traction and compression forces on the less vulnerable regions of the fetal head. Before any traction or rotation can be performed, the operator should examine for the following:

- The sagittal suture in its entire length should be symmetric and perpendicular to the plane of the shanks.
- The posterior fontanelle should be about 2 cm from the plane of the shanks.
- The posterior fontanelle should be equidistant from the upper surface of each blade.
- The handles should not require any more than minimal pressure to close completely and should be pointing directly out.
- The amount of fenestration distal to the fetal head should allow only one fingertip to be inserted into this space.

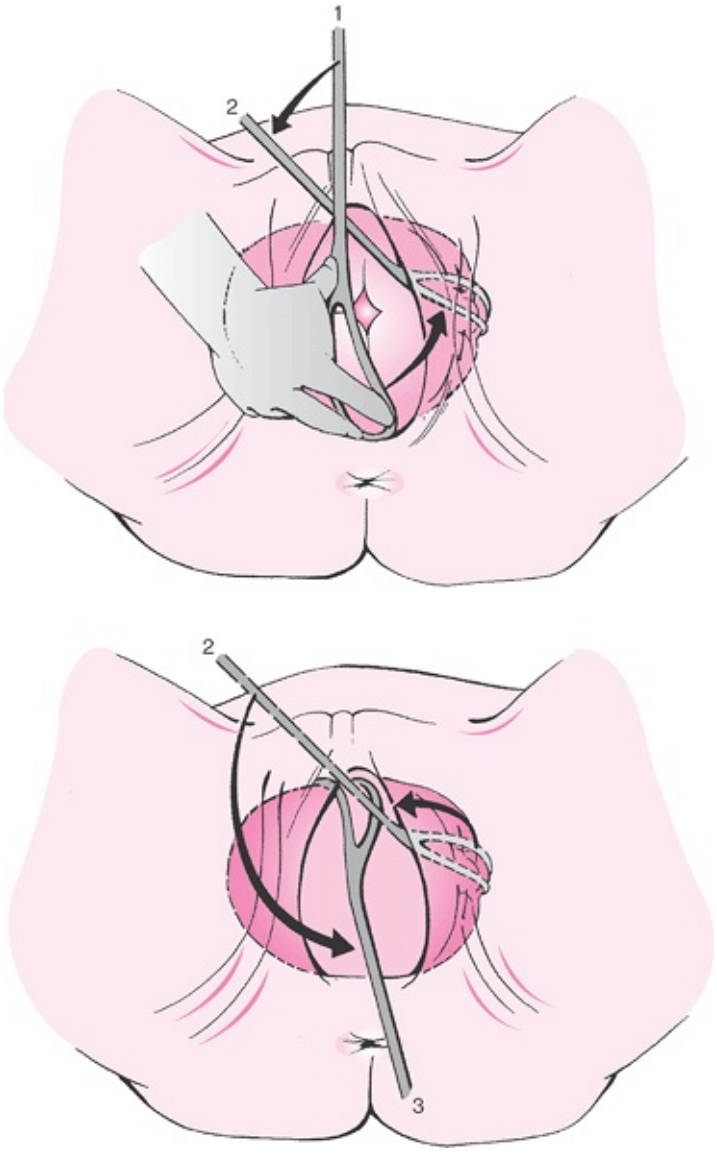

Figure 26.14 Wandering placement of specialized (Kielland) forceps in right OT position.

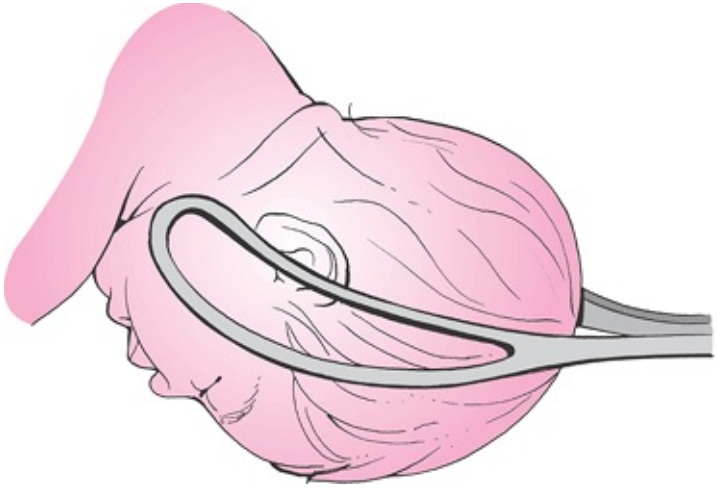

Figure 26.15 The correct biparietal bimalar application of the forceps to the fetal

head.

Forceps Traction

After the operator's examination demonstrates that the forceps have been correctly applied, traction usually is coordinated with maternal contractions and expulsive efforts. The maternal pelvis is curved, and this is important to remember when traction is initiated. In order to minimize friction, the traction forces on the fetal head should be maintained perpendicular to the axis of the pelvis by following the curve of Carus. It also is important to remember that the higher the forceps are applied, the greater is the initial downward pull that is required to negotiate the pelvic curve. As the head descends in the birth canal, the angle of traction moves forward (in the supine patient) so that it is ultimately turning upward at the outlet as delivery is accomplished.

In order to facilitate forceps traction, the operator usually will stand slightly off center with respect to the patient. It is recommended that a right-handed individual stand to the maternal right with the right hand facing upward and the shanks of the locked forceps between the index and middle fingers (Fig. 26.16). The index and middle fingers are curled around the flange of the handle, which is held loosely when employing a forceps with crossed shanks or a sliding lock. With the classical forceps such as Simpsons with parallel shanks, the operator's middle finger can be placed in the space between the shanks with the index and ring fingers being placed on the handle flange. This hand (the operator's right hand) will apply the outward traction force. Because the traction occurs at the level of the lock (as opposed to the end of the handles), compression of the fetal head will be limited. The operator's left hand is placed palm down on the shanks of the forceps to exert a downward force known as the Pajot maneuver. The combined outward (right hand) and downward force (left hand) is continuously adjusted by the operator to produce force vectors as axis traction that follows the curve of Carus (Fig. 26.16).

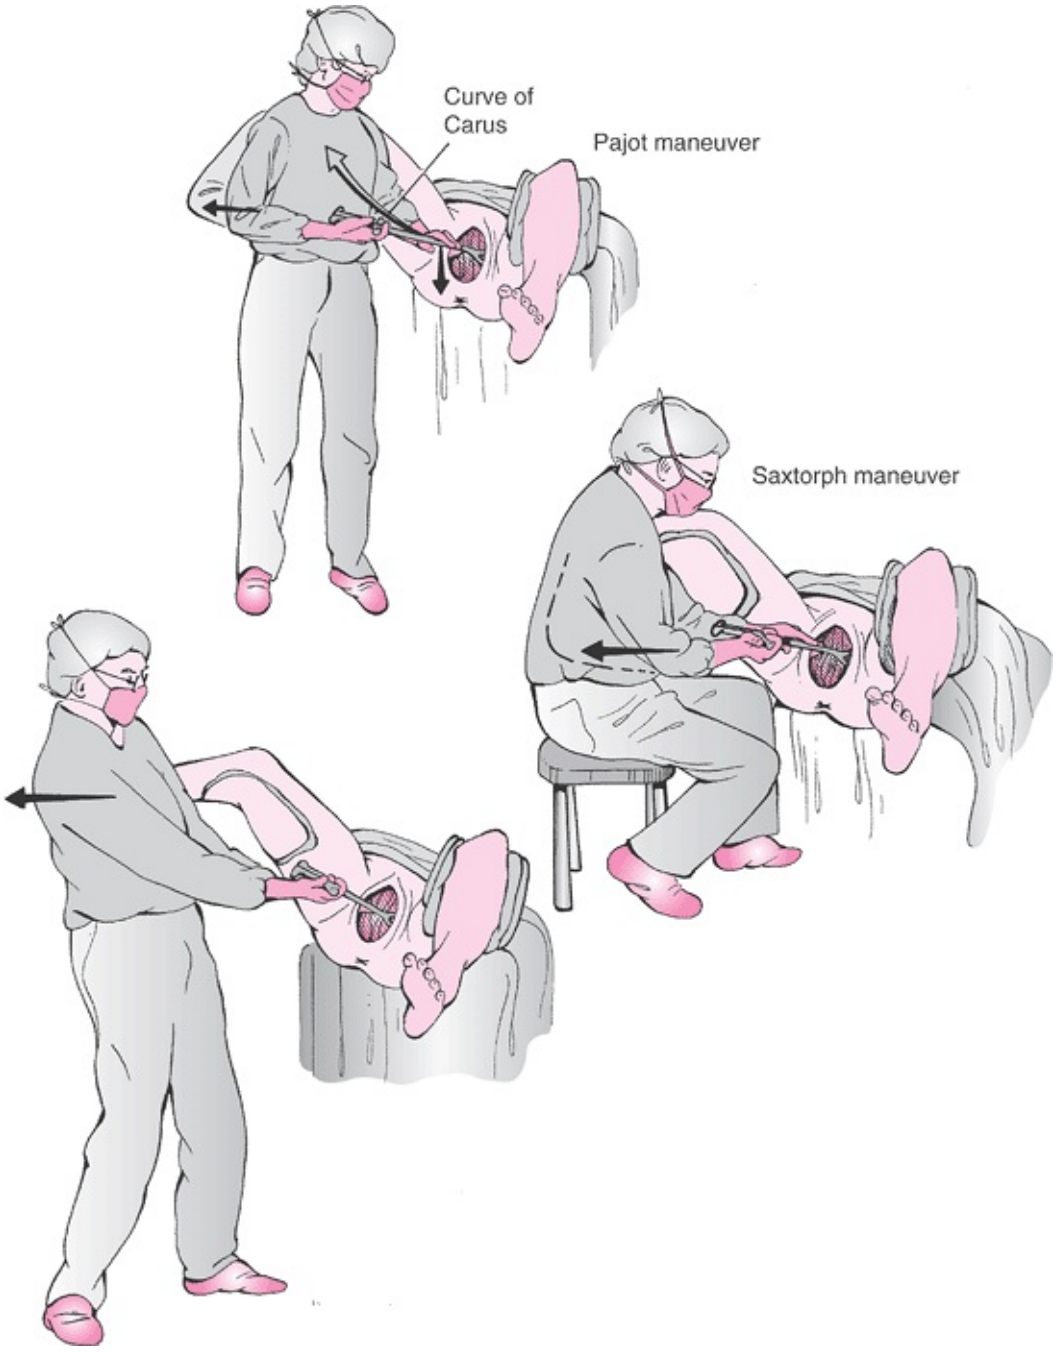

Figure 26.16 Methods of hand placement and physician stance for standard operative vaginal delivery.

Axis traction similar to the Pajot maneuver can be accomplished by using the Saxtorph maneuver, in which the operator is seated and uses the fingers of the left hand to pull the locked shanks downward (Fig. 26.16). If, while sitting, the operator pulls in a direct line with the classical forceps, the fetal head will be pulled under the symphysis. The pelvic curvature of the classical instruments results in the handles being in a plane anterior to that of the handles. Many operators prefer to sit on a stool as they perform a simple forceps delivery, reasoning that in the sitting position much less force can be applied since the operator cannot use his or her weight to produce the traction force as can happen while standing. No longer is it permissible for the operator to brace his or her feet on the underside of the delivery table in order to achieve maximal axis traction. When the fetal

head is noted to crown, the handles of the classical forceps can be elevated until they are nearly perpendicular to the floor. At this point, the delivery can be completed with the forceps or the branches can be disarticulated so that delivery can be completed by using a modified Ritgen maneuver. Lastly, when the operator uses a specialized instrument with no pelvic curve or a reverse pelvic curve, it is important *not* to elevate the handles to more than 45 degrees above the horizontal at the outlet. Exceeding this limit invites an increased likelihood for sulcal tears to occur due to pressure from the toe of the blade.

Delivery of the fetal head in an OP position, with its larger presenting diameters compared with the OP presenting head, has been associated with increased traction and compression forces. Axis traction for a persisting OP forceps delivery should be discontinued between contractions in order to reduce the intracranial pressure to which the fetus is exposed. Additionally, by releasing the pressure between contractions, any fetal bradycardia that often accompanies axis traction efforts can be ameliorated. Because of the potential for fetal heart rate abnormalities during delivery, the fetal heart rate should be monitored during operative vaginal deliveries.

Occiput Transverse Positions of the Fetal Head

The OT head position frequently results in a deep transverse arrest and dystocia. In order to accomplish vaginal delivery, these fetuses usually will require rotation of the fetal head to the OA or OP position. Occasionally, patients with a platypelloid pelvis characterized by a flat sacrum and a short AP diameter will spontaneously deliver a baby with the head in a persistent OT position. In today's obstetric practice, the options for delivery of a patient with a deep transverse arrest include the following:

- Digital or manual rotation to OA or OP
- Rotation to OA or OP with forceps
- Cesarean delivery.

A mid-1990s survey of ACOG Fellows revealed that most had stopped performing major rotational maneuvers with the obstetric forceps. The cohort of ACOG Fellows who had been in practice for fewer than 10 years did not use forceps for rotation at all. When sufficient training and clinical experience with rotational forceps delivery is lacking, cesarean delivery is the most prudent choice.

Occiput Posterior Positions of the Fetal Head

An experienced obstetrician will recognize that OP presentations commonly are associated with deflexion attitudes of the fetal head. An OP position can be managed by spontaneous delivery as a direct OP, a forceps delivery as an OP, digital or manual rotation to OA, instrumental forceps rotation to OA, or a combination of these methods. Typically, if the fetal head is well flexed in the OP position, delivery can be accomplished by maternal exertion or assisted with forceps in the direct OP position. If the head is extended or only minimally flexed, an attempt at a direct OP forceps delivery may result in an increased risk

of maternal and fetal trauma due to the greater amount of axis traction required and the larger diameter of the presenting part. Traction on a deflexed head likely will exaggerate the extension and worsen the situation. If the delivering physician is not well versed in using the forceps for flexion and rotation of the fetal head from OP to OA, a cesarean delivery likely is the safest choice.

Digital or Manual Rotation

If the operator has a small hand, digital or manual rotation often can be performed to rotate the fetal head from an OP or OT position to an OA position. Digital rotation entails placing the tips of the index and middle fingers onto the edge of the anterior parietal bone that overlaps the occipital bone near the posterior fontanelle. Thereafter, pressure is exerted upward with the tips of the fingers to rotate the posterior fontanelle toward the symphysis pubis (Fig. 26.17). This can be performed between contractions or even while the patient is pushing. With manual rotation, the whole hand is placed into the vagina, and the fingers are placed under the posterior parietal bone. The thumb is positioned on the anterior parietal bone and the head is rotated (Fig. 26.17). Care should be taken to not completely disengage the fetal head, as this could precipitate a prolapse of the umbilical cord. Manual rotation will not be possible for operators with large hands. If digital or manual rotation is successful, the patient should be encouraged to push in order to stabilize the new position of the fetal head. Alternatively, if the position now achieved is within 45 degrees of OA or OP, the forceps can be used to complete the delivery.

Postdelivery Management

Following operative vaginal delivery by using forceps or vacuum, the vagina and cervix is meticulously inspected for lacerations or other injuries. If an episiotomy was performed, this is carefully examined for the possibility of extension into the muscular anal sphincter and then repaired without delay to minimize blood loss. Minor lacerations of the genital tract or cervix (first degree, some second degree) that are not bleeding usually do not require repair, because rapid healing is expected. The inspection and repair of the maternal genital tract is accomplished without delay, and the patient is taken out of the modified lithotomy position as quickly as possible—this is done to lessen the risk of nerve injury from prolonged pressure or stretching. An indwelling Foley catheter is advised if extensive repairs are required in the periurethral areas. The periurethral and perianal/rectal areas are carefully inspected after any repairs to exclude perforating sutures. If a patient complains of severe anal pain after a forceps delivery, a prompt examination should be undertaken to exclude the possibility of a vaginal or vulvar hematoma. Any evidence of hemorrhage such as maternal tachycardia, hypotension, or a sudden drop in hematocrit should initiate a search for continued bleeding either obvious (vaginal or vulvar) or occult (retroperitoneal hemorrhage).

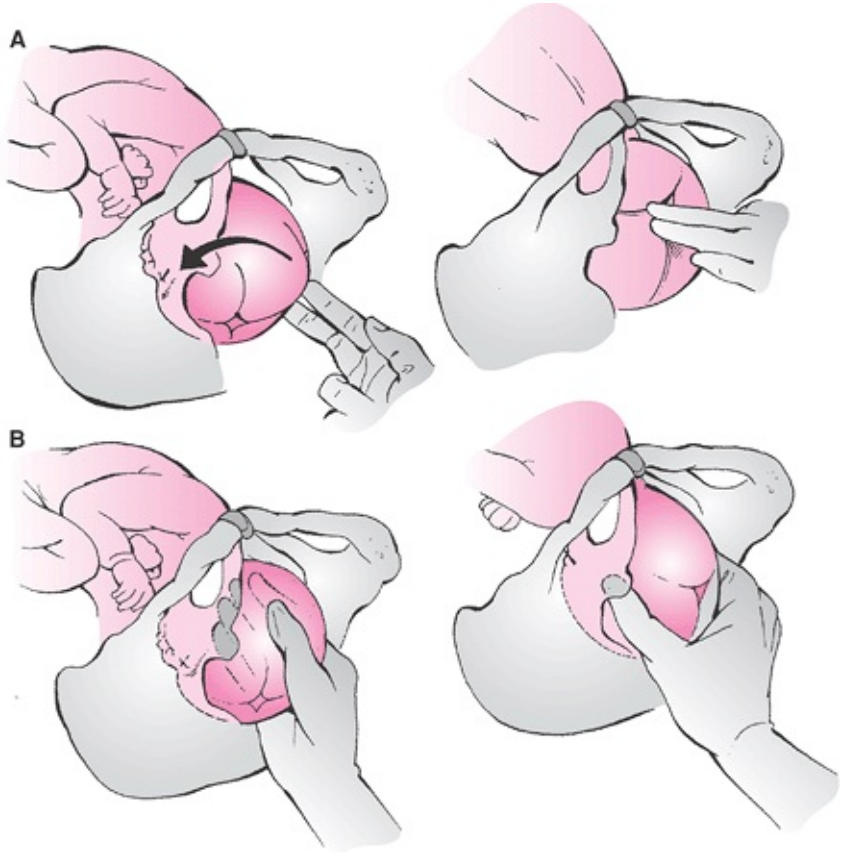

Figure 26.17 Digital (A) and manual (B) rotation of the fetal head.

Complications of Operative Vaginal Delivery

It is emphasized that many complications typically associated with operative vaginal delivery also are encountered with spontaneous delivery. Two of the major complications that may be found, especially in association with operative vaginal deliveries, are (a) an inappropriate evaluation of dystocia and (b) misuse of an instrument to accomplish delivery. Risk to the mother and the fetus–neonate can develop secondary to these two major complications. Maternal issues are considered first.

Lacerations

Third-degree and fourth-degree lacerations are encountered more commonly with forceps delivery than with vacuum extraction delivery. In most studies, the incidence of severe lacerations (or episiotomy extension) ranges between 10% and 30% with vacuum in contrast to between 40% and 50% with forceps delivery.

Stress Urinary and Anal Incontinence

The appeal of elective cesarean delivery for patients includes patient and physician convenience; the avoidance of labor with a possible concomitant reduction in the risk of hypoxic ischemic metabolic acidosis in the fetus; and the reduction of potential damage to the maternal genital tract and pelvic structures and thus less likely subsequent pelvic floor

dysfunction. The long-term effect of operative vaginal delivery on rectal or urinary incontinence is complex, and the literature remains unclear. Pregnancy itself and delivery via the vagina may contribute to persistent pelvic dysfunction. The greater the degree of perineal trauma consequent to vaginal delivery, the greater may be the likelihood that there will be residual sphincter abnormalities with resultant incontinence. For instance, anal incontinence has been reported to follow 20% to 54% of deliveries complicated by anal sphincter rupture with fourth-degree laceration. About half of women who sustained anal sphincter tears were reported to have associated anal, urinary, or perineal symptoms at a mean follow-up of 2.6 years after the injury.

In 2001, Arya and colleagues retrospectively compared the incidence of new-onset urinary incontinence after forceps and vacuum delivery with that occurring in a cohort of primiparous women who had spontaneous vaginal deliveries. Although urinary incontinence was similar among the three groups during the first 2 weeks postpartum, the proportion of women developing new-onset urinary incontinence decreased significantly over time in the spontaneous vaginal (P = .003) and vacuum delivery groups (P = .009) but not in the forceps group (P = .2). Thus, in primiparous women, the authors concluded that urinary incontinence appears to be more likely to persist following forceps delivery compared with spontaneous vaginal or vacuum delivery.

Farrell's group queried 690 Canadian primiparas by questionnaire regarding urinary incontinence during and 6 months after their first pregnancy. The rate of postpartum urinary incontinence 6 months after delivery was 26%,

---

with more patients in the vaginal than the cesarean delivery groups (22% vs. 10%; odds ratio [OR] 2.1 [range 1.1 to –3.7]). Analysis of the impact of operative vaginal delivery revealed that 33% of patients who had a forceps delivery reported postpartum incontinence (forceps vs. spontaneous vaginal delivery, OR 1.5 [range 1.0 to 2.3]); forceps vs. cesarean, OR 3.1 [range 1.7 to 5.9]). Interestingly, vacuum delivery appeared not to be associated with a higher incidence of postpartum urinary incontinence when compared with spontaneous delivery, but when compared with cesarean delivery, there was a significantly higher rate of postpartum urinary incontinence (vacuum vs. cesarean, OR 3.5 [range 1.3 to 9.1]). These authors concluded that cesarean delivery performed before or during labor appeared to reduce the likelihood of postpartum urinary incontinence.

Meyer and coworkers prospectively studied a cohort of Swiss primiparas during pregnancy, at 10 weeks postpartum, and again 10 months following delivery. The data included questionnaire, clinical examination, assessment of bladder neck and urethral sphincter function, and intravaginal/intra-anal pressures measured during pelvic floor contractions. No significant differences in urinary incontinence (20% vs. 15%) and fecal incontinence (4% vs. 5%) were observed at 10 months between the women who were delivered by forceps versus those who delivered spontaneously. However, more women in the forceps group were noted to have a weakened pelvic floor (20% vs. 6%; P = .05) and low intra-anal pressure (P = .04).

MacArthur and colleagues questioned more than 5,000 postpartum women and found evidence to suggest that forceps deliveries are associated with a higher risk of fecal

incontinence than vacuum (OR 1.94; 95% confidence interval [CI] 1.30 to 2.89), while cesarean appears to offer some protection (OR 0.58; 95% CI 0.35 to 0.97). These findings were corroborated by the prospective randomized trial of Fitzpatrick and colleagues. This group used a symptom questionnaire, anal manometry, and endoanal ultrasound at 3 months postpartum. Using “intent to treat” analysis, they found that symptoms of altered fecal continence were significantly more common following forceps as opposed to vacuum delivery. However, in this study, 16 of 69 deliveries that randomized to vacuum were completed by the forceps. As is discussed later, this practice of “sequential” use of instruments should be discouraged.

By no means should it be assumed that the vacuum will spare the patient the possibility of pelvic floor damage. Liebling and associates performed a prospective cohort study of 393 patients who either had a “difficult” operative vaginal delivery or a cesarean delivery in the second stage of labor. Of the operative vaginal deliveries, only 25% were delivered via the forceps while 51% were via the vacuum. In 24% of cases, the instruments were used sequentially. When compared with second-stage cesarean, a difficult instrumental delivery was associated with a greater risk of urinary incontinence at 6 weeks postdelivery (OR 7.8; 95% CI 2.6 to 23.6) and at 1 year (OR 3.1; 95% CI 1.3 to 7.6). While second-stage cesarean delivery did not completely protect women from pelvic floor morbidity, those with a difficult operative vaginal delivery had a significantly greater prevalence of urinary symptoms and dyspareunia.

It is anticipated that vaginal delivery with or without instrumental assistance via vacuum or forceps will continue to be the principal route of delivery in the United States for the foreseeable future. Patients should be counseled that significant perineal trauma may be related to urinary and/or anal sphincter dysfunction and incontinence but that a fairly simple operative vaginal delivery without third- or fourth-degree laceration is not expected to cause sequelae that are significantly different from those following spontaneous delivery. Longer-term epidemiologic studies of pelvic function, preferably of a prospective type, should be performed before significant changes in modern obstetric practice are considered or recommended.

Nerve Injuries

Rarely, a maternal nerve injury can result as a consequence of vaginal delivery (spontaneous or operative). This usually is caused by incorrect patient positioning and/or undue compression or traction on a nerve. When these injuries occur, most often they are temporary and the patient recovers completely. However, occasionally a nerve injury will result in long-term disability. Prolonged hyperflexion of the maternal hips at the time of delivery and genital tract repair usually is the culprit. Thus, if repair of genital tract lacerations is expected to be lengthy, it is recommended that the operator adjusts the patient's position so that there is minimal flexion of the hips. Additionally, attention should be directed to pressure points on the patient's legs to avoid nerve compression injuries; adequate padding and positioning are essential in this regard. The most common nerve injuries with their causes and presentations are shown in Table 26.5.

Neonatal Injuries Associated with Forceps

As mentioned previously, neonatal injuries occur more commonly in association with vacuum delivery than with forceps. Potential injury includes retinal hemorrhage, cephalohematoma, and subgaleal (subaponeurotic) hemorrhage. Neonatal injury that is directly attributable to a forceps delivery itself is difficult to assign accurately, as the conditions that led to the intervention, such as a protracted labor or a compromised fetal situation, can be important contributors to a poor neonatal outcome.

Superficial Scalp and Facial Markings

Forceps marks on the scalp and fetal face are nearly universal and inconsequential. A correct biparietal/bimalar

---

application of the forceps blades will prevent tissue damage to sensitive regions such as the eyelids and face. An incorrect forceps application can be indicated by off-line forceps marks and/or bruising on the baby's face during the neonatal period. It should be explained to the parents that forceps marks usually are normal, expected, temporary, and not indicative of significant fetal injury. Significant abrasions or lacerations are outside the norm, usually prompting a review of the technique of forceps application utilized and the circumstances of the labor and delivery so that a second adverse outcome can be averted. Excessive pressure on the fetal face can result in vesicle formation, lipoid necrosis, and edema. Excessive compression of the fetal skull can result in fracture and intracranial trauma (see below). Most superficial injuries are short lived, recovery is uncomplicated, and lasting sequelae are absent.

TABLE 26.5 Nerve Injuries, Presentation, and Etiologies

Femoral nerve (L2-4)

- Presentation: Quadriceps paralysis and impaired knee extension, loss of patellar reflex, hypoesthesia over the front of the thigh and medial aspect of calf, numbness of the anterolateral area of thigh.
- Etiology: Hyperflexion of the hips with traction or compression injury of the nerve, prolonged lithotomy position with kinking at Poupart ligament, midforceps delivery, retractors at cesarean, epidural anesthesia.

Lateral femoral cutaneous nerve (L2-3)

- Presentation: Numbness over lateral thigh.
- Etiology: Compression of nerve under the inguinal ligament

from prolonged or incorrect lithotomy position, retractors at cesarean.

Common peroneal nerve (L4–5, S1–2)

- Presentation: Foot drop; hypoesthesia over anterolateral aspect of lower calf, foot, and toes.
- Etiology: Compression of the nerve at the lateral aspect of the knee by a lithotomy pole, also reported after epidural anesthesia.

Lumbosacral trunk (L4–5)

- Presentation: Paralysis of the dorsiflexors of the ankle with foot drop, hypoesthesia over the lateral aspect of calf and foot, slight weakness of the quadriceps (L4), slight weakness of the hip adductors (L4–5)
- Etiology: Compression of fetal head against sacrum, more common in midpelvic operative vaginal delivery, has been reported after epidural anesthesia.

Sciatic nerve (L4–5, S1–3)

- Presentation: Inability to flex leg, pain from gluteal region down to the foot.
- Etiology: Traction injury from lithotomy position, midforceps, incorrect intramuscular injection.

Obturator nerve (L2–4)

- Presentation: Inability to adduct leg, hypoesthesia medial thigh.
- Etiology: Lithotomy position, acute flexion of hip, hematoma, trauma from forceps blades.

Saphenous nerve (L2–4)

- Presentation: Hypoesthesia medial foot and anterolateral lower leg.
- Etiology: Lithotomy position.

Facial Nerve Injury

Injury to the facial nerve can occur, usually as the result of facial nerve compression by a forceps blade at a place where the nerve runs superficially in the mastoid region. This is

almost always a transient injury.

Corneal Abrasions and External Ocular Trauma

Compared with nonoperative vaginal delivery, forceps delivery is associated with a higher incidence of fetal eyelid edema and minor external ocular trauma. Long-term sequelae are rare, and referral for ophthalmologic examination is individualized.

Intracranial Hemorrhage/Other Severe Injury

Operative vaginal delivery is a contentious topic within the obstetric medicolegal arena. The authors speculate that this is due in part to the observation that the patient who requires operative vaginal delivery may have experienced a long or difficult labor. The fetus–neonate in such a pregnancy may be injured. It usually is difficult to ascertain with assurance and with certainty assign cause and effect, the etiology of injury. This is especially true when a fetus–neonate has a significant physical problem, such as a cerebrovascular injury that may be related indirectly to the underlying circumstances contributing to the decision for operative vaginal delivery or if the injury was directly related only to the forceps. In the situation of nonreassuring fetal status with a potential for developing fetal compromise, the decision to perform a cesarean or to attempt an operative vaginal delivery is frequently quite difficult in complex circumstances with time pressures that heightens the sense of trepidation. These situations will test the mettle of even the most experienced obstetrician. If the experienced operator is confident that a timely operative vaginal delivery can be performed and it is in the best interests of the mother and fetus, then this option is clearly a viable one and the forceps may be used while simultaneously preparing for a cesarean if the forceps procedure proves problematic. An operative vaginal delivery frequently will be the quickest and safest way to deliver the infant with nonreassuring status in the second stage of labor. Performance of a cesarean delivery in these circumstances will not repel the specter of litigation.

Major fetal injuries have been reported following delivery with obstetric forceps. Standard obstetric teaching considers there to be approximately a 1% likelihood of neonatal skull fracture when a fetus is rotated by forceps from an OP to OA position with subsequent axis traction to effect

---

delivery. This type of major rotational procedure is rarely encountered in today's practice of obstetrics. Yet, in 1995, a case series of 15 neonates with high cervical spinal cord injury and dismal outcome was published. The common feature in all cases was a forceps delivery that almost always was associated with rotation of the fetal head in excess of 90 degrees.

In 1999, Towner and colleagues undertook a population-based study that examined the rates of neonatal intracranial hemorrhage associated with various modes of delivery. With this large cohort of 583,340 nulliparous women, the investigators determined that fetal-neonatal intracranial hemorrhage occurs with the following frequencies in selected circumstances:

- 1 in 334 in association with failed vacuum or forceps followed by cesarean

- 1 in 664 in association with a forceps delivery
- 1 in 860 in association with vacuum extractor delivery
- 1 in 907 in association with cesarean delivery during labor
- 1 in 2750 in association with cesarean before labor
- 1 in 1900 in association with normal spontaneous delivery.

Also noted by Towner and colleagues in this data analysis was the finding that in comparison to spontaneous delivery, vacuum extraction (OR 2.7 [range 1.9, 3.9]), forceps delivery (OR 3.4 [range 1.9, 5.9]), and cesarean after abnormal labor (OR 2.5 [range 1.8, 3.4]) were each associated with an increased incidence of intracranial hemorrhage. Interestingly, there were no statistically significant differences among the rates of intracranial hemorrhage when vacuum, forceps, or cesarean after abnormal labor were compared with each other. Towner's group also made the observation that there appear to be risks associated with the “sequential” use (unsuccessful vacuum, then forceps) of instruments to accomplish operative vaginal delivery inasmuch as the risk of intracranial hemorrhage was significantly higher in this circumstance than with either vacuum or forceps alone. Intracranial hemorrhage occurred in 1 in 256 infants delivered by the sequential use of instruments (vacuum, then forceps), which was 3.4 times the rate associated with vacuum delivery alone. Finally, the study findings point toward abnormal labor as the common risk factor for fetal–neonatal intracranial hemorrhage, not the instrument(s) chosen to resolve the difficult labor and accomplish delivery.

Instrument of Choice: Vacuum or Forceps?

Based on the variety of personal experiences and preferences among authorities, there is no uniformity of opinion with regard to which of the instruments for operative vaginal delivery is preferred over the other—the vacuum extractor or the obstetric forceps. Meta-analyses of forceps and vacuum trials have been problematic for several reasons. First, the published trials comparing vacuum with forceps have serious methodologic differences, and this has made the pooling of data difficult if not impossible. In addition, these investigations were undertaken over a 30-year span of time, during which the practice of obstetrics has undergone constant change. Finally, many different types of vacuum extractors and forceps have been employed in these investigations, and each of these different instruments have unique profiles of efficacy and complication that impedes the pooling of data for gross comparisons.

Despite these hurdles, in 2000, Johanson and Menon performed a meta-analysis of trials of vacuum and forceps as part of the *Cochrane Database of Systematic Reviews*. These researchers combined the results from 10 prospective and randomized trials published in the obstetric literature and derived some important observations. First, the forceps appear to be significantly more likely to result in a successful delivery as opposed to the vacuum extractor. However, the women who randomized to the vacuum extractor in these studies actually had a lower cesarean delivery rate because a vacuum failure was frequently followed by a forceps delivery, whereas an unsuccessful forceps delivery most often was accomplished by cesarean. Of course, in current obstetric practice, it is rare to combine

the use of instruments in a single delivery. Second, in nearly all of the studies, maternal genital tract injury was significantly higher in the forceps group, and women who were delivered by the vacuum extractor had less pain at delivery and at 24 hours postpartum, even with a lower rate of usage of regional and general anesthesia. Third, neonatal cephalohematoma and retinal hemorrhage occur more frequently with the vacuum extractor, but there reportedly is no significant difference in the need to use phototherapy for neonatal jaundice between forceps or vacuum-delivered infants.

In 2001, Wen and colleagues published a historical cohort study involving 31,015 women delivered by vacuum and 18,727 delivered by forceps in which it was concluded that vacuum delivery was associated with less maternal trauma but their use “may increase the risk of cephalohematoma and certain types of intracranial hemorrhage (eg, subarachnoid hemorrhage).” Generally, neonatal injuries with operative vaginal delivery are expected to occur more often with vacuum application, while maternal injuries occur more often with forceps use.

It would be ideal if every graduate of every U.S. residency training program were equally adept with the forceps and the vacuum extractor. However, in modern practice, the obstetrician's choice of vacuum or forceps typically depends on local tradition and the influence of the instruction that he or she received during residency training. In everyday practice, the decision to use the vacuum or the forceps probably will not be based on the results of published studies but more likely will reflect the individual provider's preferences and proficiencies.

Summary Points

- In 2004, the total rate of operative vaginal delivery in the United States was 5.2%, obstetric forceps in 1.1% of all deliveries, and vacuum extractor in 4.1%.
- Adequate assessment of “the pelvis and passenger” is essential prior to attempting any operative vaginal delivery.
- Sequential operative vaginal delivery attempts with different instruments significantly increase the risk of neonatal intracranial complications.
- Both forceps and vacuum extractor are acceptable and safe instruments for operative vaginal delivery. Operator experience should determine which instrument should be used in a particular situation.
- Recommended steps for use of vacuum-assisted vaginal delivery include gestational age ≥34 weeks, full cervical dilation and fetal head well engaged, correct knowledge of the position of the fetal head, absence of contraindications (such as malpresentations), correct application of the vacuum cup, assurance that no maternal tissue is trapped under the cup, and traction undertaken in the direction of the pelvic axis and perpendicular to the cup. In

addition, the procedure should be terminated if there are 3 "pop-offs" or if the delivery has not occurred within 20 minutes, or if there is no descent with correct application and appropriate traction. Further, intentional torsion of the cup or rocking of the cup is to be decried.

- In the United States, indications for operative vaginal delivery include prolonged second stage of labor, suspicion of immediate or potential fetal compromise, and shortening second stage of labor for maternal benefit.
- Contraindications to operative vaginal delivery include an unengaged fetal head or suspected cephalopelvic disproportion, lack of patient consent, known fetal bleeding diathesis, or fetal diseases of osseous fragility such as osteogenesis imperfecta.
- The importance of correct placement of the forceps in the vaginal canal and application to the fetal head is essential. The operator must be knowledgeable in the use of forceps and facile at checking the position of the forceps blades.
- Forceps appear to be significantly more likely to result in a successful vaginal delivery as opposed to the vacuum extractor.
- Maternal genital tract injury is higher in women having forceps deliveries, but neonatal cephalohematoma and retinal hemorrhage occur more frequently in women having delivery by vacuum extractor.
- Effort should be made to train resident obstetricians in the use of operative vaginal delivery techniques, as appropriate and safe deployment of forceps- and vacuum-assisted delivery remain an important part of modern-day obstetrics.

Cesarean Delivery

James R. Scott
T. Flint Porter

Cesarean section is the term commonly used to describe the delivery of an infant through an abdominal uterine incision. Since the words *cesarean* and *section* used together are redundant because both imply incision, cesarean delivery is preferable and is used in this chapter.

Cesarean delivery has played a major role in lowering both maternal and perinatal morbidity and mortality rates during the past century. The initial purpose of the operation was to preserve the life of the mother with obstructed labor, but indications expanded over the years to include delivery for a variety of more subtle dangers to the mother or fetus. Contributing to its more frequent use is increased safety that is largely due to better surgical technique, improved anesthesia, effective antibiotics, and availability of blood transfusions.

The cesarean rates during the past decade, both in the United States and worldwide, have increased dramatically. The percentage of women in the United States delivering by cesarean increased from <5.0% in 1965 to 30.2% in 2005 and has increased 40% since 1996. It is now the most common operation performed in the United States. There are a number of reasons for this striking increase. During the 1970s and 1980s, it was thought that cesarean delivery would be the solution to numerous obstetric problems. Facing increasing medicolegal pressures, obstetricians gradually abandoned most vaginal breech and forceps deliveries, broadened the definition of intrapartum fetal distress, and liberalized the diagnosis of dystocia. Also, a greater number of older women and primigravidas, whose primary cesarean rate is higher, were having children. This escalation in cesareans also increased during the past decade as enthusiasm for vaginal birth after cesarean (VBAC) waned and was replaced by the more frequent use of repeat cesarean. Finally, a recent trend toward primary elective cesarean delivery requested by the mother has now become a reality in many areas of the world.

Although perinatal outcome in the United States improved during the time when the cesarean rate increased, it also improved in other countries where cesarean rates remained low. Notably, the incidence of cerebral palsy has not declined during the past 20 years, primarily because perinatal morbidity and mortality more often are a function of

antepartum events, abnormal fetal growth, congenital anomalies, and premature birth.

Indications

Cesarean delivery is necessary when labor is unsafe for either the mother or fetus, when labor cannot be induced, when dystocia or fetal problems present significant risks with vaginal delivery, and when an emergency mandates immediate delivery (Table 27.1). Many indications are well accepted, a number are subjective or selectively applied in individual patients, and others are more controversial. The majority of cesareans are performed for fetal indications, a few are for only maternal reasons, and some benefit both and the mother and fetus. Repeat cesarean now accounts for more than 35% of cesarean births in the United States. Dystocia, fetal distress, breech, and other obstetric conditions are the indications for most primary cesareans cases.

Labor Contraindicated

Uterine contractions can be hazardous to the mother under certain circumstances. These include central placenta previa, previous classical uterine incision, myomectomy transecting the uterine wall, or uterine reconstruction. In these situations, labor and vaginal delivery may result in uterine rupture and hemorrhage, endangering the life or future health of the mother. Conditions where labor is dangerous to the fetus include placenta previa, velamentous insertion of the cord or other forms of vasa previa, and cord presentation. More recent indications include treatable fetal anomalies such as meningomyelocele and certain degrees of hydrocephaly.

TABLE 27.1 Common Indications for Cesarean Delivery

- Accepted
  - Failed induction
  - Cephalopelvic disproportion
  - Failure to progress in labor
  - Proven fetal distress
  - Placental abruption
  - Placenta previa
  - Umbilical cord prolapse
  - Obstructive benign and malignant tumors
  - Active genital herpes infection
  - Abdominal cerclage
  - Conjoined twins
- Selective
  - Breech presentation
  - Repeat cesarean
  - Congenital fetal anomalies, major

Cervical carcinoma
Prior vaginal colporrhaphy
Large vulvar condylomata
HIV infection

HIV, human immunodeficiency virus.

Failed Induction

Conditions such as isoimmunization, diabetes mellitus, intrauterine growth restriction, and hypertensive disorders that constitute a threat to the mother or fetus often require delivery when the cervix is unfavorable for induction. If attempts to induce labor are inappropriate or unsuccessful, cesarean is the only alternative.

Dystocia

Mechanical problems involving the uterus, fetus, or birth canal or ineffective uterine contractions that result in unsuccessful progress of labor and vaginal delivery are collectively referred to as *dystocia*. This term encompasses a variety of commonly used clinical terms, such as *failure to progress*, *cephalopelvic disproportion* (CPD), and *dysfunctional labor*. It also is a relative term. For example, fetal macrosomia sometimes causes CPD, but most cesarean births for abnormal labor involve a normal-sized infant. Dystocia occasionally is caused by soft tissue tumors and abnormal fetal presentations.

Fetal Distress

Electronic fetal monitoring improves the chance of detecting fetal distress, but its inaccuracy (false-positive rate) also has contributed to the increased number of cesarean births. Many clinicians have replaced vaginal breech deliveries with cesarean delivery to avoid the risk of intrapartum asphyxia or delivery-related trauma from head entrapment and umbilical cord prolapse.

Maternal or Fetal Emergency

Maternal or fetal conditions that require immediate delivery of the baby because vaginal delivery is either impossible or inappropriate include severe placental abruption, hemorrhage from placenta previa, prolapse of the umbilical cord, active genital herpes, and impending maternal death. Each hospital and obstetrical team should have a plan in place for these acute emergencies that includes a goal for a “decision to delivery time” within 30 minutes.

Primary Elective Cesarean on Maternal Request

Cesarean delivery on maternal requests is defined as a cesarean performed for a singleton pregnancy on maternal request in the absence of any medical or obstetric indications. This

is a controversial and relatively modern concept involving a number of ethical, emotional, and legal considerations. The National Institutes of Health held a State-of-the-Science Conference on Cesarean Delivery on Maternal Request in March 2006. The conclusions were that there is insufficient evidence to evaluate fully the benefits and risks of elective cesarean, individualization of the decision is necessary, and women who plan on having several children should avoid maternal request deliveries. It also was recommended that pain management should not be a motivating factor, and the cesarean delivery should not be performed prior to 39 weeks unless fetal maturity is verified. Women who want to deliver by cesarean list such reasons as dread of labor, fear of pain, risk of death and fetal injury, concern about damage to the pelvic floor including later anal and urinary incontinence and sexual function, and the convenience of planning and timing the delivery. The American College of Obstetricians and Gynecologists (ACOG) considers it ethical to perform a patient-choice cesarean if the physician believes that overall health of the patient and fetus is greater with cesarean than with vaginal birth. It is estimated that 4% to 18% of all cesareans worldwide are now performed because of patient choice.

Complications

Cesarean delivery is not an innocuous procedure. A variety of postpartum complications, including unexplained fever, endometritis, wound infection, hemorrhage, aspiration, atelectasis, urinary tract infection, thrombophlebitis, and pulmonary embolism, can occur in up to 25% of patients. The frequency of maternal death related to cesarean delivery varies with the institution and with the condition necessitating the procedure. Maternal mortality

---

rates are now <1 in 1,000 operations, and many deaths are related to the underlying maternal illness or anesthetic complications.

Late maternal complications of cesarean delivery include intestinal obstruction from adhesions and dehiscence of the uterine incision in subsequent pregnancies. Both of these complications are more common with the classic incision than with a lower uterine segment incision. The incidence of placenta previa and abnormal myometrial invasion by the placenta (accreta/increta/percreta) also is increased with each successive cesarean and can cause severe and intractable hemorrhage. The incidence of placenta previa or placenta accreta progressively increases from 3% with the first cesarean to 11% with the second, 40% with the third, 61% with the fourth, and 67% with the fifth. This has become a significant problem that requires careful preoperative counseling and preparation for intrapartum management, including the possibility of hysterectomy, when these conditions exists.

Types of Cesarean Operations

Almost all contemporary cesareans are performed by using a transperitoneal approach to reach the uterus. The two major types of cesarean operations are classified by the location and direction of the uterine incision. The first are those incisions made in the upper segment of the uterus (Fig. 27.1). The vertical incision usually made in the anterior fundus

is referred to as a classical incision. It is used primarily when it is difficult to deliver the infant through a low uterine segment incision. The second type is characterized by an incision made in the lower portion of the uterus after the bladder has been displaced downward (Fig. 27.2). The preferred and most frequently used is the low transverse incision. A vertical incision also may be made in this area, but it often involves the upper uterine segment unless the lower segment is quite elongated by labor.

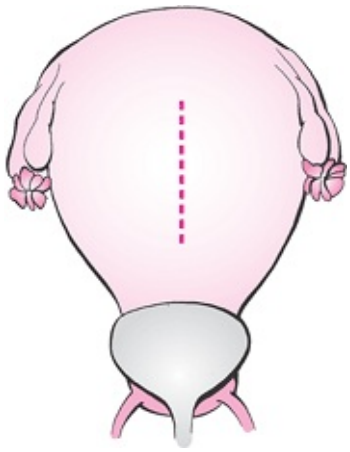

Figure 27.1 Classic incision in the upper segment of the uterus.

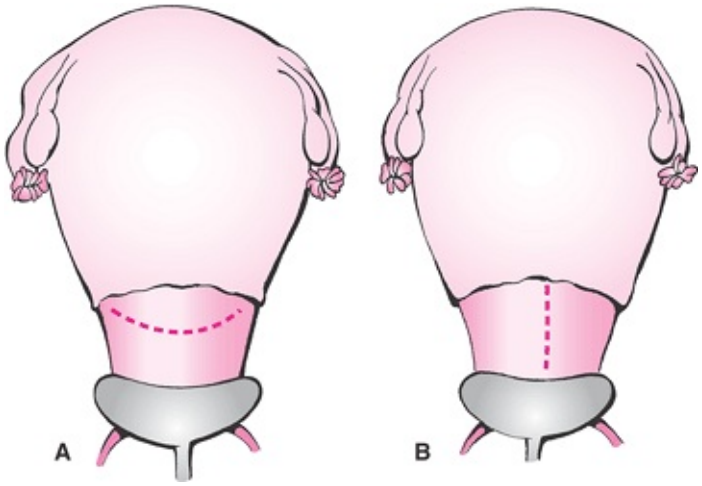

Figure 27.2 Incisions in lower uterine segment. **A:** Low transverse incision. **B:** Low vertical incision.

Variations are sometimes used because of unanticipated difficulty, but these incisions are best avoided by careful assessment and planning. (Fig. 27.3). A J-shaped incision is made when the obstetrician begins a transverse lower uterine segment incision and finds the lower uterine segment to be too narrow. It may not be realized that the incision is inadequate until delivery is attempted. The vertical extension from one end is necessary to avoid extension into the broad ligament. The T-shaped incision is made for similar reasons.

Anesthesia

The choice of anesthetic technique and agents is dictated by a number of factors. Patients with fetal distress, hemorrhage, shock, previous injury or surgery to the spine, or with skin infections of the lower back usually are not candidates for spinal or epidural anesthetic techniques. Conversely, a patient with active pulmonary disease such as pneumonia

and those who will be difficult to intubate are not good candidates for inhalation anesthesia. In most cases, the technique utilized depends primarily on such factors as urgency of delivery.

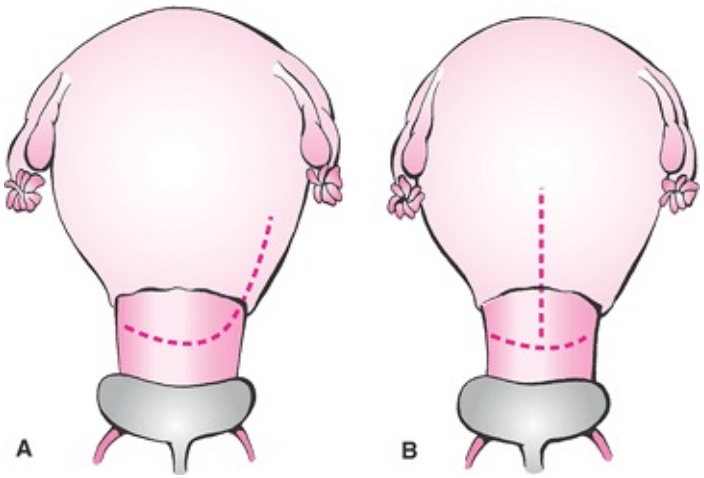

Figure 27.3 Undesirable variations of uterine incisions. **A:** J-shaped incision. **B:** T-shaped incision.

Maternal and fetal hemodynamics are markedly affected by maternal position. In the dorsal recumbent position, the gravid uterus compresses the inferior vena cava. Decreased venous return and maternal cardiac output result in hypotension and reduced uterine perfusion referred to as the inferior vena cava syndrome. The weight of the pregnant uterus also progressively compresses the aorta as the mean arterial pressure falls, thus reducing blood flow to the pelvis. Hypotension produced by regional anesthetic techniques compounds this problem. Devices attached to the operating table, inflatable wedges or towels placed under the patient, or tilting the table are used to displace the uterus to the patient's left in preparation for cesarean. Rapid intravenous infusion of fluids immediately before the placing the regional anesthetic block also reduces the incidence of hypotension.

The status of the fetus worsens as the time of exposure to anesthesia lengthens. Progressive fetal depression is prevented by avoiding unnecessary delay from induction-to-delivery time. The abdomen should be fully prepped, draped, and ready for the incision before general anesthesia is induced. On the other hand, reckless surgical techniques for rapid delivery of the fetus are unwise. An induction-to-delivery time of 5 to 15 minutes is reasonable if maternal oxygenation, blood pressure, and displacement of the uterus are monitored and maintained.

Operative Procedure

Cesarean delivery requires the same preoperative care as for any major surgery and additional consideration for the status of the fetus. A patient who is dehydrated from prolonged labor needs correction with intravenous fluids. Because anemia is relatively common in pregnancy, a hemoglobin or hematocrit should be checked preoperatively. Blood that is typed and screened may need to be available for immediate transfusion in emergencies. Routine preparation of autologous or donor blood is not cost-effective for most cesarean patients because few patients are transfused. However, autologous blood can be prepared during the antepartum period if the patient is at high risk for hemorrhage, as with placenta previa or acreta. An indwelling catheter is routinely placed before beginning surgery since the bladder is in the operative field. Informed consent from the patient and her partner includes an explanation of the details of the operation, the risks involved, and the reason it is necessary. Written permission for the procedure, anesthetic, administration of blood, and possible hysterectomy if necessary is then signed by the patient.

With elective primary or repeat cesarean delivery, it is the obligation of the physician to first document evidence of fetal maturity, as outlined in Table 27.2. These criteria do not preclude the use of menstrual dating. If the criteria confirm gestational age assessment on the basis of menstrual dates in a patient with normal menstrual cycles and no immediately antecedent use of oral contraceptives, delivery can be scheduled at >39 weeks by menstrual dates. Ultrasound is useful to confirm menstrual dates. The gestational age should agree within 1 week by crown–rump measurement obtained at 6 to 11 weeks or within 10 days by the average of multiple measurements obtained at 12 to 20 weeks. When the fetal gestational age is uncertain, amniocentesis for amniotic fluid studies should by used to ensure fetal maturity. Awaiting the onset of spontaneous labor is another option.

TABLE 27.2 Fetal Maturity Assessment before Elective Repeat Cesarean Delivery

Preparation

Preparation of the abdomen includes scrubbing the skin with soap and an antiseptic agent such as nonorganic iodide. The abdomen is then draped, leaving the area for the incision exposed.

Aspiration of the acidic contents of the stomach is a known risk when general anesthesia is used in pregnant women. The resulting pneumonitis is called *Mendelson syndrome*. Pretreatment with any of several medications reduces the risk of aspiration.

Prophylactic antibiotics are used to reduce the incidence of postpartum infection. The risk of postpartum endometritis is increased by duration of labor, prolonged rupture of the membranes, and number of cervical examinations. A single dose of a broad spectrum antibiotic, such as 1 gm of a cephalosporin, is recommended at delivery after the umbilical cord is clamped. With a clinically apparent intrapartum infection, therapeutic antibiotics started before surgery are continued into the postoperative period.

A pediatrician, neonatologist, or other physician should be available in the operating room if there is indication that the infant will need resuscitation.

Surgical Technique

The transverse Pfannenstiel and lower abdominal midline vertical are the two most commonly used skin incisions. Speed of entry through the low vertical incision facilitated by diastasis of the rectus muscles during pregnancy permits rapid access to the lower uterine segment in emergencies. This incision minimizes blood loss and allows extension for examination of the upper abdomen, if necessary. However, the transverse Pfannenstiel incision is used more frequently because of the cosmetic result preferred by most women. Moreover, entry through this incision is relatively rapid in the hands of an experienced surgeon, visualization of the pelvis is adequate, and there is less risk of subsequent herniation.

The abdomen is opened in layers, the abdominal cavity is briefly inspected, and the direction and degree of rotation of the uterus is quickly noted. Retractors placed in the abdominal incision are pulled laterally to expose the anterior surface of the uterus and the bladder covering the lower uterine segment.

The fold of peritoneum between the serosa of the uterus and the serosa of the bladder is identified (Fig. 27.4A). This loose peritoneum is elevated in the midline with forceps and incised, allowing entry into the space between the bladder and the lower uterine segment (Fig. 27.4B). The peritoneum is incised in a lateral direction, further separating the bladder from the overlying peritoneum, avoiding underlying veins in the broad and cardinal

ligaments. The operator then reflects the bladder from the lower uterine segment (Fig. 27.4C, D). Following creation of the bladder flap, a bladder blade is placed to keep the bladder out of the operative field and a retractor is placed superiorly to provide adequate exposure.

The operator is now looking directly at the fascia covering the lower uterine segment. A few centimeters below the peritoneal incision, a small transverse incision is made in the mid line with a scalpel (Fig. 27.4E). If care is taken, the fetal membranes will bulge into the incision without being ruptured. The incision is then extended either with blunt dissection by inserting both index fingers into the margins of the incision and sweeping laterally and upward or by using bandage scissors to extend the incision laterally in a gentle upward curve (Fig. 27.4F). The assistant retracts the abdominal wall firmly on the side that the operator is dissecting. Under direct vision, the incision is extended as far laterally as possible without entering the broad ligament. Once completed, a crescent-shaped or curvilinear incision is present in the lower uterine segment and the fetal membranes are bulging into the incision.

The operator now ruptures the membranes and inserts one hand beneath the lower edge of the uterine incision and over the fetal membranes to feel the presenting fetal part. With a vertex presentation, the occiput is identified and the fetal head is flexed. Gradually inserting the hand between the uterine wall and the fetal head, the head is brought into the uterine incision (Fig. 27.4G). The assistant or operator exerts fundal pressure on the fetal buttocks to gently deliver the fetal head through the incision. Once the head is delivered, the assistant suctions the mouth and the nares with a bulb syringe while the operator completes the delivery. The fetal shoulders are delivered with gentle traction on the fetal head in a manner similar to a vaginal delivery.

After delivery, the umbilical cord is clamped and divided, and the fetus is handed to an assistant outside the operative field. The placenta is delivered spontaneously, if possible. If manual removal is necessary, it is delivered by separating it bluntly from the uterine wall with the fingers held extended in a rigid manner and the back of the hand facing the uterine wall. The uterine cavity is inspected for any structural abnormality, and any retained placental tissue or adherent membranes are removed. Oxytocin is added to the patient's intravenous infusion to stimulate uterine contractions and reduce the amount of bleeding.

The cut edges of the uterine wall are then grasped with ring forceps or other noncrushing clamps for traction and to compress bleeding venous sinuses. The incision is closed with one or two layers (Fig. 27.5A) of a continuous locked or unlocked absorbable suture that is anchored securely at the angle of the incision. When the low transverse uterine segment is thin, the one-layer closure is satisfactory and commonly is used. If a second layer of closure is used (Fig. 27.5B), the suture imbricates the first with sutures placed as interrupted figure-of-eight, Lembert, or continuous sutures to completely cover the first layer. Any persistent bleeding in the incision line is controlled with interrupted figure-of-eight sutures. The peritoneum usually is left open but can be reapproximated with a continuous layer of absorbable suture.

All packs in the abdominal cavity are removed, and residual blood or amniotic fluid is

removed by suction. If meconium is present or exposure to infected amniotic fluid has occurred, the pelvic cavity should be copiously lavaged with normal saline solution. The ovaries, tubes, and other organs are inspected, and the abdomen is then closed in layers. The use of a mass ligature closure such as the Smead-Jones technique for vertical incisions should be considered for patients at high risk of disruption. A delayed absorbable synthetic suture most commonly is used on fascia, but nonabsorbable suture is acceptable as well.

Postoperative management is similar to that of any patient who has had major surgery. Since the postpartum patient who has undergone cesarean delivery is at risk for thrombophlebitis and thromboembolism, spontaneous leg movement and early ambulation are encouraged. The urinary catheter may be removed on the first postoperative day, and the patient is fed as soon as she is able to tolerate oral feedings. Currently, discharge from the hospital often is dictated by economic and insurance factors rather than medical condition. If there is a contraindication

to early discharge, the physician should recommend continued inpatient management and document the reason in the patient's record. With early discharge, adequate support and professional care at home should be an integral part of management.

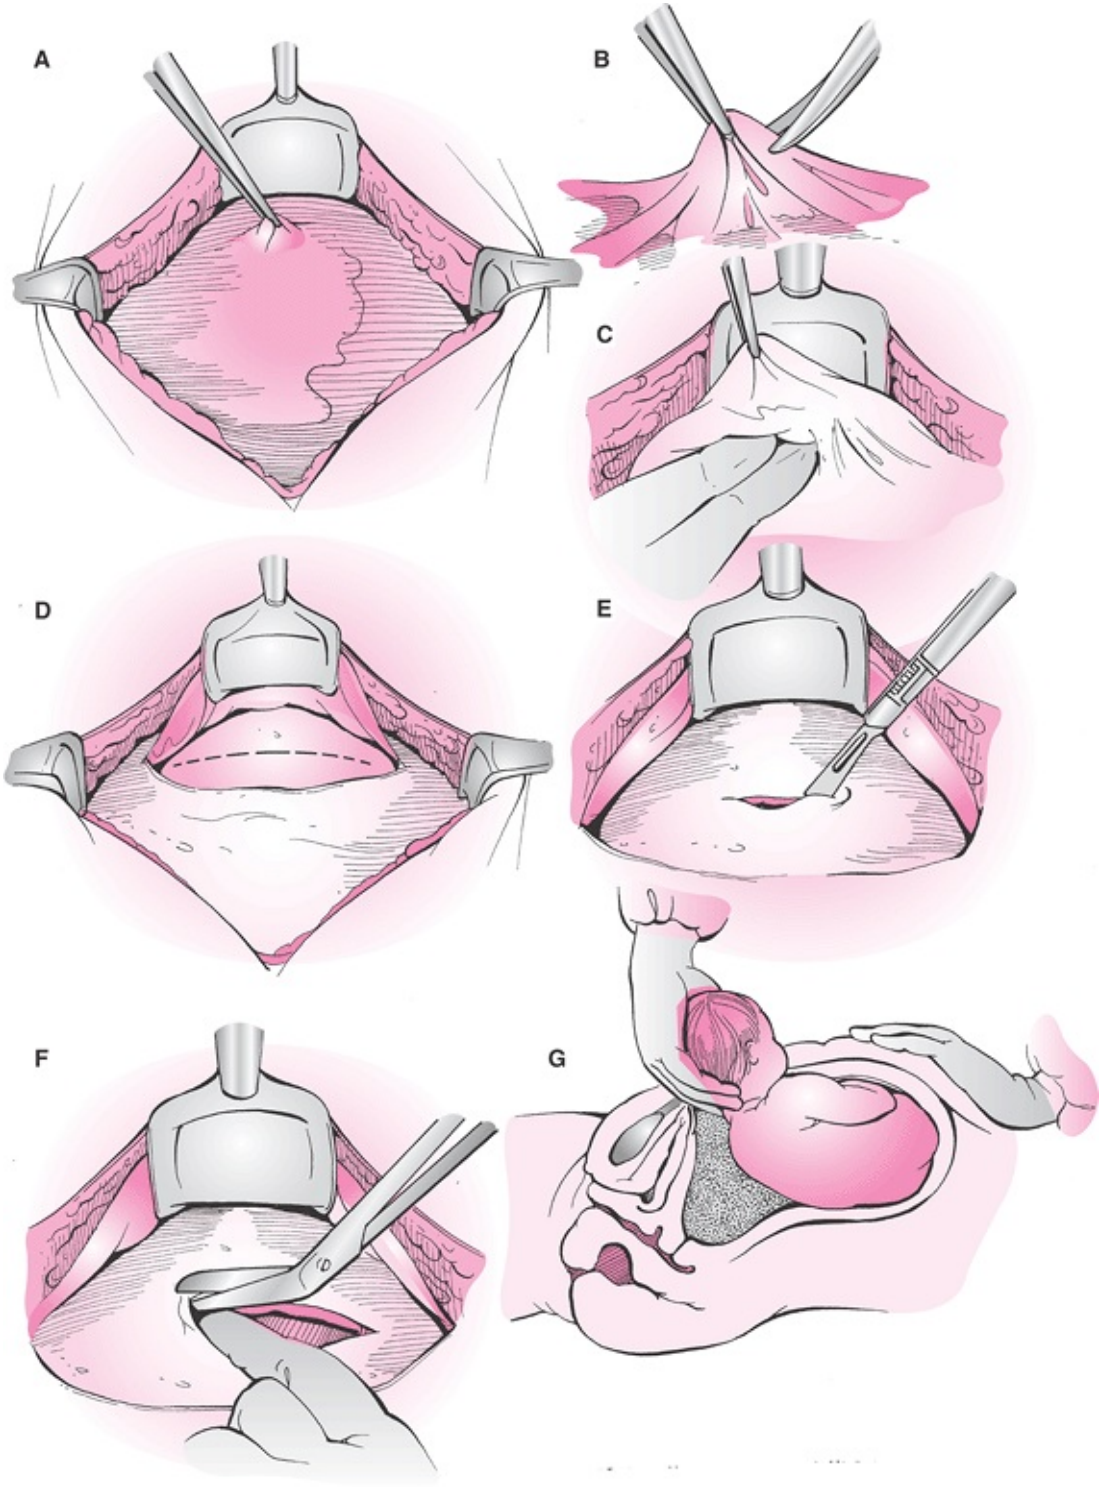

Figure 27.4 Cesarean delivery. **A:** Reflection of the peritoneum from the serosa of the uterus to the bladder is identified. **B:** Peritoneal reflection between the uterus and bladder is elevated and incised. **C:** The bladder is displaced away from the lower uterine segment. **D:** The bladder is retracted, and the incision is planned to be 2 to 3 cm below the peritoneal incision. **E:** A small incision is made through the uterine wall to the fetal membranes. **F:** A uterine incision is made in a curvilinear shape, using bandage scissors. **G:** The fetal head is elevated through the uterine incision by the operator's hand.

Closure of the Classic Incision

The thickness of the upper uterine wall may require a three-layer closure. Continuous or interrupted suture techniques may be used. The first layer should include about half the thickness of the wall. The second layer is placed to avoid leaving a space between the layers, and the third layer should close the serosa in a manner that minimizes the raw surface exposed to the abdominal cavity.

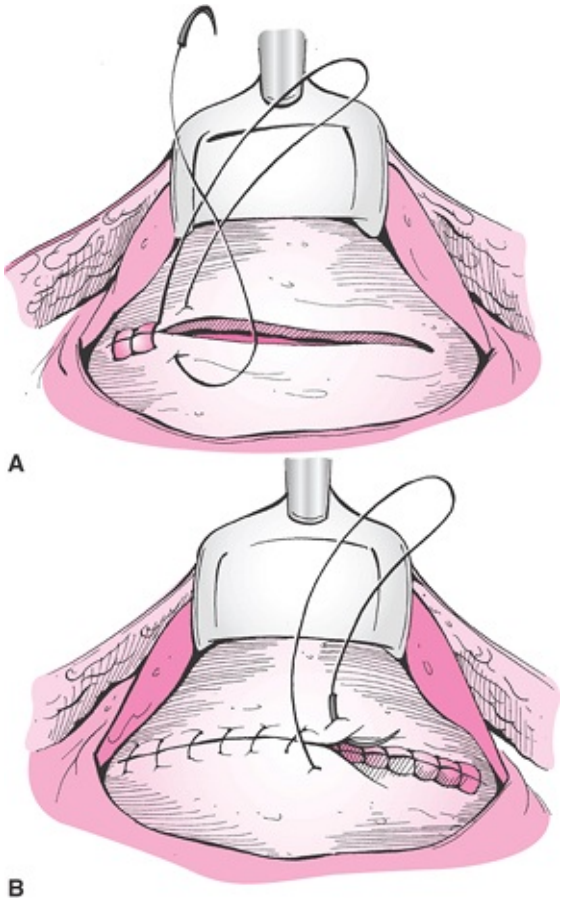

Figure 27.5 Wound closure. **A:** One layer of closure. **B:** Two layers of closure.

Variations

After prolonged obstructed labor, the fetal head can be deeply impacted in the midpelvis with a greatly elongated and thinned lower uterine segment. Under these circumstances, it may be necessary for an assistant to dislodge the fetal head with a hand inserted into the vagina either immediately before or during the cesarean. Manipulation of the fetal head necessary for the delivery combined with the thin lower uterine segment risks lateral extension of a transverse incision and laceration of uterine vessels.

In the presence of a posterior placenta previa, footling breech presentation, or preterm delivery, the lower uterine segment may be too narrow for an adequate transverse

incision. Under these circumstances, a vertical incision in the lower segment usually is necessary, even if it extends into the upper segment of the uterus. Other breech presentations after labor likely can be managed safely through a transverse low cervical incision, but the incision should be as wide as possible to deliver the after-coming head.

A transverse lie with the fetal back down or shoulder presentation is one indication for a classic incision in the uterus. Attempts to deliver the fetus through a transverse lower segment incision may result in extension of the uterine incision into the uterine vessels. A transverse lie with the fetal back up (“umbrella” position) usually does not need a classic incision for delivery.

When the maternal surface of the placenta is encountered as the uterus is opened, considerable hemorrhage can result. Suction is used to keep the operative field reasonably clear for visualization, and the operator should quickly enlarge the incision for delivery of the fetus. The placenta should not be cut or fractured, because disruption of the vessels on the chorionic plate may result in fetal hemorrhage. Instead, the placenta should be separated from the uterine wall to allow access to the fetal membranes. The membranes are then punctured, and the fetus is delivered through this opening and through the uterine incision.

Surgical Sterilization

Tubal ligation adds little time or morbidity to cesarean delivery and does not significantly prolong postpartum recovery. The Pomeroy method is the simplest sterilization technique and gives satisfactory results. Other methods may be result in fewer failures but also are associated with higher morbidity.

Perimortem Cesarean Delivery

Perimortem cesarean refers to emergency abdominal delivery in a woman who has sustained a cardiac arrest. Events that lead to cesarean birth with death of the mother are fortunately so rare that most obstetricians never perform such an operation. The certainty of maternal death and a live baby must be quickly established. Aseptic precautions are ignored, and the abdomen and uterus are opened rapidly with vertical and classical incisions. The fetus is quickly delivered, given immediate resuscitation, and moved to an intensive care nursery as soon as possible. The placenta is removed and the uterus and abdomen closed. The fetal prognosis depends on the length of gestation, cardiovascular status of the mother before death, and interval between maternal death and delivery. Unfortunately, the prognosis for the delivered infant usually is ominous. The infant may survive if delivery is accomplished within 10 minutes of maternal death, but the presence and severity of brain damage from cerebral hypoxia is difficult to predict. With modern life-support systems, the outlook for the fetus is improved if the cesarean can be done before the mother's actual death.

Vaginal Birth after Previous Cesarean

The rising number of women delivered by repeat cesarean has been one of the principal

in the cesarean delivery rate in the United States during the last 20 years. However, there is a general consensus that a trial of labor (TOL) is desirable and outweighs the risk in most cases.

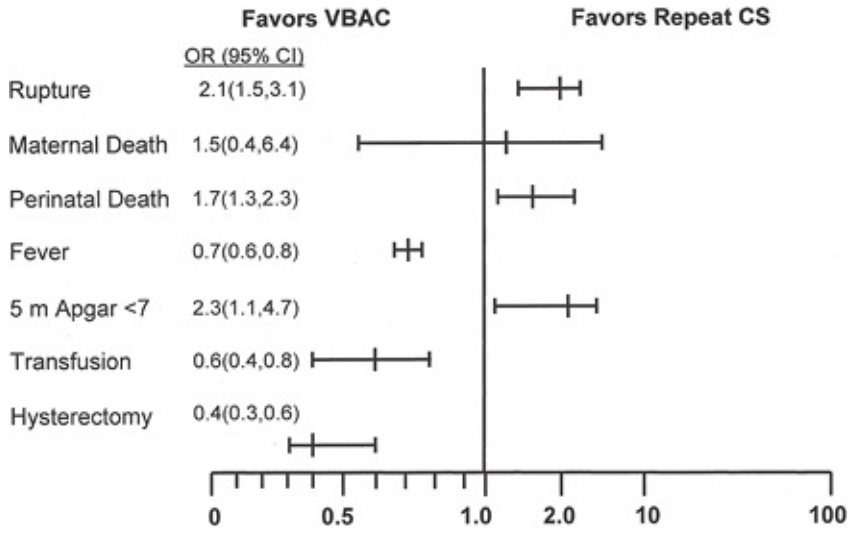

Figure 27.6 Odds ratio graph comparing morbidity of TOL versus elective repeat cesarean. (VBAC, vaginal birth after cesarean; CD, cesarean delivery.)

Following a wave of enthusiasm for VBAC, some third-party payers and managed care organizations mandated that all women who have had previous cesarean deliveries had to undergo TOL. However, it became increasingly recognized that there are potential risks to VBAC and that some repeat cesareans are clinically indicated. Common sense and clinical judgment are important when deciding whether TOL or repeat cesarean is best in each specific case.

Acceptance of VBAC varies greatly among patients and is related to the way that it is presented by the physician. It is reasonable to encourage women to undertake TOL in a safe setting after possible complications have been honestly discussed. Approximately 40% to 50% of women eligible for TOL refuse it in favor of a repeat cesarean. This is most common when the labor preceding the prior cesarean was long and painful and the patient fears a similar scenario.

Safety

Numerous reports on the benefits and safety of VBAC can be found. Recent studies have suggested that a selective and cautious approach to VBAC is warranted (Figs. 27.6, 27.7). Complications are more likely for women undergoing TOL than for those who elected repeat cesarean, primarily because of the increased incidence of infection and morbidity in women who fail a TOL. Infants born by repeat cesarean after failed TOL also have increased rates of infections.

Prelabor Considerations

Most studies of VBAC have been conducted in university or tertiary-level centers under ideal conditions with staff coverage and in-house anesthesia.

However, the majority of obstetric patients in this country are delivered where manpower may be limited. One national survey on obstetric anesthesia found that anesthesiologists were available in-house on nights and weekends in 77% of hospitals with >1,500 births per year, in 26%

of hospitals with 500 to 1,499 births per year, and in only 3% of hospitals with <500 births per year. Nevertheless, it is incumbent on the physician to provide a safe setting if VBAC is to be undertaken.

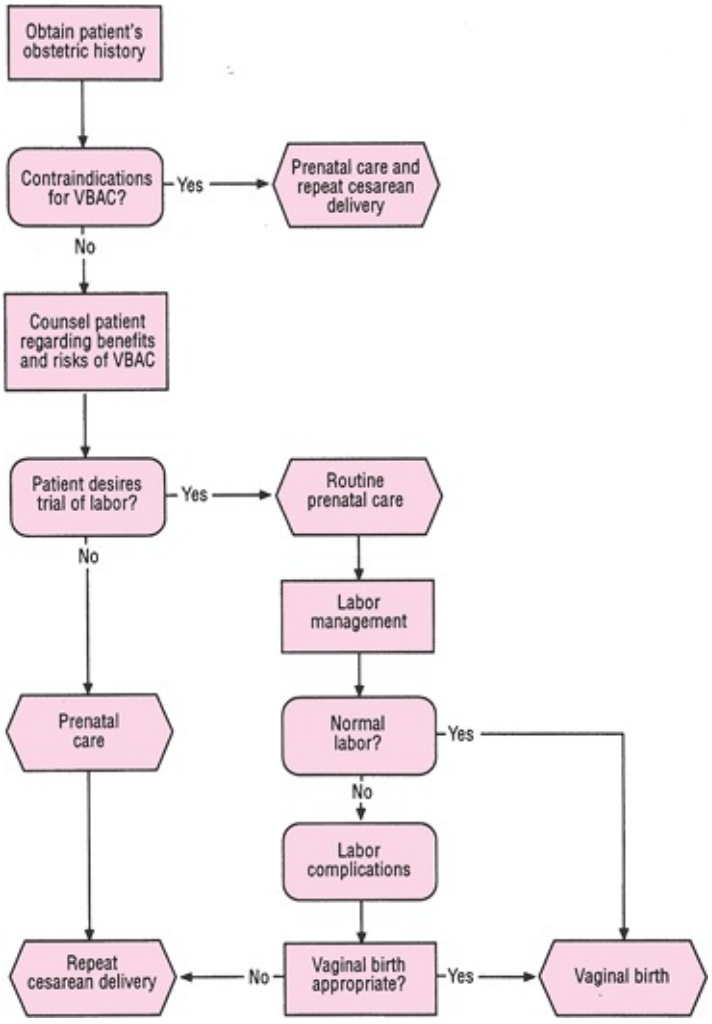

Figure 27.7 Flow sheet showing one management scheme for VBAC. (VBAC, vaginal birth after cesarean.) (Reproduced from the American College of Obstetricians and Gynecologists. *Vaginal delivery after previous cesarean birth*. ACOG Practice Patterns. Washington: Author, 1995;1:1–8, with permission.)

Although patients were carefully selected in initial studies, there has been a tendency to

expand the list of obstetric conditions for which VBAC is recommended. These conditions include multiple previous cesareans, unknown uterine scar, breech presentation, twins, postterm pregnancy, and suspected macrosomia. Although success has been reported in small series, careful and individualized analysis of the risk of adverse outcome is necessary before VBAC is attempted in these settings.

Preparation

Reports of uterine ruptures resulting in perinatal deaths and neurologically impaired infants validate a judicious approach with careful patient selection and counseling regarding the risks and possible sequelae of TOL. Thorough, impartial, and factual counseling beginning early in pregnancy is desirable to prepare for TOL after a previous cesarean. If the type of previous incision is in doubt, medical records should be obtained. It generally is agreed that contraindications to TOL include a classical scar, a low vertical scar that extends into the upper segment of the uterus, and a T-shaped scar. The patient also should be aware that problems could arise during the antepartum or intrapartum course that could necessitate repeat cesarean delivery. After appropriate evaluation, the potential success and safety of labor should be discussed with the patient and documented in the prenatal record. Once a decision is made to attempt VBAC, patient support and encouragement are in order.

Success of Labor

Approximately 60% to 80% of TOL after a previous cesarean delivery result in successful vaginal births. However, these success rates usually represent a selected population. Patients who are judged inappropriate for TOL often have been excluded, and the exact percentage of women undergoing TOL is not always stated.

For women whose first cesarean was done for a nonrecurring indication, the rate of successful vaginal delivery is similar to the overall incidence of vaginal delivery in laboring patients who have not undergone previous cesarean. A woman who has delivered vaginally at least once before or after her previous cesarean also is more likely to have successful TOL than the woman who has yet to deliver vaginally.

Many patients with a previous diagnosis of dystocia are able to deliver vaginally, but the percentage is consistently lower (50% to 70%) than those with nonrecurring indications. The lower rate is undoubtedly related to the stringency and accuracy of the original indication. Although scoring systems may be helpful, no totally reliable way to predict whether a TOL will be successful has been identified. Radiographic pelvimetry alone has not been predictive, and a proposed fetopelvic index using x-ray pelvimetry and ultrasound has not been widely adopted.

Candidates for Vaginal Birth after Cesarean

Selection

The following criteria are clinically useful to identify candidates and conditions most

predictive of a safe and successful TOL:

1. One or two prior low segment transverse cesareans
2. Clinically adequate pelvis in relation to fetal size
3. No other uterine scars, anomalies, or previous rupture
4. Patient consent
5. Physician available throughout labor capable of monitoring labor and performing a cesarean
6. Availability of anesthesia and personnel for emergency cesarean.

Potential Contraindications

There are other circumstances in which the risk of adverse outcome may outweigh the advantages of TOL:

1. Prior classical or T-shaped incision or other transmural uterine surgery; whether TOL should be encouraged after a low vertical incision is controversial
2. Contracted pelvis, macrosomia, or both
3. Medical or obstetric complication that precludes vaginal delivery
4. Patient refusal
5. Inability to immediately perform emergency cesarean because of unavailable surgeon, anesthesia, inadequate staff or facility.

Management of Labor

Labor and delivery of these patients undergoing VBAC is safest in facilities where anesthesia, obstetric, and blood bank personnel are immediately available at all times. Each hospital should develop a protocol for management. A reasonable regimen includes the following measures:

- Intravenous access on admission
- Blood count and type and screen
- Nothing by mouth
- Continuous electronic fetal monitoring
- Alert anesthesia, obstetric, and neonatal personnel.

Analgesia

There are few contraindications to epidural anesthesia, and adequate pain relief may encourage a greater percentage of women to choose TOL. Epidural analgesia rarely masks the signs and symptoms of uterine rupture, and success rates

for VBAC are similar to those experienced by women who receive other types of pain relief.

Intrapartum Management

Spontaneous labor may be preferable in the woman who has previously undergone cesarean delivery. Once labor has begun, she should be promptly evaluated and monitored, and most authorities recommend continuous electronic monitoring for these patients.

Personnel who are familiar with the potential complications of VBAC should be present to watch closely for fetal distress and inadequate progress of labor. If the patient originally was delivered by cesarean for fetal distress, fetal distress may occur again. Because 20% to 50% will have an unsuccessful TOL, these women should be considered at high risk for labor problems. When the previous cesarean was for dystocia, prompt diagnosis of a subsequent labor disorder is especially important to avoid the added risk of obstructed labor. In general, the progress of labor should be evaluated by standard criteria used for nulliparas if there have been no previous vaginal births and by criteria for multiparas if prior babies have been delivered vaginally.

Oxytocin

Oxytocin often is suspected as a factor responsible for uterine rupture. Although a meta-analysis found no relationship between the use of oxytocin and rupture of the uterine scar, several studies indicate that high infusion rates of oxytocin place women at greater risk. Therefore, oxytocin to induce or augment labor should be used cautiously to avoid hyper stimulation.

Delivery

There is nothing unique about delivery of the infant after TOL. The need to routinely explore the uterus after successful vaginal delivery is controversial. Scar separation can be difficult to palpate, rarely results in significant bleeding, and usually causes no major clinical problem. Most asymptomatic dehiscences heal well, and there are no data to suggest that future pregnancy outcome is better if the dehiscence is surgically repaired. Nor has the safety of a TOL in a subsequent pregnancy after a known dehiscence been established. Obviously, excessive vaginal bleeding or signs of hypovolemia at delivery require complete assessment of the previous scar and the entire genital tract.

Uterine Rupture

Rupture of the uterine scar is the most serious complication of VBAC. It can be life threatening for both mother and baby.

The best predictor of the safety of labor after previous cesarean is the location of the previous uterine scar (Table 27.3). Scar dehiscence is defined as an opening of the previous scar with intact overlying visceral peritoneum and no expulsion of intrauterine contents (also termed a *window*). This type of scar separation rarely produces hemorrhage or causes a major clinical problem. Incomplete or partial rupture refers to an opening of the

previous scar, but not the overlying peritoneum, and the extraperitoneal extrusion of intrauterine contents, often into the broad ligament. A complete rupture is a separation of the previous scar and overlying peritoneum with extrusion of intrauterine contents into the abdominal cavity.

TABLE 27.3 Criteria for Trial of Labor after Cesarean

1. One or two prior cesarean deliveries
2. Clinically adequate pelvis in relation to fetal size
3. No other uterine scars, anomalies, or previous rupture
4. Patient consent
5. Physician capable of monitoring labor and performing an emergency cesarean delivery immediately available throughout active labor
6. Availability of anesthesia and personnel for emergency cesarean

Spontaneous ruptures before labor most commonly are associated with classic incisions (Table 27.4). Intrapartum uterine ruptures requiring emergency treatment occur in approximately 0.5% of patients with a transverse low-segment scar. The rupture usually involves the previous scar and lower uterine segment, but it may be stellate and extend intraperitoneally or retroperitoneally. Contributing factors include hyperstimulation with oxytocin; dysfunctional labor; more than one cesarean delivery; high parity; and even previous perforation of the nonpregnant uterus at curettage, hysteroscopy, metroplasty, and myomectomy. The rate of rupture has not been shown to be increased with previous intrapartum or postpartum infection or to be related to the method or number of layers of closure.

In most cases, the reason why uterine rupture occurs in a particular VBAC patient is unknown. Unfortunately, poor

outcomes have occurred even in appropriate candidates. To date, there is no way to detect the individual patient who is at high risk for rupture of the uterine scar. Imaging techniques have been investigated as a way to identify those patients, but the reliability has not been established.

TABLE 27.4 Contraindications for Vaginal Birth after Cesarean

1. Prior classic or T-shaped incision or other transmural uterine surgery
2. Contracted pelvis
3. Medical or obstetric complication that precludes vaginal delivery
4. Patient refusal
5. Inability to immediately perform emergency cesarean because of unavailable surgeon or anesthesia personnel, inadequate staff or facility

Diagnosis

Because uterine rupture may be difficult to diagnose, close surveillance and a high index of suspicion is necessary. A constellation of signs and symptoms initially may be subtle, but they usually will gradually or rapidly progress to a clearer clinical picture. The most common sign of uterine rupture is fetal distress. An FHR pattern with variable decelerations often rapidly evolves into late decelerations, bradycardia, and undetectable fetal heart tones (Fig. 27.8). Because FHR abnormalities occur in 50% to 70% of uterine ruptures, all FHR changes in patients undergoing TOL should be evaluated thoroughly.

Uterine or abdominal pain most commonly occurs in the area of previous incision, but it may range from mild to “tearing” in nature. Uterine contractions often diminish in intensity and frequency. Vaginal or intra-abdominal bleeding is associated with anxiety, restlessness, weakness, dizziness, gross hematuria, shoulder pain, and shock. This clinical picture can be mistakenly attributed to abruption. Loss of station of the presenting part is diagnostic.

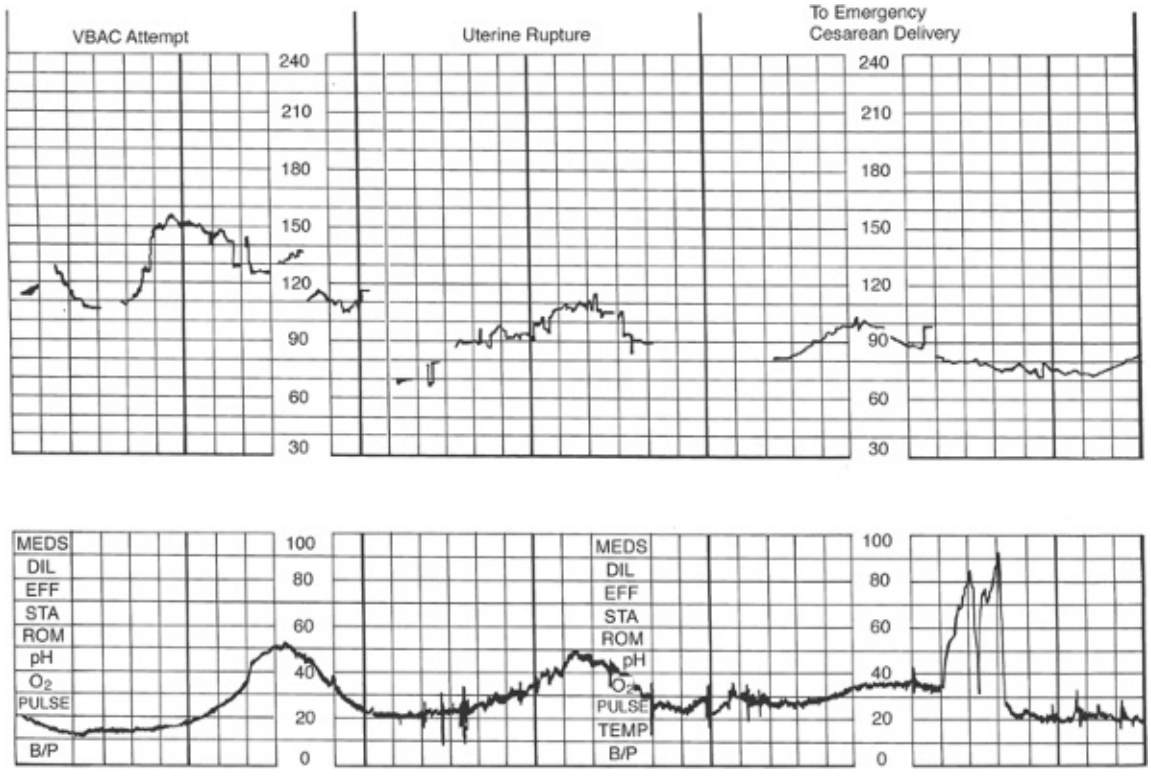

Figure 27.8 FHR tracing shows changes in FHR pattern during uterine rupture. (VBAC, vaginal birth after cesarean.)

Management

Any of the previously mentioned findings warrant an immediate exploratory laparotomy. The condition of the infant is dependent on the severity of the rupture as well as the relationship to the placenta and umbilical cord. When the umbilical cord is compressed or the placenta is detached, low Apgar scores, hypoxia with long-term neurologic morbidity, or fetal death can occur.

In the majority of patients, repair of the uterus is possible. The tear can be repaired if the patient wants to retain fertility, if her condition is not jeopardized by continued hemorrhage, and if repair is technically feasible. The wound edge should be debrided before the edges are reapproximated, and suturing techniques are similar to those used for cesarean repair. Extension of the rupture into the broad ligament vessels, extensive damage to the uterine myometrium, or associated placenta accreta may require hysterectomy.

Future Pregnancies after Uterine Rupture

If the site of the ruptured scar is confined to the lower segment, the rate of repeat rupture or dehiscence in labor is 6%. If the scar includes the upper segment of the uterus, the repeat rupture rate is 32%. Therefore, women with a prior uterine rupture are best delivered by repeat cesarean as soon as the fetus is mature or at 36 to 37 weeks gestation before the onset of labor.

Conclusions and Recommendations

There are no randomized trials comparing VBAC with elective repeat cesarean delivery to definitively prove that outcomes are better with a TOL, and overall outcomes from TOL and elective repeat cesarean delivery are nearly equivalent. When VBAC is successful, it is associated with less morbidity than repeat cesarean. With careful patient selection and close attention during labor, the majority of women who previously delivered by cesarean can safely and more economically deliver vaginally. Most problems occur when the patient is not under direct observation or when the diagnosis of uterine rupture is delayed.

Cesarean Hysterectomy

Indications

Occasionally, hysterectomy must be performed immediately after cesarean or vaginal delivery. A useful classification is based on emergency indications (e.g., uterine rupture,

uncontrollable uterine hemorrhage, placenta accreta, uterine infection) and nonemergency indications (e.g., for significant uterine pathology such as carcinoma in situ or uterine leiomyomas).

Emergency Indications

Uncontrollable uterine hemorrhage may result from uterine rupture, uterine atony, placenta accreta, placental site sinusoids after placenta previa, or a coagulation defect. When surgery is indicated to control hemorrhage of uterine origin, the patient's desire to preserve childbearing capacity as well as the current danger is assessed. Nonsurgical management is indicated in such circumstances as uterine atony and coagulation defect.

Bimanual uterine massage, oxytocin, prostaglandin administration, and blood replacement should be used before surgical intervention is considered. Hemorrhage from sinusoids in the lower uterine segment associated with placenta previa can sometimes be controlled with mattress or figure-of-eight 2–0 to 0 absorbable sutures. With persistent uterine atony and bleeding, other hemostatic management options include uterine compression sutures (B-Lynch), uterine or hypogastric artery ligation, pelvic vessel embolization, or injection of recombinant factor VIIa. If these are unsuccessful, hysterectomy often is necessary.

Nonemergency Indications

The risks and benefits of hysterectomy for nonemergency indications are much less certain than for emergency conditions. Hysterectomy performed at term is associated with hemorrhage, infection, thromboembolism, and injury to contiguous organs. The relatively infrequent use of hysterectomy despite an increase in the incidence of cesarean delivery reflects a generally accepted conservative approach in most situations. When hysterectomy is necessary for benign conditions, removal of the uterus is technically less complicated in the nonpregnant state.

Procedure

The technique for hysterectomy is described in another chapter, but some points are especially pertinent to its performance immediately after cesarean or vaginal delivery. In general, blood is conserved if the uterine wound for cesarean is rapidly closed before beginning the hysterectomy. Normal ovaries should be preserved, and the operator should be aware that the relative shortening of the utero-ovarian ligament at term necessitates extra care in the placement of clamps and sutures in this area. The increased vascularity of the pregnant uterus requires considerable care in the correct placement of clamps and sutures.

In the uterus at term, it can be difficult to determine by palpation the location of the cervix when performing a hysterectomy. Because of this difficulty, sometimes portions of the cervix are inadvertently left behind. Clips or clamps placed vaginally on the cervix preoperatively can be more easily palpated, or a vertical incision can be made in the lower uterine segment and extended caudad until the limits of the cervix can be identified. Drainage of the pelvic cavity may be necessary, depending on the adequacy of hemostasis.

In emergent situations or when the patient is unstable, a supracervical hysterectomy is simpler and quicker and may be preferable to total hysterectomy.

Summary

Cesarean delivery has contributed greatly to the low maternal and infant morbidity and mortality rates in modern obstetrics. Indications have broadened, and presently there is a debate over whether elective cesareans when requested by the patient are appropriate. VBAC is successful in many women. Although rare, uterine rupture is the most serious complication associated with VBAC. Proper selection and close monitoring of labor are warranted in all VBAC patients.

Summary Points

- The current cesarean delivery rate in the United States is >30%.
- While the rate of cesarean delivery has been rising, the rate of cerebral palsy remains unchanged.
- The incidence of placenta previa or placenta accreta progressively increases and is 3%, 11%, 40%, 61%, and 67% for the first, second, third, fourth, and fifth cesarean deliveries, respectively.
- The ACOG considers it ethical to perform a patient-choice cesarean if the physician believes that the overall health of the patient and fetus is greater with cesarean than with vaginal birth.

Psychologic Disorders of Pregnancy and the Postpartum Period

Michael W. O'Hara
Lisa S. Segre

Depressive and anxiety disorders are common during pregnancy and the postpartum period. These disorders may impair the woman's self-care during pregnancy and negatively affect her parenting after delivery. The patterns of presentation vary widely. Depressive and anxiety disorders may exist before the pregnancy, or they may develop during pregnancy or after delivery. Sometimes, they are quite apparent to the obstetrician examining an obviously sad or anxious woman. Often, they are not obvious because women may conceal emotional disturbance for reasons that include stigma, fear of the baby being taken away, not recognizing that she has a psychiatric disorder, or simply not wanting to bother the doctor. Women with severe mental illness who become pregnant usually are already under the care of a psychiatrist. However, some women develop a “postpartum psychosis” within a few weeks of delivery. Although a previous history of psychosis is the most significant risk factor, the majority of women experiencing a psychotic episode after delivery have no significant history of psychiatric illness. Thus, the tasks of the obstetrician with respect to these disorders are to (a) understand their nature, risk factors, and consequences for the mother and fetus or child; (b) detect and assess for them during clinical visits; (c) educate patients and families; and (d) make effective referrals and/or manage clinical care of these disorders.

In the first part of this chapter, perinatal psychiatric disorders are described, including their clinical presentation, prevalence, effects, and management in an obstetric setting. Because the detection of these disorders is not reliably accomplished by direct observation alone, the second part of this chapter will describe patient education and screening approaches feasible for an obstetrics office setting.

Postpartum Blues

Description

In the early postpartum period, many women experience a mild mood disturbance referred

to as “postpartum blues.” Symptoms often are most noticeable between days 3 and 5 postpartum and typically last anywhere from several hours to several days. Figure 28.1 illustrates this pattern. It shows daily mood ratings of a sample of pregnant and postpartum women at several time points in late pregnancy and the early postpartum period. By day 2 after delivery, women experience negative mood at about the same level as comparable women who have not recently delivered a child. Negative mood increases, peaking at day 6 postpartum. It is interesting to note that mood is, on average, more negative late in pregnancy than at the time in the postpartum period during which the blues peaks in intensity. Finally, although the term *blues* primarily connotes sadness, it is not a form of mild depression. It might best be considered a problem in affect regulation. Prominent symptoms include mood lability, irritability, interpersonal hypersensitivity, insomnia, anxiety, tearfulness, and even elation.

Because the blues is common and almost always occurs in close proximity to childbirth, the phenomenon is considered normal and probably hormonally driven, though

research is inconclusive in this respect. The literature does suggest that women with a history of depression are at increased risk for the blues and that the blues is itself a risk factor for later depression. These and other findings suggest that the blues may lie within the spectrum of affective disorders.

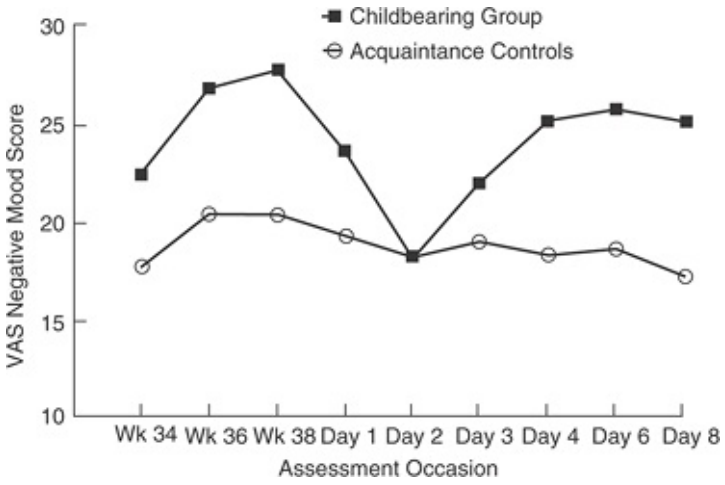

Figure 28.1 Visual Analogue Scale negative mood scale scores for childbearing and nonchildbearing subjects during pregnancy and after delivery. (VAS, Visual Analog Scale.) (From O'Hara MW, Zekoski EM, Philipps LH et al. Controlled prospective study of postpartum mood disorders: comparison of childbearing and nonchildbearing women. *J Abnorm Psychol* 1990;99:3–15.)

Prevalence and Effects

Because there is no single accepted definition of the blues, estimates of its prevalence have varied considerably, ranging from 26% to 84%. Table 28.1 includes two definitions of the blues, the Pitt and the Handley criteria. The Pitt criteria will identify about half of

postpartum women as experiencing the blues, while the Handley criteria will identify about a quarter of women as experiencing the blues. Generally, the blues lasts no more than a few days, requires no treatment, and is not associated with negative sequelae. However, in some cases, what appears to be the postpartum blues is actually the beginning of a depressive episode, which is discussed in the section on Perinatal Depression.

TABLE 28.1 Definitions of Blues Based on Pitt and Handley Criteria

Pitt Criteria for the Blues
Period lasting at least part of day (in the first week to 10 days postpartum) when woman felt very depressed and tearful.
Handley Criteria for the Blues
At least four of the following seven symptoms in the first week to 10 days postpartum:

1. Dysphoric mood for at least part of 1 day
2. Mood lability (easily changing mood) that definitely is noticeable to the woman
3. Crying frequently over at least 1 day
4. Anxiety that definitely is noticeable to the woman
5. Insomnia with at least a 1-hour delay over 3 days
6. Appetite decrease that definitely is noticeable to the woman
7. Irritability increase that definitely is noticeable to the woman

Clinical Management

Prenatal education about the frequency, normality, and the symptoms of this mild mood disturbance will help new mothers and their families keep the blues in proper perspective (i.e., recognize that the blues is a common phenomenon, that it passes quickly, and that there are no consequences). It is especially important to provide this type of normalizing information to women who experience the blues to relieve any guilt feelings or fears they may have because they are unexpectedly experiencing negative feelings about the new baby. This education can occur in childbirth preparation classes, by nurses or physicians during prenatal visits, and on the maternity ward. Patients should be instructed that if their “blues” continues beyond a week's period and they do not seem to be feeling better by the end of the second week postpartum, they should contact their obstetrician or primary care physician. The patient actually may be in the early stages of a major depression, which requires prompt treatment.

Perinatal Depression

Depression may preexist the pregnancy or begin at any time during pregnancy or the postpartum period. It is a devastating disorder that robs women of their joy and energy and creates impairment in self-care and parenting. There often is confusion surrounding this term. Major depression that occurs in the postpartum period usually is referred to as "postpartum depression." The term *postpartum depression* does not exist in the diagnostic nomenclature and, in fact, often is erroneously used to refer to cases of the postpartum blues and postpartum psychosis as well as any other mood disturbance (including anxiety) that are prevalent in the postpartum period. The *Diagnostic and Statistical Manual of the American Psychiatric Association* (DSM-IV-TR) includes "postpartum onset" as a "course specifier" if the episode of major depression begins in the first 4 weeks after delivery. In clinical practice, however, the diagnosis is applied to a major depressive episode within the first year of childbirth.

The adjective *postpartum* before *depression* also is misleading, implying that there is something about childbirth or the early postpartum period that causes or contributes to the onset of a depressive episode. Although this may be true for postpartum psychosis (see later discussion), the empirical evidence linking childbirth per se to the onset

---

of depression is at best equivocal. Several studies (admittedly with relatively small sample sizes) comparing rates of depression in postpartum and nonpostpartum women have found little evidence of elevated rates of depression associated with childbirth. Nevertheless, depression is common in the postpartum period (and pregnancy) and should be treated. Epidemiologic research confirms that the period of highest risk for depression among women is in the age range of 18 to 45 years, the years during which most women will bear children. These data also suggest that the obstetrician–gynecologist should be alert to depression even in the context of yearly exams.

Description

The diagnosis of major depression requires the presence of either sad mood or the loss of interest and pleasure in usual activities along with four additional symptoms (Table 28.2). These symptoms must be present for more days than not over a 2-week period, must represent a change from previous functioning, and must cause significant distress or impairment in social or occupational functioning. Minor depression refers to an episode of at least 2-weeks duration in which there are two or more but less than five symptoms, (including sad mood or loss of interest). Other requirements are the same as for major depression except that the requirement for impairment in functioning is somewhat less than that for major depression.

Prevalence

Estimates based on recent meta-analyses suggest that 18.4% of women will experience a major or minor depression at some point during pregnancy, and for major depression it is 12.7%. The period prevalence for major and minor depression during the first 3 months

postpartum is 19.2%, and for major depression it is 7.1%. The rates for incident episodes in pregnancy and the postpartum period are similar, 14.5% and 6.5%, respectively. Rates of depression are higher in populations that have significant risk factors, such as women with history of depression or women living in poverty.

TABLE 28.2 Criteria for Major Depressive Episode

1. A total of five symptoms that includes depressed mood and/or loss of interest or pleasure that have been present every day or nearly every day for at least 2 weeks and represents a change in usual functioning
   1. Depressed mood
   2. Markedly diminished interest or pleasure in all or nearly all activities
   3. Significant weight loss or weight gain or significant decrease or increase in appetite
   4. Insomnia or hypersomnia
   5. Psychomotor agitation or retardation
   6. Fatigue or loss of energy
   7. Feelings of worthlessness or inappropriate guilt
   8. Diminished ability to think or concentrate
   9. Recurrent thoughts of death or suicide
2. Significant distress or impairment in functioning
3. Symptoms not due to direct effects of a substance or a general medical condition
4. Symptoms not due to normal bereavement

Effects

Depressed women relative to nondepressed women during pregnancy use more alcohol, tobacco, and drugs of abuse, and they have poorer nutrition. Depressed pregnant women also are more likely to experience nausea and vomiting, prolonged sick leave during pregnancy, and increased visits to the obstetrician. There is evidence that depressed and anxious women have higher rates of operative deliveries and are at increased risk for preterm delivery and low birth weight. Finally, infants of depressed mothers are more likely to be admitted to a neonatal care unit and have lower scores on neurologic development scales.

After the infant's birth, depressed mothers are less likely to engage in positive maternal safety practices such as using electrical outlet coverings or placing the child in a car seat. Depressed mothers interact with their infants in ways that are less sensitive, more

negative, and less stimulating than nondepressed mothers. These suboptimal parental practices have a negative effect on child development—toddlers of depressed mothers have poorer social and emotional development as demonstrated by increased likelihood of insecure attachments, unfavorable self-concepts, and delays in intellectual development. Maternal depression also is associated with increased risk of child abuse. Because women may experience depression chronically, these deleterious consequences for children persist over time and include internalizing and externalizing behavior problems as well as depression during adolescence and young adulthood.

Risk Factors

Depression and its risk factors can be best understood within a biopsychosocial framework. Some women inherit a susceptibility to depression that is manifest in emotion or affect regulation. Indicators of a basic vulnerability to depression include a personal and family history of depression and related disorders. Other risk factors are more social in nature (Table 28.3). Determination of the presence of these factors early in pregnancy will alert the clinician to the need to develop plans to follow “at-risk” patients more carefully than normally would be the case (i.e., using key interview questions or using simple screening tools). Although there is no simple algorithm linking the number of risk factors to likelihood of depression, it is the case that the greater the number of risk factors (particularly those reflecting biologic vulnerability), the greater the likelihood that an episode of depression will develop.

TABLE 28.3 Risk Factors for Perinatal Depression

Risk Factors	Comments
Previous perinatal depression	Critical risk factor
Personal history of depression or anxiety outside of perinatal period	Critical risk factor
Depression during pregnancy	Depression often will continue or reemerge after delivery
Family history of depression	Note serious depression, particularly if there has been treatment

History of premenstrual dysphoric disorder	—
Young maternal age	Adolescents are at high risk
Low income/poverty	—
Poor marital relationship	—
Poor relationship with mother	—
Poor social support, particularly that provided by the partner	May be important for women who live at a great distance from their family
Stressful life events over the past 6 to 12 months	Examples include relocation, loss of income, death of family member
Trauma related to pregnancy or birth	Examples include emergency cesarean section, significant tearing
Severe postpartum fatigue	Sleep deprivation can play a role
Interpersonal violence in past or present	Domestic violence will continue during pregnancy

Special Populations

Immigrant women represent an at-risk group. These women face several issues relevant to their risk for depression. In some cases, they are cut off from their normal sources of support, both in terms of cultural supports and family supports. Moreover, these women may experience conflicts between typical American practices and norms reflecting their native culture. Complicating this picture is the fact that Western concepts of psychologic depression do not always map on well to non-Western understandings of depression. For example, in some cultures, only the most seriously mentally ill individuals are identified

and receive care. As a consequence, women may be reluctant to acknowledge that they might be unwell because of the associated stigma.

The key for the clinician is to understand as well as possible the patient's expectations about pregnancy, childbirth, and the early postpartum period. Asking questions that illuminate possible gaps between expectations and likely reality will be helpful in preparing patients and identifying those at risk for depression. Also, the clinician should be prepared to provide education about depression and other disorders to increase the likelihood that a patient will accept help if required.

Poverty is a marker for both personal and environmental characteristics that put women at risk for depression. Poor women are likely to experience environmental stressors such as substandard housing, unsafe neighborhoods, unreliable transportation, unstable employment or unemployment, and lack of adequate child care. All of these circumstances increase the likelihood that a woman will become depressed during pregnancy or after delivery. These risk factors are exacerbated if the woman does not have a good social support network of family and friends and if she already has young children living at home.

There are many other groups that have special circumstances that put them at risk for depression. Women in lesbian relationships who have children may face social disapproval in some communities. Women with disabilities will face special challenges in parenting that if not successfully negotiated will increase their risk for depression. Finally, women who have experienced miscarriages, have lost children at a young age, or who have finally succeeded in conceiving after a long period of infertility may have unrealistic expectations about their life after the birth of the child. The larger the gap between personal expectations and the reality of parenting, the greater the likelihood that a woman will experience depression.

Treatment

Antidepressant medication often is used to treat depression during pregnancy and the postpartum period. The most commonly used medicines are selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants (TCAs). Relatively few controlled trials have evaluated antidepressants for use during the postpartum period, and there have been no controlled trials of antidepressants during pregnancy. The little research that has been done suggests that antidepressants are efficacious during pregnancy and the postpartum period—conclusions that also are supported by open trials and case reports.

There is considerable controversy regarding the safety of antidepressant medications for use during pregnancy and breast-feeding. Although there is no evidence of significant teratogenic effects of SSRIs and TCAs, there is some evidence of minor anomalies associated with some of the SSRIs as well as some evidence of withdrawal or toxicity symptoms in infants after delivery associated with maternal use of SSRIs. With regard to breast-feeding, there is increasing evidence that SSRIs and TCAs are relatively safe, particularly for older infants. Decisions regarding use of medication during pregnancy and breast-feeding should be made in consultation with the patient, recognizing that untreated depression carries its own risks for the mother

and fetus or infant that may be more significant than risks associated with medication use.

Psychologic interventions are effective for depression during pregnancy and the postpartum period. Interpersonal Psychotherapy (IPT), which has been validated for the treatment of major depression in the general population, is efficacious for depression during pregnancy and the postpartum period. Cognitive-behavioral therapy, which has been widely disseminated and is effective for major depression, also is likely to be efficacious for postpartum depression. Brief supportive counseling delivered by nonmental health professionals (usually nurses) has been validated in several European studies. This approach has particular merit because it is much less costly to deliver than conventional psychotherapies, and it is more likely to be acceptable to women who may resist treatment by mental health professionals. Brief supportive counseling and other interventions that are implemented by individuals who are not professional therapists should only be used with women who are suffering from mild to moderate depression. These women should be followed by their obstetrician as well.

Postpartum Psychosis

Description

Recognized since the time of Hippocrates, psychosis in the early postpartum period is dramatic and unsettling. Postpartum psychosis is believed to be a variant of bipolar disorder. Because postpartum psychosis significantly impairs a woman's ability to function normally, it requires prompt identification and inpatient treatment. Typically, the symptoms of postpartum psychosis emerge rapidly within the first 2 to 4 postpartum weeks and often are evident on the maternity ward. Figure 28.2 displays data regarding hospitalizations for psychosis for a cohort of 54,087 women using a 4-year window (2 years before to 2 years after childbirth). The peaking of admissions in the period immediately following delivery is highly significant and dramatically reflects the fact that the first 90 days after childbirth represents the period of highest risk in a woman's life to have a psychotic episode.

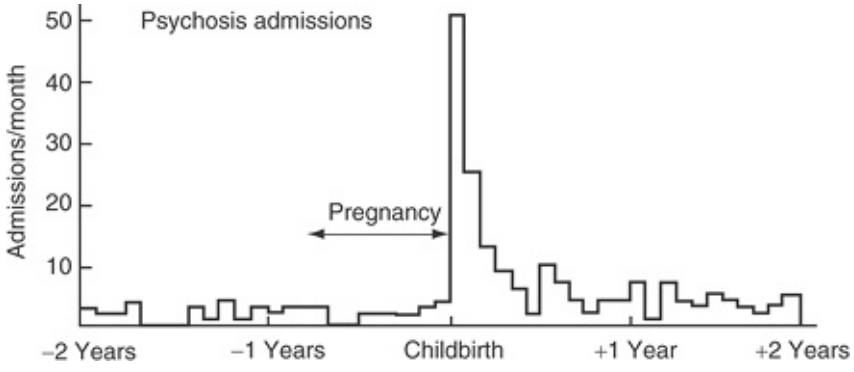

Figure 28.2 Risk for hospitalization for psychosis associated with childbirth. (From Kendell R, Chalmers J, Platz C. Epidemiology of puerperal psychoses. *Br J Psychiatry*.

1987;150:662–673.)

Clinical presentation of postpartum psychosis includes severely depressed mood; disorganized thinking; psychotic thoughts (e.g., delusions of reference, persecution, jealousy, and grandiosity); and visual, tactile, or olfactory hallucinations. Reflecting hypomania or frank mania that is common in bipolar disorder, many women with postpartum psychosis will show evidence of sleeplessness and high activity levels. The vast majority of these psychoses reflect bipolar disorder or psychotic depression. Postpartum psychosis has a rapid onset and can be associated with tragic outcome. Tragically, suicide is a leading cause of death among women in the postpartum period. A large proportion of these women will have experienced a postpartum psychosis.

Prevalence and Risk Factors

Postpartum psychosis is relatively rare, with estimates in the general population ranging between 1 and 4 women in 1,000 births. The major risk factors for postpartum psychosis are past history of postpartum psychosis, bipolar disorder, or schizoaffective disorder, which is associated with an increase in risk from 1 episode of postpartum psychosis in 500 deliveries to approximately 1 episode in 2 to 5 deliveries. Women with a history of bipolar disorder who have a first-degree relative who has had postpartum psychosis have a greater than 50% risk of experiencing a postpartum psychosis.

Treatment

Postpartum psychoses typically have a rapid onset, with the afflicted woman often being a danger to herself and her child. As a consequence, immediate inpatient hospitalization usually is indicated. Because postpartum psychoses generally present as bipolar disorder, the most common treatment is a mood stabilizer such as lithium or valproic acid or an atypical antipsychotic agent such as olanzapine or risperidone. Adjunctive psychotherapy may be indicated after the patient has stabilized. Goals for psychotherapy

in the context of postpartum psychosis include assisting the patient in regulating her mood and activity; developing or restoring her confidence in parenting; and developing skills to manage life stressors, including problematic relationships (e.g., those with the husband and/or extended family).

Perinatal Anxiety

Worry and anxiety are normal during pregnancy and the postpartum period. Women, particularly first-time mothers, face many uncertainties. Common worries of pregnant women include fears of fetal abnormality or death of the infant, being inadequate as a mother, and the physical pain of childbirth. After childbirth, new mothers commonly worry about their infant's health and safety, about being criticized in their new role as a mother, and about not having enough support.

Anxiety disorders represent clear departures from these normal concerns, are highly comorbid with depressive disorders, and are frequent in women of childbearing age. Relative to depression, there has been little research on puerperal anxiety disorders. The prevalence of generalized anxiety disorder (GAD) in the first 2 months of the postpartum period is about 8%. Comparable estimates for obsessive-compulsive disorder (OCD) and panic disorder (PD) are 3% and about 1.5%, respectively. The prevalence rate for GAD is higher than typical rates found in the community. The rates for OCD and PD are comparable to community rates.

Effects

Because anxiety and depressive disorders are highly comorbid both at the diagnostic and symptom levels, it has been difficult to tease apart the effects of anxiety and depression. Almost all of the effects on pregnancy outcomes and most of the effects associated with depression in the postpartum period are found with anxiety as well. In addition, there is evidence that independent of depression, children exposed to prenatal maternal stress display significantly more behavioral and emotional problems at 4 years of age, even after statistically controlling for postpartum maternal anxiety; antenatal, obstetric, and socioeconomic risks; and antenatal and postpartum depression. Moreover, these negative effects of exposure to maternal anxiety extend into adolescence and may affect the functioning of the hypothalamic–pituitary–adrenal (HPA) axis long term, resulting in poor affect regulation in these young adults.

Specific Anxiety Disorders

GAD is a chronic disorder characterized by uncontrollable excessive worry or anxiety (Table 28.4). It is sometimes difficult to distinguish from normal worries during pregnancy. Three diagnostic features help to make this distinction. First, in GAD, worrying is not limited to a single domain; second, it interferes with daily functioning; and, third, it is not triggered by a specific event.

TABLE 28.4 Generalized Anxiety Disorder

1. Excessive anxiety or worry about a variety of events or activities over at least 6 months occurring on most days.
2. Patient finds it difficult to control worry
3. At least three of the following six symptoms that occur on most days:
    1. Restlessness, feeling keyed up
    2. Fatigue
    3. Difficulty concentrating, mind going blank
    4. Irritability

5. Muscle tension
6. Sleep disturbance

4. Anxiety not primarily focused on features of another psychiatric disorder, such as panic attack
5. Significant distress or impairment in functioning
6. Symptoms not due to direct effects of a substance or a general medical condition
7. Does not occur exclusively in context of another disorder such as major depression

---

OCD is characterized by recurrent obsessions or compulsions that are either time consuming or cause marked distress or significant impairment and are recognized by the afflicted as unreasonable. Puerperal OCD is specifically characterized by the preponderance of intrusive aggressive obsessional thoughts (e.g., stabbing the infant, putting the infant in the microwave, throwing the infant down the stairs or out of the window, or sexually abusing the infant). As opposed to women suffering from puerperal psychosis, women with OCD consider these intrusive thoughts to be frightening and unwelcome (ego dystonic). Although obsessive thoughts generally lead to compulsive rituals outside of the postpartum period, this link is weaker in postpartum OCD. New mothers who suffer from OCD tend to simply avoid their infant (e.g., returning prematurely to work, spending large amounts of time out of the home, and avoiding giving the child a bath). One exception, however, is among new mothers who experience worry about their infant's health or safety that goes beyond ordinary worries and concerns. They often report excessive checking of the infant at night and during the day. This obsessionality also can result in the woman frequently contacting the infant's primary care provider with concerns about the baby. OCD is likely to be underreported out of fear that their infant will be removed from the home. However, once identified and treated with psychotropic medication, the symptoms typically diminish or resolve. Cognitive-behavioral therapy also appears to be effective for OCD; however, there are no treatment trials of OCD during the postpartum period.

PD is characterized by the experience of at least one unexpected panic attack (a period of intense fear) and somatic symptoms (at least four) such as palpitations, sweating, and trembling or shaking. Because some of the associated somatic symptoms (e.g., feeling of choking or chest pain) are so distressing, women with PD often will harbor fears of having an undetected and life-threatening illness. Patients with PD often overutilize health care services and typically are not reassured by negative clinical results.

Treatment

The management of anxiety disorders during pregnancy and the postpartum period is similar to that for depression. Antidepressant medication commonly is used for anxiety disorders It sometimes is supplemented with benzodiazepines in cases of severe anxiety.

Patient Education and Screening

The effective management of perinatal emotional health can be feasibly accomplished in an obstetric office setting by introducing four routine procedures. First, women should be provided educational information about their emotional health and the symptoms of perinatal mood disorders during early prenatal visits. There are many educational resources on the Internet in the form of brochures and educational materials for women and their families, including a brochure developed by the American College of Obstetrics and Gynecology (ACOG), which can be used for clinician–patient and family discussion and can be given to patients and family members (refer to the Suggested Readings section). Although the primary goal of education is to inform patients of the common symptoms of these disorders, a secondary purpose is to make the discussion of emotional health a routine and acceptable part of the prenatal visit.

Second, routine risk assessment will help to identify patients who will require subsequent monitoring. Most women without a personal or family history of psychologic disorders will successfully navigate pregnancy and the birth of their child, leaving only a few who require special attention. To identify women at risk, it is important to ask questions during early prenatal visits regarding a woman's personal and family psychiatric history and other psychosocial risk factors (Table 28.5). These questions are designed to identify women who may need to be followed more closely than the average patient or women who need to be referred to a psychiatrist for additional support and monitoring during pregnancy and the postpartum period. The major risk factors are previous personal or family history of depression, anxiety, bipolar illness, and any psychotic illness including postpartum psychosis. These women may increase their risk further by discontinuing medication (either unilaterally or in consultation with their physician) because of concern about the effects of medication on the fetus. Routine risk assessment of all women early in the antenatal period and the development of protocols for women at risk can therefore help to detect risk in these unsuspecting cases and avert tragic consequences.

Third, all patients should be screened for depression at least once during pregnancy and once in the postpartum period. The postpartum follow-up visit usually is a good time to do a screen for depression. Consistent with this standard, the U.S. Preventive Services Task Force recommends screening adults for depression in clinical practices that have systems in place to assure accurate diagnosis, effective treatment, and follow-up. Further supporting regular screening during pregnancy and the postpartum period is a 2006 New Jersey state law mandating depression screening during pregnancy, on the maternity ward, and at a postpartum visit. Despite these recommendations, many postpartum depressions will be missed because they begin after the woman's last visit to the obstetrician. Women should therefore be encouraged to contact the obstetrician if emotional problems develop later in the postpartum period.

Women who have already been educated about perinatal mood disorders in an early prenatal visit usually will be accepting of depression screening later in pregnancy and at the postpartum visit. Depression screening can be feasibly accomplished by utilizing one of the widely used screening tools. The Edinburgh Postnatal Depression Scale (EPDS) and the Postpartum Depression Screening Scale (PDSS) were both developed and validated as

screens for perinatal depression. The Patient Health Questionnaire (PHQ-9) was designed to screen for depression in general primary care settings, but it is also appropriate for depression screening during pregnancy and in the postpartum period. The procedures for routine depression screening utilizing the EPDS are described in Figures 28.3 and 28.4. In addition to the implementation of these simple procedures, routine depression screening also requires the development of a network of mental health professionals (both psychiatrists and psychotherapists such as psychologists and social workers) for referral and follow-up. This referral network is especially important for the obstetrician who prefers not to personally manage the treatment of depression or other mental health problems and for those cases that are more complicated, reflect severe symptoms, or do not respond to first-line treatment with an antidepressant.

Finally, along with assessing risk and doing screening, it is important for the physician to evaluate and rule out potential physical causes of depression or anxiety symptoms, notably hypo- or hyperthyroidism or other medical conditions that lead to symptoms that mimic depression or anxiety. Prescribed medications and drugs of abuse also may be responsible for producing depression and anxiety symptoms.

TABLE 28.5 Risk Assessment Interview

Target Risk Factor	Examples of Questions	Comments
History of depression or anxiety	Have you ever been treated (as an outpatient or an inpatient) for depression or anxiety with medication or counseling or psychotherapy? Have you ever had a period lasting 2 weeks or more when you were depressed or sad or during which you lost interest in your usual activities? Did you find it hard to function normally during this period?	If the episode is ongoing, you will want to inquire about current treatment. A referral to a psychiatrist or counselor may be indicated. These questions may already have been answered by

History of bipolar disorder or psychosis	Have you ever been treated for bipolar disorder or what is sometimes called manic-depressive disorder? Have you ever had a period during which you were seeing or hearing things that other people could not see or hear? Have you ever believed things that other people found unusual?	asking about depression and anxiety. Here you are asking about indications of hallucinations or delusions in the past. Be sure to inquire if these disorders occurred during pregnancy or the postpartum period.
Family history of psychiatric illness	Have your parents or siblings: … ever been treated for a psychiatric disorder? … ever been treated for bipolar disorder or what is sometimes called manic-depressive disorder? … ever had a period during which they were seeing or hearing things that other people could not see or hear? … or ever believed things that other people found unusual?	Here you are interested in serious psychiatric illness in family members. Be sure to inquire about postpartum episodes in mothers or sisters.
Social support	Do you have concerns about the support that you will receive after the baby comes from your husband (partner) or from your other family members or your friends?	Be alert to significant marital conflict or domestic abuse. Be alert to circumstances in which a woman has very little local support from family and friends.

Stressful life events	Are you anticipating or have you experienced any significant events such as death or serious illness of a family member, loss of income, or the need to move your household?	Negative life events can overwhelm the coping abilities of women who are already struggling to manage their current life responsibilities.
Other risk factors		You might ask about any of the factors described in Table 28.3 if you believe that they might be relevant for your patient.

The EPDS is a 10-item self-report scale, developed specifically for screening perinatal women for depression. This scale, which is easy to use and acceptable to both perinatal women and health care providers, can be completed during pregnancy and the postpartum period. Patients can complete the EPDS as a checklist and elevated items can be reviewed by either a nurse or the obstetrician. Items 1, 2, and 4 are scored 0 to 3; the rest of the items are scored 3 to 0. A review of elevated items with the patient provides a comfortable venue for the discussion of the woman's emotional state. A cutoff score of 12/13, which is associated with good diagnostic sensitivity and specificity, provides an easy to use algorithm for making referral decisions. Typically, a patient who receives an elevated EPDS score might be checked again at the next prenatal visit or someone might check-in on her mood state in between appointments. If her mood remains consistently low, referral to a mental health specialist might be considered.

Figure 28.3 Routine depression screening procedures for the Edinburgh Postnatal Depression Scale.

As you have recently had a baby, we would like to know how you are feeling. Please UNDERLINE the answer which comes closest to how you have felt IN THE PAST 7 DAYS, not just how you feel today.

Here is an example, already completed.

I have felt happy.

Yes, all the time.
Yes, most of the time.
No, not very often.
No, not at all.

In the past 7 days:

1. I have been able to laugh and see the funny side of things.

   As much as I always could.
   Not quite so much now.
   Definitely not so much now.
   Not at all.

2. I have looked forward with enjoyment to things.

   As much as I ever did.
   Rather less than I used to.
   Definitely less than I used to.
   Hardly at all.

3. I have blamed myself unnecessarily when things went wrong.

   Yes, most of the time.
   Yes, some of the time.
   Not very often.
   No, never.

4. I have been anxious or worried for no good reason.

   No not at all.
   Hardly ever.
   Yes, sometimes.
   Yes, very often.

5. I have felt scared or panicky for no very good reason.

   Yes, quite a lot.
   Yes, sometimes.
   No, not much.
   No, not at all.

In the past 7 days:

6. Things have been getting on top of me.

   Yes, most of the time I haven't been able to cope at all.
   Yes, sometimes I haven't been coping as well as usual.
   No, most of the time I have coped quite well.
   No, I have been coping as well as ever.

7. I have been so unhappy that I have had difficulty sleeping.

   Yes, most of the time.
   Yes, sometimes.
   Not very often.
   No, not at all.

8. I have felt sad or miserable.

   Yes, most of the time.
   Yes, quite often.
   Not very often.
   No, not at all.

9. I have been so unhappy that I have been crying.

   Yes, most of the time.
   Yes, quite often.
   Only occasionally.
   No, never.

10. The thought of harming myself has occurred to me.

    Yes, quite often.
    Sometimes.
    Hardly ever.
    Never

Figure 28.4 Edinburgh Postnatal Depression Scale. © 1987 The Royal College of Psychiatrists. The Edinburgh Postnatal Depression Scale may be photocopied by individual researchers or clinicians for their own use without seeking permission from the publishers. The scale must be copied in full and all copies must acknowledge the following source: Cox JL, Holden JM, and Sagovsky R. (1987). Detection of postnatal depression. Development of the 10-item Edinburgh Postnatal Depression Scale. *British Journal of Psychiatry*, 150, 782–786. Written permission must be obtained from the Royal College of Psychiatrists for copying and distribution to others or for republication (in print, online or by any other medium.) Note: Questions 1, 2, and 4 are scored 0–3, remaining questions are scored 3–0.

Women often develop a significant trust in their obstetrician during this rather vulnerable

and important time in their lives. Because of this trust, obstetricians are well situated to implement these practices of risk assessment, formal screening, clinical management, and clinical referral to ensure the emotional health of their patients.

Summary Points

- Depressive and anxiety disorders are common during pregnancy and the postpartum period. The obstetrician has a significant role in the detection and treatment of these disorders.
- Postpartum blues, common in the first week after delivery, often is experienced as a dysregulation of mood that usually diminishes within a few days. There are no significant sequelae, and it does not require treatment.
- Depressions during pregnancy and the postpartum period range from mild to severe and are diagnosed based on DSM-IV criteria for major and minor depression. The period prevalence for minor and major depression during pregnancy is 18.4%, and for the first 3 months postpartum it is 19.2%.
- Personal history of depression or anxiety, significant social stress, and poorly functioning social networks are major risk factors for depression during pregnancy and the postpartum period.
- Medical and psychologic interventions are effective for postpartum depression.
- Postpartum psychosis is a rare and extremely serious disorder characterized by psychotic symptoms such as hallucinations and delusions. It usually presents as bipolar disorder and typically requires inpatient treatment. Past history of psychosis or bipolar disorder increases the risk.
- Anxiety disorders often occur with depression in pregnant and postpartum women. Significant anxiety during pregnancy can have deleterious long-term consequences for the infant.
- Obstetrical providers should educate patients about emotional health during pregnancy and the postpartum period. All patients should be screened for depression at least once during pregnancy and once during the postpartum period.

Office Gynecology and Surgical Procedures

Marian D. Damewood
William R. Keye Jr.
Charles C. Coddington III

The number of women in the United States is approximately 153 million and increasing. Women in their reproductive years represent 49% of the total, with those under age 15 at 20% and those over 50 at 31%. The number of postmenopausal women is projected to increase to 52 million in 2010 and 62 million in 2020. The entire female population is estimated to grow over 17% in the next 20 years.

Gynecologists have a major role in the provision of health care for women, with changes in technology, patient expectations, office procedures, and health care delivery formats providing new challenges. The number, percentage, and characteristics of patients who receive care exclusively from gynecologists are increasing. Thus, the complexity and details of the gynecologic history and examination are of great importance in women's health care. Gynecologic procedures that primarily were performed in the hospital setting can now be performed in the office, such as transvaginal ultrasound with saline infusion sonography (SIS), decreasing the number of hospital-based diagnostic procedures. These changes in the specialty of gynecology coupled with recent demands on the medical community for cost control has stimulated the trend for more outpatient care and office-based surgery. The technology to perform minor gynecologic surgical procedures in an office setting or procedure room is readily available. This chapter will discuss the gynecologic history and examination and review a number of procedures that may, with the appropriate facilities and patient selection, be performed in an office surgical setting.

Preventive Care

A great deal of gynecologic care is preventative and depends on population characteristics, risk profiles, epidemiology, and statistics for screening programs. Annual examinations may be recorded on data sheets containing “check-off” lists for preventive services. An example of this type of form is available at the American College of Obstetricians and Gynecologists (ACOG) website (*http:// www.acog.com*). Reminder systems for follow-up visits for Papanicolaou (Pap) smears and mammograms can help to integrate disease prevention and health maintenance into gynecologic practice. In addition, gynecologists play a major role

in screening for domestic violence, depression, injury, and other psychosocial concerns as well as sexual dysfunction. Counseling practices for sexually transmitted diseases (STDs) human immunodeficiency virus (HIV), and human papillomavirus (HPV) infection has changed markedly over the past 2 decades.

In June 2006, the Food and Drug Administration (FDA) licensed the first HPV vaccine developed to prevent cervical cancer and other diseases in females caused by HPV infection. The quadrivalent vaccine labeled as Gardasil® protects against four HPV subtypes (6, 11, 16, 18). These types are responsible for approximately 70% of cervical cancers and 90% of genital warts. Indications at this time include the use of this vaccine in females ages 9 to 26 years. Ideally, it should be administered before the onset of sexual activity but may be useful afterward as well. The vaccine has been tested in over 11,000 women worldwide, with studies noting that there are no serious side effects. Clinical trials have

---

demonstrated close to 100% efficacy in preventing cervical, vulvar, and vaginal precancers as well as genital warts caused by the four HPV types. If the patient is already infected by one of the HPV types, the vaccine will not prevent disease from that type but will prevent against the remainder. Current studies suggest that the vaccine is effective for at least 5 years.

Additional preventative measures include genetic screening for some forms of breast and ovarian cancer, which could result in the assimilation of routine genetics into gynecologic office practice. In addition, postmenopausal women have a variety of preventive health needs including breast and cervical cancer screening and primary care such as cholesterol screening and smoking cessation. This health care interaction begins with the gynecologic history and follows up with physical examination, along with office diagnostic procedures.

Medical History

Women who want to be actively involved in decisions regarding their gynecologic care usually expect physicians to use the history to obtain information concerning not only medical issues but also concerns regarding family history, cancer risk, sexual partners, or significant personal and social issues. The quality of the medical care provided by a physician, as well as the type of the relationship between the physician and patient, may be determined largely by the depth of the gynecologic history.

A comprehensive history and physical examination should be performed on each new patient. It is important to establish a database on each patient, along with a physician-patient relationship based on good communication. Scheduling should permit dedicated time for new patient bookings to allow sufficient time to obtain the information, perform an examination, provide the management plan, and allow for health education. Many preprinted history and physical examination forms exist, some of which may be obtained at the ACOG website, including the Women's Health Record for initial and long-term follow up office care. Some physicians prefer to use patient-directed history forms, others use an assistant or nurse, and still others prefer to take the history personally. Multiple studies have documented that personally directed questioning is more productive than the use of

patient questionnaires. Understanding the preventive medicine needs based on family history, patient history and lifestyle, and integrated functional medical investigations is important. The development of personal preventive programs impacts the ongoing health and wellness relationship.

Once a good database has been established, updates should include any changes in gynecologic or pregnancy history. Additional surgery, accidents, hospitalizations, new medications, or allergies should be added. Any changes in family history should be noted. This type of history taking, both for new and established patients, results in a well-organized, problem-oriented medical record. Besides obtaining the historical details, it is important to understand why the patient is seeking care in the gynecologist's office. In addition to understanding and meeting patients' needs, physicians must be prepared to do a medical evaluation in a physically and emotionally comfortable setting, making the visit as comfortable and informative as possible so that women leave the office calm and with their questions answered. This is achieved by an understanding attitude and an ability to listen.

Several things can be done when obtaining a history to reduce patients' anxiety.

- The history should be obtained in as comfortable and private a setting as possible. Many patients prefer to be clothed and seated at the same level as the physician, especially if they are meeting for the first time. Other patients may choose to change into an examination robe before seeing the physician if the visit is for a follow-up examination. Under most circumstances, patients should be interviewed alone. Exceptions may be made for children, adolescents, and mentally impaired women or at the specific request to have an attendant or a family member present. Even in these situations, it usually is a good idea to give patients the opportunity of speaking privately.
- The initial portion of the interview should be designed to put patients at ease. This often can be accomplished by discussing neutral and nonmedical subjects, such as recent recreational activities, employment, and family. The discussion should be viewed not merely as a means of relaxing patients but also as an opportunity for gathering information about their psychologic and social backgrounds.
- Physicians should not make assumptions about patients' backgrounds. For example, a clinician usually assumes that all adult female patients are sexually active and heterosexual. Either assumption or both may be incorrect. By asking neutral, open-ended questions (e.g., “Are you sexually active?” and “Are you having sex with men?”), physicians let patients know that these assumptions have not been made.
- An appropriate length of time should be scheduled to allow a patient to tell her story without being hurried or interrupted. Interruptions from phone calls or office staff should be avoided, if at all possible, so that the patient has the physician's undivided attention.
- Patients should be made to feel that they have the respect of the physician. This means that they will have the opportunity of sharing in the decision-making process, will not be forced to endure unwanted pain, will have what they tell the physician held in strict confidence, and are free to ask questions. Patient satisfaction is related to the

time required to get an appointment, the patient mix in the reception area, the length of waiting time in the reception or examination room, the attitude of the office staff, and the billing procedures.

In this age of rapidly expanding medical knowledge and an emphasis on preventive health care, it is ironic that there is widespread dissatisfaction in physician–patient relationships. There is increasing evidence that a physician's attitude influences not only patient compliance but also the ultimate effect of therapy. The first step in effective communication is establishing a good physician–patient relationship. Research in human relations has demonstrated that a rapport is most readily established if physicians possess and display certain qualities including empathy, respect, non-possessive warmth, genuineness, non-judgmental acceptance, kindness, and interest. These qualities are common to all effective counselors and can be learned by most clinicians. They reinforce these qualities by summarizing their understanding of patients' problems in terms that patients can understand. The communication of warmth, kindness, and interest is, for the most part, non-verbal. Examples of nonverbal communication that convey these qualities include maintaining eye contact, having a relaxed open posture, facing the patient, leaning toward the patient, showing a facial expression consistent with the patient's predominant emotion, and having a modulated, nonmechanical tone of voice.

The history provides information about the total patient and is perhaps the most important part of the gynecologic evaluation. In most cases, it provides the data to establish a tentative diagnosis before the physical examination. If the gynecologic history is sufficiently comprehensive, it should in many cases permit a physician to narrow the likely diagnoses. Like a hospital chart, the office chart is a legal and medical record. As such, it is subject to subpoena, and whatever is recorded in it may someday need to be defended in court. It should not contain extraneous or casually entered material, and the notes should be sufficiently complete that the case can be reconstructed readily.

The gynecologic history should include the following information:

. Chief complaint

A. Primary problem

B. Duration

C. Severity

D. Precipitating and ameliorating factors

E. Occurrence in relation to other events (e.g., menstrual cycle, coital activity, gastrointestinal activity, voiding, other pertinent functions)

F. History of similar symptom

G. Outcome of previous therapies

H. Impact on the patient's quality of life, self-image, relationship with family, and daily activities

I. Role of other stresses in the chief complaint

. Menstrual history

A. Age at menarche
B. Date of onset of last normal menstrual period
C. Timing of menstrual periods
D. Duration and quantity (i.e., number of pads used per day) of flow
E. Degree of discomfort
F. Premenstrual symptoms
G. Contraception (i.e., current and past methods)

. Obstetric history

A. Number of pregnancies
B. Number of living children
C. Number of abortions, spontaneous or induced
D. History of previous pregnancies (i.e., duration of pregnancy, antepartum complications, duration of labor, type of delivery, anesthesia used, intrapartum complications, postpartum complications, hospital, physician)
E. Perinatal status of fetuses (i.e., birth weights, early growth and development of children, including feeding habits, growth, overall well-being, current status)
F. History of infertility (evaluation, diagnosis, treatment, outcome)

. Medical historys

A. Allergies
B. Medications currently used
C. Past and current medical problems
D. Hospitalizations (reason, date, outcome)
E. Vaccinations (type, date), including HPV vaccine

. Surgical history

A. Operative procedures (i.e., outcome, complications)

. Review of systems

A. Pulmonary
B. Cardiovascular
C. Gastrointestinal
D. Urinary
E. Vascular

F. Neurologic
G. Endocrinologic
H. Immunologic

. Breast symptoms

A. Masses
B. Galactorrhea
C. Pain
D. Family history

. Social history

A. Exercise
B. Dietary habits (including calcium or folic acid supplementation)
C. Drug use
D. Alcohol use
E. Smoking habits
F. Marital status
G. Number of years married

H. Sexual history (partners, contraception, protection from STDs)
I. Occupational history (i.e., exposure to environmental toxins, ionizing radiation, infectious agents)
J. Emotional, physical, or sexual abuse

. Family history

A. Significant medical and surgical disorders in family members

Chief Complaint

It often is effective to begin the history with an open-ended question concerning the symptoms that patients may have. This gives them the opportunity to describe their symptoms and concerns in their own words. Less information will be obtained if the interviewer asks only focused, closed-ended questions to which patients can answer only yes or no. Some clinicians find it helpful to have an outline of questions about the gynecologic history to obtain all the necessary information.

The following questions are typical of a gynecologic history:

- What were the circumstances at the time the problem began (i.e., time, place, activity, cycles)?

- What has been the sequence of events? (Having a calendar to refer to is often helpful.)
- Have you had this problem before? Can you describe the previous occurrence and what led to its disappearance?
- To what extent is the problem interfering with your daily life and the life of your family?
- Have you had previous evaluations or treatments? (Records from previous physicians may be helpful.)
- Why did you seek evaluation for the problem now?
- What questions do you want answered today? What do you expect and want from today's visit?

Menstrual History

The cycle interval is counted from the first day of menstrual flow of one cycle to the first day of next menstrual flow. There is a wide range of normal, and a recent change in the usual pattern may be a more reliable sign of a problem than the absolute interval. Although 28-day cycles are the median, only a small percentage of women have cycles of that length. The normal range for ovulatory cycles is between 24 and 35 days.

Duration of flow is usually 4 to 6 days. Estimating the amount of menstrual flow by history is difficult. The average blood loss is 30 mL (range 10 to 80 mL). The need to frequently change saturated tampons or pads (i.e., more often than one per hour for 6 or more hours) and the passage of many or large blood clots usually are signs of excessive blood flow.

Some degree of dysmenorrhea is common. It usually begins just before or soon after the onset of bleeding and subsides by day 2 or 3 of flow. The discomfort is characteristically lower midline and often is associated with backache and, in primary dysmenorrhea, with systemic symptoms such as lightheadedness, diarrhea, nausea, and headache. Mittelschmerz, or midcycle unilateral pelvic pain at the time of ovulation, usually is mild and seldom lasts for more than 1 or 2 days. It is important to ask whether or not there is bleeding between menstrual periods and whether this occurs after coitus. Intermenstrual bleeding is a characteristic sign of cervical cancer, although it also is present with benign lesions such as cervical polyps and fibroids or infection.

Finally, physicians should inquire about the presence of premenstrual syndrome (PMS). The symptoms experienced by women with PMS may be physical, emotional, and behavioral. The most common of the physical symptoms are fatigue, headache, abdominal bloating, breast tenderness and swelling, acne, joint pain, constipation, and recurring herpetic or yeast infections. Although these physical symptoms often are uncomfortable, most women with moderate to severe PMS complain most about their premenstrual emotional symptoms, especially depression, anxiety, hostility, irritability, rapid mood changes, altered libido, and sensitivity to rejection. Women with PMS also may experience changes in behavior, including physical or verbal abuse of others, suicide attempts, withdrawal, craving for or intolerance of alcohol, craving for sugar or chocolate, and binge eating. Many women report that long-standing or severe PMS causes psychologic or social problems

that may be as disruptive as the premenstrual symptoms themselves.

Sexual History

The screening for sexual history is designed to determine whether major sexual problems exist that need in-depth evaluation and therapy and whether the patient should be referred elsewhere for more intensive evaluation. In an attempt to put patients at ease, physicians can begin the sexual history by prefacing questions with statements such as “Most people experience….” or “Because sexual problems can develop as part of other gynecologic problems….” If physicians can convey a willingness to help, patients are more likely to discuss problems. In addition, the screening history should begin with a discussion of topics that are unlikely to provoke anxiety. For example, questions about the occurrence of pain during intercourse are less likely to cause anxiety than questions about orgasmic function or noncoital sexual practices.

With these principles in mind, physicians can begin with a general question, such as “Are you having any sexual problems?” If the response is non-committal, a more specific question, for example, “Are you satisfied with the frequency of sexual relations?” can be posed. If a problem is identified,

---

physicians can proceed to the problem-oriented sexual history and ask about the date of onset, severity, previous evaluation and treatment, the results of such treatment, conditions that diminish or exacerbate the problem, the patient's response to the problem, and the effect of the problem on the patient's relationship with her partner. To conclude the screening history, physicians should invite patients to discuss concerns that have not been covered by the screening history. Even if a patient denies having any problems, the screening history is of value because it demonstrates the physician's willingness to discuss sexual problems.

The problem-oriented history is designed to differentiate organic from psychogenic sexual problems, determine the complexity of the problem, determine the need for referral of the patient to a more sophisticated sexual counselor, and provide information for the formulation of a treatment program if the physician elects to treat the patient. The problem-oriented sexual history should include onset, severity, course, conditions increasing the severity of the problem, prior evaluation and treatment if any, and the impact on the patient and her sexual or marital relationship. A treatment or referral can be formulated on the basis of discussion of these and related questions.

It is important to obtain a history of STDs. Physicians should tactfully question patients about past episodes of STDs, sexual practices, number of sexual partners, background of sexual partners, use of barrier forms of contraception, intravenous drug use, previous blood transfusions, genital lesions, persistent vaginal discharge, and pelvic pain. The discussion of STDs provides an opportunity to discuss modes of prevention, including the safe sex practice and the use of barrier methods of contraception when the sexual history of a partner is unknown.

Psychosocial History

Health care providers can play a vital role in identifying women who are victims of psychologic, physical, or sexual abuse. Unfortunately, women who are abused are often hesitant to acknowledge it. Questions should include the following:

- Are you or have ever been in a relationship in which you have been physically hurt or threatened by a partner?
- Have you ever been forced to have sex against your will?
- Has your partner ever destroyed things that you care about?
- Are you or have you ever been in a relationship in which you were treated badly?

If the answer to any of these questions is yes, the physical examination may reveal signs of physical abuse. In addition, many abused women may report chronic pain, sleep or appetite disorders, and frequent vaginal and urinary infections. One may suspect an abusive relationship if the patient's partner is present at every office visit, insists on staying close to the patient, and answers questions directed to her. Once abuse is recognized, the physician must acknowledge the problem and direct the woman to an appropriate community resource. Inquiry about the woman's safety should be made before she leaves the office. Some physicians obtain wallet-sized cards or brochures from local agencies that provide support and protection for battered women and place them in the restrooms. This provides an option for those women who would not acknowledge abuse when asked by their health care providers.

Depression is another very common condition that may be detected during an annual gynecologic examination. The potential life-threatening nature of depression and the availability of effective antidepressant medications with few side effects make it even more important to diagnose depression. To aid in diagnosing depression, physicians can ask the following questions:

- Have you lost interest in the things you used to enjoy?
- Do you feel sad, “blue,” or “down in the dumps”?
- Do you have feelings of guilt or worthlessness?
- Do you have thoughts of death or suicide?
- Are you sleeping too much, or do you have difficulty falling or staying asleep?
- Do you have a loss of energy and feel tired all the time?

An affirmative answer to one or more of these questions may indicate the patient is depressed and a candidate for psychotherapy or drug therapy. More than 50% of depressed individuals will respond to antidepressant therapy.

Adolescent History

As the percentage of adolescents increases, gynecologists find themselves dealing with problems unique to the 13- to 19-year-old age group. These include menstrual and breast disorders, pubertal development problems, and the challenges presented by sexually active

adolescents. Over 50% of high school students, male and female, have had sexual intercourse, and less than half have reported that they used contraception the last time they had intercourse. The frequency of adolescent sexual activity and its consequences mean that gynecologists caring for adolescents certainly will encounter gynecologic problems such as STDs and pregnancy among their young patients. Gynecologists who provide such care to adolescents, particularly with respect to history taking, need to know their specific needs, with particular importance placed on confidentiality. The gynecologist must be prepared to handle multiple issues related to pubertal development, sexuality, self-esteem, and body image and approach the adolescent patient in a somewhat different manner than that used for adults. This includes having the parent present with young women, 14 years of age or less, during history taking and speaking to the adolescent first when she is fully clothed. If the adolescent refuses to have the parent or mother present, the physician may ask the young woman's permission to speak to her mother or guardian with respect to important issues,

especially those requiring treatment. A detailed educational pamphlet on the first gynecologic visit is available at the ACOG website.

Gynecologic Examination

The pelvic examination is one of the most commonly performed medical procedures and is considered a highly unpleasant experience by most women. Aspects of the pelvic examination, such as genital exposure, make it likely that women will have feelings of anxiety, vulnerability, apprehension, or fear. It is important that the gynecologist observes a woman's behavior, which will communicate her feelings and possibly anxieties. A complete physical examination most commonly is performed at the first visit. In order to reduce anxiety, patients should be encouraged to give feedback to the physician during the examination, especially when the examination causes pain. Description of the examination, including which portions may include mild to moderate discomfort (such as the rectal examination), should be given to the patient beforehand. When the physician enters the room, the patient should be sitting up on the examination table with the examination gown completely covering her. During the physical examination, a female chaperone, either a nurse or medical assistant, must be present. This woman can assist the physician and also lend psychologic support to the patient. The patient should be asked to lie down and place her feet in the stirrups, and the physician should be at the level of the patient's head, speaking to her when her position is changed. This dialog may include the physician asking the patient about her symptoms, location of any pain, or other pertinent questions. Studies evaluating anxiety in women with respect to pelvic examinations have found those who have had a less positive first experience have higher anxiety levels with their gynecologists.

A general impression should be recorded of patient's nutritional state, distribution and proportion of body fat, texture and condition of skin and hair, presence of facial or excessive body hair, acne, abnormal nevi (>5 mm, asymmetric outline, variable pigmentation, and indistinct borders), and any specific physical features. The patient's hair is examined for cleanliness, texture, and scalp health. The eye examination may include

ophthalmoscopy to detect retinal aberrations. The patient's nose, throat, and teeth also can be checked. Finally, the anterior cervical, posterior cervical, and supraclavicular nodes, as well as the thyroid gland, should be palpated.

Hypertension is the most common chronic disease in women over 50 years of age. Therefore, every woman, especially one over 50, should have her blood pressure measured with her annual gynecologic examination. Careful cardiac auscultation may be performed as part of the gynecologic examination. Mitral valve prolapse (MVP), the most common cardiac condition diagnosed by auscultation in asymptomatic women, can be problematic during surgery or pregnancy. From the back, a curvature of the vertebral column can be assessed by observation and palpation.

Examination of the Breasts

The breast examination begins with a breast-oriented history. Patients are asked whether they have noted any lumps, pain, discharge, or other changes in their breasts. They also should be asked about breast surgery, date and results of the last mammogram, current and past hormone use, and family history of breast cancer. The axillary and supraclavicular nodes are then palpated. The breasts should be examined with patients both sitting or standing and lying supine. In the vertical position, the nipples and inframammary folds are evaluated for asymmetry. The examiner looks for elevation of one nipple, flattening of one breast, dimpling of the skin, or asymmetry by having patients raise both arms above the head and lean forward and then contract the pectoral muscles with hands on hips. Then, with patients in the supine position with one arm above the head, all quadrants of each breast are felt with the flat part of the distal phalanges of the fingers. The subareolar area also should be palpated, because up to 15% of carcinomas occur under the areola. The axillary and supraclavicular areas should be palpated for enlarged or tender lymph nodes. The nipples and adjacent areolar tissue are then compressed in an effort to express fluid from the nipple. The examination of the breasts should conclude with a description of the examination results and a recommendation for follow-up physical or imaging examinations.

Gynecologists as primary care physicians have the responsibility for screening mammography. A diagnostic approach to the breast, including clinical breast examination, possible fine-needle aspiration, and mammography, may be implemented by the gynecologist and performed with findings of a breast mass or suspicious area. Ongoing discussion has addressed the value of screening mammography with respect to breast cancer mortality. Studies have noted that mammograms can be lifesaving and that recommendations for gynecologists based on all available information are to urge all women to follow the advice of their physicians and obtain mammograms per current clinical guidelines.

Examination of the Abdomen

Patients should be positioned supine, with arms against the body to relax the abdominal musculature. If necessary to obtain adequate relaxation, the knees can be elevated and flexed. In a methodical and consistent manner, all quadrants of the abdomen should be palpated. Relaxation of the abdomen to evaluate a suspected mass can be assisted by

having patients breathe deeply and then exhale. After all quadrants have been examined, the inguinal nodes should be palpated. Asking about the origin of abdominal scars

may provide information that was not elicited during the history.

Bulging of the flanks suggests free abdominal fluid, but thin-walled ovarian cysts and irregularly shaped uterine leiomyomata may have a similar clinical picture. Although large ovarian cysts and leiomyomata most commonly cause protrusion of the anterior abdominal wall, there are many confusing exceptions. Percussion for areas of flatness or tympany and for shifting dullness may aid in determining whether the distension is caused by intraperitoneal fluid or by intestinal gas. Auscultation is useful in differentiating among a large tumor and distended bowel.

Examination of the Extremities

Examination of the lower extremities supplies important information regarding the cardiovascular system. Any edema or varicosities should be noted. In a patient with congenital absence of the vagina, evidence of muscle atrophy in the extremities should be sought because such patients may have nerve root compression secondary to congenital vertebral anomalies. The peripheral pulses and reflexes also may be evaluated at this time. Examination of the calves and ankles for melanomas or dysplastic nevi is advisable.

Pelvic Examination

The first examination of the female genitourinary system often takes place in the neonatal period. An examination is indicated at any age when abnormal bleeding or pelvic symptoms are present, there are questions about primary or secondary sexual development, or sexual activity is being initiated. For teenagers, the first pelvic examination should probably occur at 18 years of age or at the initiation of sexual activity, whichever comes first. Examinations usually are repeated at yearly intervals, at which time a Pap smear should be performed in addition to a pelvic examination and a screening for breast cancer and hypertension in the later reproductive years.

The pelvic examination provides physicians with an opportunity to answer questions and to educate with respect to pelvic anatomy, physical development, and sexual function. Patients often are reassured if the physician carries on a running dialogue, describing the findings, asking and answering questions, and demonstrating on occasion the physical findings with the aid of a handheld mirror. To maximize the educational aspects of an examination, clinicians can (a) describe all procedures in advance; (b) maintain eye contact with patients during the examination, whenever possible; and (c) explain all findings clearly.

The pelvic examination is performed with the patient lying on her back with both knees flexed. The buttocks are positioned at the edge of the examining table, and the feet are supported by stirrups. This position allows the necessary exposure of the pelvic organs. Traditionally, patients have been placed with the head and body in a horizontal position. This position does not allow maintaining eye contact and increases a patient's sense of

vulnerability. The alternative, assuming the availability of an adjustable examination table, is to elevate the head of the table at an angle between 30 and 90 degrees. There are no apparent technical disadvantages to this alternative position, and many patients find it easier to relax, actually making the bimanual part of the examination more accurate. The patient should empty her bladder just before the examination.

The minimal equipment needed to perform a pelvic examination includes a good light source, a speculum of the correct size, a nonsterile glove, and a water-soluble lubricant. Additional supplies that should be available in the examination room include a variety of speculum sizes, materials to obtain cytologic samples including fixatives, various culture media, large cotton-tipped swabs, pH indicator paper, and screening tests for fecal occult blood. Specialized examinations require other specific equipment.

The pelvic examination begins with inspection of the vulva. Physicians should note and record evidence of developmental abnormalities as well as the general state of cleanliness, discharge, hair growth and distribution, and abnormalities of the skin, including tumors, ulcerations, scratch marks, rashes, and minor lacerations or bruises. Vulvar varicosities or hemorrhoids also should be noted. A careful inspection of the skin folds, vulva, and pubic hair may reveal occult lesions or infection. The vulva should be palpated for subcutaneous lesions. The labia are then spread, and the condition of the hymen and vulvovaginal skin and the size of the clitoris are noted. The examination should be performed in a systematic manner and include the labia majora, labia minora, vestibule, urethral opening, periurethral glands, Bartholin glands, perineum, anus, and perianal areas. With an index finger in the outer vagina and the thumb on the perineum, the labia and urethra are palpated for masses or tenderness. Patients are asked to contract the muscles of the vaginal opening to assess the tone of the levator muscles and the degree of perineal support and then to strain to reveal the presence of a urethrocele, cystocele, rectocele, enterocele, or vaginal or cervical prolapse.

The vagina should first be inspected with the aid of a speculum. Specula come in various sizes, and an appropriate size should be selected, using the largest size that is comfortable and provides the best visualization. Painless insertion of the speculum may be aided by several techniques. First, the muscles at the opening of the vagina may be relaxed by gentle downward pressure with one or two fingers. The speculum may be moistened with warm water before insertion, but other types of lubricants should be avoided if cultures or cytologic samples are to be collected. The speculum blades should be inserted obliquely, not vertically, through the introitus; immediately rotated to the horizontal plane; and then slowly opened after the vaginal apex is reached. The vaginal walls and cervix should

---

be inspected for lesions. Any vaginal discharge should be assessed for volume, color, consistency, and odor. The endocervical mucus also should be examined. Samples for cervical or vaginal cytologic examination and cultures and direct microscopic examination of the vaginal or cervical discharge should be obtained as indicated. Before the speculum is removed, the cervix should be evaluated for ectropion, erosion, infection, discharge, lacerations, polyps, ulcerations, and tumors. As the speculum is removed, with the patient bearing down, the degree of vaginal wall relaxation and uterine prolapse can be assessed. With the speculum removed and the patient still bearing down, they physician can screen

for stress incontinence.

The technique for the bimanual examination is shown in Figures 29.1,29.2,29.3,29.4,29.5. After the speculum has been withdrawn, the physician should gently insert the index and middle fingers along the posterior wall of the vagina. At the same time, the other hand is placed on the patient's abdomen in the midline. The first palpable structure is the cervix. Next is the uterine fundus. The bimanual technique can outline its position, size, shape, consistency, and degree of mobility. Uterine or cervical mobility can be assessed further by placing the fingers on one side of the uterus and moving them to the contralateral side. This can be done on both the right and left sides to detect chronic or acute inflammatory changes and fixation. The other hand is then placed on one lower quadrant of the abdomen and slowly moved inferiorly and medially to meet the fingers of the hand examining the vagina. In this way, adnexal structures on that side can be appreciated. The degree of adherence of an adnexal structure to the uterus often can be ascertained. Enlargement, consistency, and position of ovaries and tubes can be noted. The ovary is a sensitive structure, and patients differ in tolerance to palpation. The contralateral side should be examined similarly. Finally, the vaginal walls and adjacent structures (bladder and rectum) are palpated. The glove of the hand used for vaginal examination is then replaced with a clean glove for the rectovaginal or rectal examination.

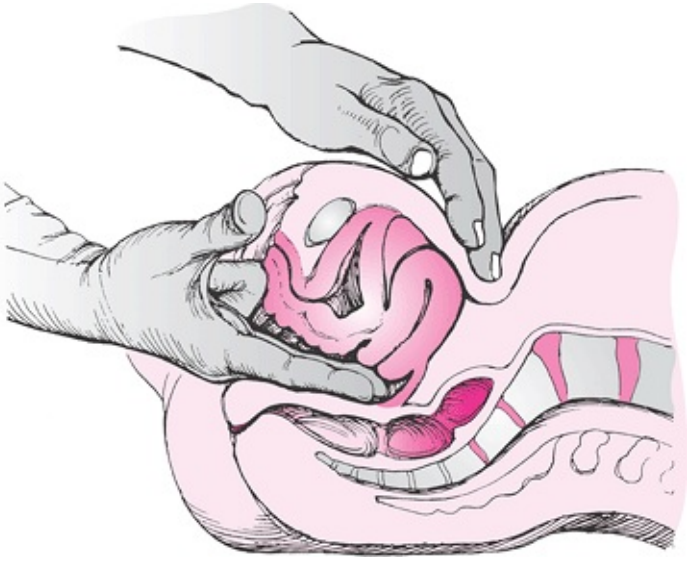

Figure 29.1 Bimanual examination, first step. The fingers that are placed in the vagina to feel the consistency and symmetry of the cervix and its axis in relation to the axis of the vagina. They then elevate the uterus toward the abdominal wall so that the total length of the uterus can be determined. (From Duncan AS. In: Bourne A, ed. *British gynaecological practice*. Philadelphia: FA Davis Co, 1955; drawn by G. McHugh, with permission.)

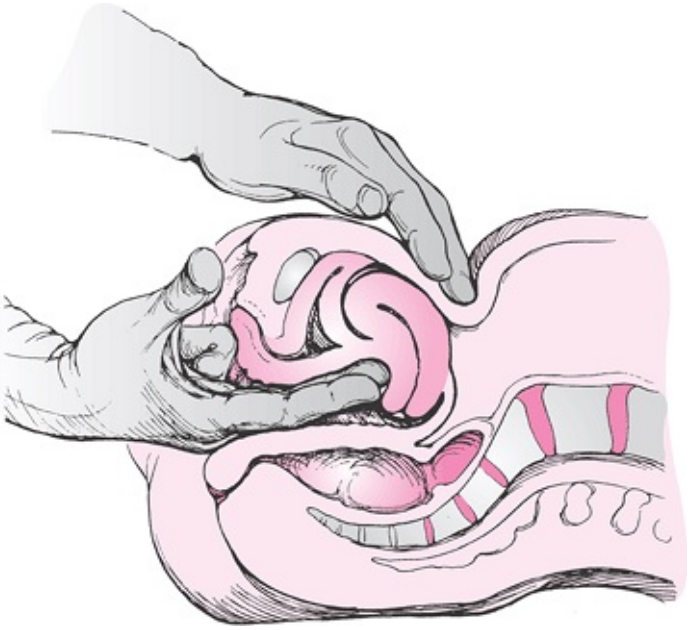

Figure 29.2 Bimanual examination, second step. The fingers examining the vagina are moved into the anterior fornix to permit palpation of the uterine corpus. If the abdominal wall is thin and well relaxed, it is possible to define even minor irregularities in the contour or consistency of the uterus. Third step: With the fingers still in the anterior fornix and with the aid of the hand palpating the abdomen, the uterus is moved gently toward a retroverted position and then from side to side to determine its mobility and the presence or absence of pain on movement of the uterus. (From Duncan AS. In: Bourne A, ed. *British gynaecological practice*. Philadelphia: FA Davis Co, 1955; drawn by G. McHugh, with permission.)

The rectal examination is uncomfortable, but it can be made less so if the physician gently places a finger into the anal opening, requests that the patient valsalva and wait for the anal sphincter to relax before proceeding. The middle finger is inserted into the rectum and the index finger into the vagina. The tone and symmetry of the sphincter are determined. The parametrial tissue is then palpated between the index finger in the vagina and the middle finger in the rectum. Finally, the posterior uterine surface, adnexal areas, uterosacral ligaments, and pouch of Douglas, along with the ano-rectal area, are palpated. The rectovaginal examination enhances the evaluation of cul-de-sac or ovarian pathology. Particles of hard fecal material may interfere with an accurate examination.

Additional important information can be gathered from a separate rectal examination. Exerting pressure against the perineum allows introduction of the index finger. Hemorrhoids, polyps, and tumors of the rectum may be felt. The rectal examination can be assisted by placing one hand on the lower abdomen to make it a bimanual procedure. This examination is useful when a vaginal examination is

impossible, such as in infants and children. The rectal wall is palpated throughout its circumference and as far as the finger permits. Almost one half of all rectosigmoid cancers can be detected by this palpation. The finger also can explore the surface of each pelvic

wall, feeling for enlarged nodes or other abnormalities. Any fecal material can be tested for occult blood. Following the rectal examination, the patient is instructed to slide up on the table while the lower one third of the table is replaced. The examiner can answer any questions about the examination and then step out of the room while the patient dresses. Physicians should always wash their hands after examining a patient.

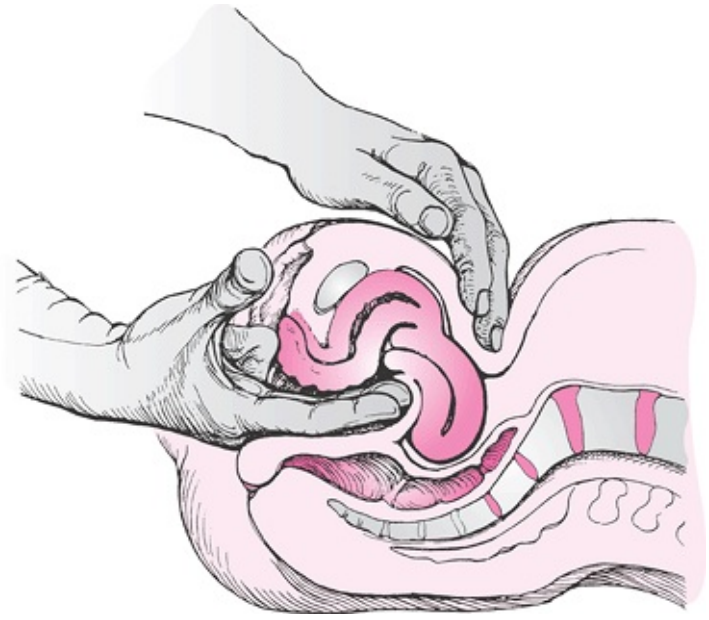

Figure 29.3 If the fingertips of both hands come together when carrying out the second step of the bimanual examination, it can be concluded that the uterus is retroverted; the fingers in the vagina are then moved to the posterior fornix to outline symmetry, consistency, and mobility of the retroverted corpus. (From Duncan AS. In: Bourne A, ed. *British gynaecological practice*. Philadelphia: FA Davis Co, 1955; drawn by G. McHugh, with permission.)

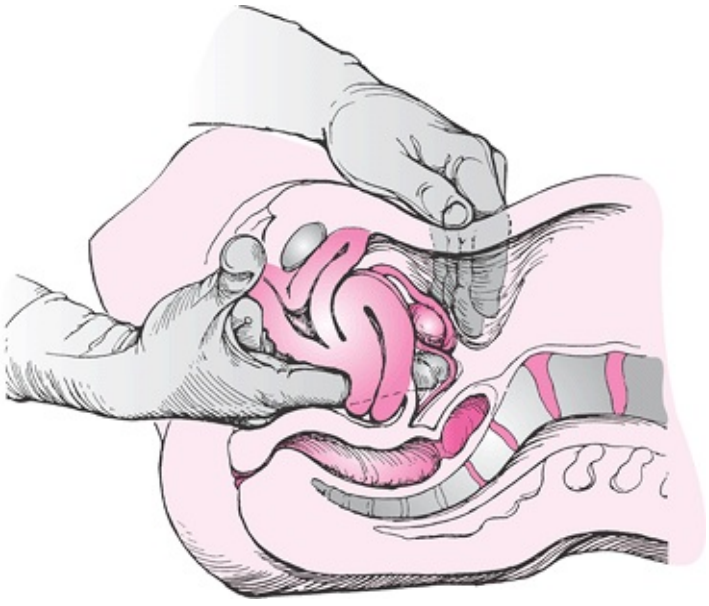

Figure 29.4 Bimanual examination, fourth step. To outline the adnexa, the fingers examining the vagina are moved to the right fornix, and the examiner attempts to bring the fingers of both hands together at a point presumed to be superior to the fallopian tube and ovary. (From Duncan AS. In: Bourne A, ed. *British gynaecological practice*. Philadelphia: FA Davis Co, 1955; drawn by G. McHugh, with permission.)

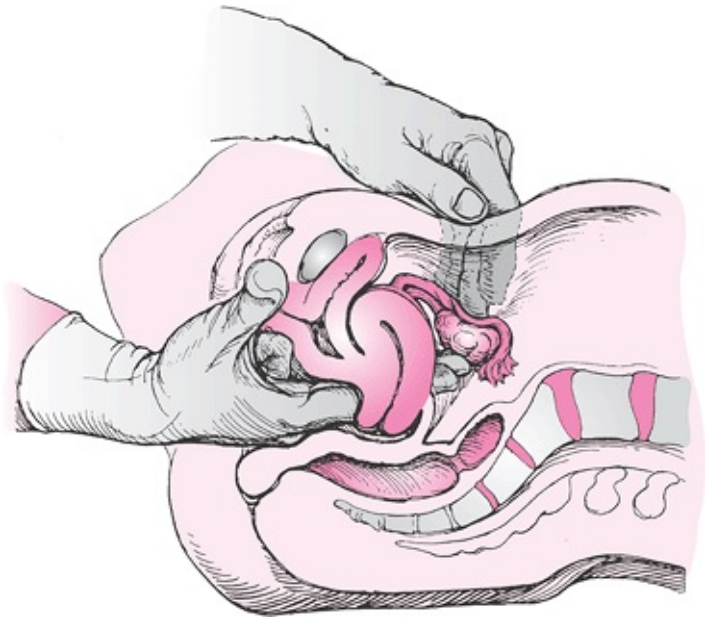

Figure 29.5 Bimanual examination, fifth step. When the fingers of both hands are quite close together (it is desirable but not always possible to approximate these fingers), they are then moved gently toward the examiner so that the adnexa slip between the fingers and can be outlined. (From Duncan AS. In: Bourne A, ed. *British gynaecological practice*. Philadelphia: FA Davis Co, 1955; drawn by G. McHugh, with permission.)

Physical examination can be recorded electronically or on preprinted forms as shown on the ACOG website and should be organized according to the following elements:

. Perineum—lacerations, scarring

. External genitalia—stage of development, color, lesions, Bartholin glands

. Vestibule—Skene glands, urethral orifice, hymenal ring

. Vagina—color, lesions, leucorrhea, tone, rugae

. Cervix—shape, consistency, mobility, parity, lesions

. Uterus—position, mobility, size, shape, consistency

. Adnexa—position, mobility, masses, tenderness

. Rectovaginal examination—confirmation of pelvic findings

. Rectal examination—additional findings, occult blood

Back in the consultation room, the findings, diagnoses, and plans for therapy are explained to the patient in terms that she can understand. This is especially important when surgery is contemplated, because the nuances of an operation may be unclear to patients. The physician should explain carefully what the patient may expect if any special diagnostic or therapeutic procedures were performed, such as bleeding after cervical biopsy. In some situations, patients may be instructed to abstain from sexual activity

for a specific length of time. The importance of a follow-up examination should be stressed. Prescriptions for medications should be detailed adequately and restrictions on refills stated explicitly.

Diagnostic Procedures

Pap Smear

The diagnosis of precancerous lesions of the cervix is based on periodic cytologic screening of the cervix. Despite extensive debates regarding the optimal frequency and accuracy of the Pap smear, it has become the standard method of screening. In addition to cancer screening, the Pap smear also can be used to assess hormonal status and to assist in identifying sexually transmitted pathogens, such as herpes simplex, HPV, *Chlamydia trachomatis*, and *Trichomonas vaginalis* as well as benign conditions. Pap smears should be obtained at periodic intervals in women after they reach the age of 18 or become sexually active, whichever comes first. They should be obtained yearly, especially in women who have had coitus with more than one sexual partner, began to have coitus as an adolescent, or have a history of an STD. A Pap smear should be performed annually in women who have had a hysterectomy for pelvic cancer or in situ disease, although it may not be necessary in women who have had a hysterectomy for benign disease.

After visualizing the cervix, a plastic or wooden spatula is used to scrape the squamocolumnar junction and any areas on the cervix or vagina that look suspicious (Fig. 29.6). In premenopausal women, the squamocolumnar junction is likely to be within the endocervical canal. The spatula is wiped on a clean glass slide, and the slide is sprayed immediately with a fixative (i.e., alcohol and ether) before the cells dry. A second specimen is taken from the endocervix with a cotton-tipped applicator or cytobrush that is placed into the endocervical canal and rotated 360 degrees three to five times. The cytobrush is more effective than a cotton swab in obtaining endocervical cells. The cells are then transferred to the slide, and a fixative is used to preserve the cellular material. The slide, previously labeled to identify its source, is then sent for cytologic evaluation.

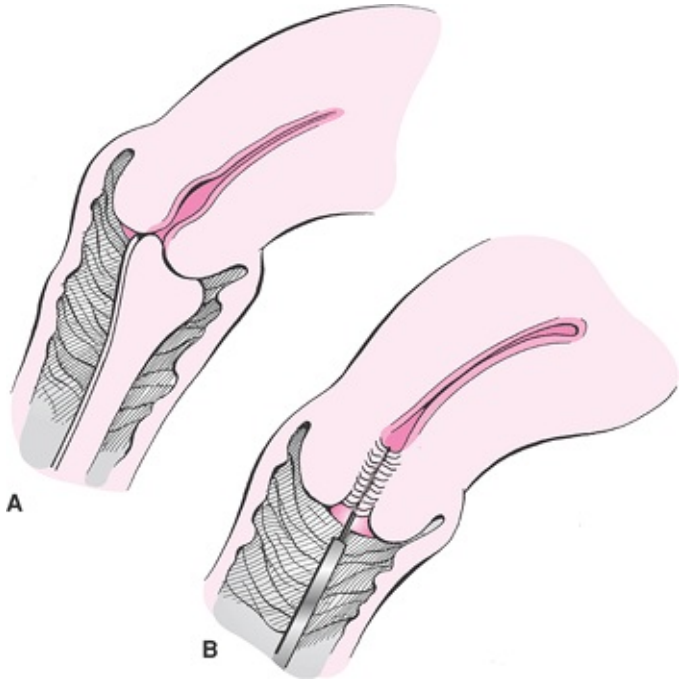

Figure 29.6 Pap smear. **A:** Cells obtained from transformation zone using an Ayers spatula. **B:** Cells obtained from the cervix by using a cytobrush.

Studies evaluating automated preparation systems versus conventional cervical cytologic preparation have shown excellent cellular presentation and superior sensitivity for automated systems compared with conventional techniques. Thin-layer cytology for Pap smears has become widely accepted during the last decade, addressing some of the imperfections with traditional Pap smear screening. In traditional Pap smear screening, there is a 5% to 10% false-negative result rate. Yearly testing decreases the possibility of a false-negative result for any particular woman. The thin-layer liquid-based cytology, or "thin prep," appears to decrease the false-negative rate by picking up more potentially precancerous changes. Thin-layer cytologic preparation is made by submerging the sample in a vial of liquid fixative and mixing the cells in the solution. This avoids difficulties with the fixative, piled up cells, and air drying common to smears on glass. The thin prep also appears to decrease the false-positive rate from inflammatory conditions. The atypical squamous cells of undetermined significance to squamous:intraepithelial cell ratio was reduced by 54% in a thin-prep group. Controversy still exists as to the optimal cytologic screening approach.

Testing for Vaginitis

Although normal vaginal secretions are clear or white, homogenous, and odorless, with vaginitis there may be an abnormal discharge, vulvar irritation, dysuria, and vaginal odor. The majority of cases of vaginitis are due to bacterial vaginosis, vaginal candidiasis, *T. vaginalis*, or atrophic vaginitis. Additionally, STDs such as gonorrhea and chlamydia may cause an abnormal vaginal discharge. Detailed history should include the description of the discharge, presence or absence of odor, duration of symptoms, sexual history, and history of infections. Standard office procedures include preparation of a wet mount, with material

from the swab or the speculum placed on each end of a plain microscope slide, and microscopic examination to assess for bacterial vaginosis. Patients with bacterial vaginosis complain of thin white, yellow, or gray vaginal discharge, commonly with a musty or fishy odor. The pH of the vaginal fluid is usually 5.0 or 6.0. Clue cells on the microscope slide on saline wet mount are described as vaginal squamous epithelial cells that have bacteria adhering to the membrane, giving them a speckled appearance as the focus shifts. Treatment of symptomatic patients and pregnant patients is routinely recommended. *T. vaginalis* may be diagnosed by a saline wet mount showing polymorphonuclear

leukocytes and motile flagellating organisms. The female partner complains of copious frothy yellow to green vaginal discharge. The patient and sexual partner should be treated simultaneously. Atrophic vaginitis is seen often in postmenopausal women and may be associated with a blood-tinged discharge. Evidence of atrophy on the vulvar vaginal examination may be present. The saline wet mount shows numerous leukocytes with small, round epithelial cells. Topical therapy usually is prescribed, although oral therapy can be utilized. Patients who have vulvar itching and a thick, white, curdlike discharge usually have vaginal candidiasis. The diagnosis is confirmed by examining a slide treated with 10% potassium hydroxide, with a sample of the discharge showing filaments, hyphae, or spores. Topical therapy usually is undertaken with oral antifungals saved for resistant infections or immunocompromised women.

Colposcopy

Colposcopy aids in examining the visible portion of the female reproductive tract (i.e., vulva, vagina, cervix) once a cytologic abnormality has been identified. This technique complements cytologic evaluation and localizes the source of abnormal cells seen on cytologic examination guiding selective biopsy. Vulvar diseases amenable to colposcopic evaluation include HPV infections, *Herpes genitalis*, and preinvasive cancers. The magnification afforded by the colposcope may aid in the selection of areas for biopsy. The application of 3% acetic acid for 3 to 5 minutes also may help to highlight abnormal areas, which typically turn white and display sharp borders (i.e., acetowhite epithelium). The colposcope may aid in the recognition of clinically inapparent vaginal intraepithelial neoplasia or HPV infection. These lesions also are characterized by acetowhite epithelium. Colposcopy is used most commonly for evaluating the cervix in a patient with abnormal Pap smear results. After it is visualized and excess mucus is gently removed with a dry cotton ball, the cervix is treated with 3% to 5% acetic acid. As noted, flat condylomata or dysplastic areas turn white or develop a vascular pattern with a mosaic appearance or punctuation. The squamocolumnar junction and transformation zone are then inspected thoroughly, and biopsy of suspicious areas is performed. In addition, a nonpregnant patient with an abnormal Pap smear result should have an endocervical biopsy. Bleeding occurring as a result of the biopsy can be controlled easily with ferric subsulfate (Monsel solution).

Endometrial Sampling

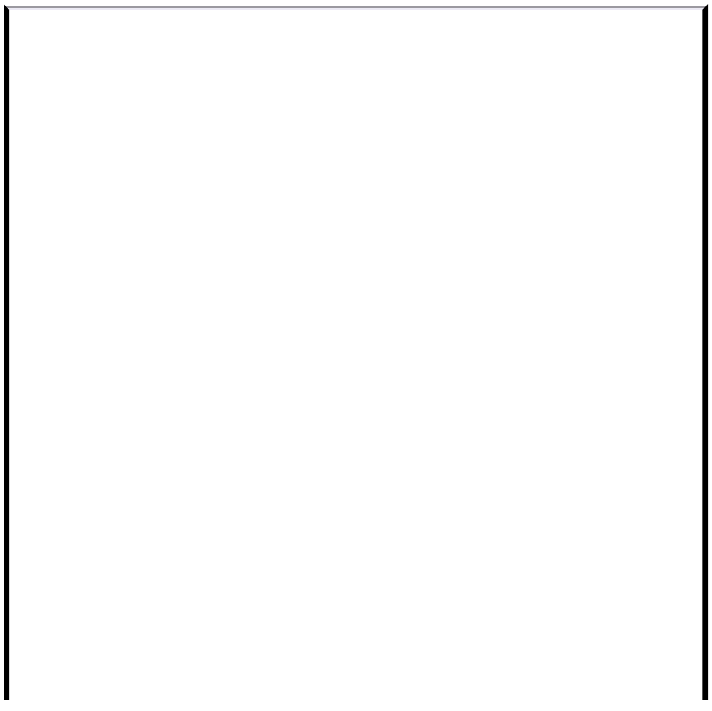
Advances in the technique used for endometrial sampling have simplified the evaluation of abnormal uterine bleeding. Endometrial sampling is of greatest value in the evaluation of

abnormal bleeding when diffuse rather than focal endometrial changes are suspected. Before obtaining an endometrial sample for biopsy, the physician should have the patient's informed consent. The physician should then rule out intrauterine pregnancy, cervical or endometrial infection, and cervical stenosis. The size and position of the uterus are determined by a pelvic examination or by ultrasonography, and a speculum is placed in the vagina. If the patient is sensitive to cervical manipulation, a paracervical block can be administered. When endometrial cancer is suspected, an endocervical biopsy sample can be obtained before endometrial sampling. The cervix and upper vagina are then cleansed with an antiseptic such as povidone-iodine. If the uterus is not anteflexed or retroflexed, a biopsy sample often can be obtained without placing a tenaculum on the cervix. If the degree of flexion is marked, a tenaculum aids in straightening the uterus. It is necessary in some women to anesthetize the anterior cervix with 1% lidocaine to avoid discomfort when the tenaculum is applied.

The instrument used to collect the sample is inserted to the top of the fundus and the length of the uterine cavity noted (Fig. 29.7). It is not necessary to dilate the cervix with sounds before obtaining the biopsy sample in most situations. Several samples are then obtained from the endometrial cavity and submitted for histologic evaluation. If cervical stenosis is present, instruments as narrow as 2 to 3 mm in diameter can be used or the cervical os dilated. There are several instruments available for sampling the endometrium. The most commonly used is the Unimar Pipelle endometrial suction curette (Cooper Surgical, Shelton, CT). Others include the Novak endometrial suction biopsy curette (Miltex Instrument Company, Lake Success, NY) and Tis-U-Trap uterine suction curette set (Milex Products, Chicago, IL). Patients may experience vasovagal syncope during the procedure and cramps or bleeding afterward. When sampling the endometrium, it is important to consider that the device used can adjust to the shape and curvature of the uterus, which minimizes

---

pressure on the uterine wall, reducing the likelihood of pain and cramping. Bleeding usually stops within 1 to 2 days after the biopsy.



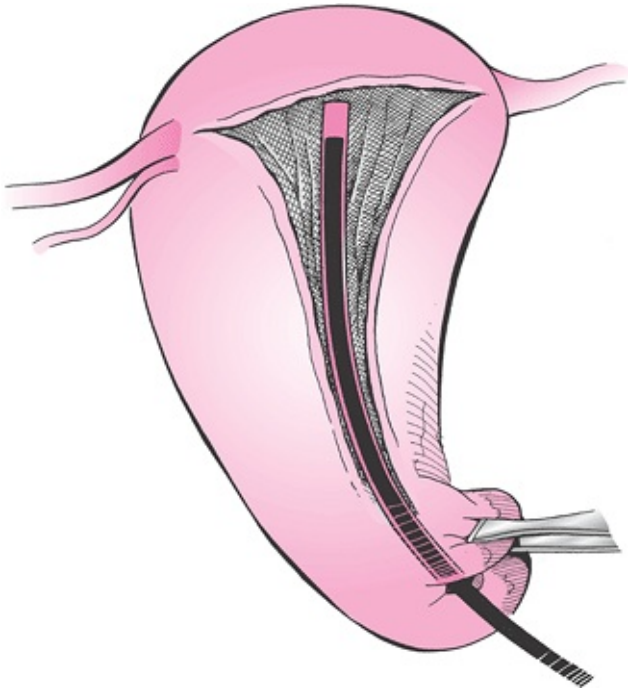


Figure 29.7 Endometrial biopsy.

Vulvar Biopsy

Due to the high rate of false-positive and false-negative results associated with tolidine blue staining, colposcopy has been shown to be a very sensitive tool for diagnosing vulvar lesions such as HPV infections. The only definitive way to exclude invasion is to perform a biopsy of, and to examine microscopically, suspicious areas of the vulva. Vulvar biopsy samples usually are simple to obtain in the office. The area under suspicion is cleansed with an antiseptic solution and then infiltrated with 1% lidocaine by using a 25-gauge needle. Then, a 3- to 6-mm Keyes punch is used to obtain a sample (Fig. 29.8). Any bleeding that occurs can be controlled with silver nitrate or Monsel solution and gentle pressure. For larger areas, a single interrupted suture usually is all that is required to achieve hemostasis.

Ovulation Detection and Prediction

The confirmation of ovulation is always an important part of the evaluation of patients with infertility or abnormal uterine bleeding. It also is useful in timing donor and homologous artificial insemination. Methods used to detect ovulation reflect a preovulatory follicle or progesterone secretion by the corpus luteum. The simplest among these is the determination of a biphasic temperature pattern by recording the basal body temperature (BBT). Serial ultrasonographic studies of follicular growth and disappearance and subsequent formation of a corpus luteum is another method of detecting and timing ovulation. The serial sonographic changes associated with ovulation include a preovulatory follicle of 20 mm or more, a change in the shape of the follicle, thickening of the follicular wall, disappearance of the follicle, and the appearance of fluid in the cul-de-sac. However, these changes can occur without actual ovulation, and ovulation can occur without these

characteristic changes. The introduction of home test kits for detecting the midcycle surge of luteinizing hormone (LH) in urine has made it possible for patients to predict when ovulation will occur. A peak in urinary LH typically occurs between 8 a.m. and 3 p.m., and ovulation usually occurs 12 to 36 hours later. This makes it possible for infertile couples to time coitus or insemination more accurately than ever before. False-positive results may occur in women with polycystic ovary syndrome, whose LH levels may be elevated in the range of an LH surge and in those taking ovulation-inducing drugs.

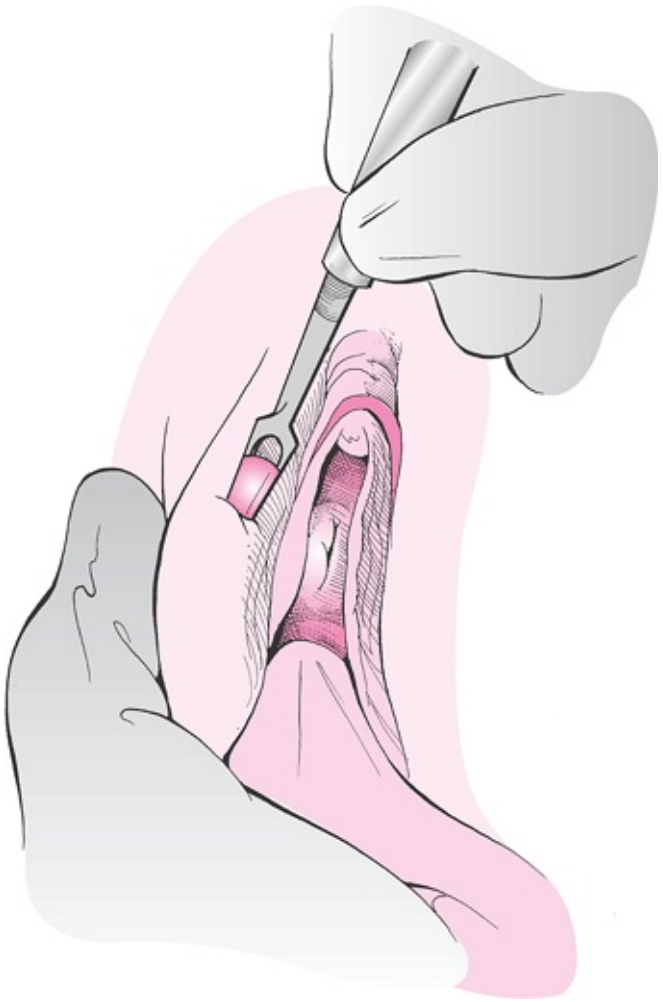

Figure 29.8 Vulvar biopsy by using a Keyes punch.

Testing for Bone Mineral Density

Osteoporosis is a major health threat in the United States, which is particularly prevalent in the postmenopausal woman. The gynecologist often is called on to assess risk factors for osteoporosis in the menopausal population and in those women who are hypoestrogenic. Although the dual energy x-ray absorptiometry (DEXA) scan of the spine and hip is the gold standard for evaluation of osteopenia and osteoporosis, newer screening measures of bone strength, such as heel ultrasonography, have been introduced and used in a gynecology office setting. Measurements of bone mineral density are determined as a T score in the heel, as with the spine and hip density measurements. This additional service in the

gynecology office will help in screening women for osteoporosis, with appropriate referral for a spine and hip study. In addition, a combination of risk factor evaluation and the bone mineral density measurement in the office may increase the ability to predict the development of osteoporosis and fracture risk and improve evaluation and treatment decisions in the menopausal patient.

Transvaginal Ultrasonography

Although there is no substitute for a bimanual pelvic examination, transvaginal ultrasonography may enhance and extend the pelvic examination. Ultrasonographic examination cannot replace the physician's physical determination of the mobility and texture of tissues or the presence

---

of tenderness, but it can provide objective confirmation of the size, shape, and location of pelvic organs. The introduction of lightweight, mobile machines with 5- and 7.5-MHz probes has made office-based ultrasonography a valuable diagnostic technique. Compared with other methods of imaging, ultrasonography is unsurpassed in safety and in providing inexpensive images. Several advantages of ultrasonography available in the gynecology office include picture clarity, ease of operation, and dynamic use of the probe. Office-based ultrasonography can be helpful in the following situations, including evaluating pelvic masses, abscesses, cysts, leiomyomata, monitoring follicular growth, differentiating intrauterine from ectopic pregnancies, and evaluation of the endometrium.

Another important area in which ultrasonographic evaluation is valuable is in the postmenopausal woman. In evaluating endometrial abnormalities, endometrial thickness of 5 mm is used to determine whether further evaluation is needed. Women whose endometrium measures ≤5 mm are considered to have normal results, and those women whose endometrium measures >5 mm are subjected to endometrial biopsy in a screening study performed in a private office setting. However, a suboptimal examination may have serious consequences. The ultrasonographic image is only as good and as useful as the clinical skills used to relate the sonographic findings to the situation under evaluation.

Saline Infusion Sonography

Since the development of high-resolution ultrasound, SIS has been gaining in popularity. Numerous studies have looked at the benefit of ultrasound in establishing the diagnosis in women with abnormal uterine bleeding. The use of fluid instillation into the uterine cavity coupled with ultrasound has become a useful diagnostic tool. SIS is easily performed in the clinical setting and is remarkably well tolerated in most patients. The clinical use of SIS is not in its use to replace surgery but to identify those patients who need surgical intervention. Principles of SIS are listed in Table 29.1.

The minimum supplies required to perform SIS include a SIS catheter, instillation medium, a 20-cc syringe, povidone-iodine solution, scopettes, an open-sided speculum, and an ultrasound that preferably has transvaginal capabilities. The most widely used medium for instillation into the uterine cavity is saline; however, other echolucent contrast media can be used but do not appear to perform better than normal saline and are more costly. SIS

can be performed during any time of the cycle; however, performing SIS during the follicular phase will avoid the potential disruption of an early pregnancy. In addition, there is a thinner endometrium during the follicular phase, which may aid in better evaluation of the uterine lining. Instilling saline during menses may lead to poor uterine distention, so avoiding the procedure during the menstrual cycle is preferred. There are several SIS catheters on the market, and pediatric Foley catheters, insemination catheters, and pediatric feeding tubes can be used. The choice of the catheter will depend on the patient, and therefore several catheter types should be available to the physician performing the SIS. In particular, one should have a thin, stiff catheter available for the nulliparous cervix to occlude the os.

TABLE 29.1 Saline Infusion Sonography

Useful for evaluation of bleeding in pre-, peri-, and postmenopausal women
SIS or transvaginal ultrasound alone: 94.1% vs. 23.5% detection of focal pathology
SIS and biopsy: 96.2% sensitivity and 98.0% specificity
Advantage: can determine fibroid penetration depth
Disadvantage: small irregularities may be misinterpreted as polyps

After performing a bimanual exam or baseline ultrasound to determine uterine position, a speculum is inserted and the cervix is identified. The cervix may be cleansed with povidone-iodine or similar antiseptic solution. The catheter is primed with saline and then inserted through the cervical os. The exact placement will depend on the catheter used. For a balloon-type catheter, the balloon should be positioned in the cervical canal or lower uterine segment and inflated. However, the Goldstein SIS cone-type catheter is inserted to 7 cm, or near the uterine fundus, with the white acorn cone occluding the cervical os (Fig. 29.9). A ring forceps may be needed to assist in placing the SIS catheter. Once the catheter is in place, the

speculum is removed with special care taken so that the catheter is not dislodged. The vaginal ultrasound probe is inserted into the vagina, and the uterus is imaged as the saline is infused slowly. Usually, about 5 to 10 cc of saline is used in order to get good distention. It is important to remember that the seal will not be watertight. Although a watertight seal may produce better images, this will result in significantly more cramping with the procedure. When there is a large efflux of saline out of the cervix, more saline may be needed to get good images. Visualization in both the longitudinal and transverse axis should be performed. The entire uterine cavity should be visualized from left to right broad ligaments longitudinally and from the cervix to the fundus in the coronal plane (Fig.

29.10). It is important to realize that full distention of the uterus is not necessary to get a good-quality evaluation. Most patients have minimal discomfort after a SIS procedure. Patients usually do well by using nonsteroidal anti-inflammatory drugs (NSAIDs) or similar analgesics for pain control. Patients should be advised to call if they are experiencing heavy bleeding that is not associated with menses that continues for more than 4 days. Additionally, patients should be evaluated if they have a fever >100.5°F or develop a vaginal discharge.

Contraceptive Procedures

As part of residency training, most obstetrician–gynecologists will obtain the clinical training needed to perform

insertion and removal of an intrauterine device (IUD) in the office. Two IUDs are available in the United States: Mirena and ParaGard. IUDs are generally recommended as a contraceptive method to women in a stable monogamous relationship who are not at risk for pelvic inflammatory disease, STDs, or ectopic pregnancies. IUDs are contraindicated in the following situations:

- Suspicion of pregnancy
- Congenital uterine anomaly
- Fibroid uterus that severely distorts the uterine cavity
- Pelvic infections

- Unresolved abnormal Pap smear
- Untreated cervicitis or vaginitis
- Genital bleeding of unknown etiology
- Women with multiple sexual partners
- Leukemia
- AIDS
- Breast cancer
- Ectopic pregnancy or history of ectopic pregnancy.

The Mirena IUD consists of a T-shaped polyethylene frame with a steroid reservoir around the vertical stem (Fig. 29.11). The reservoir consists of a cylinder made up of a mixture of the progestin widely used in contraception, levonorgestrel, and silicone. The levonorgestrel within the stem provides release of levonorgestrel at a rate of 20 mcg per day initially. This level declines to half the 52-mcg level at 5 years, so it is approved for 5 years of contraception. There is a stable blood level of 150 to 200 pg/mL 3 weeks after insertion of the Mirena device. The T-shaped system is 32 mm in length and width. The T-shaped body also has barium embedded, which makes it radiopaque. There is a monofilament string attached to the bottom of T-shaped stem. Although the exact mechanism for contraception is not clearly identified, it appears that the Mirena IUD has mostly local effects within the uterine cavity. Additionally, it may have an effect on ovulation. In a 1-year study of the system, only 45% of cycles were ovulatory; however, in a 4-year study, 75% of cycles were noted to be ovulatory. Contraceptive effectiveness is quoted to be 0.2 pregnancies per 100 women, and the cumulative 5-year pregnancy rate is 0.7 per 100 women. Half of the pregnancies that occur while using the Mirena IUD are ectopic gestations, at a rate of 1 ectopic pregnancy per 1,000 users per year. It is important to inform patients that the Mirena IUD can alter the menstrual bleeding pattern. During the first 3 to 6 months of use, there may be an increase in vaginal spotting. Additionally, it has been noted that approximately 20% of users will be amenorrheic after 1 year of use.

The ParaGard IUD has a T-shaped polyethylene body. The vertical portion of the T is wound with 176 mg of copper wire along with a copper collar of 68.7 mg on each of the transverse arms. The exposed areas of copper are approximately 380 mm^2. ParaGard has a monofilament thread attached to the bulb end of the base of the T-shaped device. The available data indicate that the copper is released continuously into the uterine cavity. The additional copper load to the body from a copper IUD may precipitate symptoms in patients with Wilson's disease. The exact mechanism in which the copper provides contraception is unclear; however, it is thought that there is interference with sperm transport, fertilization, and embryo implantation. ParaGard is approved for 10 years of contraceptive use, twice the interval of the Mirena. Women who use the copper IUD should be advised that blood loss at the

---

time of menses might increase. There is an approximately 35% increase in menstrual blood loss among copper IUD users.

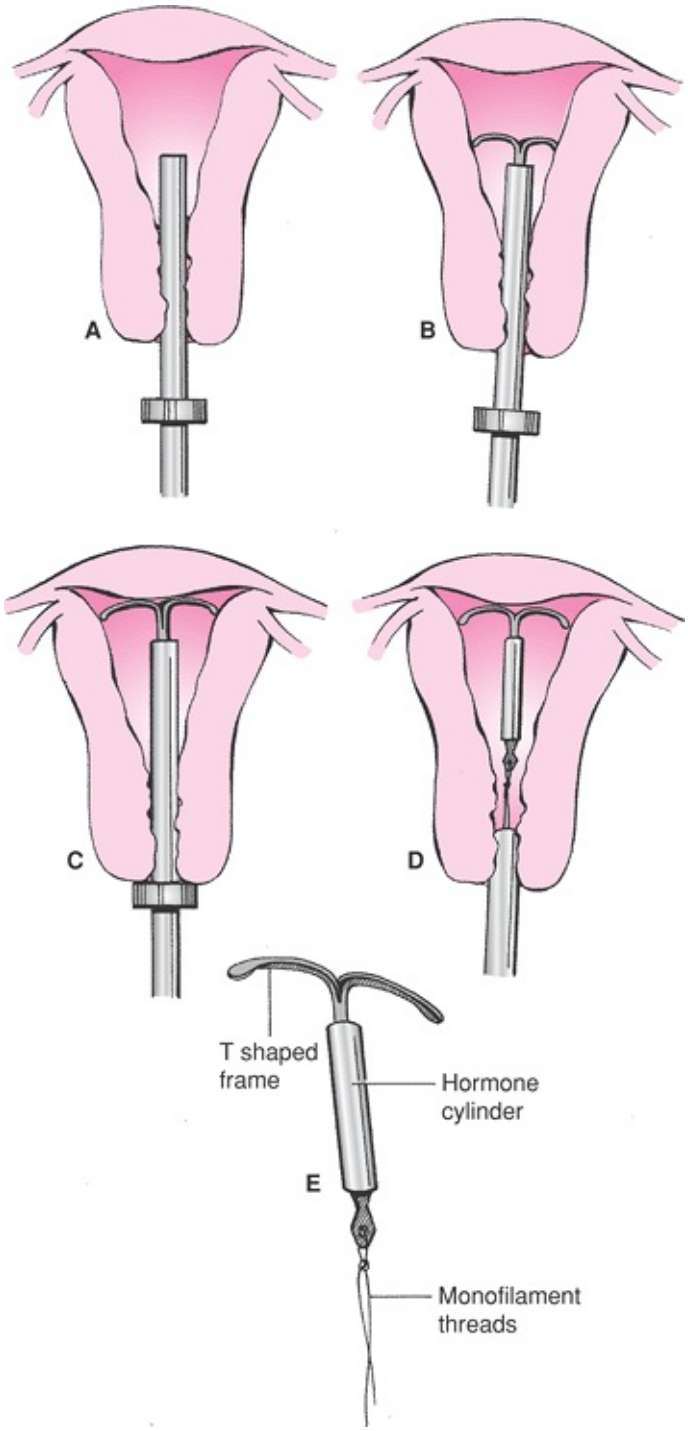

Figure 29.11 The Mirena IUD. **A:** Insertion of the Mirena into the uterine cavity. **B:** The arms of the Mirena are released. **C:** The Mirena is positioned near the uterine fundus. **D:** Releasing the Mirena IUD and withdrawing the inserter. **E:** The Mirena IUD.

If a woman becomes pregnant while an IUD is in place, the manufacturers recommend removing the IUD if the string is visible. It is important to confirm the location and viability of the pregnancy prior to removal of the IUD. Patients in whom the IUD cannot be removed or in those who choose not to have the IUD removed should be informed that there is an increased risk of septic abortion and preterm labor and delivery and should be monitored accordingly if they choose not to terminate the pregnancy after understanding the risks.

Intrauterine Device Insertion Technique

An IUD should be inserted, managed, and removed only by clinicians trained in IUD use. The Mirena and ParaGard have different techniques for preparing the IUD insertion, so clinicians should refer to the package inserts for guidance. IUDs can be inserted at any time during the menstrual cycle. Traditionally, physicians have preferred to insert an IUD at the time of menses to insure that the patient is not pregnant. However, insertion at the time of menses increases the risk of expulsion of the IUD during the first 2 months of use. It is best to give patients an NSAID 1 hour prior to IUD insertion. After loading the IUD into its insertion device, the uterus should be examined by bimanual examination and a speculum inserted into the vagina and the uterus sounded. With both IUDs, there is an adjustable flange that should be set to the length to which the IUD should be inserted. A single tooth tenaculum is applied to the anterior lip of the cervix to aid in cervical and uterine straightening. Benzocaine spray or local infiltration of lidocaine may be used prior to tenaculum placement. The IUD must be inserted within 5 minutes of loading so that the arms will spring back open after insertion. The IUD is then passed through the cervical canal to the fundus. The plastic flange should be at the level of the internal os if the IUD is inserted correctly. Once correct placement is confirmed, the insertion device is used to release the arms of the IUD. The insertion device is then removed gently so as not to disturb the placement of the IUD. The monofilament thread should be cut approximately 2 cm from the external os. The risk of uterine perforation is 1 in 1,360 insertions. Insertion immediately in the postpartum period, particularly during lactation, has been associated with an increased risk of uterine perforation. However, there is no increased risk of perforation if the IUD is inserted immediately after expulsion of the placenta. It is preferred, however, to delay insertion of an IUD until the second postpartum month. After insertion of an IUD, the patient should be taught how to palpate the strings monthly. Patients should be seen in 3 months to review bleeding patterns and concerns with the IUD. At that time, a speculum examination should be performed to rule out partial expulsion of the IUD.

It is important to note the type of IUD prior to removal. The strings are grasped with a ring forceps and pulled outward through the vagina until the IUD is expelled. If the strings break off during removal or the strings are not visible, removal under ultrasound guidance is advisable. Under ultrasound guidance, while using packing forceps, the lower stem is located. Using gentle traction, it is removed through the internal then external os. If gentle force does not produce the IUD, then the IUD may be embedded and, in such cases, hysteroscopic removal in the operating room may be needed. It is important to note that some IUDs that are used outside the United States do not have strings and are designed for permanent placement. These should not be removed in the office setting.

Implantable Contraception

The levonorgestrel implant (Norplant) is no longer marketed in the United States due to difficulties encountered in insertion and removal. A long-lasting single rod etonogestrel (ENG) implant is highly effective and was approved by the FDA in July 2006. Marketed as Implanon, this device has been used in over 30 countries worldwide and in more than 2.5

million women. This progestin-only implant consists of a single sterile rod (4 cm by 2 mm) implanted subcutaneously and provides up to 3 years of continuous contraception. It also is very useful for those patients who cannot tolerate estrogen. The ENG implant is designed for rapid, simple insertion and removal. However, a physician should be trained in the specific technique in an appropriate training program. The average insertion time for Implanon is approximately 1 to 2 minutes, and the disposable applicator comes preloaded, including a needle tip that has two cutting edges (Fig. 29.12). The implant is placed subdermally on the inner aspect of the nondominant arm, 6 to 8 cm above the elbow under local anesthesia. Removal of the implant requires a 2- to 3-mm incision at the distal tip of the implant and pushing the other end of the rod until it pops out. If that technique does not work, a small tissue forceps may be used to remove the implant, with removal time usually <5 minutes. Complications of insertion and removal of ENG include pain, local inflammation, and hematoma at the insertion/removal site. The most common adverse effects associated with the use of the single rod implant is bleeding, which results in discontinuation of use in up to 11% of patients. Infrequent bleeding is described in up to 33.6% of patients. The Pearl Index of the ENG implant is 0.3, demonstrating that this is a highly efficacious method.

Office Surgical Procedures

Although many diagnostic procedures can be performed in an office setting, the particular layout, procedure room sizes, equipment availability, and staffing issues may make it possible for the practitioner to perform certain office

surgical procedures. Basic medical supplies needed include pulse oximeters, basic airway management equipment, electrocardiogram monitoring, intubation equipment, rooms equipped with call alarm buttons, intravenous line stands, and a crash cart. An electronic table that is capable of placing patients in the Trendelenburg position, with cushioned knee stirrups, is preferred for procedures that last over 10 minutes or require complete anesthesia. It is important to keep in mind that in some states, there are regulations for specific facility requirements when conscious sedation is used. Before developing an office surgical suite, physicians should check with local regulatory committees so that they will be able to meet any local standards, anesthesia requirements, and needs assessments.

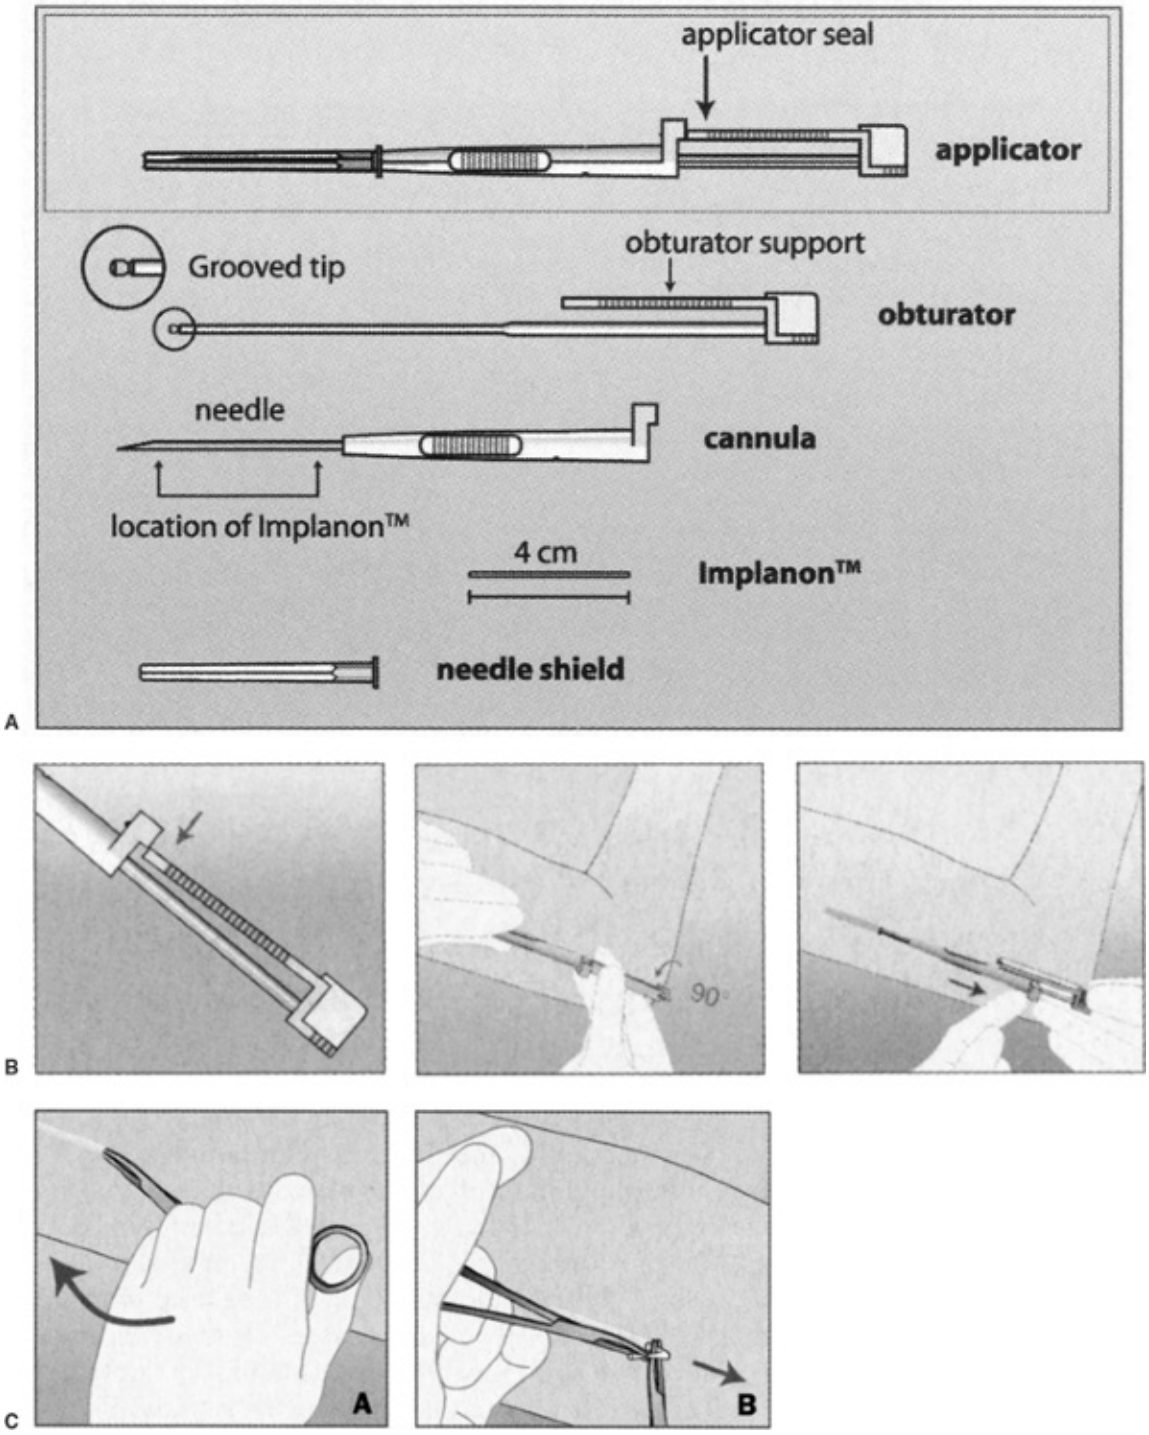

Figure 29.12 Implanon contraceptive insert **A:** Implanon applicator parts. **B:** Insertion method. The full length of the needle is inserted, and the obturator is pressed to break the seal. The obturator is then rotated 90 degrees in either director while retracting the cannula. **C:** Removal "pop-out" method. Forceps are inserted into the incision, grasping the implant. The forceps are turned *(A)* and a second pair *(B)* dissects around the implant to remove it. (Reprinted with permission from Organon, Roseland, NJ.)

Important attention should be paid to the medical history and past medical history to make sure that the patient is a good candidate for an in-office procedure and is of low anesthetic risk. Patients with multiple medical problems, cardiovascular disease, or neurologic disease may be better served in the hospital setting. Consents similar to what one would obtain for

a day-surgery hospital procedure should be signed. Basic preparatory instructions for the individual procedure should be given as well as postprocedure instructions in case discharge planning is needed. Fasting is recommended when conscious sedation is required, which is abstinence from food for 8 hours and clear liquids for 2 hours.

Anesthesia

Although some office procedures can be performed without anesthesia, some will require oral or intravenous sedation. The term *conscious sedation* implies a state in which patients can tolerate procedures with adequate cardiopulmonary function and respond to verbal commands. The American Society of Anesthesiologists (ASA) has published guidelines for sedation and analgesia performed by medical staff who are not trained in the practice of anesthesia. In the office setting, non-anesthesia residency-trained physicians should limit patients to ASA classification I or II (Table 29.2). The clinician should avoid procedures on patients with significant cardiac, respiratory, or neurologic disease in the office setting.

Per hospital policy, anesthesia records should be maintained on the patient's ventilatory and oxygenation status. Hemodynamic variables should be recorded frequently and at a minimum should be recorded in the following situations:

- Prior to the administration of anesthetic agents
- Following the administration of sedation
- On completion of the procedure
- On recovery
- At the time of discharge.

A designated medical professional (nurse, physician's assistant, or physician) other than those performing the procedure should be present to monitor the patient's vital signs throughout the procedure. A staff member trained in advanced cardiac life support (ACLS) should be immediately available. The patient should have intravenous access. Naloxone and flumazenil should be available when opioids and benzodiazepines are used. Anesthesia techniques will vary depending on the physician's training and facility requirements. Most obstetrician–gynecologists performing office surgical procedures should be versed in conscious sedation, administration of local analgesia, and paracervical blocks. Ideally, patients undergoing diagnostic and therapeutic procedures receive moderate sedation.

TABLE 29.2 American Society of Anesthesiologists Patient Classification

Status	Description
I	Healthy patient

II	Mild systemic disease
III	Severe systemic disease, not incapacitating
IV	Severe systemic disease that is a constant threat to life; moribund, not expected to live 24 hours irrespective of operation

Local anesthesia can be a safe and effective means of providing analgesia for office procedures. Local anesthesia is defined as the elimination of sensations, especially pain in one part of the body, by using topical or regional injections of medications. Most obstetrician–gynecologists are educated in the use of local anesthetics during residency training. The secrets of success with local anesthetic use is injecting slowly, using a sufficient amount of medication, and waiting for the medication to take effect. Several agents may be used, including benzocaine, mepivacaine, bupivacaine, and lidocaine. It is important to remember that local anesthetics have cardiac and central nervous system toxicity, particularly with intravasation into the venous system. Local anesthetics are frequently mixed with epinephrine. Symptoms of epinephrine overdose include tachycardia and hypertension, and the physician should watch for these signs when using local anesthetics containing epinephrine.

Most gynecologists are proficient in performing a paracervical block. Paracervical blocks are useful not only for cervical biopsies, cervical conization, and loop electroexcision procedures but also for office dilation and curettage (D&C) procedures and office hysteroscopy. In performing a paracervical block, in addition to the supplies needed for the local infiltration, it is useful to have available a needle extender or long spinal needles. The application of 1% benzocaine spray or lidocaine ointment prior to insertion of the needle may relieve some of the discomfort from inserting the needle. For the paracervical block, injecting 10 mL of anesthetic (usually 1% lidocaine) at the 4 and 8 o'clock positions and waiting 10 minutes gives excellent results. This is believed to limit sensation from the uterosacral nerve bundles from S2, S3, and S4. With this technique, the only area of tenderness appears to be the fundus of the uterus, and providing local anesthesia to this area is difficult, as it is supplied by the tenth thoracic nerve.

Conscious sedation is defined as a minimally depressed level of consciousness whereby a patient can maintain her own airway independently and respond to verbal commands. The medications used for conscious sedation procedures include local anesthetics, sedatives, and anxiolytic and opioid analgesics. The ideal drugs to use in an office setting should have a quick onset and quick clearance rate. The medications used should have a predictable onset of action and minimal side effects. Anxiolytics and opioids are more

commonly used by non-anesthesiologist practitioners for conscious sedation. The window of safety between effect and oversedation is narrow for sedatives and therefore limits their

use in the outpatient setting for most physicians. It is important that the surgeon avoids turning a conscious sedation case into general anesthesia, especially in the office setting. There is an approximately a 0.2% mortality rate with conscious sedation, mostly due to oversedation and inadequate monitoring.

Preventing Complications

There are two basic groups of complications from surgical procedures: allergic reaction to the medications used and technical difficulty with the procedure. Being prepared is the key to managing procedure complications. Careful evaluation of the patient's history will help to eliminate most allergic reactions, but a staff member trained in resuscitation and having agents like Benadryl (50 mg intravenously) and epinephrine may be lifesaving. It is imperative that the recommended limits for in-office sedation for the medication being used are not exceeded. An approximately 0.2% mortality rate occurs with conscious sedation. Those deaths are mostly due to the lack of adequate monitoring of cardiac and respiratory functions during the procedure. It is much better to discontinue the office procedure if it appears more complex than originally planned.

Office Hysteroscopy

Office hysteroscopy is a useful tool for the evaluation of abnormal uterine bleeding, infertility, and recurrent pregnancy loss. Typically, an office hysteroscopy can be performed in a regular exam room without much modification. The most common medium used for distention with office hysteroscopy procedures is carbon dioxide (CO_2), which is inexpensive, readily available, and uses a low-flow insufflator (100 mL per minute). It is essential to note that a CO_2 insufflator for laparoscopy is a high-flow insufflator that should never be used for office hysteroscopy. Advantages of CO_2 are its overall performance and safety. However, it is important to remember that CO_2 is not a good medium for evaluation of patients while they are bleeding. These patients may be better served with a “liquid” distention medium such as high-molecular-weight dextran, sorbitol, normal saline, or lactated Ringer solutions. Several hysteroscopy manufacturers have developed low-cost complete fluid systems for office hysteroscopy procedures that aid in making the procedure safe and simple.

For office hysteroscopy, there are two different kinds of hysteroscopes—rigid and flexible. Most physicians prefer rigid hysteroscopes for office procedures. The standard office rigid hysteroscope is 4 mm in size; however, microhysteroscopes with 2.4 mm and 2.7 mm optics are available. The smaller size decreases the need for cervical dilation, which decreases the discomfort and bleeding associated with the procedure. In addition to the sheath size for the hysteroscope, physicians have a choice of telescope angle. Most physicians prefer to use a telescope at 0, 12, 15, or 30 degrees. Several systems should be tested in the office setting prior to selecting one.

After the patient's vital signs have been taken, adequate analgesia should be given. An attempt to pass the hysteroscope without dilation should be made. However, if the cervix needs to be dilated, good techniques include the use of laminaria or misoprostol. Since

these techniques require preplanning, it is best to assess the cervix at the preoperative appointment to determine if dilation will be necessary. Laminaria insertion requires a visit to the office the day prior to the procedure, and many patients experience severe cervical/uterine cramping. Another option is the use of misoprostol 400 mg orally 4 to 6 hours prior to the procedure.

The hysteroscope usually is inserted with direct visualization of the cervical canal as it passes into the endometrial cavity. To aid in visualization during the hysteroscopy, the cervix should be cleared of all blood by using a sponge forceps prior to entering the cervical canal. Another way to keep the lens clean when using a liquid distention medium is to start the distention medium prior to entering the cervix. The running fluid at the tip of the hysteroscope aids in keeping the lens clean and in visualization at the start of the procedure. In addition, if the medium is cloudy on entry, waiting 15 to 30 seconds to allow the continuous flow process to clear the cavity will improve the view. In contrast, if CO_2 is used as the distention medium, it is better not to start the CO_2 until after entering into the cervical canal. This will avoid having blood-tinged bubbles within the cavity, which can obstruct the view. Once the hysteroscope is passed through the cervical canal into the uterus, a systematic review of the cavity should be performed prior to any operative procedures. Inspect the fundus and locate both tubal ostia first, then pull back to the level of the internal os and inspect the entire anterior and posterior wall of the uterus (Fig. 29.13).

Most patients will have light spotting or light bleeding for up to 5 days after the procedure. Intercourse and douching should be restricted for 24 hours; however, tampons may be used for any postoperative bleeding. Patients should be advised that they could have minimal cramping, which is best resolved with an NSAID or other analgesic. Patients should be instructed to call if they have heavy bleeding, severe pain unresolved by the NSAID, or fever >100.5°F.

Microlaparoscopy

Microlaparoscopy under local anesthesia has interested the medical community due its cost-effectiveness. Several different microlaparoscopy procedures can be performed in the office setting. The difficulty in performing office microlaparoscopy for most physicians is not in obtaining the training or equipment needed but rather in having adequate office facilities to accommodate a microlaparoscopy suite. In addition to adequate facility size, the following equipment should be available for the office procedure:

- Microlaparoscope and microlaparoscope lens
- Video camera
- Video monitor
- Trocar sheaths
- Laparoscopic scissors, graspers, and bipolar coagulation

- A table capable of accommodating the Trendelenburg position
- Resuscitation equipment
- Intravenous line supplies
- Sterile surgical gowns and drapes.

Figure 29.13 Demonstrating a posterior wall intrauterine mass in an office hysteroscopy evaluation.

Several microlaparoscopes are available for use. The refinements in fiber-optic technology have led to excellent-quality 2-mm laparoscopes. Microlaparoscopes range from 25 to 27 mm in working length and have a 0-degree angle of view. There are 2-mm accessories available such as graspers, blunt probes, and biopsy forceps. While concerns remain over optical clarity with these microlaparoscopes, comparison of the accuracy of a 1.98-mm microlaparoscope with the standard 10-mm laparoscope (endometriosis scores and adhesions scores) yields little difference. To avoid major complications, candidates for office laparoscopy should have not have had significant prior abdominal surgery and should have no medical history suggesting a significant risk of abdominal adhesions. Even experienced laparoscopic surgeons will find the “micro” equipment more difficult to use at first until gaining experience with the depth perception and smaller field of view when compared to their full-size counterparts. Procedures best suited for the microlaparoscopic technique include infertility evaluations with chromopertubation, tubal ligation procedures, conscious pain mapping, and “second-look” procedures. The average length of an infertility evaluation by microlaparoscopy is 18 minutes. Some patients can have the procedure performed with only local anesthesia. However, this limits the length of the procedures and the amount of gas that can be used for insufflation. Most patients are better served with some conscious sedation, as this often allows the procedure to last 30 to 45 minutes in contrast to only 15 minutes with local anesthetic alone. For the microlaparoscopy procedure, the patient is placed in dorsal lithotomy position on a table capable of performing Trendelenburg. A paracervical block should be give if a uterine

manipulator is used. The patient is sterilely prepped and draped. If conscious sedation is used, this is given according to the standard ASA guidelines. Local anesthetic is then given in the area of the umbilicus. The use of a Verres needle/sheath combination system allows entry of the Verres needle without a separate introduction of the trocar sheath. The abdomen is insufflated and the pelvic organs visualized. Insufflation pressures will be higher in these patients because they do not have their abdominal muscles relaxed pharmacologically. Pressures and gas flow should be titrated for patient comfort. Observation and chromopertubation are performed in a manner similar to that when using the 10-mm laparoscope. The routine postoperative care used for conventional laparoscopic procedures should be followed for patients undergoing office microlaparoscopy. Patients should be clinically stable prior to discharge and return for a postoperative incision check in 1 to 2 weeks. They should be advised to call if they experience heavy vaginal bleeding, pain that is not resolved by NSAIDs, or a fever >100.5°F.

Office Dilation and Curettage

The vast majority of office D&C procedures can be performed with minimal modifications of that normally performed in the operating room. Most of the equipment needed is readily available and disposable. In addition to the obvious cost savings for an office D&C, the office procedures are more time efficient for the physician. Office D&Cs may be performed for a variety of reasons, but the most common indications include elective pregnancy termination and management of an incomplete abortion prior to 12 weeks gestation. It is very important to confirm pregnancy status and location by ultrasound prior to performing the procedure. The most common reasons for in-office endometrial sampling include evaluation for abnormal uterine bleeding, postmenopausal bleeding, recurrent pregnancy loss evaluation, and procedures that are part of an infertility treatment.

A common technique for office D&C uses the Karman cannula. The Karman cannula is a soft catheter and is an efficient suction device, as it has two suction ports. The larger the bore of the catheter, the more effective the aspiration procedure. The soft catheter probably reduces the

---

risk of uterine perforation when compared with the traditional sharp curette. When choosing the diameter of the cannula, it should roughly equal the size of the uterus by using the standard sizing of the number of weeks of pregnancy. Therefore, when performing a D&C for an incomplete abortion in a uterus measuring 8 weeks gestational size, an 8-mm cannula should be used. Office procedures should be used only on those patients with a uterine size <12 weeks gestation, unless specialized skill is coupled with an available operating room, if it is needed. Prior to arrival at the office, pretreatment with oral diazepam, 5 to 10 mg, is helpful. After routine vital signs are obtained, a bimanual exam is performed to determine the uterine size. A speculum is inserted and a paracervical block placed. After adequate anesthesia, the catheter should be passed through the cervical os. Cervical dilation sometimes is needed, and this may be accomplished with dilators, laminaria (or its synthetic counterpart), or misoprostol as for hysteroscopy. Most patients will do very well after an office D&C. The patients should be advised that they might experience cramping and bleeding for 3 to 4 days after the procedure and that NSAIDs

should be used for any uterine cramping. They should be advised to call the office if they develop a fever, have vaginal discharge, or have bleeding past 4 days.

Endometrial Ablation

New technology now allows the performance of endometrial ablation in an office setting. Several types of endometrial ablation devices are available. Hydrothermal ablation involves the use of heated free fluid along with hysteroscopy. This system appears to achieve similar results as with rollerball electrosurgical endometrial ablation. The Her Option uterine cryoablation therapy system is FDA approved for clinical use with data indicating that cryoablation is safe and effective for treatment of abnormal uterine bleeding and requires less anesthesia than rollerball electrosurgical ablation. In randomized studies, 46% of women were able to tolerate balloon ablation in the office under local anesthesia, albeit some requiring intravenous sedation, while 73% tolerated bipolar radio frequency ablation (Table 29.3).

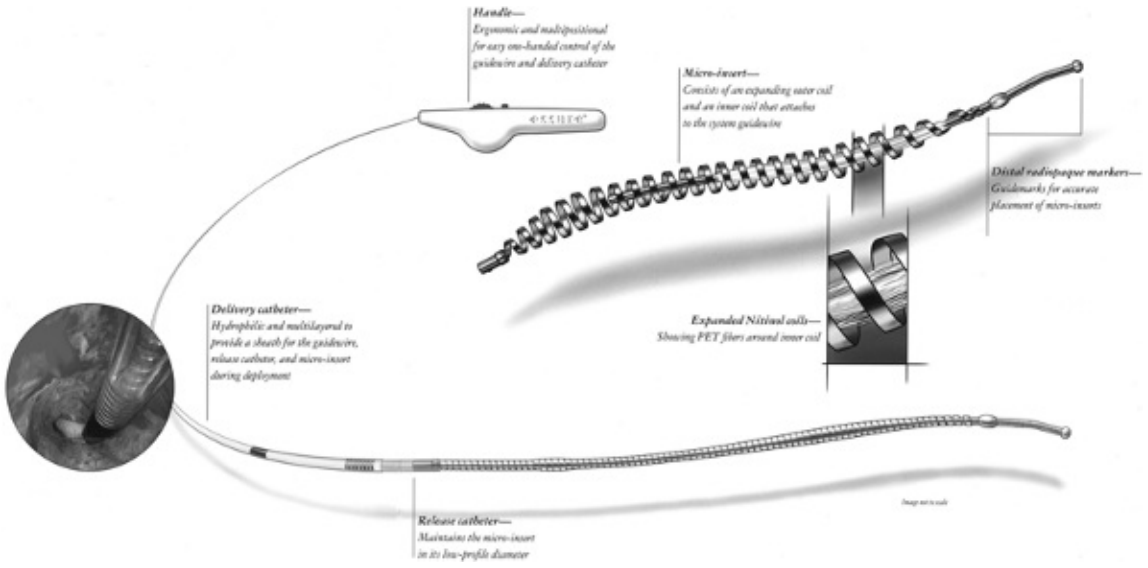

Figure 29.14 NovaSure endometrial ablation technology. The electrode expands to conform to the endometrial cavity, and the cavity is assessed by using a small amount of CO_2. Contoured ablation occurs in approximately 90 seconds, and the electrode array is retracted into the sheath for removal. (Reprinted with permission from Cytyc, Mountain View, CA.)

TABLE 29.3 Thermal Balloon Ablation Procedure

Insert sheath under direct visualization

Perform diagnostic hysteroscopy
Position sheath inside the internal cervical os
Treatment at 90°C for 10 minutes
One-minute cool flush

NovaSure (bipolar radio frequency) technology can be performed as an outpatient surgical or office-based procedure. The average treatment time is 90 seconds, compared with 8 to 12 minutes for balloon ablation. With the NovaSure system, the introducer sheath is inserted through the cervical os (Fig. 29.14). The three-dimensional

bipolar electrode expands from the introducer sheath and with the aid of CO_2 conforms and checks the integrity of the uterine cavity. When the ablation is accomplished, the electrode is retracted into the sheath and removed. There is a 91% success rate (decrease in flow) and 41% amenorrhea rate. The endometrial balloon (ThermaChoice) also is straightforward to use, as noted in Figure 29.15.

Figure 29.15 ThermaChoice endometrial ablation technology. (Reprinted with permission from Gynecare, Somerville, NJ.)

Generally, an NSAID or similar medication is prescribed to control postoperative discomfort. Patients should be advised to contact the office with excessive postoperative pain that is not relieved by the NSAIDs or if they experience excessive bleeding. In order to ensure that the patient has realistic expectations regarding ablation results, it is important to educate patients as to the anticipated results with endometrial ablation. Most patients will not experience a decrease in the menstrual flow for approximately three menstrual cycles after the ablation. The percentage of decreased flow and amenorrhea rates vary with the technology used and should be reviewed prior to the procedure (Table 29.4). As many as 30% to 40% of women may need further intervention within 4 to 5 years; however, patient satisfaction remains high if the realistic limitations of ablation are discussed preoperatively.

TABLE 29.4 Food and Drug Administration-reported Data o Effectiveness of Endometrial Ablation Techniques

	ThermaChoice Uterine Balloon Therapy System	Hydro ThermAblator Endometrial Ablation System	Her Option Uterine Cryoblation Therapy System	Nova Sys
Rate of success (%)	80	68	67	7
Rate of amenorrhea (%)	15	35	22	1
Treatment time (minutes)	8.0	10.0	10.0–12.0	4
Local + intravenous anesthesia (%)	39	45	39	7
Patient satisfaction (%)	96	NA	86	9

Hysteroscopic Permanent Sterilization

The Essure permanent sterilization system provides a hysteroscopic sterilization approach where one Essure micro-insert is placed in the proximal isthmic segment of each fallopian tube lumen. The micro-insert expands on release, anchoring itself in the fallopian tube. A natural tissue response occurs, and in-growth of the micro-insert permanently anchors the device and occludes the fallopian tube. After 4 years of follow-up, it has been noted to be

99.80% effective in preventing pregnancy, with a 99.74% effectiveness at 5 years. The technique includes utilizing a working channel, continuous flow channel and a 12- to 30-degree angle lens. The micro-insert is 4 cm in length and 0.8 mm in diameter in a wound-down configuration. When released, the outer coil expands to 1.5 to 2.0 mm, activating insertion. The insertion system includes a single ergonomic handle containing a delivery wire release cap or a delivery cap that houses the Essure insert. Performing the Essure procedure requires similar preparation as for operative hysteroscopy. Correct placement across the uterotubal junction of the micro-insert is critical, and anatomic variations in women are taken into account in the design of the flexible micro-insert. Hysteroscopic visualization of the coils of the micro-insert can easily be seen at the tubal ostium, confirming proper placement within the fallopian tube (Fig. 29.16). Additional hysteroscopically placed devices to occlude the proximal isthmic segments and provide sterilization may be available in the near future.

Summary Points

- A thorough gynecologic history and examination should include an evaluation of personal health habits and psychosocial issues, including sexuality; abuse; emotional disorders; and drug, alcohol, or tobacco addiction.
- Preventative care including HPV vaccination should be offered when appropriate.
- A thorough summary of the physician's findings and a discussion of their implications will reduce the patient's anxiety and improve compliance with medical therapies.

- General office procedures include Pap smear, colposcopy with biopsy, and endometrial biopsy.
- Transvaginal ultrasonography may enhance and extend the examination of the pelvis.
- Office bone mineral density testing with a heel scanner may be useful in combining risk factor evaluation and the scan result with respect to evaluation and treatment decisions.
- Many gynecologic procedures can be performed by a clinician with sufficient training in an office setting, as they require minimal anesthesia and have minimal risk of complication.
- Procedures that may be performed in the office include SIS, IUD placement, subcutaneous implant placement, D&C, hysteroscopy, endometrial ablation, microlaparoscopy, and Essure hysteroscopic sterilization.
- The expertise and experience of gynecologists make them excellent agents for consolidating the health care of women while providing the majority of care for a large female population. The office-based focus of current and future gynecologists is a significant component of their ongoing contribution to the health care of women.

Acknowledgment

The authors wish to thank Mrs. Alyce Soffer for her assistance in the preparation of this manuscript.

Gynecologic Ultrasound

Mika Thomas
Bradley J. Van Voorhis

The use of sonography has become widespread in gynecology. Its accessibility, relatively low cost, and high patient acceptance make it applicable as an initial step in assessing many gynecologic disorders. This chapter discusses and illustrates the common uses of ultrasound (US) in the evaluation and treatment of a variety of gynecologic disorders. The subsections are divided according to the most common indications for gynecologic US, and a list of suggested readings is available at the end of the chapter for further in-depth reading on the subject.

Sonographic Instrumentation and Technique

US uses high frequency sound waves at various frequencies to allow imaging of internal organs and vessels. The waves emitted by the transducer pass through the soft tissue, and a portion of the wave reflects off perpendicular tissue/fluid interfaces. This reflection, or return echo (much like a sonar), is detected by the transducer, while the remaining portion continues through until the waves encounter another perpendicular tissue/fluid interface, sending back another reflected echo delayed in time. The US machine collates the information from the reflected echoes, based on the time required for their return and intensity, and reconstructs a two-dimensional (2D) sonographic image. Both the origin of the signal, the transducer, and the receiver are contained in the same unit. Three-dimensional ultrasonography (3D-US) characterizes an entire soft tissue volume by storing multiple 2D images, and the computer software rapidly collates the multiple 2D images thus yielding a 3D image. Once the information is electronically stored, this computerized storage system allows reconstruction of images within the defined volume in any plane and provides the opportunity to reorient the scan relative to internal soft tissue landmarks, which enhances the usefulness of the technology.

US is particularly useful in defining the internal acoustic characteristics of a soft tissue structure, thus distinguishing fluid-filled structures from solid structures. This makes US the imaging modality of choice in evaluating the ovary for cysts or neoplasms. This imaging technique is not as well adapted to distinguish solid structures from other adjacent, or surrounding, solid structures. A perfect example of this is the ease at which an intrauterine gestational sac can be visualized, while a comparably sized intracavitary uterine polyp or

fibroid may be quite difficult to distinguish from the adjacent endometrium or myometrium with a similar acoustic appearance.

Diagnostic US of the pelvic organs can be performed by using the transabdominal sonography (TAS) approach, in which the uterus and adnexa are imaged through a distended urinary bladder, or transvaginal ultrasound (TVUS), where the probe is inserted into the vagina for imaging with an empty bladder. In general, the lower the frequency emitted by the US transducer, the further the penetration and the deeper the window of visibility but the smaller the amount of discrimination between soft tissues. Therefore, TAS uses lower frequency sound waves (3.5 to 5.0 MHz) to allow for the deeper penetration required to visualize intra-abdominal structures beneath the subcutaneous tissue, which can be quite variable in depth between patients. A TAS is most useful in fully assessing large masses that extend out of the pelvis or in situations where TVUS cannot be performed, such as in pediatric or adolescent patients. Due to problems visualizing the pelvic organs through intervening tissues such as the small and

large bowel or the anterior abdominal wall, the transabdominal approach is best performed with a fully distended urinary bladder, enabling a better acoustic window without interfaces to reflect echoes to visualize the uterus and adnexa. However, TAS remains limited by body habitus and any intervening bowel or preperitoneal fat, which can increase artifacts and scatter the incident US beam.

TVUS uses higher frequency sound waves (5 to 8 MHz), which allow higher image resolution but with less tissue penetration, thus limiting the ability to “see” objects more distant than 10 cm clearly but images the closer tissues much better. TVUS is a better modality with which to image obese women because the US transducer can be positioned immediately adjacent to the uterus and ovaries without the hindrance of subcutaneous tissue. For most applications, a slightly curved transducer probe that has high line density affords the most detailed image (Fig. 30.1). It becomes increasingly difficult to see the uterine fundal region if it extends above the pelvis, as in the case of a large fibroid uterus or the pregnant uterus in the second and third trimesters. By contrast, the transvaginal component of an examination of the uterus typically can better visualize the proximity of fibroids to the endometrial cavity than can TAS. Image clarity with TVUS usually is superior when evaluating ovarian abnormalities as compared with TAS and also can be helpful as a means of distinguishing between ovarian and uterine masses. In addition, TVUS with Doppler sonography affords assessment of the flow of blood within vessels adjacent to and within the uterus and ovaries.

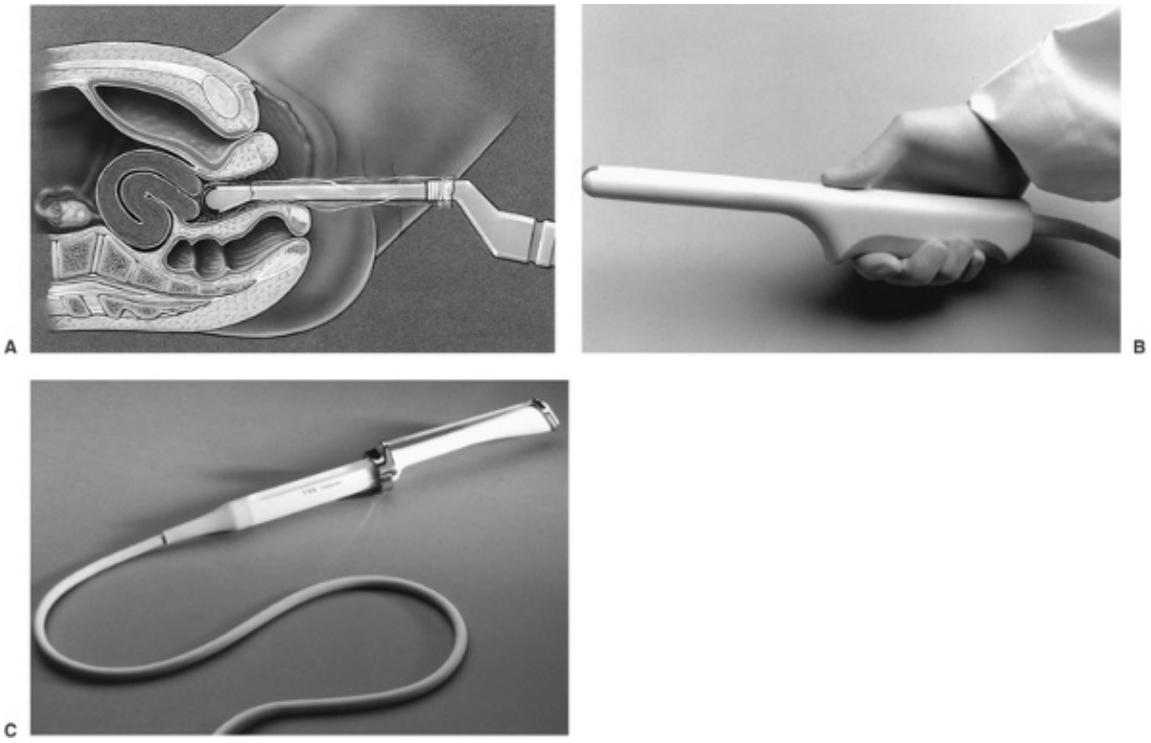

Figure 30.1 Transvaginal ultrasound. **A:** Diagram showing a transvaginal probe adjacent to the cervix in a retroflexed uterus. (Drawing by Paul Gross, MS.) **B:** Picture of a tightly curved curvilinear array transvaginal transducer probe. **C:** Flat-faced transvaginal probe with a needle guide attached to the shaft.

TVUS is best performed in patients placed in the lithotomy position with an empty bladder. The vaginal probe should be disinfected and covered with a sheath prior to insertion. For optimal patient comfort, the probe should be inserted into the vagina while the operator's finger gently depresses the posterior introitus. Alternatively, the patient may insert the probe herself. A US examination must be thorough and reproducible; for this reason, most would suggest performing each US in a proscribed fashion, following the same routine with every scan. A complete pelvic US examination begins with images of the uterus as the central pelvic landmark both in the sagittal and coronal axes. The probe can be withdrawn into the midvagina and directed anteriorly to provide views of an anteflexed uterus. The retroflexed uterus is imaged easily without major manipulation of the probe because it is closer to the plane of the vagina, though some vaginal probes angle the US beam superiorly, making this somewhat more difficult or uncomfortable for the patient. The operator can then orient the probe for imaging the adnexal regions by using the internal iliac artery and vein as landmarks for delineation of the ovarian fossa. The normal ovary usually can be found just medial to the internal iliac artery and vein, but there is substantial variation in the location of the ovaries, particularly in women who have undergone pelvic surgery or

hysterectomy or who have enlarged ovaries that may extend upward out of the pelvis. Typically, enlarged ovaries or ovaries containing cysts are relatively easy to identify, while the normal postmenopausal ovary might be more difficult to visualize. The operator can

use one hand to mildly compress the abdominal wall and evaluate the mobility of these organs. If there are no adhesions, the uterus and ovaries should move smoothly away from each other as the probe is advanced. This has been termed the *sliding organ sign* and, if absent, may suggest the presence of agglutinating pelvic adhesions.

To evaluate the vascularity of an organ, US machines make use of the physics principle known as the Doppler effect. This principle states that sound or light waves reflected by a moving object will undergo a change in frequency proportional to the relative velocity of that object, toward or away from the transducer (e.g., like the difference in sound made by an approaching and departing train). Detecting these frequency changes can help to determine the blood flow to a structure being imaged. Transvaginal color Doppler sonography (TV-CDS) combines the anatomic information provided by TVUS with blood flow information provided by CDS (Fig. 30.2). TV-CDS assesses blood flow and resistance to blood flow in larger vessels supplying pelvic organs. The flow within a vessel can be characterized in several different ways by TV-CDS. First, the flow waveform recorded by the Doppler can be described (e.g., the presence or absence of diastolic flow through the vessel). Alternatively, the waveform can be analyzed by measuring resistive indices that indicate the downstream impedance to blood flow within a vessel. These resistive indices are only indirect measures of the actual blood flow to an organ. Commonly measured indices are the resistive index (peak systolic velocity minus minimum end diastolic velocity divided by peak systolic velocity) or the pulsatility index (peak systolic velocity minus end diastolic velocity divided by the mean velocity over the cardiac cycle.) These parameters are unitless values and are measures of relative impedance to forward flow. One must obtain signals from between 30 and 60 degrees to the longitudinal axis of the vessel in order to provide optimal waveforms. Actual blood flow volume and velocity can be determined in larger vessels, but these measurements are not accurate in the smaller vessels. Standard, frequency-based color Doppler is assigned red colors for flow toward the transducer and blue colors for flow away from the transducer.

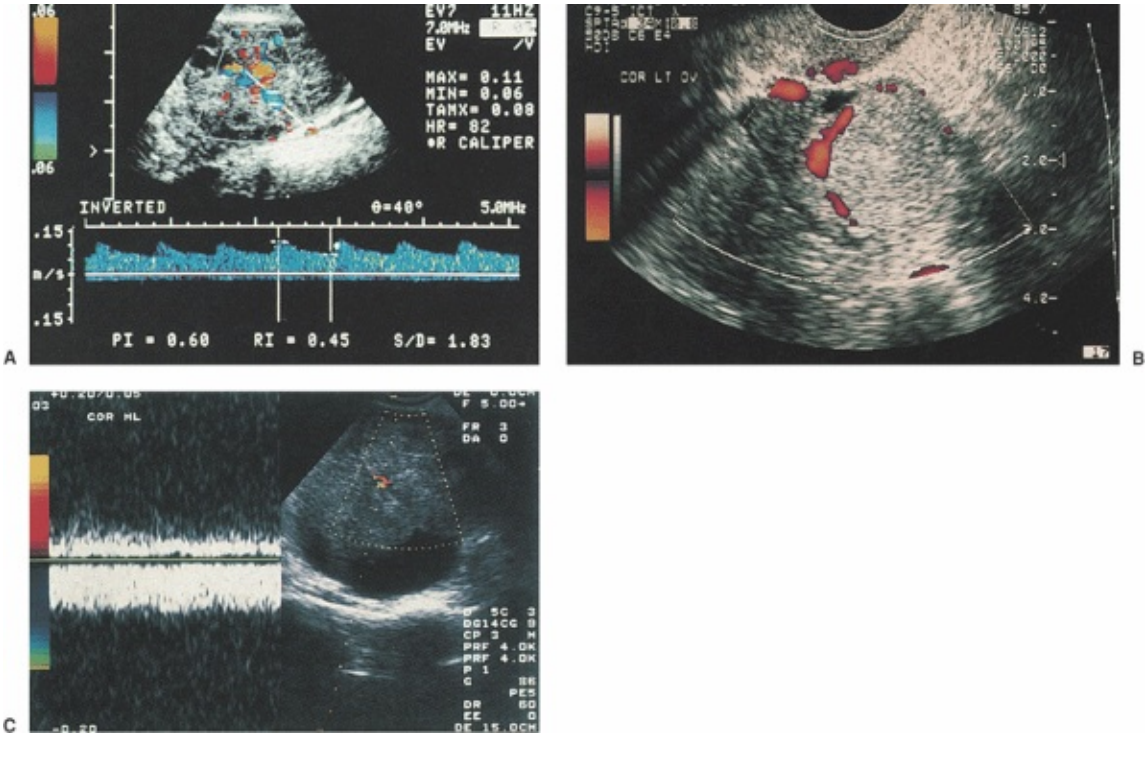

Figure 30.2 Transvaginal color Doppler sonography. **A:** TV-CDS showing low-impedance flow (resistive index = 0.45; pulsatile index = 0.60) within the wall of a corpus luteum. **B:** Amplitude color Doppler image of hemorrhagic corpus luteum showing no flow within the center of the mass, which contained an organized clot. **C:** Complex mass with low-impedance arterial and increased venous flow within an irregular solid area, which is highly indicative of ovarian cancer. (See Color Plate)

A new type of processing known as power Doppler has been developed for the detection of flow within much smaller vessels. This technique is more sensitive, which allows for the detection of areas of low blood flow, and the information is independent of the angle of insonation of the vessel. The main disadvantages are that there is no information about speed or direction of flow, and there is high motion sensitivity leading to false readings. The principal

aim of power Doppler is to determine the simple presence or absence of flow, although computer analysis of images allows for quantification of blood flow for research purposes.

Clearly, the accuracy of TVUS is operator dependent, and significant clinical experience with anatomic correlation is required for effective use. For those who do not routinely perform pelvic sonograms as part of their practice but rather order them, it is crucial that they have a working understanding of not only the lexicon of US but also at least a rudimentary ability to interpret the images that are collected. US images and reports must also be saved for medicolegal reasons. US, to some extent, is subjective and documentation of results is incomplete without a narrative description of the overall impression by the operator.

While becoming more widely available and used in obstetric practice, the clinical value of 3D-US in gynecology over the standard 2D technique has yet to be demonstrated. With 3D-US, data is captured and stored during a “sweep” of the pelvis with the vaginal probe. This allows for the rapid acquisition of data and the ability to subsequently display the images in three dimensions. Since data from the entire volume of the pelvis has been stored, any 2D plane can be recreated that is oriented toward the internal organs and thus display the optimal section through the region of interest. For example, the true coronal image of the uterus can be displayed, which cannot be viewed in standard 2D images from an external orientation. 3D-US has been shown to be efficient and accurate in characterizing Müllerian abnormalities and in measuring ovarian and fibroid volumes and shows promise in some urogynecologic applications. Whether or not the improved imagery actually improves the detection rate of pathology has not been demonstrated for most gynecologic applications. An even more recent advance is the ability to display 3D images live on the screen (sometimes called live 3D- or “4D”-US). The true clinical advantage of these newer techniques currently is under investigation.

Abnormal Uterine Bleeding

Irregular uterine bleeding is a common presenting complaint for the gynecologist, and it is necessary to differentiate abnormal uterine bleeding (AUB) from dysfunctional uterine bleeding (DUB), as their management approaches differ greatly. DUB, which may only be diagnosed once organic or anatomic sources have been ruled out, is most commonly caused by anovulation due to estrogenized anovulation, or polycystic ovary syndrome (PCOS). Ultrasonic diagnostic criteria for PCOS is discussed later in the Infertility section. AUB, on the other hand, may be caused by a variety of conditions including uterine fibroids, endometrial polyps, endometrial hyperplasia or carcinoma, and endometritis. TVUS plays an important role in evaluating these women.

Because of the proximity of the transvaginal probe to the uterus, the endometrial and myometrial architecture can be accurately depicted in detail in most patients. One of the most important structures to image in the evaluation of a woman with AUB is the endometrial stripe. It becomes very clear when measuring the endometrial stripe that proper imaging technique is critical, as the endometrium is not a precise geometric shape and operator error can account for over- or underestimation of its thickness. Thus, it is of utmost importance to properly orient the scan of the endometrium in its greatest long-axis plane and maximal thickness in the fundal region, which optimizes its bilayer measurement (Fig. 30.3).

Normal endometrial thickness varies depending on both the patient's reproductive endocrine status and the use of hormones. In women of childbearing age, the endometrial thickness changes according to the stage of the menstrual cycle. During menses, the normal endometrium is 3- to 5-mm thick with a mildly echogenic texture. As the endometrium proliferates in the periovulatory period, a multilayered texture can be seen with thicknesses ranging from 5 to 8 mm. The outer echogenic layer represents the basalis, whereas the inner layer is the enlarging functionalis. In the secretory phase, the endometrium becomes diffusely echogenic and enlarges up to 12 to 14 mm in thickness. This is in contrast to the thin endometrial stripe of the postmenopausal patient, which typically measures <3 mm unless the patient is taking hormonal therapy, which will lead to a thicker proliferative endometrium, or has true endometrial pathology.

Clinically, it is important to remember that the prevalence of different causes of AUB differ depending on the age of the woman. In general, premenopausal bleeding often is associated with pathology such as intracavitary fibroids or endometrial polyps and less commonly with endometrial neoplasia. In the postmenopausal patient, however, pathologies including atrophic endometritis, hyperplasia, and endometrial carcinoma are more common.

Indeed, one of the more valuable roles of TVUS is evaluating unexplained bleeding in the postmenopausal woman. A thickened or highly echogenic endometrium in a postmenopausal patient can suggest the presence of polyps, abnormal endometrial histology such as adenomatous hyperplasia, or even cancer. However, there is no endometrial stripe thickness above which carcinoma or hyperplasia is always found, and there is also no thickness below which cancer is never encountered. Many studies have been published assessing whether there is a stripe thickness cutoff below which one can safely presume a low likelihood of pathology and avoid invasive diagnostic procedures to

assess endometrial histology. Meta-analyses have concluded that using 5 mm as the cutoff, irrespective of whether the patient is on hormone replacement therapy, results in a sensitivity of 92% in identifying any endometrial pathology and 96% for detecting carcinoma. An endometrial thickness of <5 mm was associated with a significantly reduced risk of an underlying carcinoma. As suggested by these findings, a thin endometrial stripe reduces but does not eliminate the chance that there is an area of cancer present. Therefore, particularly in the face of continued bleeding or in a high-risk patient, tissue sampling should always be considered.

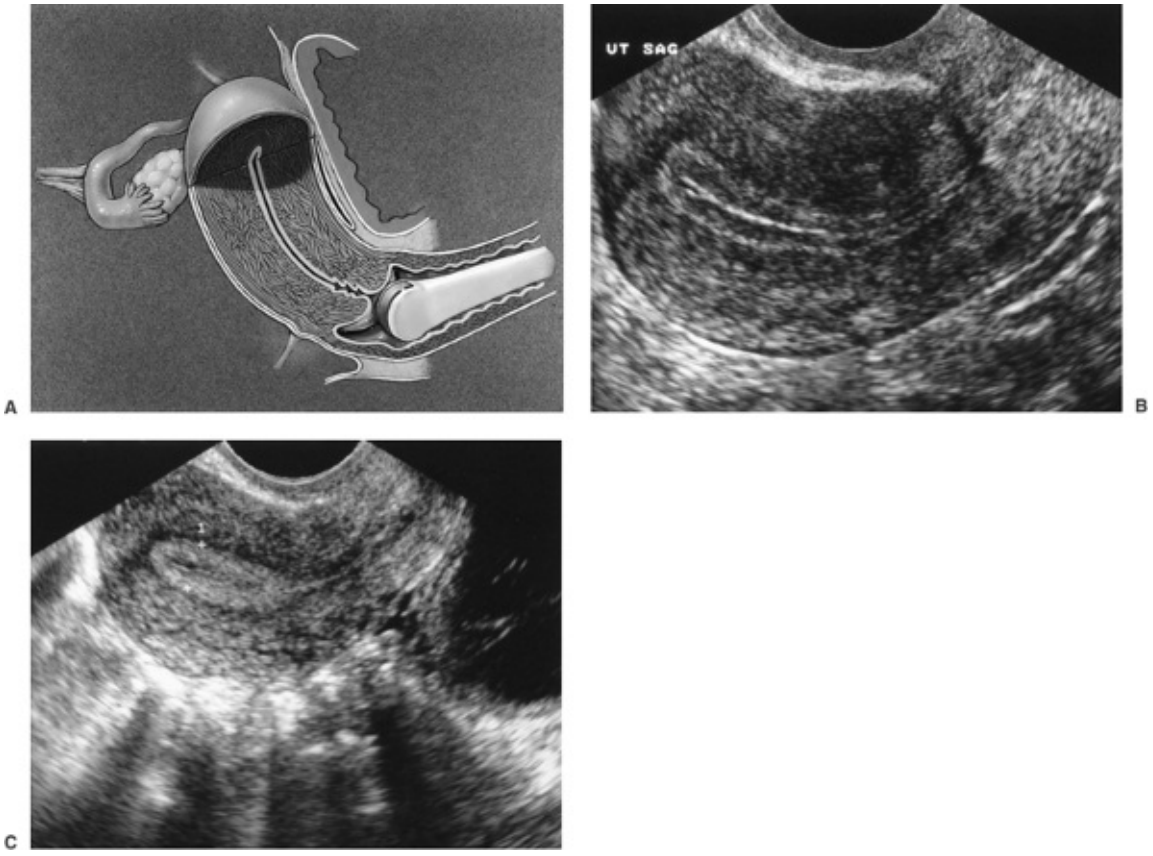

Figure 30.3 Endometrial disorders. **A:** Diagram showing proximity of the endometrium of an anteflexed uterus to the transvaginal probe. The field of view depicting the long axis of the uterus and endometrium is shown. (Drawing by Paul Gross, MS.) **B:** TVUS showing multilayered endometrium typical of follicular phase endometrium. **C:** Typical secretory phase endometrium demonstrating increased thickness (between cursors) and homogeneous echogenicity. (See Color Plate)

In the premenopausal patient, there are several US findings that are suggestive of an intracavitary abnormality that might be the cause of abnormal bleeding such as a thickened endometrium or an endometrial stripe that is distorted or has an acoustic appearance that is heterogenous. Uterine fibroids, a common source of AUB, can result in any one of the mentioned US findings. Uterine fibroids typically are hypoechoic or of mixed echogenicity when compared with normal myometrium with “shadowing” or low ultrasonic

reflection beyond the fibroid. Some fibroids contain calcifications that appear as areas of high acoustic reflection similar to that seen in bone. The endometrial stripe adjacent to the fibroid should be visualized to assess the fibroid's effect on the endometrium. Submucosal fibroids typically displace and thin the overlying endometrium and sometimes are best visualized with saline infusion sonohysterography (SIS). Occasionally, fibroids may be present as solid masses in the adnexal regions, representing either interligamentary or pedunculated tumors.

Another common cause of AUB is the presence of endometrial polyps. These usually arise from the endometrium in the uterine fundus and appear as focal areas of increased endometrial thickening and/or irregularity. They may be pedunculated or sessile, and may be difficult to distinguish from intracavitary fibroids. Endometritis, also a cause of AUB, can produce a thickened endometrium, as well as accumulation of intraluminal fluid.

Saline infusion sonohysterography (SIS) has become an important and effective adjunct to standard TVUS. The endometrial cavity is a potential space where the anterior and posterior endometrium are in direct apposition to one another. Fibroids, polyps, and even scar tissue (intrauterine synechiae), such as that seen in Asherman's syndrome, within the endometrial cavity are often difficult to visualize on standard TVUS because the US characteristics are similar to the contacting endometrium. Using saline infusion as an acoustic contrast medium to distend the endometrial cavity, enables visualization of structures within

---

the endometrial potential space in greater detail than with TVUS alone (Fig. 30.4). With saline infused into the cavity, the walls of the uterus separate, and polyps, intracavitary fibroids, and synechiae that might otherwise have been missed are readily visualized.

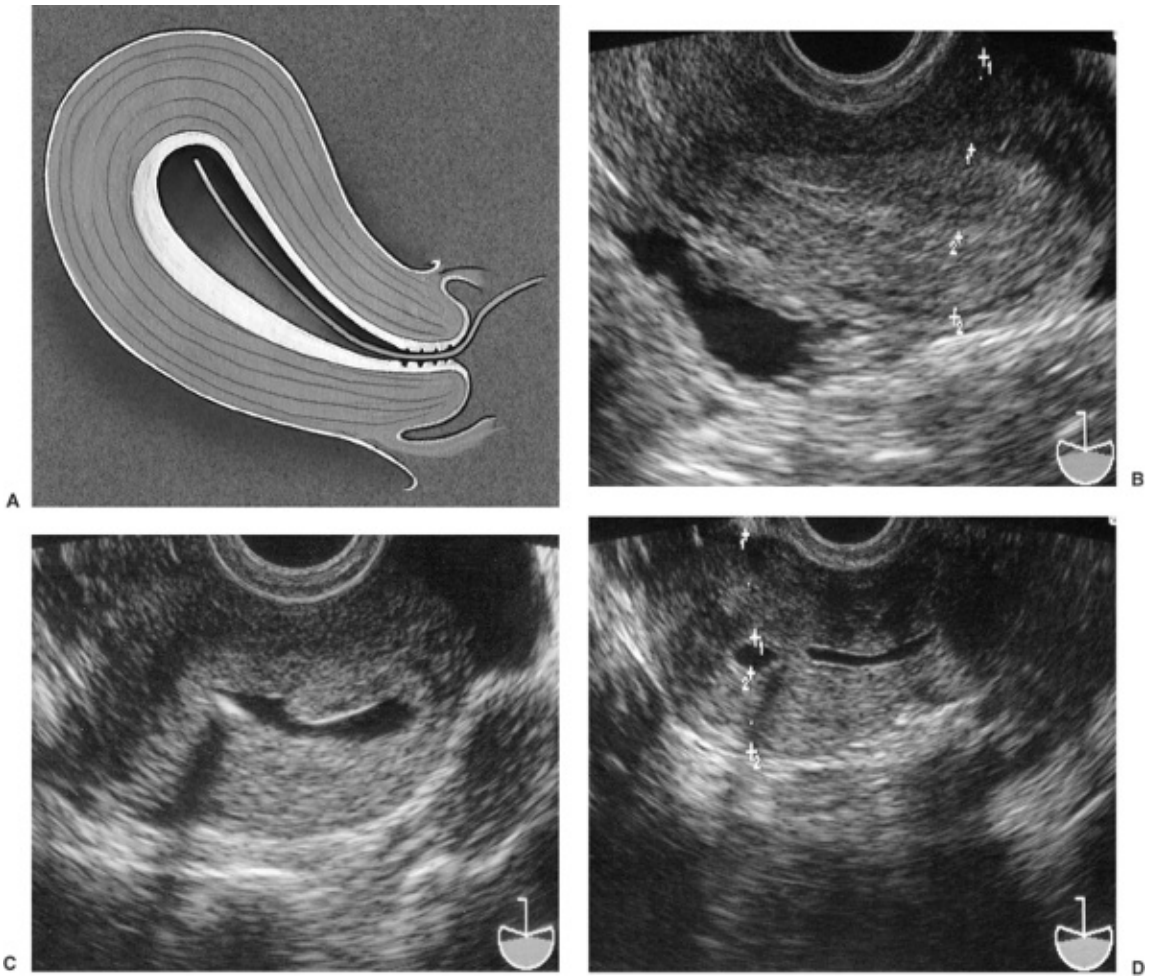

Figure 30.4 Saline infusion SIS. **A:** Diagram showing an intrauterine catheter used for distension of lumen with saline for detailed evaluation of the endometrium from the inside. (Diagram by Paul Gross, MS.) **B:** Standard TVUS showing a secretory phase endometrial stripe. **C:** Same uterus evaluated with SIS, revealing an anterior endometrial polyp not seen with standard sonography. **D:** SIS revealing intrauterine synechiae with saline having filled above and below the adhesion. On standard sonography, the endometrial stripe appeared normal with a 6-mm thickness. (See Color Plate)

Pelvic Mass

Sonography provides a means to evaluate the size, location, and internal acoustic characteristics of pelvic masses (Fig. 30.5). TVUS provides important information about the location of the pelvic mass relative to the ovary and uterus and provides higher resolution for better delineation of the internal architectural characteristics compared with TAS. Larger masses (>10 cm) that may rise out of the pelvis, however, may best be delineated by using TAS. A general outline of diagnostic considerations for pelvic masses according to location and internal acoustic characteristics is shown in Table 30.1.

Any woman of childbearing age can have a physiologic or functional “cyst” present when undergoing TVUS. Most of these functional “cysts” have smooth walls, are free of internal echoes or septations, and are typically <5 cm in size. In the follicular phase, there may be

multiple unilocular cysts <2 cm in size that represent the pool of developing follicles from which a dominant follicle is selected.

Following ovulation, this dominant follicle becomes a corpus luteum, which typically is unilocular but has more internal echogenicity. Hemorrhagic corpus luteum cysts often exhibit thin fibrin strands of echogenic material within a mostly hypoechoic mass contained by a somewhat thickened and irregular wall. Visualization with CDS may show a peripheral "ring of fire" surrounding the highly vascular structure. Labeling these physiologic structures as cysts is the source of a great deal of unnecessary concern for women that can be best avoided by using terms such as *follicle*, *corpus luteum*, or *functional* and by emphasizing the fact that these are completely normal findings in women of reproductive age. In the absence of abnormal or suspicious US findings or in the absence of symptoms such as continuing pelvic pain, repeat sonography of physiologic or functional-appearing cysts found on US is unnecessary.

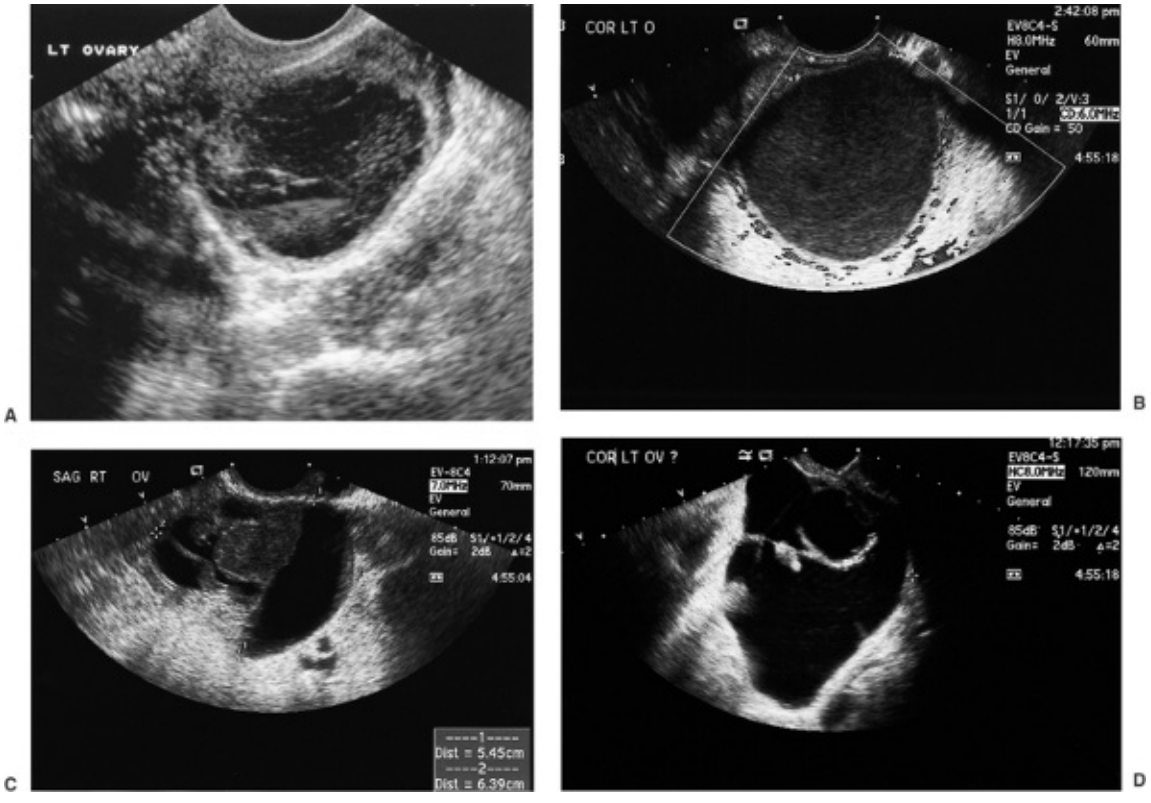

Figure 30.5 Pelvic masses. **A:** TVUS of a hemorrhagic corpus luteum with organized hemorrhage containing thin fibrin strands and internal echoes within the mass. **B:** Endometrioma showing its classic ground-glass appearance. **C:** Complex ovarian mass containing both solid and cystic components. **D:** Papillary excrescence arising from the wall of a mostly cystic ovarian mass. This morphologic feature is highly suggestive of cancer.

TABLE 30.1 Differential Diagnoses of Pelvic Masses by Transabdominal and Transvaginal Sonography

Location	Internal Acoustic Appearance		
	Cystic	Complex	Solid
Ovarian	Physiologic cyst Neoplastic cysts	Dermoid cysts Neoplastic cysts Hermorrhagic cysts Tuboovarian abscess	Metastases Solid ovarian tumors Fibroma
Adnexal Extraovarian Uterine Other	Paraovarian cyst Hydrosalpinx Developmental cyst	Endometrioma — Degenerated fibroid Arteriovenous malformation Diverticulosis Complicated appendicitis	Tubal tumor — Pedunculated fibroid Bowel tumor Lymphadenopat

Up to 15% of asymptomatic postmenopausal women have been shown to have simple ovarian cysts with acoustic characteristics associated with benign histology. Indeed, one of the pitfalls of the readily available office US may be that incidental masses might be found in this age group, prompting unnecessary concern and even surgery. It has been shown that the risk of malignancy in unilocular cysts or cysts with a single septation is very low in both premenopausal and postmenopausal women, especially if the mean diameter is <5 cm. Conservative management is appropriate for women with such cysts identified by TVUS. Larger simple cysts or cysts with more complex internal architecture including papillations or solid areas with blood flow warrant surgical excision due to a higher risk of malignancy.

In the premenopausal woman, it is important to differentiate benign masses that regress (functional cysts) or are stable in size from the rare ovarian cancer that will continue to enlarge. This is sometimes accomplished by observing the mass over time. Some US findings are more characteristic of benign ovarian neoplasms. For instance, ovarian endometriomas are often but not always unilocular, and they have a homogeneous “ground-glass” appearance caused by the degraded old blood within the endometrioma, which is avascular when imaged by CDS. Dermoid cysts frequently have a complex

appearance but often have areas of calcification or skin elements such as hair and sebaceous secretions that yield characteristic sonographic patterns. With the improved resolution of modern US scanners, it is not uncommon to see small teratomas that appear as heterogenous echogenic regions within a normal ovary. If a dermoid cyst is found in one ovary, it is important to evaluate the contralateral ovary carefully because approximately 15% of patients have bilateral dermoid cysts.

TABLE 30.2 Sonographic Features of Benign and Malignant Pelvic Masses

	Benign	Malignant
Transvaginal Ultrasound		
US morphology	Smooth walled, anechoic	Papillary excrescences, mural nodules, irregular solid areas
Color Doppler Study		
Vasculature	Regularly spaced	Irregularly spaced, clustered
Impedance	High	Low
Velocity	Low	High
Size change	Regress or no change	Progress or no change
Other findings	No ascites, no liver masses or lymphadenopathy	Ascites, no liver masses or lymphadenopathy

US, ultrasound.

Sonographic features of benign and malignant pelvic masses are listed in Table 30.2.

Malignant masses are found with increasing frequency in older women, so correlation of US findings with clinical details can be useful in assessing the risk of malignancy. Findings from CDS can help to differentiate benign from malignant masses. Blood vessels within cancers often are poorly developed and chaotic and have low resistance to flow, resulting in low resistive indices with CDS. On power Doppler studies, blood flow is found more often in solid, central regions of the malignancy. Although US can be helpful in predicting the likelihood of malignancy, it is not accurate enough to depend on entirely for decisions regarding the risk of malignancy. Complex masses, particularly in older women, must be regarded as highly suspicious for malignancy regardless of the Doppler findings associated with vascularity, as there is significant overlap between benign and malignant tumors in these measures.

Pelvic Pain

TVUS plays an important role in evaluating patients with acute pelvic pain (Fig. 30.6). Demonstrably normal-appearing ovaries with no free intraperitoneal fluid on TVUS virtually eliminate a primary ovarian source for acute pain. The uterus can be evaluated sonographically, and

pathologic causes of pelvic pain such as uterine fibroids, with or without degeneration, can be ruled out. TVUS is relatively poor at identifying peritoneal endometriosis that is more commonly seen in the setting of chronic pain but is excellent at detecting ovarian endometriomas that when ruptured can cause an acute exacerbation. Tuboovarian abscesses can be visualized easily by TVUS and the diagnosis considered in the presence of pelvic pain, fever, and complex adnexal masses.

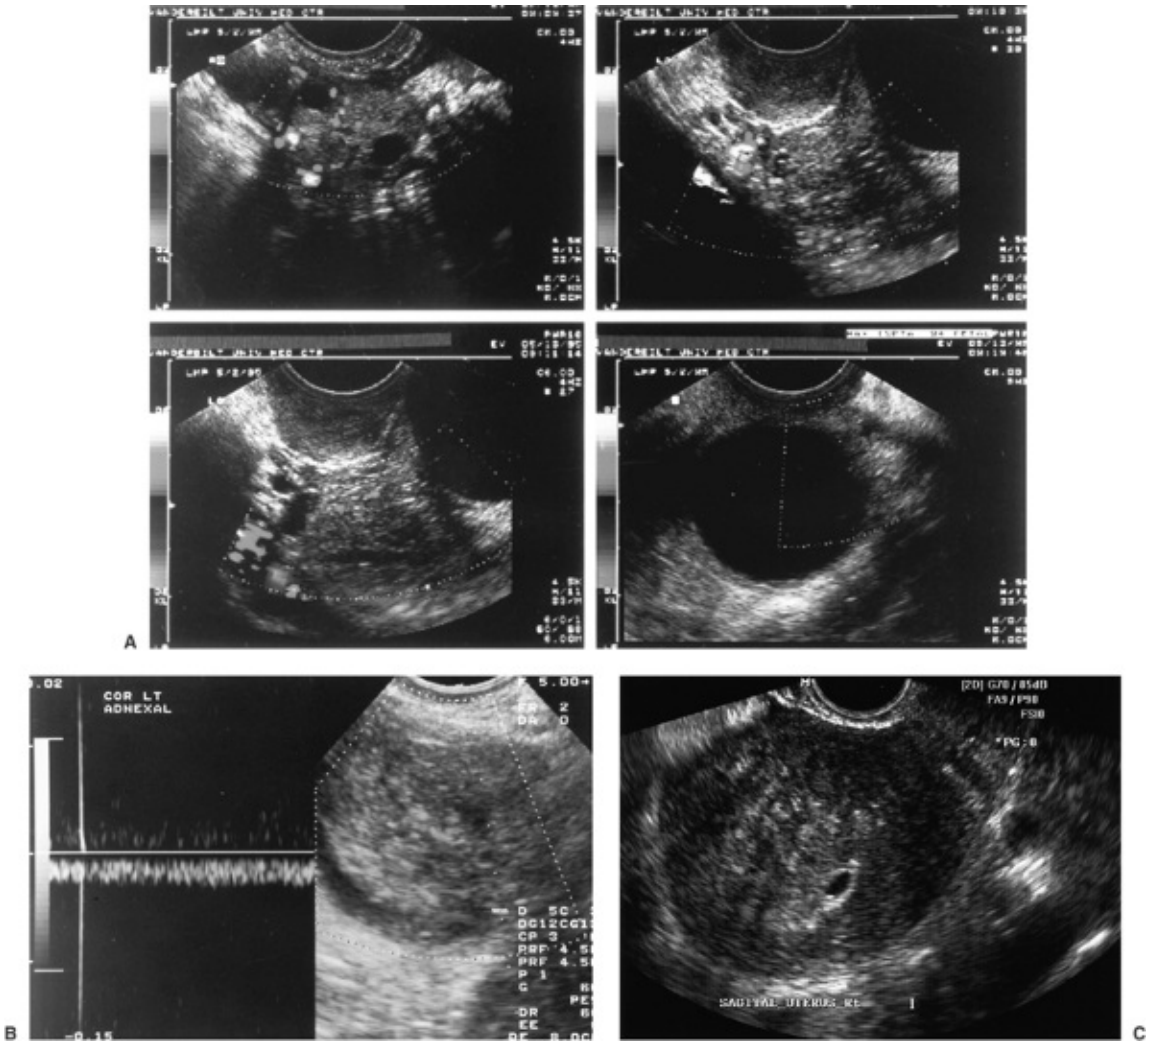

Figure 30.6 Pelvic pain. **A:** Composite TVUS showing an enlarged left ovary **(top right and bottom left)** without flow and associated with a paraovarian cyst in the left adnexa **(lower right)**. The right ovary **(top left)** was normal, showing intraparenchymal flow. The left adnexa was found to be twisted three times and was surgically untwisted with a good result. **B:** Doppler sonogram of an enlarged left ovary containing venous flow. This finding suggests potential viability of this partial ovarian torsion. **C:** Irregular echogenic area within the myometrium, which is suggestive of adenomyosis. (See Color Plate)

Ovarian torsion, a surgical emergency, must be eliminated as a cause of acute pelvic pain when a tender mass is noted on pelvic examination. Commonly, the ovary is enlarged with a thickened capsule due to a mass that predisposed the patient to be at risk for torsion. Other nonspecific findings include an ovary located higher than normal and an increase in free fluid in the cul-de-sac. CDS provides additional useful information by determining whether there is blood flow to the ovary. The complete absence of blood flow, a late finding in patients with ovarian torsion, is highly suggestive of torsion provided that Doppler settings are sufficiently sensitive enough to detect flow in the contralateral ovary. The presence of blood

flow does not rule out the diagnosis, however, since torsion can be intermittent or partial

with arterial flow maintained early in the process. Isolated torsion of a paraovarian or paratubal cyst or a fallopian tube is possible and is characterized by a cystic structure separate from but adjacent to the ovary without blood flow.

One of the most common causes of acute pelvic pain is a hemorrhagic ovarian cyst. Blood within the hemorrhagic cyst can have several sonographic appearances. Fresh or acute bleeding within an ovarian cyst can appear echolucent. Organized clot has a more heterogenous and echogenic appearance. The hemorrhagic component typically demonstrates no flow, whereas the surrounding normal ovary has both arterial and venous flow. Free peritoneal fluid from a ruptured hemorrhagic cyst also can be observed and certainly is not a rare cause of acute pelvic symptoms as blood irritates the peritoneum. Other ovarian neoplasms, such as endometriomas and benign cystic teratomas, can rupture as well, leading to peritoneal irritation accompanied by acute pelvic pain.

Pelvic pain often originates within the uterus. Fibroids can be a source of pelvic pain, and degenerating fibroids (most often seen during pregnancy) may cause severe pelvic pain. TAS or TVUS usually can confirm the presence of fibroids, though there is no specific US appearance of a fibroid with degeneration. The presence of fibroids on US does not necessarily mean that they are the cause of the pain, as asymptomatic fibroids are quite prevalent in the general population. Adenomyosis is a cause of acute and chronic pelvic pain and may produce subtle findings that can be seen on TVUS, which include an enlarged uterus with irregular echogenic or hypoechogenic areas in the subendometrial myometrium. Rarely, actual cystic spaces within the myometrium are observed. Because of the nonspecific nature of the sonographic findings, US is not an ideal test for the detection of adenomyosis, and if this diagnosis is suspected, pelvic magnetic resonance imaging (MRI) may be a better modality. It sometimes can be difficult to distinguish adenomyosis or an adenomyoma from an intramural fibroid. The vascularity associated with adenomyosis usually is diffuse compared with that of a fibroid, which has flow concentrated on the periphery of the tumor.

When evaluating acute pelvic pain, non-gynecologic causes of pain such as appendicitis and renal calculi also must be considered. An understanding of pathologic findings possible in these settings is important. On TAS, an inflamed appendix may not be identified or may appear as a noncompressible fusiform structure in the right lower quadrant that has a thickened (>6 mm) wall. When ruptured, fluid may be noted surrounding the abnormal appendix. US also can detect hydronephrosis suggestive of ureteral obstruction that may accompany ureterolithiasis. In the hands of skilled operators, TAS may be able to localize renal calculi in the distal ureter in some patients; these will appear as a highly echogenic focus within the ureter. If a ureteral jet is clearly seen within the urinary bladder on CDS, ureteral patency can be confirmed and complete ureteral obstruction ruled out.

Ectopic Pregnancy

Prior to the advent of sensitive ß-human chorionic gonadotropin (ß-hCG) assays and US, the diagnosis of ectopic pregnancy most often was made after the tube had ruptured and the patient became hemodynamically unstable with an acute abdomen, necessitating immediate laparotomy. With TVUS and sensitive ß-hCG assays, ectopic gestations are now

most often diagnosed prior to the onset of symptoms, making a ruptured ectopic pregnancy much less common and providing an opportunity for medical management with methotrexate.

When pregnant women in the first trimester present with abdominal pain or vaginal bleeding, a TVUS and ß-hCG are necessary to rule out an ectopic pregnancy (Fig. 30.7). The discriminatory hCG zone, which is the range of serum hCG above which a normal singleton intrauterine pregnancy (IUP) can consistently be visualized, is a useful tool in this evaluation. This discriminatory zone is different for TVUS and TAS. In most women, TVUS allows the visualization of a gestational sac within the uterus when the ß-hCG level is between 1,500 and 2,000 mIU/mL and fetal cardiac activity when the level is between 5,000 and 6,000 mIU/mL. These levels are higher when TAS is used. The absence of an intrauterine gestational sac at ß-hCG levels >2,000 mIU/mL is suggestive of either an ectopic pregnancy, a failed IUP, or multiple gestation. In the case of a multiple gestation, the hCG level will reach the discriminatory zone earlier, before an IUP can reliably be seen.

Detection of an intrauterine gestational sac virtually eliminates the presence of an ectopic pregnancy. The exception to this rule is in patients who have undergone ovulation induction or assisted reproductive technology to achieve pregnancy. In these situations, the incidence of a heterotopic pregnancy (simultaneous pregnancies in the uterus and the fallopian tube) is approximately 1%. The usual position of a normal gestational sac is in the mid to upper uterus. The presence of a yolk sac, which creates a “double ring” sign on TVUS, becomes apparent at 5 to 6 weeks gestational age and is diagnostic of an IUP.

An ectopic pregnancy may or may not be observed on TVUS. If the ß-hCG level is above the discriminatory zone and no IUP is observed by US, the patient either has a nonviable intrauterine gestation or an ectopic pregnancy. Oftentimes, an ectopic pregnancy will be associated with a fluid collection in the uterus, termed a *pseudosac*, mimicking the appearance of a gestational sac. Pseudosacs typically are located in the center of the endometrial stripe, whereas an IUP is often eccentric, having invaded the endometrium in one wall. It can be very difficult to differentiate the two, however, and one must use other US findings or sequential imaging to help decipher this dilemma. Other US findings

that are suggestive of an ectopic pregnancy are the presence of a cystic circular structure or mass in the adnexa separate from the ovary and the presence of free fluid in the pelvis. The presence of intraperitoneal fluid combined with an extraovarian adnexal mass in a pregnant patient without an intrauterine gestation should be viewed as a surgical emergency. Careful examination of the uterus with TVUS also can help to identify cornual and cervical ectopic pregnancies as well be as aid in the diagnosis of an abdominal pregnancy. Use of CDS at the time of TVUS allows visualization of increased vascularity surrounding ectopic pregnancies.

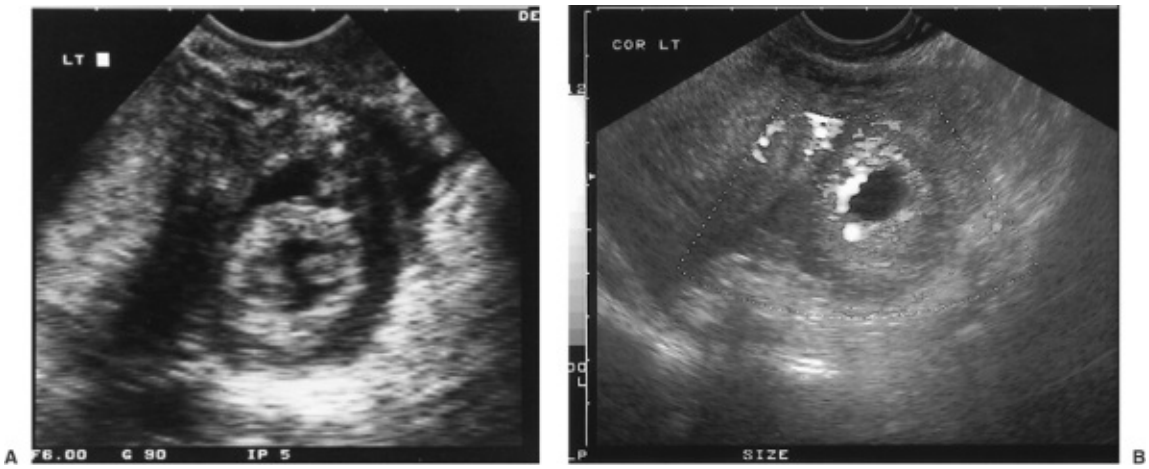

Figure 30.7 Ectopic pregnancy. **A:** Unruptured ectopic pregnancy appearing as a tubal ring in the left adnexa. **B:** TV-CDS showing vascularity of the tubal ring of an unruptured ectopic pregnancy. (See Color Plate)

Müllerian Anomalies

Müllerian anomalies present in a variety of ways, including primary amenorrhea, severe dysmenorrhea with the onset of menarche, recurrent miscarriage, and preterm labor. Their accurate diagnosis is important when differentiating surgically correctable forms of Müllerian anomalies from those that are inoperable. MRI has long been considered the imaging modality of choice; however, recent advances in US, specifically with the advent of 3D-US, have made it an acceptable first-line diagnostic tool (Fig. 30.8). Specifically, 3D-US offers the advantages of lower cost, shorter scan time, and greater accessibility. In addition, TAS can easily be performed concurrently to assess the urinary system, given the high association of Müllerian anomalies with renal and ureteral anomalies.

Correct diagnosis of Müllerian anomalies relies on evaluation of the endometrial cavity as well as the configuration of the uterine fundus. While hysterosalpingogram and hysteroscopy selectively provide useful information regarding the endometrial cavity, little information is offered with regard to uterine fundal contour. Diagnostic laparoscopy, on the other hand, allows visualization of the outer contour of the uterus; however, no information on the endoluminal contour is provided. 2D-US often can suggest the uterine contour, but this is probably best imaged with 3D-US, which allows simultaneous visualization of both the endometrial cavity and its surrounding myometrium in the coronal plane. This permits differentiation between anomalies such as septate and bicornuate uteri, which are managed very differently. Studies have reported the accuracy of 3D-US in the evaluation of Müllerian anomalies to be >90%. Use of SIS enhances diagnostic precision. An additional use of US in patients with Müllerian anomalies is guidance during hysteroscopic uterine septoplasties. TAS can be a useful tool in determining the proximity of the uterine repair to the serosal surface, thus preventing unnecessary complications such as bleeding and uterine perforation.

Infertility

TVUS can provide important information in the evaluation of the infertile patient (Fig. 30.9) and is indispensable in the management of controlled ovarian hyperstimulation (COH) induced by parenteral gonadotropins necessary for modern assisted reproductive technology such as in vitro fertilization (IVF). During COH, TVUS is used in the serial assessment of follicular maturity as well as for the evaluation of the thickness and texture of the endometrium. The number of follicles and their size can be determined, with mature preovulatory follicles measuring between 18 and 20 mm. In the periovulatory period, the endometrial thickness typically is 7 to 11 mm, and a trilaminar appearance of the endometrial stripe has been associated with higher rates of embryo implantation. Prior to the widespread use of TVUS for oocyte retrieval, egg collection from mature follicles was accomplished by laparoscopy under general

anesthesia. Today, oocyte retrieval is routinely accomplished by a TVUS-guided, multifollicle aspiration. TVUS or TAS also is used to monitor the transfer of embryos to the uterus at the completion of an IVF cycle.

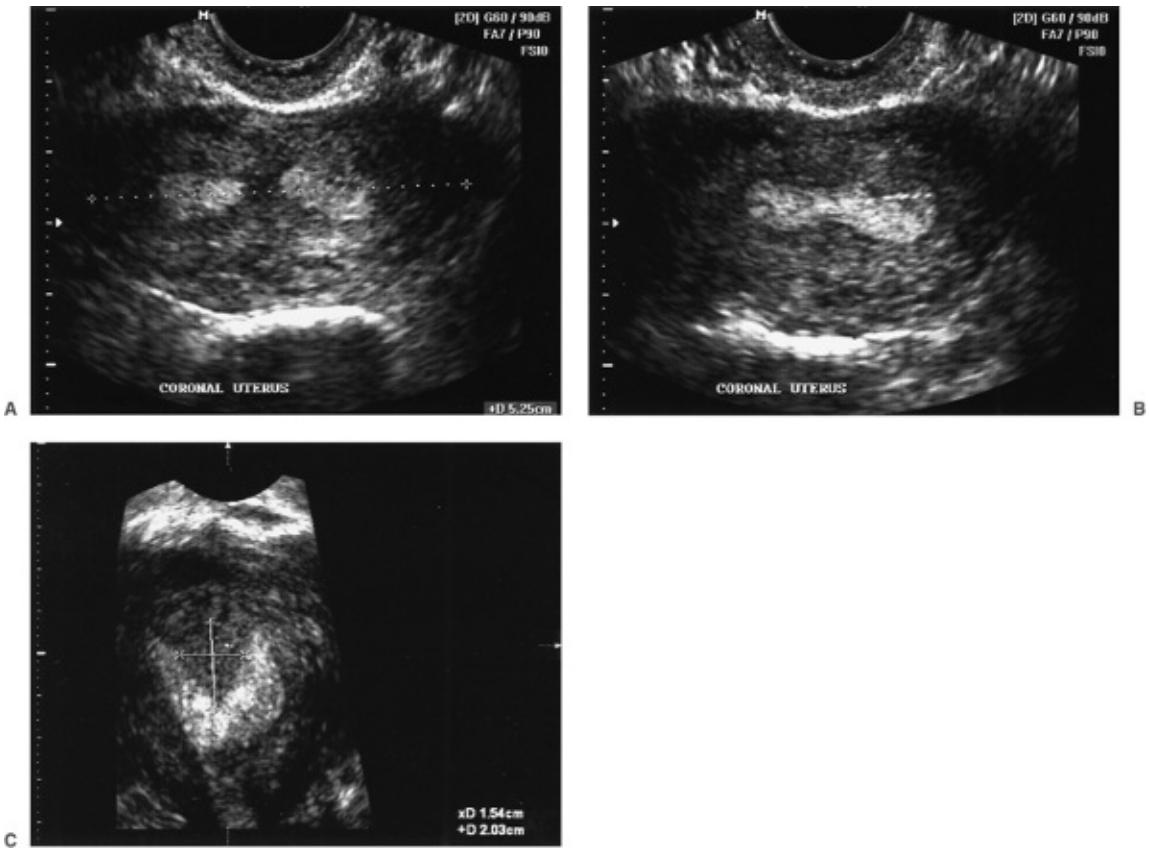

Figure 30.8 TVUS examination of a septate uterus. **A:** 2D transverse view of the upper uterus revealing two uterine horns. **B:** 2D transverse view of the lower uterine segment. **C:** 3D coronal view showing normal uterine fundal contour and a 1.5 cm septum.

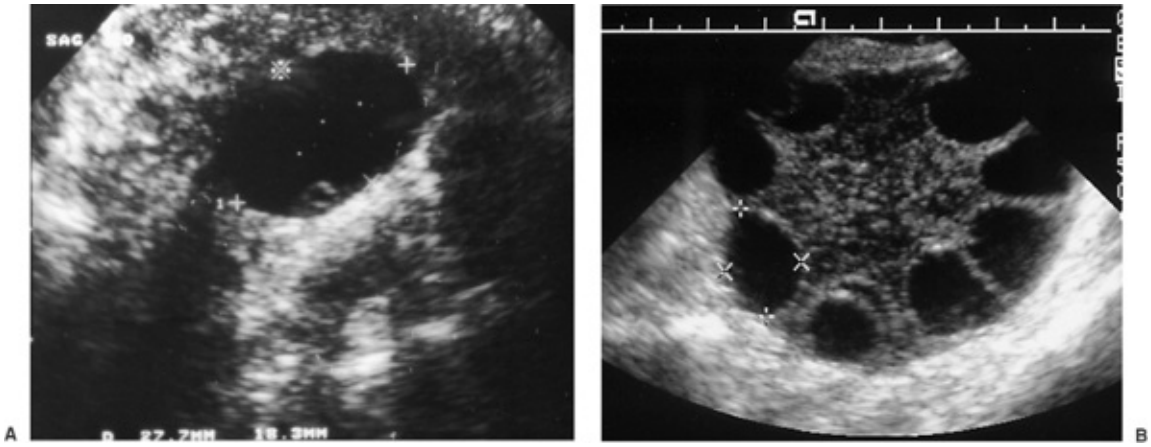

Figure 30.9 Infertility. **A:** Mature follicle (between cursors) containing a small protrusion from the posterior wall representing the cumulus oophorus. **B:** Classic appearance of an ovary seen in women with PCOS ("string of pearls").

Women with polycystic ovarian syndrome often present with infertility due to anovulation. In 2003, the Rotterdam criteria for the diagnosis of PCOS were established. One of the three diagnostic criteria included in the definition was based on US findings. Polycystic ovaries are now defined as having 12 or more follicles in one plane measuring 2 to 9 mm in diameter and/or increased ovarian volume (>10 mL) in the absence of other follicular development. Peripheral follicular distribution and an increased ovarian stromal volume commonly are seen in PCOS, but these findings are subjective and are not included in the diagnostic criteria. The diagnosis of PCOS cannot be made on US findings alone, however, as evidenced by the fact that many other conditions are associated with "polycystic ovary–appearing" or "polyfollicular" ovaries on TVUS. In fact, up to 25% of normally ovulatory women may have a polycystic ovarian appearance on US exam.

More recently, various investigators have used TVUS in conjunction with uterine cannulation as a screening tool for assessing the endometrial cavity and tubal patency. At this time, this newer mode of tubal assessment should not replace the gold standard method of hysterosalpingography. Using various contrast media (including saline, as in SIS), the endometrial cavity can be evaluated for the presence of fibroids or polyps that may result in subfertility as well as for Müllerian abnormalities such as a uterine septum, which often is associated with recurrent miscarriage. In conjunction with SIS, the escape of saline out of the fimbriated end of the tube is readily apparent in women with patent fallopian tubes as the cul-de-sac fills rapidly with fluid. The presence of cul-de-sac fluid during or after SIS confirms that at least one fallopian tube is patent. Attempts have been made to use CDS to assess in real time the efflux of echogenic contrast from each fallopian tube, with varying degrees of success.

Sonographically Guided Procedures

US can be very useful in assisting difficult gynecologic procedures, particularly those

involving the uterus. In cases in which dilation of the uterine cervix has been unsuccessful or more difficult than usual, simultaneous TVUS or TAS can decrease the risk of uterine perforation and creation of a false tract. If perforation of the uterus is suspected, the path that the dilator or curette has followed as well as its tip can be readily visualized by using sonography, as long as the instrument has not been moved once perforation is suspected. Traditionally, the internal US transducer was placed in the rectum or the abdominal transducer, with the aid of a distended bladder, was used to assist in directing the dilator as it traversed the cervix or confirmed the correct path to take. With the smaller transducers found on most vaginal US probes today, the transducer usually can be placed next to the cervix through an open speculum, particularly in patients whose cervix is flush with the vagina, as in postmenopausal patients, or in those who have undergone cervical conization. Once the dilator is through the internal cervical os, TVUS or TAS can localize the dilator or curette within the uterine cavity. Real-time monitoring of the procedure can greatly reduce the risk of uterine perforation. US also can be helpful in monitoring a curettage being performed for the surgical management of either an incomplete miscarriage or early pregnancy termination. A US done at the end of the procedure can decrease the likelihood of the patient needing a second procedure at a later date by identifying those with an inadequate curettage. TAS also can be used to ensure correct placement of a uterine tandem being used for local radiation treatment of cervical or uterine cancer.

TVUS can provide real-time delineation of the location of a needle relative to an area of interest within the ovary or adjacent structures. For this purpose, a needle guide with an internal opening can be attached to the shaft of the vaginal transducer, which confines the course of the needle to a prescribed path in the exact plane of the 2D scan. The most common use of this technique is transvaginal oocyte retrieval during an in vitro fertilization or in vitro maturation cycle, which is accomplished by aspirating individual follicles under direct US guidance. Cystic ovarian or adnexal masses may be drained in this manner as well. Ovarian or adnexal masses that are amenable to transvaginal drainage include endometriomas (at the start of a COH cycle or when needed for the short-term relief of acute pain), symptomatic yet relatively small simple ovarian cysts (where there is no concern for malignancy), or hydrosalpinges (at the time of transvaginal oocyte retrieval for an in vitro fertilization cycle, particularly for those in whom surgical intervention is relatively contraindicated). Likewise, tuboovarian abscesses may be drained by using the TVUS-guided approach. In the case of endometriomas or hydrosalpinges, it is unlikely that transvaginal drainage will be curative, as they typically reaccumulate over time.

If an ovarian cyst is drained and subsequently reaccumulates, two options are available—surgical excision and transvaginal needle aspiration followed by instillation of a sclerosing agent such as alcohol or tetracycline. In postmenopausal patients and patients who are poor surgical candidates, the latter offers conservative management of a simple ovarian cyst as an outpatient without the need for general anesthesia. Very similar to TVUS-guided oocyte retrieval, a needle is directed under US guidance through the vaginal mucosa into the cyst. The cyst contents are then drained, and the sclerosing agent is infused and left in place for 20 minutes, after which time it is aspirated. This conservative treatment method also has been used for the treatment of ovarian remnant syndrome.

Summary Points

- Transabdominal and transvaginal scanning are both useful in establishing the source of AUB, characterizing pelvic masses found on physical examination, evaluating acute pelvic pain, diagnosing ectopic pregnancies, and assessing and treating infertility.
- Advances in technology such as higher transducer frequencies for improved resolution, rapid computerized assembly of 2D images to yield virtual 3D images, and smaller equipment have fostered wider clinical applications and made office use routine.
- US guidance during gynecologic surgical procedures has proved very useful in making difficult intrauterine procedures safer and diagnosing and treating selective pelvic masses by needle aspiration. It is the single most important advance in collecting oocytes for in vitro fertilization.
- SIS has improved the diagnostic capability of TVS in circumstances of AUB.
- Pelvic US is the initial diagnostic modality of choice in most circumstances, whereas secondary tests such as CDS, MRI, and computed tomographic scanning provide a means to further enhance diagnostic specificity in difficult or nondiagnostic US studies.

Pediatric and Adolescent Gynecology

Ann J. Davis

Pediatric and adolescent gynecology is frequently viewed as a single focused aspect of gynecology. In fact, these two areas are reasonably distinct, with a logical division being at the onset of puberty and the activation of the hypothalamic–pituitary–ovarian (HPO) axis. Prepubertal girls differ from postpubertal girls in anatomy, etiologies of similar symptoms, and the spectrum of likely and common syndromes. However, both groups require specific and different communication skills. Psychosocial and developmental milestones and characteristics help to guide the obstetrician and gynecologist in how to communicate with each age group in an effective manner. Involvement of the family or adult caretaker also is critical in achieving the goals of providing excellence in gynecologic care. This chapter will discuss topics in both of these age groups, with an emphasis on the differences in children and teens as compared with those of mature reproductive women.

Examination

The Prepubertal Child

The genital examination of the prepubertal child should be approached quite differently from the gynecologic examination of an adolescent or adult. However, the complete exam may include all of the same elements as the examination of the more mature reproductive female: examination of the external genitalia, examination of the vagina, and palpation of the uterus and adnexal structures.

External Genitalia

It is often helpful to examine a toddler on her mother's lap while the mother elevates or abducts the child's hips for the so-called “frog-leg position.” It is important to place the child on a towel or chuck pad in case urination occurs. An older child can sit straddling her mother's lap fully clothed while the mother places the child's legs in the stirrups. Usually, children between the ages of 4 and 6, and sometimes as young as 3, can position themselves in classic lithotomy with use of the stirrups. Clinicians can use their hands to provide lateral and downward traction on the area of the labia majora (Fig. 31.1). This will allow full visualization of the hymen and vaginal orifice.

Care should be taken to inform the child of the necessary steps of the exam. Continuously conversing with the child during the exam will allow her to relax. Children should never be forced or held down in order to perform a genital exam.

Vagina

Various positions have been described to visualize the vagina. In the very young infant or toddler, a Valsalva maneuver can be helpful in the exam; the child can be asked to pretend that she is blowing up a balloon or blowing out her birthday candles. This will often allow visualization of the distal 1 to 2 cm of the vagina. The knee–chest position is very helpful; children 3 years of age and older can typically cooperate and hold the knee–chest position. The child places her buttocks in the air with knees placed apart and allows her abdomen to sag. The examining physician and one assistant provide lateral and upward traction on the labia and buttocks. An otoscope can be used as a magnification instrument and light source to shine into the vagina, allowing visualization to the level of the cervix even without inserting the instrument. A vaginal speculum is neither appropriate nor indicated in the examination of the prepubertal child in the office (Fig. 31.2).

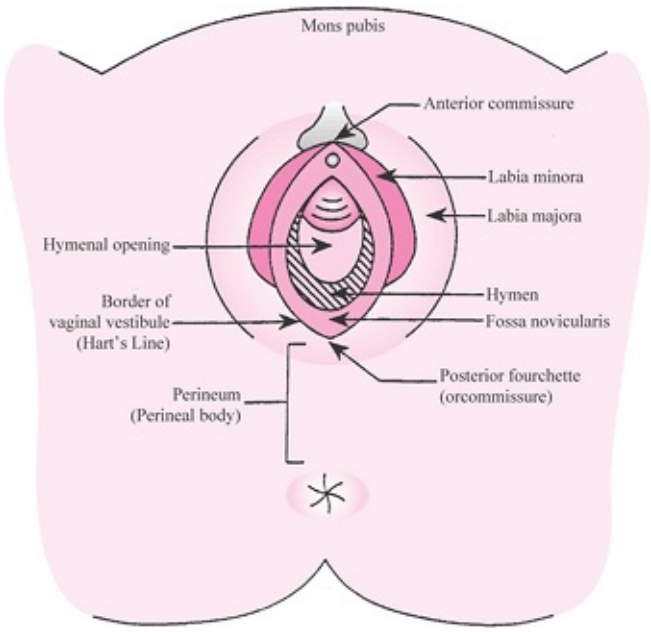

Figure 31.1 Diagram of the genital anatomy of a prepubertal girl. This drawing shows a crescent hymen. (From Pokorny SF. *Pediatric and adolescent gynecology*. New York: Chapman and Hall, 1996.)

Uterus and Adnexa

Examination of the uterus and adnexa requires a rectal examination and should be reserved for the pediatric gynecology patient when information regarding the uterus or adnexa is necessary in the evaluation. Rectal bimanual examination should not be done routinely in every child requiring gynecologic examination.

In prepubertal children, the adnexa should not be palpable. In children, the ovaries lie at the level of the pelvic brim and drop into the pelvis with the onset of puberty. If an adnexa is palpable, there is, by definition, an adnexal enlargement that will require swift and careful evaluation of a possible ovarian neoplasm.

In the normal prepubertal child, the uterus should be easily palpable on rectal examination. Prior to puberty, two thirds of the uterine volume is cervical in contrast to the one third proportion in adults. The cervix, therefore, is a relatively easy structure to palpate on rectal examination in prepubertal children.

Figure 31.2 The knee–chest position can be used to examine the vagina of a prepubertal child: the otoscope is used for a light source and magnification and is not inserted into the vagina.

The Newborn

The obstetrician–gynecologist should be encouraged to observe the normal genitalia of the female infants that he or she delivers. Under the influence of maternal estrogens, the labia are generous in size, and the estrogenized hymen is prominent, turgid, and fimbriated or redundant in appearance. The female infant will sometimes experience an estrogen-withdrawal spotting episode within several days after birth. Parents should be informed of this normal phenomenon in an effort to preclude maternal anxiety and even unnecessary visits to the pediatric emergency department (ED). In a series of pediatric patients seen in the ED of Cleveland's Children's Hospital for vaginal bleeding, the vast majority of those under the age of 2 were seen for this reason. These ED visits are completely avoidable through parental education. Previously, before early obstetrical discharge, this estrogen-withdrawal spotting occurred in the hospital nursery.

Observation of the genitalia of female infants at birth allows the detection of various developmental and congenital abnormalities, some of which may be life threatening. If ambiguous genitalia are observed, the obstetrician must use excellent communication skills in the delivery room to help set the stage for the evaluation of the infant and to assist in decreasing parental anxiety. The parents should be informed that the baby's genitals are not fully developed and a simple examination of the external genitalia cannot determine

the actual sex. The parents should be told that they definitely have either a girl or a boy; but because development is not complete, data will have to be collected before they are told what sex the baby is and what treatment is required. Guesses must be avoided. It is critical to wait until all the information allows that the initial sex assignment given to the parents is the final and correct assignment.

The problem of ambiguous genitalia represents a social and potential medical emergency that is best handled by a team of specialists, which may include urologists, neonatologists, endocrinologists, and pediatric gynecologists. The differential diagnosis of ambiguous genitalia includes chromosomal abnormalities, enzyme deficiencies (such as 21-hydroxylase deficiency, which is a form of congenital adrenal hyperplasia [CAH]), and prenatal masculinization of a female fetus resulting from maternal androgen-secreting ovarian tumors or, rarely, drug exposures. The etiology of these problems as well as intersex disorders that may be discovered in an older child can be complex.

The possibility of CAH is especially critical to exclude. With the salt-wasting form of this disease, death can occur in the neonatal period, so electrolytes should be obtained immediately. Often overlooked is one simple physical exam finding that rules out CAH; the presence of gonads in the

---

labial scrotal folds in the infant with ambiguous genitalia eliminates the diagnosis.

One additional benefit of an observation of the genitalia of female infants at the time of birth is that some genital anomalies such as an imperforate hymen, vaginal agenesis, or other hymeneal anomalies may be diagnosed. Hymeneal abnormalities occur in <1% of newborn females and include imperforate hymens, cribriform hymens, and septate hymens. Normal hymeneal variations include hymeneal bumps, ridges, or bands. If there is any doubt about hymeneal patency, a rectal thermometer or small plastic catheter may be used to gently test for the vaginal space. Obstructive lesions include imperforate hymen, vaginal agenesis, or vaginal septa.

The timing of repair of an imperforate hymen remains controversial. Some experts recommend repair at puberty after full estrogenization. Others repair imperforate hymens after the neonatal interval when convenient for the family. This approach may avoid anxiety during the critical preadolescent years of psychosexual identity if the girl perceives there is something wrong with her genitalia that is awaiting repair. In some rare cases, a mucocolpos develops behind the imperforate hymen. This may be seen in the newborn, in which the mucus production is under the direction of maternal estrogens, or at the time of breast budding, in which endogenous estrogens orchestrate stimulation of mucus production. Very rarely, the mucocolpos may cause urinary obstruction that would necessitate urgent hymenectomy. Care must be taken to delineate the exact anatomic nature of the obstruction, and the clinician performing a hymenectomy should be comfortable that the obstruction is at the level of the hymen. Opening a thin imperforate hymen is a relatively easy surgical procedure, whereas the correction of other types of obstructive lesions such as vaginal septae requires careful planning, experience, and a high degree of skill.

Vulvovaginitis

Vulvovaginitis is the most common cause of vulvar symptoms in the prepubertal age group and the most common gynecologic complaint in prepubertal children. In children, the primary site of infection is often the vulva, in contrast to mature reproductive women in which the vagina is usually the primary site of infection. Vulvovaginitis in prepubertal children may be caused by specific pathogens, including *Streptococcus pneumoniae*, *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Shigella*, *Haemophilus influenzae*, and pinworms. More commonly, however, the vulvovaginitis is nonspecific with no pathogenic organism responsible.

Cultures of the vagina in children with nonspecific vulvovaginitis will often reveal normal rectal flora such as *Escherichia coli*. Overgrowth of enteric bacteria can cause a primary vulvitis and a secondary vaginitis. In prepubertal children, the normal flora may invade and irritate the vulvar area. This invasion in prepubertal children is due to several circumstances. First, the labia minora are thin and unestrogenized. Second, there is no anatomic barrier between the vaginal orifice and the anus, since the labia majora are undeveloped and, prior to somatic growth, the anal and vaginal orifices are almost abutting one another. The unestrogenized vulva and vestibule normally appear mildly erythematous and may appear to be infected even when they are not, if examined by clinicians unaccustomed to routinely examining prepubertal children. Smegma around and beneath the prepuce resembles patches of candidal vulvitis to the inexperienced examiner. The prepubertal vagina is alkaline in contrast to the acidity of the mature reproductive woman's vagina. At puberty, bacilli in the completely estrogenized vagina begin to produce larger amounts of lactic acid.

Presentation

It often is difficult for a young child to describe vulvar sensations such as pruritis, pain, or a burning sensation. She may only be able to communicate a discomfort. Parents sometimes note that the child cries during urination, scratches herself, touches herself frequently, or squirms when sitting in an effort to rub the sore vulva. Often, the child's pediatrician will have evaluated the child for a urinary tract infection (UTI) and pinworms. Vulvovaginal complaints of any sort in a young child should prompt the consideration of possible sexual abuse.

Diagnosis

Most cases of vulvovaginitis are nonspecific, caused by normal intestinal flora. Specific pathogenic organisms must be excluded. When the initial presentation is compatible with nonspecific vulvovaginitis, some clinicians recommend proceeding with therapy based on the provisional diagnosis of nonspecific vulvovaginitis without performing diagnostic tests. In cases where treatment has been unsuccessful, it is important to perform diagnostic testing for specific pathogenic organisms. This may include cultures of the vagina to rule out *S. pneumoniae*, *N. gonorrhoeae*, *C. trachomatis*, *Shigella*, and *H. influenzae*. Both *N. gonorrhoeae* and *C. trachomatis* cause a vaginitis rather than cervicitis in children, so a

vaginal culture is appropriate to exclude these pathogens. Use of DNA technology to diagnosis sexually transmitted diseases (STDs) in children currently is not recommended as a diagnostic strategy by the Centers for Disease Control and Prevention (CDC). Use of indirect tests for STDs (such as enzyme-linked immunosorbent assay–based technology) is inappropriate in prepubertal children given the high possibility of false-positive results.

Several methods of obtaining vaginal cultures from the vagina of children are applicable. One such method is insertion into the vagina of a Dacron-tipped swab that is moistened with nonbacteriostatic saline. Avoiding touching the hymen helps to avoid any unnecessary discomfort to the child. Another method for obtaining cultures consists of

placement of a catheter through which nonbacteriostatic saline can be injected, aspirated, and sent for culture.

Therapy

The first step in treatment of nonspecific prepubertal vulvovaginitis involves attention to vulvar hygiene and toileting. Proper wiping will decrease rectal flora in the vulvovaginal areas. In addition, avoidance of vulvar irritants such as shampoo and deodorant soaps decreases the vulvar abrasion and irritation, making it more difficult for the rectal flora to invade the vulvar epithelium. Sitz baths are very helpful in relieving symptomatology. Scrubbing the vulvar area should be avoided, as this will only abrade the epithelium. Soaking the vulva clean is the preferable hygienic approach. A short course of broad-spectrum antibiotics can eliminate the overgrowth of enteric bacteria; however, unless the child changes her hygienic practices, the nonspecific vulvovaginitis is likely to recur when colonization recurs.

Fungal Infections

Fungal infections as a cause of vulvovaginitis are uncommon in prepubertal children. The prepubertal vagina is very alkaline and will not support fungal growth, which requires a more acidic environment. Exceptions to this rule may occur in immunosuppressed children such as organ recipients, children with HIV, or children receiving high-dose steroids. Diaper rash, which may present with erythema, excoriations, and satellite lesions primarily outside the vulvovaginal area, usually is fungal related.

Labial Agglutination

Labial agglutination is another common presenting complaint in prepubertal children between 3 months and 6 years of age. These are the years of a nadir in circulating estrogens. The abraded unestrogenized labia minora agglutinate and form a telltale line at the point of the agglutination that is visible on genital examination. These girls sometimes complain of genital discomfort and dripping of urine. Urine can be trapped in the “pouch” behind the agglutination. Despite the fact that the urethra may not be visible on genital examination, urinary obstruction typically is not a feature of this pediatric gynecologic problem.

Labial adhesions are extremely common and usually are symptomatic. Some small degree of adhesions is seen in many 3- to 4-year-old girls. Most experts agree that treatment should be reserved for symptomatic adhesions. The treatment consists of a short course of externally applied estrogen cream for several weeks. The area of agglutination will become thin and may spontaneously separate or can easily be separated in the office with the use of topical lidocaine jelly or anesthetic creams. It is critical that the estrogen be applied to the telltale line of adhesion and not lateral to the adhesion line. If pigmentation is seen lateral to the line of adhesion after estrogen application, this indicates improper application of the estrogen cream. Manual separation of thick adhesions should not be done in the office, as it is quite painful.

Attention must be given to the prevention of subsequent adhesions, as they clearly have a risk of recurring. One option is to recommend the use of a topical emollient, such as zinc oxide ointments (over-the-counter [OTC] “diaper rash” preventive creams) to prevent reagglutination in a tapering like manner after initial separation has occurred. Resolution of labial agglutination occurs at the onset of signs of endogenous estrogen production (breast budding).

Lichen Sclerosis et Atrophicus and Other Chronic Skin Conditions

Chronic skin conditions such as lichen sclerosis, seborrheic dermatitis, and atopic dermatitis may occur in young children. Lichen sclerosis et atrophicus (LSA) is a skin dystrophy usually seen in prepubertal girls or postmenopausal women. The appearance of LSA is consistent in both of these age groups: a “cigarette paper” type of appearance in a figure-of-eight distribution around the vulva and anus, ending at the labia majora. Breaks in the integument with small blood blisters and abrasion are common, with inexperienced clinicians misinterpreting the condition as trauma possibly secondary to sexual abuse. LSA is likely to occur in irritated vulvar areas in susceptible children. Appropriate first-line treatment in children is to prevent genital irritation and trauma. This may include avoidance of straddle activities, use of gel bike seats, and so forth. The extremely potent steroid (clobetasol) has been used in adults with success and is being used by experts in children despite a paucity of studies in this age group and the fact that clobetasol is not labeled for pediatric use. However, adrenal suppression from LSA treatment is extremely unlikely given the very small surface area where the potent steroid is applied. When this condition begins in childhood, it may regress with puberty, although this is not invariable. Some series suggest that it becomes less symptomatic during the reproductive years.

Vaginal Bleeding

Vaginal bleeding in a prepubertal child warrants a careful investigation. The differential diagnosis of vaginal bleeding hinges on the absence or presence of other signs of pubertal development. In young children with breast development, an evaluation for precocious puberty is warranted. Most children with genital bleeding will not have concomitant signs of pubertal development, and local causes of the bleeding are the most likely causes. The differential diagnosis in a child with genital bleeding without pubertal development is

labial adhesions, urethral prolapse, and malignant tumors of the vagina or cervix.

Evaluation should include consideration of genital cultures, careful genital examination, and vaginal visualization. In cases where the vagina cannot be visualized in the office or bleeding continues despite a negative exam, an examination under anesthesia is indicated. The exam should rule out foreign objects and rare malignant vaginal tumors (sarcoma botryoides and endodermal vaginal sinus tumors) primarily seen in girls younger than 6 years of age.

Sexual Abuse

The possibility of sexual abuse should be considered in children presenting with a variety of presenting complaints including, but not limited to, vulvar vaginal symptoms, vaginal discharge, and genital bleeding. Sensitive but direct questioning of the parent or caretaker and the child by herself should be a part of any evaluation. The parent should be asked about any significant changes in behavior (such as the recent onset of nightmares, difficulties in school, changes in personality, etc.) that may accompany sexual abuse. Questioning the child who is verbal can be a useful “teachable moment” in which the physician explains the concept of the genital area as a “private zone” and the idea that touching in this area should be reported to a parent. One concrete way to explain the private-zone concept to a young child is to describe this as the areas that are covered by two-piece bathing suits. If the history is suspect or the injuries or physical findings are inconsistent with the reported history, a report must be made to the appropriate social service agency.

The possibility of sexual abuse must be assessed in children presenting with genital bleeding. However, it should be noted that the vast majority of children who have been sexually abused will have normal exams and not present with bleeding symptomatology. Hymeneal size is not an accurate way to determine if a child has been abused. The genital examination in abused children usually does not differ from the exam in non-abused children. The child's history is of primary importance in the prosecution of sexual abuse. If forensic evidence is found, the source in the majority of cases is clothing and linens, which should always be collected in cases of recent assault.

Acute trauma and bleeding may result from a straddle injury or from sexual assault. Unintended trauma most commonly results in injury to the anterior vulva or laterally to the labia. Straddle injuries may result in the formation of a large vulvar hematoma, which may require evaluation. Penetrating injuries with transection of the hymen are quite rare in patients with straddle injuries. If a patient presents with a straddle injury and a hymeneal transection is present, significant consideration should be given to the possibility of sexual abuse. Any bleeding laceration of the vulva, and particularly hymeneal transactions, requires a careful examination to assure that there are no vaginal lacerations and to completely repair the injury. This may require an examination under anesthesia or the use of conscious sedation in the ED.

Precocious Puberty

Precocious puberty should be considered in children presenting with vaginal bleeding with or without other signs of pubertal development or in children presenting with early breast development or adrenarche. The definition of early development is changing. Data from a large study involving pediatric office practices indicate that black girls have an earlier onset of pubertal development than do white girls. Precocious puberty traditionally has been defined as pubertal development occurring before age 8. Data from pediatric office practices reveal that 27% of black girls and 7% of white girls had signs of breast budding or pubic hair development at age 7. Thus, the definition for precocious puberty should be reassessed in light of these data. Some experts recommend that precocious puberty be defined as breast budding prior to age 6 in black girls and prior to age 7 in white girls. Others argue that breast development in black girls after age 6 or white girls after age 7 but prior to age 8 warrants evaluation, as these signs may be hallmarks of serious central nervous system (CNS) lesions or pathology. Most gynecologists will refer girls with possible precocious development to specialists for a thorough evaluation because of the rarity of the condition. The causes of precocious puberty include ovarian neoplasm, CNS lesions and tumors, McCune-Albright syndrome, and idiopathic precocious puberty.

Adolescent Gynecology

Normal and Abnormal Puberty

The mean age of menarche in the United States is 12.16 years for black girls and 12.88 years for white girls. Menarche occurs within 2 to 3 years after thelarche. Menstrual cycles in the first several years after menarche frequently are anovulatory. The younger a girl is at menarche, the earlier ovulation occurs. Cycle length typically is 28 days but falls within a range of about 21 to 45 days. Mean duration of bleeding generally is <7 days. The patient's estimate of quantity of menstrual flow is typically unreliable, and adolescents may have less basis for comparison than older women. Measurement of hemoglobin/hematocrit provides objective evidence of heavy bleeding.

First Gynecologic Visit

The American College of Obstetricians and Gynecologists (ACOG) *Guidelines for Women's Healthcare* indicates that the adolescent's first visit to an obstetrician–gynecologist

---

should take place sometime between the ages of 13 and 15. This is in recognition of the role that obstetrician–gynecologists can potentially play in providing preventive guidance, screening, and preventive services to adolescents. Obstetrician–gynecologists are uniquely suited to provide these services in that the consequences of adolescent risk-taking behaviors include unintended pregnancies, STDs, ectopic pregnancies, pelvic inflammatory disease (PID), and infertility—all conditions with which the gynecologist is familiar. This initial visit is an ideal opportunity to discuss normal adolescent development and concerns related to adolescents with a girl and her parents. In at least two surveys, adolescents

have indicated their desire to discuss health issues such as STDs, contraception, and sexual abuse. These surveys also have indicated that these issues were infrequently addressed by clinicians.

At this visit, issues of confidentiality should be discussed with the adolescent and her parents. Numerous studies have concluded that without assurances of confidentiality, many teens will not divulge their health concerns, particularly those that relate to sex, substance use, and other risk-taking behaviors. However, confidentiality does not mean secrecy. Involvement of the parent or guardian should be strongly encouraged and developed. Facilitating a discussion regarding risk behaviors between the parent or guardian and the adolescent (with the adolescent's approval) is an ideal approach.

The initial preventive visit usually does not require a pelvic examination. The ACOG guidelines state that the provision of additional services beyond guidance and screening should be based on information obtained at this visit. If the adolescent has had intercourse, a pelvic exam and screening for STDs usually is appropriate. If she has been sexually active for approximately 3 years, a screening Pap smear is indicated.

When a pelvic exam is required, careful attention to education and gentle technique at the first exam is particularly critical. Adolescents are less apprehensive if the clinician describes sensations (i.e., “this will cause a pressure sensation that is not painful but may be a bit uncomfortable”) rather than only describing the purpose of the exam (i.e., “I am now putting the speculum in your vagina”). It is more important that this exam not be traumatic than that it confirm uterine or ovarian dimensions. The exam should be tailored to the needed information. If an adolescent has not been sexually active but is experiencing severe dysmenorrhea, the bimanual and rectovaginal components of the exam are more important than a speculum examination of the cervix. If a speculum exam is deemed appropriate and necessary (e.g., evaluating a sexually active adolescent for mucopurulent cervicitis), an appropriately sized speculum is indicated. The Huffman or “virginal” speculum is quite narrow and can be used with a narrow or rigid hymen. However, visualization of the cervix with the Huffman speculum often requires manipulation that may be more uncomfortable than that required with the more frequently used Pederson speculum. The Pederson speculum should be the most frequently used speculum for adolescents and can be used comfortably for almost all teens. The Graves speculum, which is commonly used for adults, may be necessary for some obese or parous adolescents or when cervical procedures (colposcopy and biopsy) are indicated. Adolescents should be informed about the need for an examination; the amount of information that is provided before the exam should be tailored to the adolescent's wishes. The adolescent should be offered the opportunity to have a parent or friend accompany her during the exam. The exam itself should be performed slowly and gently with forewarning of each successive step of the exam.

The Guidelines for Adolescent Preventive Services (GAPS) is a set of recommendations arrived at by a panel of experts from a number of different disciplines. They are based on the following rationale:

. The primary health threats to adolescents are behavioral rather than biomedical.

1. An increasing number of adolescents are involved in behaviors with the potential for serious consequences.
2. Adolescents are engaging in these behaviors at earlier ages.

The comorbidities that adolescents experience are related to the risk-taking behaviors of unsafe sexual practices, substance use/abuse, and violence. The GAPS report concludes that many adolescents are engaged in multiple health risks simultaneously and that most adolescents engage in some type of behavior that is a threat to their health and well-being. The multiplicity of risk factors points out the futility of trying to deal with only one specific issue. For example, alcohol and drug abuse is related to irresponsible sexuality decisions and motor vehicle accidents. The ACOG guidelines were developed in an effort to screen for and detect the risk-taking behaviors that result in significant morbidities for adolescents and to provide early or preventive interventions and services.

Abnormal Bleeding

Menstrual irregularity is one of the most common presenting problems in the adolescent years. After menarche, most adolescents will have an interval of anovulatory cycles. The duration of anovulation varies with the age of menarche. If a teen is younger than 12 years of age at menarche, approximately half of her cycles will be ovulatory within 1 year, in contrast to the teen who is 12 to 13 at menarche and in whom it will be 3 years before half of the cycles are ovulatory.

During this anovulatory interval, menstrual cycles will generally be somewhere between 21 to 45 days apart with great cycle-to-cycle variation. This pattern is due to an intact HPO feedback system creating estrogen withdrawal bleeds. As estrogen climbs, follicle-stimulating hormone (FSH) levels decline, lessening follicular stimulation with

a corresponding drop in estrogen. At the estrogen nadir, an estrogen withdrawal bleed is initiated. As puberty proceeds, HPO maturity progresses and levels of estrogen production become high enough to induce a luteinizing hormone (LH) surge with resulting ovulation. Cycles consistently outside the 21- to 45-day range, even in the year after menarche, are often signs of true pathology. The American Academy of Pediatrics (AAP) and the ACOG committees on adolescents recommend that menses occurring more often than 21 days or less often than 45 days warrant evaluation.

Differential Diagnosis of Menstrual Disorders

The differential diagnosis of menstrual disorders in the adolescent is extensive, and specific diseases are covered in other chapters of this text. However, a basic approach is the division of the disorders into two distinct groups: those due to aberrations involving the HPO axis and those unrelated to the HPO axis (Table 31.1). It is most important to exclude pregnancy.

Examples of disorders unrelated to aberrations in the HPO axis include cervical bleeding (from cervicitis), endometritis, polyps, bleeding disorders, and abnormal bleeding related to congenital anomalies of the reproductive tract, arteriovenous malformations (AVMs),

and rarely fibroids. The adolescent with a menstrual disorder should be assumed to be pregnant until proven otherwise by pregnancy testing. The potential medical consequences of missing a pregnancy-related complication dictate that a pregnancy test be performed in all cases of abnormal bleeding in an adolescent. The adolescent should be questioned privately, without her parents, about a history of sexual intercourse, whether voluntary or involuntary. In one study in which pregnancies were diagnosed in a pediatric ED, 10% had denied sexual activity. In offices where the clinicians have an environment where they can establish rapport more easily with teens, teens may be more likely to give accurate sexual histories. The clinician's skills will certainly be tested in the situation of an unexpected diagnosis of pregnancy. The adolescent should be strongly encouraged to tell her parent(s) or a responsible adult. Counseling about pregnancy options should take place immediately. The clinician must be aware of any relevant state laws that mandate parental notification or consent when an adolescent chooses abortion.

TABLE 31.1 Menstrual Irregularity in the Adolescent

1. Aberrations in the HPO axis
   1. Hypothalamic menstrual disorders (associations)
      1. Stress
      2. Dietary practices
      3. Exercise
      4. Body fat
   2. Endocrinopathies
      1. Prolactinoma
      2. Thyroid disease
      3. Hyperandrogenic anovulation (PCOS)
      4. CAH
      5. Cushing syndrome
2. Normal HPO axis
   1. Pregnancy
   2. Bleeding disorders
   3. Anatomical bleeding (cervicitis, polyp, endometritis, fibroid, congenital anomaly)

HPO, hypothalamic–pituitary–ovarian; PCOS, polycystic ovary syndrome; CAH, congenital adrenal hyperplasia.

Bleeding from cervicitis is another important consideration. Cervicitis due to *C. trachomatis* can cause abnormal bleeding patterns. Bleeding disorders also deserve careful

consideration, including idiopathic thrombocytopenic purpura (ITP) and von Willebrand disease. These clotting disorders should be considered in all teens with heavy bleeding but are particularly likely to present with menorrhagia at menarche. In one series, approximately half of all girls presenting with menorrhagia at menarche had a bleeding disorder.

Most menstrual irregularity in adolescents is related to aberrations in the HPO axis. These aberrations can be divided into two general groups: hypothalamic menstrual abnormalities and the endocrinopathies (Table 31.1).

A variety of factors such as stress, body weight, exercise, and diet are related to hypothalamic menstrual disorders. The factors affect neurotransmitter patterns that in turn impact a pulsatile release of gonadotropin-releasing hormone (GnRH).

The endocrinopathies include thyroid disease, hyperprolactinemia, adult-onset CAH, and hyperandrogenic anovulation (sometimes referred to as polycystic ovarian syndrome). Other rarer diagnoses include Cushing syndrome and steroid-producing ovarian tumors. All of these disorders are covered in detail in other chapters.

In teens, hypothalamic disorders are the most common cause of menstrual cycling abnormalities. The diagnosis of a hypothalamic menstrual disorder is a diagnosis of exclusion. Historical questioning will often point toward hypothalamic causes. All teens with menstrual disorders should be specifically questioned about stress; dietary practices; their current, past, and desired body weight; and exercise practices. The physical exam should always include height, weight, temperature, and vital signs. The exam also should include consideration of physical signs of eating disorders. For example, the presence of bradycardia or carotene pigmentation may be critical findings leading to the diagnosis of a serious eating disorder. Eating disorders are a critical consideration given the high mortality associated with this diagnosis.

The psychiatric definition of anorexia nervosa includes amenorrhea as one criterion. Amenorrhea may even precede severe weight loss. Anorexia nervosa should be

---

managed by a skilled clinician who is familiar with the medical effects of the disorder, and psychologic counseling is always indicated. When the adolescent is in counseling, the approach to the amenorrhea may become a type of “wait and watch.” There is evidence that the bone loss associated with anorexia nervosa may not be rapidly or completely reversible with the use of estrogen supplementation. In one study, approximately 50% of women with bulimia had menstrual abnormalities. Thus, eating disorders should always be considered as a possible cause when adolescents present with menstrual irregularities.

An individual with menorrhagia and signs of hirsutism should be evaluated with hormonal testing for disorders of androgen excess. For individuals without ovarian or adrenal androgen-producing tumors, oral contraceptives usually provide menstrual management and a decrease in acne and hirsutism.

Acute adolescent menorrhagia initially should be managed similarly to acute menorrhagia occurring in older women with hormonal therapy. Curettage is very rarely necessary. Various hormonal protocols have been published for severe menorrhagia, including tapering

regimens of combination oral contraceptives and intravenous estrogens.

Tapering regimens of combination oral contraceptives may be associated with thrombosis in older reproductive women, but the risk of thrombosis in young women without thrombophilias or a family history of thrombophilia is extremely low. Well-controlled studies have not adequately compared these approaches, but there is some evidence that there is no additional benefit to intravenous over oral therapy. Some clinicians are adamant that in patients with unopposed estrogens, such as those with polycystic ovary syndrome, the most critical aspect of the hormonal therapy is the progestin. The long-term approach to the patient with menorrhagia is dictated by the diagnosis; a patient with hyperandrogenic anovulation will require different ongoing therapy than the patient with a bleeding diathesis.

Primary Amenorrhea

Primary amenorrhea is defined as the absence of menses by age 15 or 16. Approximately 98% of girls in the United States are menstruating by age 15. Current recommendations are that the following patients deserve evaluation:

- Primary amenorrhea at age 15 or 3 or more years after breast budding
- No menarche by age 13 without other signs of puberty
- No menarche by age 14 in girls with hirsutism or histories suggestive of excessive exercise or eating disorders.

In one large series from a tertiary referral center, ovarian failure was the most common cause of delayed sexual development. Congenital absence of the uterus and vagina and a physiologic delay of puberty also were frequently diagnosed etiologies. Other etiologies were diverse and numerically less frequent. Only 14% of all patients presenting with abnormalities of pubertal development had subsequent normal reproductive potential. All of these patients were in the physiologic delay category. Thus, the authors of the study concluded that pubertal aberrancy should not be considered a benign entity because it is associated with significant morbidity, mortality, and compromise of reproductive potential.

Pregnancy must always be considered as a possible etiology of amenorrhea, whether it is secondary or primary amenorrhea. Recommendations are that girls with amenorrhea longer than 90 days, even during the first menarchal year, deserve evaluation. Also, girls with regular periods that change and become markedly irregular warrant evaluation. Just as with excessive or abnormal bleeding, the consequences of missing the diagnosis of pregnancy are serious, and a pregnancy test should always be performed to confirm the history.

Müllerian agenesis and obstructing vaginal septa are associated with primary amenorrhea and thus are most frequently diagnosed during adolescence. Treatment options may include both surgical and non-surgical management but also should focus attention on the psychologic ramifications of this diagnosis.

Dysmenorrhea

Primary dysmenorrhea, beginning with the onset of ovulatory menstrual cycles, is common, occurring in up to 90% of adolescents. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) usually is helpful in relieving the prostaglandin-mediated symptoms, and many adolescents with dysmenorrhea have already tried OTC medications, although not always in appropriately therapeutic doses. Adolescents may be unaware that NSAIDs are more effective in relieving dysmenorrhea than other OTC analgesics. Severe dysmenorrhea and premenstrual molimina can affect the performance of adolescent activities (particularly school attendance but also athletic endeavors), and these girls can benefit from the use of oral contraceptives. Parents may need to be informed of the potential noncontraceptive benefits of these medications, the rare risk of serious complications, and the fact that oral contraceptive use does not accelerate the initiation of sexual activity in this age group.

Adolescents who have persistent dysmenorrhea despite the use of NSAIDs and oral contraceptives should be evaluated for other causes of pelvic pain, such as irritable bowel syndrome and endometriosis. At one time, it was thought that endometriosis did not occur in adolescents. However, when teenagers with severe dysmenorrhea undergo laparoscopy, endometriosis can be found in a significant percentage. The percentage of adolescents with chronic pain who have endometriosis is not well established. In reported series of adolescents undergoing laparoscopy for chronic pain (generally defined as pain unresponsive to oral contraceptives and NSAIDs), up to 75% with this

---

complaint have endometriosis. However, the percentage of teenagers with endometriosis found at laparoscopy depends on the indications for the surgical procedure and the criteria for diagnosis. Traditionally, visual confirmation was deemed sufficient; but, when strict criteria are used for diagnosis, endometriosis is not always confirmed. Endometriosis in adolescents most frequently is minimal or mild and may be atypical, with clear, white, or red lesions rather than the classic “powder-burn” lesion seen most frequently in older women. It also should be noted that endometriosis staging does not reflect pain severity and that atypical lesions may be particularly painful. It has been suggested that there is an age-related change in the appearance and color of endometriotic lesions. There is good evidence supporting a familial occurrence of endometriosis; the evidence is most consistent with a polygenic/multifactorial etiology. An asymptomatic individual with a first-degree relative with endometriosis has a 7% risk of developing the disease.

Pelvic Masses

Pelvic masses in adolescents may be detected as a result of symptoms (pain, pressure, urinary symptoms) or signs (the presence of a pelvic or abdominal mass on examination). These masses are most likely to be ovarian rather than uterine, although pregnancy should always be considered a possibility and ruled out.

Fewer than 5% of ovarian malignancies occur in children and adolescents. Ovarian tumors account for only 1% of all tumors in these age groups. Germ cell tumors make up one half to two thirds of ovarian neoplasms in individuals younger than 20 years. A review of studies conducted from 1940 until 1975 concluded that 35% of the neoplasms occurring during childhood and adolescence were malignant. In girls younger than 9 years, approximately

80% of ovarian neoplasms were found to be malignant. Germ cell tumors make up approximately 60% of ovarian neoplasms in girls compared with only 20% of those in adults.

Because neoplastic tumors are rare, these studies come from tertiary care centers and may not be representative of the true prevalence of these lesions. Some reports include only neoplastic masses, whereas others include non-neoplastic masses. One community survey of ovarian masses revealed that the frequency of malignancy was much lower; only 10% of masses were neoplastic, and only 6% of all masses were malignant. Another series reported that non-neoplastic masses in individuals younger than 20 years constituted two thirds of the total; even in girls younger than 10 years, 60% of the masses were non-neoplastic and two thirds of the neoplastic masses were benign.

The mature cystic teratoma (a.k.a., a “dermoid” cyst) is the most frequent neoplastic tumor of children and adolescents, accounting for more than one half of ovarian neoplasms in women younger than 20 years. Ovarian cystectomy of the teratoma with careful palpation of the contralateral ovary is the best approach in order to maximize future reproductive potential in young women. Bivalving the contralateral ovary is not necessary, as most contralateral tumors will be palpable.

Functional follicular cysts can occur at any age and have been reported in female fetuses, newborns, prepubertal children, adolescents, and mature reproductive women. Unilocular cysts usually will resolve spontaneously, and surgical therapy should be reserved for symptomatic masses, masses that do not resolve, suspected torsion, or masses that include a solid or multiloculated appearance on ultrasound. Attention to the long-term effects of ovarian function and future fertility dictate a conservative approach to ovarian masses in young girls; preservation of ovarian tissues with oophorocystectomy is a priority for benign tumors. Functional cysts in prepubertal girls may rarely be associated with sexual precocity, particularly when recurrent.

Unintended Pregnancy

The teen pregnancy rate in the United States is significantly higher than those seen in all other industrialized countries. Currently, the U.S. rate is almost twice the rate in England and Canada and eight times that in the Netherlands and Japan. The level of sexual activity of U.S. teens is similar to the level in Canadian, English, French and Swedish teens. However, U.S. teens are much less likely to use contraceptives compared with teens from these countries, and a real decline in the U.S. teen pregnancy rate has been seen since the 1990s. In 1990, the teen pregnancy rate was 117 pregnancies per 1,000 teen girls; this decreased to 97 pregnancies per 1,000 teen girls in 1996 and 75 per 1,000 in 2002. Approximately 14% of this decline between 1995 and 2002 was due to abstinence or less frequent sex, and 86% was due to an increase in contraceptive use.

As reported in 2002, approximately 6 out of 10 teenage women and 5 out of 10 teenage men have had sexual intercourse prior to their 18th birthday. The younger the age at initiation of intercourse, the more likely the experience was involuntary. In one older study, 74% of those who reported first intercourse at age 13 or younger reported that they had experienced involuntary intercourse.

Approximately 80% of adolescent pregnancies are unintended. Many adolescents use a method of contraception but do not always use the method consistently, correctly, and continuously. Developmental factors contribute to an adolescent's risk for unintended pregnancy. During early and mid-adolescence, concrete thinking is developmentally normal, and the “personal fable” and magical thinking mitigate against the reality that pregnancy could happen to the individual. Middle adolescents enjoy showing off their new “adult” bodies, frequently seek peer-group approval, and feel invulnerable. However, they also have increased mobility and independence coupled with less adult

supervision and protection. These factors frequently lead to risk-taking behaviors and experimentation with driving, substance use, and sexual activity. These teens may be unable to anticipate or prevent the consequences of these activities because of inexperience in abstract thinking. While they are developing the ability to perceive causal relationships and future consequences, this ability is variably applied, particularly in stressful situations such as an intimate or sexual relationship. There may be discordance among an individual adolescent's physical, social, sexual, and cognitive development. Thus, adolescents may not be developmentally equipped to use contraceptives effectively. Postponing sexual intercourse therefore is the preferred form of sexual behavior for most adolescents until they are developmentally capable of responsible sexual behavior.

Various approaches to promotion of abstinence have been studied. Curriculum-based approaches have been divided into two groups: abstinence only and abstinence plus, sometimes labeled “comprehensive sex education.” Abstinence-only education is common, given the 1996 federal law that at that time granted $85 million dollars in funding solely for this approach. Funding amounts for abstinence only from the federal level has continued to increase in amount, with total funding reaching approximately 176 million in 2006. Interestingly, in an analysis of published or known U.S. or Canadian studies with an experimental or quasiexperimental design, no programs that were abstinence-only–based demonstrated a delay in sexual activity or increased contraceptive use in sexually active teens. In contrast, there have been some abstinence-plus curricula with positive results in delay of sexuality and increasing contraceptive use. It should be noted, however, that there are only a handful of studies on abstinence-only programs.

Given the lack of available evidence, the ACOG issued a committee opinion noting the limitation of the abstinence-only approach in 1998. Evidence-based medicine has not documented that abstinence education delays sexual activity. By 2002, approximately one third of teens had received no formal instruction on contraception. In 1995, 72% of sexually experienced female teens had contraceptive instruction before their coital debut compared to 62% in 2002.

Contraceptive Patterns

Approximately one third of adolescents wait a year after initiating intercourse before seeking medical contraceptive services, and another one third have not sought medical care. Despite these figures, however, an increasing percentage of adolescents are using contraception at first intercourse. In 1982, 52% used no method of contraception at the

time of first intercourse; in 1988, 35% reported using no method; and in 1995, 23% did not use any method of contraception at first intercourse. Birth control pills and condoms are the most popular methods of contraception among adolescents.

Adolescents generally have higher failure rates of various methods of contraception during typical use, primarily because of problems with compliance—defined for contraception as the use of a method in both a consistent and ongoing manner. Failure rates among adolescents using oral contraceptive pills can be as high as 15% to 18%; as many as 50% or more adolescents have discontinued the method by the end of 1 year. Missed pills are frequently a problem for women of all ages but are particularly frequent among the youngest adolescents. In one study, only one fourth of adolescents 14 years or younger took their oral contraceptive pill every day. For many adolescents, the longer-term methods of contraception—depot medroxyprogesterone acetate, contraceptive patches, or contraceptive rings—may more appropriate methods, given the problems of compliance.

Sexually Transmitted Diseases

Biologic factors that impact an adolescent's risk of STD acquisition or complications include the active cervical metaplasia and ectopy, which may increase the risk of *Chlamydia* or human papillomavirus (HPV) acquisition. Aspects of adolescent development also affect the risks for STDs. The feeling of invulnerability may result in decreased use of condoms or denial of symptoms. In addition, the clinical presentation of STDs may be affected by both an excessive attention to hygiene (e.g., douching) or excessive neglect of perineal hygiene. When infection is suspected, the adolescent typically reacts with embarrassment and fear, which results in delays in seeking treatment. Once an STD is diagnosed, adolescents may fail to complete therapy, especially if symptoms decrease; they also frequently fail to keep follow-up appointments and have difficulty informing their partners of the STD acquisition.

Behavioral factors placing adolescents at increased risk include the fact that they may be more likely to have multiple sexual partners rather than single, long-term relationships; adolescents may have either concurrent partners or engage in serial monogamy. Almost half of all sexually active women between ages 15 and 19 have had two or more partners during the previous year. Teens may be more likely to engage in unprotected intercourse and may select partners at higher risk for STDs.

Adolescents have the highest rates of gonorrhea and HPV of any age group. Routine screening for *Chlamydia* is recommended by the CDC for all sexually active adolescents, regardless of other risk factors. Routine screening for *N. gonorrhea* should at least be done in all high-risk teens (previous STDs, multiplicity of partners) and in teens living in areas where prevalence levels warrant routine screening, such as the southern United States. In many areas of the United States, it is cost-effective to screen for both of these STDS in the sexually active teen population. On careful

---

examination, the definition of high-risk teens often is the majority of sexually active teens.

Chlamydia screening has been shown in a randomized clinical trial to be associated with a lower risk of PID among those screened when compared with those individuals who were not screened. When control rates of sexual activity are applied (approximately 50% for

adolescents between the ages of 15 and 19), adolescents have the highest rates of PID.

Clinicians should be aware that in the United States, all adolescents can legally consent to be screened and treated for STDs and have the right to these services without parental consent or knowledge. Barriers to STD prevention in adolescents and young adults include financial constraints, lack of transportation, discomfort with facilities and services designed for adults, and concerns about confidentiality.

Hepatitis B is the only completely preventable STD, due to the available vaccine. The Advisory Committee on Immunization Practices (ACIP) now recommends the hepatitis B vaccination series at age 11 to 12. However, a cohort of adolescents currently exists who did not receive the vaccine at this age. Based on this finding, the AAP and ACOG both recommend that all adolescents receive the vaccine at the time of their next visit to their health care provider.

HPV infection is common in sexually active teens. It usually is a transient and subclinical infection. A fraction of HPV-infected patients will present with genital warts or cervical cytology abnormalities. Younger women clear the HPV virus better than older reproductive women. Given the natural history of HPV, cervical abnormalities cytology (Pap smears) is now recommended annually at approximately 3 years after coital debut and no later than 21 years of age.

Treatment of cervical dysplasia in teens has become less aggressive. For example, some experts recommend following rather than treating cervical intraepithelial neoplasia II (CINII) lesions in reliable adolescent patients. It is likely that these recommendations will be included in future guidelines.

In 2006, the ACIP recommended routine use of a quadrivalent HPV vaccination. This vaccine is effective against HPV types that cause approximately 70% of all cases of cervical cancer and 90% of HPV types that cause genital warts. The vaccine is administered in three doses over a 6-month interval; the first at approximately 11 to 12 years of age. Catch-up vaccination is recommended for females between 13 and 16 years of age.

Treatment of STDs among adolescents is identical to treatment in adults. The difference in STD presentation in adolescents compared with adults relates to the developmental and risk-profile differences noted previously, which place adolescents at increased risk. In addition, problems of compliance with medication are common; single-dose therapies may thus be more appropriate for teens with uncomplicated gonorrhea or *Chlamydia* cervicitis.

Summary Points

- This chapter has outlined and summarized the basic aspects of pediatric and adolescent gynecology, highlighting the differences from the manner in which conditions are evaluated and managed in adults. Psychosocial and behavioral factors greatly influence the health of adolescents. Preventive guidance and screening may be able to prevent or minimize these health problems.
- The gynecologic care of children and adolescents requires attention to a set of pathologic entities and treatments as well as

psychosocial issues that are different from those of adults.

- A nonspecific vaginitis is the most common cause of vulvovaginal symptoms in prepubertal children; sexual abuse must always be considered as a possible etiology.
- Most prepubertal children who have been sexually molested will have normal genital examinations.
- Most health threats in adolescents are related to risk-taking behaviors such as early sexual activity, alcohol, and other substance abuse.
- Menstrual irregularity in adolescents can be divided into two groups: those due to an aberration of the HPO axis and those with a normal HPO axis. The aberrations are usually due to either the hypothalamic menstrual disorders or endocrinopathies. The most common cause of menstrual irregularity in teens with a normal HPO axis is pregnancy.
- Contraceptive compliance is difficult for adolescents and is the major factor that leads to higher failure rates during typical use for this age group than for older individuals.
- Adolescents with dysmenorrhea unresponsive to NSAIDs and oral contraceptives may have pelvic endometriosis.
- Pap smears are recommended annually beginning approximately 3 years after initiation of intercourse but no later than 21 years of age. Treatment guidelines for evaluation and treatment of cervical pathology in adolescents is less aggressive than for mature adults. Younger patients clear HPV more readily than mature adults.

Contraception

Lisa Memmel
Melissa Gilliam

> *Reproductive rights embrace certain human rights that are already recognized in national laws, international human rights documents, and other relevant consensus documents. These rights rest on the recognition of the basic right of all couples and individuals to decide freely and responsibly the number and spacing and timing of their children and to have the information and means to do so, and the right to attain the highest standard of sexual and reproductive health.*
>
> —Beijing Platform for Action, 1995

All women have a basic human right to determine whether and when they will become pregnant. Sexually active women and men have a wide variety of contraceptive choices for implementing this right, ranging from temporary to permanent methods. Most women have the potential to become pregnant over at least 3 decades of their lives, and most men are fertile for virtually their entire adulthood. Thus, a series of different contraceptive decisions may be made over a person's reproductive life span. Since 2000, the range of contraceptive choices in the United States has increased with a wide range of new contraceptive methods, including a vaginal ring, a contraceptive patch, a progestin-releasing intrauterine device (IUD), an implantable contraceptive device, and a transcervical method of tubal occlusion. This chapter focuses on information with which the health professional can counsel women and men to make the contraceptive choices that best address their needs and circumstances.

Contraceptive Use in the United States and around the World

Data from the U.S. National Survey of Family Growth indicate that in 2002, 61.9% of women between the ages of 15 and 44 used some method of contraception. Among women who used contraception, permanent methods were the most popular; 16.7% had undergone tubal sterilization, and 6.3% had partners who had undergone vasectomy. Oral contraceptives were the most popular temporary method, but the proportion of pill users decreased from

27% of contraceptive users in 1995 to 19% in 2002. In addition, the proportion of condom users decreased from 20.0% in 1995 to 11.1% in 2002. Only 3.3% and 1.0%, respectively, used the injectable depot medroxyprogesterone acetate (DMPA) and the IUD. Despite this level of reported contraceptive use, 49% of pregnancies concluding in 2002 were unintended, with 42% of those ending in elective abortion.

Globally, according to the Demographic and Health Surveys, tubal sterilization is the most common method of contraception (in 1997, 20% of couples in which the woman was of reproductive age and who used a contraceptive method used tubal sterilization), followed by IUDs (15%), oral contraceptives (8%), and condoms (5%).

Choosing a Method of Contraception

Although sterilization is the most widely used method of contraception in the United States and in much of the rest of the world, it is appropriate only for women and couples who have made a decision to permanently prevent pregnancy. Thus, many couples will choose reversible contraceptive methods. Factors that influence the appropriateness of any contraceptive choice include the relative safety and effectiveness of the method for that individual, the frequency and acceptability of side effects, the willingness and ability to use the method consistently and correctly, cost, and the importance of personal factors such as societal attitudes as well as religious or cultural beliefs regarding method acceptability. Other factors include the frequency of coitus, the length of time that intended pregnancy is to be delayed, the impact on lactation and the breast-fed infant, and any potential impact of the method on future

---

fecundity. In addition, many women are at risk for sexually transmitted infections, including HIV infection, and must consider dual goals of protection against pregnancy and prevention of sexually transmitted infections. Doing both entails the correct and consistent use of condoms or use of another contraceptive method in conjunction with condoms. The need for such dual protection produces special challenges, as there is some evidence that the use of a highly effective method of contraception other than condoms may affect a person's willingness or ability to use condoms for disease prevention.

Contraceptive Effectiveness

Contraceptive effectiveness is measured as reduction in the probability of conception with use of a contraceptive method over a defined period; it cannot be measured directly, largely because studies cannot determine the proportion of women in a given population who would have become pregnant during that time had they not been using contraception. By contrast, contraceptive failure rates can be directly determined and are the most clinically useful measures of effectiveness. Yet, it is important to note the limitations of the widely used Pearl Index method in which contraceptive failures occur per 100 woman-years of use, which limits the comparability of the new method being studied to an older regimen. Instead, the life-table method, which considers failures over time, may be preferable.

Widely used estimates of contraceptive failure rates are shown in Table 32.1. These rates

are provided in two categories: “typical use” and “perfect use.” The former is similar to “use effectiveness” and is characteristic of a typical couple starting to use a method (some use the method properly and others do not); the latter is similar to “method effectiveness,” which is the result of consistent and correct use of the method. For some methods, the typical and perfect use rates are substantially different, which indicates that the user's willingness and ability to use these methods consistently and correctly are more important than they are for those methods that have similar typical and perfect use rates. For example, according to Trussell and colleagues (Table 32.1), although women who take a combined oral contraceptive (COC) pill each day should have a near-zero probability of pregnancy, 8% of couples in which the woman initiates use of oral contraceptives experience an unintended pregnancy during the first year if they do not discontinue pill use for any other reason. By contrast, the typical and perfect use failure rates are virtually the same for IUD users and for users of etonorgestrel implants. Published estimates of contraceptive failure rates apply to groups and may vary substantially among individuals within those groups, particularly among those who use methods with major differences in estimates between typical and perfect use. Most failure rates address the risk of pregnancy within 12 months of starting to use the method. The risk of pregnancy for some methods, particularly those that depend on proper use, is likely to decline over time.

Oral Contraception

Combined Oral Contraceptives

COCs, which contain both estrogen and a progestin, have been available in the United States since 1960, have been used by millions of women worldwide, and have been extensively studied. Formulations for oral contraceptives have changed over time from higher to lower doses of the synthetic components. Today, COCs prescribed in the United States contain between 20 and 35 mcg of ethinyl estradiol. The progestin component of COCs varies and may include a first-generation progestin (estranes) such as norethindrone, norethindrone acetate, ethynodiol diacetate, and norethynodrel; a second-generation progesti, (gonanes), including levonorgestrel and norgestrel; or a third-generation progestin such as desogestrel, norgestimate, and gestodene (gestodene is not available in the United States). A recently developed contraceptive uses drospirenone, a spironolactone derivative, as its progestin. Monophasic pills have constant doses of estrogen and progestin, whereas multiphasic pills vary the doses of estrogen, progestin, or both throughout the cycle.

The primary mechanism of progestins is inhibition of ovulation by suppressing follicle-stimulating hormone and luteinizing hormone. In addition, the pharmaceutical progestin thickens the cervical mucus, impeding the ascent of sperm into the upper genital tract, lowers embryo receptivity of the endometrium, and may also act by altering tubal transport. Although COCs are highly effective in preventing pregnancy when used consistently and correctly, 29% of COC users reported missing one or more pills or not starting on time in the last 3 months in the 1995 National Survey of Family Growth. COCs are substantially less effective when used inconsistently (i.e., as seen with many typical users) (Table 32.1).

Metabolic Effects

The estrogen and progestin components of COCs induce some metabolic changes, but for most healthy women, the changes associated with the current low-dose COCs have little or no clinical significance.

Estrogens generally alter lipid metabolism in a fashion that is considered beneficial, including slightly increasing levels of high-density lipoprotein (HDL) and decreasing low-density lipoprotein (LDL). Depending on their level of androgenicity, progestins can counteract these effects, decreasing HDL and increasing LDL. Therefore, the net effect depends on the doses of both estrogen and progestin as well as the type of progestin; however, most changes are within the normal range and not clinically relevant.

TABLE 32.1 Percentage of Women Experiencing an Unintended Pregnancy during the First Year of Typical Use and the First Year of Perfect Use of Contraception and the Percentage Continuing Use at the End of the First Year in the United States

Method	% of women experiencing an unintended pregnancy within the first year of use		% of Women continuing use at one year[c]

Emergency contraceptive pills: Treatment initiated within 72 h after unprotected intercourse reduces the risk of pregnancy by at least 75%[i].
Lactational amenorrhea method: LAM is a highly effective, *temporary* method of contraception[j]

[a]Among *typical* couples who initiate use of a method (not necessarily for the first time), the percentage who

experience an accidental pregnancy during the first year if they do not stop use for any other reason.

[b]Among couples who initiate use of method (not necessarily for the first time) and who use it *perfectly* (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

[c]Among couples attempting to avoid pregnancy, the percentage who continue to use a method for 1 year.

[d]The percentages becoming pregnant in columns two and three are based on data from populations where contraception is not used and from women who cease using contraception in order to become pregnant. Among such populations, about 89% become pregnant within 1 year. This estimate was lowered slightly (to 85%) to represent the percentage who would become pregnant within 1 year among women now relying on reversible methods of contraception if they abandoned contraception altogether.

[e]Foams. creams, gels, vaginal suppositories, and vaginal film.

[f]Cervical mucous (ovulation) method supplemented by calendar in the pre-ovulatory and basal body temperature in the post-ovulatory phases.

[g]With spermicidal cream or jelly.

[h]Without spermicides.

[i]The treatment schedule is one dose within 72 h after unprotected intercourse, and a second dose 12 h after the first dose. Plan B (1 dose is 1 white pill) and Preven (1 dose is 2 blue pills) are the only dedicated products specifically marketed in the United States for emergency contraception.The Food and Drug Administration has, in addition, declared the following 13 brands of oral contraceptives to be safe and effective for emergency contraception: Ovral or Ogestrel (1 dose is 2 white pills), Alesse or Levlite(1 dose is 5 pink pills), Aviane (1 dose is 5 orange pills). Nordette or Levlen (1 dose is 4 light-orange pills), Lo/Ovral, Levora or Low-Ogestrel (1 dose is 4 white pills), Triphasil orTri-Levlen (1 dose is 4 yellow pills), and Trivora (1 dose is 4 pink pills),

[j]However, to maintain effective protection against pregnancy, another method of contraception must be used as soon as menstruation resumes, the frequency or duration of breast-feeds is reduced, bottle feeds are introduced, or the baby

reaches 6 months of age.
Adapted from Trussell J. In Hatcher RA, Trussll J, Stewart F, et al, eds. *Contraceptive technology*, 18th ed. New York: Ardent Media, 2003.

Although some studies of older formulations of high-dose COCs reported progestin-associated elevated glucose and insulin levels and higher rates of relative peripheral insulin resistance, clinical studies of low-dose COCs have not found clinically significant effects on glucose metabolism. A large, cross-sectional study of U.S. women found no elevation in hemoglobin A_1C, fasting glucose, insulin, and C-peptide levels among current COC users compared with those who never used COCs. Large, prospective studies have not found increased risks of diabetes mellitus among COC users with either high-dose or low-dose pills.

Cardiovascular Diseases

Epidemiologic research confirms that the overall risk of serious cardiovascular complications attributable to COC use is extremely low for the vast majority of users of the current low-dose ethinyl estradiol preparations (≤35 mcg). However, individual user characteristics and the type of COC modify the risk. Cardiovascular complications associated with COC use occur while the pill is being used; once pills are discontinued, risk levels return to baseline.

Hypertension

COC use may slightly increase blood pressure among normotensive women, but studies suggest that this increase is reversible when COC use is discontinued. Among women with mild hypertension, COC use also has been associated with increased blood pressure. In a cross-sectional study of 94 women with mild hypertension, COC users had significantly increased daytime and nighttime ambulatory systolic blood pressure values (mean 8.3 mm Hg increase for daytime and mean 6.1 mm Hg increase for nighttime). No significant differences in diastolic blood pressure values were found.

Venous Thromboembolism

The incidence rate of venous thromboembolism (VTE) in healthy nonpregnant white women is estimated to be between 10 and 30 per 100,000 woman-years. When such women use COCs, the incidence increases to between 30 and 120 per 100,000 woman-years, or three to four times higher than non-COC users, depending on personal characteristics and the type of pill. By comparison, the risk of thrombosis associated with pregnancy is about 200 per 100,000 pregnant women. The case fatality rate of VTE is 1 to 2 per 100 and the risk of death from thromboembolism attributable to COC use is extremely low, at 1 to 5 per million per year of use. The most important risk factor for thromboembolism is family

history of the disease, which often is related to genetic thrombophilia. The most common genetic cause of thrombophilia is resistance to activated protein C (factor V Leiden mutation), which occurs in about 5% of whites but is rare in non-whites. The presence of the factor V Leiden mutation substantially increases the risk of COC-associated venous thrombosis; screening for the condition before starting pill use has been considered. However, cost–benefit considerations lead most authorities to recommend against screening before starting COCs unless women have a family history of thrombosis.

The third-generation low-dose pills with the progestins desogestrel or gestodene have been associated with a nearly two-fold increased risk of thrombosis relative to second-generation or first-generation pills, which contain levonorgestrel or norethindrone. Although these elevated risks are noteworthy, they are nonetheless very low in absolute terms—an estimated excess of 4 deaths per 1 million woman-years of use.

Stroke and Myocardial Infarction

Older age, smoking, diabetes, and hypertension are major risk factors for arterial diseases such as stroke and myocardial infarction. For women with these risk factors, COC use increases their already elevated baseline risk; thus, women with multiple major risk factors for cardiovascular disease generally should not use COCs.

The annual incidence rates of hemorrhagic and ischemic stroke in healthy, nonsmoking women between 20 and 24 years of age are estimated to be 2.0 and 0.5 per 100,000, respectively. In women between 40 and 44 years of age, these annual rates are 5 and 1 per 100,000, respectively. Non-smoking women younger than 35 years with normal blood pressure who use COCs have no extra risk of hemorrhagic stroke and only a marginally increased risk of ischemic stroke. Among such women 35 years or older, the risk of hemorrhagic or ischemic stroke is increased 1.5- to 2-fold during use of COCs. Smoking and hypertension increase the COC-associated risk of hemorrhagic and ischemic stroke. Use of COCs by women with classic migraine further elevates their moderately increased risk of ischemic stroke.

In healthy, non-smoking women of reproductive age with normal blood pressure, the risk of myocardial infarction is extremely low, and the use of COCs causes little if any increase in risk. On the other hand, women who smoke, have hypertension, or have hyperlipidemia elevate their baseline risk of myocardial substantially by COC use. Myocardial infarction is rare in women younger than 35 years, even if they have risk factors; for women 30 to 34 years old who use COCs and smoke, the risk is estimated to be 2 per 100,000 woman-years. By contrast, women 40 to 44 years old who use COCs and smoke have an estimated risk of 25 per 100,000 woman-years. Some studies suggest that women who take pills containing the progestins desogestrel or gestodene may have an even lower risk of myocardial infarction than that associated with the very low risk of pills containing levonorgestrel or norethindrone, but findings are inconsistent.

Malignant Neoplasia

COCs clearly reduce the risk of some cancers and may increase the risk of some others.

the currently available pills; studies suggest that lower-dose preparations are likely to have similar effects on cancer risk.

Breast Cancer

A pooled analysis of 54 studies found a small increased risk of breast cancer (relative risk = 1.24) while COCs were being used or recently discontinued. The excess risk was among women with localized disease, and there was a corresponding decrease in metastatic disease. These findings argue that women who use COCs are:

- Simply more likely to have existing breast cancers diagnosed because they are more likely to have clinical exams or mammograms
- More likely to have late-stage promotion of tumors that subsequently are more likely to remain localized to the breast.

The observation that the duration of COC use does not increase breast cancer risk argues for the former explanation. The excess risk of breast cancer disappears 10 years after cessation of pill use. Thus, women who use the pill from age 15 to age 35 years have the same breast cancer risk at age 50 as comparable women who never took COCs. Because the incidence of breast cancer is low at ages when COC use is most common, any effect would affect a relatively small number of women. For example, among women who stop using COCs at 25 years of age, the cumulative risk from ages 25 through 34 years is estimated to be 1 excess cancer diagnosed per 10,000 women. In women who stop COC use at age 40, when incidence rates are higher, an estimated 19 excess cancers will be diagnosed from ages 40 through 49 years. As noted, even these excess cancers may represent only an earlier detection of existing disease; at worst, they represent a small absolute excess occurrence of localized disease.

Cervical Cancer

In the past, several studies suggested that COC use of 5 years or longer increased the risk of cervical cancer 1.3- to 1.8-fold, but the causality of this association was uncertain. Persistence of genital human papillomavirus (HPV), particularly HPV 16 and 18, cause cervical cancer, and oral contraceptive users may be more likely to have sexual intercourse and less likely to use a barrier method of contraception. Exposure to COCs does cause eversion of the columnar epithelial cells of the cervix exposing these metaplastic cells to sexually transmitted HPV virus. A meta-analysis has shown that the relative risk of cervical cancer with COC use is 1.1 after 5 years and 2.2 for women who have used COCs for 10 or more years. Available data suggest that the increased risk decreases over time after stopping pill use. Questions remain about whether the risk is related to pill use per se; to other characteristics of pill users, such as sexual behavior; or to other factors associated with pill use, such as cytologic screening. Regardless, where screening services are available, COC users should avail themselves of these services as advised for other women. COC users do not require special screening procedures or recommendations.

Ovarian Cancer

Use of COCs reduces the risk of epithelial ovarian cancer, the most common type of cancer of the ovary. Risk reduction is positively correlated with the duration of use. Using COCs for 5 years or longer confers at least a 50% reduced risk that persists for up to 15 years after cessation of use.

Endometrial Cancer

COC use reduces the risk of cancer of the endometrium. As with ovarian cancer, the risk reduction is related to duration of use. After 5 years of use, the risk of endometrial cancer is at least 50% lower than in women who never used COCs. Furthermore, the risk reduction persists for 15 to 20 years after stopping pill use.

Liver Tumors

Long-term use of high-dose oral contraceptives has been associated with the development of benign liver tumors such as focal nodular hyperplasia and adenomas. Though benign, adenomas of the liver can lead to significant problems related to rupture of the liver capsule. In COC users who have an enlarged liver or tenderness to palpation on physical examination, the COC should be stopped and evaluation is warranted.

Primary cancer of the liver is rare in populations where hepatitis B or C is not endemic. Some studies in the 1980s pointed to a substantially increased risk of primary liver cancer after long-term use of COCs. In populations where chronic hepatitis is common, pill use has not been associated with primary liver cancer. Liver cancer is rare and usually fatal within 1 year of diagnosis; thus, the fact that there has been no increase in liver cancer deaths in the United States in the 4 decades that COCs have been in widespread use argues against any substantial risk.

Other Cancers

Some studies have found a lower incidence of colon cancer among women who have used COCs, but it is unclear whether the association is causal. Previous speculation of an increased risk of tumors of the pituitary and the skin in users of COCs have not been confirmed.

Medical Eligibility Criteria for Combined Oral Contraceptive Use

Most women can safely use COCs. There are, however, some conditions under which COCs should not be used. These conditions include the following:

- Age >35 years and smoking >15 cigarettes per day
- Multiple risk factors for arterial cardiovascular disease (e.g., older age, smoking, diabetes, hypertension)

- Elevated blood pressure of 160 mm Hg systolic or 100 mm Hg diastolic hypertension with vascular disease
- Current or history of deep vein thrombosis or pulmonary embolism
- Major surgery with prolonged immobilization
- Current or history of ischemic heart disease
- Stroke
- Complicated valvular heart disease
- Migraine with focal neurologic symptoms (migraine with aura)
- Migraine without focal neurologic symptoms and age >35 years
- Current breast cancer
- Diabetes with nephropathy, retinopathy, neuropathy, vascular disease, or diabetes of >20 years duration
- Severe cirrhosis
- Liver tumors.

In addition, there are several other conditions in which women generally should not use COCs (Table 32.2).

Noncontraceptive Benefits of Combined Oral Contraceptive Use

In addition to protecting against pregnancy, including ectopic pregnancy, and the noted protection against endometrial and ovarian cancers, COC use provides other health benefits including preventing and treating menstrual abnormalities (bleeding problems and pelvic pain), reduced risk of symptomatic pelvic inflammatory disease (PID) (although there is no protection against lower genital tract infections and HIV infection), reduced risk of benign breast cysts, reduced risk of iron deficiency anemia, and treatment of acne. While low-dose contraceptives have not been shown to affect the size of preexisting leiomyomata or lead to new ones, they can be effective in controlling menstrual bleeding due to leiomyomata. The protection against ovarian cysts, seen with higher dose COCs, is reduced in low-dose monophasic COCs and may not be present for triphasic COCs.

Return to Fertility after Discontinuing Combined Oral Contraceptives

Women who discontinue COCs have no overall reduction in fertility. There may be a very short delay in time to conception compared with women not using COCs based on the time required to begin ovulating. This delay is temporary, and by 3 to 12 months after discontinuation, there are no differences in fertility rates.

Side Effects

Nausea and breakthrough bleeding are the most common side effects of COC use, although they often diminish or disappear after the first few months of use. Breakthrough bleeding may relate to the specific pill formulation, but it also may be caused by missed pills. If breakthrough bleeding lasts beyond the first 3 months of use, is a problem for the woman, and other gynecologic causes have been ruled out, it may be beneficial to switch to a different COC formulation, typically containing a higher ethinyl estradiol dose. Other approaches to managing breakthrough bleeding include adding concurrent oral estrogen (1.25 mg conjugated equine estrogen or its equivalent, daily for 1 week at the time the breakthrough bleeding occurs), doubling up on active pills for 2 or 3 days until the breakthrough bleeding stops, doubling up on active pills through the end of the cycle, or using active pills in a continuous regimen. Nonsteroidal anti-inflammatory drugs (NSAIDs) may also help alleviate breakthrough bleeding. Other common side effects associated with COCs are breast tenderness and headaches. Weight changes are reported frequently, but most recent studies suggest that little, if any, weight gain can be attributed to COC use.

Choices for Pill Initiation

Standard regimens for pill initiation include the following:

Sunday Start: In this commonly used regimen, the woman is counseled to begin the active pills on the first Sunday after her menses begins. If her menses begins on a Sunday, she should start her pills that day. The advantage to this approach is that the woman will likely not be on her menses over the weekend. Alternatively, disadvantages include not being able to get prescriptions filled on weekends.

Thursday Start: With the newly approved 24-day active pill/4-day placebo regimens, a Thursday start will accomplish the same goal of no menses on the weekend.

First-day Start: This approach has the woman start her active pills on the first day of her menses, as long as she has a normal cycle and has no concern of being pregnant.

Quick Start: With the quick-start method, the patient begins taking the pills on the first day of her office visit, as long as she is not pregnant. She should be counseled to use a back-up method for the first 7 days and be informed that her menses will be delayed until she completes the active pills in the pack. This method does not lead to increased spotting or bleeding. In addition, this method helps women to start and continue the pill as they avoid complex counseling regarding pill initiation. In one study, 25% of women counseled for Sunday or menstrual start did not initiate their COCs as prescribed for reasons such as an interim pregnancy, failing to fill the prescription, or misunderstanding instructions.

Continuous or Extended-Use Pills

Most conventional pill packaging contains 3 weeks (21 days) of active pills followed by 1 week (7 days) of placebo pills to provide a predictable withdrawal bleed mimicking normal menstruation. Recently, a different regimen has been introduced with 24 days of active pills followed by 4 days of placebo pills. Menses still occurs at a 28-day interval but with fewer days of bleeding and less quantity of blood loss. However, some women prefer to bleed less than once a month or not at all. Thus, extended or continuous use of pills may be a good option for many women. Extended use of pills involves taking only the active pills in a pill pack and immediately starting the next pack of active pills, skipping the placebo tablets. This pill-taking pattern often is adhered to for 60 to 80 days, then a withdrawal bleed is allowed. Formulation of pills are marketed and packaged in this fashion, with 84 active pills followed by 7 placebo pills. This induces a “seasonal” withdrawal bleed, or once every 4 months. If the woman chooses, she can opt to skip a withdrawal week altogether and take active pills continuously. Any monophasic pill may be used in this manner, and those with high progestational activity usually result in less breakthrough bleeding. A formulation is now marketed for continuous use with no breaks.

Progestin-Only Oral Contraceptive Pills

Progestin-only pills are an appropriate alternative for women who desire an oral contraceptive but who are not candidates for COCs. They commonly are used by breast-feeding women in the postpartum period. Progestin-only oral contraceptives act on the cervical mucus by reducing sperm penetration and may act on the endometrium to prevent pregnancy, but they do not consistently inhibit ovulation. Progestin-only pills are estimated to be as effective as COCs when taken consistently (Table 32.1), but they are less forgiving of inconsistent use and indeed must be taken regularly (at approximately the same time each day) to be effective. The most common side effect associated with progestin-only pill use is changed vaginal bleeding patterns.

Progestin-only Injectables

Progestin-only injectables first became available to women in the United States with

approval of the U.S. Food and Drug Administration (FDA) in 1992. The injectable, containing 150 mg of DMPA, inhibits ovulation, produces an atrophic endometrium, and alters cervical mucus to decrease sperm penetration. Intramuscular injections are administered every 3 months (within a window of 2 weeks on either side). A subcutaneous form consisting of 104 mg is now available and dosed every 3 months. Most women who want to use a progestin-only injectable can safely do so. However, women with current breast cancer should not use this method. Several other conditions for which women generally should not use progestin-only injectables are listed in Table 32.2.

The most common side effect experienced by progestin-only injectable users is the same as with oral progestins—changed vaginal bleeding patterns. During the first few months of use, many women experience irregular and prolonged bleeding. However, as use continues, bleeding becomes less frequent, and up to half of women become amenorrheic by 1 year of use. Some women also report weight gain during the first several years of use; studies suggest a mean weight gain of 3 to 5 lb per year.

Because of the highly effective suppression of ovulation leading to amenorrhea in many women, there also is a significant delay in return to fertility after discontinuation of progestin-only injectables. The median time to pregnancy is 6 to 9 months after the last injection. Progestin-only injectables are the only temporary contraceptives with a substantial delay in return to fertility.

Concern has been raised that progestin-only injectable use may adversely affect bone mineral density with prolonged use. Concern was raised for adolescents, who have not yet reached peak bone mass. A meta-analysis of 12 studies concluded that women who currently were using DMPA had a lower average bone mineral density than nonusers, with some suggestion that women with longer duration of use had greater reductions in bone mineral density. No differences in bone mineral density were found between past users and those who had never been users. Premenopausal women who discontinue progestin-only injectables can regain much of their lost bone mass. However, data on adolescents are still pending. Likewise, whether perimenopausal use will precipitate a decline in bone mass associated with menopause is unclear. In addition, a Cochrane review found that although the progestin-only injectable may alter bone mineral density, it cannot be determined from existing information whether this influences fracture risk. It was concluded that clinical circumstances must determine whether the advantages outweigh concerns about fracture risk for adolescents and women over 45 years of age.

Estrogen–Progestin Injectables

In 2001, the FDA approved the first combined estrogen–progestin injectable for use in the United States. However, this injectable was removed from the market in 2002.

Implants

In 2006, the FDA approved the use of a single-rod progestin implant that is 4 cm long and releases etonogestrel at the rate of 68 mcg per day. This method provides 3 years of contraceptive efficacy. A six-rod implant, which was removed

from the market in 2002. In the new system, the single rod is inserted subcutaneously in the woman's upper inner arm under local anesthesia. Its incisionless insertion and single rod are designed to facilitate placement and removal. Progestin implants prevent pregnancy by suppressing ovulation in most women. Despite inhibition of ovulation, there is incomplete suppression of ovarian function and women do not become hypoestrogenic. Additional mechanisms include thickening of the cervical mucus with inhibition of sperm penetration and endometrial atrophy. This method is highly effective, long term, and nonuser dependent. No pregnancies occurred in the first 70,000 cycles studied.

Most women can safely use etonogestrel implants. However, women with current breast cancer should not use them. Other conditions for which women generally should not use etonogestrel implants are similar to those for levonorgestrel implants, which are listed in Table 32.2. Most implant users experience changes in vaginal bleeding patterns, including prolonged or irregular bleeding. As bleeding changes are among the most common reasons for discontinuation of implants, women should be counseled about these bleeding changes before initiating implant use. Other reported side effects include weight gain, headaches, acne, and mood changes.

Contraceptive Patch

In 2001, the FDA approved the first transdermal contraceptive patch. The patch is designed to release 20 mcg ethinyl estradiol and 150 mcg norelgestromin, the active metabolite of norgestimate, daily for 1 week. The patch acts similarly to oral contraceptive pills in that the user applies the patch weekly for 3 weeks, followed by a patchfree week to allow for withdrawal bleeding. The patch is similar to oral contraceptive pills in effectiveness, side effects, and incidence of breakthrough bleeding. It may be less effective among women who weigh ≥90 kg. In a study that compared the patch with an oral contraceptive, patch users experienced higher rates of breakthrough bleeding or spotting and reported more breast discomfort in the first 2 months of use but not thereafter. Dysmenorrhea and headaches were infrequent reasons for discontinuation but were more frequent among patch users than among COC users. In clinical trials, patch users have demonstrated high compliance with method use—significantly better than COC users in one study.

In a 2005 press release, the FDA stated that women who use the patch are exposed to about 60% more total estrogen (i.e., the area under the curve) compared with 35 mcg birth control pills. This statement sparked concern over the risk of VTE. Peak ethinyl estradiol concentrations are 25% lower than with oral contraceptives. The risk of VTE has been studied in two nested-case control studies using electronic health care claims data. One study found an increased risk of VTE among users of the contraceptive patch compared with that among COC users (odds ratio [OR] 2.4; 95% confidence interval [CI] 1.1 to 5.5). In another study, there was no increased risk of VTE (OR 0.9; 95% CI 0.5 to 1.6). Patients should be counseled regarding the available data on VTE risk and the contraceptive patch. However, clinical judgment should be used in helping women to decide whether this method is right for them.

Vaginal Ring

Most steroid hormones are absorbed efficiently through the vaginal epithelium and can be released from vaginal rings made out of polymers such as silastic or ethylvinyl acetate. As a delivery system, the vaginal ring is the only long-acting method that is under the user's immediate control. It can be easily inserted, checked, removed, and replaced by the user. Other advantages include the following:

- Its use is not related to coitus
- It provides a constant rate of drug release, resulting in a steady plasma level of the minimum dose required for contraception
- Metabolic side effects are reduced by avoiding the first-pass effect through the liver
- In the case of accidental pregnancy or if protection is no longer required, plasma levels fall rapidly to zero.

Fertility returns promptly after the ring is removed. In 2001, the FDA approved the first contraceptive ring for use in the United States. The ring, which releases 15 mcg ethinyl estradiol and 120 mcg etonogestrel daily, is left in place for 3 weeks and then removed for 1 week to allow for withdrawal bleeding. Like the pill, it acts mainly by inhibiting ovulation and is highly effective when used correctly. Experience to date suggests that it is well accepted by users and their partners and that it does not cause untoward local effects.

Intrauterine Devices

Although IUDs are the most commonly used reversible method of contraception worldwide, their use in the United States has plummeted from 7.1% of married women in 1981 to just 1.3% of women between the ages of 15 to 44 years in 2002. Much of the decrease in use of this long-term, highly effective method of contraception can be attributed to concerns about the risk of pelvic infections stemming from studies of IUDs in the 1970s. In particular, the Dalkon Shield IUD was associated with an increased risk of infection and was removed from the market in 1975. Today, pelvic infection among users of modern IUDs is primarily associated with exposure to sexually transmitted infections; the risk among IUD users at no risk for sexually transmitted infections is extremely low.

Currently, two IUDs are available for use in the United States. The most commonly used IUD is the copper T 380A,

---

made of polyethylene with fine copper wire wound around the stem and copper sleeves on the two arms of the “T.” It remains an effective contraceptive for at least 10 years. The copper IUD is the most cost-effective method of contraception in the United States over 5 years of use. The FDA approved a progestin-releasing IUD in 2000; this IUD releases 20 mcg of levonorgestrel per day for 5 years. The progestin plays a role in the mechanism of action and decreases the amount and duration of menstrual bleeding and dysmenorrhea. Both IUDs are highly effective, with typical use failure rates ranging between 0.1% and 0.8% in the first year of use (Table 32.1). Over the long term, IUD failure rates are similar to those

of tubal sterilization, which makes it an ideal reversible alternative to sterilization for many women. Both the copper and levonorgestrel IUDs protect against ectopic pregnancy. However, among women who become pregnant while using an IUD, the proportion of pregnancies that are ectopic is higher compared with ectopic pregnancies occurring in women who use no contraception.

The primary mechanism of action of IUDs appears to be prevention of fertilization, as demonstrated by studies finding significantly decreased numbers of fertilized ova in the fallopian tubes of copper IUD users compared with women who use no contraception. IUDs also act by stimulating an inflammatory response in the uterine cavity, which decreases sperm transport, impedes the ability of sperm to fertilize the ovum, and may be spermicidal. The copper in copper-bearing IUDs enhances this response. In the progestin-releasing IUD, the hormone also acts on the cervical mucus and ovarian function to prevent fertilization. IUDs may also act to prevent implantation if fertilization occurs.

The primary health concern with the use of IUDs has been the risk of upper genital tract infection. Early studies overestimated the association between IUD use and PID due to inappropriate comparison groups and lack of control for confounding factors. However, studies of modern IUDs among women at low risk for sexually transmitted infections have shown that the risk of infection primarily is associated with insertion of the IUD, is low (1 per 1,000 woman-years), and is largely limited to the first 20 days after insertion (Fig. 32.1). A randomized clinical trial of 1,833 U.S. women undergoing IUD insertion compared antibiotic prophylaxis with placebo and found very low rates of infection (one participant in each group) during the 90 days after insertion. A large international cohort study reported an incidence rate of acute PID of 0.6 per 1,000 woman-years of copper IUD use. Some studies of levonorgestrel IUDs have shown decreased risk of PID compared with copper IUDs, possibly due to thickening of the cervical mucus, which could act as a barrier to bacteria; this finding needs to be confirmed in future studies.

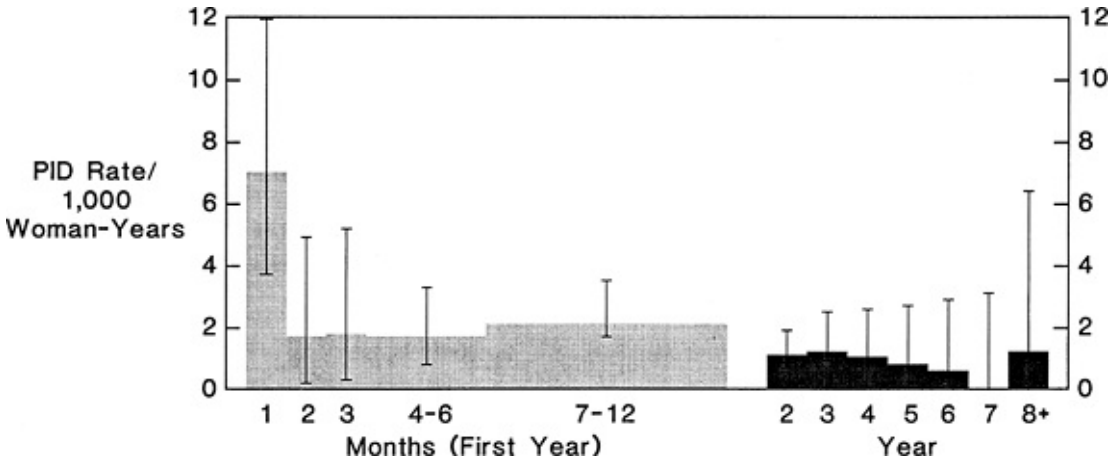

Figure 32.1 Incidence of PID by duration of IUD use. The 95% CIs are shown. (From Farley TMM, Rosenberg MJ, Rowe PJ, et al. Intrauterine devices and pelvic inflammatory disease: an international perspective. *Lancet* 1992;339:785–786.)

The IUD is an appropriate method of contraception for many women. The IUD offers many advantages: it is a long-term, highly effective, reversible method, with little action required of the user. In 2005, changes were made to package labeling, removing language stating that the preferred IUD patient should be multiparous, in a monogamous relationship, and without history of PID. While IUDs are suitable in nulliparous women, the increased risk of expulsion for nulliparous women and adolescents (independent of parity) should be noted. Here, the issue seems to be gravidity, as women who have had a first-trimester pregnancy ending in miscarriage or abortion have a decreased risk of expulsion. IUD use in nulliparous women is not associated with tubal infertility, and there is no delay in return to fertility after IUD removal. Thus, the IUD can safely be used in women who are adolescents, nulliparous, nonmonogamous, or have a past history of PID. These women are not at increased risk of infertility. However, if a potential IUD user is at risk of sexually transmitted infections, then she, like all at-risk contraceptive users, should be encouraged to use condoms. Conditions for which women should not use an IUD include the following:

- Pregnancy
- Puerperal sepsis
- Immediate postseptic abortion

- Anatomic abnormalities that distort the uterine cavity
- Unexplained bleeding, suspicious for a serious condition
- Malignant gestational trophoblastic disease
- Cervical cancer (awaiting treatment)
- Endometrial cancer
- Uterine fibroids with distortion of the uterine cavity
- PID—current or within the last 3 months
- Sexually transmitted infections—current or within the last 3 months
- Known pelvic tuberculosis.

Other conditions for which women generally should not use IUDs are listed in Table 32.2.

IUDs can be inserted at any time during the menstrual cycle if the woman is not pregnant. The IUD also can be inserted after 4 weeks postpartum without an increased risk of perforation or expulsion. Following an uncomplicated first-trimester abortion, an IUD can be inserted immediately without increased risk of infection or perforation. However, following a second-trimester abortion, it is recommended that IUD insertion be delayed 4 weeks until involution of the uterus to avoid an increased risk of expulsion.

A pelvic exam is necessary before IUD insertion to rule out pregnancy and pelvic infection and to identify the position and mobility of the uterus. Accurate determination of uterine position is necessary to prevent perforation; the incidence of perforations with IUD insertion is about 1 per 1,000 insertions. The main risk of infection occurs with insertion,

and careful aseptic technique is required. However, a large randomized controlled clinical trial demonstrated that antibiotic prophylaxis at the time of IUD insertion is not indicated. In a meta-analysis of randomized controlled trials on this topic, there was no difference in rates of infection or early discontinuation of the IUD, although there was a decrease in unscheduled return visits for those receiving antibiotics in one trial. Use of NSAIDs before insertion may reduce discomfort; local anesthesia is another option that is infrequently needed. Once the IUD is inserted, the woman should check for the IUD string so that she will later be able to confirm its presence and length.

IUD users have high rates of continuation—approximately 80% at 1 year of use in the United States. Increased menstrual bleeding and pain are the most common side effects reported with copper IUD use and are a primary reason for discontinuing the method. Treatment with NSAIDs has been shown to effectively reduce pain and bleeding. Because levonorgestrel-releasing IUDs generally reduce the amount of cramping and bleeding, women with heavy menstrual bleeding or dysmenorrhea may benefit from these IUDs. In contrast to the copper IUD, amenorrhea is a cause of discontinuation of the levonorgestrel-releasing IUD, affecting about 5% of users in the first year of use.

IUD expulsions occur in about 5% of users. Risk factors for expulsion include young age, nulliparity, and heavy bleeding. IUD users should check for the presence and length of the IUD strings frequently, at least after every menstrual period, to confirm that the IUD is still in place. Patients typically are asked to return to their health care provider 4 to 6 weeks after the IUD is placed to visualize the IUD strings.

Mechanical Barrier Methods

The male latex condom is the only method of contraception proven to be highly effective in preventing both pregnancy and HIV infection when used consistently and correctly. Male condom use also reduces the risk of gonorrhea and chlamydial infection. Inconsistent or incorrect use, however, undermines this large potential benefit. Polyurethane male and female condoms have been less fully evaluated for contraception and disease prevention, but consistent and correct use of these methods should provide substantial dual protection. The potential for condoms to be highly effective if used consistently and correctly is in stark contrast to the long-standing notion that condoms are not highly effective. In fact, as shown in Table 32.1, perfect use of male condoms is more effective than typical use of oral contraceptives, which highlights the role of male condom users. It is now clear that true condom failure is infrequent but that failure to consistently and correctly use condoms is not.

Diaphragms and cervical caps also may provide some protection against some sexually transmitted infections, particularly gonorrhea and chlamydial infections, but there is substantially less evidence for this protection than for male condoms. Pending further evidence, protection against sexually transmitted infections should be presumed to be less complete than for male condoms, and protection against HIV infection should not be assumed at all.

Male Condom

The Centers for Disease Control and Prevention provide the following instructions for correct use of male condoms:

1. Use a new condom with each act of sexual intercourse.
2. Handle the condom carefully to avoid damaging it with fingernails, teeth, or other sharp objects.
3. Put the condom on after the penis is erect and before any genital contact with the partner.
4. Ensure that no air is trapped in the tip of the condom.
5. Ensure adequate lubrication during intercourse, possibly requiring the use of exogenous lubricants.
6. Use only water-based lubricants with latex condoms (oil-based lubricants can weaken latex).
7. Hold the condom firmly against the base of the penis during withdrawal, and to prevent slippage, withdraw while the penis is still erect.

Condom breakage rates in the United States are low, about 2 broken condoms per 100 used. Proper use reduces the risk of breakage. Condom slippage may be more likely to contribute to pregnancies than condom breakage, which highlights the importance of following instruction 7 given above. Most condom failures are the result of inconsistent or incorrect use rather than failures of the product per se.

Female Condom

In 1993, the FDA approved the female condom for marketing and distribution in the United States. The device is a prelubricated, loose-fitting polyurethane sheath that is 17 cm in length and has a flexible ring at each end. One ring is loose inside the condom and is used to insert the condom into the vagina; the other ring lines the opening of the condom, remains outside the vagina, and covers a portion of the external genitalia during intercourse. The woman should insert the condom by holding the sheath at the closed end and grasping the inner ring; the inner ring should then be inserted toward the apex of the vagina by the index finger, making sure that the sheath is not twisted and that the outer ring remains outside the vagina. It is important that the penis is guided into the opening of the sheath to reduce the likelihood that penetration around the sheath occurs during intercourse. Thus, although this condom is female inserted, its proper use, like that of the male condom, requires the cooperation of both partners.

Diaphragm

The diaphragm is a latex, dome-shaped cup with a flexible spring rim. Diaphragms range in size from 50 to 95 mm and require vaginal examination for proper fitting. An appropriately placed diaphragm should completely cover the cervix; the posterior rim should lie in the posterior fornix, and the anterior rim should be just behind the symphysis pubis, with about

1 cm between the rim and the symphysis pubis. In general, the largest diaphragm that is comfortable for the woman should be prescribed. If the diaphragm is too small, it may be displaced during coitus; if it is too large, it may cause discomfort or trauma. Diaphragms are used with spermicidal creams or jellies applied to the inside of the dome. After insertion, the diaphragm substantially reduces the risk of pregnancy for about 6 hours. If coitus occurs after that time, additional spermicidal cream or jelly should be placed intravaginally without removing the diaphragm. Likewise, additional spermicide should be placed intravaginally if coitus is repeated within 6 hours. The diaphragm should remain in place for at least 6 hours after coitus but for no longer than 24 hours to reduce the risk of toxic shock syndrome. Diaphragms may be used by all women who have been fitted properly but may cause an increase in urinary tract infections.

Cervical Cap

The cervical cap is a latex cup with a firm rim that covers the cervix and fits snugly around its base. Four sizes of the cap are available (with inner diameters of 22, 25, 28, and 31 mm). The properly fitted cap has a rim with an inner diameter that is almost the same as the diameter of the base of the cervix, so the cap remains in close contact with the cervix. The cap should be long enough to cover the entire cervix without resting on the cervical os. If the cap is too large, it is more likely to be displaced during coitus; if it is too small, it may cause trauma. The device is used with spermicide placed in the cap before insertion and is effective for 48 hours after insertion. It should be removed no longer than 48 hours after insertion to reduce the risk of toxic shock syndrome.

Contraceptive Sponge

A contraceptive sponge was recently put on the market again after being removed for a short time. The sponge is small, polyurethane, and pillow-shaped, containing 1 g of nonoxynol-9 spermicide. The concave side with a slight dimple fits over the cervix, decreasing the chance of slipping. The opposite side has a woven loop to ease removal. The sponge is sold over the counter, is one size, and protects for 24 hours once put in place, regardless of the number of times of intercourse during that time. After intercourse, it must be left in place at least 6 hours before it is removed and discarded but should not be left in place more than 24 hours.

Spermicides

Spermicides, formulated as vaginal foams, gels, creams, film, suppositories, and tablets, usually contain the surfactant nonoxynol-9 in the United States; the surfactants octoxynol and benzalkonium chloride are widely available elsewhere. Spermicides are not highly effective for contraception when used alone, even when used consistently and correctly. When used alone, or with a mechanical barrier (condoms, diaphragms, sponge, or cervical caps), spermicides should be inserted just before coitus.

The hope that vaginal use of nonoxynol-9 would reduce the risk of sexually transmitted infections, including HIV infection, has met with disappointment. Three randomized, controlled trials have failed to demonstrate any benefit in preventing HIV infection, and

the most recent of these suggests that frequent use of spermicides containing nonoxynol-9 may actually enhance the risk of acquiring infection, including transmission of HIV. The U.S. Centers for Disease Control and Prevention and the World Health Organization now recommend that spermicides containing nonoxynol-9 not be used for prevention of sexually transmitted infections, including HIV infection. Furthermore,

evidence suggests that vaginal spermicides containing nonoxynol-9 are not effective in preventing cervical gonorrhea or chlamydial infection.

Fertility Awareness-based Methods

Fertility awareness–based methods use signs and symptoms to estimate a woman's fertile period, during which time the couple should refrain from unprotected intercourse. Calendar methods estimate the fertile days based on the length of a woman's usual menstrual cycle; the other three fertility awareness–based methods are based on monitoring physiologic changes throughout the menstrual cycle. About 25% of typical users of fertility awareness–based methods become pregnant in the first year of use. Failure rates are based on couples who abstain from sex during the fertile period and may be different for couples who choose to use barrier methods during that time. The relatively high failure rates are partially due to inconsistent use of the method, but they are also due to the lack of reliability in estimating the fertile window. One study that measured timing of ovulation with daily urine samples found that in only 30% of women did the actual fertile window fall within the days of the fertile window as estimated from calendar calculation. Training in how to use these methods as well as monitoring the menstrual cycles for several months is necessary for successful use.

Calendar Methods

Calendar-based methods require abstaining from unprotected intercourse during the woman's fertile period, which is estimated from the typical length of her menstrual cycle and from assumptions about the timing of ovulation, the length of time the ovum is capable of being fertilized, and the length of time sperm can survive in the female genital tract. One method estimates the fertile period to be from the length of the shortest cycle minus 18 to the length of the longest cycle minus 11. For example, if the woman's shortest cycle was 25 days and her longest cycle was 29 days, her fertile period (i.e., when abstinence is required) would be from day 7 through day 18. Another version, the standard days method, simply states that for women whose cycle lengths are between 26 and 32 days, the fertile period is from days 8 through 19 of the cycle.

Cervical Mucus Method

The cervical mucus method entails checking the quality and quantity of cervical mucus each day; the fertile period is indicated by clear, wet, and slippery mucus. Abstinence from unprotected intercourse is necessary during menses, every other day during the preovulatory period (as intercourse interferes with interpreting the cervical mucus signs), and from the time fertile mucus appears through 3 days after the last day of fertile mucus.

Basal Body Temperature Method

The basal body temperature method is based on temperature changes throughout the menstrual cycle. A rise of 0.4° to 0.8° above the mean temperature of the preovulatory phase for 3 days indicates ovulation has occurred. Therefore, abstinence is required from the time of menses until 3 days after the rise in temperature.

Symptothermal Method

The symptothermal method is the use of at least two of the previously described methods simultaneously and also may rely on other physiologic changes during the menstrual cycle, including midcycle pain and bleeding as well as position and texture of the cervix.

Emergency Contraception

Emergency contraception (EC) was once called “the best kept secret of family planning.” In the early 1970s, Yuzpe and colleagues tested combinations of ethinyl estradiol and norgestrel for postcoital contraception. Interestingly, the dosing and timing of this regimen was not derived in clinical studies. Subsequent clinical trials led them to conclude that the most successful regimen consisted of two doses of 100 mcg ethinyl estradiol and 500 mcg levonorgestrel, with the first dose taken within 72 hours of unprotected intercourse, and the second dose taken 12 hours later.

More recently, a dedicated emergency contraceptive containing levonorgestrel alone has become the standard of care. Various doses of levonorgestrel have been tested since the 1970s for EC. A large multinational, randomized, double-blind clinical trial was conducted comparing the Yuzpe regimen and levonorgestrel treatment (one 750 mcg dose followed by a second 750 mcg dose 12 hours later) when started up to 72 hours after unprotected intercourse. Results showed that levonorgestrel was not only better tolerated but also was more effective than the Yuzpe regimen, preventing 89% of expected pregnancies among women who correctly used the treatment. It also showed that the earlier either treatment was taken after the act of unprotected intercourse, the more effective it was. Since then, it has been demonstrated that both 750 mcg pills can be taken together in a single dose (a total of 1.5 mg levonorgestrel) with the same effectiveness and side effects as the two-dose regimen. In addition, efficacy has been shown for up to 120 hours after unprotected intercourse. The levonorgestrel treatment is now the single dedicated product available for EC, although EC is still used by combining regular oral contraceptives in the correct dosage (Table 32.1).

A primary mechanism of action of EC is to inhibit, delay, or otherwise interfere with normal ovulation, thereby preventing fertilization. EC also may alter the endometrium and impair implantation, although one study found that use of levonorgestrel EC did not impair endometrial morphology. EC use does not disrupt an established pregnancy.

EC is safe for use by almost all women. Concerns about EC distribution have included those regarding advance provision and multiple administrations. Studies have shown that women

who were given an advance supply of EC had the same rates of unprotected intercourse as controls, followed the treatment regimen correctly, and were more likely to use one dose of EC but were no more likely than the control group to use EC repeatedly. In August 2006, the FDA approved over-the-counter status for levonorgestrel EC for women age 18 and older. Although this decision was hailed by many women's reproductive rights groups, the restrictions that deny teenagers over-the-counter access have not been supported by scientific evidence. Randomized controlled trials have been conducted in adolescents, showing that advanced provision of EC resulted in increased use but did not compromise their use of routine contraception or increase their sexual risk behavior.

Emergency Use of Copper-Bearing Intrauterine Devices

Copper-bearing IUDs are extremely effective when used as EC (99%). The IUD must be inserted within 7 days of unprotected intercourse. This method is most appropriate for women who want long-term, highly effective contraception and have no contraindications to IUD use.

Future Emergency Contraception

Other agents may emerge as effective forms of EC in the future. A recent randomized controlled trial found that a new progesterone receptor modulator is at least equally effective and has a similar side-effect profile as levonorgestrel.

Sterilization

Tubal sterilization and vasectomy are intended to be permanent and are appropriate only for women and men who have made a fully informed and well-considered decision to permanently prevent pregnancy. Although some sterilizations are potentially reversible, depending on multiple factors including the sterilization procedure, the length of normal fallopian tube remaining, the age of the woman (tubal sterilization), and the length of time between the sterilization and reversal procedures (vasectomy), many sterilizations are not reversible. Further, the costs of sterilization reversal or in vitro fertilization are prohibitive for many who regret having had a sterilization procedure.

Although tubal sterilization and vasectomy have been shown to be safe and highly effective, vasectomy is somewhat safer, partly because most vasectomies are done with local anesthesia and tubal sterilizations are intra-abdominal procedures. Vasectomy is believed to be somewhat more effective than tubal sterilization, and its effectiveness is easily assessed by semen analysis. The long-term effectiveness of vasectomy, however, has been less completely studied than that of tubal sterilization; some trials suggest that the effectiveness of vasectomy, like tubal sterilization, may vary according to the method of occlusion.

Counseling of those considering sterilization is critically important. Such counseling should include not only the anticipated risks and benefits of the surgery but also the possibility of later regretting having had the procedure. The strongest predictors of later regretting tubal sterilization are young age at the time of sterilization and substantial conflict

between the woman and man at the time of sterilization. Women considering tubal sterilization should understand that pregnancy is possible even remote from sterilization, and they should understand that a high proportion of pregnancies after tubal sterilization are ectopic gestations.

Vasectomy

Vasectomy, or transection and occlusion of the vas deferens, usually is performed in an outpatient setting with local anesthesia and without premedication. After incising or puncturing the skin of the scrotum, the vas is identified, dissected free of its fascial sheath, and divided. The cut ends of the vas are then occluded by ligation, coagulation of the mucosa, or rarely by clip application. Fascial interposition is frequently performed after ligation or coagulation by pulling the sheath over one of the vas ends and suturing it to reduce the likelihood of subsequent spontaneous anastomosis. The most frequent complications of vasectomy are hematoma formation and infection, each of which occurs in about 2% of procedures. Death and serious morbidity are rare. No long-term serious adverse health effects have been documented, and the best available evidence suggests no effect on risk of cardiovascular disease, prostate cancer, or testicular cancer.

Although there is a substantial decrease in the concentration of sperm in the semen by 3 days after vasectomy, complete absence of sperm may take 16 weeks or more, depending in part on the number of ejaculations. Semen analysis should be performed, where feasible, after 12 weeks or 20 ejaculations, and temporary contraception should be used in the interim. The time to azoospermia after vasectomy is under study and may vary according to surgical technique.

Tubal Sterilization

The proportion of tubal sterilizations done on an interval basis (not pregnancy associated) varies from country to

country. Approximately one half of tubal sterilizations in the United States are performed after vaginal delivery or at cesarean delivery, and the other half are performed at a time unrelated to pregnancy. The timing of the procedure with respect to pregnancy can affect the surgical approach, the method of tubal occlusion, and the choice of anesthetic. For example, interval procedures are usually performed in the United States by laparoscopy using coagulation (Fig. 32.2), silicone rubber bands (Fig. 32.3), or clips (Fig. 32.4) under general anesthesia; laparoscopic sterilization can be even more safely performed with local anesthesia. By contrast, procedures at the time of cesarean delivery require no additional anesthesia and usually involve partial salpingectomies (Fig. 32.5); procedures following a delivery usually are performed by minilaparotomy through subumbilical incisions and likewise usually involve partial salpingectomies.

The likelihood of pregnancy after tubal sterilization varies according to age at the time of the procedure and sterilization technique (Table 32.3). The chance that pregnancies are ectopic varies by method. Among women in the U.S. Collaborative Review of Sterilization, the highest proportion of pregnancies that were ectopic occurred after bipolar coagulation

(65%), followed by interval partial salpingectomy (43%), silicone rubber band application (29%), postpartum partial salpingectomy (20%), unipolar coagulation (17%), and spring clip application (15%). Further, the proportion of pregnancies that were ectopic for all methods combined increased over time, being three times as high (61%) in 4 to 10 years after sterilization as in the first 3 years (20%).

Death from tubal sterilization is rare, 1 to 2 deaths per 100,000 procedures, with most deaths attributable to complications of general anesthesia. Major complications, principally unintended laparotomies, occur in 1% to 2% of procedures.

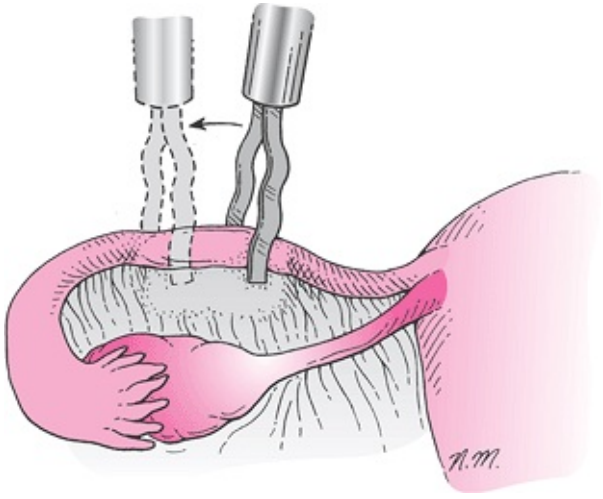

Figure 32.2 Bipolar method. A 3-cm minimum zone of isthmic tube is desiccated with bipolar forceps. The paddles of the forceps extend across the tube onto the mesosalpinx. (From Peterson HB, Warshaw J, Pollack A. Tubal sterilization. In: Rock JA, Thompson JD, eds. *TeLinde's operative gynecology*, 8th ed. Philadelphia: JB Lippincott Co, 1997:529–547.)

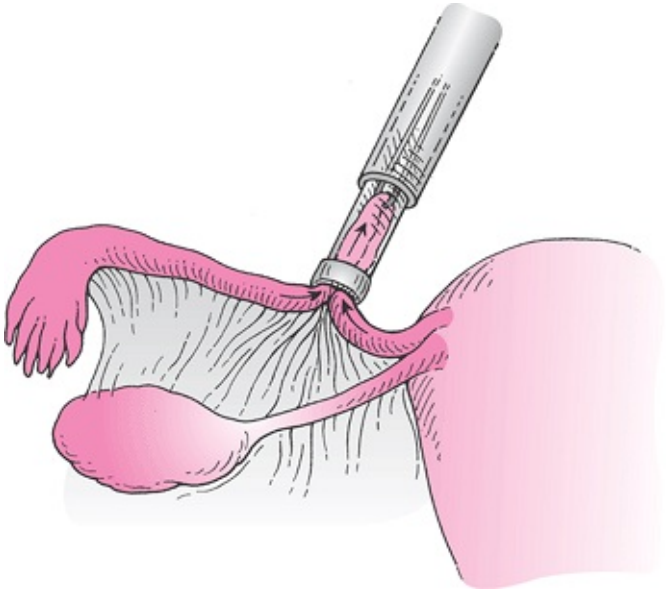

Figure 32.3 Silicone rubber band method. The isthmic portion of the tube is retracted into the applicator barrel by using grasping tongs, which should completely surround the tube. To avoid excessive traction on the tube and its mesentery, the applicator barrel is advanced toward the tube during this retraction process. (From Peterson HB, Warshaw J, Pollack A. Tubal sterilization. In: Rock JA, Thompson JD, eds. *TeLinde's operative gynecology*, 8th ed. Philadelphia: JB Lippincott Co, 1997:529–547.)

The potential for late sequelae of tubal sterilization has been assessed. There is strong evidence against a purported post–tubal ligation syndrome of menstrual abnormalities. Sterilized women in the U.S. Collaborative Review of Sterilization were no more likely than women whose partners

underwent vasectomy to have menstrual abnormalities within 5 years after sterilization. In the same study, sterilized women were more likely to undergo hysterectomy than women whose partners were sterilized, but nonbiologic factors were the likely explanation.

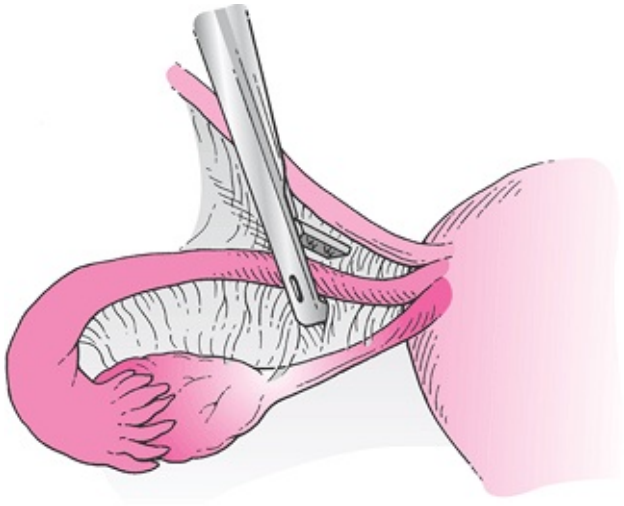

Figure 32.4 Spring clip method. The clip is applied to the midisthmus at a 90-degree angle to the long axis of the tube. The hinge of the clip should be pressed against the tube, and the tips of the clip should extend onto the mesosalpinx. (From Peterson HB, Warshaw J, Pollack A. Tubal sterilization. In: Rock JA, Thompson JD, eds. *TeLinde's operative gynecology*, 8th ed. Philadelphia: JB Lippincott Co, 1997:529–547.)

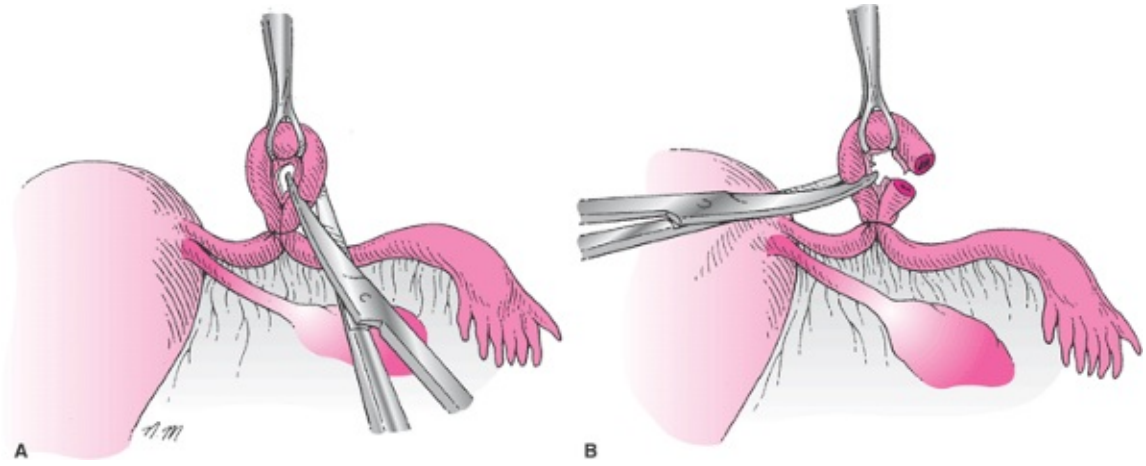

Figure 32.5 Pomeroy method. **A:** A loop of the isthmic portion of the tube is elevated and ligated at its base with one or two ties of no. 1 plain catgut suture. If performed through a minilaparotomy incision, these ties should be held long to prevent premature retraction of the tubal stumps into the abdomen when the loop of tube is transected. **B:** A fenestration is bluntly created through the mesentery within the tubal loop, and each limb of the tube on either side of this fenestration is individually cut. The cut ends of the tube are inspected for hemostasis and allowed to retract into the abdomen. (From Peterson HB, Warshaw J, Pollack A. Tubal sterilization. In: Rock JA, Thompson JD, eds. *TeLinde's operative gynecology*, 8th ed. Philadelphia: JB Lippincott Co, 1997:529–547.)

TABLE 32.3 Life-table Cumulative Probability of Pregnancy among Women Undergoing Tubal Sterilization in the U.S. Collaborative Review of Sterilization by Age[a]

Age at sterilization	Probability of pregnancy (%) (range)
18–27y	
Bipolar coagulation	54.3 (28.3–80.4)
Unipolar coagulation	3.7 (0.0–11.1)
Silicons rubber band application	33.2(10.6–55.9)

Spring clip application	52.1 (31.0–73.3)
Interval partial salpingectomy	9.7 (0.0–28.6)
Postpartum partial salpingectomy	11.4(1.6–21.1)
28–33 y	
Bipolar coagulation	21.3(9.6–33.0)
Unipolar coagulation	15.6(0.0–31.4)
Silicone rubber band application	21.1 (6.4–35.9)
Spring clip application	31.3(15.1–47.5)
Interval partial salpingectomy	33.5 (0.0–74.3)
Postpartum partial salpingectomy	5.6(0.0–11.9)
34–44 y	
Bipolar coagulation	6.3(0.1–12.5)
Unipolar coagulation	1.8 (0.0–5.3)
Silicone rubber band application	4.5 (0.6–8.4)
Spring clip application	18.2 (0.0–36.4)
Interval partial salpingectomy	18.7 (0.0–39.6)

Postpartum partial salpingectomy	3.8(0.0–11.4)

"Cumulative probability per 1,000 procedures and 95% confidence interval.
Source: Adapted from Peterson HB, Xia Z, Hughes JM, et al. The risk of pregnancy after tubal sterilization: findings from the U.S. Collaborative Review of Sterilization. *Am J Obstet Gynecol* 1996; 174:1161–1170, with permission.

Young age at sterilization, regardless of the number of children, is a strong predictor of later regretting having had the procedure. Among women sterilized at 18 to 24 years who were followed in the U.S. Collaborative Review of Sterilization, the cumulative probability of requesting information about reversal within 14 years was 40%.

Transcervical Tubal Occlusion/Inserts

In 2002, the FDA approved a soft, flexible, micro-insert device placed hysteroscopically in the proximal section of each fallopian tube. This device consists of two concentric metal coils that act to occlude the tubes over a few months time, after the growth of fibrous tissue is stimulated by the inner coil. By 3 months, 96% of women had both tubes occluded, and by 6 months, 100% of women had both tubes occluded, as determined by follow-up hysterosalpingogram (HSG). The tubal inserts can be done as an office procedure under local anesthesia. It is a permanent procedure, and because it is not effective for a few months time, women should be advised to use a back-up method until an HSG demonstrates tubal occlusion. Long-term safety and efficacy studies are currently under way, although results from 3-year studies show greater than 99% efficacy after confirmation by HSG.

Summary Points

- The effectiveness of some contraceptive methods, including oral contraceptives, barrier methods, and fertility awareness–based methods, is highly dependent on whether they are used consistently and correctly. The effectiveness of other methods, including IUDs, implants, and injectables, is less dependent on user characteristics.
- Oral contraceptives have been studied more extensively than any other method. They are nearly 100% effective if taken daily, but they are substantially less effective with typical use. For healthy, non-smoking women, the health benefits of oral contraceptive use far exceed the health risks.
- The levonorgestrel EC pill is now available over the counter for

women 18 years of age and older and is about 89% effective in preventing pregnancy if taken within 72 hours of unprotected intercourse. Efficacy has been shown up to 120 hours following unprotected intercourse; early use should be encouraged.

- Five new contraceptive methods are available in the United States—a contraceptive patch, a vaginal ring, a hormonal IUD, a single-rod implant, and a transcervical sterilization procedure.
- Many women who desire contraception also are at risk for sexually transmitted infections, including HIV. For such women, consistent and correct use of a male latex condom is highly effective in protecting against both pregnancy and some sexually transmitted infections, including HIV infection. Spermicides containing nonoxynol-9 are no longer recommended for preventing sexually transmitted infections, including HIV; frequent use of spermicides may actually enhance the risk of acquiring HIV infection.
- IUDs are highly effective and provide long-term protection against pregnancy. Women at low risk of sexually transmitted infections are at exceedingly low risk of PID with IUD use.
- Male and female sterilization are highly effective but should be chosen only by those who wish to permanently prevent pregnancy. Young age at sterilization is a key risk factor for regretting having had a tubal sterilization.

Induced Abortion

Sabrina Holmquist
Melissa Gilliam

Recent estimates find that approximately 1.29 million abortions were performed in the United States in 2003, a 2% decrease from 1.31 million in 2000. Each year in the United States, 2% of women of reproductive age (15 to 44 years) terminate a pregnancy legally. Given the current rate, it is estimated that over one third of women in the United States will have had an abortion by age 45. The abortion rate in 2000 was about 21.3 per 1,000 women. This rate has decreased from 27.4 abortions per 1,000 women in 1990 (Fig. 33.1). While nearly all women in the United States have used some form of contraceptive at some point in their lives and contraceptive use has increased considerably since the legalization of abortion, about half of the 6 million pregnancies occurring each year are reportedly unplanned. Roughly half of these unplanned pregnancies, one in five pregnancies overall, are terminated by induced abortion. Women who opt for abortion tend to be never married, in their 20s, live below the federal poverty level, and are mothers of at least one child. Over half of women who have had an abortion used some form of contraception during the month that they became pregnant. Since legalization in 1973, abortion in the United States has become very safe (Fig. 33.2). Yet, worldwide, 19 of the 46 million abortions performed annually are done so illegally. Illegal abortion remains very unsafe and account for some 68,000 deaths globally each year.

Legalization

The landmark 1973 Supreme Court decision in *Roe v. Wade* effectively legalized abortion in the United States. Since that time, federal and state legislators have proposed or enacted hundreds of pieces of legislation aimed at restricting access to abortion or challenging the Court's *Roe* decision, making induced abortion the most actively litigated and highly publicized area in medicine. As early as 1976, the Hyde Amendment prohibited the use of federal Medicaid funding for abortions. In 1992, the Supreme Court's decision in *Planned Parenthood v. Casey* reaffirmed a woman's right to an abortion “before viability” but at the same time opened the door for states to impose additional restrictions that would not impose an “undue burden” on the woman.

Antiabortion legislation seeks to chip away at access to abortion through a variety of means. The federal so-called “partial-birth abortion” ban of 2003 attempted to abolish

certain late-second-trimester abortion procedures, but due to its vague language, it could have further reaching effects; at the time of this writing, a Supreme Court case challenging the ban awaits a decision. A number of states have mandated parental notification or consent before a minor is able to obtain an abortion. In some states, women seeking abortions must undergo a waiting period of at least 24 hours or receive state-sanctioned counseling beforehand; in some cases, this counseling contains ideologically charged or scientifically disputed information that is meant to discourage women from ultimately choosing abortion. A handful of states, most notably South Dakota in 2006, have attempted to pass bans on almost all abortions with the express purpose of challenging *Roe*.

Abortion Counseling

Pregnancy options counseling is an essential element of abortion provision, whether in a dedicated abortion clinic, a private office, or an inpatient setting. This type of counseling has three primary goals: helping the patient make an informed decision about her pregnancy, increasing the patient's knowledge and comfort with the abortion procedure, and alleviating anxiety and pain during the procedure while providing emotional support for her decision. Pregnancy options counseling can be performed by nursing staff, physicians, or dedicated counselors but is most effective when performed by an experienced options counselor

with knowledge of local laws governing consent procedures and state-mandated counseling requirements.

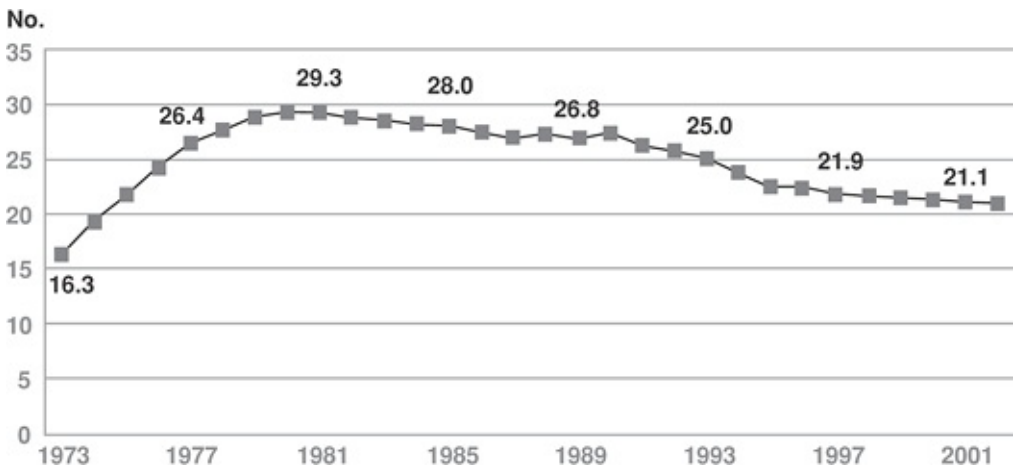

Figure 33.1 Number of abortions per 1,000 women ages 15 to 44, by year. (From Guttmacher Institute. *Facts on Induced Abortion in the United States*. New York: Guttmacher, 2006. Available at: *http://guttmacher.org/pubs/fb_induced_abortion.html*. Accessed August 29, 2007.)

Preprocedure counseling has two primary components: pregnancy options counseling and decision making and preprocedure counseling and informed consent for women who choose to have an abortion. The initial part of the counseling session should center on exploring

feelings about the pregnancy, including when and under what circumstances the patient became pregnant, how she feels about that pregnancy, and what options she has considered regarding its outcome. Women choose to have an abortion for a variety of reasons (Fig. 33.3) and have a wide variety of emotional responses to unplanned pregnancy, ranging from acceptance to ambivalence to anger, shame, and fear. Maintaining an open, nonjudgmental atmosphere is essential in allowing women to explore their feelings regarding their pregnancy and options that are open to them. The full range of pregnancy options should be discussed, including parenting, adoption, and abortion. Women should be encouraged to consider how each of these options would impact her life personally, financially, and emotionally as well as how they mesh with her values and those of her partner and family, if applicable. Any misconceptions regarding pregnancy options should be corrected, and the provider should assure that she is not being coerced into a decision.

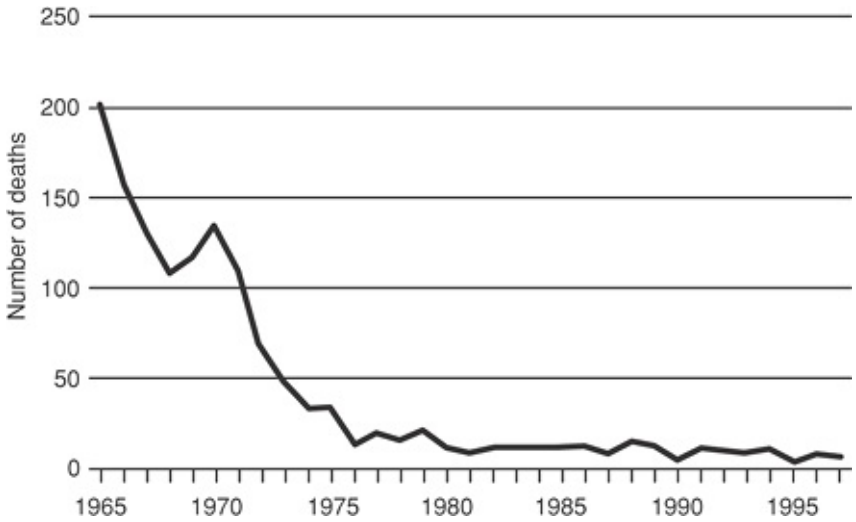

Figure 33.2 The number of deaths from abortion has declined dramatically since *Roe v. Wade*. (From Alan Guttmacher Institute, *Trends in Abortion in the United States, 1973-2002*. New York: Author, 2005.)

For women who choose abortion as their best option, the next step is helping them select an appropriate procedure. Before 9 weeks gestation, women can choose a medication or surgical abortion. Medication abortion is a process by which a pregnancy is terminated by use of medication without surgical intervention. It generally requires two visits, and patients must be willing to administer medication at home and be prepared for cramping, bleeding, and passage of tissue outside of a medical setting. For women without contraindications to medication abortion (allergy to mifepristone or misoprostol, bleeding dyscrasias, severe anemia) who are able to come for one follow-up visit, medication abortion provides a nonsurgical alternative to traditional dilation and curettage (D&C). For women who choose a surgical procedure, there are two options for first-trimester abortion: manual vacuum aspiration (MVA) and suction D&C. The characteristics of each of these modalities are listed in Table 33.1. Acceptability studies reveal that patients are highly satisfied with any of these procedures as long as they are able to make their own choice. The specifics of each procedure are covered in subsequent sections of this chapter as well

informed consent for each. Women presenting after the first trimester also have the option of undergoing a medication or surgical procedure; these procedures are discussed in subsequent sections.

Figure 33.3 Most important reasons given for terminating an unwanted pregnancy. (From Guttmacher Institute, *An Overview of Abortion in the United States*. New York, Author, 2006.)

Preprocedure Assessment

Prior to providing an abortion procedure, whether medication or surgical, each patient requires a preoperative assessment. Obstetric, medical, and surgical history should be recorded, emphasizing sexually transmitted disease history, contraception, menstrual history, the outcomes of previous pregnancies, previous uterine or cervical surgery, and any medication allergies. Previous anesthetic complications, bleeding problems, or transfusions also should be noted. Special attention should be paid to any conditions that may affect minor surgical procedures, including asthma, current medications, alcohol or drug abuse, chronic steroid use, HIV disease, coagulopathies, heart disease, or seizure disorders. Vital signs as well as a brief heart, lung, abdominal and thorough pelvic exam should be performed, including ascertainment of uterine size and position and abnormal or mucopurulent cervicovaginal discharge. Screening for cervical gonorrhea and chlamydial organisms prior to performing an abortion procedure can be employed universally, in at-risk patients only (based on clinical history and risk factors), or not at all depending on the practice setting. Because untreated chlamydial infection at the time of a transcervical procedure is associated with a 19% rate of postoperative salpingitis, prophylactic periabortal antibiotics should be administered to all patients regardless of preprocedure cervical screening. While Pap testing can be done for women who are due for their annual screening, it is not a necessary part of abortion care.

TABLE 33.1 Characteristics of Medication and Surgical Abortion in the First Trimester

Medication Abortion	Dilation and Curettage
May be used up to 9 weeks gestation	May be used up to 14 weeks gestation
High success rate (95% – 99%)	High success rate (99%)
Requires at least two visits	May be done in a single visit
Avoids instrumentation of the uterus	Requires instrumentation of the uterus
Abortion occurs within 24 hours in most cases	Procedure takes 5–10 min
Some of the process will occur at home	Procedure is done in a clinic/medical office
Oral pain medications can be used	Oral or intravenous sedating medications can be used
Patient will have to administer some medications at home	Procedure performed by a health care provider
Medications will induce cramping and bleeding, with passage of tissue akin to a miscarriage	Minimal pain or bleeding following the procedure in most cases

Accurate estimation of gestational age is key to both procedure selection and ascertainment of surgical risk; incorrect estimation of gestational age is an important cause of abortion complications. In the absence of a certain last menstrual period and

clinical correlation of uterine size by an experienced provider, ultrasound examination is a highly accurate way of confirming and dating an intrauterine pregnancy as well as a means for ruling out an ectopic or anembryonic gestation. In the absence of an intrauterine gestation, comprehensive pelvic ultrasound and serum human chorionic gonadotropin (hCG) testing should be employed to locate the pregnancy prior to attempted termination either by medication or surgical means. If the patient is too early in gestation to detect a gestational sac, the procedure should be delayed until a sac is visible. Absolute hCG levels at which an intrauterine gestation should be visible vary depending on ultrasound resolution and the skill of the sonographer; however, a hCG discriminatory threshold of 1,500 mIU/mL typically is accompanied by a gestational sac detectable by transvaginal ultrasound. Laboratory tests should include Rh(D) typing, with administration of Rh immune globulin to Rh-negative patients immediately after their procedure as well as hemoglobin/hematocrit to assess for anemia.

Most generally healthy women can safely obtain abortion procedures in the outpatient setting. Patients with severe medical or psychiatric conditions requiring intraoperative monitoring as well as those with pregnancy complications requiring pre- or postoperative monitoring or administration of intravenous antibiotics are best served in the inpatient operative setting. Induction termination procedures generally are performed in a hospital setting.

Surgical Abortion in the First Trimester

Surgical abortion in the first trimester can be performed between approximately 5 and 13 completed weeks gestation (depending on when an intrauterine sac is visible). Considered the gold standard for pregnancy termination,

a first-trimester surgical procedure is very effective (99.0% efficacy rate), very safe (major complication rate of 0.5%), and very common—89.0% of abortions provided in the United States occur before 13 completed weeks gestation; more than half occur before 8 weeks (Fig. 33.4). The D&C procedure includes both dilation of the cervix, which can be achieved chemically, mechanically, or a combination of the two, and emptying of the uterine contents, which is most commonly achieved by suction curettage either by using a traditional electric suction aspirator or via MVA.

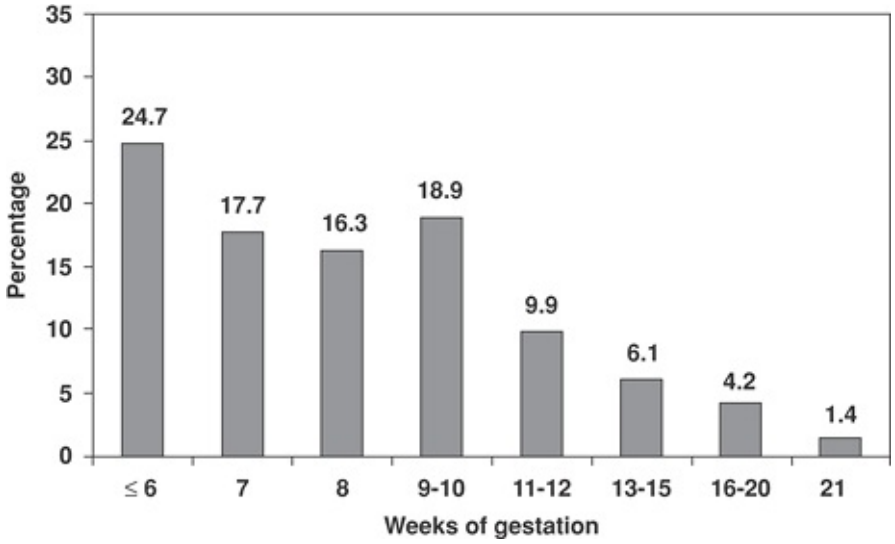

Figure 33.4 Abortions in the United States by gestational age. (From Strauss et al. MMWR, 2004).

Anesthesia for first-trimester procedures typically is achieved by using deep paracervical infiltration with lidocaine—6 cc at the 4 o'clock and 8 o'clock positions, respectively, in tandem with oral analgesics such as ibuprofen (400 to 800 mg) and an oral anxiolytic, usually a benzodiazepine such as lorazepam 1 to 2 mg. A support person to calm and help focus the patient during the procedure is another vital component to providing comfortable procedures under local anesthesia. Approximately 58% of women receive only local anesthesia for early surgical abortion. Many providers also offer the option of light to moderate intravenous sedation, typically employing a short-acting anxiolytic such as midazolam and a short-acting narcotic such as fentanyl. Preoperative nonsteroidal anti-inflammatory drugs (NSAIDs) are often employed as well. Satisfaction surveys reveal that patients are highly satisfied with either anesthesia option as long as they are given a choice. Providers who wish to offer conscious sedation must have appropriate perioperative monitoring equipment available, including pulse oximetry, a continuous supply of oxygen, reversing medications, and resuscitation equipment, as well as adequate staff to provide postoperative monitoring.

Cervical Dilation

Cervical dilation is one of the most important aspects of abortion care, as it confers safety to the procedure. Inadequate or forced dilation is the primary cause of surgical complications in the first trimester. Dilation can be achieved chemically with the use of cervical ripening agents such as misoprostol or mechanically by using rigid cervical dilators. A mixed approach is employed most often, particularly after 10 weeks gestation. Mechanical dilation is accomplished with progressive use of graduated cervical dilators to serially enlarge the cervical canal; tapered dilators such as the Pratt (Fig. 33.5) or Denniston (Fig. 33.6) are easiest to pass through the internal cervical os. After administration of local anesthetic, the provider should don sterile gloves; grasp the anterior lip of the cervix with a single-tooth tenaculum, ring forceps or similar stabilizing

instrument; and gently and progressively dilate the cervix to a diameter roughly equal to the gestational age in weeks (i.e., an 8-week pregnancy should be dilated to 8 mm, or 23 to 25 French. To decrease the risk of infection, particularly in a nonsterile environment, a "no-touch" technique is employed by which no part of an instrument that enters the uterine cavity is touched by the provider during the dilation process. This includes both mechanical dilator tips and the suction cannula. Use of a uterine sound to measure uterine size prior to dilation is discouraged, as uterine size can be estimated in other ways and the uterine sound is the most common instrument responsible for uterine perforation.

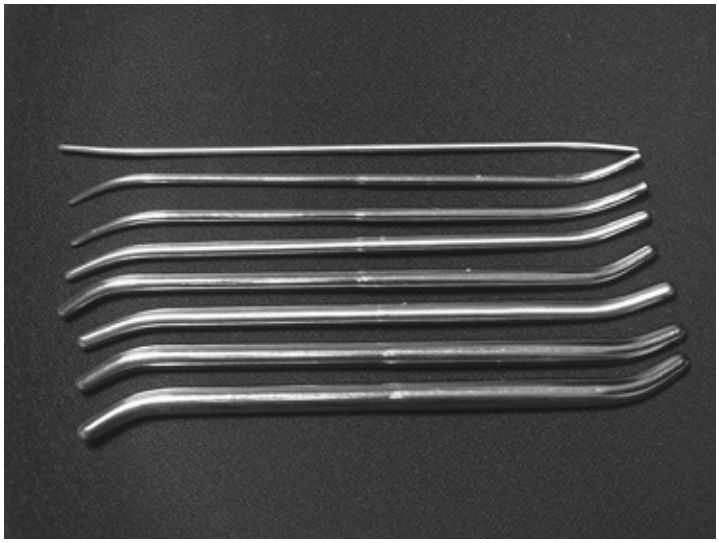

Figure 33.5 Pratt dilators. (From MedGyn website. Available at: *http://www.medgyn.com/picprattdilator.htm*.)

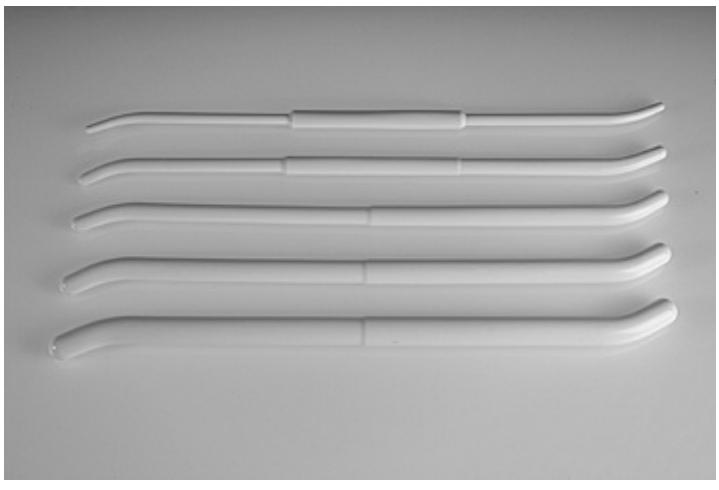

Figure 33.6 Denniston dilators. (From Ipas website. Available at: *http://www.ipas.org/products/Ipas_Denniston_Dilators.aspx*.)

Mechanical dilation should never be forced. If a dilator does not pass easily, allow the dilator that is one size smaller to remain in the cervix for a few minutes before advancing the next. Forcing mechanical dilation can lead to cervical fracture, uterine perforation, or creation of a false passage within the cervix. Ultrasound guidance can be employed in patients with a tortuous cervical canal or other anatomic abnormality. For nulliparous patients or those with cervical stenosis or higher gestational ages, preoperative misoprostol can be used from 20 minutes to 24 hours prior to the procedure. Patients can be given a low (200 to 400 mcg) dose orally the night before the procedure; alternately, 400 to 800 mcg of misoprostol can be administered vaginally 40- to 90-minutes preprocedure or 400 mcg buccally or sublingually 20 to 40 minutes prior. Some providers use premedication with misoprostol with all patients regardless of gestational age to aid with speed and comfort of dilation. Many patients at <8 weeks gestation may require no mechanical dilation at all following misoprostol administration. However, patients given a preoperative dose the night before their procedure should be aware that misoprostol causes uterine activity that could result in bleeding and possible expulsion of the pregnancy at home.

Suction Aspiration

Once the cervix has been adequately dilated, a suction cannula is advanced gently to the uterine fundus. Suction cannulas range in size from 5 to 16 mm (corresponding to their diameter in millimeters); the cannula should be roughly equal in diameter to the gestational age (i.e., an 8-week pregnancy is most easily evacuated with a no. 8 suction cannula). Suction can then be generated either with a mechanical suction aspirator or traditional electric suction aspirator. Both techniques are equally safe and efficacious; MVA confers the extra benefits of being portable, not requiring electricity, and eliminating the expense and noise of a traditional electric aspiration machine. Equal and high patient satisfaction has been documented for both techniques.

A mechanical vacuum aspirator consists of a 60-cc locking syringe with a single or double value system that generates approximately 60 to 70 mm Hg of pressure (equivalent to an electric suction aspirator). This handheld device, which may be disposable or reusable depending on the manufacturer, is attached to a flexible suction cannula. The cannula is introduced into the uterine cavity to the fundus by using a no-touch technique. Suction is then activated by release of the double-valve system (Fig. 33.7) or pulling back on the plunger, and the entire syringe unit is rotated, shearing the products of conception from the walls of the uterus and into the collection syringe. A gentle curetting motion also can be employed, with careful attention to not advancing the cannula past the posterior uterine wall or fundus. Complete emptying is detected by cessation of the flow of tissue into the syringe and the characteristic gritty texture palpated in all four quadrants of the uterine cavity. Loss of suction can occur due to a clogged cannula or a full syringe; the cannula may be removed and unblocked and the syringe emptied and reloaded. This procedure may be repeated until the uterus is completely evacuated. MVA is most often employed before 9 weeks gestation (as more advanced gestations require serial emptying and reloading of the syringe) but can be used for later gestations, including dilation and evacuation (D&E) up to 16 weeks gestation.

For gestations >8–9 weeks, many providers prefer electric suction aspiration, which has the advantage of providing continuous suction without reloading of the collection chamber and more commonly employs rigid suction cannulas (Fig. 33.8). Larger tubing and cannulas that are up to 16 mm in diameter also can be employed. Rigid suction cannulas may be straight or curved; a curved cannula will conform more anatomically with the position of the uterus and consequently may be easier to pass to the fundus. The technique for electric suction aspiration is

identical to MVA; signs of complete uterine evacuation include bubbles in the suction tubing and the characteristic gritty texture of the empty uterine cavity.

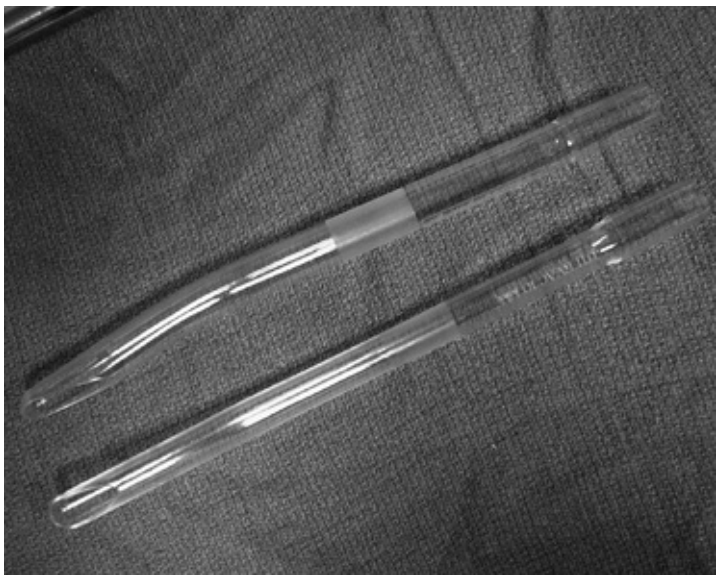

Figure 33.8 Rigid suction cannula.

Meticulous examination of the uterine aspirate is essential in confirming complete uterine emptying. The uterine aspirate can be washed with water or saline and examined with backlighting though a clear receptacle (such as a glass pie plate and a light box) (Fig. 33.9). Identification of the gestational sac in early pregnancy is essential in preventing an incomplete or failed procedure. At later gestational ages, all fetal parts should be identified. If there is any question regarding completeness of the procedure, transvaginal ultrasound can be performed to confirm and document complete uterine emptying (Fig. 33.10).

Pathologic examination of tissue is indicated for suspected abnormal pregnancies (i.e., hydatidiform mole), and cytogenetic examination can be employed in the cases of miscarriage or known or suspected genetic abnormality. Otherwise, pathologic confirmation is not mandatory, provided all products of conception are examined and villi identified. Blood loss should be minimal, at 15 to 30 cc. Aftercare should include perioperative antibiotic prophylaxis as detailed previously, NSAIDs for analgesia, and commencement of a contraceptive method before resuming sexual activity. Placement of an intrauterine device (IUD) immediately after first-trimester surgical termination is safe and convenient and has not been associated with an increased rate of expulsion. Cervical cultures should be obtained in all patients who are planning to receive a postabortal IUD.

Figure 33.9 Transillumination of villi floating in saline allows visualization for placental tissue confirmation after pregnancy termination.

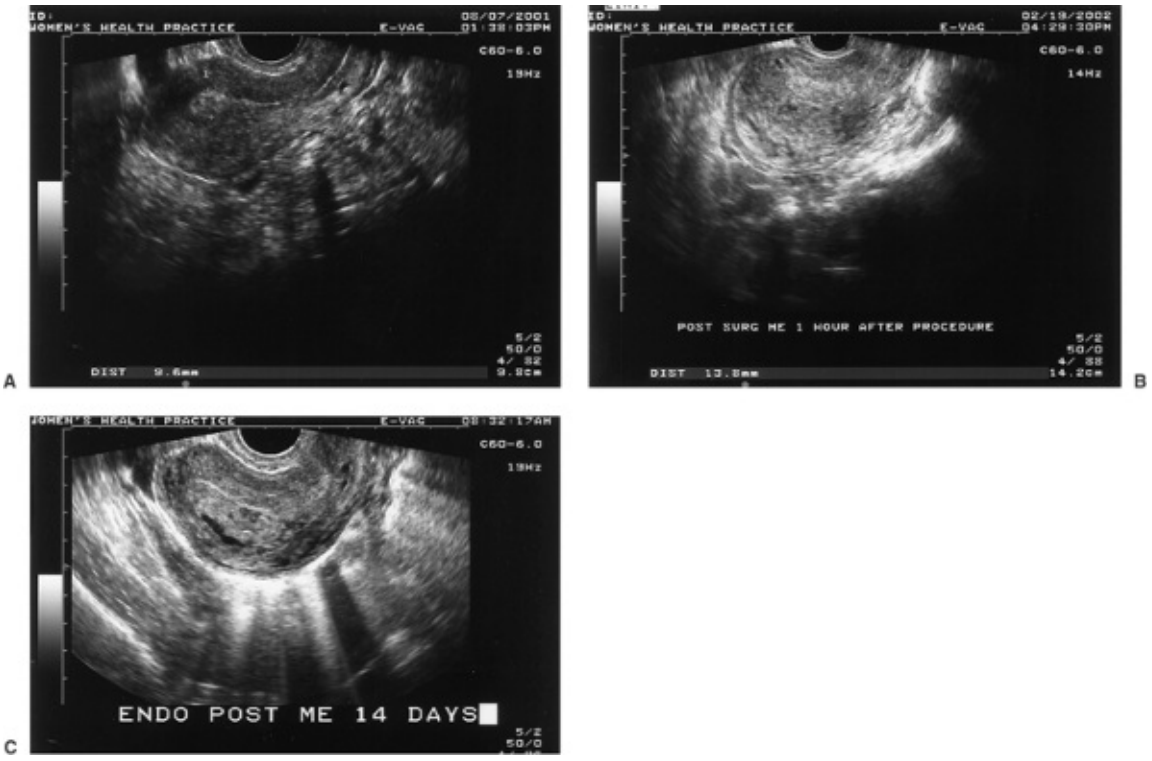

Figure 33.10 A: Longitudinal view of the uterine cavity within minutes after a surgical abortion showing the endometrial stripe and constricted endocervical canal. **B:** Transvaginal ultrasound image taken in a longitudinal view of an 11-week gestation 1 hour after uterine evacuation shows evidence of procedure completion, but the endometrial stripe is less prominent due to the natural accumulation of blood within the endometrial cavity. **C:** Two weeks after suction curettage, transvaginal endometrium shows 16 mm of endometrial tissue, likely to be decidua and a few chorionic villi consistent with the normal involution process, and warrants observation if clinically stable.

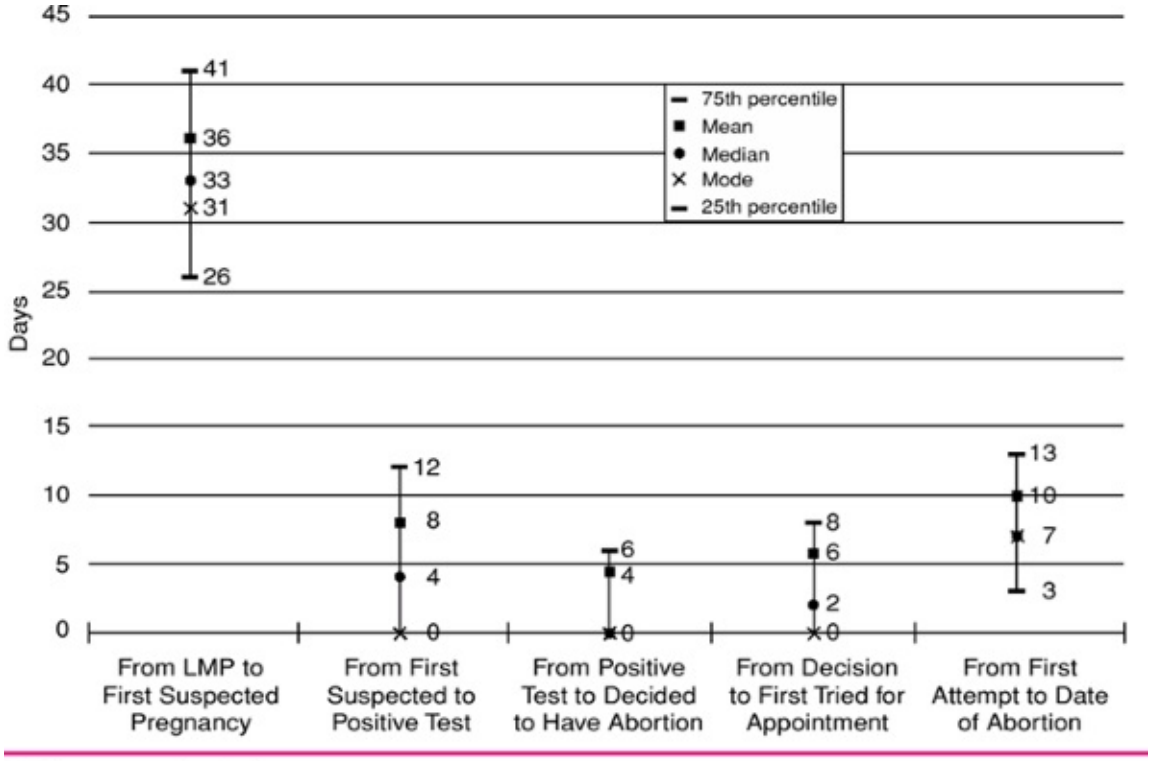
Second-trimester Abortion

Approximately 12% of abortions performed in the United States occur after 12 completed weeks gestation. More than 95% of these are performed surgically by D&E. More second-trimester abortion procedures are performed in the United States than in any other country worldwide, which likely is due to the higher abortion numbers in the United States overall, better record keeping, and the relative delay in accessing services in the United States in comparison to countries with socialized medicine where abortion care is widely available and provided under national health care policies (Table 33.2). Abortion after the first trimester is a riskier procedure than earlier procedures; while the major complication rate is still <1%, the overall risk of mortality is ten times that of suction D&C in the first trimester.



LMP, last menstrual period.

TABLE 33.2 Timing of steps in the Abortion Process: Median, 25th and 75th percentiles, Mean, and Mode, 2004

Dilation and Evacuation

D&E is the most common method of second-trimester abortion. Dilation in the second trimester is both more involved and extremely important, as the cervix must be dilated to a sufficient diameter to allow a larger fetus to be removed safely without trauma to the cervical canal or uterus while still maintaining adequate cervical patency to carry a future pregnancy to term. This is achieved with osmotic dilators and often augmented with pharmacologic

agents such as misoprostol. There are three types of osmotic dilators: *Laminaria japonica*, Dilapan, and Lamicel (Fig. 33.11), of which laminaria are the most frequently used. Made of dried compressed seaweed, laminaria range in size from 2 to 10 mm in diameter and are placed through the internal cervical os longitudinally. They swell to three to four times their dry weight in situ, reaching maximal diameter in approximately 6 hours. The radial force exerted on the cervical os, in tandem with the release of F-series prostaglandins, causes the cervix to dilate and soften slowly over time. Dilapan-S, a synthetic hygroscopic polyacrylamide rod, works similarly to laminaria, although it swells to a uniform diameter of 15 mm more quickly and with more radial force than laminaria. While greater dilation can be achieved with Dilapan in a shorter period of time, it does have a higher rate of

"dumb-belling" in the cervix, whereby the distal portion of the device swells wider than the intracervical portion, making it much more difficult to remove and increasing the risk of dilator incarceration. An earlier version of Dilapan, introduced in 1986, was prone to shattering or breaking into numerous shards during removal, necessitating a time-consuming hunt for all of the pieces and the risk of leaving dilator shards in situ. Consequently, the reformulated Dilapan-S released in the United States in 2002 was designed to avoid fracturing. These are most often used as an adjunct to the less expensive and more readily available laminaria; when both are placed in the cervix together, the laminaria can be removed first, allowing safer removal of the Dilapan-S device. The newer formulation has not been associated with breakage; product labeling limits its use to one device placed up to 4 hours prior to suction abortion in gestations <16 weeks. Conversely, Lamicel consists of a compressed polyvinyl alcohol sponge impregnated with magnesium sulfate. When inserted into the cervical canal, it stimulates collagenolytic activity in the cervix, causing softening and dilation. Because it works by chemical means alone, Lamicel has limited utility beyond 16 weeks gestation.

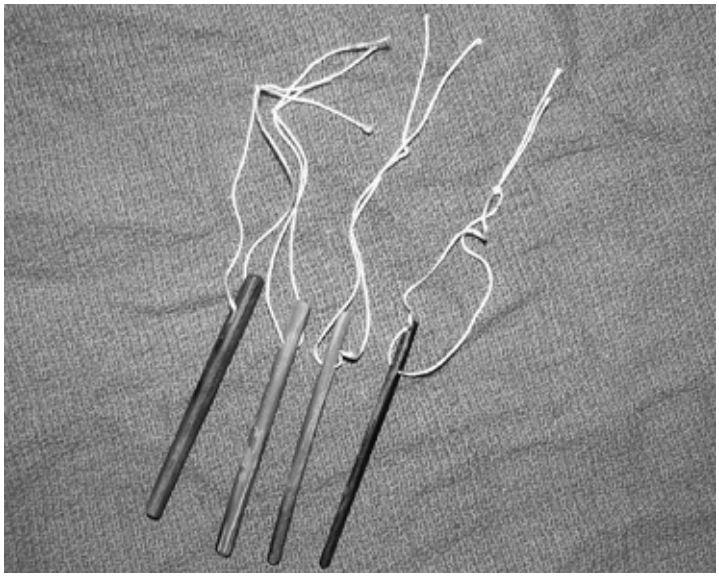

Figure 33.11 Dilapan-S dilators for second-trimester procedures.

Analgesia for second-trimester D&E can range from local anesthesia with a paracervical block and NSAIDs as described previously to general or regional anesthesia, depending on the setting and available personnel. While patients with adequate dilation and a support person tolerate D&E under local anesthesia well, many practitioners prefer a deeper level of sedation for later-term procedures. Schulz and colleagues demonstrated that adding 4 U of vasopressin to the paracervical block (4 U in 12 cc of 1% lidocaine) significantly reduced intraoperative blood loss after 15 weeks gestation.

Evacuation of the uterine contents is most often achieved by using heavy Sopher or Bierer forceps to grasp, disarticulate, and remove the products of conception through a cervical os dilated to sufficient diameter to admit and allow manipulation of the instruments (at least 1.0 to 1.5 cm). Blood loss with these procedures typically is in the 100- to 300-mL

range. The use of ultrasound during the procedure to ensure that the forceps are within the uterine cavity and afterward to verify complete removal of the products of conception, while not associated with fewer complications or a shorter procedure time, has been shown to increase physician comfort, especially in teaching situations (Fig. 33.12).

Intact Dilation and Extraction

In situations where cervical dilation is adequate (2 to 5 cm, depending on gestational age), it is possible to perform a D&E procedure where the majority of the fetus is removed relatively intact via a modified breech extraction technique, often with collapse of the fetal calvarium to

facilitate delivery. This procedure is referred to as *intact dilation and extraction* (D&X). Intact procedures often involve less instrumentation of the uterus, but their success is dependent on adequate cervical dilation, position of the fetus, and provider comfort; consequently, it is impossible to predict prior to assessing the patient at the beginning of the procedure, which can be done intact. Data comparing intact with nonintact procedures has shown no difference in major complication rates, blood loss, or future pregnancy outcomes. This procedure should *not* be confused with the term *partial-birth abortion*, which is a political term conceived in an effort to limit access to surgical abortion. It does not describe a recognized medical procedure but as written can be applied to many surgical abortion procedures occurring after 12 weeks gestation.

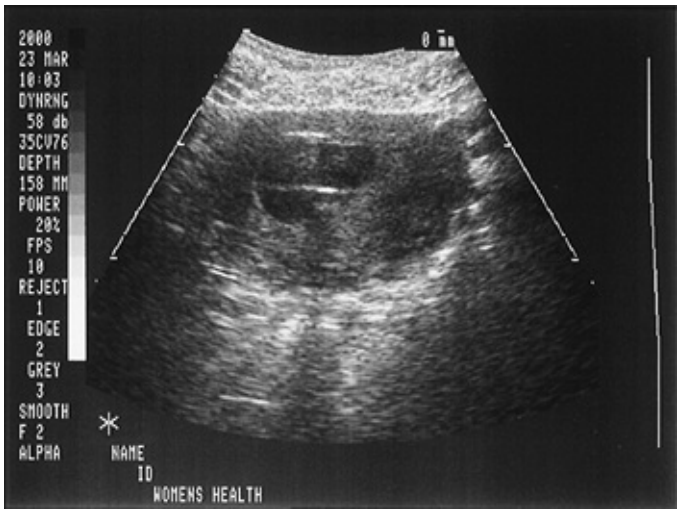

Figure 33.12 Abdominal ultrasound anteroposterior view of a 16-mm straight vacuum curette visualized in an intrauterine location during a D&E procedure for pregnancy termination.

Prostaglandin-Induced Abortions

Labor induction with prostaglandins is the preferred strategy for medical induction in the second trimester of pregnancy. Options include prostaglandin PGE_2, dinoprostone, 20-mg

suppositories, or 15-methyl-PGF_2, carboprost 250 g and tromethamine, for intramuscular injection. Misoprostol, a PGE1 analogue, is widely used. Protocols are 200–800 mg orally or intravaginally 4–12 hours apart. Isolated reports of fetal survival in cases of prostaglandin induction exist. To avoid delivery of a nonviable but living fetus, intracardiac injection of digoxin or potassium chloride can be given prior to induction. Induction techniques may offer some advantages for the postmortem evaluation of fetal anatomic abnormalities, but 97% of anomalies can be evaluated after D&E. Preoperative karyotyping through amniocentesis is the best assurance of accurate chromosomal evaluation, as this avoids more terminal cell contamination (i.e., the decidua) and the requirement for optimal handling of the tissue to maintain viability.

Postoperative Care

Antibiotic prophylaxis against infection reduces the incidence of postoperative salpingitis and endometritis, as cultures are not typically available preoperatively. A recent meta-analysis to determine the efficacy of antibiotics to prevent upper genital infection in women undergoing D&C found a protective effect in universal antibiotic prophylaxis, with routine use preventing up to 6,500 cases of postoperative salpingitis annually. Lichtenberg and colleagues found that a 3-day course of doxycycline, 100 mg twice daily, was effective in preventing postprocedure salpingitis. If the patient is allergic to doxycycline, metronidazole or ampicillin can be considered as alternatives. Postoperative pain management often requires little more than NSAIDs such as ibuprofen, even at later gestational ages. Patients with NSAID allergy or significant pain intolerance respond well to opioid analgesics such as hydrocodone and acetaminophen (Vicodin) or codeine. Routine use of uterotonic agents such as Methergine postoperatively in the absence of hemorrhage is not necessary, as blood loss postprocedure is minimal. Patients found to be Rh(D) negative prior to the procedure should receive Rho(D) immune globulin within 72 hours. For gestations <13 weeks, a dose of 50 mg is given. This amount is effective in preventing sensitization. For gestations >13 weeks, a full dose of 300 mg typically is recommended. Women undergoing a late-second-trimester procedure (>20 weeks) may experience breast engorgement following their procedure. A tight, well-fitting bra, ice packs, analgesics including ibuprofen or acetaminophen, and reassurance are most effective in managing this self-limited condition.

All patients undergoing an abortion, regardless of method, should have a contraceptive plan. All forms of hormonal contraception, including oral contraceptive pills/patches/rings, injectables (Depo-Provera, Depo-SubQ), and implantable contraception (Implanon, Jadelle) may be initiated immediately after a completed abortion procedure. Waiting for commencement of menstruation is unnecessary and puts the patient at risk for an immediate repeat pregnancy. An IUD (Copper-T) or intrauterine system (Mirena IUS) can be inserted immediately after a first- or second-trimester procedure, although the expulsion rate is slightly higher than if it is inserted after complete uterine involution. Expulsion rates for IUDs inserted immediately following first-trimester procedures are not significantly different from expulsion rates following delayed insertion, while expulsion rates following second-trimester postprocedure insertions are increased. However, multiple studies comparing immediate versus delayed insertion of an IUD after abortion show a loss

to follow-up rate among the delayed group as high as 42%.

Postoperative appointments, 1 to 3 weeks later, can ensure and confirm that the induced abortion has been completed, evaluate for complications, reassess psychologic status, and continue contraceptive and gynecologic care. However, compliance with follow-up visits is low due to a variety of factors, including the distance women often have to travel, the fact that most women feel well after their procedure, and that most do not receive gynecologic care from their abortion provider. Further, most serious abortion complications, including endometritis and uterine perforation, occur within the first week of the procedure, rendering a 2-week follow-up visit ineffective in detecting most complications. Consequently, a recent Cochrane review concluded that scheduling a follow-up visit for the express purpose of detecting complications is unnecessary, and abortion and contraceptive care can be safely rendered in a single visit. Some providers offer women the option of a follow-up visit to address any ongoing problems or questions.

Complications of Abortion

Abortion remains a very safe procedure when performed legally. The overall mortality from abortion in the United States began falling in the late 1960s as states began liberalizing their abortion laws and fell precipitously after legalization. The overall major complication rate for first-trimester abortions is 0.5%, which doubles to approximately 1.0% in the second trimester. Complications can include missed or failed abortion, incomplete abortion, hematometria, hemorrhage, infection, and uterine perforation. Approximate rates of each are listed in Table 33.3. The risk of complications increases with increasing parity and maternal and gestational age.

Failed surgical abortion is an uncommon complication, occurring most frequently when abortion is attempted before 6 weeks gestation. The National Abortion Federation (NAF) reports a rate of 0.5 in 1,000 cases over 10 years. Failed abortion can be best avoided by meticulously examining the uterine aspirate and with judicious use of transvaginal ultrasound postprocedure in very early gestations. Avoiding performing an abortion before an intrauterine sac is visible also is advised. In women with persistent symptoms of pregnancy and evidence of a continuing pregnancy, repeat evacuation most commonly is encouraged. Incomplete evacuation of the uterine contents is more common, occurring in 0.29% to 1.96% of first-trimester cases and 0.40% to 2.70% of second-trimester cases. Patients will present with crampy abdominopelvic pain and continued vaginal bleeding, most often within the first week of the abortion. Ultrasound examination will reveal a thickened, heterogeneous endometrial echo, which may represent retained products of conception or hematometra. These conditions often can be distinguished by patient presentation. In cases of hematometra, where a stenotic cervix traps blood in the uterine cavity postprocedure, the patient often will complain of more severe pelvic pain and very little, if any, vaginal bleeding. While a patient with hematometra may respond to a cervical softening agent such as misoprostol, which allows opening of the cervix with subsequent passage of old blood and immediate relief of symptoms, women with retained tissue in the uterus should undergo prompt repeat suction aspiration, as infection and

continued bleeding post a real risk.

TABLE 33.3 Rate of Abortion Complications in the First Trimester

Complication	Approximate Rate
Missed/failed abortion (ongoing pregnancy)	<0.3%
Incomplete abortion (tissue remains in the uterus)	0.3%–2.0%
Hematometria (retained blood in the uterine cavity)	<0.2%
Hemorrhage requiring transfusion	0.02%–0.30%
Infection	0.1%–2.0%
Uterine perforation	<0.4%

Hemorrhage is a rare complication of early abortion, becoming slightly more common at more advanced gestational ages, in multiparous women, and with the use of inhaled anesthetics such as nitrous oxide. Bleeding may be due to cervical injury, incomplete evacuation of the uterus, atony, perforation, placental abnormalities, or coagulopathy. Careful examination to ascertain the source of bleeding is indicated, with repeat aspiration of the uterus under ultrasound guidance recommended to ensure complete uterine emptying. Brisk, bright red bleeding from the cervix in the presence of good uterine tone and complete uterine evacuation suggests a cervical laceration, which should be identified and repaired. Uterine bleeding most often is caused by atony, which is more common after 10 weeks gestation. Intraoperative use of uterotonic agents, including oxytocin, ergots, vasopressin, and prostaglandins, can significantly reduce blood loss in late first- and second-trimester procedures. Atony is best treated with vigorous bimanual uterine massage, followed by low-dose intracervical vasopressin injection, intravenous oxytocin, intramuscular prostaglandins, and misoprostol, up to a gram of which can be administered rectally.

Uterine perforation is recognized at a rate of 0.09 to 2.8 in 1,000 cases and is more

common in teaching settings and higher gestational ages. Because the most commonly perforated area is the relatively avascular uterine fundus, many perforations go undetected, with subsequent resolution and no long-term consequences for the patient. Kaali and colleagues documented a suspected perforation rate of 2.8 in 1,000 cases in women undergoing pregnancy termination and concurrent laparoscopic tubal sterilization; the actual perforation rate was 15.6 in 1,000 at laparoscopy. Uterine perforation is suggested when instruments pass further into the uterine cavity than appropriate for the gestational age and is confirmed with the appearance of fat or bowel in the suction curette or at the cervical os. The uterus most commonly is perforated during dilation or uterine sounding. Perioperative ultrasound can help to identify a suspected perforation and monitor for blood accumulating in the cul-de-sac, and if the perforation occurred before suctioning, it can allow for ultrasound-guided evacuation of the uterus. For patients with a uterine perforation who are otherwise asymptomatic without evidence of intraperitoneal bleeding or visceral injury, observation in the outpatient setting is appropriate. Patients should be given oral antibiotics and explicit discharge instructions indicating when and whom they should call with fever, continuing pain, or orthostasis. For symptomatic patients or those with suspected visceral injury, laparoscopy is indicated with careful examination and repair of bowel or other intraperitoneal injuries.

Postabortal infection is rare when abortions are performed legally, with rates of 0.28% to 0.10% in the United States. Sawaya and associates documented a decrease of 42% in postabortal infections with the use of universal antibiotic prophylaxis at the time of first-trimester abortion. Signs and symptoms of postabortal infection, including fever, pelvic tenderness, and increased white blood cell (WBC) count, occur 48 to 96 hours postprocedure. Cervical cultures should be collected and patients treated with broad-spectrum antibiotics. Patients without evidence of sepsis or immune compromise can receive outpatient therapy; nonresponders, those too sick to tolerate oral medications, and patients with HIV disease or other immune problems are best treated with parenteral therapy. Any evidence of retained tissue should be treated with prompt aspiration.

Medication Abortion Overview

Medication abortions can benefit a woman seeking pregnancy termination by increasing her control over the process and may allow abortions to be more widely available in terms of the number of physicians who could provide this service in their offices. Both providers and patients can be shielded from the highly politicized abortion debate, allowing women to have an abortion without delay compared with waiting for a scheduled surgery. Medication abortion reduces the risk of cervical laceration and uterine perforation and eliminates any anesthetic risk. For many years, the options for medication abortion were limited. Currently, three abortifacients are used: antimetabolites (methotrexate), antiprogesterones (mifepristone), and prostaglandins (misoprostol). Methotrexate is a potent teratogen, and its use in the first trimester is associated with major congenital malformations. Mifepristone may be a teratogen, but its effects have not been well studied. Misoprostol has been reported to be a teratogen when used in the first trimester. The mechanism of misoprostol action may be due to alteration of transplacental

oxygenation or possibly a direct effect of the drug.

Methotrexate

Methotrexate is an antimetabolite that blocks dihydrofolate reductase, an enzyme essential for the production of the DNA nucleotide thymidine during DNA assembly. As rapidly dividing cells are most affected, it causes trophoblastic cell death. Methotrexate has been used clinically for the treatment of gestational trophoblastic disease (i.e., molar gestation, ectopic pregnancy, and early medication abortion). Although methotrexate is not Food and Drug Administration (FDA) approved for early medication abortion, the protocols for abortion have been extensively studied. Toxicity is dose dependent, and in the dosages given for these regimens, blood levels of methotrexate are undetectable 2 days after administration. At the low doses used in regimens for ectopic pregnancy, side effects of methotrexate are primarily gastrointestinal, with nausea, vomiting, and diarrhea, although there have been isolated reports of marrow suppression (leukopenia) and alopecia (Table 33.4). At high doses, methotrexate can cause renal toxicity or damage to the gastrointestinal lining. Methotrexate in the 50- to 150-mg range should not induce ovarian toxicity and has no known long-term toxicity with regard to reproductive function. The protocols with methotrexate are more complex than those for surgical abortions, requiring more evaluation and more provider visits (Table 33.5, Fig. 33.13). Failure rates are marginally higher than with mifepristone/misoprostol protocols.

Mifepristone and Misoprostol

On September 28, 2000, the FDA approved mifepristone, a progesterone receptor antagonist, for use in medication abortion. Mifepristone acts by opposing the progestational affects of endogenous progesterone, thus inhibiting further growth of the embryo. The addition of misoprostol, a synthetic prostaglandin E_1 analogue, augments the effect of mifepristone by causing the uterus to contract. The regimen approved by the FDA begins with the oral administration of mifepristone and is followed by the oral administration of misoprostol. The misoprostol is administered in the health care provider's office and is approved for gestations up to 49 days. This method results in a 92% to 97% completed abortion rate. Yet, as medication abortion has become more widely practiced, alternatives to the FDA-approved regimen have become more widely available. These evidenced-based regimens use the same two agents, but by altering timing, dose, location of procedure, and route of administration, they enable greater flexibility compared with the FDA regimen.

Mifepristone

Progesterone plays a key role in the initiation and maintenance of pregnancy. By inhibiting gap junctions, cells are decoupled and the myometrium remains in a relaxed state. Mifepristone binds to the progesterone receptor with an affinity that is five times that of progesterone. Binding of antiprogestins results in progesterone inhibition and causes the uterus to contract in a coordinated fashion. In addition, the trophoblast separates from the decidua, local prostaglandins release, and the cervix ripens. However, mifepristone alone

results in an inadequate pregnancy termination rate (64% to 85%) up to 49 days.

Misoprostol

Bygdeman and Swahn showed that the addition of a prostaglandin 36 to 48 hours after mifepristone improves the abortion success rate above that of mifepristone alone.

Misoprostol, a prostaglandin analogue, is the agent of choice in the United States and offers many advantages, as it is orally stable, can be stored at room temperature, and is inexpensive. Further, routes of administration for misoprostol include oral, vaginal, buccal, and sublingual. Misoprostol is a powerful teratogen in the first trimester. The most common anomaly reported is a frontal facial set of lesions, termed *Möbius syndrome*, but over two dozen healthy pregnancies have been reported after failed medication abortion regimens.

TABLE 33.4 Medications used in pregnancy terr

	Mechanism of Action	Side Effects	Contraindicatic
Prostaglandins Misoprostol 400–800 µg p.o. or p.v.	Interact with myometrial cell receptors, causing strong myometrial cell contractions leading to expulsion of embryonic or fetal tissue. Also causes	Diarrhea Vomiting Nausea Cramping Bleeding	Glaucoma, sick cell anemia, hypotension, mitral stenosis, pregnancy not intended for termination, hypersensitivit misoprostol

	cervical softening and dilation.			
Antiprogesterones Mitepristone (RU-486) 200–600 mg p.o.	Five times greater affinity for progesterone receptors. Binds to progesterone receptors and blocks progesterone from binding, thus inhibiting its action and leading to increased uterine contractility. Also softens and dilates cervix.	Abdominal pain Uterine cramping Nausea Vomiting Diarrhea	Severe anemia, adrenal disease chronic corticosteroid administration, severe kidney disease, severe liver disease, severe pulmona disease, cardiovascular disease, inheri porphyuria, clotting disorde anticoagulant therapy, ectopi pregnancy, undiagnosed adnexal mass, in place, hypersensitvity mifepristone	
Antimetabolites Methotrexate 50 mg/m^2 i.m. 25–	Blocks dihydrofotate reductase, thus inhibiting folate production and DNA synthesis.	Nausea Vomiting Diarrhea Hot flushes	Severe anemia, inflammatory bowel disease, clotting disorde acute liver or kidney disease, alcoholism, immunodeficie

Medication Abortion Regimens

Guidelines govern the provision of medication abortion. A physician with the ability to assess gestational age and diagnose ectopic pregnancy must provide or supervise the provision of medication abortion. Similarly, arrangements for the follow-up of incomplete abortion must be in place. In addition, practitioners of medication abortion must complete a prescriber's agreement prior to receiving mifepristone that details guidelines and responsibilities in prescribing mifepristone, including counseling the patient thoroughly, providing the medication guide, and having her sign a patient agreement. Patients must be aware of the need to undergo a surgical abortion in the case of failure. In the United States, mifepristone is licensed to Danco Laboratories. Contraindications to medication abortion with mifepristone and misoprostol appear in Table 33.6.

Standard Food and Drug Administration Regimen

According the regimen approved by the FDA for gestations up to 49 days, medication abortion is completed over 3 days. On day 1, the woman takes mifepristone, 600 mg orally. Rh(D) immune globulin should be administered prior to misoprostol, if indicated. A small percentage of women, 2% to 5%, will abort following mifepristone alone. A 50-mcg dose is adequate. On day 3, the woman returns to the provider's office. Unless abortion has already occurred, she receives 400 mcg of misoprostol orally. On day 14, the patient returns for follow-up. If there is a suspicion of an ongoing pregnancy, an ultrasound is obtained. If there is cardiac activity, surgical abortion is recommended (Fig. 33.14).

The efficacy of this regimen has been studied in clinical trials by Peyron, Aubény, and Spitz. These trials demonstrated an efficacy of up to 95% for gestations at <49 days. These studies, using 600 mg of mifepristone, showed that the majority of women abort within the first 24 hours following misoprostol administration (approximately 50% within 4 to 5 hours and 80% at <24 hours). These studies also showed that medication abortion with the standard regimen is less effective as gestational age increases.

Evidence-Based Regimens

Following the clinical trials of Peyron, Aubény, and Spitz, investigators began to examine ways of improving medication abortion with mifepristone and misoprostol. Trials have examined lowering the dose of mifepristone, increasing the dose of misoprostol, alternative routes of administration of misoprostol, raising the gestational age for medication abortion, at-home administration of misoprostol, alternate timing for the dosing of misoprostol, and medication abortion without ultrasound.

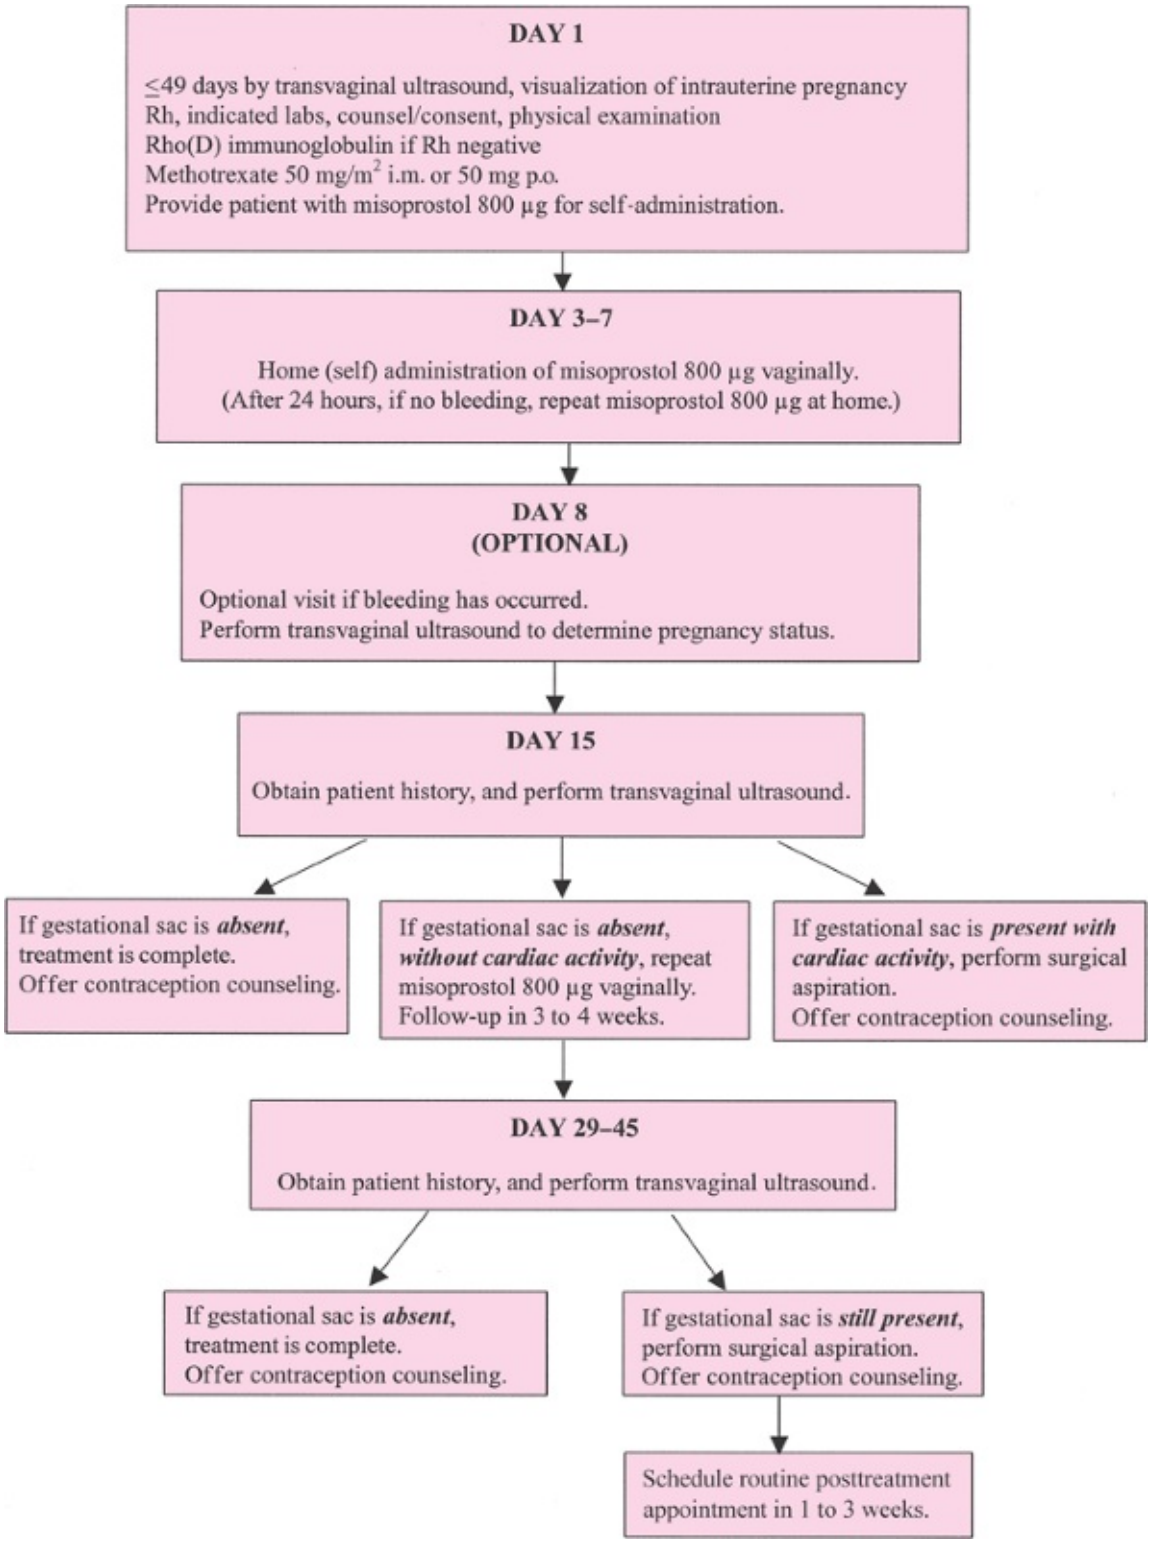

Figure 33.13 Nonsurgical methotrexate/misoprostol abortion.

TABLE 33.6 Complications of Abortion and Complication Rates

	Surgical	Medical

Complication:	Regimens (%):	Regimens (%):
Immediate postabortion		
Failure to dilate cervix	0.1	NA
Perforation	0.09–0.50	NA
Acute hematometria	0.1–1.0	NK
Anesthetic reaction, mild/severe	0.2	NA
Hemorrhage (>500 mL)	0.05–4.90	<1.0
Pain (moderate to severe)	0.5–5.0	10–30
Allergic reaction to medications	0.00–0.05	NK
Delayed		
Retained products of conception	0.5–1.0	4.0–7.0
Endometritis/salpingitis/infection	0.1–4.7	0.09–0.50
Transient fever	2.0	NK
Persistent positive hCG (>3 wk)	0.5–5.0	4.0–7.0
Continuing pregnancy	0.05	4.0–7.0[c]
Postabortion molar gestation	0.01–0.05	<1.0
Long term		
Cervical injury	0.1–1.6	NA

Asherman syndrome, complete/partial	0.1–2.3	NK
Infertility	1.0–2.0	NK
Chronic pelvic inflammatory disease	1.0–2.0	NK
Psychologic sequelae	0.5–1.0	NK

NA, not applicable: hCG, human chronic gonadotropin; NK, not yet known.

[a]Rates of serious complications <1/100.

[b]Estimates based on cumulative data in medical literature for a variety of gestational ages and procedures.

[c]Needs surgical abortion.

These studies have led to increased convenience, efficacy at greater gestational ages, flexibility, decreased cost as less misoprostol is used, and greater privacy with home use of misoprostol. These additional trials established that 200 mg of mifepristone works as well as 600 mg of mifepristone. As mifepristone binds to alpha-I-acid glycoprotein in serum, the relatively low levels of this molecule are easily saturated at lower oral doses of mifepristone. This change in mifepristone dose lowers the cost of the medication abortion substantially and is associated with fewer side effects. Using 800 mcg vaginally, misoprostol increases the efficacy of medication abortion. An elegant pharmacokinetic study demonstrated that the area under the curve was much greater for vaginal administration, with a slower rate of onset and a sustained effect. This change in dose and route of administration led to increased efficacy and fewer gastrointestinal side effects. The efficacy of medication abortion up to 63 weeks improved over oral

administration of misoprostol (95% vs. 87%), and 93% of women aborted within 4 hours of misoprostol administration. The findings of increased efficacy and safety have been supported in many subsequent clinical trials. Further studies by Schaff and others demonstrated the efficacy and acceptability of home administration of misoprostol in which women self-insert misoprostol tablets one at a time high into the vagina while lying in the supine position. Additional studies have shown that the timing of misoprostol can be varied quite significantly with initial studies by Schaff and colleagues, demonstrating the efficacy of 800 mcg misoprostol administered at 24, 36, and 48 hours after the 200 mg dose of mifepristone with follow-up at 4 to 8 days after mifepristone. The FDA regimen as well as commonly used evidence-based regimens are summarized in Table 33.7. More recent studies by Creinin and associates have shown the efficacy of decreasing the time interval

between mifepristone and misoprostol to <24 hours. Finally, while ultrasound has been used throughout clinical trials and is routinely used in the United States for medication abortion, it should be noted that it is neither mandatory nor routinely used in other countries (Fig. 33.13).

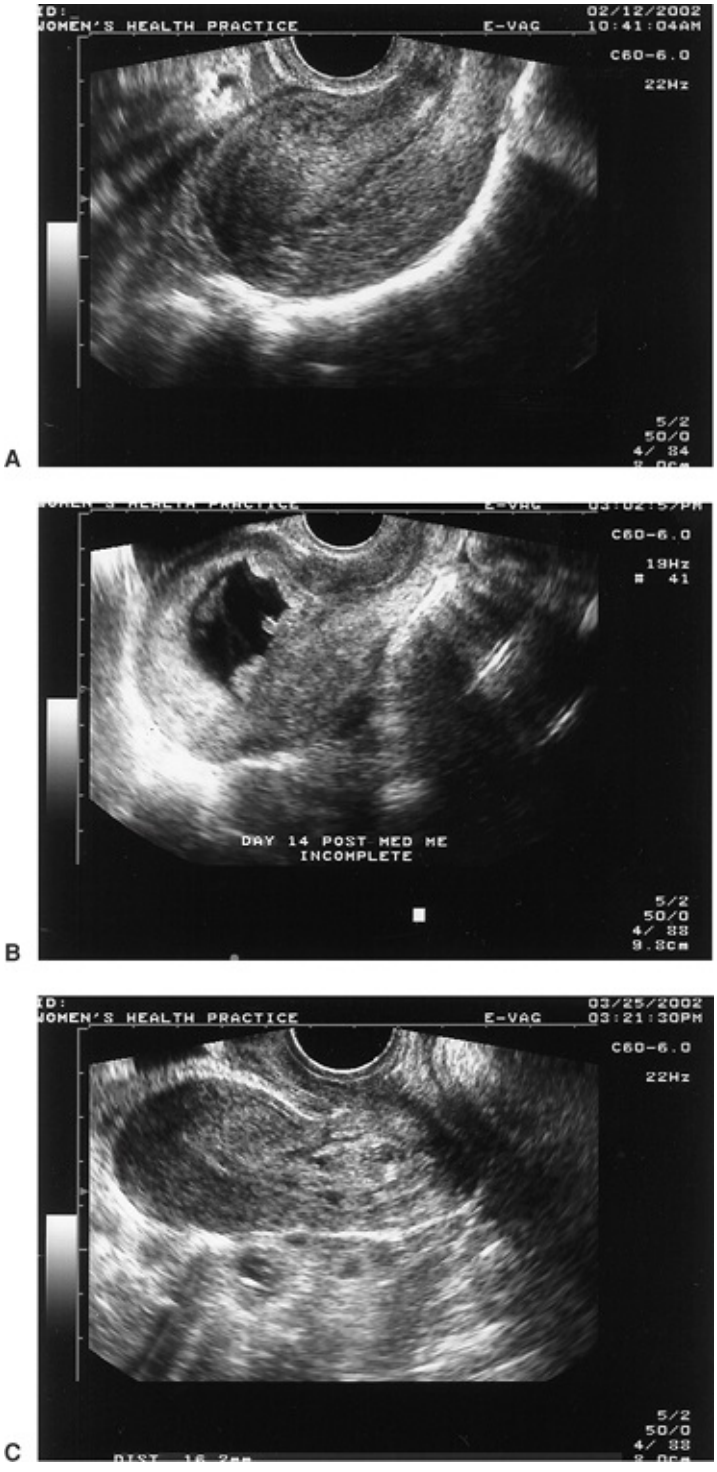

Figure 33.14 A: Transvaginal ultrasound of a 42-day pregnancy 4 hours after misoprostol ingestion. Heavy bleeding and passage of tissue indicated that the pregnancy termination had probably completed; the ultrasound confirms the absence of a gestational sac and that the medication abortion was effective. **B:** Day 14 after a medication abortion of a 47-day pregnancy. Transvaginal ultrasound shows retention of gestational sac, although no fetal development or fetal cardiac activity is seen. This is

consistent with an incomplete medication abortion. Follow-up or surgical termination are options if the patient is medically stable at this point. **C:** Three-and-a-half weeks after medication abortion of a 35-day pregnancy. Transvaginal ultrasound shows a sac in the endocervix, not in the uterine cavity. Abortion is not yet complete.

Side Effects

The most common side effects of medication abortion are vaginal bleeding, nausea, and cramping. The bleeding can begin with the administration of mifepristone, and women should have sanitary supplies available after initiation of the regimen. The majority of bleeding occurs within 1 to 2 hours of misoprostol administration, peaking with expulsion of pregnancy and waning after that time. Light bleeding can continue for up to 2 weeks. Bleeding at the time of expulsion can be heavy, and blood clots might be visible. Mifepristone and misoprostol can cause nausea, vomiting, and diarrhea, with nausea occurring most commonly. Some women also will experience an increase in temperature, which can be associated with a fever or chills. In general, a low-grade fever is not of clinical importance. The pain of medication abortion is similar to that of early spontaneous abortion, and most women do well with non-steroidal inflammatory agents alone, although many practitioners provide narcotics as well.

TABLE 33.7 Differences between Food and Drug Administration-approved and Evidence-based Regimens[a]

	FDA-approved Regimen	Evidence-based Alternatives
Mifepristone dosage	600 mg (three 200-mg tablets)	200 mg (one 200-mg tablet)
Misoprostol dosage	400 μg p.o.	800 μg p.v./s.l.
Where misprostol taken	At doctor's office or clinic	At home
When misoprostol taken	Day 3	Day 1–4

Timing of initial follow up examination	Approximately day 14	From day 4–14
Gestational limit	49 days LMP	Up to 63 days LMP Only in studies using 800-μg VAGINAL misoprostol

FDA, Food and Drug Administration; LMP, last menstrual period.

[a]Both regimens have an efficacy rate of 95%–98%

Counseling for Medication Abortion

Counseling is the cornerstone of medication abortion, as most of the procedure occurs at home outside of the practitioner's gaze. Distinct features of counseling for medication abortion include a discussion of its efficacy, timing of medication administration, and the at-home procedures as listed previously. Patients must fully understand the FDA-approved regimen and variations used based on medical evidence. The patient must understand the side effects of medication abortion. In addition, the woman will need to be prepared for a potential emergency, particularly heavy bleeding. A common message is that a woman should call and/or be seen if she experiences bleeding such that she soaks two maxi pads per hour consecutively for 2 hours. Other commonly used indications for contacting the medical facility are severe pain and prolonged fever for more than 6 hours. Women should be provided with written instructions and contact numbers for 24-hour access to a clinician and should be encouraged to call with questions or concerns.

Complications of Medication Abortion

Complications of medication abortion are rare and experienced by <0.5% of women. Thus, women can be assured of both its safety and efficacy. Incomplete abortion occurs in <3% of women who are undergoing abortion at <49 days gestation. A failed abortion is defined as the presence of a gestational sac following medication abortion. Ongoing cardiac activity should be managed by surgical abortion. A persistent gestational sac can be managed by the administration of additional misoprostol or by suction curettage. This definition is specific, and thus, blood in the uterine cavity is not a sign of a failure. Indeed, a close interval of follow-up after medication abortion increases the likelihood of seeing a thickened endometrial stripe. Endometritis following medication

abortion occurs rarely (0.09% to 0.05%) and is one of the advantages of medication abortion. On July 19, 2004, the FDA issued a report of four deaths following mifepristone/misoprostol medication abortion. These deaths were due to sepsis, all involved the same bacterial agent *Clostridium sordellii*, and all occurred among women in the same region of the country. The FDA did not establish causality in these cases, and no batches of mifepristone were found to be contaminated. Since the initial report, an additional death is under investigation. Women opting for medication abortion should be aware of this information as well as the FDA guidelines for use of mifepristone and should be informed of the risks and benefits of medication abortion along with the signs and symptoms of infection.

Summary Points

- An estimated 1.2 to 1.6 million elective abortions have occurred in the United States in each of the past 10 years, making this a very common procedure and choice for women with unwanted pregnancies.
- Extensive research indicates that induced abortions continue to be requested by women regardless of religious conviction or socioeconomic status.
- The most common surgical approach in the first trimester is suction curettage. In the second trimester, D&E is the most common approach.
- Medication abortion is performed by initial administration of mifepristone followed by misoprostol. A non–FDA-approved alternative is the use of methotrexate.
- The complications of induced abortion are relatively few, and the death rates remain <1 woman per 100,000, comparing favorably to maternal mortality.
- It is important for health care providers to understand the process of induced abortion and to recognize and be able to counsel women regarding the potential risks, benefits, and complications of both surgical and medication abortion procedures to keep these procedures safe and widely available.

Pelvic and Sexually Transmitted Infections

David A. Eschenbach

Recent reports using DNA technology rather than traditional culture methods identify a vast array of previously unrecognized bacterial microbes in the genital tract. The role of these previously unrecognized microbes relative to well-recognized microbes needs further determination for pelvic infections. Many pelvic infections are sexually transmitted (Table 34.1). This chapter provides new data on and updated treatment of pelvic infections.

The impact of infections on women ranges from minor vaginal annoyance to serious illness and, rarely, even death. However, women bear a vast increase in serious consequences of genital infections relative to men. Further, the cost to treat pelvic infections is enormous from both direct medical costs and indirect costs, including time lost from work. Using pelvic inflammatory disease (PID) as an example, previous estimates were that by now, one of every four women who reached reproductive age in the 1970s had an episode of PID. Of women with PID, 25% will be hospitalized, 25% will have major surgery, and 15% will have tubal sterility.

Upper genital tract sites (endometrium, fallopian tubes, ovaries) formerly considered sterile are subject to ascending microbial traffic and occasionally to infection from lower genital tract microbes. Some microbes preferentially infect certain sites and give rise to characteristic symptoms, while other microbes cause few symptoms until major pathologic changes occur or until congenital neonatal infection or male-partner infection ensues. Clinicians should have special knowledge of the infections caused by *Neisseria gonorrhoeae*; *Chlamydia trachomatis*; group A and B streptococci; *Treponema pallidum*; anaerobic bacteria, particularly Clostridia; bacteria associated with bacterial vaginosis (BV); and *Mycobacterium tuberculosis*, because these infections either are common or produce potentially severe sequelae. Most viral infections of the genital tract are asymptomatic. Several viruses are common and produce severe disease in both adults and neonates, including herpesvirus, cytomegalovirus, hepatitis B virus, human papillomavirus, and HIV.

Vulva

Herpes

Type-specific serologic assays indicate that about 20% of women 14 to 49 years of age are exposed to herpes simplex virus type 2 (HSV-2) and almost 60% to herpes simplex virus type 1 (HSV-1). About 60% of women who acquire HSV-2 are asymptomatic, a rate that increases further among those with prior HSV-1 antibody. Despite the frequency of asymptomatic infection, HSV remains a common cause of vulvar ulcers. Infectious genital ulcers also are caused by syphilis and chancroid. HSV ulcers usually occur 2 to 12 days (mean 4) after exposure. Symptomatic primary (first) genital infections typically consist of multiple bilateral vesicles that rapidly ulcerate and can be exceedingly painful. The cervix and vagina also may be involved, producing a gray, necrotic cervix and profuse leukorrhea. External dysuria is common, and bilateral inguinal lymphadenopathy is usual. Vulvar lesions may last up to 3 weeks before healing. Constitutional symptoms of fever, malaise, headache (i.e., aseptic meningitis), and urinary retention (i.e., myelitis) can persist for a week.

After primary infection, HSV becomes latent and localizes in the sacral ganglion and perhaps the dermis. Up to 90% of patients have a recurrence. Additionally, 50% of women have asymptomatic viral shedding, which

---

occurs on about 3% of days with no symptoms or physical evidence of infection. Most patients develop a secondary symptomatic (recurrent) infection from latent virus weeks to months after the primary infection. Symptomatic recurrence rates increase among women with a severe primary infection. About 50% of patients with recurrence have prodromal symptoms. Secondary lesions usually are less painful, localized, unilateral, and last for a shorter time (3 to 10 days) than primary infection. Systemic manifestations are unusual with secondary infection.

TABLE 34.1 Sexually Transmitted Infections

Microorganisms	Diseases
Bacteria	
Neisseria gonorrhoeae	Gonorrhea
Chlamydia trachomatis	Chlamydia
Treponema pallidum	Syphilis
Haemophilus ducreyi	Chancroid

Klebsiella granulomatis	Granuloma inguinale
Gardnerella vaginalis, anaerobes	Vaginitis
Group B β-hemolytic streptococcus	Group B streptococcal infection
Mycoplasmas	
Mycoplasma hominis	Mycoplasmosis
Ureaplasma urealyticum	Mycoplasmosis
Mycoplasma genitalium	Cervicitis, endometritis
Viruses	
Herpes simplex virus	Genital herpes
Cytomegalovirus	Cytomegalovirus infection
Hepatitis B virus	Hepatitis B
Human papillomavirus	Condylomata acuminata
Molluscum contagiosum virus	Molluscum contagiosum
HIV	AIDS
Protozoa	
Trichomonas vaginalis	Vaginitis
Entamoeba histolytica	Proctitis
Fungi	

Candida albicans	Vaginitis
Parasites	
Sarcoptes scabiei	Scabies
Phthirus pubis	Pediculosis pubis

From 75% to 85% of genital herpes infections are caused by HSV-2, with the remainder caused by HSV-1, the primary cause of oral herpes. The two types of herpes infections are clinically indistinguishable except that genital recurrence is less common following HSV-1. Vesicles and ulcers contain many highly infectious virus particles, and viral shedding occurs until lesions disappear. Thus, direct contact with either genital or oral HSV lesions causes a high rate of infection. Transmission usually occurs by direct contact with ulcerative lesions. Transmission is greatest during a primary infection, intermediate during a secondary infection, and probably least with asymptomatic shedding.

The diagnosis of herpes can be made clinically by finding typical, painful, shallow multiple vulvar ulcers. However, most HSV lesions are atypical. Laboratory confirmation of atypical lesions and lesions that appear during pregnancy is best attained by polymerase chain reaction (PCR) identification or viral culture (which is less sensitive than PCR). Other direct HSV identification methods, including Pap smear, fluorescein tagging, and immunoperoxidase staining, are too insensitive to exclude HSV infection. Type-specific serology uses glucoproteins; gG2 distinguishes HSV-2 from gG1, which signals HSV-1 antibody. Antibodies develop within 3 weeks of HSV infection. However, even high antibody levels do not protect against recurrent HSV infection or the acquisition of HSV, although antibody passively transferred to the fetus offers considerable protection against invasive neonatal infection.

The rising incidence of herpes infection and potentially serious fetal infections makes HSV an important infection in pregnancy. New guidelines for herpes are discussed in Chapter 19.

The following therapies shorten the ulcerative phase of primary infection when used for 7 to 10 days: oral acyclovir (Zovirax), 400 mg three times daily or 200 mg five times daily; famciclovir (Famvir), 250 mg three times daily; or valacyclovir (Valtrex), 1 g twice daily. Antiviral therapy does not eradicate HSV or prevent recurrence. Patients with episodic recurrent herpes should be provided with a supply of drugs to take for 5 days beginning with prodromal symptoms or within a day of the lesion appearance. Patients with six or more yearly recurrences have a 70% reduction in recurrence with the following suppressive therapy when used for up to 1 year: acyclovir, 400 mg twice daily; famciclovir, 250 mg twice daily; valacyclovir, 500 mg daily; or valacyclovir, 1 g daily. The drug expense limits routine or prolonged use. Wet-to-dry therapy for skin lesions is helpful (i.e., 10-minute sitz bath three or four times daily followed by drying with hair dryer), but corticosteroids and

antimicrobial ointments actually delay healing. Sexual partners of patients with genital HSV benefit from counseling to prevent contraction of HSV.

Human Papillomavirus

Genital human papillomaviruses (HPVs) are DNA viruses that are distinct from papovaviruses that cause the common wart. Up to 40% of patients have HPV infection that most commonly is subclinical. HPV 6 and 11 cause about 80% of genital warts. Only 1% of HPV-infected women develop visible warts, and only 9% have a history of genital warts. The average incubation period for visible warts is 3 months. Genital warts most often occur on the labia and posterior fourchette (Fig. 34.1). They originally appear as individual lesions, although large confluent growths can occur if neglected. Vaginal and cervical warts are even more common than labial warts; most cervical warts are flat lesions that are visible only by colposcopy. The flat-wart variant is caused by HPV types 16, 18, 31, 33, and 35 (found in 22% of college women tested). A biopsy of flat or atypical-appearing cervical warts is required to exclude cervical

neoplasia. Biopsies of warts also should be performed for pigmented, unresponsive, or fixed lesions or in immunocompromised patients. HPV types 16, 18, 31, 33, 35, and 45 are associated with high-grade cervical dysplasia and cervical cancer, where HPV DNA is integrated into the cancer cell. Women with flat warts should have frequent Pap smears. Routine typing of HPV with the Digene Hybrid Capture II can aid management of women with low-grade or atypical Pap smear interpretations; women with high-risk HPV DNA need referral for colposcopy and possible cervical biopsy, while those with low-risk HPV DNA can receive routine Pap smear testing.

Figure 34.1 Condylomata acuminata of the vulva.

Vulvar warts must be differentiated from the less verrucous, flatter growths of syphilitic

condyloma latum (Fig. 34.2) and from carcinoma in situ of the vulva; dark field examination or punch biopsies may be required to differentiate these lesions. Treatment should be guided by available medication, as no regimen is superior to others. Small- to medium-sized verrucous warts usually can be treated with patient-applied podofilox (Condylox), imiquimod (Aldara), or by providers (cryotherapy, podophyllin, or trichloroacetic or bichloroacetic acid). Intralesional interferon and laser surgery represent expensive alternative regimens. Small amounts of podophyllin (0.25 mL) should be used to avoid severe burns. Podophyllin, imiquimod, and podofilox are contraindicated during pregnancy. Large amounts of podophyllin have produced coma in adults and fetal death in pregnancy. A biopsy should be done on atypical lesions before therapy is initiated, because podophyllin causes bizarre histologic changes that persist for months. Vaginal wart treatment or wart treatment in pregnancy is limited to cryotherapy, trichloroacetic acid, or laser ablation. Recurrence rates of 50% probably relate to a failure of these methods to kill the virus in adjacent untreated areas. Severe burns have occurred from the use of 5-fluorouracil (5-FU) to treat warts; as a result, its use is not recommended. Large warts may not respond to surgical or laser removal alone but also may require pretreatment with regional interferon to begin an immune response against HPV. Examination of sexual partners is unnecessary, because most partners already have HPV.

Figure 34.2 Condylomata lata of the vulva and perineum. (From Curtis AH, Huffman JW. *A textbook of gynecology*, 6th ed. Philadelphia: WB Saunders, 1950, with permission.)

A quadrivalent HPV vaccine 6/11/16/18 viruslike particle that does not contain live virus

(Gardasil) has a per protocol efficacy rate of 94% against cervical intraepithelial neoplasia (CIN) or adenocarcinoma in situ formation and a per protocol efficacy rate of 95% against external genital wart formation. The per-protocol efficacy rate is the efficacy among ideal candidates (i.e., no prior exposure to these viral types, completed regimen on schedule) and measures protection against disease caused by the types in the vaccine. The vaccine has an excellent safety profile, and it is recommended for the immunization of girls and women 9 to 26 of age in doses at 0, 2, and 6 months. The duration of immunity is unknown. Cervical screening is still needed for those vaccinated because of unrecognized HPV before vaccination and for high-risk HPV genotypes (31, 45) not in the vaccine.

Vestibulitis

Patients with vestibulitis characteristically have pain with vaginal penetration (i.e., intercourse or tampon insertion) and, in extreme cases, pain with sitting or wearing tight clothing. This condition is frequently mistreated as vaginitis because acidic vaginal discharge increases introital

---

irritation. Patients typically have an erythematous area, most commonly at the 4 o'clock and 8 o'clock positions just outside the hymenal ring. There is no clear evidence that HPV or bacteria cause the inflammation, but an accelerated inflammatory response to Candida is suspected in some patients. Treatment is often not effective, but regimens include topical corticosteroids ointments (i.e., without an alcohol base); local corticosteroid injection; oral tricyclic antidepressants; pelvic floor muscle physical therapy; and in severe cases, skinning vulvectomy.

Furunculosis

Hair follicles or areas of hidradenitis in the vulva may become infected by staphylococci or other bacteria, giving rise to pustules. Methicillin-resistant staphylococci (MRSA) often cause repetitive and severe recurrences. This condition can be distinguished from herpetic and syphilitic lesions by finding pus within the pustules; confirmation can be made by culture or by finding gram-positive cocci on a Gram stain. If only a few small lesions are present, treatment with hot, wet compresses or hexachlorophene soap helps. If a larger area is involved, administration of antistaphylococcal antibiotics is required until infection subsides, which may take weeks. Daily low-dose suppressive antibiotic therapy (e.g., erythromycin 250 mg) can reduce frequent recurrences. MRSA treatment should include vancomycin or a wide variety of both older and new antibiotics.

Bartholinitis

Two stages of Bartholin gland infection occur. The first is an acute infection of the duct and gland, usually caused by either *N. gonorrhoeae* or *C. trachomatis*. If acute infection causes duct obstruction, an abscess can result. Anaerobic bacteria are present in the abscesses. Rarely, diabetics develop synergistic vulvar gangrene from bartholinitis.

Cultures and a Gram stain of material expressed from the duct and detection of gonorrhea and chlamydia should be routine. Acute infection should be treated with regimens that are

effective against at least these two pathogens. Patients with an abscess require adequate anesthesia and abscess marsupialization or incision with placement of a catheter in the abscess cavity for 3 to 6 weeks to establish a new duct. Simple incision and drainage has to be avoided because it does not establish mucous drainage by connecting a functioning gland with the introitus. Recurrent infection and mucous cyst formation are common sequelae of bartholinitis; thus, proper marsupialization is critical to prevent sequelae.

Chancroid

The soft chancre of chancroid is a painful ulcer with a ragged, undermined edge and a raised border. In contrast, the syphilitic chancre is painless and indurated. “Kissing ulcers” occur on opposing vulvar surfaces. Tender, unilateral adenopathy is common, and node suppuration occurs in about 50% of patients with lymphadenopathy. The incubation period of this sexually transmitted infection (STI) is 4 to 10 days. The infection is caused by *Haemophilus ducreyi*, a gram-negative bacterium that forms a school-of-fish pattern on Gram stain preparation. The microbe is fastidious and is best identified by culture of material from aspirated lymph nodes or from the chancre by using special selective media or PCR tests. The differential diagnosis includes syphilis, genital herpes, and lymphogranuloma venereum (LGV). Chancroid is rarely diagnosed in the United States, but it may cause infection in 10% to 40% of genital ulcers in high-STI-risk populations.

Preferred treatment is azithromycin (Zithromax), 1 g orally, or ceftriaxone sodium (Rocephin), 250 mg intramuscularly, in single doses; ciprofloxacin, 500 mg twice daily for 3 days; or erythromycin, 500 mg three times daily for 7 days. Sexual partners should be examined and treated.

Granuloma Inguinale

Granuloma inguinale is rare in temperate climates and usually is considered an STI, although gastrointestinal transmission can occur. Initial papular lesions typically ulcerate and develop into a soft, painless, progressive granuloma that is often covered by a thin, gray membrane. The granuloma may spread over the course of months to involve the anus and rectum. Lymph nodes are moderately enlarged and painless, but they do not suppurate. The infection can become chronic, and long-standing disease may cause genital scarring and depigmentation as well as lymphatic fibrosis with genital edema.

Infection is caused by a gram-negative bacillus, *Klebsiella* (formerly *Calymmatobacterium*) *granulomatis*, which is difficult to culture because it is an intracellular parasite. The identification usually is made from scraped material or a biopsy obtained from the periphery of the lesion. Bipolar-staining bacteria are best identified within mononuclear cells (i.e., Donovan bodies) by Wright or Giemsa staining; no Food and Drug Administration (FDA)-approved PCR assay is available.

Therapy of choice is a 3-week course of doxycycline, 100 mg; alternatives are trimethoprim/sulfamethoxazole (double strength), azithromycin, ciprofloxacin, and erythromycin.

Lymphogranuloma Venereum

The incubation period for LGV is 2 to 5 days. Thereafter, a transient, primary, painless genital or anorectal ulcer develops. Multiple, large, confluent inguinal nodes develop 2 to 3 weeks later and eventually suppurate. Acute infection may cause generalized systemic symptoms. If untreated, the infection enters a tertiary phase that can lead to

extensive lymphatic obstruction. This development, together with continued infection, can cause fistulae or strictures of the anal, urethral, or genital areas. Women with LGV are particularly susceptible to rectal stricture. Edema and elephantiasis of the external genitalia and lower extremities are other serious sequelae.

The L 1–3 serovars of *C. trachomatis* produce an acceleration of tissue destruction in vitro and LGV in vivo. The diagnosis of LGV can be confirmed by finding *C. trachomatis* in genital lesions or lymph nodes by culture or nucleic acid detection. Diagnosis of LGV by serologic testing is not standardized, but the most specific serologic test is the microimmunofluorescent antibody test, in which the specific L immunotypes are identified. Complement fixation (CF) tests are positive in 95% of patients with LGV, but the CF test lacks specificity; test results often are falsely positive from prior infection with the more usual genital serotypes.

LGV responds to 3-week regimens of doxycycline or erythromycin in the usual doses. Large lymph nodes should be aspirated to avoid chronic drainage. Surgical excision of scarred areas may be necessary.

Acute Urethral Syndrome

Dysuria can occur either from urethral or bladder inflammation or from vulvar inflammation. Acute cystitis is present in approximately 50% of women with symptoms of dysuria and urinary frequency. Cystitis is defined by pyuria and a midstream urine culture that contains $>10^5$ organisms per milliliter of coliform or staphylococcal bacteria. It is now apparent that about one half of remaining symptomatic women also have cystitis but with $<10^5$ coliforms or *Staphylococcus saprophyticus* bacteria per milliliter of urine. Virtually all women with cystitis have pyuria with eight or more leukocytes per high-power field of urine. Acute urethral syndrome refers to the other 25% of women who have pyuria with recent onset of internal dysuria and urinary frequency but a negative urine culture. These patients usually have *C. trachomatis* or, less often, *N. gonorrhoeae*. The remaining 25% of patients with these symptoms have no pyuria, bacteriuria, or chlamydial infection; they have a variety of diseases, including Candida or herpetic vulvitis, vaginitis, and noninfectious diseases. Thus, women with dysuria and no pyuria need a pelvic examination to exclude vulvitis and vaginitis. Treatment of acute urethritis consists of therapy for the infectious agent, whether it is coliform or *S. saprophyticus* cystitis or *C. trachomatis* urethritis.

Vaginitis

Vaginitis is the most common reason for a gynecologic visit. Symptoms of vaginitis include increased external dysuria, vulvar irritation and pruritus, vaginal discharge, and a foul odor or yellow discharge color. However, symptoms are very poor indicators of the specific cause of vaginitis. Women with infectious vaginitis have either an STI (i.e., trichomonads) or a quantitative increase in normal flora (i.e., Candida, anaerobes). At least four types of infectious vaginitis are found: candidal, trichomonal, bacterial, and gonococcal (in children). Every effort should be made to establish a specific diagnosis of vaginitis, because a specific diagnosis is mandatory to select a specific and thus effective therapy.

Other conditions that may cause excessive vaginal discharge include cervicitis, normal cervical mucus from cervical ectopy, vaginal foreign bodies (most commonly, retained tampons), and allergic reactions to douching or vaginal contraceptive agents. Atrophic vaginitis among postmenopausal women can produce burning and dyspareunia, but no infectious cause is established.

A small amount of vaginal discharge may be normal, particularly midcycle, when large amounts of cervical mucus produce a clear vaginal discharge. A normal vaginal discharge should not be yellow, have a foul odor, or produce irritation or pruritus.

Examination

External genitalia may be normal or edematous, erythematous, excoriated, or fissured from vaginitis. Local vulvar disease, especially vestibulitis, lichen sclerosis, and lichen planus, must be excluded from the secondary effect of vaginitis.

On speculum examination, the vaginal mucosa may be erythematous. Discharge characteristics that are important to observe are viscosity, floccular appearance, color, and odor. Vaginal pH status must be determined. A pH less than 4.5 indicates either Candida or a normal vaginal discharge. A microscopic examination is necessary, consisting of a normal saline and 10% KOH wet mount. A drop of each solution is mixed with discharge. Before placing a cover glass over the two separate drops, the KOH portion is tested for the presence of a fishy amine odor (KOH odor test). Microscopic examination is made of the saline portion for trichomonads, clue cells and white blood cells (WBCs) with the 400× objective, and of the KOH portion for hyphae with the 100× objective. Multiple causes of vaginitis are frequent.

Vaginal cultures are not particularly helpful except when used selectively to identify Candida. Microscopy is specific but only 80% sensitive to identify various types of vaginitis. When infectious vaginitis is suspected in patients in whom a specific diagnosis cannot be established, a repeat examination should be performed 2 weeks later.

Candidiasis

The most prominent symptom of candidiasis is vulvar and vaginal pruritus. Increased vaginal discharge is infrequent. Vulvar signs may occur, including edema, geographic

---

erythema, and fissures. Classically, the vaginal walls are red and contain adherent, white, curdy plaques. However, most women with candidiasis have atypical symptoms and little

vaginal discharge or erythema.

Candida albicans causes about 90% of vaginal yeast infection. Noncandidal species cause the remaining infections. These saprophytic fungi are isolated from the vagina in up to 25% of asymptomatic women. Thus, the mere presence of vaginal Candida does not always identify an infection. Usually large numbers of Candida lead to symptomatic vaginitis. However, severe symptoms also can develop in selected sensitized women with only a few microbes but who have an accelerated immune response to Candida. Candidiasis occurs because changes in host resistance or immune response produce an immunologic response that causes inflammation. The most potent risk factors for candidiasis include pregnancy, diabetes, and use of immunosuppressive drugs and broad-spectrum antibiotics. Frequent vaginal intercourse also can cause candidiasis. Because cellular, not humoral, immunity is required to resist candidal infections, pregnant women and other immunosuppressed patients with decreased cellular immunity are predisposed to candidiasis. Candidal overgrowth also is favored by high urine glucose levels that can occur in diabetes or pregnancy. Broad-spectrum antibiotics cause suppression of the normal vaginal and gastrointestinal bacterial flora, allowing fungal overgrowth. The role of oral contraceptives in candidal infection remains controversial.

Most women have uncomplicated infection defined as sporadic and mild *C. albicans* infections in those with normal immunity. About 5% of women have complicated infection defined as recurrent, four or more per year; severe, or nonalbicans infection; or infection in pregnant, diabetic or immunocompromised women.

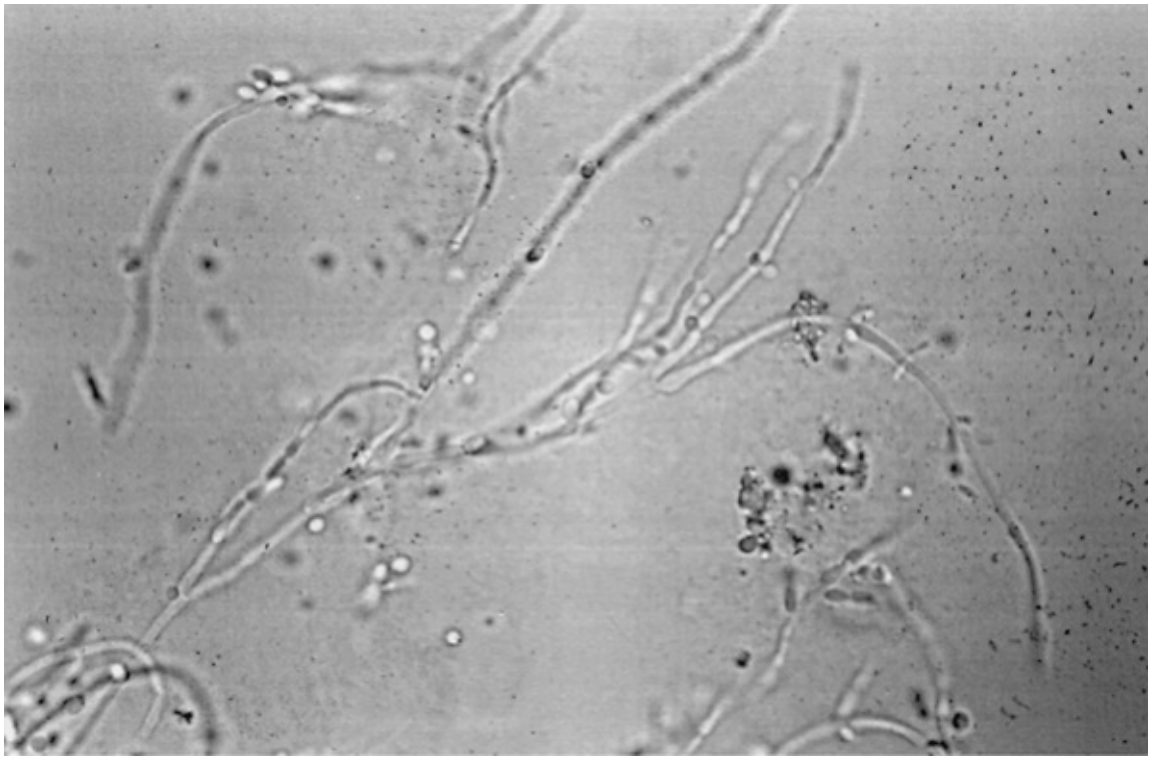

Figure 34.3 *C. albicans* growing as hyphae and pseudohyphae within infected tissue (320×). (From Monif GRG. *Infectious diseases in obstetrics and gynecology*. Hagerstown, MD: Harper & Row, 1974, with permission.)

Candidiasis is best diagnosed in KOH wet mounts. Vaginal plaques, vaginal discharge, or vulvar scrapings from the edge of the erythematous border are mixed with 10% KOH (Fig. 34.3). The mycelial form usually is found only during an infection and can be identified by KOH wet mount in 80% of cases. The pH of vaginal discharge is normal (i.e., 4.5 or less). Fungi can readily be isolated on various media. In fact, 50% of women with candidiasis have a negative wet mount but a positive Candida culture. However, Candida is part of normal vaginal flora, and a positive culture does not necessarily indicate infection, so cultures for Candida should be limited to KOH wet mount–negative patients with symptoms or signs of candidiasis.

Local vaginal therapy is used because most antifungal preparations are not absorbed from the intestinal tract. For uncomplicated infection, various intravaginal azole agents used for 1 to 3 days are equally effective for women with infrequent uncomplicated Candida vaginitis. These agents include clotrimazole (Lotrisone), miconazole (Monistat), butoconazole (Femstat), terconazole (Terazol), and tioconazole (Vagistat-1). Azole drugs are not absorbed from the vagina, and these local regimens can be used safely in pregnancy. The insertion of a capsule containing boric acid powder into the vagina for 7 days also is effective but should not be used in pregnancy. A one-time dose of fluconazole (Diflucan), 150 mg orally, or itraconazole (Sporanox),

400 mg initially and then 200 mg for 2 days, is effective for uncomplicated infection. Patients with complicated infection or severe symptoms need 7 to 14 days of intravaginal azole therapy or fluconazole, 150 mg with one to two repeat doses every 3 days. Oral nystatin administration to decrease gastrointestinal colonization does not markedly improve therapeutic cure rates or diminish recurrence rates. The 15% of male sexual contacts of women with candidiasis with symptomatic balanitis should be identified and treated to prevent recurrent female infection. In addition, some women with candidiasis have other concurrent vaginal infections that may be clarified by a repeat physical and wet mount examination.

The number of nonalbicans candidal infections appears to have increased. Such infections respond poorly to azole therapy, including fluconazole. Vaginal boric acid or nystatin (100,000 U) therapy works best, but nystatin is no longer commercially available. A gentian violet 1% aqueous solution is a poor second choice.

Patients with frequently recurrent candidiasis represent the most difficult problem in treatment. Extended 2- to 3-week female therapy, male therapy, and reduction of sugar intake usually are ineffective. A glucose tolerance test and HIV testing should be performed in recurrent or resistant cases to exclude unrecognized diabetes and HIV infection. However, these tests are seldom positive.

Complicated infection from frequently recurrent candidiasis (four or more times a year) should be treated first with standard anti-Candida therapy for 2 weeks, followed by suppressive therapy with intravaginal azole or boric acid twice weekly; an intravaginal azole daily for 5 days once monthly; oral fluconazole, 150 mg weekly; or oral itraconazole, 400 mg monthly. Suppressive treatment should continue for at least 6 to 12 months;

recurrent candidiasis usually is reduced to zero to one infection yearly, but 30% to 40% of patients develop frequent recurrence of Candida on cessation of therapy.

Trichomoniasis

Characteristic symptoms of trichomoniasis include a profuse, yellow, malodorous vaginal discharge, often with uncomfortable vulvar irritation. *Trichomonas vaginalis* is a common STI, present in 3% to 15% of asymptomatic women and in up to 20% of women who attend clinics for STIs. *T. vaginalis* is most likely identified in symptomatic women with recent acquisition. However, about 50% of all women with *T. vaginalis* are asymptomatic. Most male contacts of women with trichomoniasis carry the microbe asymptomatically in the urethra and prostate.

The classic profuse, frothy, yellow vaginal discharge is present in only about one third of women. The vulva may be edematous and inflamed by inflammation from the discharge. Rarely, subepithelial redness of the cervix (i.e., strawberry cervix) is seen with the naked eye; smaller red areas are more commonly identified colposcopically. The discharge in women with symptomatic trichomoniasis usually has a pH greater than 4.5 and forms an amine odor with 10% KOH. Motile trichomonads are demonstrated in the saline wet mount smear (Fig. 34.4). Trichomonads are larger than WBCs and have a jerky motility. The wet mount usually also contains many polymorphonuclear leukocytes. Although the wet mount can identify trichomonads with 80% sensitivity among symptomatic women, less than 50% of all women identified with *T. vaginalis* by culture have positive wet mounts. Trichomonads also are occasionally seen on a Pap smear.

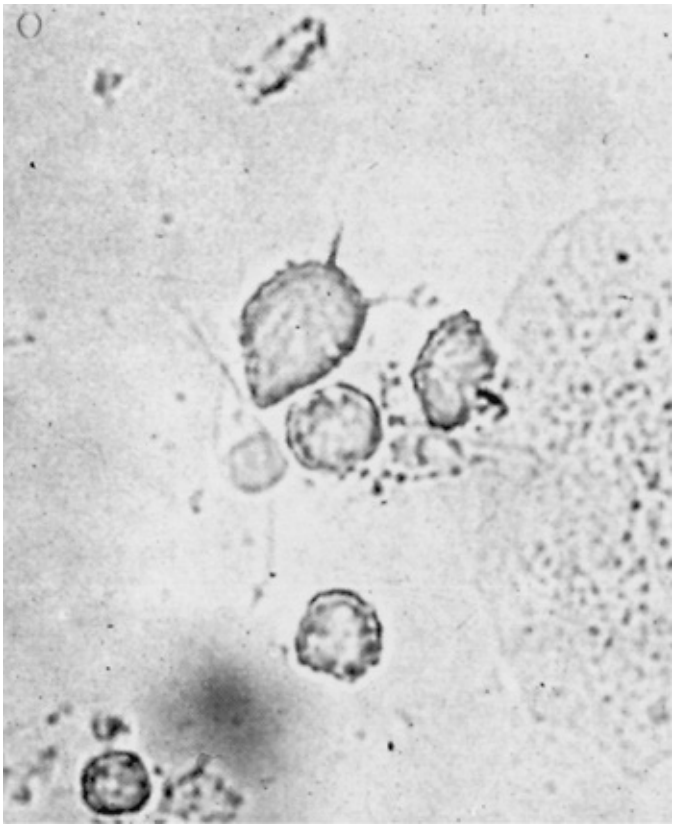

Figure 34.4 Characteristic configuration of a trichomonad seen in wet smear at high-

power magnification. (From Monif GRG. *Infectious diseases in obstetrics and gynecology*. Hagerstown, MD: Harper & Row, 1974, with permission.)

T. vaginalis is an anaerobic protozoan. A culture of this microbe is easy to perform. A commercially available medium is the InPouch (BioMed Diagnostics, White City, OR) device. Culture should be limited to cases where the diagnosis is suspected but cannot be confirmed by wet mount. Screening cultures are not recommended in asymptomatic women except for select high-risk populations. Women with *T. vaginalis* also should be cultured for *N. gonorrhoeae* because of the close association between microbes.

T. vaginalis resides not only in the vagina but also in the urethra, bladder, and Skene glands of women, so systemic, rather than local, therapy is required. The recommended regimen is 2 g of either metronidazole or tinidazole in one dose because of complete patient compliance and high effectiveness. A 7-day, 500 mg twice daily metronidazole course does not increase the 95% cure rate of a single

dose. Simultaneous treatment of the male sexual partner is recommended. Recurrent trichomoniasis usually is attributable either to a lack of compliance or to sexual reexposure to an untreated partner. A single recurrence should be treated with the recommended regimens. However, increasing in vitro and in vivo resistance of *T. vaginalis* to metronidazole exists, and repeated treatment failure should be treated with metronidazole, 2 g daily for 3 to 5 days. The Centers for Disease Control and Prevention (CDC) has consultation available for patients who fail this regimen.

Metronidazole therapy has slight controversy because of tumor-causing potential. In animals, large (equivalent to 350 to 1,000 human) doses cause tumors. However, increased tumor rates were not found in a small series of women evaluated for up to 10 years after metronidazole therapy, but larger studies are needed. Metronidazole is a category B drug, and it can be used for symptomatic infection in pregnancy. A meta-analysis showed no consistent evidence of teratogenesis with metronidazole use in pregnancy. However, because treatment of asymptomatic *T. vaginalis* has not reduced and may even increase prematurity, asymptomatic women should not be treated in pregnancy. Persistent discharge after adequate treatment for trichomoniasis should lead to repeat examination for Trichomonas, candidiasis, and gonorrhea.

Bacterial Vaginosis

BV describes the vaginal condition resulting from overgrowth of both a variety of anaerobic bacteria and to a lesser degree of *Gardnerella vaginalis*. Recently, a wide variety of difficult-to-culture bacteria were found by DNA technology to be the predominant microbes in BV. These microbes are normal inhabitants of the vagina, but overgrowth of the normal Lactobacillus-dominant flora by these bacteria causes BV, which results in a thin, homogeneous, fishy-smelling, gray vaginal discharge that adheres to the vaginal walls and often is present at the introitus. In contrast to findings in other causes of vaginitis, the vaginal epithelium appears normal, and WBCs usually are not present. The fishy amine odor

produced by anaerobes is accentuated when 10% KOH is placed on the discharge.

The diagnosis of BV is based on the presence of three of the following four characteristics of the vaginal discharge: pH greater than 4.5, a homogeneous thin appearance, a fishy amine odor with the addition of 10% KOH, and clue cells. Clue cells are vaginal epithelial cells with so many bacteria attached to the cell border that it is obscured. In BV, 20% to 50% of the epithelial cells are clue cells. Polymorphonuclear leukocytes and lactobacilli are notably absent. Gram stains used for diagnosis rely on a reduction in Lactobacillus morphotypes and an increase in small gram-negative rods and gram-positive cocci. Commercially available point-of-care tests for high concentrations of *G. vaginalis* (Affirm), pH and trimethylamine (FemExam), pH and amines (QuickVue Advance), sialidase (OSOM BV Blue), and proline aminopeptidase (PIP Activity Test Card) are available. Routine vaginal cultures are not helpful, because the microbes implicated in BV can either be recovered from women without BV (40% of asymptomatic women without vaginitis carry *G. vaginalis*) or not recovered in those with BV. Instead, the microbiology of BV is distinguished by the 10- to 1,000-fold increased concentration of anaerobic bacteria compared with that found in normal vaginal flora.

Factors leading to the overgrowth of these microbes are poorly established but include the absence of Lactobacillus. Sexual transmission is a risk factor suggested by the association of BV with a new sexual partner, more than one partner, and shared sex toys among female partners.

Treatment is not advocated for most asymptomatic women with BV, as it can spontaneously disappear. However, the increased concentration of potentially virulent bacteria in the vagina is related to upper genital tract infection following surgery. A significant, increased relative risk (RR) of postoperative infection was reported in patients with BV following cesarean section (RR 6), hysterectomy (RR 3 to 4), and induced abortion (RR 3). BV also is associated with PID and postpartum endometritis after vaginal delivery. Treatment of BV is particularly beneficial for women who are undergoing elective surgery. BV in pregnancy also is related to premature delivery (RR 2 to 4), amniotic fluid infection (RR 2 to 3), and chorioamnionitis (RR 2 to 3); treatment of women with prior preterm delivery has reduced the incidence of preterm delivery, but treatment of low-risk asymptomatic women to date has had no effect on preterm delivery.

Recommended regimens for BV include metronidazole, 500 mg orally, twice daily for 7 days; 0.75% metronidazole gel, intravaginally once daily for 5 days; and 2% clindamycin cream, intravaginally at bedtime for 7 days. Alternative regimens include 300 mg of oral clindamycin twice daily for 7 days, and 100 mg clindamycin ovules placed intravaginally at bedtime for 3 days. Metronidazole and clindamycin are particularly effective against the anaerobes. Treatment of the male sexual contact with metronidazole is not recommended, because it does not prevent recurrent BV.

Toxic Shock Syndrome

Toxic shock syndrome (TSS) is an acute illness caused by toxin-producing *Staphylococcus aureus*. About 6% of women carry *S. aureus* in the vagina, but only 2% of women have *S. aureus* capable of producing the toxic shock toxin. The syndrome is highly associated with

menstruation and probably with tampon use, but it also has occurred from *S. aureus* infection of the breast and endometrium after delivery and from abdominal surgical wounds. Characteristic features include a high fever (>102°F [38.9°C]); a diffuse rash; hypotension; skin desquamation (usually 1 to 2 weeks later);

and a wide variety of systemic effects, including gastrointestinal (vomiting, diarrhea), muscular (myalgia), mucous membrane (hyperemia), renal (elevated blood urea nitrogen or creatinine level), hepatic (enzyme abnormalities), hematologic (thrombocytopenia), and neurologic (disorientation, coma). Vaginal or specific-site cultures are needed to recover *S. aureus*. Blood, throat, and cerebrospinal fluid cultures, together with serologic tests for Rocky Mountain spotted fever, leptospirosis, and measles, also are usually indicated to exclude diseases with a similar clinical presentation.

A vaginal tampon, if present, should be removed. Patients with TSS should be hospitalized and, when indicated, given large fluid volumes for blood pressure maintenance. Beta-lactamase–resistant antibiotics are recommended, and if other causes of bacterial sepsis such as meningococcemia cannot be excluded, additional antibiotics are necessary. Other life-supporting measures such as intubation, vasopressor administration, and dialysis often are necessary. The case fatality ratio from TSS was reduced from 15% to 3% with supportive therapy. Antibiotics are of no proven benefit in the acute stage, but antibiotics reduce recurrent TSS rates from 30% to 5%.

Although the effectiveness is uncertain, it is prudent for all women to avoid the prolonged and overnight use of tampons. It is recommended that postpartum women not use tampons for 6 to 8 weeks after delivery. Women with TSS should be warned of recurrent episodes and advised against resuming tampon use.

Syphilis

Physicians must constantly be aware of possible syphilitic infection, particularly in populations with high rates of HIV infection. Most women with syphilis are asymptomatic and have only serologic evidence of infection. *T. pallidum* rapidly enters the lymphatics after exposure, but a primary chancre lesion usually takes 3 weeks to develop. The classic chancre ulcer of syphilis is painless and firm with sharply defined, raised edges; however, most syphilitic ulcers are atypical. Any suspicious genital ulcer should be studied by dark field examination. Serous material expressed from the ulcer base is mixed with saline, and because *T. pallidum* is an anaerobe, the mixture must be immediately placed under a cover slip with the edges occluded by petroleum jelly. Identification of typical spirochetes by dark field microscopy establishes a diagnosis of primary syphilis. Dark field examination of ulcer material from possible syphilitic ulcers should be done on three consecutive days. The Venereal Disease Research Laboratory (VDRL) test or rapid plasma reagin (RPR) and fluorescent treponemal antibody (FTA) serology should be performed for a patient with a suspicious lesion. If the serologic results are nonreactive and spirochetes cannot be demonstrated by dark field examination, serologic testing should be repeated in 1 month.

Secondary syphilis appears 6 or more weeks later and is characterized by a symmetric, macular, papular, or papulosquamous rash and generalized, nontender lymphadenopathy.

Condylomata lata (Fig. 34.2) are highly infectious, hypertrophied, wart like lesions of secondary syphilis that usually occur in moist skin areas such as the vulva or perineum; they must be distinguished from other vulvar lesions. Superficial, painless mucosal erosions of the mouth or vagina, called *mucous patches*, develop in one third of patients. Systemic symptoms of fever, weight loss, and malaise may occur. Serologic tests are positive in the secondary stage.

Untreated patients will enter a latent phase of syphilis during which clinical and physical manifestations are absent. Diagnosis in the latent phase is established by serologic tests. Intermittent spirochete bloodstream invasion may occur in the early latent phase within the first years of exposure. In pregnancy, the risk of congenital fetal infection in the primary and secondary phases of syphilis is 80% to 95%; the risk during the early latent phase is 70%. During the late latent phase, immunity develops, which reduces blood invasion, and the risk of congenital syphilis decreases to 10%. Congenital syphilis is reported to be on the rise, affecting 1 in 10,000 live-born infants. Fetal or perinatal death occurs in 40% of those with congenital syphilis. About one third of adult patients with untreated late syphilis manifest central nervous system or cardiovascular symptoms of tertiary syphilis.

VDRL and RPR tests detect a nontreponemal, nonspecific reagin antibody. The tests can be titrated, and the titer either falls or disappears after therapy for early or secondary syphilis. Thus, the VDRL test can be used to judge the activity of either a first episode or reacquired infection in a patient with documented syphilis. However, treated patients with latent syphilis often retain high, stable VDRL titers. Acute bacterial or viral infections can give rise to acute false-positive serologic reactions that last up to 6 months. Several conditions, such as aging, addiction to drugs, autoimmune disease, and pregnancy, can cause chronic, nonspecific, false-positive VDRL reactions. False-positive VDRL titers usually are 1:8 or less. By contrast, the FTA test involves a specific antitreponemal antibody, and false-positive FTA reactions are rare. Patients with a positive VDRL reaction must have a confirmatory FTA test to exclude a false-positive VDRL reaction. Patients with a false-positive VDRL reaction have a negative FTA test. In patients with syphilis, the FTA test remains positive indefinitely, and because the test is not titrated, repeat FTA testing should not be done in a known positive patient.

The treatment schedules for syphilis currently recommended by the U.S. Public Health Service's CDC are as follows:

Early syphilis: Early syphilis is defined as primary, secondary, or early latent syphilis of <1 year duration. The recommended drug is penicillin G benzathine,

---

2.4 million U intramuscularly in a single dose. Alternative choices for penicillin-allergic patients include 2-week regimens of doxycycline, 100 mg twice daily, or tetracycline, 500 mg four times daily. Ceftriaxone, 1 g daily intramuscularly for 8 to 10 days, may be used if close follow-up can be ensured.

Syphilis lasting longer than 1 year or of unknown duration: Penicillin G benzathine, 2.4 million U intramuscularly each week for 3 successive weeks (7.2 million U total), is the drug of choice. Alternative choices for penicillin-allergic women include doxycycline and

tetracycline for 4 weeks. Intravenous aqueous penicillin G or penicillin G procaine is recommended for neurosyphilis. Erythromycin is not recommended for neurosyphilis. Spinal tap to exclude asymptomatic neurosyphilis is recommended for those with neurologic or ophthalmologic signs, other evidence of active disease (aortitis, gummas), HIV infection, treatment failure, and infection for more than 1 year with a titer of 1:32 or greater. Tertiary syphilis and syphilis in HIV-positive patients should be treated by infectious disease specialists.

Syphilis in pregnancy: Parenteral penicillin is the only documented treatment in pregnancy to effectively treat the fetus. Treatment with penicillin is the same as for the corresponding stage of syphilis among nonpregnant women. Pregnant patients who are allergic to penicillin should not receive tetracycline (because of toxicity) or erythromycin (because it leads to high fetal failure rates). Penicillin is so superior to other antibiotics to treat syphilis in pregnancy that pregnant, penicillin-allergic patients should be desensitized. The Jarisch-Herxheimer reaction commonly occurs in early syphilis, and pregnant women should be hospitalized in anticipation of this possibility for monitoring of themselves and the fetus. The reaction is ascribed to the sudden massive destruction of spirochetes by antibiotics; it is marked by fever, myalgia, tachycardia, and occasionally hypotension. The reaction usually begins within 24 hours and subsides spontaneously in the next 24 hours. All patients need to be followed with quantitative serologic tests to monitor treatment results and offered HIV testing. All sexual partners need to be contacted and tested for syphilis.

Cervicitis

Acute cervicitis is defined as the presence of yellow cervical mucopus or an increased number of polymorphonuclear leucocytes (PMNs) in cervical mucus. Symptoms usually are limited to a purulent vaginal discharge. Physical findings include mucopus in the endocervical canal or bleeding after swabbing of the cervix. Microbes that infect the cervical columnar epithelium such as *C. trachomatis*, *N. gonorrhoeae*, or *Mycoplasma genitalium* are isolated separately or in combination from about 60% of women with purulent cervicitis. Unknown microbes cause the other cases. The diagnosis also can be established by the finding of more than 10 PMNs per 1,000x microscopic field. Nucleic acid amplification testing (NAAT) is recommended for *C. trachomatis* and *N. gonorrhoeae*.

Infectious ulcers of the cervix caused by herpesvirus, syphilis, and chancroid must be distinguished from a cervical erosion and the other conditions described in Chapter 33. Depending on the nature of the lesion, Gram stain, Pap smear, NAAT, dark field examination, colposcopy, and, in some cases, biopsy may be required.

Women with *N. gonorrhoeae* should be treated for gonorrhea, including treatment for coexisting *C. trachomatis*. If *N. gonorrhoeae* is not found, the azithromycin or doxycycline regimens used for *C. trachomatis* are recommended. Persistent cervicitis resistant to repetitive antibiotics can be considered for loop electrical excision treatment.

Endometritis

Lymphocytes and PMNs normally appear in the endometrium in the second half of the menstrual cycle; their presence does not necessarily constitute endometritis. However, plasma cells are not normally in the endometrium, as they represent an immune response, usually due to a bacterial antigen.

Endometritis produces nonspecific symptoms, and its diagnose should depend on the histologic presence in the endometrium of both plasma cells in the stroma and PMNs in the superficial epithelium.

Endometritis may occur in the following situations: with puerperal endometritis (Chapter 19); chlamydial or gonococcal endometritis, often occurring with salpingitis; endometritis after endometrial instrumentation; pyometra caused by a cervical stricture or after radium insertion; endometritis characteristically present with an intrauterine device (IUD); and tuberculous endometritis.

C. trachomatis, *N. gonorrhoeae*, and *M. genitalium* are strongly linked to spontaneous endometritis in the nonpregnant woman. BV has a less consistent link to endometritis. Prior PID appears to increase the rate of endometritis among women with *C. trachomatis* and *N. gonorrhoeae*, possibly due to immune signaling from a prior infection. An increased number of B cells in endometritis further suggests a rate of the adoptive immune system in endometritis.

Histologic endometritis has a divergent prevalence: 5% to 10% in asymptomatic women undergoing infertility workup, 25% to 40% in women with cervical *C. trachomatis* or *N. gonorrhoeae*, and 40% in postpartum women.

Clinical symptoms include intermenstrual or heavy menstrual bleeding. Cervical motion and mild uterine tenderness may be present. Few treatment trials are reported.

However, oral azithromycin, oral cefixime, and 7 days of metronidazole reduced abnormal bleeding, cervicitis, uterine tenderness, and histologic endometritis.

Gonorrhea

Gonorrhea is caused by the gram-negative diplococcus *N. gonorrhoeae*, which attach only to columnar or transitional cells by pili and are rapidly brought intracellular by pinocytosis. *N. gonorrhoeae* attracts PMNs, commonly causing a purulent discharge. Gonorrhea usually is sexually transmitted, although organisms can be acquired by neonates passing through an infected cervix, causing gonorrheal ophthalmia.

Course of the Disease

N. gonorrhoeae in the lower genital tract infects the urethra, Bartholin glands, and endocervix. The anus and rectum can be infected either from cervical infection or during anal coitus. Urinary frequency, dysuria, and a purulent vaginal discharge are the first symptoms to appear 2 to 5 days after exposure. However, about 50% of women with *N. gonorrhoeae* infection have no symptoms. Many additional women do not seek medical attention if symptoms are mild. The discharge occasionally is locally irritating and causes

vulvar edema and soreness. Pharyngitis may result from gonorrheal pharyngeal infection. In 2% of infected women, disseminated gonococcal infection occurs, causing fever, septicemia, dermatitis, arthritis, endocarditis, or meningitis, in various combinations. Untreated gonorrhea is associated with premature delivery and premature rupture of membranes.

In 10% to 17% of women with untreated gonorrhea, the microbes ascend to produce upper genital tract infection or acute PID (Fig. 34.5). Acute PID is the most common serious sequelae of gonorrhea. The mechanical and antibacterial properties of cervical mucus probably provide a barrier against upward extension of infection, but during menstruation the mucus barrier is lost, and gonococci can disseminate to the uterus and fallopian tubes, where an acute and usually bilateral inflammatory reaction occurs. The tubes characteristically become swollen and reddened when the muscularis and serosa become inflamed. If exudate drips from the fimbriated ends of the tubes, pelvic peritonitis occurs that ultimately can cause peritoneal adhesions. The swollen and congested fimbriae may adhere and produce tubal occlusion.

The process can take any of the following courses. With prompt, appropriate antibacterial therapy, infection may subside with little permanent damage to the reproductive tract. The fimbriae may occlude to produce permanent tubal infertility. The swollen and congested fimbriae may adhere to one another or to the ovary, trap exudate in the tube, and produce a pyosalpinx, or if the ovary becomes infected, a tuboovarian abscess. The mucosal folds may adhere to one another and form glandlike spaces that are filled at first with exudate and later, as the process becomes chronic, with the watery secretion of follicular salpingitis. If the infection subsides after agglutination of the fimbriae and closure of the distal tube, watery secretion can accumulate and distend the tube, forming a hydrosalpinx (Fig. 34.6).

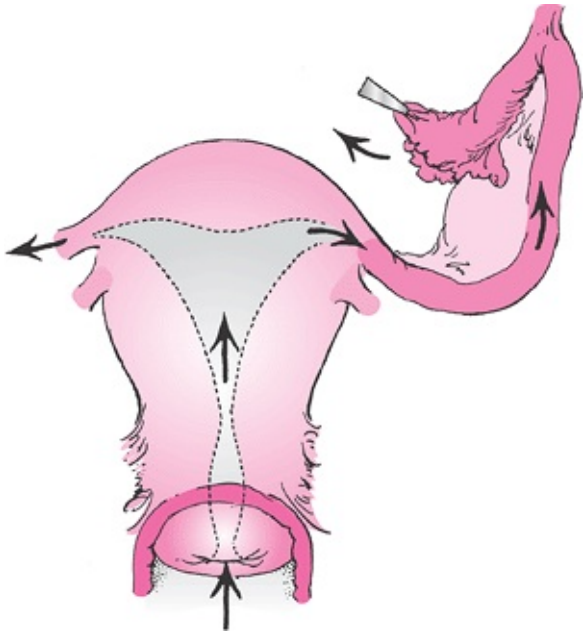

Figure 34.5 Mode of transmission of gonococcal pelvic infection. Portal of entry is the external genitalia. The organism enters the cervix, follows the mucous membrane,

passes up through the uterine cavity, and attacks the fallopian tube. Pelvic peritonitis results from escape of pus from the tubal fimbriae. (From Wharton LR. *Gynecology and female urology*. Philadelphia: WB Saunders, 1943, with permission.)

Symptoms and Signs

Except for the discharge, which can be milked from the urethra or is present in the vagina or cervix, few signs may occur in women with acute gonococcal infection. Bilateral, mild to severe lower abdominal pain may occur with acute salpingitis. Pelvic peritonitis can cause pain on movement of the cervix, direct and rebound abdominal tenderness, muscle guarding that prevents abdominal palpation, and tender adnexa to various degrees on bimanual examination. However, a sizable proportion of women with salpingitis experience either mild or no symptoms. In subacute salpingitis, infection continues with signs and symptoms that are even less overt than those of the acute stage. In the end stage of salpingitis, the uterus and the adnexa can be fixed by pelvic peritoneal adhesions. The adnexa may be either adherent to the posterior aspect of the uterus or prolapsed in the cul-de-sac. Notable features are dyspareunia; sterility; and chronic, aching pelvic pain that increases before menstruation.

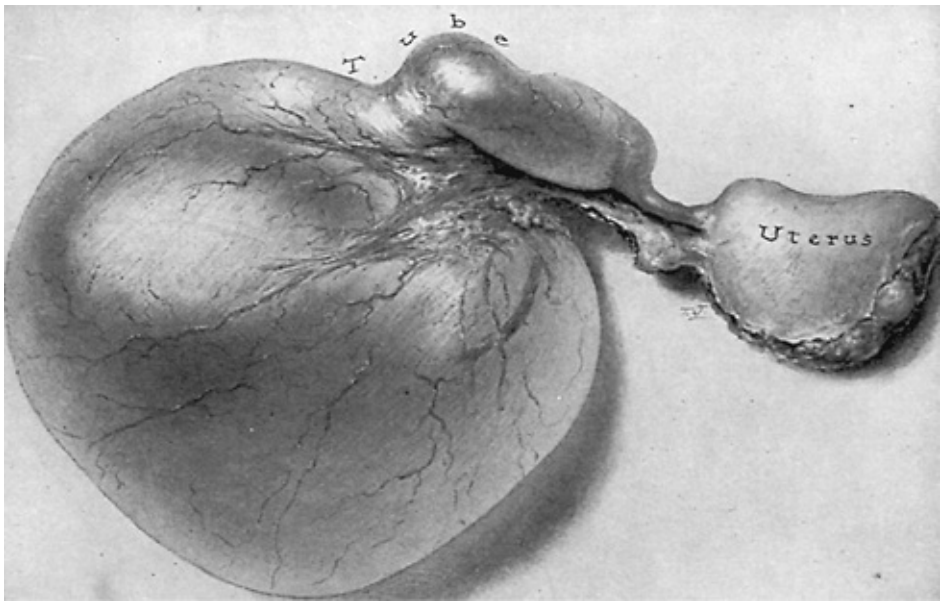

Figure 34.6 Hydrosalpinx. (From Curtis AH, Huffman JW. *A textbook of gynecology*, 6th ed. Philadelphia: WB Saunders, 1950, with permission.)

Diagnosis

The diagnosis of gonorrhea depends on a *N. gonorrhoeae* culture or NAAT. NAAT can be done in urine or on vaginal and endocervical swabs. The finding of intracellular gram-

negative diplococci in the Gram stain of cervical or urethral exudate points to gonorrheal infection, but Gram stains for gonorrhea are insensitive. *N. gonorrhoeae* testing should be performed on women with positive Gram stains, symptoms or signs suggestive of gonorrhea (e.g., cervicitis, undiagnosed vaginitis, dysuria), other STIs, bartholinitis or skenitis, acute lower abdominal pain suggestive of acute salpingitis, or suspected disseminated gonococcal infection as well as on women who are sexual contacts of men with gonorrhea. Patients with gonorrhea also should receive a test for chlamydial infection, because 10% to 30% of women with *N. gonorrhoeae* also have *C. trachomatis*.

High Risk

It is recommended that all high-risk, asymptomatic, sexually active women be screened for gonorrhea. This group includes women <25 years old, those with prior gonorrhea or STIs, those with new partners, and commercial sex workers or drug users.

Because gonorrhea is an STI, it usually is present in the male sexual partner. The fact that more than 40% of the male contacts of women with gonorrhea are asymptomatic carriers who otherwise do not seek treatment underscores the importance to identify and treat male sexual contacts. Sexual contacts can be referred for treatment. Patient delivered therapy can be considered; either medication or prescription delivered by the patient for the sexual partner should be accompanied by treatment instruction and appropriate warnings.

Drug Therapy of Uncomplicated Lower Genital Tract Gonorrhea

The new CDC-recommended treatment schedules for gonorrhea reflect a markedly increased resistance to penicillin, tetracycline, and quinolones. Those three regimens are no longer recommended to treat gonorrhea. Resistance to quinolones has increased to 6.7% in the United States, beyond the 5% threshold of where the drug is considered ineffective.

The new recommended drug therapy regimens are given in Table 34.2. A loading dose of cephalosporin is used to inhibit *N. gonorrhoeae*. Patients who are allergic to penicillin should receive spectinomycin (Trobicin) or other cephalosporins. However, the 400-mg dose of cefixime and spectinomycin currently are not available in the United States. If *C. trachomatis* is not excluded by testing, azithromycin or doxycycline is indicated. Quinolones and doxycycline should not be given to pregnant women. Special antibiotic regimens are recommended for patients with complicated gonococcal infections. These regimens are published in the widely circulated “Sexually Transmitted Disease Treatment Guidelines, 2006,” from the CDC and the April 2007 *Morbidity and Mortality Weekly Report* update. Prophylactic regimens to prevent ophthalmia neonatorum include silver nitrate, erythromycin, and tetracycline applications.

The first-choice regimens are so effective that test-of-cure cultures are not recommended. A rescreening at 1 to 2 months to detect reinfection is reasonable. Patients treated with alternative regimens should have a test-of-cure culture (not NAAT) 4 to 7 days after therapy. Those with a suspected recurrence shortly after treatment also should be cultured

to detect gonococcal resistance. All male sexual contacts need referral for evaluation and treatment.

TABLE 34.2 Treatment Regimens for Gonorrhea and Chlamydial Infection

Gonorrhea
Recommended loading dose regimen (choice of one plus treatment for chlamydia):
Ceftriaxone (Rocephin), 125 mg i.m.
Cefixime (Suprax), 400 mg p.o.
Alternative regimen (choice of one):
Spectinomycin (Trobicin), 2 g i.m.
Ceftizoxime (Cefizox), 500 mg i.m.
Cefoxitin (Mefoxin), 2 g i.m. with probenecid
Cefotaxime (Claforan), 500 mg i.m.
Chlamydial Infection
Follow-up regimen to treat chlamydia (choice of one):
Azithromycin (Zithromax), 1 g p.o. in a single dose
Doxycycline, 100 mg p.o. b.i.d. for 7 d
Alternative regimen (choice of one):
Erythromycin (see Pregnant Patients below)
Ofloxacin, 300 mg p.o. b.i.d. for 7 d
Levofloxacin, 500 mg p.o. for 7 dPregnant patients (choice of one):
Preferred regimen
Azithromycin, 1 g p.o. in a single dose
Amoxicillin, 500 mg p.o. t.i.d. for 7 d
Alternative regimen (choice of one)
Erythromycin base, 500 mg p.o. q.i.d. for 7 d
Erythromycin base, 250 mg p.o. q.i.d. for 14 d
Erythromycin ethylsuccinate, 800 mg p.o. q.i.d. for 7 days or 400 mg q.i.d. for 14 d

Patients with gonorrhea should have serologic tests for syphilis. Those with incubating syphilis (i.e., seronegative, without clinical signs of syphilis) are likely to be cured by all the regimens mentioned except those using quinolones and spectinomycin. Patients treated with these regimens need a follow-up serologic test for syphilis.

Chlamydial Infection

C. trachomatis is a sexually transmitted bacterium that often is associated with gonorrhea. C. *trachomatis* infects the same tissues and produce the same symptoms and diseases as gonorrhea. Chlamydial infection causes urethritis, bartholinitis, cervicitis, endometritis, salpingitis, Fitz-Hugh and Curtis syndrome (i.e., perihepatitis), and LGV. Treatment of *C. trachomatis* in pregnancy reduces premature delivery. Neonates born of mothers with chlamydial cervical infection have up to a 40% risk of chlamydial conjunctivitis and a 20% risk of chlamydial pneumonia. As with gonococcal infection, male sexual partners can have either symptomatic or asymptomatic urethritis.

C. trachomatis is an obligate intracellular bacterium that attaches to columnar or transitional epithelial cells, is engulfed by pinocytosis, and remains within a phagosome membrane that protects it from host defense mechanisms. The bacteria replicate until they replace most of the cell and ultimately cause the cell to rupture. Replication time is a relatively slow 24 to 48 hours, explaining the characteristically long latent period between the time of exposure and the onset of symptoms, which ranges from weeks to months.

C. trachomatis is three to five times more common than *N. gonorrhoeae* in developed countries because it is not routinely sought in asymptomatic patients, despite recommended annual *C. trachomatis* testing for all sexually active women ≤25 years of age and all women with a new or multiple sexual partners. Chlamydial infection most often is asymptomatic. Infection is particularly common among women <25 years, especially teenagers. *C. trachomatis* is associated with serious sequelae, including PID, tubal infertility, and ectopic pregnancy, and it appears able to produce permanent tissue damage more readily than *N. gonorrhoeae*. Permanent tissue damage appears to be largely related to the immune response to infection; reinfection, chronic infection, and infection in the presence of antibody to chlamydial heat shock protein are particularly associated with tissue damage.

Chlamydial infection should be suspected with acute urethritis, mucopurulent cervicitis, and salpingitis. The rate of chlamydial salpingitis approximates that of gonorrhea. Chlamydial infections can be diagnosed by culture, a direct monoclonal antibody slide test, an enzyme-linked immunosorbent assay, or DNA techniques. New NAAT of urine or vaginal swabs is highly sensitive and specific.

Azithromycin and doxycycline are the most effective drugs to treat chlamydia (Table 34.2). Erythromycin, ofloxacin (Floxin), and levofloxacin (Levaquin) offer alternatives. In pregnancy, azithromycin and amoxicillin are recommended; erythromycin is a poor alternative. Except in pregnancy, a test of cure is not recommended. As with gonorrhea, test of cures within a month of therapy should use culture and not NAAT because the latter may detect dead microbes and thus provide a false-positive result. Sexual partners should be treated; patient-delivered partner therapy decreases reinfection of the partner. Retesting of women with NAAT in 3 to 12 months detects reinfection.

Genital Mycoplasmas

Genital mycoplasmas often have been thought to be a microbe in search of a disease because they are ubiquitous and not highly virulent. *Mycoplasma hominis* is recovered from the vagina in 15% to 70% of women, and *Ureaplasma urealyticum* is recovered from 40% to 95%. A third and possibly more virulent isolate, *M. genitalium*, is now associated with cervicitis and endometritis. These organisms are phylogenetically positioned between bacteria and viruses.

The most convincing role for mycoplasmas in human female infections is as a pathogen in postpartum fever. Mycoplasmas are recovered from the blood of 10% to 15% of women with postpartum fever, and antibodies to

---

M. hominis are demonstrated in 50% of such women. Their role in salpingitis is less clear. Mycoplasmas are recovered from the tubes of 5% to 15% of women with salpingitis, but in primate model studies, *M. hominis* produces an adnexitis and not salpingitis.

U. urealyticum in the lower genital tract is not associated with low birth weight, and treatment of *U. urealyticum* does not reduce preterm births. However, *U. urealyticum* is recovered from intra-amniotic infection and is found in the cerebrospinal fluid and in lung infections of premature neonates. Recovery of *U. urealyticum* from fetal tissue of midtrimester spontaneous abortuses also suggests a relationship with abortion. The role of *U. urealyticum* in fertility is unsettled, but in recent reports, mycoplasmas were not related to infertility.

Both *M. genitalium* and *M. hominis* are sensitive to tetracycline. Erythromycin inhibits *U. urealyticum* in vitro but not *M. hominis*. However, neither antibiotic very effectively eradicates mycoplasmas from the vagina.

Anaerobic Bacteria

Anaerobic bacteria are highly associated with pelvic infections. Multiple anaerobic species, usually together with one or more aerobic bacteria, typically combine to form a polymicrobial infection. Intra-abdominal abscess and postoperative, postpartum, and postabortion infections are the most important examples of anaerobic infection.

Anaerobic bacteria are part of the normal vaginal flora. Although many mechanisms by which anaerobic bacteria become pathogenic are unknown, two mechanisms known to cause anaerobic infection include (a) production of anaerobic anatomical sites that occurs with tissue trauma from surgery and (b) antibiotic selection that preferentially inhibits aerobic but not anaerobic bacteria. Clinicians can virtually assume the presence of anaerobes in infections with a foul-smelling odor, as only anaerobes produce odorous metabolic products. Anaerobes also are virtually always present in an abscess. Anaerobic infections can also produce gas and cause thromboembolism.

The anaerobic bacteria most commonly cultured from genital infections include anaerobic gram-positive cocci (Porphyromonas and Peptostreptococcus species), gram-negative rods (Prevotella [*P. melaninogenicus*, *P. bivia*], Bacteroides [*B. fragilis*], and Fusobacterium species), and gram-positive rods (Clostridium species). Advanced nonculture DNA technology will undoubtedly uncover new species within typical anaerobic infections.

Cultures should be obtained before antimicrobial therapy is begun. Because anaerobes are part of the normal flora, deep tissue cultures are required that are not contaminated by surface bacteria. Anaerobe isolation is required for 48 hours or more, so antibiotic selection is usually based on clinical signs. Anaerobic infection should be particularly suspected with abscess formation, a foul odor, gas formation, tissue necrosis, sterile cultures from obviously infected sites, and thromboembolism. Antibiotic sensitivity testing is only a rough guide to antibiotic susceptibility, but in vitro and in vivo experience has shown that clindamycin, metronidazole, imipenem/cilastatin sodium (Primaxin), second- and third-generation cephalosporins (cefoxitin sodium [Mefoxin], cefotaxime sodium [Claforan]), and extended-spectrum penicillins (ticarcillin disodium/clavulanate potassium [Timentin], amoxicillin/clavulanate potassium) are effective to treat anaerobic infections.

Salpingitis

Acute primary salpingitis results when pathogenic bacteria in the cervix invade the fallopian tubes. *N. gonorrhoeae*, *C. trachomatis*, normal flora aerobic and anaerobic bacteria, and perhaps *M. genitalium* are known causes of tubal infections. New DNA nonculture technology likely will detect new microbes. Virtually all primary salpingitis occurs among sexually active, menstruating, nonpregnant women. About 50% to 60% of salpingitis is caused by gonococcal and chlamydial infections. Tuberculous, parasitic, or fungal salpingitis is rare in industrialized countries. About 85% of salpingitis usually occurs spontaneously without instrumentation of the genital tract; however, 15% of cases occur after instrumentation (e.g., IUD insertion, dilation and curettage, abortion, hysterosalpingography). Perisalpingitis secondary to acute appendicitis or other intra-abdominal infections accounts for less than 1% of cases.

Acute salpingitis is a common event that annually develops in up to 1% of women between 15 and 39 years of age. Young, sexually active women between 15 and 24 years of age have the highest rate of infection. This infection has tremendous cost; at least $1 billion is required to treat the 800,000 women with acute salpingitis in the United States annually, and $40 billion is spent to diagnose and treat tubal infertility.

Epidemiology

Most women are infected with sexually transmitted organisms. The rate of salpingitis is increased in women with multiple sexual partners and in young women is due to their increased rates of gonorrhea and chlamydial infection. Routine screening for *C. trachomatis* and *N. gonorrhoeae* has reduced the occurrence of salpingitis in Europe and parts of the United States. This reduction in salpingitis is impressive in screened populations. Annual screening for gonorrhea and chlamydial infection is recommended for women younger than 25 years and in those with multiple sexual partners. Such screening in turn prevents salpingitis, but it is expected to prevent subsequent tubal infertility and ectopic pregnancy more effectively than any

---

other means. Previous salpingitis also predisposes women to subsequent salpingitis, probably because mucosa damaged from prior infection is more susceptible to infection

than normal tissue. Patients with prior uncomplicated gonorrhea and chlamydial infection have a high rate of subsequent salpingitis.

The presence of an IUD is an independent risk factor for salpingitis. IUD users have a twofold to fourfold increased rate of both salpingitis and tubal infertility compared with non-IUD users. The highest rate of salpingitis in IUD users occurs within a few weeks of insertion as a result of the introduction of cervical bacteria into the endometrial cavity along with the IUD. However, most infections in IUD users occur long after insertion, probably because bacteria wick along the IUD tail from the vagina into the uterus and adhere to the IUD surface. IUDs also appear to enhance anaerobic bacterial growth, and IUD use is associated with Actinomyces and BV infection. Because IUD use also is associated with tubal infertility, an IUD should not be inserted in women who desire future pregnancy. By contrast, barrier or oral contraceptive methods appear to protect against salpingitis.

The role of male contacts with untreated gonococcal or chlamydial urethritis often is ignored by gynecologists. Only 25% of male contacts of women with gonococcal salpingitis are treated by the time the female partner develops symptomatic salpingitis, and most male contacts are asymptomatic. Men with nongonococcal urethritis represent reservoirs of chlamydial salpingitis. To reduce the rate of new and recurrent salpingitis, all male contacts of women with any type of salpingitis should be examined and tested. If positive, they should be treated appropriately.

Bacteriology

Neisseria Gonorrhoeae

In most U.S. studies, *N. gonorrhoeae* is recovered from 40% to 50% of women with acute salpingitis. However, gonococcal prevalence varies greatly: *N. gonorrhoeae* is isolated from less than 20% of salpingitis cases in Sweden and from 80% of cases in certain U.S. urban populations. In women with both cervical gonorrhea and salpingitis, *N. gonorrhoeae* is isolated from the tubes in only 30% of cases; the remainder have either no microbes or other microbes. Positive tubal gonococcal cultures are usually present only during the early stages of infection. Chlamydial infection frequently coexists with gonorrhea; in some studies, more than 50% of women with gonorrhea also had cervical *C. trachomatis*.

Chlamydia Trachomatis

C. trachomatis is as important as *N. gonorrhoeae* as a cause of acute salpingitis. From 30% to 60% of women with salpingitis have *C. trachomatis*, and in most of these women, the organisms was isolated from the fallopian tube. Application of new DNA tests for *C. trachomatis* identifies even more chlamydial infections. Chlamydial salpingitis is underdiagnosed because many patients have mild symptoms and remain undiagnosed. It is now evident that women with mild symptoms and signs have the same amount of severe tubal damage as those with severe symptoms. Chlamydial salpingitis often produces mild symptoms and signs, but tubal damage appears more severe than that shown in gonococcal salpingitis.

Nonsexually Transmitted Aerobic and Anaerobic Bacteria

Nonsexually transmitted aerobic and anaerobic bacteria are normally present in cervical and vaginal flora and particularly include organisms associated with BV. These microbes can be a direct cause of salpingitis, but they also cause secondary infection in combination with *N. gonorrhoeae* and *C. trachomatis*, IUD use, or instrumentation. Polymicrobial infection with these agents is common in salpingitis. In such cases, many different gram-positive and gram-negative aerobic and anaerobic organisms are isolated, particularly *Porphyromonas*, *Prevotella*, and *Bacteroides* spp., including *B. fragilis*. Anaerobic organisms are especially common in serious infections, and they virtually always are found in abscesses.

Mycoplasmas

Genital mycoplasmas are recovered from the tubes or cul-de-sac in 2% to 20% of patients with salpingitis. These organisms lack the virulence of *N. gonorrhoeae* and *C. trachomatis*, and they appear to cause an adnexitis rather than salpingitis. *M. genitalium* identified by DNA technology is related to endometritis.

Pathogenesis

Salpingitis occurs from vaginal and cervical bacteria ascending into the endometrium and fallopian tubes. This ascent of bacteria probably increases during menses, as evidenced by the onset of pain within 7 days of starting menses in one half to two thirds of patients with gonococcal salpingitis. Virulent gonococci also proliferate at menstruation, and less virulent gonococci are present at other times of the cycle. Other risk factors for salpingitis exist. Virulent bacteria in the cervix are more likely to cause salpingitis than nonvirulent bacteria, and *C. trachomatis* and *N. gonorrhoeae* represent virulent microbes particularly capable of causing salpingitis.

Specific bactericidal antibodies to *N. gonorrhoeae* appear to reduce salpingitis. Clinically recognized salpingitis develops in only 10% to 17% of women with cervical gonorrhea, and most of these women probably develop tubal infection during the first one or two menstrual periods after gonococcal acquisition and before antibody development.

C. trachomatis may not depend on menses for ascent into the endometrium. Endometritis caused by *C. trachomatis* appears to be a common chronic intermediate infection

---

that exists through several menstrual cycles. As mentioned, tubal damage from *C. trachomatis* appears to occur from the immune response to infection; thus, repetitive chlamydial infections can cause a hyperimmune response that accelerates tissue damage.

The usual route of infection with either microbe is the contiguous spread along mucosa from the cervix to the endometrial cavity and fallopian tubes (Fig. 34.5). Lymphatic or hematogenous dissemination of microbes to the adnexa is uncommon in nonpregnant women. It also is possible that organisms may be transported along the fallopian tubes by cilia or even carried by their attachment to spermatozoa.

Fitz-Hugh and Curtis Syndrome

Perihepatitis consisting of liver capsule inflammation without liver parenchymal damage is referred to as Fitz-Hugh and Curtis syndrome (Fig. 34.7). Swelling of the liver capsule produces pain with inspiration, usually in the right upper quadrant. A purulent or fibrinous exudate appears on the capsular surface. Violin-string adhesions between the liver capsule and the anterior abdominal wall are a late inflammatory manifestation.

Perihepatitis can be caused by both *N. gonorrhoeae* and *C. trachomatis*. Chlamydial heat shock protein is particularly associated with perihepatitis, indicating that the syndrome is another manifestation of a hyperimmune response to *C. trachomatis*. Some microbes travel transperitoneally from the fallopian tubes to reach the liver surface, but microbes may reach the liver by lymphatic and hematogenous routes as well. The syndrome usually occurs from salpingitis, but it occasionally follows appendicitis and other causes of peritonitis.

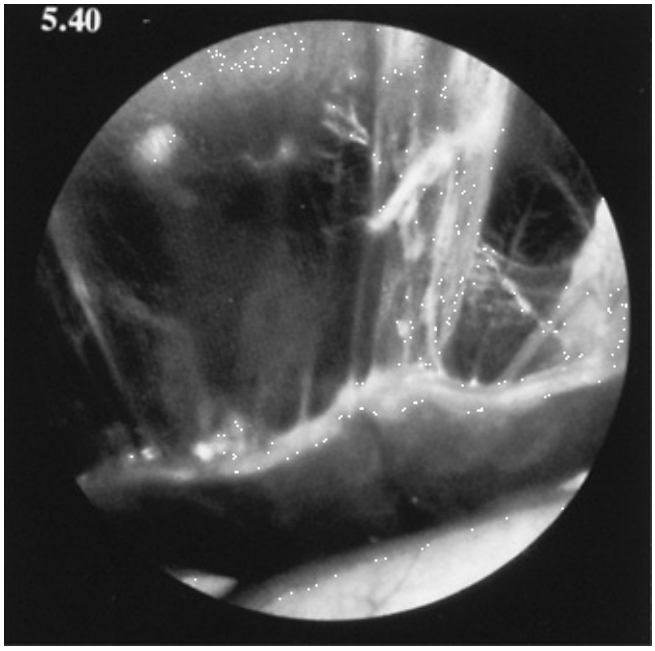

Figure 34.7 Liver adhesions in Fitz-Hugh and Curtis syndrome.

The Fitz-Hugh and Curtis syndrome is frequently misinterpreted as cholecystitis, viral pneumonia, or pyelonephritis. Liver enzyme levels may be mildly elevated. In women with salpingitis, 5% to 10% developed symptoms, but another 5% of women have asymptomatic perihepatitis. This latter group may have typical violin-string adhesions recognized as an incidental finding at a subsequent surgery. Many women with Fitz-Hugh and Curtis syndrome note the onset of lower abdominal pain before or with the upper abdominal pain, but some develop such severe upper abdominal pain that they fail to continue complaints of lower abdominal pain. Given the frequency of salpingitis and the infrequency of acute cholecystitis in women 15 to 30 years of age, Fitz-Hugh and Curtis syndrome is a more likely cause of upper quadrant pleuritic pain than cholecystitis and should be suspected in any

woman with pleuritic upper quadrant pain and physical signs of salpingitis. Laparoscopy is useful to diagnose unclear cases.

Diagnosis

The largest unsolved problem with salpingitis is the lack of sensitive and specific diagnostic criteria. For an estimated one half of women, salpingitis does not cause sufficiently typical symptoms to be diagnosed. In Table 34.3, women are presented who, despite not having a recognized episode of salpingitis, had severe enough tissue damage to cause infertility from tubal obstruction. Thus, patients with mild abdominal pain and other mild manifestations often are not identified. Emphasis must be placed on increasing the sensitivity of the diagnosis. The other problem is a varied and broad spectrum of clinical severity among patients with salpingitis. Although severe manifestations usually are recognized as salpingitis, they occur in only 30% of patients.

Insistence on rigid criteria, such as fever, severe tenderness, leukocytosis, and an elevated erythrocyte sedimentation rate (ESR), leads to a failure of diagnosis in a large number of nonovert cases.

From Eschenbach DA. Epidemiology and diagnosis of pelvic inflammatory disease. *Obstet Gynecol* 1980;55:142S, with permission.

On the other hand, a clinical diagnosis of salpingitis that relies on the history, physical examination, and nonspecific laboratory tests also has a large false-positive error rate. Several studies demonstrate that a clinical diagnosis of salpingitis can be confirmed by laparoscopy in about 65% of patients (Table 34.4); about 20% of patients had no disease observed, and another 15% had other pelvic conditions, most commonly ovarian cyst, ectopic pregnancy, appendicitis, or endometriosis at laparoscopy.

History

Important history and physical findings in patients with presumed PID are listed in Table 34.5. However, none of these findings distinguish women with salpingitis from those with other causes of pelvic pain. Lower abdominal pain is the most consistent symptom in women with overt salpingitis, although it may be mild or even absent. Acute pain is present for <15 days in 85% of patients who present with PID. Most women with gonococcal salpingitis experience acute pain around menses; in chlamydial salpingitis, the onset of pain is often insidious and not associated with menses. The abdominal pain usually is continuous and most severe in both lower quadrants; pain increases by movement, the Valsalva maneuver, and intercourse. Abnormal vaginal bleeding occurs in 15% to 35% of women with salpingitis. Symptoms of appendicitis and ectopic pregnancy overlap with those of PID. The risk of STI can be helpful to form a tentative opinion. An increased risk of PID would be expected for women with multiple sexual partners, other STIs, symptomatic male sexual partners, and prior gonorrhea or PID.

TABLE 34.5 Clinical Findings in 176 Women with Suspected Acute Pelvic Inflammatory Disease

Finding	When PID Is Present (%) (n = 134)	When PID Is Not Present (%) (n = 142)
Mean duration of symptoms (d)	11	24
Abnormal vaginal bleeding	16	26

Nausea/vomiting	28	31
Mean temperature on admission	37.6°C	37.3°C
Abdominal rebound/guarding	61	52
Cervical motion tenderness	80	69
Adnexal tenderness	90	79
Adnexal mass, fullness	19	12

PID, pelvic inflammatory disease.
From Morcos R, Frost N, Hnat M, et al. Laparoscopic versus clinical diagnosis of acute pelvic inflammatory disease. *J Reprod Med* 1993;38:53, with permission.

Physical Examination

Most patients with overt salpingitis have lower abdominal, cervical, and bilateral adnexal tenderness (Table 34.5). Cervical motion tenderness is a sensitive indicator of salpingitis. However, none of these findings is specific for PID, and patients with other disease or with no apparent disease can have similar physical findings. Other associated findings lack the sensitivity to be useful. For example, although a temperature of 100.4°F (38°C) or higher is present more often in patients with salpingitis than in those without it, only 45% of patients with laparoscopically confirmed salpingitis have a temperature >100.4°F.

Laboratory Tests

Nonspecific tests such as the peripheral WBC count and the ESR are helpful only when the results are abnormal, but they often are normal. Of patients with laparoscopically confirmed salpingitis, 50% have a normal WBC count and 25% have a normal ESR. C-reactive protein levels may be more useful.

Laboratory signs such as yellow cervical mucopus and a cervical Gram stain with an increase of PMNs of more than 30 per high-powered field appear to offer a more specific

indication of salpingitis in patients with pelvic tenderness. It is mandatory to test for gonorrhea and chlamydial infection. Cervical culture for other organisms is not recommended.

Endometrial Biopsy

Endometrial biopsies are easy and safe to obtain. Standard histologic criteria of endometritis are listed in the Endometritis section. Histologic endometritis has a 90% sensitivity and specificity to diagnose salpingitis compared with laparoscopy.

Ultrasound and Computed Tomography

Abnormal vaginal ultrasound findings correlate with a diagnosis of salpingitis made by laparoscopy, but such findings remain too insensitive in women with mild tubal abnormalities for a certain diagnosis. Ultrasound is useful to distinguish an abscess from an inflammatory mass within the adnexa, define a mass in obese or excessively tender patients, and follow the size of a mass with treatment. Computed tomography has been used successfully for the same purposes; it may be especially helpful if ultrasound is difficult to perform.

Laparoscopy

Laparoscopy currently provides the most accurate way to diagnose salpingitis. It should be used when the diagnosis is unclear, particularly in patients with severe peritonitis, to exclude a ruptured abscess or appendicitis. It is estimated that for every 100 times a clinical diagnosis of PID is made without visual confirmation, three patients with appendicitis are treated for PID (Table 34.4), resulting in a critical delay in the correct diagnosis. Pain and tenderness from acute PID should abate 3 or 4 days after antibiotics begin. Patients without reduced tenderness on antibiotic therapy also benefit may from laparoscopy. About 20 of 100 women with a clinical diagnosis of PID have no abnormality at laparoscopy, and women not responding to antibiotics without PID can be detected by laparoscopy rather than providing another antibiotic. In all cases where laparoscopy is performed, cultures should be taken from the fimbriae of tubes, regardless of the findings, to detect the small number of patients with endosalpingitis and normal-appearing tubes.

Open laparoscopy can be used to identify and percutaneously drain pelvic abscesses. The abscess is visualized, and a 14-French catheter is placed into the abscess, which is drained of pus and carefully rinsed with sterile bacteriostatic water. A closed drainage system is then connected to the catheter for 1 to 3 days until drainage ceases. About 90% of abscesses are successfully treated by percutaneous drainage.

Examination of the Male Partner

Examination of the male sexual partner helps to establish the diagnosis of PID and treat STIs. At least 80% of male contacts of women with PID are not treated by the time PID occurs in the female partner. If there is no urethral discharge, a Gram stain and urethral

material should be tested for *N. gonorrhoeae* and *C. trachomatis*.

Treatment

Adequate treatment of salpingitis includes an assessment of severity, antibiotic therapy, additional general health measures, close patient follow-up, and treatment of the male sexual partner. Patients with mild clinical manifestations can be treated as outpatients. Specific indications for hospitalization include severe clinical manifestations (i.e., severe peritonitis, severe nausea, or fever higher than 100.4°F [38°C]), a suspected abscess, outpatient antibiotic failure, pregnancy, and an uncertain diagnosis.

Patients should be examined within 2 to 3 days and again at 7 and 21 days later to verify a satisfactory response to treatment. If an IUD is in place, it should be removed 24 to 48 hours after therapy is started. Ideally, an antibiotic should be selected according to the microbe isolated, but in salpingitis, empiric therapy is used. The treatment regimens recommended by the CDC were designed to treat gonococcal, chlamydial, and anaerobic salpingitis. Inpatient regimens include either intravenous cefoxitin or cefotetan disodium (Cefotan) and oral doxycycline or intravenous clindamycin and gentamicin, followed by doxycycline or oral clindamycin for a total of 14 days. The clindamycin regimen also is effective for patients with chlamydial infection. Parenteral therapy can be stopped 24 hours after clinical improvement. Outpatient regimens include a loading dose of an antibiotic recommended to treat gonorrhea and chlamydial infection with an option to treat for anaerobic infection. Treatment regimens that involve quinolones are no longer recommended to treat PID because of gonococcal resistance to quinolones. The outpatient regimens include ceftriaxone, cefoxitin with probenecid or ceftizoxime or cefotaxime in a single dose plus doxycycline with or without or metronidazole, 500 mg twice daily for 14 days. Alternative regimens of levofloxacin or ofloxacin should be used only in areas with low gonococcal resistance; a gonococcal culture is needed before treatment. Gonococcal salpingitis responds more rapidly to antibiotics than nongonococcal salpingitis. Recommended agents must be used in full doses because partially treated, subacute salpingitis may result from lower antibiotic doses.

Hospitalized patients with peritonitis but no adnexal abscess usually respond rapidly to any regimen. An adnexal abscess, even if systemic manifestations are mild, should be treated with antibiotics such as clindamycin, metronidazole, cefoxitin, or imipenem/cilastatin that inhibit *B. fragilis* because of its frequency in pelvic abscesses.

A ruptured abscess requires emergency abdominal surgery to prevent septic shock. Colpotomy drainage usually is preferable for an unruptured midline abscess in the cul-de-sac attached to the vagina. If laparotomy is performed for a presumptive diagnosis of appendicitis but

---

instead acute salpingitis is found, the procedure should be limited to microbiologic testing and closure of the abdomen. If laparotomy is required for an unresolved abscess or adnexal mass, surgery should be limited to the most conservative procedures that will effectively eliminate infection. Unilateral abscesses respond to unilateral salpingo-oophorectomy if appropriate antibiotic regimens are used, and routine hysterectomy and bilateral salpingo-

oophorectomy are seldom needed to treat acute salpingitis in young women. As mentioned, percutaneous drainage of abscesses usually is successful, but ovarian abscess after gynecologic surgery is particularly resistant to antimicrobial treatment.

When chronic pain occurs, surgery should be deferred as long as possible to allow maximum healing. Analgesics and oral contraceptives to prevent ovulation may suffice until swelling and tissue fixation decreases. Surgery may be indicated for persistent pain that is not responsive to conservative measures, for recurrent attacks of pelvic pain, or for an unresolved pelvic mass. Laparoscopy with lysis of adhesions usually suffices, but adnexectomy or, rarely, even hysterectomy is required.

Genital Tuberculosis

Female genital tuberculosis remains relatively uncommon in the United States. Less than 1% of salpingitis is attributed to *Mycoplasma tuberculosis*. Pulmonary tuberculosis remains a problem throughout the world, where the rate has paralleled that of HIV infection. Although the spread of tuberculosis from the primary pulmonary infection to the pelvis usually occurs early in tubercular infection, early detection of genital infection is seldom feasible. Genital tuberculosis develops in about 10% of patients with pulmonary tuberculosis.

Pathogenesis

Virtually all genital infections are secondary to a pulmonary infection. Genital infection occurs when *M. tuberculosis* spreads through the bloodstream from a pulmonary site to the fallopian tubes, usually within a year of primary infection (Figs. 34.8, 34.9). Direct extension occurs from the tube to several directions: the pelvic peritoneum and ovary, the endometrium, and the cervix. Less common lymphatic extension to the genitalia can occur from abdominal sources or by direct extension from the intestinal tract. Genital tuberculosis seldom occurs because of an ascending infection from a sexual partner.

The initial tubal lesion may remain localized for considerable time (in some cases years), or it may extend to the interior tubal mucosa. Endosalpingitis results in an exudative phase where ulcer formation at the site of caseous degeneration produces a typical moth-eaten pattern hysterosalpingogram. In contrast to bacterial salpingitis, tubal occlusion, particularly fimbrial closure, does not occur early in tuberculous, and the tubes may remain patent despite marked tubal wall destruction. Dense peritubal adhesions are characteristic of tubercular infection.

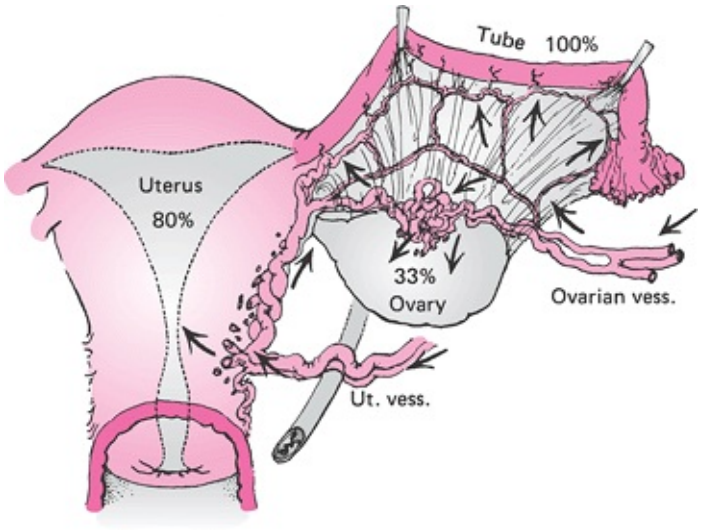

Figure 34.8 Mode of transmission of tuberculous pelvic infection. Tubercle bacillus invades pelvic organs by way of the bloodstream from distant focus in the lung or other organ. (From Wharton LR. *Gynecology and female urology*. Philadelphia: WB Saunders, 1943, with permission.)

Tubal infection is present in virtually all women with genital tuberculosis. Endometrial infection is present in 50% to 80% of cases. Infected endometrium is shed monthly at menses, and the endometrium becomes reinfected from tubal seeding. Cervical infection occurs in only

10% to 25% of patients, resulting in either a papillomatous or ulcerative lesion that can grossly resembles cervical carcinoma.

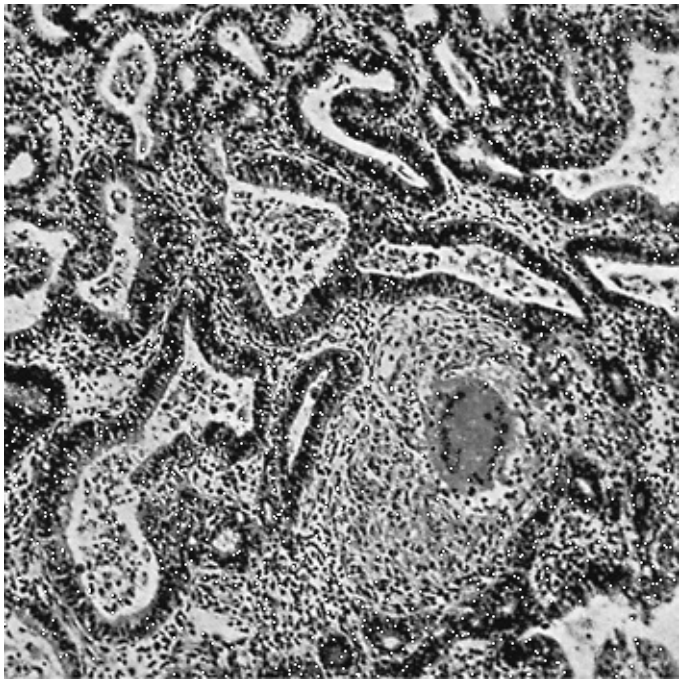

Figure 34.9 Tuberculosis of fallopian tube (105×). (From Curtis AH, Huffman JW. *A*

textbook of gynecology, 6th ed. Philadelphia: WB Saunders, 1950, with permission.)

Clinical Forms

Latent Genital Tuberculosis

In the latent form, genital tuberculosis appears partially or completely arrested after the initial tubal infection, and patients have few or no pelvic complaints. Pelvic physical findings are normal. The diagnosis usually is made during the investigation of infertility (by endometrial sampling) or by chance at laparotomy. In the latent phase, a precarious balance exists between the disease and the host defense mechanisms. Active but latent infection can occur 30 years after an initial infection.

Tuberculous Salpingitis

Tuberculous salpingitis is a more advanced infection that may develop immediately after the primary hematogenous tubal spread, or it may follow a prolonged latent phase. The tubes are grossly enlarged by inflammation. Although the symptoms and findings can mimic those of acute bacterial salpingitis, clinical manifestations usually are indolent and prolonged. Tuberculous salpingitis does not respond to the antibiotic therapy used for acute bacterial salpingitis. Despite these differences from bacterial salpingitis, tuberculosis is often discovered only by histologic examination of an excised tube.

Tuberculous Peritonitis

In tuberculous peritonitis, widespread infection of all peritoneal surfaces produces ascites, fine egg-white–appearing adhesions, and innumerable small nodules (i.e., tubercles) throughout the abdomen from hematogenous or lymphatic spread. The serosal surfaces of the pelvic organs are typically involved, and the tubes are often patent.

Diagnosis

A history of pulmonary tuberculosis commonly is present in patients with genital tuberculosis, but simultaneous active pulmonary infection is uncommon. A normal chest film does not exclude genital tuberculosis; pulmonary lesions are found in only 30% to 50% of genital tuberculosis cases. The most common complaints are sterility and pelvic pain. Deteriorating health and menstrual abnormalities also may occur. Menorrhagia may be associated with abdominal pain, but amenorrhea or oligomenorrhea also occurs with tuberculous peritonitis. Most women with genital tuberculosis are in their 20s and 30s, but because of the frequent tendency for long latency periods, the disease may activate even after menopause. As mentioned, tubal tuberculosis may mimic acute bacterial salpingitis. However, when a pelvic problem does not conform to expected rules, the first consideration should be ectopic pregnancy and the second should be pelvic tuberculosis. Pelvic tuberculosis should be strongly considered when salpingitis occurs in a virginal

woman.

A first-strength, purified protein derivative tuberculin skin test is important because a negative result virtually rules out tuberculosis. Diagnosis is best established by endometrial biopsy, which should be performed in the week before menstruation, when the endometrium is thickest and most likely to contain tubercles. A portion of the specimen should be cultured for *M. tuberculosis* and the remainder submitted for histologic examination. Repeated cultures of menstrual blood also can be obtained. If cultures of either biopsy specimens or menstrual blood are negative, endometrial curettage may be positive. Antimicrobial susceptibility testing should be performed to detect drug resistance.

Endometrial tissue can provide an exact diagnosis of genital tuberculosis if the results are positive; if the results are negative, tuberculosis cannot be excluded. Diagnostic laparotomy is indicated if these measures fail to verify a diagnosis in a patient with a history and pelvic findings suggestive of genital tuberculosis. Diagnostic laparoscopy may be performed if there is minimal likelihood of tuberculous peritonitis, but caution must be used because of the possibility of perforating a loop of adherent bowel. Hysterosalpingography may reveal a characteristic tubal pattern, but it also may cause disease exacerbation and should not be used if tuberculosis is possible.

The incidental discovery of reproductive tract tuberculosis may be the first indication of tuberculosis. In such patients, it must be determined whether or not other sites (e.g., lungs, urinary tract, bone, and gastrointestinal tract) also are infected.

Treatment

A four-drug initial phase therapy for 2 months is then followed by isoniazid and rifampin alone for 4 to 7 months. The initial drugs taken daily are isoniazid, 300 mg; rifampin, 600 mg; pyrazinamide, 1,500 mg; and ethambutol, 1,200 mg. Extended regimens for 9 months are used in indicated conditions. Patients without adnexal masses should have an endometrial biopsy for culture and microscopic examination 6 and 12 months after starting therapy. Persistent *M. tuberculosis* needs to be susceptibility tested to identify drug-resistant strains. Laparotomy is performed if adnexal masses persist for 4 months, and rifampin or streptomycin should be given preoperatively. Bilateral salpingectomy and removal of other tuberculous foci may be performed in young women with minimal disease. A bilateral salpingo-oophorectomy and total hysterectomy are indicated for advanced disease or advanced age. Pregnancy after tubal tuberculosis is rare, even in women with minimal disease. If the tubes are damaged by genital tuberculosis, efforts to improve fertility by tubal operations usually are futile.

Summary Points

- STIs are common, particularly in young sexually active women with multiple sexual partners. However, most STIs occur among the larger population of women who are not at high risk for STIs.
- STIs often are asymptomatic for both women and their sexual

partners.
- Many classic symptoms associated with various STIs are common in women without infection, and conversely, they are not present in many women with STIs.
- Many signs present in women with STIs are common, and they are present in women with no identifiable infection. Specific laboratory tests usually are required to confirm infection.
- The best course of treatment for STIs incorporates a combination of antimicrobial therapy directed at the patient and her partner; education about reducing STI exposure; and when appropriate, careful follow-up examination and testing.

Benign Vulvovaginal Disorders

Lori A. Boardman
Colleen M. Kennedy

Vulvovaginal symptoms are common, often chronic, and can significantly interfere with women's sexual function and sense of well-being. Obtaining expert medical advice to deal with such complaints can be frustrating. The goal of this chapter is to provide a working knowledge of appropriate diagnostic and counseling tools and a structured framework in which to approach the evaluation and management of common, but frequently problematic, as well as uncommon vulvovaginal disorders. To that end, commonly encountered infectious conditions, such as various manifestations of human papillomavirus (HPV)-associated disease, herpetic infections, and the acute vaginitides, as well as chronic forms of common infections, such as vulvovaginal candidiasis and bacterial vaginosis, will be discussed. Other topics to be covered include autoimmune disorders, including lichen sclerosus and lichen planus; inflammatory disorders, including contact dermatitis and lichen simplex chronicus; an overview of common benign cysts and pigmented vulvar lesions; and lastly, vulvodynia.

Vulvovaginal Infections (Viral, Fungal, Bacterial, Other)

Human Papillomavirus and External Genital Warts

Genital HPV, the most common sexually transmitted viral infection, is associated with a number of vulvar epithelial disorders such as genital warts, vulvar intraepithelial neoplasia (VIN), and some vulvar carcinomas. In excess of 100 HPV subtypes have been identified, of which more than 30 are specific to the anogenital tract. Although low-risk HPV types are implicated in the development of genital warts (90% of which are associated with types 6 and 11) and oncogenic HPV 16 is commonly found in warty-basaloid or undifferentiated VIN, the routine use of HPV testing in the diagnosis of vulvar HPV-related disease is not currently recommended.

Genital warts often present as bumps or growths on the moist surfaces of the vulvovaginal or perianal mucosa and can cause itching, burning, pain, or bleeding. Distinguishing warts from vulvar neoplasia based on appearance alone is not always possible. In general, hyperpigmented, indurated, fixed, or ulcerative lesions and lesions that do not respond to

treatment or worsen during treatment should be biopsied, as VIN can present as red, white, dark, raised, or eroded lesions (Figs. 35.1, 35.2). If the diagnosis is uncertain or the patient is immunocompromised, biopsy should be undertaken. Women with genital warts should undergo routine cervical cancer screening. The use of HPV testing, a change in the frequency of cervical cytologic screening, or cervical colposcopy are not indicated in the presence of genital warts. If exophytic cervical warts are detected during examination or if vulvar neoplasia is confirmed by biopsy, referral for colposcopic evaluation is indicated.

Although spontaneous regression of genital warts can occur in up to 30% of affected patients, many patients opt for therapy. Currently recommended treatment options for genital warts focus largely on physical destruction or removal of visible disease. These include podofilox 0.5% solution or gel (patient-applied) as well as the provider-administered therapies: cryotherapy, podophyllin resin 10% to 25%, trichloroacetic or bichloroacetic acid 80% to 90%, surgical removal, and laser therapy (Table 35.1). Such therapies have been the mainstay of treatment, along with imiquimod, a targeted antiviral therapy. Local irritation (e.g., pain, burning, and soreness), erythema,

edema, and, at times, ulceration can result from the use of any of these medications. Surgical excision or laser vaporization should be reserved for patients with extensive disease.

Figure 35.1 Vulvar intraepithelial neoplasia 3.

Podofilox (keratolytic) and imiquimod (antiviral) are newer therapeutic choices that patients and providers find both efficacious and preferable. Clearance rates for the two treatments are similar and compare favorably to any of the treatments listed previously. The added benefit of imiquimod, as demonstrated in numerous studies, has been its significantly lower recurrence rates (9% to 19%).

Intralesional interferon, a medication with antiproliferative, antiviral, and immunomodulatory properties, has, unlike imiquimod, demonstrated limited efficacy and is

not recommended for first-line therapy in treating either warts or VIN. Its use, however, can be considered an alternative regimen for the treatment of external genital warts. Finally, with regard to pregnancy, the data regarding long-term sequelae in infants and children infected with HPV at delivery are inconsistent and do not justify routine cesarean section in women with genital warts.

TABLE 35.1 Treatment of Genital Warts

Therapy	Treatment	Application	Use in Pregnancy	Recur Rates
Patient applied	Imiquimod 5% cream	Apply at bedtime three times a week for up to 16 wk. The area treated should be washed with soap and water 6–10 h after use.	Safety not established	9–19
	Podofilox 0.5% solution and gel	Apply twice daily for 3 d followed by 4 d without therapy; the cycle may be repeated up to four times. The total wart area treated should not exceed 10 cm^2, and the total volume should be limited to 0.5 mL per day.	Safety not established	4–91

Provider applied	Cryotherapy	Liquid nitrogen or cryoprobe. May repeat applications every 1–2 wk.	Yes	21
	Podophyllin resin 10% to 25% in compound of tincture of benzoin	Carefully applied to the wart and then washed off by the patient between 1 and 4 h after application. May repeat weekly if needed. To avoid toxicity, (a) application should be limited to <0.5 mL podophyllin or an area of <10 cm^2 warts treated per session and (b) no open lesions or wounds present in treatment area.	Safety not established	23–65
		First, coat the surrounding normal epithelium with a protective substance (e.g., 5%		

		lidocaine gel) and then use a small cotton-tipped applicator to apply		
Trichloroacetic or bichloroacetic acid 80% to 90%		medication to the wart. Allow to dry before the patient sits or stands. If excess acid used, treated area should be powdered with talc, sodium bicarbonate, or liquid soap preparations. May repeat weekly, if needed.	Yes	63
Surgical removal		Tangential scissor excision, tangential shave excision, curettage, or electrosurgery	Yes	19–29

Herpes Simplex Virus

Herpes simplex virus (HSV) is the most common cause of ulcerative genital lesions. Less common causes of ulcerative vulvar disease are shown in Table 35.2. HSV-1 typically causes orolabial lesions and herpes keratitis, while HSV-2 primarily infects the anogenital tract via genital–genital sexual contact with an infected partner who is shedding virus. Infection with HSV-2 is common, involving 25% of adults aged 30 and older in the United States, although most remain unaware that they are infected. Significant crossover of subtypes, however, does exist, with estimates indicating HSV-1 infection in approximately 20% of current cases of genital herpes in the United States.

Primary infection with HSV presents with multiple, superficial, painful ulcerations of the lower genital tract and tender inguinal adenopathy. Systemic symptoms (including fever, malaise, and headache) occur in approximately 60% of women. Periodic reactivation results in either clinically apparent lesions or, more commonly, asymptomatic infection. Recurrent lesions, in general, are less severe. Approximately half of patients who recognize recurrences report prodromal symptoms in the hours to days before the onset of genital lesions. In recurrences, the duration of viral shedding is shorter, and few lesions are present. Asymptomatic viral shedding, however, accounts for most HSV transmission.

While 90% of patients with a first documented episode of genital HSV-2 infection will have a least one recurrence within the first year following diagnosis, 38% will have six or more recurrences, and 20% will suffer ten or more recurrences. Compared with HSV-2 infections, genital HSV-1 infections recur less frequently. With time, recurrences do decrease, irrespective of viral type and use or nonuse of suppressive therapy. The major complications of HSV infection include multiple neurologic sequelae, the most common of which is aseptic meningitis, seen in approximately one third of women with primary infection. Immunocompromised patients are at risk for prolonged or severe episodes of genital, perianal, or oral herpes. HSV-related lesions are common in HIV infection, and shedding is increased in this population, even in the presence of antiretroviral therapy.

Clinical history and physical findings often guide the diagnosis of genital herpes. Viral culture can be used to confirm the diagnosis, realizing its inherent limitations. While roughly 95% of the early vesicular lesions of herpes will grow HSV, only 70% of ulcerative lesions and 30% of crusted lesions will yield evidence of the virus. Type-specific serologic testing for HSV may be of use in confirming infection in patients with crusted lesions or with an unclear history of past infection for whom the diagnosis would be clinically helpful (e.g., women with HIV infection or those with partners known to be HSV positive). Finally, any woman presenting with genital ulcers should undergo HIV testing as part of her evaluation.

The cornerstone of treatment for HSV infection consists of the nucleoside analogue antiviral medications: acyclovir, famciclovir, and valacyclovir. All may be used in the treatment of primary and nonprimary first episodes, episodic recurrent episodes, and as suppressive therapy in patients with six or more annual outbreaks. Suppressive therapy also can be considered in patients with less frequent recurrences, as the use of such therapy has been shown to be safe, efficacious, and associated with improvement in quality-of-life indicators. All three medications significantly decrease the number of days of viral shedding, local pain and dysuria, hasten the healing of lesions, and decrease the production of new lesions 48 hours after initiating therapy. No one therapy emerges superior, although valacyclovir can be administered less frequently due to enhanced absorption following oral administration. Topical therapy with acyclovir cream or ointment has not been shown to be effective. Current recommendations for antiviral regimens are included in Table 35.3.

Tinea Cruris (Dermatophytosis)

A superficial fungal infection caused most commonly by *Epidermophyton floccosum* and *Trichophyton rubrum* or less commonly by *Trichophyton mentagrophytes*, tinea cruris presents as a pruritic, pale red skin eruption with annular scaling margins. Over the course of weeks, the rash will spread slowly from the groin. The infection usually is found in young adults and results from either sexual transmission or autoinoculation. The rash associated with tinea cruris typically is well defined and sharply marginated, spreading in an annular pattern peripherally from the groin. In women, the rash normally first appears in the hair-bearing portion of the vulva but can extend to the inguinal area and buttocks (Fig. 35.3). The diagnosis can be confirmed by microscopic evidence of hyphae. A sample can be obtained by scraping scale from the leading edge of the rash onto a glass slide. A drop of 10% potassium hydroxide is placed on the slide, followed by a cover slip.

While more than 25 randomized controlled trials document the efficacy of antifungal therapy, few evaluate the two different classes of antifungals used for tinea cruris head to head. Based on available evidence, however, no superior treatment emerges between the topical allylamines or allylamine derivatives (terbinafine available as a 1%

---

emulsion gel, cream, or spray/solution; naftifine 1% cream, or butenafine 1% cream) as compared with the azole antifungals (such as 1% clotrimazole cream or 2% miconazole cream). While the allylamines are significantly more costly, they do allow for a shorter

duration of treatment (once daily for 1 week compared with 2 to 3 weeks for the topical azoles).

Acyclovir prophylaxis, beginning at 36 weeks gestation, is recommended for women with a history of first-episode herpes during the pregnancy or recurrent genital herpes. Prophylaxis has been shown to reduce the risk of recurrences at term, thereby decreasing the need for cesarean section. Recommendations adapted from Centers for Disease Control and Prevention, 2006.

Vulvovaginal Candidiasis

Estimates indicate that 75% of sexually active women will experience the symptoms of itching, irritation, soreness, dyspareunia, and dysuria associated with candidiasis; 45% of women will experience two or more vaginal yeast infections; and 5% will suffer from recurrent (four or more episodes a year) vulvovaginal candidiasis. Most candidal infections are sporadic and, in over 90% of cases, are caused by *Candida albicans*. Uncomplicated vulvovaginal candidiasis is defined as sporadically or infrequently occurring, of mild to moderate intensity, most likely secondary to *C. albicans*, and involving immunocompetent women. Complicated candidiasis includes women with recurrent infection, severe manifestations of candidiasis (extensive vulvar erythema, edema, excoriation, and fissure formation) (Fig. 35.4), or infection with nonalbicans species as well as women with uncontrolled diabetes, debilitation or immunosuppression, or those who are pregnant. Women with complicated candidiasis, particularly recurrent disease, account for the majority of physician visits by women for chronic vaginitis, and it is this group that will be the focus of the remaining discussion. Women with recurrent candidiasis present a challenge both in terms of evaluation and treatment. Although nonalbicans species should be suspected and culture clearly is warranted in this population, it should be remembered that repeated vulvovaginitis most commonly occurs with persistent *C. albicans*. Nonalbicans *Candida* sp. occur in approximately 10% to 20% of women with recurrent disease. While testing for diabetes or immunosuppression is often suggested for women with recurrent disease, in only a minority of patients will such testing be profitable. For example, postmenopausal women with recurrent yeast infections should be assessed for the presence of diabetes. Recurrent vulvovaginal candidiasis, however, should not be used as the sole indication to prompt HIV testing.

A reliable diagnosis cannot be made based on symptoms or signs in the absence of corroborative laboratory data. Determination of the vaginal pH as well as direct microscopy should be performed. A vaginal pH <4.5 is consistent with candidiasis, although an elevated pH does not exclude this diagnosis, as concomitant infection with bacterial

raise the vaginal pH. The sensitivity of KOH microscopy, while reportedly better than that of saline microscopy, has been estimated to range from 38% to 83%; as a result, the absence of yeast argues against but cannot exclude candidiasis. Given the limitations of current office testing and the increased likelihood of nonalbicans species among women with recurrent disease, initial evaluation should include vaginal cultures obtained on at least two occasions, preferably while the patient is symptomatic. If two consecutively obtained cultures are negative for *Candida* sp., the diagnosis of recurrent disease can be excluded.

Figure 35.3 Tinea cruris.

For uncomplicated candidiasis, a variety of topical and oral medications can be used (Table 35.4). Treatment results in relief of symptoms and mycologic cure rates in 80% to 90% of patients who complete therapy. While cure rates are similar between topical and oral therapies, patients strongly prefer the oral route of administration. Side effects of topical medications are limited largely to local reactions (burning, itching, and irritation), while oral fluconazole is associated more commonly with nausea and headache.

Conventional antifungal therapy is not as effective in patients with complicated candidiasis. In general, patients with severe disease and patients who are pregnant, immunosuppressed, or debilitated will require longer courses of topical therapy (7 to 14 days) or if not pregnant, sequential doses of fluconazole (taken on days 1 and 4). For recurrent infection with *C. albicans*, the patient should be treated with the same regimen

used for severe disease followed by maintenance therapy with 6 months of either oral medication (weekly fluconazole in a 100-mg, 150-mg, or 200-mg dose) or clotrimazole (200 mg topically twice a week or a 500-mg vaginal suppository weekly). In a recent randomized controlled trial of suppressive therapy with fluconazole, women with recurrent disease on maintenance medication for 6 months, compared with those on placebo, were significantly more likely to remain diseasefree at both 6 months (91% vs. 36%) and at follow-up off medication 6 months later (43% vs. 22%). Lastly, while often a concern, complicated candidiasis caused by fluconazole-resistant *C. albicans* remains uncommon.

Figure 35.4 Severe vulvovaginal candidiasis.

Nonalbicans infections (e.g., *C. glabrata*, *C. krusei*, *C. parapsilosis*, *and C. tropicalis*) do not typically respond to treatment with fluconazole, often secondary to an intrinsic resistance to this medication. Recommended first-line therapy, then, is a 7- to 14-day course of a nonfluconazole azole (oral or topical). If treatment fails, a 2-week course of nightly boric acid vaginal suppositories (600 mg in a 0 gel capsule) is recommended. Both clinical and mycologic cure rates with this regimen approach 70%. If not successful, however, the patient should be referred to a specialist

for further management. For recurrent disease, suggested maintenance therapy regimens include a 6-month course of a nightly nystatin vaginal suppository or twice-weekly boric acid vaginal suppositories.

TABLE 35.4 Treatment of Uncomplicated Vulvovaginal Candidia Bacterial Vaginosis, and Trichomoniasis

BV, bacterial vaginosis.
*Cells highlighted in gray indicate alternative regimens.
Adapted from Centers for Disease Control and Prevention, 2006.

Bacterial Vaginosis

BV is a complex polymicrobial disorder characterized by decreased lactobacilli, primarily the hydrogen peroxide–producing strains *Lactobacillus crispatus* and *L. jensenii* and increased colonization by facultative or strictly anaerobic microorganisms such as *Gardnerella vaginalis*, *Peptostreptococcus* sp., *Prevotella* sp., *Mobiluncus* sp., *Bacteroides* sp., and *Mycoplasma hominis*. Although BV is the most common cause of vaginitis, its prevalence varies. For example, black, non-Hispanic women as well as women reporting a history of douching in the past 6 months were found to be at increased risk of BV in a recent study using data from the National Health and Nutrition Examination surveys. In other studies, rates vary from 5% to 26% among pregnant women worldwide, while higher rates have been documented in women attending sexually transmitted disease (STD) clinics (24% to 37%). From an epidemiologic standpoint, BV is thought to be sexually associated at minimum, although multiple studies have failed to show a benefit from partner treatment in preventing recurrent BV.

BV has been associated with a number of reproductive complications, including preterm labor, premature rupture of membranes, and low birth weight. Possible gynecologic sequelae consist of a variety of postsurgical complications, including postabortal endometritis and vaginal cuff cellulitis or abscess formation following hysterectomy as well as pelvic inflammatory disease (PID). Finally, BV appears to be a risk factor for the acquisition and transmission of HIV infection as well as the acquisition of HSV-2 infection.

The gold standard for diagnosing BV is the Nugent score, derived based on the Gram stain and used primarily in the research setting. For the practitioner, the diagnosis of BV most often is made clinically by using vaginal pH and the wet or saline preparation. To secure the diagnosis, three of four Amsel criteria must be met: (a) homogeneous, thin, white discharge that smoothly coats the vaginal walls;

(b) vaginal pH >4.5; (c) a fishy odor of vaginal discharge before or after the addition of 10% potassium hydroxide (positive amine or “whiff” test); and (d) the presence of more than 20% of epithelial cells as clue cells on microscopy. Compared with the Nugent score, Amsel criteria have a sensitivity of 92% and a specificity of 77%, although evidence suggests that

the combination of any two of these clinical criteria will achieve similar sensitivity and specificity. Women found to have evidence consistent with the diagnosis of BV on a Pap smear should be evaluated clinically only in the presence of symptoms and treated if Amsel criteria are fulfilled.

The Centers for Disease Control and Prevention (CDC) currently recommend three treatment protocols for BV—oral metronidazole, topical metronidazole, or topical clindamycin (Table 35.4). Women using metronidazole should avoid alcohol intake during the course of therapy and for 24 hours thereafter due to the possibility of a disulfiramlike reaction. Clindamycin cream can weaken latex condoms and diaphragms, an effect that can persist up to 5 days following treatment. In addition, therapy with either metronidazole or clindamycin is associated with an elevated risk of candidiasis (10% to 30%).

Although there is no published data on the effect of treatment for BV prior to hysterectomy, a randomized, double-blind study of treatment prior to first-trimester abortion showed a significant reduction in PID among those in the treatment arm. Based on such evidence, the CDC recommends screening and treatment for BV before invasive gynecologic procedures. Although not explicitly recommended, the CDC STD treatment guidelines for PID state that many experts recommend oral metronidazole in addition to the standard outpatient regimen for PID.

Short-term studies indicate that while initial cure rates for BV range from 70% to 90%, recurrence rates are high. Within 3 months of therapy, recurrences are seen in approximately 15% to 30% of women, although rates of 60% to 70% have been documented. Despite promising evidence, there currently is no clearly superior evidence-based method of treatment for recurrent BV. Multiple regimens have been suggested, including lactobacilli replacement therapy, maintenance acetic acid gel, and prolonged therapy with metronidazole. In a placebo-controlled trial of *L. crispatus* vaginal capsules, recolonization with *L. crispatus* occurred in the majority of women with recurrent BV, and in those colonized, relapses were significantly less likely to occur compared with those not colonized. Among women who failed to become recolonized, recurrences were more common among those on placebo. Currently, Phase III clinical trials are under way to assess the efficacy of recolonization with vaginal-specific lactobacilli (i.e., *L. crispatus* and *L. jensenii*).

In 2006, Sobel published data on a multicenter trial of metronidazole gel among 157 women with BV. All participants initially received a 10-day course of nightly 0.75% metronidazole gel and if cured were then randomized to either gel or placebo twice weekly for 16 weeks. An intent-to-treat analysis done at week 16 showed that 26% of patients using the gel had a recurrence of BV compared with 59% of those on placebo.

Trichomoniasis

Trichomonas vaginalis, a sexually transmitted parasite, is the most common sexually transmitted infection in the United States aside from HPV. Although often considered of minor importance compared with other sexually transmitted infections, growing evidence of the adverse health consequences of trichomoniasis suggests otherwise. Upper genital

tract infections (including those following delivery, abortion, or surgical procedures), PID, tubal infertility, preterm delivery, and increased risk of HIV transmission have all been described in association with trichomoniasis. Risk factors for infection include a change in sexual partners, frequent intercourse, three partners or more in the past month, and another coexistent STD.

Symptomatic women may present with abnormal discharge, itching, burning, or postcoital spotting. An elevated vaginal pH is typical, and motile trichomonads and signs of inflammation often are present on microscopy. The sensitivity of the wet mount, however, ranges from 45% to 60%, and culture (either in Diamond's medium or via use of a two-chambered plastic bag culture system [InPouch, BioMed Diagnostics, White City, OR]) remains the standard for diagnosis.

Treatment recommendations are included in Table 35.4. Patients taking metronidazole should be advised to refrain from alcohol consumption for 24 hours after completion of therapy; for tinidazole, abstinence should be maintained for 72 hours. Sexual partners should be treated as well, and intercourse should be avoided until both partners are cured (i.e., therapy completed and both partners asymptomatic). Cure rates for metronidazole and tinidazole are high (90% to 95% for metronidazole, 86% to 100% for tinidazole), although randomized trials comparing the 2-g doses of both medications point to increased parasitologic cure and resolution of symptoms with tinidazole. It should be noted that metronidazole gel is not recommended for treatment of trichomoniasis secondary to poor efficacy (<50%).

Metronidazole-resistant trichomoniasis has been reported, although the resistance seen is usually of low level. If treatment fails with the 2-g metronidazole dose (and reinfection is not present), the patient should be treated with either the 7-day oral regimen of metronidazole or the 2-g tinidazole in a single dose. If failure occurs with either one of these doses, clinicians should consider treatment with the 2-g dose of either metronidazole or tinidazole daily for 5 days. If persistence occurs, consultation with an infectious disease specialist is warranted (this service as well as *T. vaginalis* susceptibility testing is available from the CDC (telephone, 770–488-4115; website, *http://www.cdc.gov/std*).

Other Vaginitides

Atrophic Vaginitis

Local changes in the genital area may precede the more well-recognized systemic symptoms of menopause. Vulvar tissue becomes increasingly sensitive to irritants at this time, and in the absence of estrogen, the vulvovaginal area becomes pale, thin, and often dry. Vaginal secretions are reduced, the vaginal pH becomes more alkaline, and the vaginal flora becomes altered. Activities that once were not associated with discomfort may become so. The genital area becomes increasingly susceptible to trauma, chemical irritants, and bacterial overgrowth. In severe atrophic vaginitis, a purulent, noninfectious discharge may develop, along with fissuring of the vestibule. A comparison of common acute vaginitides is shown in Table 35.5). The diagnosis is made based on an elevated

vaginal pH and the presence of parabasal or intermediate cells on microscopy. An amine test will be negative in this setting (although BV continues to be a problem in this population as well).

TABLE 35.5 Typical Features of Vagi

Condition	Populations at Risk	Symptoms	Examinati Findings
BV	Black, non-Hispanic women Douching within past 6 mo	Increased thin, white discharge Increased “fishy” odor	Thin, whitish-g homogene discharge
Candidiasis	Reproductive-age women Pregnancy Uncontrolled diabetes mellitus Immunosuppression Debilitation	Increased thick, white discharge Pruritus Dysuria	Thick, wh curdlike discharge Vulvovagi erythema edema, excoriatic fissures m be preser
Trichomoniasis		Increased yellow to green, frothy discharge Increased odor Pruritus Dysuria	Yellow, frothy discharge Vaginal or cervical erythema Strawberr cervix rar

		Can be asymptomatic	(2%–5% of cases)
Atrophic vaginitis	Postmenopausal women	Abnormal vaginal discharge Dryness Pruritus Burning Dyspareunia	Purulent discharge Decreased rugae
DIV	Perimenopausal or postmenopausal women	Increased yellow or green discharge Burning Dyspareunia	Purulent discharge with vary amounts vestibular and vagin erythema

BV, bacterial vaginosis; DIV, desquamative inflammatory vaginitis.

Treatment of vaginal atrophy can be accomplished through a variety of estrogenic preparations (in the forms of creams, pessaries, tablets, and the estradiol-releasing vaginal ring). In a systematic review of local estrogen for the treatment of vaginal atrophy in postmenopausal women, efficacy was found to be significantly better with the use of the cream, ring, and tablets when compared with placebo and nonhormonal gels. Results also showed a significant patient preference for the use of the ring. Finally, side effects associated with topical estrogen therapy include the possibility of endometrial hyperplasia, endometrial overstimulation, and breast pain.

Several studies indicated a significantly greater chance of endometrial overstimulation with the use of the cream when compared with the tablet or ring. Although not statistically significant, there was a 2% incidence of simple hyperplasia in the ring users compared with cream users and a 4% incidence of hyperplasia in the cream group compared with tablet group.

Desquamative Inflammatory Vaginitis

Desquamative inflammatory vaginitis (DIV), a rarer form of vaginitis, also can be seen in perimenopausal and postmenopausal women. Burning, dyspareunia, and an abnormal yellow or green vaginal discharge, often copious in nature, are typical symptoms with which women present for evaluation. Examination confirms a purulent discharge with

varying amounts of vulvar and vaginal erythema. The vaginal pH is elevated, the amine test is negative, and microscopy reveals large numbers of polymorphonuclear cells and parabasal cells. Although easily mistaken for trichomoniasis, motile trichomonads will not be in evidence. Confirmation with cultures for *T. vaginalis* will likewise be negative.

The etiology remains unclear, although DIV has been associated with a number of conditions, including erosive lichen planus, pemphigus vulgaris, and mucous membrane pemphigus. Whether an idiopathic DIV subset of lichen planus exists remains controversial, with some authors postulating that all cases of DIV represent undiagnosed erosive lichen planus. Treatment currently is based on cohort studies. Sobel reported the successful use of 2% clindamycin suppositories, although relapses were common. The use of high-potency intravaginal steroids alone or in combination with clindamycin also has been reported. Medication regimens usually are recommended for 4 to 6 weeks, although recurrences are often seen, requiring retreatment. In postmenopausal women with DIV, supplementary estrogen therapy has been reported to be of help.

Inflammatory Disorders

Dermatitis

The term *dermatitis* (or eczema) describes a poorly demarcated, erythematous, and usually itchy rash. Burning can sometimes occur in cases of mucosal involvement. Subtypes are numerous and can be classified as either exogenous (irritant or allergic contact dermatitis) or endogenous (atopic or seborrheic dermatitis). Dermatitis is common and has been reported to occur in 20% to over 60% of patients seen with chronic vulvar symptoms, with atopic dermatitis being by far the most frequently encountered. Unfortunately, the clinical appearance of the vulva often does not help to secure the diagnosis, and in many cases, more than one process has led to the symptoms the patient reports. It is not uncommon to see a mixed picture where endogenous dermatitis or another epithelial disorder has been worsened by use of ointments or creams to which the patient has adversely reacted.

Irritant contact dermatitis has been identified in 5% to 26% of women diagnosed with vulvar dermatitis, often as a result of exposure to irritants such as detergents, soaps, perfumes, semen, and propylene glycol, which is an additive found in many topical medications. Allergic contact dermatitis, in contrast, is an immunologically mediated inflammatory reaction (type IV delayed hypersensitivity) to an allergen in a previously sensitized woman. Although distinguishing allergic from irritant contact dermatitis can be difficult, the intermittent nature of the symptoms and the timing of symptom onset (10 to 14 days following exposure but may be <24 hours if already sensitized) serve as an important keys to making the diagnosis of the former. The list of commonly encountered allergens, while similar to that of common irritants, also includes a variety of topical medications such as antibiotics (e.g., neomycin, bacitracin), antifungals (clotrimazole, miconazole), all corticosteroids, and the greatest offenders—the topical anesthetics.

On examination, clinical signs can range from mild erythema, swelling, and scaling to marked erythema, fissures, erosions, and ulcers. Secondary infection may be present as

well. Confirmation of the diagnosis should include assessment to rule out candidiasis. Biopsy, which will show nonspecific changes such as spongiosis, parakeratosis, and some dermal inflammatory infiltrate, is not helpful. Treatment consists of removal of the offending agent or practice, correction of barrier function, elimination of scratching, and reduction of inflammation. Barrier function should be restored through the use of sitz baths, estrogen therapy if indicated, treatment of concomitant infection if present, and application of a thin layer of plain petrolatum. Medications with antihistamine and sedative properties, such as doxepin or hydroxyzine, can be added to control nocturnal itching, while cetirizine or a selective serotonin reuptake inhibitor (SSRI), for example, can used during the day. Anti-inflammatory therapy should also begin, with a mid- to high-potency corticosteroid for 2 to 3 weeks (Table 35.6). A weaker corticosteroid, such as 1% hydrocortisone, can then be continued as needed. In recalcitrant cases, oral or intramuscular corticosteroids may be necessary.

Lichen Simplex Chronicus

Vulvar lichen simplex chronicus, a common vulvar dermatosis, is a chronic eczematous disease characterized by intense and unrelenting itching and scratching. In vulvar specialty clinics, lichen simplex chronicus accounts for 10% to 35% of patients evaluated. From 65% to 75% of patients will report a history of atopic disease (hay fever, asthma, childhood eczema), and as such, lichen simplex chronicus can be seen as a localized variant of atopic dermatitis. All patients report pruritus, and most will admit to vigorous scratching or rubbing and often report resultant sleep disturbances. Lichen simplex chronicus represents an end-stage response to a wide variety of possible initiating processes, including environmental factors (e.g., heat, excessive sweating, and irritation from clothing or topically applied products) and dermatologic disease (e.g., candidiasis, lichen sclerosus).

TABLE 35.6 Common Topical Steroid Formulations

Topical Steroid Class	Name (Trade)	Name (Generic)	Common Uses
Class I Superpotent	Temovate (0.05% cream, ointment)[a] Ultravate (0.05% cream, ointment)	Clobetasol propionate Halobetasol propionate	Lichen sclerosus Lichen planus

Class II High potency	Lidex (0.05%)	Fluocinonide	Psoriasis Lichen simplex chronicus
Class III	Valisone (0.1% ointment)	Betamethasone valerate	
Class IV Midpotency	Kenalog (0.1% cream) Westcort (0.2% ointment)	Triamcinolone Hydrocortisone valerate	Eczema Mild irritation
Class V	Locoid (0.1% cream) Valisone (0.1% cream) Westcort (0.2% cream)	Hydrocortisone butyrate Betamethasone valerate Hydrocortisone valerate	—
Class VI Low potency	—	—	Solution/ lotion formulations commonly used[a]
Class VII Mild	Hydrocortisone 1.0%, 2.5%	Hydrocortisone	Mild eczema Maintenance

[a]Creams tend to work better in the vagina due to better absorption. Ointments work well on the vulva, as they are less irritating than creams, solutions, jelly, or lotions and provide a soothing barrier.

Clinically, lichen simplex chronicus appears as one or more erythematous, scaling, lichenified plaques (Figs. 35.5, 35.6). Various degrees of excoriation are often visible. In long-standing disease, the skin appears thickened and leathery, and areas of hyperpigmentation and hypopigmentation may be present. Erosions and ulcers can develop as well, most commonly from chronic scratching. Vaginal fungal cultures are helpful in determining the presence of an underlying condition on which lichen simplex chronicus is superimposed. Biopsy (which would demonstrate marked hyperkeratosis with widening and

deepening of the rete ridges) is rarely necessary unless an underlying disease (such as lichen sclerosus or psoriasis) is suspected or the patient fails to respond to treatment.

Treatment consists of identification and removal of the initiating factor, repair of the skin's barrier layer function, reduction of inflammation, and disruption of the itch–scratch cycle. Mid- to high-potency topical corticosteroids (depending on the presence of underlying disease) should be applied nightly until symptoms begin to abate; less frequent use (e.g., alternate nights, then twice weekly) should continue until the condition resolves. Again, medications with antihistamine and sedative properties can be added to control nocturnal itching, an SSRI can be added for

daytime use, and oral or intralesional steroids can be used for refractory cases.

Figure 35.5 Lichen simplex chronicus.

Figure 35.6 Lichen simplex chronicus.

Hidradenitis Suppurativa

Hidradenitis suppurativa, also termed *acne inversa* and *Verneuil's disease*, is a common chronic, suppurative, cutaneous process that results from occlusion of follicles and secondary inflammation of apocrine glands. Scarring of the affected sites results from chronic infection and draining abscesses. Unlike acne vulgaris, acne inversa is localized to nonfacial regions, sebum excretion is not increased, and affected areas tend to be rich in apocrine glands that are involved, but are not the original source, of the inflammatory process.

The incidence of hidradenitis suppurativa is estimated to be 1 in 300, although hidradenitis suppurativa is most likely under-recognized and underdiagnosed. Women are more likely to be affected than men. Other causal factors in women may include both acquired and genetic characteristics including onset after puberty and prior to age 40 years, obesity (with hyperandrogenism), association with other endocrine disorders (e.g., diabetes), and an apparent familial predisposition in some patients.

The onset of hidradenitis suppurativa is insidious. Early symptoms consist of pruritus, erythema, burning, and local hyperhidrosis. Occlusion of a hair follicle results in a cyst, similar to the comedones of acne. As the area heals, it becomes scarred and fibrotic. With recurrent cyst formation, induration and inflammation leads to spontaneous rupture and sinus tract formation. Ultimately, hyperpigmentation, scaring, pitting, and multiple fistulous sites are noted, with associated pain.

Early diagnosis of hidradenitis suppurativa is easily overlooked and often attributed to simple comedones of acne. While specific diagnostic criteria do not exist, the diagnosis becomes apparent with disease progression; biopsy is neither required nor diagnostic. Clinical criteria suggesting hidradenitis suppurativa include recurrent deep boils for more than 6 months in flexural apocrine gland skin sites (typically involving the axilla, inguinal, and anogenital areas), onset after puberty, poor response to conventional antibiotics, and tendency toward relapse and recurrence. Late disease is characterized by chronic infection, draining abscesses, nodules, sinus tracts, scarring, and hyperpigmentation.

Follicular pyodermas, acne vulgaris, Crohn's disease, and Fox-Fordyce disease comprise other potential causes to be considered in the differential diagnosis of hidradenitis suppurativa. Follicular pyodermas (e.g., folliculitis, furuncles, carbuncles), however, do not result in the widespread manifestations such as that observed with hidradenitis suppurativa. Acne vulgaris is a disease of the sebaceous follicles and sebum production rather than suppurative inflammation with secondary involvement of apocrine glands. Crohn's disease may present with perianal and vulvar manifestations (e.g., abscesses, fistula formation, and scarring). The classic appearance of vulvar Crohn's includes “knife cut” ulcers in the inguinal, genitocrural, and interlabial folds, findings that are not present in hidradenitis suppurativa. Fox-Fordyce disease, while similar to hidradenitis suppurativa in that both are diseases of skin appendages, primarily affects hair follicles rather than apocrine glands and does not result in abscess formation. Finally, squamous cell carcinoma arising in hidradenitis suppurativa is rare but has been reported. Thus, while biopsy is not indicated for the diagnosis of hidradenitis suppurativa, it is indicated when there is concern for malignancy.

Treatment of hidradenitis suppurativa is challenging and based primarily on anecdotal evidence. Current treatment is directed at prevention of new lesions through medical management and elimination of existing lesions surgically when appropriate. In order to improve the local environment, avoidance of irritants, heat, sweating, and reducing friction (e.g., avoidance of tight clothing, limit pad use) is encouraged. Additionally, weight reduction often is helpful. Medical treatment including antibiotics, antiandrogens, corticosteroids, retinoids, and skin care are commonly employed with varying success (reviewed later). Other treatments have been tried, including cyclosporine and infliximab (tumor necrosis factor (TNF)-alpha inhibitor infusion) in small numbers of patients with moderate improvement and significant side effects.

Topical clindamycin (1% lotion twice daily for 3 months) and systemic therapy with tetracyclines (500 mg twice daily) have been shown to be effective in placebo-controlled trials. The use of long-term antibiotic therapy, however, does not appear to alter the natural history of hidradenitis suppurativa, and recurrence following discontinuation is the rule. Treatment with antiandrogens has produced mixed results in women with hidradenitis suppurativa. For mild hidradenitis suppurativa, both intralesional triamcinolone acetate and low-dose isotretinoin have demonstrated some efficacy.

Surgery is heralded as the primary treatment of severe, extensive hidradenitis suppurativa. However, all treatment options are noted to have a high recurrence rate, including radical surgery. While simple incision and drainage of individual nodules is helpful in short-term

pain management, lesions will recur. Further surgical options include unroofing of sinus and fistulous tracts, local excision, and wide excision (with or without skin grafting). Thus, the extent of excision should be individualized based on the stage and location of the disease.

Autoimmune Disorders

Lichen Sclerosus

Lichen sclerosus, a chronic disorder of the skin, most commonly is seen on the vulva, with extragenital lesions reported in 5% to 20% of patients. While lichen sclerosus

may affect any age group, the mean age of onset occurs in the fifth to sixth decade. The exact etiology of this condition is unclear, although an autoimmune process or possible genetic link is likely. Numerous studies have now demonstrated a strong association, particularly in women, between lichen sclerosus and a variety of autoimmune-related disorders including alopecia, vitiligo, thyrotoxicosis, hypothyroidism, and pernicious anemia. Patients presenting with lichen sclerosus most commonly complain of pruritus, followed by irritation, burning, dyspareunia, and tearing. Because lichen sclerosus may be asymptomatic, the prevalence of this condition remains unknown.

Women with lichen sclerosus appear to be at a significantly increased risk (4% to 5%) of squamous cell carcinoma of the vulva. Whether treatment will decrease this long-term risk of malignant change remains unclear pending more information from long-term follow-up studies. While age and the concomitant presence of squamous hyperplasia did appear to be independently associated with the finding of the vulvar carcinoma in women with lichen sclerosus in a recent case-control study, neither the presence nor duration of symptoms or the loss of vulvar architecture proved to be useful indicators of potential cancer risk.

On examination, typical lesions of lichen sclerosus are porcelain-white papules and plaques, often with areas of ecchymosis or purpura. The skin commonly appears thinned, whitened, and crinkling (hence the description “cigarette paper”) (Figs. 35.7, 35.8). Although the genital mucosa is largely spared with lichen sclerosus, involvement of the mucocutaneous junctions may lead to introital narrowing (Fig. 35.9). Perianal involvement can create the classic “figure of eight” or hourglass shape. Other findings include fusion of the labia minora, phimosis of the clitoral hood, and fissures. Because other vulvar diseases can mimic lichen sclerosus, a biopsy is necessary to confirm the diagnosis.

The recommended treatment for lichen sclerosus is a high-potency topical steroid, the most studied of which is clobetasol propionate. In a cohort study of over 300 girls and women with lichen sclerosus, 23% demonstrated complete resolution of the vulvar skin to normal texture and color and 68% showed partial resolution of the hyperkeratosis, purpura, fissuring, and erosions associated with this disorder. Ultrapotent steroid therapy is not without complication (including not only skin changes but also the possibility of adrenal suppression with overuse of topical therapy), and to this end, initial studies were undertaken to assess the preliminary efficacy of tacrolimus for the treatment of lichen sclerosus. While promising,

subsequent reports of a possible link to skin cancer and lymphoma based on animal studies and case reports in humans limit the use of this medication. Tacrolimus and other medications of the same class should therefore only be considered as second-line agents for short-term and intermittent treatment in patients unresponsive to or intolerant of other treatment. Surgery, while not curative, is reserved exclusively for the treatment of malignancy and postinflammatory sequelae (e.g., release of labial adhesions). Finally, treatment with other topical therapies, including testosterone and progesterone, has inconsistently resulted in improvement in lichen sclerosus and therefore, they are not currently recommended.

Figure 35.7 Lichen sclerosus.

Figure 35.8 Lichen sclerosus in pregnancy.

Figure 35.9 Lichen sclerosus with introital narrowing.

Psoriasis

Psoriasis is a common skin disorder, occurring in 2% to 3% of the population, which can frequently affect the genital skin. Vulvar psoriasis, which is usually pruritic, can be seen in girls and women of all ages. The thickened plaques associated with this disorder result from rapid proliferation of the epidermis. What underlies this rapid cellular turnover is unclear, although a genetic predisposition is present and immunologic factors likely play a role.

The typical clinical features of anogenital psoriasis are symmetric “salmon pink” plaques that can contain silvery scales. When psoriasis presents on the vulva, however, the silver scaling typically seen elsewhere on the body can be lost, but the bright erythema and well-defined outline of the disease tend to remain. The plaques commonly occur on the mons pubis. Although usually not associated with loss of architecture, this can occur. The differential diagnosis includes tinea cruris, intertrigo, seborrheic dermatitis, and lichen simplex chronicus. Definitive diagnosis is made through biopsy, although in more long-standing cases, biopsy may be nonspecific and interpreted as psoriasiform dermatitis. A negative biopsy, then, does not preclude the presence of disease.

When limited to the vulva, local treatment with mid- to high-strength topical corticosteroids is the treatment of choice. If not adequately controlled, calcipotriene may be added, although patients should be cautioned that it may take 1 to 2 months for improvement to be noted. For disease that is unresponsive to the above measures,

systemic therapy with oral methotrexate, retinoids, or cyclosporine should be considered in consultation with a physician who is experienced with the use of such medications.

Lichen Planus

Lichen planus, an inflammatory mucocutaneous disorder most likely related to cell-mediated immunity, exhibits a wide range of morphologies. The most common form and the most difficult to treat is the erosive form, which can lead to significant scarring and pain. Most commonly recognized on the skin or oral mucosa, this condition may affect the lower genital tract. Approximately 1% of the population has oral lichen planus, and of women with oral disease, roughly 20% to 25% have genital vulvovaginal disease. Because genital lesions may be asymptomatic and often go unrecognized during examination, the incidence of genital disease most likely is underestimated. Other autoimmune disorders, including diabetes mellitus, thyroid disease, and celiac disease, are commonly reported in women with vulvovaginal lichen planus. Setterfield found that the human leukocyte antigen DQB1*0201 allele was present in 80% of women with vulvovaginal lichen planus, suggesting a genetic predisposition to the vulvovaginal form of lichen planus.

While most commonly seen in its erosive form, lichen planus also can present as white epithelium or as red or purple papules. The classic presentation of lichen planus on mucous membranes, including the buccal mucosa, is that of white, reticulate, lacy or fernlike striae (Wickham's striae). On occasion, the skin may appear uniformly white, and thus lichen planus can be confused with lichen sclerosus. The pruritic, purple, shiny papules typically associated with lichen planus are occasionally found on the genital skin. If present, however, they appear dusky pink in color, without an apparent scale and less well demarcated.

In erosive lichen planus, deep, painful, erythematous erosions appear in the posterior vestibule and often extend to the labia minora, resulting in agglutination and resorption of the labial architecture (Fig. 35.10). The vaginal epithelium can become erythematous, eroded, acutely

---

inflamed, and denuded of epithelium. Erosive patches, if present, are extremely friable. Over time, these eroded surfaces may adhere, resulting in synechiae and eventual complete obliteration of the vaginal space. Symptoms commonly reported by patients with erosive vulvar lichen planus include dyspareunia, burning, and increased vaginal discharge. Examination of the vaginal discharge reveals predominance of inflammatory cells and immature parabasal and basal epithelial cells (these will appear small and round, with relatively large nuclei). The vaginal pH is increased, usually in the range of 5 to 6. This discharge often has been labeled as DIV, but whether DIV is a type of erosive lichen planus or a distinct type of vaginitis remains controversial.

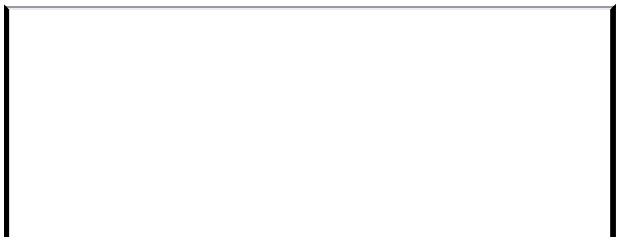

Figure 35.10 Lichen planus.

Biopsy, which reveals a bandlike infiltrate of lymphocytes and colloid bodies in the basal layers of the epidermis, may be relatively nonspecific because of the complete loss of the vaginal epithelium. On the other hand, a histologic specimen can help to rule out immunobullous diseases, such as cicatricial pemphigoid, bullous pemphigoid, and pemphigus vulgaris, which may mimic lichen planus (Table 35.7). The prognosis for spontaneous remission of vulvovaginal lichen planus is poor. Although squamous cell carcinomas are encountered rarely, women with lichen planus should be followed carefully.

Treatment, while not curative, can improve patients' symptoms and sense of well-being. Therapeutic options, shown in small trials to be effective, include topical and systemic corticosteroids, topical and oral cyclosporine, topical tacrolimus, hydroxychloroquine, oral retinoids, methotrexate, azathioprine, and cyclophosphamide. For example, in one study of 43 patients with vulvovaginal lichen planus treated with twice-daily 25-mg intravaginal hydrocortisone suppositories (initially used daily for several months, then tapered to two times weekly), both symptoms and physical signs of disease improved significantly. However, neither vaginal stenosis nor sexual function improved.

Ultrapotent topical steroids (ointments will cause less stinging than creams), and at times oral steroids for severe erosions and exudation, are often required. If used intravaginally, care should be taken to monitor the potential side effects of high-dose steroids, including not only atrophy, striae, and steroid dermatitis but also systemic absorption resulting in adrenal suppression. With frequent use of steroids, infections (e.g., yeast, herpes) also should be suspected when symptoms flare. To help maintain vaginal patency, the use of

vaginal dilators should be encouraged. Surgery in general is not advocated, although Stany recently reported the successful use of an acellular dermal graft for vulvovaginal reconstruction in a patient with refractory lichen planus. The problem with most current therapies for erosive lichen planus is that significant control of symptoms and restoration of sexual function is difficult. Patients should therefore be advised that while improvement is possible, complete control is not the norm.

Common Benign Pigmented Lesions

Lentigo Simplex/Melanosis Vulvae

The most common pigmented lesion biopsied on the vulva, lentigo simplex appears clinically as a flat, pigmented area on the skin that has relatively normal surface skin markings (slightly hyperplastic or hyperkeratotic areas may be noted). Lentigo simplex represents an area of increased melanin with associated melanocytes. By definition, lentigo simplex is ≤5 mm in diameter; for larger lesions with the same histopathologic features, the term *melanosis vulvae* is used (Fig. 35.11). While treatment is not indicated, biopsy is needed to determine the diagnosis. Similar lesions may be seen in the vagina as well (melanosis vaginae).

Vulvar Junctional, Compound, Intradermal, and Atypical Vulvar Nevi

Junctional, compound, and intradermal nevi consist of benign nevus cells, the location of which determines their description. Junctional nevi are located within the epidermis and dermal–epidermal junction, while intradermal nevi are completely contained within the dermis. Compound nevi represent a continuum between junctional to intradermal nevi and thus can be found within the epidermis, dermal–epidermal junction, and/or dermis. Atypical vulvar nevi have features of compound nevi in terms of location but importantly contain cytoatypia. Atypical nevi most commonly are found in adolescent and premenopausal women and can clinically and histopathologically resemble malignant melanoma (Fig. 35.12). In general, then, elevated pigmented lesions of the vulva that are ≥5 mm in greatest dimension as well as any suspicious lesions should be biopsied.

Seborrheic Keratosis

Seborrheic keratoses typically present as multiple, macular or papular pigmented lesions that feel waxy in consistency on palpitation. Biopsy is necessary to establish the diagnosis and differentiate such lesions from VIN. Treatment of seborrheic keratosis usually involves local superficial excision or cryotherapy or topical therapy with imiquimod.

Benign Cysts of the Vulva

Epidermal Inclusion Cysts

Epidermal inclusion cysts are relatively common and can involve the labia majora, clitoris,

and perineal body as well as other vulvar sites. In general, cysts range in size from 2 to 5 mm, are typically superficial, and can be numerous (Fig. 35.13). Epidermal inclusion cysts (also called

keratinous cysts) can occur at any age and have been documented in association with episiotomy scars and female genital mutilation. Clinically, the cysts are filled with keratinous material that is white to pale yellow in color and cheesy in character. Treatment is not necessary if the cysts are asymptomatic, although excision should be considered if the diagnosis remains in question or if the cysts are enlarging, symptomatic, or infected.

TABLE 35.7 Less Common Immunob

	Cicatricial Pemphigoid	Bullous Pemphigoid
Age; epidemiology	Age 50–70 y; women are affected twice as often as men. No gender predilection.	Age 60–80 y predominantly but can occur at any age. Occurs equally in men and women.
Appearance	Early genital disease shows nonspecific erosions and rarely blisters of the non-hair-bearing vulva and vagina. Agglutination occurs.	Blisters, erosions, and often intense pruritus. The hair-bearing skin of the inner thighs, inguinal crease, perineum, and labia majora are the most affected areas of the genitalia. Tense, straw-colored blisters are most common. Mucous membrane involvement of the anogenital area may

		occur but is uncommon and presents as erosions.
Nongenital manifestation	Most commonly affects mouth and eyes. Non-mucous membrane disease presents as vesicles and bullae. No significant associations with malignancy or other autoimmune diseases.	Oral involvement develops in about one third. Minimal risk of concurrent autoimmune diseases.
Diagnosis	Skin biopsy is characteristic and should include the edge of a new blister when possible.	The diagnosis of bullous pemphigoid should be confirmed by a biopsy that includes the edge of a blister.
Histology; immunofluorescent	Subepidermal blister with lymphocytic infiltrate, often also eosinophils or neutrophils. Direct immunofluorescent staining reveals linear deposition	Subepidermal blister with a variable degree of dermal inflammation. Direct

localization	of immunoglobulins and complement along the basement membrane (most common IgG, C3; less common IgM, IgA).	immunofluorescence demonstrates linear deposits of IgG and or C3 at the basement membrane.
Course and prognosis	Chronic, sometimes poor response to therapy. Progressive scarring and morbidity.	Chronic, usually responsive to therapy.
Pathogenesis	Autoimmune disease that develops as a result of circulating autoantibodies that bind to the target antigen in the basement membrane at the dermal–epidermal junction.	Autoimmune disease with immunoglobulin deposition and complement activation.
	Usually requires systemic treatment. Predominantly	Systemic corticosteroids are the mainstay of treatment.

Treatment	corticosteroids. Oral azathioprine, cyclophosphamide, and dapsone are useful in some patients as steroid sparing agents. Patients must be followed by an ophthalmologist.	Occasional patients with local disease can be controlled with topical preparations. Oral azathioprine, cyclophosphamide, dapsone, and tetracycline are useful in some patients.
Differential diagnosis	HSV and other scarring mucous membrane diseases (e.g., erosive lichen planus, erosive lichen sclerosus, bullous pemphigoid).	Differential diagnosis of genital bullous pemphigoid includes any blistering and erosive diseases that affect the genitalia. Direct immunofluorescent finding does not differentiate bullous pemphigoid from cicatricial pemphigoid.

IgG, immunoglobulin G; IgM, immunoglobulin M; IgA, immunoglob

Mucous Cyst

Mucous cysts occur primarily in the vulvar vestibule and arise from occlusion of minor vestibular glands. Treatment generally is not indicated in the absence of symptoms.

Bartholin Cyst/Abscess

The Bartholin cyst is a result of the distal obstruction of the Bartholin gland (Fig. 35.14). The most likely diagnosis in a woman with a unilateral, tender, swollen labial mass is an abscess of the Bartholin gland. Such an abscess should occur in the lower third of the introitus between the vestibule and the labia majora. Gonococcal infection has been implicated in a number of cases, although the infection largely is polymicrobial. While

abscesses of the Bartholin gland constitute a relatively frequent finding in the ambulatory setting, agreement as to their most efficacious treatment remains unclear. Currently employed treatment modalities include outpatient, less invasive procedures such as needle aspiration with antibiotic coverage, incision (on the mucosal surface of the abscess), and drainage with and without placement of a Word catheter as well as more radical surgical therapies such as marsupialization.

Figure 35.11 Melanosis vulvae.

Vulvodynia

The International Society for the Study of Vulvovaginal Disease (ISSVD) recently defined *vulvodynia* as vulvar discomfort, most commonly described as burning pain occurring in the absence of relevant visible findings (such as infection or inflammation) or a specific, clinically identifiable neurologic disorder (e.g., postherpetic neuralgia). Current evidence indicates that the lifetime cumulative incidence of vulvodynia approaches 15%, which suggests that nearly 14 million women in the United States will at some point experience the symptoms of chronic vulvar burning and pain. Indeed, a localized form of vulvodynia involving the vulvar vestibule is thought to be the leading cause of painful intercourse in premenopausal women.

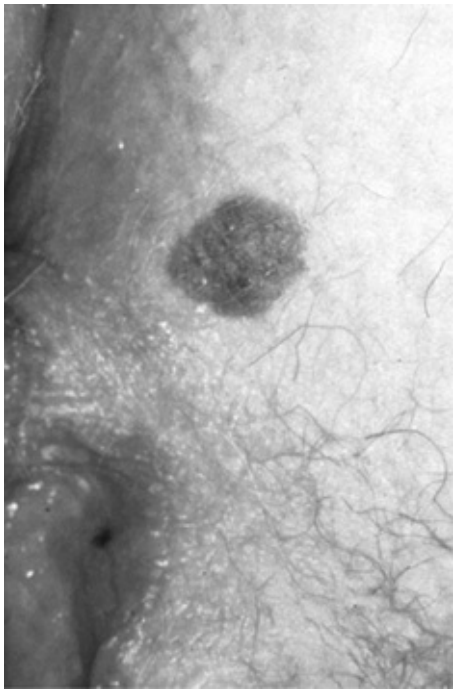

Figure 35.12 Vulvar atypical nevus in an adolescent. (From Wilkinson EJ, Stone IK. *Atlas of vulvar disease*. Philadelphia: Lippincott Williams & Wilkins, 1995, with permission.)

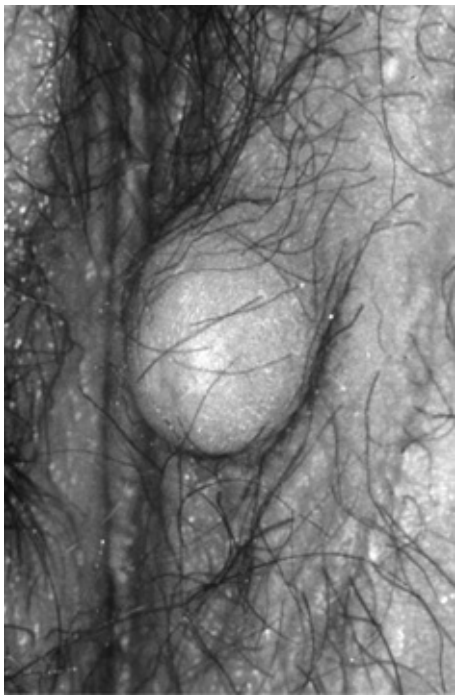

Figure 35.13 Epidermal inclusion cyst. (From Wilkinson EJ, Stone IK. *Atlas of vulvar disease*. Philadelphia: Lippincott Williams & Wilkins, 1995, with permission.)

Patients with vulvodynia tend to fall into different groups based on the location of their pain. Generalized vulvodynia is used to describe involvement of the entire vulva by

persistent, chronic pain that is burning, stinging, or irritating in nature, while localized vulvodynia specifies

involvement of only a portion of the vulva, most commonly the vestibule (termed *vestibulodynia* or *vulvar vestibulitis*). In both generalized and localized vulvodynia, the pain may be provoked (i.e., triggered by physical contact of a sexual or nonsexual nature), unprovoked, or both. In the case of provoked pain, common triggers include vaginal intercourse, tampon insertion, and the wearing of tight-fitting clothing.

Figure 35.14 Bartholin cyst. (From Wilkinson EJ, Stone IK. *Atlas of vulvar disease*. Philadelphia: Lippincott Williams & Wilkins, 1995, with permission).

While a multifactorial process is most likely involved in the development of vulvar pain (e.g., recurrent vaginal infections, use of oral contraceptives, history of destructive vulvar treatments), the end result appears to be neuropathically mediated pain manifested predominantly as burning. In general, neuropathic pain is believed to result from damage to and loss of peripheral afferent elements, a loss that leads ultimately to changes in the central nervous system. For patients with localized vulvar pain, the damage has been proposed to result from neurogenic inflammation. This inflammation then leads to sensitization of first the primary afferents (predominately nociceptors or pain receptors) by inflammatory peptides, prostaglandins, and cytokines and then the spinal cord. Impulses are transmitted along the afferent sympathetics to the central nervous system, where a reinforcing signal (returned via efferent fibers) sustains the pain loop. The allodynia (pain to light touch) and hyperalgesia (excessive response to slight pain) seen in women with vestibulodynia can be explained by this hypothesis.

A final component to consider, particularly in the assessment of patients with vulvar

vestibulitis, is the concomitant role of pelvic floor pathology. The pelvic floor changes seen in women with vestibulitis appear to be reactive in nature, a conditioned, protective guarding response that results from repeated attempts at vaginal penetration. In Reissing's study of women with vestibulitis and age-matched controls, significant hypertonicity was observed only at the superficial, and not the deep, muscle layers of the pelvic floor. This suggests that hypertonicity may be the result of and not the cause of vestibulitis. What appears to occur is that tension begins as a protective guarding response to pain at the vestibule. Over time, this response leads to an increase in the resting tone of the muscle. As a result of the guarding and the increase in resting tone, any pressure applied to the vestibule leads to increased pain, and the cycle becomes self-perpetuating. The pelvic floor hypertonicity seen in women with vestibulitis, then, appears to both maintain and exacerbate pain.

The initial criteria for the diagnosis of vestibular pain were introduced by Friedrich in 1987 and included the following: (a) severe pain on vestibular touch or attempted vaginal entry, (b) tenderness to pressure localized within the vulvar vestibule, and (c) physical findings confined to vestibular erythema of various degrees. In a number of subsequent studies assessing the reliability and validity of physician ratings for this diagnosis, only the first two criteria have been found to be consistently reproducible. The finding of vestibular erythema, then, while frequently present in women with vestibulitis, is not a requirement for the diagnosis.

A diagnostic algorithm proposed by Haefner and colleagues (Box 35.1) is particularly useful in approaching the patient presenting with chronic (defined as 3 or more months) vulvar pain. First, the pain should be characterized to the best of the patient's ability; use of a questionnaire (e.g., the McGill Pain Questionnaire) may help facilitate this process and better define the qualities of the pain the patient is experiencing. The provider then establishes both the duration and nature (generalized/localized, unprovoked/provoked, with or without spontaneous pain) of the patient's discomfort. During the physical examination, other causes of vulvar discomfort (e.g., ulcerations or lesions) are noted and biopsied and/or cultured (e.g., for herpes) as indicated. A vaginal examination is then done to exclude other common causes of vulvovaginal irritation, including yeast and BV.

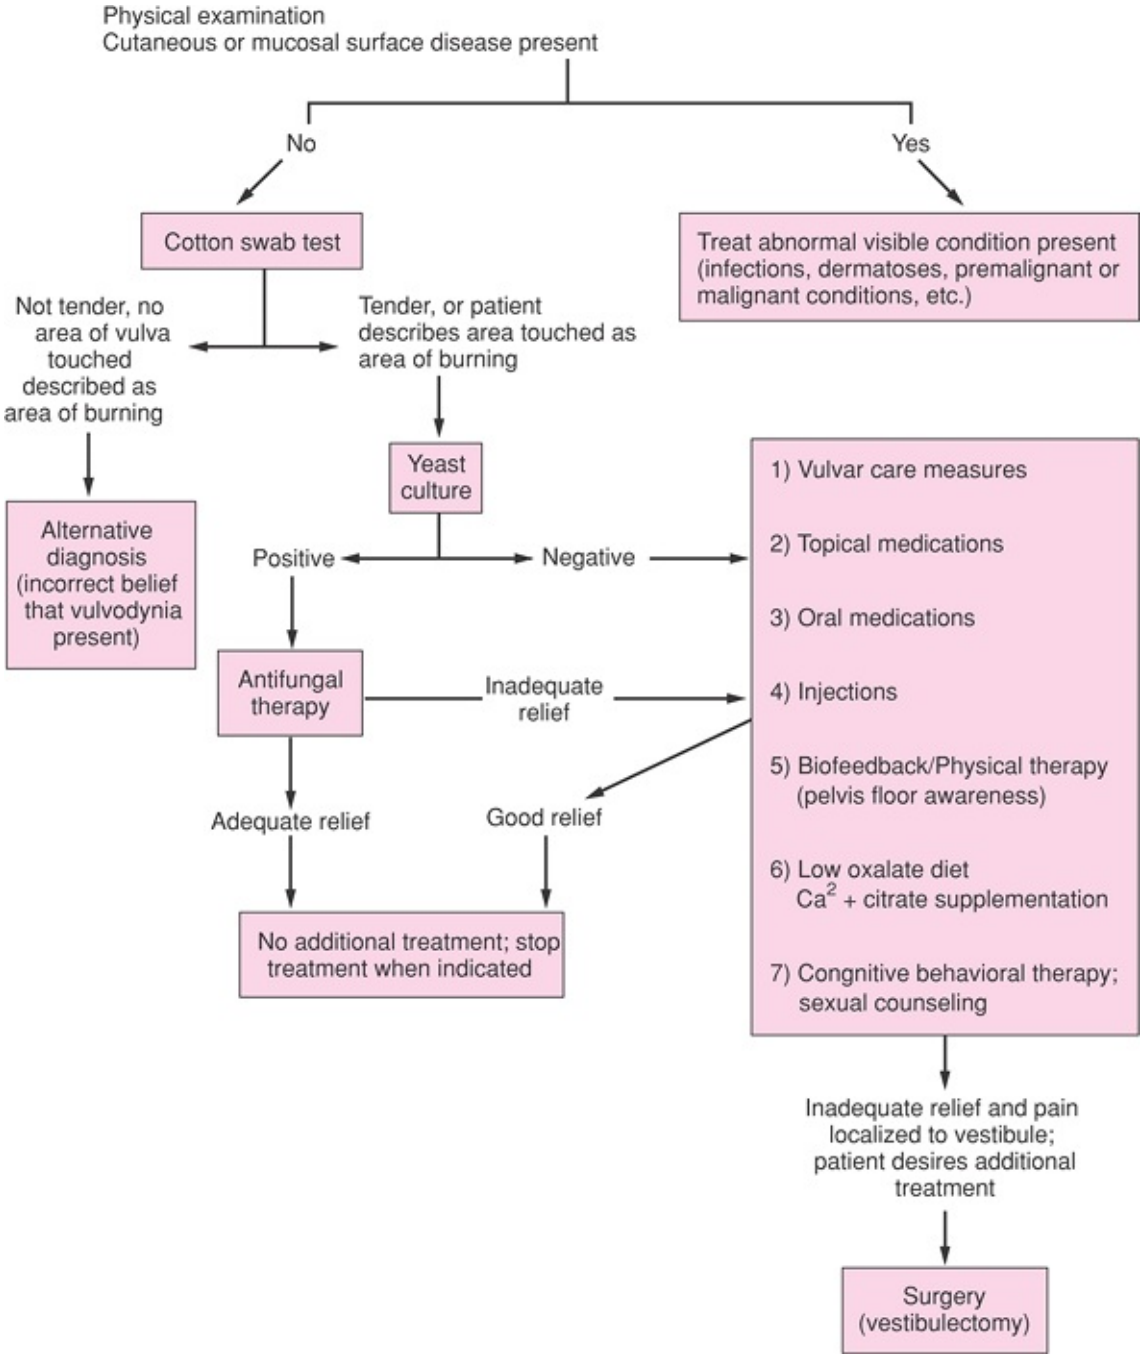
In the absence of abnormal visible findings, the provider performs the cotton swab test, an examination used to specifically localize any painful areas. Using a moistened cotton swab, the vulva is tested starting at the thighs and moving medially toward the vestibule. The vestibule is systematically palpated at the 2-, 4-, 6-, 8-, and 10 o'clock positions by using light pressure. The patient is asked to rate the pain with palpation on a scale of 0 (no pain) to 10 (worst pain ever). Visual analogue scales are useful in this setting. If pain is confirmed, a vaginal fungal culture is obtained in order to definitively rule out a yeast infection, as yeast infections caused by atypical *Candida* sp. are often not obvious on examination. A negative fungal culture, in conjunction with the patient's history and positive findings on the cotton swab test, confirms the diagnosis of vulvodynia.

The National Institutes of Health have characterized vulvodynia as a poorly understood and under-researched focal pain syndrome for which optimal treatment remains unclear. Treatment recommendations, while numerous, have rarely been evidence based. In the

few published randomized clinical trials among vestibulitis patients, investigators have evaluated a range of modalities including topical therapy, biofeedback, behavioral therapy, and surgery. In a study of topical cromolyn sulfate among women with recalcitrant vestibulitis, Nyirjesy found that placebo users, as compared with topical cromolyn users, were slightly, though not significantly, more likely to experience resolution of their pain. On the other hand, in a randomized trial of cognitive behavioral sex therapy, biofeedback, and vestibulectomy, participants in all three groups experienced significant improvement in their pain, yet those undergoing surgery averaged the greatest pain reduction. Although highly efficacious, surgical treatment often remains an option only after less invasive therapies have been exhausted.

Of the above trials, however, none evaluated the tricyclic antidepressants (TCAs) and anticonvulsants, medications which have become mainstays of therapy for women with

both generalized and localized vulvodynia. TCAs, the most studied of which is amitriptyline, and gabapentin are the most commonly used, largely based on evidence of their efficacy from studies of other pain syndromes. Data confirming the efficacy of these medications in women with vulvar pain remains sparse, although recent evidence from a large cohort study points to significant pain improvement when using amitriptyline in over 270 women with vulvodynia. Of note, neither the TCAs nor the anticonvulsants should be abruptly discontinued, as significant side effects can occur.



Box 35.1 Diagnostic and treatment algorithm. (Adapted from Haefner, 2005).

Investigators also have similarly demonstrated favorable clinical responses by using a variety of local therapies in a number of case series and small, uncontrolled trials. Injectable interferon, injectable steroids and lidocaine, topical nitroglycerin, topical lidocaine, and topical capsaicin have shown some efficacy. Of the topical preparations, all have demonstrated promise as treatments for localized vulvodynia. For example, in a treatment trial of 5% lidocaine ointment among 61 women with vulvar pain, Zolnoun found a significant increase in patients' ability to have intercourse (76% vs. 36% at baseline) and a significant decrease in intercourse-related pain. On average, patients performed a nightly regimen of topical lidocaine application for 7 weeks, although many continued to use the ointment at least sporadically in the following months.

The success of treatment interventions using vaginal surface electromyographic

biofeedback in this population, coupled with the recent evidence demonstrating increased vaginal hypertonicity, lack of vaginal muscle strength, and restriction of the vaginal opening in women with vestibulitis, suggests that targeting pelvic floor muscle functioning can be successful in relieving the pain that these patients

experience with intercourse and improving sexual function. Physical therapy treatment techniques include internal (vaginal and rectal) and external soft tissue mobilization and myofascial release, trigger-point pressure application, electrical stimulation, and bladder and bowel retraining as well as home vaginal dilation.

While physical therapy and biofeedback can clearly be effective in reducing the instability and hypertonicity associated with vestibulitis and improving sexual function, compliance with this treatment option requires repeated visits. For strongly motivated patients and patients who wish to avoid the side effects of medical or surgical therapy, of whom there are many, biofeedback and physical therapy is an excellent choice. Vestibulectomy, associated with clinical cure rates in excess of 80% in a number of uncontrolled trials, or local excision for patients with precise localization of small painful areas is reserved for patients with localized pain who have not responded to more conservative therapy. In performing a vestibulectomy and prior to induction of either spinal or general anesthesia, the provider should carefully demarcate and outline the areas of pain. The incision, based on the extent of the patient's pain, may begin as anteriorally as the periurethral area. From the anterior starting point, a U-shaped incision is made, encompassing laterally the Hart's line; medially just inside the hymenal ring; and posteriorly, the superior portion of the perineum. The skin, mucous membrane, hymen, and adjacent tissue are removed, and the vagina is then undermined, mobilized, and brought down to cover the defect. Closure should occur in two layers by using absorbable 3–0 and 4–0 sutures. Again, surgery is not indicated for women with generalized pain. Referral to a pain specialist should be considered for women with generalized vulvodynia who remain unresponsive to previous behavioral and medical treatments.

Conclusion

The evaluation of patients with vulvovaginal complaints begins with a thorough history and physical examination. In cases of acute vulvar pruritus, infections (most commonly, vulvovaginal candidiasis and BV) and contact dermatitis should be suspected. Chronic vulvar pruritus, on the other hand, should signal a search for underlying dermatoses, such as lichen sclerosus, lichen simplex chronicus, or psoriasis; neoplasia (including VIN, squamous cell carcinoma, Paget's disease of the vulva); or vulvar manifestations of systemic diseases, such as Crohn's disease. Patients presenting with pain should first be evaluated to rule out underlying organic causes, including inflammatory conditions, neoplasias, infections, or neurologic disorders. When organic causes are ruled out, the diagnosis of vulvodynia can be made and attention should then be paid to more fully elucidating the nature of the pain disorder (generalized vs. localized, spontaneous vs. provoked).

In the evaluation of infectious causes of vulvovaginal complaints, microscopy using both

saline and potassium hydroxide preparations, in conjunction with vaginal pH determination, helps to guide the use of subsequent diagnostic tools, including vaginal fungal cultures, a variety of Food and Drug Administration (FDA)-approved point-of-care tests, culture or polymerase chain reaction (PCR) for confirmation of HSV, and specific serologic tests. For autoimmune disorders and suspected cases of neoplasia, biopsy is invaluable and should be employed liberally.

If possible, treatment should be evidence based, although such evidence has not yet been accrued for many vulvar disorders. For a number of disorders, including pain syndromes, providers should be aware that often more than one modality will be required, and treatment must be individualized. Patient education in vulvar hygiene measures and avoidance of many common irritants and triggers will help to reduce the risk of both development of contact dermatitis and lichen simplex chronicus and well as exacerbation of other underlying vulvar dermatoses.

Consultation with or referral to a specialist in vulvovaginal disorders, if available, can help obstetrician–gynecologists provide comprehensive care and optimal management of their patients' conditions. Lastly, consultation with providers in dermatology as well as selected use of other specialists, including but not limited to ophthalmologists, dentists, gastroenterologists, and rheumatologists, often is essential to the appropriate diagnosis and management of patients with more complicated disorders.

Summary Points

- Vulvovaginal complaints are encountered commonly and largely fall into two categories: pruritus and pain.
- In cases of acute pruritus, infections (most notably, candidiasis and BV) and contact dermatitis should be ruled out.
- For chronic pruritus, causes to be considered include common dermatoses (e.g., lichen simplex chronicus and lichen sclerosus), neoplasia, and vulvar manifestations of systemic diseases.
- In assessing patients with vulvar pain, organic causes must first be eliminated prior to making the diagnosis of vulvodynia.
- Microscopy, vaginal pH determination, vaginal fungal cultures, and vulvar biopsy (where indicated) are essential elements of the assessment of many vulvovaginal complaints.
- For vulvar pain syndromes, multiple treatment modalities may be necessary.
- Careful instruction in vulvar hygiene measures is critical to the care of patients with vulvovaginal complaints.
- Referral to specialists in vulvar disorders and to other health care providers (e.g., dermatologists, dentists) should be considered where appropriate.

Amenorrhea

David P. Cohen

Amenorrhea is defined as either the absence or cessation of menses. It is a common symptom and may be anatomic (developmental or acquired), organic, or endocrinologic in nature. This chapter outlines the differential diagnosis of amenorrhea, the indications and methods of evaluation, and options for treatment once a diagnosis is clearly defined. The most common cause of amenorrhea in women of reproductive age is pregnancy, which should always be excluded before considering other etiologies.

The Normal Menstrual Cycle

Normal cyclic menstruation comprises a complex integration of endocrine signals, involving autocrine and paracrine mechanisms, operating at four distinct levels: the genital tract, the ovary, the pituitary gland, and the hypothalamus. First, a normal and patent genital outflow tract is necessary. The uterus must have functional endometrium capable of responding to estrogen and progesterone and be contiguous with a patent cervix, vagina, and introitus. Second, the ovaries must contain follicles responsive to pituitary follicle-stimulating hormone (FSH) and luteinizing hormone (LH) stimulation. The two-cell gonadotropin mechanism of steroidogenesis explains how FSH and LH, together with follicular theca and granulosa cells, orchestrate the production steroids by a dominant follicle. It also describes how a dominant follicle is selected from a cohort of developing follicles in the later half of the follicular phase. In summary, each follicle competes for FSH, and the follicle best able to exploit the diminishing FSH in the early follicular phase is selected. Third, pituitary gonadotrophs must have the capacity to synthesize and secrete gonadotropins in response to pulsatile hypothalamic gonadotropin-releasing hormone (GnRH) stimulation. The relative amounts of FSH and LH released reflect changes in the pulsatile pattern of GnRH secretion and the feedback modulation by ovarian steroid and peptide hormones. Finally, specialized neurosecretory cells located in the medial basal hypothalamus (arcuate nucleus) must communicate with the pituitary gland by synthesizing and releasing GnRH in a pulsatile pattern into the hypophyseal portal system, which responds to stimuli from the environment and feedback signals from peripheral endocrine organs.

Amenorrhea may result from congenital or acquired disease or dysfunction at the level of the genital tract, the ovary, the pituitary, or the hypothalamus. In fact, the single most

common cause of amenorrhea—chronic hyperandrogenic anovulation (polycystic ovary syndrome [PCOS])—involves a number of interrelated pathophysiologic mechanisms that operate at the ovarian, pituitary, and hypothalamic levels and does not fall neatly into one specific category. Despite the numerous potential sites of dysfunction, the evaluation is relatively straightforward and logical and requires tests and procedures with which all gynecologists should be quite familiar. With few exceptions, an accurate diagnosis can be confidently established in very little time and without great expense.

Differential Diagnosis of Amenorrhea

Although the list of potential causes of amenorrhea is long, the majority of cases relate to one of five conditions: pregnancy, PCOS, hypothalamic amenorrhea, hyperprolactinemia, and ovarian failure (Table 36.1). All of the remaining causes are relatively uncommon and only occasionally are encountered in a lifetime of clinical practice.

Genital Tract Abnormalities

Female genital tract development involves medial-caudal migration and midline fusion of the paired Müllerian (paramesonephric) ducts to form the tubes, uterus, cervix,

and upper vagina. Fusion of the downward migrating Müllerian duct system with the invaginating urogenital sinus forms the lower vagina and the introitus. Outflow tract abnormalities that result from failure of Müllerian duct development include vaginal or Müllerian agenesis and androgen insensitivity syndrome (AIS), where the uterus is absent. Abnormalities caused by failure of fusion include imperforate hymen, transverse vaginal septum, and cervical atresia. When the uterus is present but outflow obstruction is seen, the result is an accumulation of menstrual effluent above the level of obstruction (cryptomenorrhea). Asherman syndrome and cervical stenosis/obstruction are acquired conditions that cause secondary, not primary, amenorrhea. Asherman syndrome results from intrauterine adhesions that obstruct or obliterate the endometrial cavity as a consequence of inflammation (postpartum endometritis, retained products of conception) usually coupled with surgical trauma (curettage). Severe cervical stenosis, with complete outflow obstruction, is a rare complication of cervical conization procedures or other surgical treatments for cervical intraepithelial neoplasia.

TABLE 36.1 Causes of Amenorrhea

Pregnancy
Genital tract abnormalities
  Congenital:
  Hymeneal obstruction
  Absence of all or a portion of the vagina or cervix
  Absence of the Müllerian duct system

AIS
Acquired:
Cervical obstruction/stenosis
Intrauterine adhesions
Ovarian failure
Gonadal dysgenesis (45X, 46XX, and 46XY)
POF (postpubertal)
Pituitary disorders
Functional hyperprolactinemia (including hypothyroidism and drug induced)
Prolactin-secreting and other pituitary tumors (including craniopharyngioma)
Empty sella syndrome and Sheehan syndrome
Hypothalamic disorders
Congenital (Kallmann syndrome)
Stress (weight loss, exercise, emotional)
PCOS

AIS, androgen insensitivity syndrome; POF, premature ovarian failure; PCOS, polycystic ovary syndrome.

Ovarian Disorders

Ovarian failure occurs when no follicles capable of producing estradiol in response to pituitary gonadotropin stimulation remain. Follicular depletion may occur during embryonic life with no follicles remaining by infancy or early childhood, after puberty has begun but before menarche, or after menarche. Therefore, depending on when the available supply of ovarian follicles is functionally depleted, puberty may not occur, it may begin normally but stop before the first menses, or it may progress normally but menses stop prematurely before the anticipated age of menopause.

When the depletion of follicles occurs prior to puberty, it is termed *gonadal dysgenesis*. It is the most common cause of primary amenorrhea (approximately 30% to 40%) and results either from an absence of ovarian follicles or accelerated follicular depletion during embryogenesis or the first few years of life. The gonads of affected individuals contain only stroma and grossly appear as fibrous streaks. The most common form of gonadal dysgenesis is Turner syndrome, classically associated with a 45,X karyotype, but also with an assortment of other structural X chromosome abnormalities (deletions, ring, and isochromosomes). These X chromosome anomalies may be present in all or only in some of the cells of the body (mosaicism), depending on the stage of postzygotic, embryonic, development when the defect occurs. Although less common, individuals with gonadal dysgenesis may have a normal 46,XX or a 46,XY karyotype (Swyer syndrome) in all cells or in one or more cell lines in mosaic individuals (e.g., 45,X/46,XX; 45,X/46,XY). Most affected women have no significant secondary sexual development since there is an absence of

hormone-producing ovarian follicles. A small percentage may go through puberty and have transient normal ovarian function depending on when the supply of ovarian follicles is depleted. Approximately 15% begin but do not complete pubertal development, and approximately 5% have sufficient follicles to complete puberty and begin spontaneous menstruation. It is not surprising, therefore, that spontaneous pregnancies rarely occur and are associated with a high risk of sex chromosome aneuploidy and spontaneous abortion.

Premature ovarian failure (POF) results in secondary amenorrhea after completion of puberty and before 40 years of age. Approximately 1% to 5% of women will develop POF. It is distinguished from gonadal dysgenesis on the basis of ovarian morphology and histology; instead of streak gonads, the ovaries in POF more closely resemble those of postmenopausal women. The karyotype in individuals with POF is most often normal (46,XX) but also may be mosaic (e.g., 45,X/46,XX). A specific cause for early follicular depletion in POF frequently cannot be determined and is presumed to result from inadequate germ cell migration during embryogenesis or accelerated atresia. POF is frequently associated with autoimmune disorders and in some cases (e.g., Addison disease) appears to result from an autoimmune lymphocytic oophoritis. Radiation and chemotherapy are two other important causes; the effects of both are dependent on dose and the age at time of treatment. Galactosemia is an autosomal recessive disorder of galactose metabolism caused by a deficiency of the enzyme galactose-1-phosphate uridyltransferase and another, albeit very rare, cause of POF. Affected women

have fewer primordial follicles presumably due to the cumulative toxicity of galactose metabolites on germ cell migration and survival.

Other rare disorders that may cause amenorrhea include 17α-hydroxylase deficiency, aromatase deficiency, and the gonadotropin-resistant ovary syndrome. Unlike ovarian failure, the ovaries of individuals with these disorders contain follicles and oocytes but do not produce estrogen. The enzyme 17α-hydroxylase mediates an early step in steroid hormone synthesis, without which progesterone cannot be converted to androgens and subsequently aromatized to estrogens. The enzyme aromatase mediates the conversion of androgenic precursors to estrogens; individuals with aromatase deficiency generally exhibit sexual ambiguity at birth, virilization at puberty, and multicystic ovaries. The gonadotropin-resistant ovary syndrome results from genetic mutations in the FSH or LH receptor or post-receptor signaling defects that prevent the ovaries from responding normally to gonadotropin stimulation. In this circumstance, ovarian follicles fail to develop beyond the early antral stage and therefore produce little estrogen.

Pituitary Disorders

Pituitary tumors may cause amenorrhea by directly compressing pituitary gonadotrophs or obstructing the portal venous network that delivers hypothalamic GnRH stimulation, resulting in decreased FSH and LH secretion. They also may cause inadequate or excessive production of other pituitary hormones. Directly or indirectly, these tumors may disrupt normal ovarian function and cause amenorrhea. Virtually all pituitary tumors are benign adenomas that may or may not be functional. Functional tumors may secrete prolactin,

growth hormone (GH), thyroid-stimulating hormone (TSH), or adrenocorticotropic hormone (ACTH). Primary malignant pituitary tumors are extremely rare.

Other uncommon pituitary disorders that may cause amenorrhea include the empty sella syndrome and Sheehan syndrome. The empty sella syndrome results from herniation of the arachnoid membrane, containing cerebrospinal fluid, into the sella turcica compressing the pituitary stalk and the pituitary gland. The sella contains spinal fluid but appears “empty” when viewed by computed tomography (CT) or magnetic resonance imaging (MRI). Sheehan syndrome results from acute infarction and necrosis of the pituitary gland. It is a rare complication of shock due to obstetric hemorrhage. Depending on the extent of pituitary damage, clinical consequences may be limited to disorders of reproductive function (failed lactation, amenorrhea) or multisystem failure due to panhypopituitarism.

Hypothalamic Disorders

The most common cause of amenorrhea results from absent or abnormal patterns of pulsatile hypothalamic GnRH secretion. This, in turn, leads to abnormal levels, or pulse patterns, of pituitary gonadotropin secretion. Both PCOS and hypothalamic amenorrhea that may result from emotional, nutritional, or physical stress have dysfunctional secretion of gonadotropins, but their pathophysiology and clinical presentations differ. Women with PCOS exhibit an increased frequency of pulsatile GnRH secretion, increased LH synthesis, hyperandrogenism, and impaired follicular maturation. In contrast, the inconsistent and generally lower frequency of pulsatile GnRH secretion in women with hypothalamic amenorrhea results in inadequate pituitary gonadotropin release, which is a failure to stimulate or sustain progressive follicular development.

Occasionally, a hypothalamic tumor (craniopharyngioma, meningioma, hamartoma, chordoma) may distort the tuberoinfundibular tract (pituitary stalk) with its portal venous network, interfering with effective delivery of GnRH, resulting in decreased pituitary FSH and LH secretion. Alternatively, interference with hypothalamic dopamine delivery to pituitary lactotrophs releases these cells from tonic inhibition, resulting in hyperprolactinemia. Hypothalamic tumors, therefore, may result in hypogonadotropic hypogonadism and amenorrhea. In other rare instances, GnRH deficiency may be congenital as well. Kallmann syndrome results from a defect in the Kalig-1 gene and is associated with midline craniofacial defects and/or anosmia. Failure of olfactory and GnRH neuronal migration during embryogenesis results in primary amenorrhea and sexual infantilism.

Evaluation of Amenorrhea

A detailed medical history and physical examination are always important. In the patient with amenorrhea, elements of particular interest include growth and secondary sexual development (breast and pubic hair); menstrual history (if any); previous surgery or trauma to the pelvis or central nervous system (CNS); family history of hereditary disorders; evidence of physical, psychological or emotional stress; and symptoms and signs of hirsutism or galactorrhea as well as reproductive tract anatomy.

Medical History

In general, menarche should occur within 2 to 3 years after the initiation of pubertal development. In most young girls (approximately 80%), the first sign of puberty is an acceleration of growth, followed by breast budding (thelarche) and the appearance of pubic hair (adrenarche). In the remainder, adrenarche precedes thelarche, but the two events typically are closely linked in temporal appearance. Consequently, menarche should be expected as early as age 10 (when puberty begins at age 8) and rarely later than age 16 (when puberty initiates at age 13). Importantly, in the United States, the mean ages for thelarche, adrenarche,

---

and menarche in black girls are 6 to 12 months earlier than in white girls. Evaluation is indicated when secondary sexual development fails to begin by age 14 or fails to progress at a normal pace. Once menstrual cycles have been established, amenorrhea for an interval equivalent to three previous cycles, or 6 months, should also provoke an evaluation.

Questions relating to past medical history and lifestyle may identify a severe or chronic illness (diabetes, renal failure, inflammatory bowel disease); head trauma; or evidence of physical, psychologic, or emotional stress. Weight loss or gain and the frequency and intensity of exercise may be revealing. Headaches, seizures, vomiting, behavioral changes, or visual symptoms may suggest a CNS disorder. Vaginal dryness or hot flushes are evidence of estrogen deficiency and suggest either ovarian failure or profound pituitary–hypothalamic dysfunction. Progressive hirsutism or virilization is evidence of hyperandrogenism that may result from PCOS, nonclassic (late-onset) congenital adrenal hyperplasia (CAH), or an androgen-producing tumor of the ovary or adrenal gland; galactorrhea suggests hyperprolactinemia. An obstructed genital tract may present with cyclic pelvic pain or urinary complaints. Developmental anomalies include imperforate hymen, transverse vaginal septum, and cervical atresia. A previous inguinal hernia repair or curettage suggests the possibility of a developmental anomaly or damage to the reproductive tract. Finally, the timing and duration of any treatment with progestational agents (oral contraceptive pills [OCPs], depot medroxyprogesterone acetate), GnRH agonists, or other medications (phenothiazines, reserpine derivatives, amphetamines, opiates, benzodiazepines, antidepressants, dopamine antagonists) or drugs (opiates) may provide important diagnostic clues.

Physical Examination

Body habitus often provides important clinical information in the evaluation of amenorrhea. Height, weight, and body mass index (BMI) should be recorded. Short stature (<60 inches) is a hallmark of gonadal dysgenesis. Lack of secondary sexual characteristics, webbing of the neck, low set ears and posterior hairline, widely spaced nipples, short fourth metacarpals or metatarsals, and a wide carrying angle of the arms (cubitus valgus) are among the classical stigmata of Turner syndrome. Low body weight and poor dentition are frequently associated with hypothalamic amenorrhea resulting from poor nutrition (eating disorders); bulimia; or physical, psychologic, or emotional stress. Conversely,

obesity, or an increased waist-to-hip ratio (>0.85), is frequently associated with insulin resistance and hyperandrogenic chronic anovulation.

Examination of the skin may reveal a soft, moist texture as seen in hyperthyroidism; a rapid pulse and classic eye signs (exophthalmos, lid lag), a fine tremor, and hyperreflexia may provide further evidence to suggest a diagnosis of Graves disease. Hypothyroidism, on the other hand, should be considered when dry and thick skin, bradycardia, blunted reflexes, and thinning of the hair are identified. Orange discoloration of the skin, in the absence of scleral icterus, may result from hypercarotinemia associated with excessive ingestion of low-calorie, carotene-containing fruits and vegetables in dieting women. Acanthosis nigricans—velvety hyperpigmented skin most commonly observed at the nape of the neck, in the axillae, and beneath the breasts—strongly suggests severe insulin resistance and the possibility of Type II diabetes. Acne and hirsutism are indications of hyperandrogenism often associated with chronic anovulation (PCOS), nonclassic CAH, or ingestion of androgenic anabolic steroids. When accompanied by any sign of frank virilization (deepening of the voice, frontotemporal balding, decrease in breast size, increase in muscle mass, or clitoromegaly), the possibility of ovarian hyperthecosis or an ovarian or adrenal androgen-secreting neoplasm must be considered, especially if the temporal appearance of the symptoms is rapid.

Breast development, as assessed by Tanner staging, is a reliable indicator of estrogen production or exposure to exogenous estrogens. Arrested breast development suggests a disruption of the hypothalamic–pituitary–ovarian (HPO) axis. When menarche has not followed adult breast development, a developmental anomaly of the reproductive tract should be considered as well. The breast examination should include gentle compression, beginning at the base and moving toward the nipple. Microscopic examination of any nipple secretions that demonstrate lipid droplets indicates hormone-sensitive galactorrhea and suggests hyperprolactinemia.

Abdominal examination may reveal a mass resulting from hematometra or an ovarian neoplasm. Growth of hair from the pubic symphysis to the infraumbilical region suggests hyperandrogenism. Abdominal striae raise the possibility of Cushing syndrome but much more often result from progressive obesity or previous pregnancy.

As noted previously, thelarche and adrenarche typically are closely linked events during puberty, and in general, breast development and growth of pubic hair progress in a predictable sequence and tempo. The Tanner stages of breast and pubic hair development, therefore, should be consistent. Absent, or scant growth of pubic hair, is a classic sign of AIS, particularly when breast development is asymmetrically advanced. Although examination of the vagina in sexually immature girls, or in those with a small hymeneal ring, is often difficult, whenever possible, a speculum examination should be performed, occasionally requiring anesthesia. A patent vagina and visible cervix excludes Müllerian/vaginal agenesis, AIS, and most obstructive causes of amenorrhea. In those girls with an absent or infantile vaginal orifice, rectal examination should be performed and may reveal a distended hematocolpos above the obstruction when the uterus is present and functional.

Diagnostic Evaluation

A careful history and physical examination will always narrow the range of diagnostic possibilities. Laboratory investigation and imaging should be focused on that differential diagnosis, and with few exceptions, a diagnosis can be quickly and easily established.

Abnormal Genital Tract Anatomy

A history of primary amenorrhea accompanied by an absent or blind vagina confirms a developmental anomaly of the genital outflow tract. The list of diagnostic possibilities is short and includes an imperforate hymen, a transverse vaginal septum, cervical atresia, Müllerian/vaginal agenesis, and AIS (Fig. 36.1). Because each of these disorders has unique features, they generally are not difficult to distinguish.

Patients with an imperforate hymen or transverse vaginal septum/cervical atresia typically present close to the anticipated time of menarche with cyclic perineal, pelvic, or abdominal pain and exhibit an otherwise normal pubertal sequence. With an imperforate hymen, examination reveals no obvious vaginal orifice but does reveal a thin, often bulging, blue perineal membrane and a mass, resulting from the accumulation of mucus and blood in the obstructed vagina. When a transverse vaginal septum or cervical atresia is present, examination reveals a normal vaginal orifice, a short blind vagina, and a pelvic mass above the level of obstruction (hematocolpos, hematometra, hematosalpinx). Differentiation of imperforate hymen and transverse vaginal septum/cervical atresia generally requires no laboratory investigation. A transabdominal or transperineal ultrasound examination will reveal the level and volume of sequestered menses; MRI provides greater anatomic detail and helps to define the anatomy of the anomaly (Fig. 36.2). In some instances, however, laparoscopy may be useful to more clearly define the anatomy. Patients with amenorrhea resulting from Müllerian agenesis usually are asymptomatic. They exhibit normal breast and pubic hair development but no vagina and no symptoms or signs of cryptomenorrhea because the uterus is absent. The diagnosis is usually self-evident from physical examination alone. Further evaluation to exclude skeletal and urinary tract anomalies is indicated. Approximately 12% to 15% of women with Müllerian agenesis have skeletal abnormalities (vertebral and distal extremity anomalies are most common), and one third or more have urinary tract anomalies (ectopic kidney, renal agenesis, horseshoe kidney, abnormal collecting system).

Figure 36.1 Congenital absence of the vagina. The external genitalia are entirely normal in appearance without any evidence of ambiguity, but no vagina present is present. The normal pubic hair indicates androgen responsiveness and eliminates the possibility of AIS, indicating that this simply is congenital absence of the Müllerian duct system.

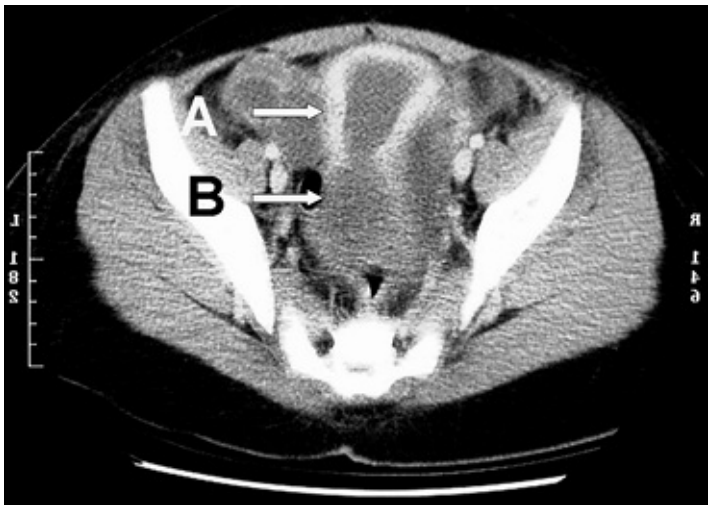

Figure 36.2 Congenital absence of the lower one third of the vagina. MRI demonstrates that a uterus is present *(A)* as well as an upper vaginal pouch *(B)*. The upper vagina has formed a hematocolpos, which began soon after menarche and presented as a pelvic mass.

In girls in whom a uterus is present but who have not yet reached the age when menarche (and cryptomenorrhea) would be expected, imaging must be interpreted cautiously because imaging studies can be misleading when the reproductive organs are immature. Careful observation over time is preferable to repeated invasive investigations.

Normal breast development, absent or sparse growth of pubic hair, and a short blind vagina clearly suggest AIS. Although the chromosomal sex is male (46,XY), the phenotype is female. The testes are undescended, occasionally palpable in the inguinal canals (most commonly at the level of the external inguinal ring), and produce normal male levels of testosterone and Müllerian inhibitory hormone (MIH). Whereas end-organ insensitivity to androgen action, due to abnormalities of the androgen receptor, prevents normal masculinization of the external genitalia, MIH secretion is unaffected, resulting in inhibited internal Müllerian development. Consequently, the external genitalia are phenotypically female, the uterus is absent, and the vagina is short and ends blindly, likely derived from the invaginating urogenital sinus. The diagnosis may be suspected when other family members (e.g., aunt, sister) are affected with this X-linked disorder. Incomplete penetrance may result in impeded but not absent androgen action with growth of more pubic hair than might be expected, but a serum testosterone concentration easily distinguishes AIS from Müllerian agenesis (normal range for a female) and a karyotype firmly establishes the diagnosis.

Cervical obstruction/stenosis and Asherman syndrome are abnormalities of genital tract anatomy, but physical examination of the genital tract most often is normal. When cervical stenosis causes symptoms, worsening dysmenorrhea or prolonged light staining or spotting after menses are the most common complaints; amenorrhea is a rare occurrence. In women with a history of previous conization or other cervical excisional or ablative therapy, uterine sounding may help to establish a diagnosis. Similarly, most women in whom previous infection or surgical trauma caused intrauterine synechiae present with dysmenorrhea, hypomenorrhea, subfertility, or recurrent early pregnancy loss, not amenorrhea. In women whose history clearly suggests the possibility of intrauterine adhesions, ultrasound and hysterosalpingography can reveal their location and extent, but hysteroscopy is the definitive method for diagnosis.

Normal Genital Tract Anatomy

When physical examination reveals normal genital tract anatomy, further evaluation is required to determine the cause of amenorrhea. The possibility of pregnancy should always be considered and excluded.

When breast growth is absent or inconsistent with age and associated with primary amenorrhea, the cause of delayed puberty should be determined. The vast majority of these cases have no pathology. In the remainder, evaluation may reveal thyroid disease, chronic illness (malabsorption, renal disease, eating disorders, inflammatory bowel disease), ovarian failure (e.g., gonadal dysgenesis), a pituitary disorder (tumor, empty sella syndrome, hyperprolactinemia), or a hypothalamic cause (Kallmann syndrome; physical, emotional, or psychologic stress; tumor). Wrist x-rays for bone age and a GnRH stimulation test are important components of the evaluation for delayed puberty in children and adolescents; the differential diagnosis and evaluation in adolescents and adults with primary or secondary amenorrhea are the same.

Thyroid Function Tests

Initial evaluation should include a measurement of serum TSH to detect both primary hypothyroidism (elevated TSH) and primary hyperthyroidism (low TSH). Either may rarely result in amenorrhea. Any abnormal value should be confirmed and accompanied by measurement of serum thyroxine (tetraiodothyronine [T4]) to better define the nature and extent of the thyroid disorder.

When TSH is elevated and the T4 concentration is normal, the diagnosis is subclinical hypothyroidism, best viewed as a compensated state wherein normal levels of T4 are maintained but with increased pituitary stimulation. On rare occasions, both TSH and T4 levels may be low, suggesting hypothyroidism of pituitary origin that will require additional evaluation to include hypothalamic/pituitary imaging (MRI) and careful assessment to determine whether other pituitary functions also are affected.

Prolactin

A serum prolactin determination is another component of the initial evaluation. If hyperprolactinemia occurs before menarche, it may result in delayed puberty and primary amenorrhea. After puberty, it is among the most common causes of secondary amenorrhea. Hyperprolactinemia inhibits pulsatile hypothalamic GnRH secretion, resulting in decreased levels of pituitary FSH and LH secretion. Hypogonadotropic hypogonadism leads to oligo- or amenorrhea. Importantly, one cannot rely on galactorrhea to identify individuals with amenorrhea resulting from hyperprolactinemia. Only one third of hyperprolactinemic women will exhibit galactorrhea, probably because breast milk production requires several other hormones, including GH, T4, cortisol, insulin, and estrogen and progesterone. Serum prolactin determinations, therefore, should be obtained in all amenorrheic women.

Causes of hyperprolactinemia include:

- Primary prolactin-secreting pituitary tumors
- Other pituitary or hypothalamic tumors that may distort the hypophyseal portal circulation and prevent delivery of hypothalamic dopamine to maintain tonic inhibition of prolactin secretion.
- Drugs that lower dopamine levels or inhibit dopamine action (amphetamines, benzodiazepines, butyrophenones, metoclopramide, methyldopa, opiates, phenothiazines, reserpine, and tricyclic antidepressants)
- Breast or chest wall surgery, cervical spine lesions, or herpes zoster (all activate afferent sensory neural pathways and stimulate prolactin secretion)
- Chronic estrogenized anovulation (PCOS), associated with modest elevations in prolactin caused by the effect of tonic estrogen on the galactotrophs but is not a cause for amenorrhea
- Primary hypothyroidism (increased hypothalamic thyrotropin-releasing hormone stimulates prolactin secretion)

- Pharmacologic estrogens (OCP)
- Rare, nonpituitary sources (lung and renal tumors) or causes of decreased prolactin clearance (renal failure).

A careful history will eliminate many of these possibilities. When medications are the cause, prolactin

---

concentrations usually are only moderately elevated, frequently <100 ng/mL. Although medications may offer an obvious explanation, one cannot confidently assume that they are the cause of hyperprolactinemia. If possible, a discontinuation or use of an alternative medication should be considered. When that is not possible and hypothyroidism has been excluded, further investigation to exclude hypothalamic and pituitary tumors and other causes of hyperprolactinemia is appropriate.

Imaging of the hypothalamic and pituitary regions to exclude mass lesions in hyperprolactinemic patients can be accomplished with CT or MRI. MRI generally is regarded as the superior method because it is more accurate for identification of very small lesions or an empty sella and better defines tumor margins and relationships to surrounding structures. The indications for CT or MRI in the evaluation of hyperprolactinemia remain controversial. Those who advocate liberal use of imaging correctly emphasize that the likelihood of a pituitary tumor does not correlate with the prolactin concentration. Pituitary microadenomas (<10 mm) are very common (10% to 30% prevalence in autopsy studies), and even macroadenomas (>10 mm) may be associated with only modest elevations of prolactin (25 to 100 ng/mL) when they are non-functional tumors or may have undergone aseptic necrosis. In addition, imaging may reveal signs of other hypothalamic disease that may be important (tumor, tuberculosis, sarcoidosis, aqueductal stenosis) and amenable to specific treatment. Those who prefer a more selective approach stress that imaging is costly and has a relatively low yield when performed routinely. They correctly emphasize that pituitary tumors rarely grow (even in pregnancy) and are not a contraindication to hormone replacement or OCP and that their natural course is unaffected by treatment with dopamine agonists (bromocriptine, pergolide, cabergoline). In this view, because diagnosis of a pituitary microadenoma generally has little or no impact on clinical management decisions, MRI should be limited to individuals with grossly elevated prolactin levels (>100 ng/mL) who are hypoestrogenic and to those with suspicious symptoms (visual disturbances, headaches) or findings (visual field defects, abnormal optic fundi) suggestive of a macroadenoma. For asymptomatic patients with moderate hyperprolactinemia (20 to 100 ng/mL), some advocate a less costly coned down lateral view of the sella turcica, reserving MRI for those with an enlarged or abnormal appearing sella (erosion of the sellar floor or clinoid processes) or hypothalamic calcifications that suggest a tumor (e.g., craniopharyngioma). The most prudent approach is to obtain an MRI whenever persistent hyperprolactinemia cannot be confidently attributed to medication, estrogenized anovulation, or hypothyroidism.

Follicle-Stimulating Hormone

Initial evaluation of amenorrheic women with normal genital tract anatomy should include

serum FSH to distinguish ovarian failure, manifested by an elevated FSH, from hypothalamic/pituitary disease or dysfunction associated with inadequate or ineffective patterns of gonadotropin secretion (low or normal FSH).

An elevated FSH level is a reliable indicator of ovarian failure but must be interpreted in the context of the clinical presentation. During the perimenopause, regardless of whether it occurs prematurely or at the expected age, FSH levels may rise well before menses have ceased. Remaining follicles may be relatively insensitive to FSH but will respond when the requisite threshold FSH concentration is achieved. Once follicular growth begins and estrogen levels rise, FSH concentrations are transiently suppressed, before rising again to stimulate new follicular growth. FSH levels therefore are dynamic and often fluctuate widely during the perimenopause and must be interpreted cautiously.

FSH levels are high in the gonadotropin-resistant ovary syndrome, which may result from inactivating mutations in the FSH receptor. However, specific efforts to diagnose these rare conditions (ovarian biopsy, genotyping) have no practical clinical value, as the prognosis for future fertility is extremely poor; treatment options for these patients are no different from those offered to women with true ovarian failure. Serum FSH concentrations also are elevated in individuals with 17α-hydroxylase or aromatase deficiencies and galactosemia, but these conditions are extremely rare and do not enter into clinical consideration.

With few exceptions, a high serum FSH level is an indication of ovarian failure. A history of previous radiation or chemotherapy may provide an obvious explanation. Doses of radiation under approximately 100 rad generally have no significant effect, but risk of ovarian damage rises progressively with higher doses. Individuals treated when young may have only transient amenorrhea with a return of menstrual cycles months or years later but are more likely to ultimately develop POF. Women treated as adults are at greater risk for immediate and irreversible ovarian failure. Alkylating agents (e.g., cyclophosphamide), used in the treatment of malignancies and other diseases (systemic lupus erythematosus), are extremely toxic to gonadal tissues. As with radiation, the dose required to induce ovarian failure is inversely related to age at the time of treatment. Other chemotherapeutic agents have the potential for ovarian damage, but their effects are less clear; risk increases with the number of agents involved in combination therapies.

When ovarian failure occurs before age 30 and cannot be confidently explained, a karyotype should be obtained. An abnormal karyotype may be observed in up to one half of all women with primary amenorrhea. Classic Turner syndrome (45,X), structural abnormalities of the X chromosome (deletion, ring, isochromosome), and mosaicism (e.g., 45,X/46,XX) are the most common abnormalities found. A karyotype also will detect the presence of a Y chromosome. The phenotype in Swyer syndrome

---

(46,XY gonadal dysgenesis) and in some with Turner mosaicism (45,X/46,XY) is female because the dysgenetic (streak) gonads fail to produce both MIH and androgens. Consequently, the uterus, fallopian tubes, cervix, and vagina develop normally but the external genitalia do not masculinize. Importantly, however, a peripheral leukocyte karyotype alone cannot exclude the presence of occult Y chromosomal material. Further analysis with fluorescence in situ hybridization (FISH), using one or more probes that are

specific for segments of the Y chromosome, is required and should be performed in any individual with a 45,X karyotype or 45,X mosaic cell line. An occult Y chromosome must be identified because affected individuals are at risk (approximately 25%) for developing a unique type of germ cell tumor (gonadoblastoma) that may contain malignant elements (dysgerminoma, embryonal cell carcinoma, choriocarcinoma). Virtually all such tumors arise early in life. Over the age of 30, therefore, karyotype is unnecessary, and ovarian failure can be confidently regarded as premature menopause. Approximately 25% of patients with gonadal dysgenesis have a normal karyotype (46,XX). Finally, as gonadal dysgenesis with a normal karyotype is associated with neurosensory deafness, audiometry should be considered.

In women with secondary amenorrhea and unexplained POF, further evaluation to exclude autoimmune disease is appropriate, as up to 40% of these individuals may have autoimmune disorders. POF develops in 10% to 60% of women with Addison disease (adrenal insufficiency) and is more common in women with diabetes mellitus (type 1), myasthenia gravis, and parathyroid disease than in healthy women. However, only those with Addison disease are likely to have a demonstrable autoimmune lymphocytic oophoritis. Ovarian biopsy is not indicated in clinical practice, but POF may be a component of a polyglandular syndrome, so screening for autoimmune disorders is indicated. Thyroid abnormalities are the most common and can be identified by measuring TSH, T4, and thyroid autoantibodies (antiperoxidase, antithyroglobulin). Screening also may include 24-hour urinary free cortisol, fasting blood glucose, serum calcium, and a complete blood count. More extensive or specific testing for autoimmune disorders is unnecessary in the absence of other clinical signs and symptoms of disease. Unfortunately, there is no reliable autoimmune screen to confirm a diagnosis of autoimmune ovarian failure.

A recent iatrogenic cause of POF involves the use of uterine artery embolization (UAE) for the treatment of symptomatic uterine fibroids. In this therapy, interventional radiologists catheterize the uterine arteries and infuse microspheres, coils, or other agents to induce occlusion of the uterine arteries. As the uterine and ovarian arteries often share significant anastomoses, the injected material may travel to the ovarian vessels, causing reduced blood flow to the ovary resulting in a significant loss of oocyte numbers and occasionally POF. As with chemotherapy, the older the patient, the greater the likelihood of POF and elevated FSH levels following UAE.

Low normal serum FSH concentration is an indication of hypothalamic or pituitary dysfunction and is the most common result observed in clinical practice. PCOS and hypothalamic amenorrhea are the two main diagnostic possibilities and are easily distinguished by their clinical presentations.

Polycystic Ovary Syndrome

Although there is no universally accepted definition of PCOS, diagnosis generally is based on three criteria—chronic anovulation, clinical evidence of hyperandrogenism (hirsutism, acne, androgenic alopecia) or hyperandrogenemia, and exclusion of other disorders (hyperprolactinemia, thyroid abnormalities, nonclassic CAH). Women with PCOS more commonly exhibit oligomenorrhea (75%) than amenorrhea (25%); irregular and infrequent

menses typically begin soon after menarche but may emerge later, often in association with progressive weight gain. Signs of androgen excess generally do not become evident until years later and usually progress gradually. Transvaginal ultrasound examination typically reveals ovaries that are modestly enlarged and contain numerous small follicles aligned in the periphery ("string of pearls"). Unfortunately, however, up to one third of normal women between the ages of 18 and 25 years have similar ultrasound findings. Women with PCOS frequently are insulin-resistant (insulin sensitivity is reduced by 30% to 40%), exhibit compensatory hyperinsulinemia (up to 80%), and are predisposed to glucose intolerance. Approximately 30% are frankly glucose intolerant; fasting glucose is elevated in <10%. A fasting glucose/insulin ratio <4.5 is a fairly specific, but somewhat insensitive, diagnostic criterion for insulin resistance. Obesity is a common feature in women with PCOS (50% to 75%) and exacerbates insulin resistance and the hyperinsulinemia that is associated with elevated androgen levels. Prolactin levels are mildly elevated in 10% to 25% of women with PCOS. Although the ratio of serum LH/FSH is frequently increased (>2.0), measurement of the serum LH level generally is not useful or necessary. In most cases, therefore, the diagnosis of PCOS is not based on findings of ovarian or hormonal abnormalities but on a history of chronic estrogenized anovulation and clinical findings of androgen excess or obesity.

When hirsutism is severe or perimenarchial in onset, the possibility of nonclassic CAH must be considered. Most commonly, nonclassic CAH results from a deficiency of the enzyme 21-hydroxylase, which mediates an essential step in cortisol synthesis. Affected individuals cannot efficiently convert 17-hydroxyprogesterone (17-OHP) to 11-deoxycorticosterone (DOC; an intermediate step in cortisol synthesis). A follicular phase 17-OHP level

>2 ng/mL merits further evaluation with an ACTH stimulation test (serum 17-OHP before and 30 to 60 minutes after intravenous injection of 250 g ACTH) to confirm the diagnosis (poststimulation serum 17-OHP concentration >1,000 ng/dL).

Determination of Estrogen Status

Evaluation of estrogen levels would seem logical for differentiating PCOS from hypothalamic amenorrhea and other hypoestrogenic disorders. Unfortunately, available methods cannot easily and reliably define the level of ovarian estrogen production. One cannot always rely on symptoms and signs of estrogen deficiency to identify hypogonadal women. Genitourinary atrophy develops only gradually and is uncommonly observed in young women, even when estrogen levels are extremely low, and vasomotor symptoms typically are absent in women with hypothalamic dysfunction. Other methods for assessing the level of ovarian estrogen production include immunoassay of the serum estrogen concentration and "bioassays" based on clinical observation of the amount and character of cervical mucus ("estrogenic" mucus being clear, watery, and relatively abundant) or results of a "progestin challenge test" (presence or absence of withdrawal bleeding after administration of an exogenous progestin). Each of these methods may be useful, but each has pitfalls.

A serum estradiol measurement is easy to perform and relatively inexpensive. One might

reasonably expect low estrogen levels in women with hypothalamic amenorrhea and normal levels in women with PCOS. Unfortunately, estradiol concentrations fluctuate erratically and may be normal or low on any given day and therefore can be misleading. Whereas observations of estrogenic cervical mucus clearly suggest a normal level of ovarian estrogen production, the absence of such findings cannot be confidently interpreted, because many women exhibit such mucus only in the late follicular phase of the cycle when estrogen levels are relatively high.

The progestin challenge is based on the observation that progestin administration (e.g., medroxyprogesterone acetate 10 mg daily for 5 to 7 days or progesterone in oil 100 mg intramuscularly) will induce menses only in those whose circulating estrogen concentrations are adequate to induce endometrial growth. A pure progestational agent must be used; endogenous estrogen status cannot be inferred from the response to an OCP that contains both estrogen and progestin. A positive test (bleeding after completion of progestin treatment) implies normal (or sufficient) levels of estrogen production and a negative test (no withdrawal menses) suggests hypogonadism or an abnormal endometrium. Unfortunately, however, withdrawal bleeding correlates poorly with estrogen status; both false-positive (withdrawal bleeding despite generally low levels of estrogen production) and false-negative (absent bleeding despite significant estrogen production) results are common. Up to 20% of women with oligomenorrhea or amenorrhea in whom substantial estrogen is present do not exhibit withdrawal bleeding. Conversely, up to 40% of women whose amenorrhea relates to stress, exercise, weight loss, or hyperprolactinemia, in whom estrogen levels are generally low, exhibit withdrawal bleeding. A false-positive progestin challenge also has been observed in women with POF.

Hypothalamic Amenorrhea

In the absence of obesity or evidence of hyperandrogenism characteristic of PCOS, the most likely cause of amenorrhea in women with a normal or low serum FSH level is a functional disorder of the hypothalamus or higher CNS centers. Women with hypothalamic amenorrhea generally present with secondary amenorrhea that is frequently accompanied by a history of emotional stress, weight loss (dieting), poor nutrition (eating disorders, chronic illness), or regular strenuous exercise (endurance training). In contrast to women with PCOS, they typically have normal or low body weight and are poorly estrogenized. If estrogen production is poor, a low or normal serum FSH implies a dysfunctional HPO axis because the expected compensatory increase in FSH secretion is not observed. A low or normal serum FSH therefore clearly suggests hypothalamic or pituitary dysfunction. Most women with hypothalamic amenorrhea have normal FSH levels; extremely low or undetectable FSH levels are seldom seen except in women with large pituitary tumors or anorexia nervosa.

Amenorrhea associated with weight loss due to dieting is common; anorexia nervosa is fortunately much less common (15 in 100,000 women per year). In athletic women, particularly long-distance runners, the risk of amenorrhea is increased approximately threefold compared with less athletic women. Chronic debilitating diseases (e.g., end-stage renal disease, malignancy, AIDS, malabsorption) also may result in anovulation and

amenorrhea. In these cases, hypothalamic amenorrhea represents a functional suppression of the reproductive system that may be viewed as an adaptive response to psychologic, physical, or nutritional stress. A unifying hypothesis emphasizes the concept of energy balance: when available energy is excessively diverted (exercise) or insufficiently provided (dieting, malnutrition, bulimia), reproduction is suspended in order to support essential metabolism for survival. The mechanism responsible may involve a stress-induced increase in hypothalamic corticotropin-releasing hormone (CRH) and endogenous opioid secretion that inhibits pituitary gonadotropin release. Pulsatile hypothalamic GnRH secretion is diminished by dopamine and opioids.

The Role of Pituitary Imaging

The diagnosis of hypothalamic amenorrhea cannot be established until organic disease of the CNS, hypothalamus,

or pituitary gland is excluded. Imaging is prudent, even when emotional stress, weight loss, poor nutrition, or regular strenuous exercise appear to offer an explanation for hypothalamic dysfunction and amenorrhea. MRI may reveal a pituitary tumor; an empty sella; or evidence of a hypothalamic tumor, anomaly, or other disease.

The vast majority of pituitary tumors are prolactinomas or nonfunctioning adenomas, but other varieties are rarely identified. Additional evaluation can help to define the nature of a tumor and the extent to which other pituitary functions are compromised. Grossly elevated prolactin levels clearly suggest a prolactinoma; more modest prolactin elevations may be observed when large tumors infarct or a nonfunctioning adenoma distorts sellar anatomy and disrupts normal dopamine delivery to pituitary lactotrophs.

When the clinical presentation suggests Cushing syndrome, screening (e.g. 24-hour urinary free cortisol or an overnight dexamethasone suppression test) is indicated and additional testing (serum ACTH, adrenal CT or MRI) is required when results are abnormal. Physical findings that suggest acromegaly are an indication to measure serum insulinlike growth factor-1 (IGF-1; somatomedin-C); if elevated, an oral glucose tolerance test with GH levels should be performed since a lack of GH suppression is diagnostic. Pituitary function testing (TSH, T4, prolactin, 24-hour urinary free cortisol, IGF-1) also is indicated when imaging reveals a macroadenoma, or an empty sella, to insure that the other trophic pituitary hormones are normal. Dynamic testing is unnecessary in otherwise asymptomatic women with a microadenoma or normal sella. Generally, the empty sella syndrome is a benign condition and not progressive, but because of the possibility of an unrecognized coexisting tumor, periodic surveillance with a prolactin determination and MRI are indicated.

Anatomic abnormalities of the hypothalamus are very uncommon. Hypothalamic tumors (craniopharyngioma, hamartoma, meningioma) are rare, and other mass lesions (tuberculosis, sarcoidosis) are even more infrequent. Congenital hypogonadotropic hypogonadism associated with anosmia or hyposmia (Kallmann syndrome) is another rare inheritable disorder associated with a specific anatomic defect—hypoplastic or absent olfactory sulci. The condition results from a failure of both olfactory axonal and GnRH neuronal migration during development and can be X-linked, autosomal dominant, or

autosomal recessive. The most common form (X-linked) derives from mutations in a single gene (KAL) on the short arm of the X chromosome that encodes a protein (anosmin-1) needed for normal neuronal migration. The clinical presentation (primary amenorrhea, sexual infantilism, hypogonadotropic hypogonadism, and anosmia) and other anatomic (cleft lip and palate) and neurologic (hearing loss, cerebellar ataxia, color blindness) abnormalities are not difficult to recognize. Quite often, imaging fails to reveal any anatomic abnormality of the pituitary or hypothalamus, and the diagnosis of hypothalamic dysfunction is by exclusion.

Treatment of Amenorrhea

Treatment of amenorrhea is obviously focused on the specific etiology, when known, and is always tailored to the patient's needs.

Genital Tract Abnormalities

In women with vaginal/Müllerian agenesis, the primary goal of treatment—creation of a functional vagina—can be accomplished with a variety of methods at the appropriate time after puberty. Frequently, progressive vaginal dilation will be successful in the motivated patient, and surgery can be avoided. The technique involves application of pressure to the point of moderate discomfort (approximately 20 to 30 minutes per day) by using commercially available vaginal dilators, first in a posterior direction (to create a pouch) and then in the usual line of the vaginal axis (after about 2 weeks). After the desired depth is achieved, increasingly larger dilators expand the vaginal diameter and create a functional vagina in approximately 3 to 6 months.

Operative treatment of women with vaginal/Müllerian agenesis generally should be reserved for those who refuse or poorly tolerate vaginal dilation. Traditionally, a neovagina has been created by dissection of the rectovaginal space and placement of a split-thickness skin graft, held in place with a soft mold (the McIndoe procedure). Subsequently, regular intercourse or vaginal dilation must be maintained to avoid the risk of permanent closure by scar contraction. More recently, an operation that employs a transabdominal traction device has been described that can create a functional vagina within 7 to 9 days. This technique offers significant advantages over the traditional vaginoplasty procedure. In the rare woman with vaginal and cervical agenesis with a well-formed uterine body, it may be technically possible to create a neovagina continuous with the uterus and preserve fertility, but the potential for infectious morbidity in the absence of a cervix has led most to conclude that an isolated uterine body usually should be removed.

Reassurance and support are important elements in the management of vaginal/Müllerian agenesis. Affected women should be counseled that normal sexual function can be expected and that genetically normal offspring can be achieved by in vitro fertilization. Oocytes retrieved from their normal ovaries can be fertilized and the resulting embryos transferred to a gestational surrogate. AIS presents different treatment challenges. A functional vagina again can be created by any of the techniques described previously, but surgical treatment is less often required since the vagina is typically short but not completely absent. Genetic offspring are not possible, of course, because women

with AIS do not have oocytes. They have testes, commonly located within the abdomen or in the inguinal canals at the level of the external inguinal ring. Like women with gonadal dysgenesis whose karyotype contains a Y chromosome (46,XY; 45,X/46,XY), individuals with AIS are at increased risk for tumors, as are men with undescended testes. Therefore, the testes should be surgically removed. However, the risk of neoplasia is somewhat lower (approximately 5% to 10% vs. 25%) and tumors are rarely encountered before puberty, so removal of the testes after puberty, generally between age 16 and 18, is recommended. This allows normal secondary sexual development in women with AIS, which results from the aromatization of testosterone and is more natural than can be accomplished pharmacologically.

Initial treatment of women with an imperforate hymen, transverse vaginal septum, or cervical atresia emphasizes relief of symptoms related to accumulated menstrual fluid and debris. Surgical correction of imperforate hymen is straightforward, using a cruciate incision in the hymen and excision of its central portion to allow drainage and normal menstruation from then on. Surgical management of a transverse vaginal septum, on the other hand, is more challenging. The problem is the variable distance between the margins of the lower and upper vaginal canals. Connecting the upper and lower portions of the vagina may be possible or may require a skin graft if the distance between the two precludes a primary junction without tension. Care must be taken not to simply excise the septum, as circumferential scar contraction can lead to severe stenosis and compromise the goal of a functional vagina. Interdigitating flaps of the septal tissue to shift to a more longitudinal orientation of the incisions in the vagina results in a much more functional vagina. In rare women with cervical atresia and a functional uterine body, efforts to preserve the uterus and fertility should be avoided, and removal of the Müllerian structures is the safest management strategy.

Symptomatic cervical stenosis may be resolved with uterine sounding and gentle cervical dilation. For intrauterine synechiae, operative hysteroscopy is the preferred method of treatment to lyse by blunt dissection, scissors, electrodissection, or with a laser; any of these methods achieves results superior to blind curettage. Many clinicians leave an intrauterine balloon catheter in place for 7 to 10 days to separate the walls of the uterine cavity. Concurrently, treatment with an antibiotic and a nonsteroidal anti-inflammatory drug helps to minimize the risk of infection and uterine cramping, and exogenous estrogen treatment (2.5 mg conjugated equine estrogens per day or its equivalent for approximately 4 weeks) accelerates endometrial reepithelialization. Repeated procedures may be required to restore a normal uterine cavity, and risks of preterm labor, placenta accreta, placenta previa, and postpartum hemorrhage are increased, but 50% to 75% of women should be expected to achieve a successful pregnancy.

Ovarian Disorders

Women with gonadal dysgenesis and sexual infantilism should be offered hormone replacement therapy to promote growth, normal bone density development, and secondary sexual maturation. Treatment with exogenous recombinant human GH (50g/kg per day)

accelerates growth that can be sustained for 6 years or more and results in more normal adult height as much as 10 cm over the initial predicted height. Sex hormone replacement should be postponed until the bone age reaches ≥12, to avoid premature epiphyseal closure and allow a longer time for long bone growth. In addition, therapy should follow the normal sequence of sex hormone production observed during adolescence and begin with low doses of estrogen alone (0.3 mg conjugated equine estrogens or 0.5 mg micronized estradiol). Dosage should be increased gradually, and cyclic progestin therapy should be added after 6 to 12 months or first evidence of vaginal bleeding. To achieve maximum bone and breast development, higher doses (1.25 to 2.50 mg conjugated equine estrogens or 2 to 3 mg micronized estradiol) are frequently required. Once secondary sexual development is completed, prescription of long-term hormone replacement should be recommended (e.g., a low-dose OCP) to avoid the emergence of estrogen deficiency symptoms and diminished bone mineral density.

Pregnancy may be achieved in women with gonadal dysgenesis through in vitro fertilization by using donor oocytes. However, pregnancy carries a unique risk for women with 45,X gonadal dysgenesis (Turner syndrome), as numerous cases of aortic dissection, aneurysm, and spontaneous rupture during pregnancy have been reported. Preconceptional echocardiography may identify patients at risk, but catastrophic events still may occur despite the absence of abnormal anatomic findings. Should they conceive spontaneously or by using donor oocytes, echocardiography should be performed at least once in each trimester, and the practitioner should remain alert to any evidence of progressive dilation of the ascending aorta. Women with 46,XY or 45,X/46,XY gonadal dysgenesis should have their gonads removed soon after diagnosis to avoid the risk of gonadal tumors discussed previously. Unlike those with AIS and functional testes, women with gonadal dysgenesis have nonfunctional streak gonads, so there is no advantage to delay their removal.

The primary goals of treatment for women with POF that develops after puberty is complete are relief from symptoms of estrogen deficiency and prevention of premature bone mineral depletion. Standard regimens of cyclic or combined continuous estrogen/progestin hormone replacement therapy or a low-dose OCP will meet the need. Again, in vitro fertilization with donor oocytes offers the possibility of pregnancy, and the prognosis for success is excellent since the uterus is normal. Monitoring or treatment should be offered for any associated autoimmune disorders.

Pituitary Disorders

The overwhelming majority of pituitary tumors are prolactin-secreting adenomas or nonfunctioning tumors. TSH-, ACTH-, or GH-secreting adenomas are extremely rare. A pituitary tumor is frequently discovered when imaging is performed in women with hyperprolactinemia and occasionally in euprolactinemic women with hypogonadotropic hypogonadism that cannot be confidently attributed to weight loss, eating disorders, or regular strenuous exercise (Fig. 36.3). It may be difficult to differentiate a prolactin-secreting adenoma from a nonfunctioning tumor that disrupts normal hypothalamic dopamine delivery, except perhaps when prolactin levels are markedly elevated. However,

because treatment options in hyperprolactinemic amenorrheic women with small intrasellar tumors are the same in either case, a specific diagnosis is not critical. The nature of a tumor may become clear only after treatment with a dopamine agonist restores normal prolactin levels; the majority of prolactin-secreting adenomas shrink in size during treatment, and those that do not are more likely to be nonfunctioning tumors. Importantly, in euprolactinemic amenorrheic women, a small pituitary tumor may be an incidental finding and have no clinical significance.

Transsphenoidal surgery was commonly performed in the past to remove pituitary tumors, but it is now reserved for women with rare TSH-, ACTH-, or GH-secreting adenomas and for those with large nonfunctioning tumors associated with complaints of headache or visual disturbances. As well, surgical intervention may be needed if medical therapy fails or is poorly tolerated. Surgery achieves immediate reduction of prolactin levels and restores cyclic menses in approximately 30% of women with prolactin-secreting macroadenomas and in up to 70% with microadenomas. However, residual or recurrent tumors and hyperprolactinemia are common, and surgery may be complicated by cerebrospinal fluid leakage, meningitis, diabetes insipidus, or other trophic pituitary hormone deficiencies that require further treatment. Postoperative monitoring involves periodic serum prolactin determinations and repeated imaging. Radiation therapy for pituitary tumors is even less attractive and usually is reserved for postoperative recurrence of large tumors because the response to radiation is slow and radiation risks the development of panhypopituitarism.

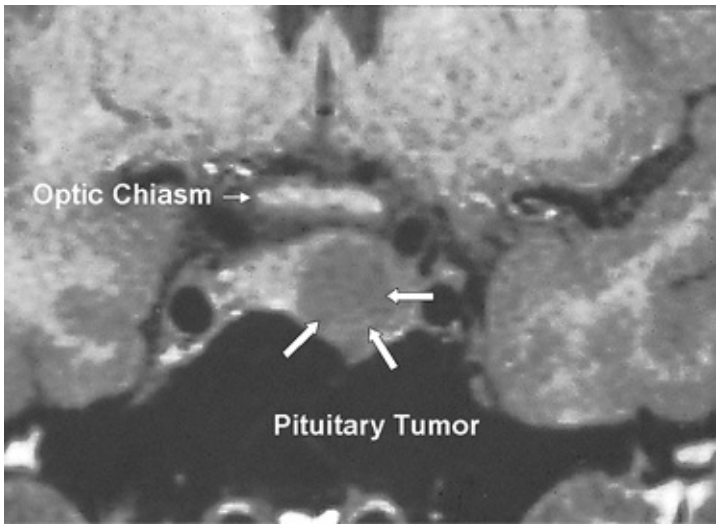

Figure 36.3 A pituitary tumor. MRI of a prolactin-secreting pituitary tumor (*three large arrows*). Note the lateral location and elevation of the diaphragm sella. However, the tumor does not compress the optic chiasm (*single arrow*), and thus no visual disturbances would be anticipated.

Dopamine-agonist therapy is the primary treatment for hyperprolactinemia, independent of whether a pituitary tumor is identified. Bromocriptine is highly efficacious, but side effects (nausea, headache, orthostatic hypotension, dizziness, nasal congestion) are common. The dose should be titrated incrementally to normalize serum prolactin levels, beginning with a

small dose (1.25 to 2.50 mg) at bedtime. Ultimately, most patients will require ≤5 mg per day.

Cabergoline is a more appealing initial therapeutic choice, as it is better tolerated and requires less frequent dosing (0.25 to 3.00 mg every 3 to 7 days). Vaginal administration of bromocriptine or cabergoline is effective because of excellent absorption and may help to reduce side effects when oral treatment is poorly tolerated. Both medications restore menses and ovulatory function in up to 80% of amenorrheic hyperprolactinemic women within 6 to 8 weeks; reduction or cessation of galactorrhea typically requires longer-term treatment.

Medical treatment with a dopamine agonist promotes shrinkage of pituitary macroadenomas in most cases within 6 to 12 weeks. Large tumors that fail to shrink despite effective suppression of excess prolactin secretion are non-functioning adenomas and cause hyperprolactinemia by interfering with delivery of dopamine from the hypothalamus.

Regardless of the treatment they receive, women with macroadenomas should be monitored with serum prolactin determinations and imaging every 6 to 12 months for at least 2 years—less often thereafter if tumor size and prolactin levels remain stable and sooner if prolactin levels rise significantly or symptoms of headache or visual disturbances emerge or recur. Similar monitoring with serial prolactin determinations and periodic imaging is recommended for those with microadenomas. MRI scans are preferable to avoid accumulation of the radiation dose to the pituitary. Dopamine-agonist therapy is the best initial choice for persistent or recurrent tumor or hyperprolactinemia. For the few patients who may require radiation therapy, ongoing surveillance must be implemented to detect any evidence of developing panhypopituitarism.

Pituitary tumors grow slowly or not at all during pregnancy. Approximately 5% of women with pituitary microadenomas will experience tumor growth during pregnancy, even fewer develop signs or symptoms as a result, and only a rare patient will require surgical intervention. The risk is greater but still modest for those with macroadenomas (approximately 15%). Routine serial

---

visual field examinations and serum prolactin determinations in pregnancy usually are unnecessary, but one must be alert to symptoms that may emerge in any trimester. If headaches or visual disturbances appear, however, monitoring with visual field examinations and imaging should begin. The usefulness of prolactin measurements in pregnancy remains controversial, as prolactin levels are very elevated secondary to placental estrogen production. With rare exceptions, dopamine-agonist therapy will arrest and reverse tumor expansion and eliminate associated symptoms and pose no significant risk to the mother or fetus.

Dopamine-agonist therapy also is the treatment of choice for anovulatory hyperprolactinemic women who desire pregnancy or have significant breast tenderness or galactorrhea, with or without a pituitary adenoma. In the absence of other coexisting causes of infertility, approximately 80% of anovulatory hyperprolactinemic women treated with dopamine agonists may be expected to conceive. In the few who cannot tolerate this medical treatment but desire pregnancy, ovulation induction with exogenous gonadotropins

is an effective alternative, since prolactin does not alter the effect of the gonadotropins on the ovarian follicles. Women not seeking pregnancy should be offered hormone replacement therapy or low-dose OCPs to restore menses and effectively prevent the consequences of estrogen deficiency.

The uncommonly encountered empty sella syndrome is benign and does not typically progress to pituitary failure. Treatment and surveillance are the same as in women with a pituitary adenoma. In the rare patient whose amenorrhea results from Sheehan syndrome with more severe pituitary destruction, therapies other than only sex steroid hormone replacement therapy may be required. Depending on the extent of pituitary damage, such women also may require glucocorticoid and thyroid hormone replacement. For those affected women who desire pregnancy, ovulation induction with exogenous gonadotropins is very effective, as the gonadotropin response of the ovaries is normal.

Polycystic Ovary Syndrome

Treatment of women with PCOS is based on whether pregnancy is an immediate goal. Those who desire pregnancy frequently require ovulation induction. For those not seeking pregnancy, the goals of treatment are to establish regular menses and prevent the consequences of chronic unopposed estrogen stimulation on the endometrium (dysfunctional uterine bleeding, endometrial hyperplasia, endometrial adenocarcinoma), to prevent the emergence or progression of hirsutism, and to reduce the longer-term risks of diabetes and cardiovascular disease associated with the disorder.

The therapeutic options to induce ovulation in anovulatory women with PCOS who desire pregnancy are only summarized here. If obese, weight loss should always be encouraged and may be all that is required to restore ovulatory cyclicity, but if weight loss does not restore ovulatory function, it should improve the response to ovulation-inducing agents. The costs, risks, and logistic demands of ovulation induction are significant, so it obviously is preferable to achieve ovulation with weight loss alone.

Clomiphene citrate is the initial treatment of choice since it is safe, inexpensive, and has few serious side effects. Clomiphene is a selective estrogen receptor modulator (SERM) that depletes hypothalamic estrogen receptors and interferes with estrogen-negative feedback and stimulates increased pituitary gonadotropin release and ovarian follicular activity. Treatment should begin with a low dose (50 mg per day on cycle days 3 to 7 or 5 to 9 after a spontaneous or progestin-induced menses) and subsequently increase in 25- to 50-mg increments until ovulation is achieved. Most women with PCOS will respond to clomiphene, but many prove resistant and ultimately require alternative treatment. Among clomiphene-resistant women with PCOS, a significant majority have insulin resistance. For these women, metformin is an insulin-sensitizing agent that can restore cyclic ovulation and spontaneous menses. Consequently, metformin can be used as the first treatment option for ovulation induction, particularly in women with clear insulin resistance and/or women especially concerned about the Clomid-associated risk of multiple gestations. Individuals resistant to clomiphene and metformin are candidates for treatment with exogenous gonadotropins. Women with PCOS frequently are very sensitive to gonadotropins, so unifollicular ovulation may be difficult to achieve and the risk of

multiple pregnancy and ovarian hyperstimulation syndrome is increased. Consequently, treatment must be carefully monitored and is best provided by clinicians with the necessary training and experience.

Ovarian drilling is a newer version of the classic ovarian wedge resection and is another treatment option to induce ovulation in clomiphene-resistant, hyperandrogenic, and anovulatory women with PCOS (Fig. 36.4). The technique involves laparoscopic cautery or laser vaporization of the ovaries at multiple sites. The objective is to decrease

circulating and intraovarian androgen levels by reducing the volume of the ovarian stroma. Unfortunately, the effects of treatment are temporary, and postoperative adhesions that may compromise fertility are a concern. Drilling also may destroy oocytes and shorten reproductive life span; it is therefore best limited to those for whom all other alternatives have been exhausted.

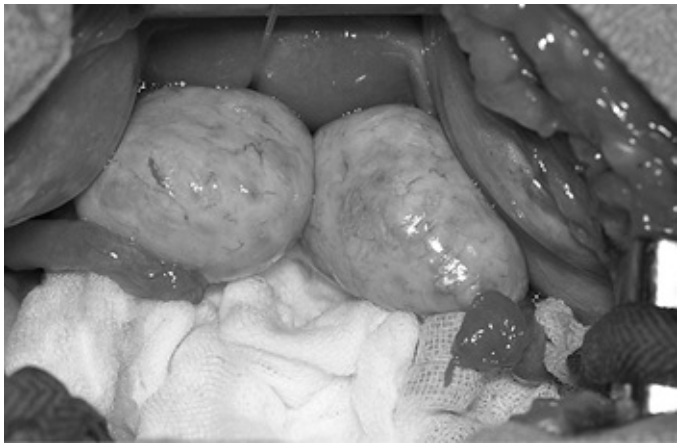

Figure 36.4 Ovaries in of a woman with PCOS, shown at laparotomy. Note the large size of the ovaries, relative to the uterus, with a smooth ovarian capsule and without evidence of ovulatory events.

OCPs have long been the mainstay of treatment for amenorrheic women with PCOS if pregnancy is not desired. Cyclic OCP treatment restores regular and predictable menses, protects the endometrium from the adverse effects of unopposed estrogen stimulation, and provides effective contraception for the occasional spontaneous ovulation. In addition, OCPs decrease circulating androgens by suppressing serum LH levels that stimulate ovarian thecal androgen production and reduce levels of circulating free androgen by stimulating hepatic production of sex hormone–binding globulin. Consequently, within 3 to 6 months after initiation of treatment, hair typically grows more slowly, becomes both finer and lighter in color, and is less noticeable and more easily managed.

For those with more severe hirsutism, OCPs alone may fail to achieve the desired effect. In these patients, spironolactone can be added (100 to 200 mg per day in divided doses) to provide more effective control. Spironolactone acts as a competitive androgen receptor antagonist and blocks androgen action on the pilosebaceous unit (hair follicle, sebaceous

glands, and arrector pili muscle). The multiple actions of combined treatment with and OCP and spironolactone are complementary and frequently effective in the management of hirsutism. In extreme cases, however, a more profound suppression of excess androgen production can be achieved by treatment with a GnRH agonist (e.g., leuprolide acetate) with superimposed cyclic or combined continuous hormone replacement to prevent the consequences of estrogen deficiency. Suppression of adrenal androgen production by chronic glucocorticoid treatment should be reserved for those with documented nonclassic CAH. Suppression risks the inhibition of the adrenal response to stress, immunosuppression, and progressive bone mineral depletion, so monitoring is critical.

Insulin resistance contributes to the pathophysiology of PCOS. It amplifies LH-stimulated ovarian androgen production (directly or via IGF-1) and reduces hepatic sex hormone–binding globulin synthesis (directly). Moreover, hyperandrogenism is associated with an atherogenic lipid profile. Interestingly, there is evidence that in individuals with glucose intolerance, metformin reduces the risk of progression to diabetes and, presumably, the associated increased risk of cardiovascular disease. Unfortunately, these longer-term potential benefits of primary metformin therapy remain unproven. Moreover, the drug often is poorly tolerated (nausea, vomiting, diarrhea). Given these observations, whether primary metformin treatment offers sufficient benefits to justify its use as an alternative, or complement, to other treatment strategies (weight loss, exercise, OCP, statin therapy) remains controversial. Therefore, based on the evidence available to date, primary metformin treatment cannot be recommended for all women with PCOS but merits consideration in selected individuals.

Hypothalamic Disorders

Chronic anovulation resulting from abnormal patterns of pulsatile hypothalamic GnRH secretion is the cause of amenorrhea most commonly encountered in practice. The hypothalamus is implicated only after peripheral, ovarian, and pituitary disorders are excluded. Less commonly, there is profound hypogonadism with very low levels of estrogen production (hypothalamic amenorrhea), often in association with a history of emotional, nutritional, or physical stress.

In the absence evidence of PCOS, the most likely cause of amenorrhea in women with a normal or low-serum FSH level is a functional disorder of the hypothalamus or higher centers. Treatment for hypothalamic amenorrhea depends on whether pregnancy is an immediate goal. Those who desire pregnancy are candidates for ovulation induction. For those not seeking pregnancy, the goals of treatment are to prevent the consequences of chronic estrogen deficiency (genitourinary atrophy, progressive bone demineralization) and to establish regular menses, if desired. Most women with hypothalamic amenorrhea exhibit low levels of endogenous estrogen production.

The options for ovulation induction in women with hypothalamic amenorrhea (Fig. 36.5) are narrower than for those with PCOS and again are only summarized here. In women with a low BMI, weight gain should be encouraged, but weight gain, like weight loss, can be very difficult to achieve. Women should be educated on the relationship between weight and menstrual function and advised that

weight gain may be all that is needed to restore menstrual cyclicity and ovulation. At the least, weight gain is expected to increase the likelihood of a successful response to a simpler, less expensive, and less risky ovulation induction strategy (e.g., clomiphene citrate). Individuals with signs and/or symptoms (fasting, purging) that suggest a serious underlying eating disorder (bulimia, anorexia) should be offered psychiatric evaluation and care before attempting pregnancy to avoid risks to both the mother and fetus.

Figure 36.5 The ovary in hypothalamic amenorrhea. Laparoscopy of the pelvis demonstrates a normal-appearing uterus with the left ovary having a smooth capsule without evidence of follicular activity. This is consistent with the lack of gonadotropin stimulation with a normal but unstimulated ovary.

Similarly, women whose hypothalamic amenorrhea is associated with a high level of regular strenuous exercise should be advised that reducing physical activity might restore menstrual cyclicity and ovulation. At the least, less exercise may improve the response to conservative methods of ovulation induction. However, once again, reduced levels of exercise should not be a prerequisite for treatment. Ovulation induction should be offered to those who desire pregnancy, but unlike women with PCOS, those with hypothalamic amenorrhea often fail to respond to clomiphene. Clomiphene response requires an intact and functional HPO axis, and most women with hypothalamic amenorrhea do not have this, as reflected by low or normal serum FSH levels. Consequently, one of two alternative approaches to ovulation induction is frequently required. Exogenous synthetic GnRH, administered in a pulsatile fashion via a portable and programmable infusion pump, can effectively restore normal levels of pituitary gonadotropin secretion and spontaneous ovulatory function. Pumps require relatively little monitoring once the effective dose has been established; they provoke spontaneous ovulation and are associated with a modest risk of multiple pregnancy. However, many women object to having an indwelling catheter for an extended time (approximately 3 weeks) and reject this option.

Most often, treatment with exogenous gonadotropins to directly stimulate folliculogenesis is preferred. After gonadotropins, exogenous human chorionic gonadotropin is administered to trigger ovulation when follicular maturation is complete. Treatment requires careful monitoring of serial serum estrogen levels and transvaginal ultrasound examinations to determine the size, number, and maturity of developing follicles. The goals of monitoring are to minimize the risks of the ovarian hyperstimulation syndrome and multifetal pregnancies.

Hormone replacement therapy is indicated in women with hypothalamic amenorrhea if pregnancy is not desired and if increased weight or decreased exercise fails to restore menstrual function. In individuals who are anovulatory and not hypoestrogenic or at risk for unwanted pregnancy, cyclic progestational therapy may be all that is required to restore predictable menses and prevent the endometrial consequences of chronic unopposed estrogen stimulation. Treatment with cyclic or combined continuous hormone replacement or an OCP is simplest, however, to prevent any prolonged interval of hypoestrogenism and the depletion of bone mineral that may result.

Summary Points

- Amenorrhea is a common symptom resulting from an abnormality in the reproductive system that may be anatomic (developmental or acquired), organic, or endocrinologic in nature.
- Congenital anomalies of the Müllerian duct system typically present with normal puberty and may be associated with abdominal pain if there is functional endometrium present.
- Gonadal dysgenesis represents the lack of any ovarian function prior to puberty leading to sexual infantilism.
- POF presents as amenorrhea associated with an elevated FSH level and, if occurring prior to age 30, may be associated with the presence of a Y chromosome.
- Pituitary tumors are very common, with the majority secreting prolactin and associated with hypoestrogenic amenorrhea and galactorrhea.
- Hypothalamic amenorrhea is the general term used to describe hypoestrogenic amenorrhea when no anatomic abnormality is identified. It commonly is associated with weight loss or athletic stress.
- PCOS is a very common clinical problem that may present with amenorrhea but is associated with excess androgen production. A significant majority of these women have insulin resistance.
- The most common cause of amenorrhea in women of reproductive age is pregnancy.

Abnormal Uterine Bleeding

Steven R. Goldstein

Abnormal Uterine Bleeding

Abnormal uterine bleeding is a significant issue and accounts for 20% of all gynecologic visits. Like most of medicine, the clinical approach begins with a thorough detailed history. Many physicians have simply encompassed the all inclusive term *menometrorrhagia*. Much more information can be gleamed from the timing and character of the bleeding as well as the clinical backdrop in which it occurs. The American College of Obstetricians a Gynecologists (ACOG) Practice Bulletin No. 14 states, “There is a distinct increase in the incidence of endometrial carcinoma from ages 30–34 years (2.3/1000,000 in 1995) to ages 35–39 (6.1/1000,000 in 1995). Therefore, based on age alone, endometrial assessment to exclude cancer is indicated in any woman older than 35 years who is suspected of having anovulatory uterine bleeding.”

Although endometrial carcinoma is rare in women younger than 35 years, patients between age 19 and 35 who do not respond to medical therapy or have prolonged periods of unopposed estrogen stimulation secondary to chronic anovulation are candidates for endometrial assessment.

The hallmark of ovulation is the regularity and predictability of the cycle, usually within 3 days in terms of the interval between them. To most women, any bleeding from the vagina is thought of as their “period.” To the astute clinician, however, a menses is a bleed that is preceded by ovulation. If a pregnancy does not ensue 14 days after ovulation, a menses will occur. If a woman does not ovulate, estrogen is produced but without corresponding progesterone. The timing of bleeding probably is the result of fluctuating levels of estrogen, which can destabilize the functionalis of the endometrium and cause some degree of shedding. Such anovulatory dysfunctional uterine bleeding, often explained to patients as “hormone imbalance,” is characterized by its lack of predictability in terms of cyclicity, amount, and/or duration of flow as well as accompanying symptoms, if any. Thus, it usually results in metrorrhagia, which is defined as intermenstrual, irregular, or otherwise noncyclic bleeding. The problem for clinicians is that organic pathology including polyps, submucous myomas, hyperplasia, or even frank carcinoma can result in irregular vaginal bleeding that can be indistinguishable from dysfunctional anovulatory bleeding. Menorrhagia, by itself, without a component of metrorrhagia, may be physiologic. With

increasing parity, the amount of surface area of the endometrial cavity will increase, resulting in heavier flow. However, organic pathology such as an enlarged uterine cavity associated with myomas even if there is no submucous component, functional endometrial polyps in synchrony with the surrounding endometrium, adenomyosis, or coagulation defects can also be present. Finally, many women may present with a combination of menorrhagia and metrorrhagia and may have more than one process to account for it. For instance, a woman with an asynchronous endometrial polyp who is still ovulatory or a patient with submucous myomas may display a mixed picture. Furthermore, many patients may not keep good menstrual calendars or may have so much irregularity as to render their ability to help meaningless.

Obviously, other pertinent historic information concerning contraceptive method, possibility of pregnancy, and concomitant medications as well as potential medical confounders should be included. In addition, although this chapter deals with abnormal uterine bleeding, a thorough pelvic examination is essential to exclude any vaginal

---

or cervical pathology as the source of the bleeding. Pregnancy also must always be excluded.

Postmenopausal bleeding is a unique but crucial subset. Since menopause is defined as the final menstrual period, it obviously is a retrospective diagnosis. In late perimenopausal patients, ovarian function may be wildly sporadic, so long episodes of amenorrhea, hot flashes, and even laboratory determinations interpreted as menopausal (increased follicle-stimulating hormone [FSH], decreased estradiol) may be followed by some bleeding, staining, or spotting that may represent agonal episodes of ovarian function. Thus, an absolute definition of postmenopausal bleeding may be difficult; but generally, *any* bleeding, spotting, or staining after 12 months of amenorrhea should be viewed as “endometrial cancer until proven otherwise” and endometrial evaluation becomes mandatory.

Endometrial Evaluation

There are a number of procedures to evaluate the endometrium in premenopausal women with abnormal uterine bleeding as well as postmenopausal women with bleeding in whom endometrial evaluation is indicated. Although numerous studies exist, there are no good prospective, patient-outcome, randomized head-to-head trials. Thus, patient preference; clinician training; and skill, cost, and access issues will determine what method of evaluation best suits a patient. Initially, curettage in the hospital with anesthesia was the gold standard. First described in 1843, it was once the most common operation performed on women in the world. Even 50 years ago, it was understood that the technique missed endometrial lesions in many cases, especially those that were focal (polyps). Furthermore, less then half of the endometrial cavity went unsampled.

In the 1970s, vacuum suction curettage devices first allowed for endometrial sampling without anesthesia in an office setting. Such procedures, although office based, were cumbersome and resulted in great patient discomfort.

Subsequently, cheaper, smaller, less painful plastic catheters with their own internal pistons

to generate suction became popular. These were found to have similar efficacy but better patient acceptance when compared with the vacuum suction devices. One study showed that the percentage of endometrial surface area sampled by one such suction piston biopsy device (Pipelle) was 4%.

In one widely publicized study by Stovall and colleagues, the Pipelle had a 97.5% sensitivity to detect endometrial cancer in 40 patients who were undergoing hysterectomy. The shortcoming of that study was that the diagnosis of malignancy was known before the performance of the specimen collection.

In another study, however, Guido and associates also studied the Pipelle biopsy in patients with known carcinoma who were undergoing hysterectomy. Among 65 patients, a Pipelle biopsy provided tissue adequate for analysis in 63 (97%). Malignancy was detected in only 54 patients (83%). Of the 11 with false-negative results, five (8%) had disease confined to endometrial polyps, and three (5%) had tumor localized to <5% of the surface area of the cavity. The surface area of the endometrial involvement in that study was ≤5% of the cavity in three of 65 (5%); 5% to 25% of the cavity in 12 of 65 (18%), of which the Pipelle missed four; 26% to 50% of the cavity in 20 of 65 (31%), of which the Pipelle missed four; and >50% of the cavity in 30 of 65 patients (46%), of which the Pipelle missed none. These results provide great insight about the way endometrial carcinoma can be focally distributed over the endometrial surface or confined to a polyp. Because tumors localized in a polyp or a small area of endometrium may go undetected, the authors in that study concluded that the “Pipelle is excellent for detecting global processes in the endometrium.”

Other studies of the Pipelle in patients with known carcinoma have shown sensitivities of 82% to 93%. From these data, it seems that undirected sampling, whether through curettage or various types of suction aspiration, often will be fraught with error, especially in cases in which the abnormality is not global but focal (polyps, focal hyperplasia, or carcinoma involving small areas of the uterine cavity).

Transvaginal Ultrasound

Introduced in the mid 1980s, the vaginal probe utilizes higher frequency transducers in close proximity to the structure being studied. It yields a degree of image magnification that is a form of “sonomicroscopy.” In the early 1990s, it was utilized in women with postmenopausal bleeding to see if it could predict which patients lacked significant tissue and could avoid dilation and curettage (D&C) or endometrial biopsy and its discomfort, expense, and risk. Consistently, the finding of a thin distinct endometrial echo ≤4 to 5 mm has been shown to effectively exclude significant tissue in women with bleeding.

Among 163 women with postmenopausal bleeding and an endometrial echo ≤4 mm, there was one cancer (0.6%). Among 97 women with postmenopausal bleeding and endometrial echo <5 mm, there were no cancers. In another Scandinavian study of 394 women with postmenopausal bleeding, there were no cases of cancer as compared with curettage, as well as through follow-up for 10 years, if the endometrial echo was <4 mm.

Since that time, a number of large multicentered trials have taken place. In the Nordic

trial, of 1,168 postmenopausal women with bleeding and transvaginal ultrasound echo ≤4 mm, there were no cancers on curettage. An Italian multicentered study of 930 women with postmenopausal bleeding had an incidence of endometrial cancer of 11.5%. When the endometrial echo was ≤4 mm,

there were two cases of endometrial cancer (negative predictive value 99.79%). When the endometrial echo was ≤5 mm, there were four cases of endometrial cancer (negative predictive value 99.57%). When the endometrial echo was ≤5 mm, there were no cases of complex hyperplasia.

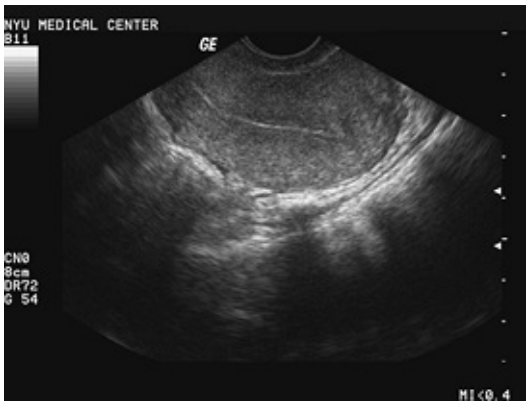

Figure 37.1 Long axis transvaginal ultrasound image of a postmenopausal patient with a history of uterine bleeding. A thin, linear, distinct endometrial echo here has a negative predictive value of 99%. Notice how it is clearly seen taking off from the endocervical canal.

Endometrial thickness should be measured on a sagittal (long axis) image of the uterus, and the measurement should be performed on the thickest portion of the endometrium, excluding the hypoechoic inner myometrium. It is a “double-thickness” measurement from basalis to basalis. If fluid is present, it usually is associated with cervical stenosis and atrophy. In such cases, the layers are measured separately and should be symmetric. The endometrial cavity is a three-dimensional structure, and attempts must be made to image the entire cavity. A well-defined endometrial echo should be seen taking off from the endocervical canal (Fig. 37.1) and should be distinct. Often, fibroids, previous surgery, marked obesity, or an axial uterus may make visualization suboptimal. In these cases, ultrasound cannot be relied on to exclude disease. The next step for such patients with bleeding should be either hysteroscopy or saline infusion sonohysterography, depending on the skill set and preference of the physician and patient.

Sonohysterography

The use of fluid instillation into the uterus coupled with high-resolution transvaginal probes allows tremendous diagnostic enhancement with an inexpensive, simple, well-tolerated office procedure.

The addition of saline infusion sonohysterography can reliably distinguish perimenopausal patients with dysfunctional abnormal bleeding (no anatomic abnormality) from those with globally thickened endometria or focal abnormalities.

A clinical algorithm was proposed and studied in a large prospective trial of perimenopausal women with abnormal bleeding by using unenhanced transvaginal ultrasonography, followed by saline infusion sonohysterography for selected patients, and then either no endometrial sampling, undirected endometrial sampling, or visually directed endometrial sampling, depending on whether the ultrasonographically based triage revealed no anatomic abnormality, globally thickened endometrium, or focal abnormalities, respectively (Fig. 37.2). In that study, 280 patients (65%) displayed a thin, distinct, symmetric endometrial echo ≤5 mm on days 4 to 6, and dysfunctional uterine bleeding was diagnosed. Saline infusion sonohysterography was used in 153 patients (35%). Of these procedures, 44 (29%) were performed because of the inability to adequately characterize and measure the endometrium (Fig. 37.3), and 109 (71%) were done for endometrial measurement ≥5 mm. Sixty-one of those patients then had both anterior and posterior endometrial thickness that was symmetric and <3 mm, compatible with dysfunctional uterine bleeding. Fifty-eight patients (13%) had focal polypoid masses (Fig. 37.4) that were removed hysteroscopically and confirmed pathologically. Twenty-two patients (5%) had submucous myomas, although 148 patients (34%) had clinical and ultrasonographic evidence of fibroids. Ten patients had symmetrical single-layer measurements of endometrium at saline infusion sonohysterography >3 mm (range 3 to 9 mm). Of these, histologic type was proliferative endometrium in five patients and hyperplastic endometrium in five patients. Saline infusion sonohysterography was technically inadequate in two patients who then underwent hysteroscopy with curettage. Undirected office biopsy alone without imaging potentially would have missed the diagnosis of focal lesions such as polyps, submucous myomas, and focal hyperplasia in up to 80 patients (18%).

Based on these results, it seems apparent that any “blind” endometrial sampling should be preceded by fluid instillation sonohysterogram. A process must be shown to be symmetrically “pan uterine” or global to justify a blind procedure. When changes are focal (e.g., polyps, some hyperplasias, some carcinomas), they can be appreciated as such with fluid instillation sonohysterography and then directed biopsies must be carried out.

Polyps usually are clearly discernable, as are submucous myomas. However, sometimes a broad-based polyp will be difficult to distinguish from a submucosal myoma. This may be important for preoperative triage, in that a truly pedunculated submucous myoma will behave more like a polyp in terms of skill and equipment required for its removal in the operating room whereas a broad-based polyp may behave more like a myoma and require resectoscopic capability.

Timing of the Procedure

The uterus is an organ that has had multiple procedures in many women, including D&Cs, childbirth, myomectomy, Cesarean sections, and abortion. As the endometrium proliferates, it is not always a smooth, homogeneous layer. Sonohysterography is best

after the bleeding cycle has ended, when the endometrium is as thin as it is going to be all month long. Otherwise, focal irregularities in the contour of the endometrium may be mistaken for small polyps or focal areas of endometrial hyperplasia (Fig. 37.5).

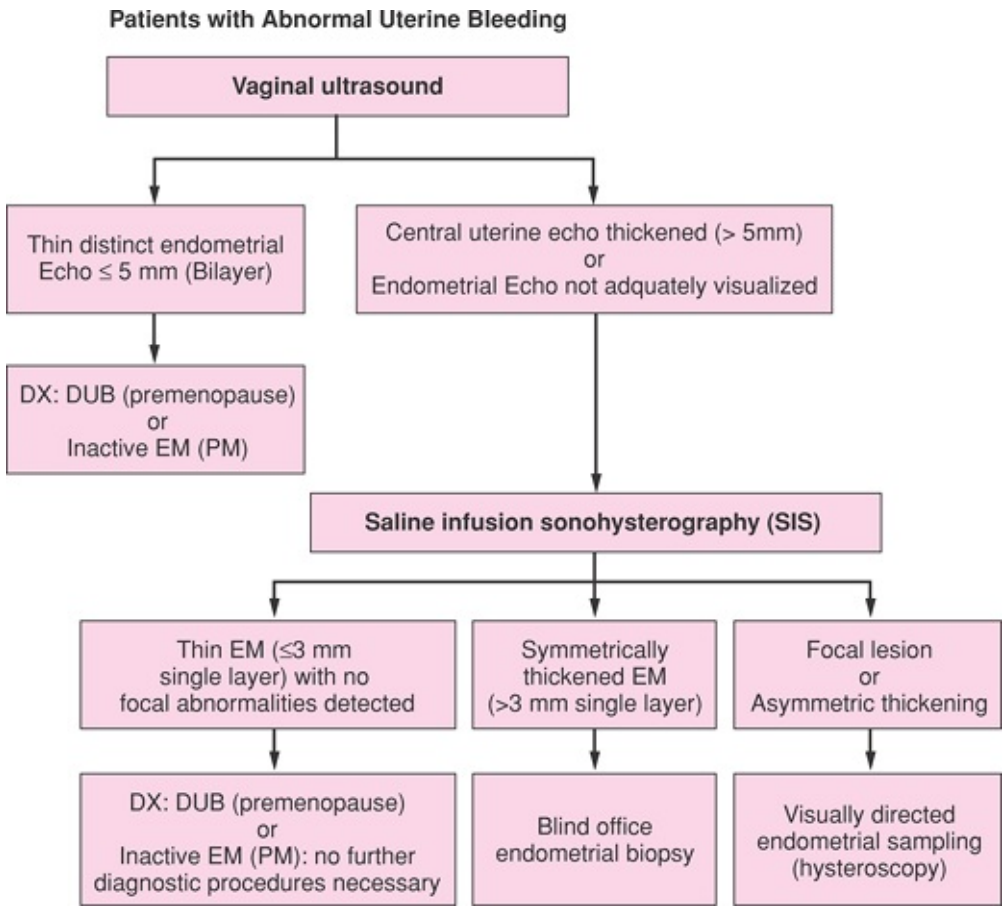

Figure 37.2 Clinical algorithm for ultrasound-based triage for any patients with abnormal uterine bleeding. (DX, diagnosis; DUB, dysfunctional uterine bleeding; EM, endometrium; PM, premenopause.)

The patient sometimes has such irregular bleeding that she cannot tell what an actual menses is. It may be helpful in these cases to use an empiric course of a progestogen such as medroxyprogesterone acetate 10 mg daily for 10 days as a “medical curettage” and then time the ultrasound evaluation to the withdrawal bleed.

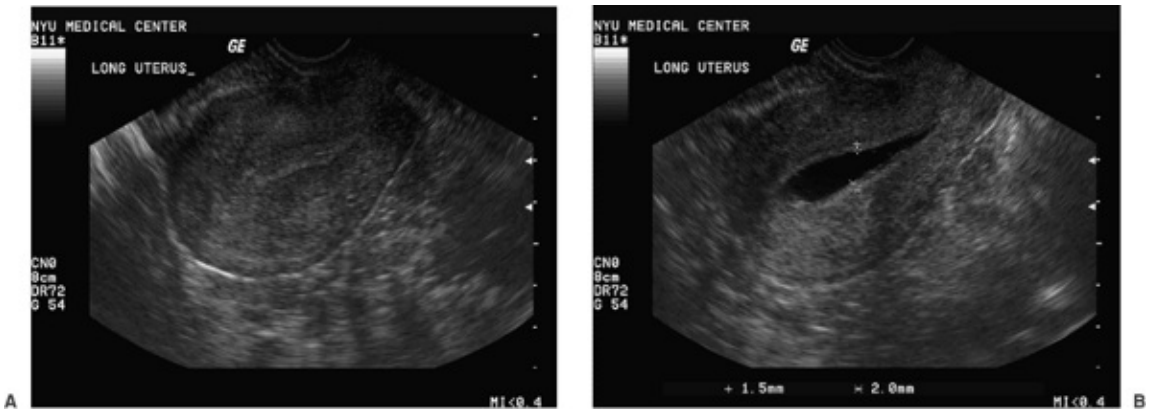

Figure 37.3 A: Transvaginal scan in long axis view of a perimenopausal patient with abnormal uterine bleeding. The endometrial echo is not sufficiently seen along its entirety to make an accurate diagnosis. **B:** Same patient as scanned in **(A)**. Saline infusion sonohysterography reveals a lack of any endoluminal mass. The anterior and posterior endometrium measure 1.5 and 2.0 mm (calipers), respectively.

Hysteroscopy

Hysteroscopy is a procedure in which a small endoscope is inserted into the vagina and through the cervix to view the uterine lining directly. It is useful in identifying and

taking biopsies or removing endometrial polyps and submucous myomas. By skilled operators, it can sometimes be done in an office setting for diagnostic purposes with little or no anesthesia (pretreatment with nonsteroidal anti-inflammatory drugs [NSAIDs], oral or intravenous sedation, paracervical block, etc.). Most often, it accompanies D&C in an operating room setting with at least conscious sedation if not general anesthesia.

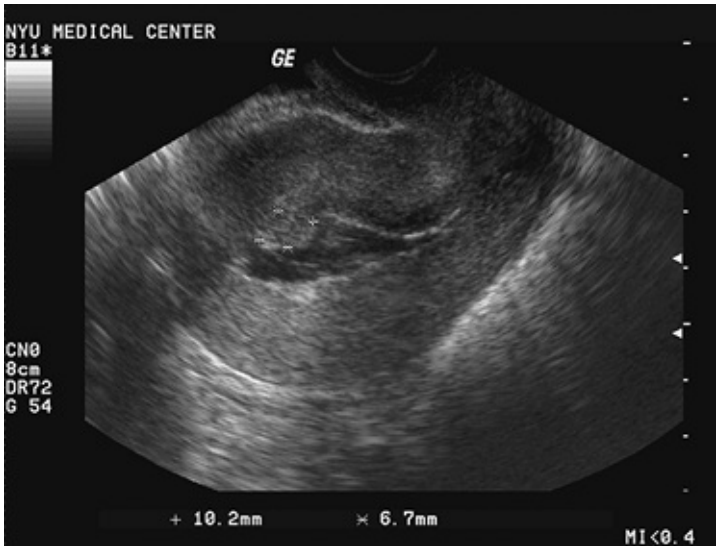

Figure 37.4 Saline infusion sonohysterogram of a perimenopausal patient with abnormal uterine bleeding. A polypoid lesion is seen extending near the anterior fundal region. This measures 10.2 × 6.7 mm (calipers). At the time of D&C with hysteroscopy,

a polyp was identified and confirmed by pathology.

Figure 37.5 Transvaginal pelvic scan of a patient 19 days since her last episode of bleeding. The endometrial surface is irregular. The irregular surface is not unusual, especially in patients who have had previous D&Cs, myomectomies, childbirth, and other procedures. The irregular surface to the endometrium here identified as "moguls" can be misleading. Performing the procedure this long after the last bleeding episode can be fraught with error and should be avoided.

Management of Abnormal Uterine Bleeding

Clinicians have a number of effective options, both medical and surgical, for the management of abnormal uterine bleeding in both pre- and postmenopausal women. As discussed previously, the most common cause of abnormal uterine bleeding in premenopausal women is oligoanovulation, which reflects dysfunction in the hypothalamic–pituitary–ovarian axis. Without cyclic progesterone, the endometrial lining remains proliferative and in some women can become hyperplastic. Such women will present with noncyclic menstrual blood flow ranging from heavy to spotting, with timing and amount that may be erratic.

Also, as discussed previously, in addition to disturbances of ovulation, abnormal uterine bleeding may be caused by anatomic conditions including polyps, fibroids, hyperplasias, and even frank carcinoma, especially with increasing age. Appropriate evaluation of such women prior to therapy has been discussed.

Any bleeding in postmenopausal women who are not on hormone therapy or uterine bleeding that persists longer than 6 months with continuous combined hormone therapy must be evaluated. The most common cause of such bleeding is endometrial atrophy, although organic pathology must be excluded. In such patients, if endometrial proliferation

or hyperplasia without atypia is found, progestin-based medical management may be indicated with follow-up evaluation after several months. If progestin therapy does not result in histologic regression, D&C with hysteroscopy should be performed before definitive surgical therapy because of the possibility of underlying endometrial malignancy. It has been reported that as many as 43% of patients with biopsy diagnosis of atypical endometrial hyperplasia will actually have endometrial carcinoma found on hysterectomy that was undetected by blind sampling.

Medical Therapies

Hormonal Management

Oral Contraceptives

Low-dose combination oral contraceptive pills are considered to be the first-line treatment of abnormal uterine bleeding when it occurs in otherwise healthy, nonsmoking, premenopausal women, regardless of their contraceptive status. Clinical trials have shown that oral contraceptives will normalize irregular bleeding and decrease menstrual flow. Oral contraceptives are not Food and Drug Administration (FDA) approved for the treatment of abnormal uterine bleeding, although considerable evidence exists for such use. The effectiveness of oral contraceptive pills for women with fibroids is variable.

Oral contraceptive pills are not recommended for women with a history of deep vein thrombosis; for those over age 35 who smoke; or for those with other cardiovascular risk factors, particularly hypertension. Although approved for use right into the menopausal transition in normotensive nonsmoking women, some clinicians may be reluctant to use these agents in perimenopausal women with other risk factors. A detailed discussion of the risks and benefits associated with oral contraceptive groups is beyond the scope of this particular chapter. Further resources are available in the Suggested Readings section.

If oral contraceptives are selected for patients with dysfunctional anovulatory bleeding, cycle control will be an important issue. Different birth control pill formulations have different effects on irregular bleeding depending on the estrogen dose and the type of progestin employed. There is more unscheduled bleeding observed in women taking oral contraceptives with lower-dose ethinyl estradiol (20 mcg) than with traditional-dose pills (30 to 35 mcg).

Clinicians should be aware that no clinical trials have assessed the use of oral contraceptive pills in the treatment of dysfunctional anovulatory bleeding. Furthermore, for those perimenopausal patients with some vasomotor symptoms, oral contraceptive pills will often lead to an additional benefit of controlling those symptoms.

Continuous Progestin-Only Contraceptives

Injectable long-acting medroxyprogesterone acetate in a depo form (DMPA) will produce amenorrhea over time and provides contraception if needed. The FDA has issued a black

box warning for DMPA in terms of loss of bone mass as measured by dual x-ray absorptiometry (DXA). This should be factored into therapy of such patients.

The levonorgestrel-releasing intrauterine system (IUS) will result in decreased bleeding over time and is effective in the treatment of menorrhagia. It also provides contraception. Although not specifically FDA approved for treating abnormal uterine bleeding, trials have shown the IUS to be a cost-effective alternative to hysterectomy, although more than 40% of women in the IUS group eventually underwent hysterectomy.

For perimenopausal women with dysfunctional anovulatory bleeding and vasomotor symptoms, menopausal doses of estrogen can be added to DMPA or the IUS system. Such a combined approach can prevent vaginal atrophy, improve the bone density profile, and still minimize uterine bleeding while reducing risks of hyperplasias or uterine malignancy.

Cyclic Oral Progestogen

In the past, cyclic oral progestogen therapy (progestin or progesterone) has been a standard medical therapy for dysfunctional anovulatory bleeding in perimenopausal women. This usually entails administering cyclic progestogen for 12 to 14 days each month. Most often, this results in predictable bleeding episodes. If vasomotor symptoms occur, adding postmenopausal doses of estrogen may be appropriate.

Withdrawal bleeding may continue indefinitely in perimenopausal women who are treated with cyclic progestogen-only therapy, particularly those who are obese and producing peripheral estrogen. When this occurs, it may be appropriate to continue progestogen therapy due to their increased risk for endometrial hyperplasia and neoplasia.

Many perimenopausal women with dysfunctional anovulatory bleeding are not candidates for combination oral contraceptive pills because of cigarette smoking, hypertension, diabetes, migraine headaches with aura, or obesity with a propensity for metabolic syndrome. Cyclic progestin therapy may be an option for these women.

Parenteral Estrogen

For acute excessive abnormal uterine bleeding, the use of intravenous estrogen works well to temporize a volatile situation. Because high-dose intravenous estrogen can acutely increase thrombosis risk, measures to prevent thrombosis should be considered in that setting.

Gonadotropin-Releasing Hormone Agonists

Gonadotropin-releasing hormone (GnRH) agonists induce a reversible hypoestrogenic state. This will ultimately result in endometrial atrophy. These agents are effective in reducing menstrual blood loss in premenopausal patients. They are limited by their expense and side effects including hot flashes, reduction of bone density, and temporary nature. Long-term use often requires add-back therapy of hormones for treatment of symptoms and maintenance of bone density.

Nonhormonal Management

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs reduce endometrial prostaglandin levels by their inhibition of cyclooxygenase. Therapy usually is started 24 to 48 hours prior to menstrual onset, if possible, and then continued for 5 days or until cessation of menstruation. Randomized controlled trials have shown a decrease in menstrual blood loss of 20% to 50% and improvement in dysmenorrhea in up to 70% of women.

Iron

All women experiencing abnormal uterine bleeding should be evaluated for anemia due to iron deficiency. Iron supplementation of such women may be appropriate, depending on laboratory determinations.

Surgical Management

Dilation and Curettage

D&C, by itself, is a blind surgical procedure that usually requires general anesthesia. Because it is a blind procedure

---

when performed without concurrent hysteroscopy, D&C can miss localized disease such as polyps, submucous myomas, or focal hyperplasias. Furthermore, D&C does not completely remove all intracavitary tissue. Modern management of abnormal uterine bleeding no longer includes blind D&C alone. Hysteroscopy—the ability to introduce fiber optic hysteroscopes into the endometrial cavity by using various distending media—allows for both diagnostic visualization and operative intervention for appropriate patients. Resection of endoluminal masses (sessile polyps or submucous myomas) can be readily carried out. Preoperative assessment for an appropriate triage of patients will enhance the overall surgical experience.

Endometrial Destruction

Surgical techniques for endometrial resection and ablation have emerged as alternatives to hysterectomy in selected patients for the treatment of abnormal uterine bleeding. Adequate endometrial histologic evaluation should take place prior to an ablative procedure. Some approaches to ablation do not involve visualization of the endometrial cavity. Thus, they may not effectively treat abnormal bleeding caused by polyps or submucous myomas. Prior to an endometrial destructive procedure, clinicians should thoroughly evaluate the endometrial cavity with sonohysterography or diagnostic hysteroscopy. Any endoluminal masses should be dealt with prior to a destructive ablative procedure.

Ablative procedures may not successfully treat abnormal uterine bleeding when the

anatomic lesion is located in the uterine wall, such as intramural myomas that extend into the endometrial cavity or extensive adenomyosis. Endometrial ablation may result in scarring that may limit the ability to evaluate subsequent abnormal uterine bleeding with traditional methods (biopsy, transvaginal ultrasound, sonohysterography). If patients have multiple risk factors for development of endometrial hyperplasias or neoplasia later in life, this should be taken into consideration.

The advantages of avoiding hysterectomy with an outpatient ablative procedure are obvious both in terms of cost, disability, and the like. Technologies include radio frequency electrical source, heated intrauterine fluid, and cryoablation. However, serious complications and even deaths have been reported. This underscores the need for meticulous patient selection and appropriate surgical training.

Uterine Artery Embolization

In uterine artery embolization, a catheter is introduced into the femoral artery and advanced to the uterine artery under fluoroscopic guidance in an interventional radiology suite using intravenous conscious sedation, local anesthetics, and NSAIDs for the management of anxiety and pain. Tiny particles or microspheres are used to embolize arterial blood flow, which will result in infarction of fibroids and thus control bleeding. Following the procedure, most women experience postembolization syndrome, which consists of pelvic pain, cramping, nausea, vomiting, fatigue, fever, myalgias, and malaise. This usually is self-limited, improves over 7 days, and can be managed as an outpatient. The reported improvement in abnormal bleeding occurs in more than 85% of women. Bulk related symptoms are reportedly controlled more than 60% of the time.

Hysterectomy

Hysterectomy (total or supracervical) is the only definitive cure for benign abnormal uterine bleeding that has failed to respond to medical treatment. The risk and benefits of hysterectomy are discussed elsewhere. Needless to say, many women with abnormal uterine bleeding can be managed either medically or less invasively.

Summary Points

- Abnormal uterine bleeding is a significant issue and accounts for 20% of all gynecologic visits.
- Endometrial assessment to exclude cancer is indicated in any woman older than 35 years who is suspected of having anovulatory uterine bleeding.
- An absolute definition of postmenopausal bleeding may be difficult, but generally, *any* bleeding, spotting, or staining after 12 months of amenorrhea should be viewed as "endometrial cancer until proven otherwise," and endometrial evaluation becomes mandatory.
- Curettage or various types of suction aspiration often will be fraught with error, especially in cases in which the abnormality is

not global but focal (polyps, focal hyperplasia, or carcinoma involving small areas of the uterine cavity).
- Fluid instillation into the uterus coupled with transvaginal sonography enhances the diagnostic accuracy especially in perimenopausal patients with dysfunctional abnormal bleeding (no anatomic abnormality) from those with globally thickened endometria or those with focal abnormalities (polyps, myoma).
- Low-dose combination oral contraceptive pills are considered to be the first-line treatment of abnormal uterine bleeding when it occurs in otherwise healthy, nonsmoking, premenopausal women, regardless of their contraceptive status.
- Oral contraceptive pills are not recommended for women with a history of deep vein thrombosis; for those over age 35 who smoke; and for those with other cardiovascular risk factors, particularly hypertension.
- Hysterectomy (total or supracervical) is the only definitive cure for benign abnormal uterine bleeding that has failed to respond to medical treatment.

Premenstrual Syndrome

Robert L. Reid

Molimina, Premenstrual Syndrome, and Premenstrual Dysphoric Disorder

During the reproductive years, up to 80% to 90% of menstruating women will experience symptoms (breast pain, bloating, acne, constipation) that forewarn them of impending menstruation, so-called premenstrual molimina. Available data suggest that as many as 30% to 40% of these women are sufficiently bothered by such molimina that they would seek relief if it were readily accessible, simple, and safe. Since the term *premenstrual syndrome* (PMS) has become so ingrained in lay culture, most women describe the symptoms of molimina as PMS. However, moliminal symptoms show a variable association with the more severe psychologic symptoms typically required to meet the research diagnostic criteria for PMS.

Researchers in the field have argued that the term *premenstrual syndrome* should be reserved for a more severe constellation of symptoms that affects closer to 5% of women during their reproductive years. To capture the true severity of PMS in this population, the definition describes not only the symptoms but also their functional impact. PMS has been defined as “the cyclic recurrence in the luteal phase of the menstrual cycle of a combination of distressing physical, psychological, and/or behavioral changes of sufficient severity to result in deterioration of interpersonal relationships and/or interference with normal activities.”

The American Psychiatric Association, following years of debate about whether to include PMS in their *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV), included as an appendix (meaning that the subject requires further study) a condition labeled *premenstrual dysphoric disorder* (PMDD) (Table 38.1). Such a designation was intended to alert physicians to a combination of specific severe symptoms (mostly psychiatric in nature) that could mimic other psychiatric disorders with the exception that the symptoms recurred in the premenstrual phase of the menstrual cycle.

Diagnosis

History and Charting

A typical woman suffering from PMS may describe herself as a well-adjusted person for most of the month who is productive at work and in other endeavors and, if she has children, a good mother. However, starting 7 to 10 days prior to menstruation, she awakes in the morning with feelings of anger, anxiety, or sadness. At work, she may have difficulty concentrating on the tasks at hand and may overreact to otherwise typical actions of coworkers, friends, her partner, or her children. She feels depressed but cannot understand why because she typically enjoys life and is happy with most of its aspects. Occasionally, depression, anger and aggression, or anxiety may be extreme and result in concerns for the welfare of the affected woman or those around her.

A “black and white” diagnostic cutoff for determining if someone suffers from PMS is not presently possible. Although many women report feeling bloated and irritable before menstruation, further questioning usually reveals that these symptoms have little substantive impact on their lives.

In part, the distinction between troublesome premenstrual moliminal symptoms and PMS may have to do with the duration and severity of symptoms. Particularly in the first few years after symptoms appear, the severity of PMS

may vary dramatically from month to month. The nature of symptoms and their functional impact is best established by self-report using a prospective calendar record. Any calendar used for this purpose must obtain information on four key areas: specific symptoms, severity, timing in relation to the menstrual cycle, and baseline level of symptoms in the follicular phase.

TABLE 38.1 Diagnostic Criteria for Premenstrual Dysphoric Disorder

1. Timing of symptoms
   Symptoms are present during the last week of the luteal phase, remit within the first few days of menses, and are absent during the week following menses. The symptoms occur during most, if not all, menstrual cycles.
2. Symptoms
   At least five symptoms are required, including at least one of the first four symptoms:
   - Markedly depressed mood
   - Marked anxiety
   - Marked affective lability
   - Persistent and marked anger

Decreased interest in usual activities
Lethargy
Marked change in appetite
Hypersomnia or insomnia
A sense of being overwhelmed or out of control
Physical symptoms

3. Severity
   The symptoms markedly interfere with work, school, social activities, and relationships with others.
4. Other disorders
   Rule out that the disorder is not merely an exacerbation of a major affective, panic, dysthymic, or personality disorder, although PMDD can be superimposed on any of these disorders.
5. Confirmation of the disorder
   The above criteria must be confirmed by prospective daily self-ratings for two consecutive menstrual cycles.

PMDD, premenstrual dysphoric disorder.
Adapted from American Psychiatric Association. *Diagnostic and statistical manual of mental disorders*, 4th ed. Washington, DC: Author, 1994.

Retrospective accounts about symptoms often fail to provide critical information on timing of symptoms or baseline level of symptoms during the follicular phase of the cycle. For example, many individuals with underlying psychiatric disease will experience premenstrual exacerbation of their symptoms. They will recall the severe symptoms prior to menstruation and may give a history that sounds typical for PMS. However, when they complete a 2-month calendar record, it usually becomes apparent that symptoms are present all the time and are at their worst premenstrually. This has been termed *premenstrual magnification* of an underlying psychiatric disorder.

PMS symptoms typically appear after ovulation, worsen progressively leading up to menstruation, and are relieved at varying rates after the onset of menstruation. In some women, there is almost immediate relief from any psychiatric symptoms with the onset of bleeding, while for others the return to normal is more gradual. The most severely affected women report symptoms beginning shortly after ovulation (2 weeks before menstruation) and resolving at the end of menstruation. Such individuals typically report having only one “good week” per month. If this pattern is long standing, then it becomes increasingly difficult for interpersonal relationships to rebound during the good week with the result that symptoms may start to take on the appearance of a chronic mood disorder. Whenever charting leaves the diagnosis in doubt, a 3-month trial of medical ovarian suppression (discussed later in the chapter) usually will provide a definitive answer.

About 5% to 10% of women who suffer from PMS experience a brief burst of symptoms (coincident with the midcycle fall in estradiol that accompanies ovulation) with a return to normal later in the luteal phase when symptoms recur (Fig. 38.1). The different patterns of PMS symptoms are shown in Figure 38.2.

Information should be sought about stresses related to the woman's occupation and personal life, as these may tend to exacerbate PMS. Past medical and psychiatric diagnoses may be relevant in that a variety of medical and psychiatric disorders may show premenstrual exacerbation. A prospective symptom record should usually be maintained for a minimum of two complete cycles prior to establishing a diagnosis, since an unfavorable life event occurring during the follicular phase of a single month could give the erroneous impression that symptoms were continuously present. Key components of a prospective symptom record are listed in Table 38.2.

One example of such a calendar record, the PRISM calendar (prospective record of the impact and severity of menstrual symptoms) (Fig. 38.3) allows rapid visual confirmation of the nature, timing, and severity of menstrual cycle–related symptomatology and at the same time provides information on life stressors and the use of PMS therapies. Although symptoms are rated in severity on a scale from 1 to 3, the actual interpretation of the calendar requires no mathematical calculations. An arm's length assessment of the month-long calendar usually allows a rapid distinction to be made between PMS and other more chronic conditions (Fig. 38.4).

Physical Findings

History should usually be accompanied by a physical and gynecologic exam, since many women with apparent PMS may have coexisting medical conditions. The summation of premenstrual and menstrual symptoms often determines the overall experience of women who suffer from PMS, and therapy directed at gynecologic disorders such as dysmenorrhea or heavy flow can dramatically reduce the perceived severity of menstrual-related symptoms. Organic causes of PMS-like symptoms must be ruled out. Marked fatigue may result from anemia, leukemia, hypothyroidism, or

diuretic-induced potassium deficiency. Headaches may be due to intracranial lesions. Women attending PMS clinics have been found to have brain tumors, anemia, leukemia, thyroid dysfunction, gastrointestinal disorders, pelvic tumors including endometriosis, and other recurrent premenstrual phenomena such as arthritis, asthma, epilepsy, and pneumothorax. Efforts to rule out such causes for premenstrual distress are important before choosing any PMS therapy.

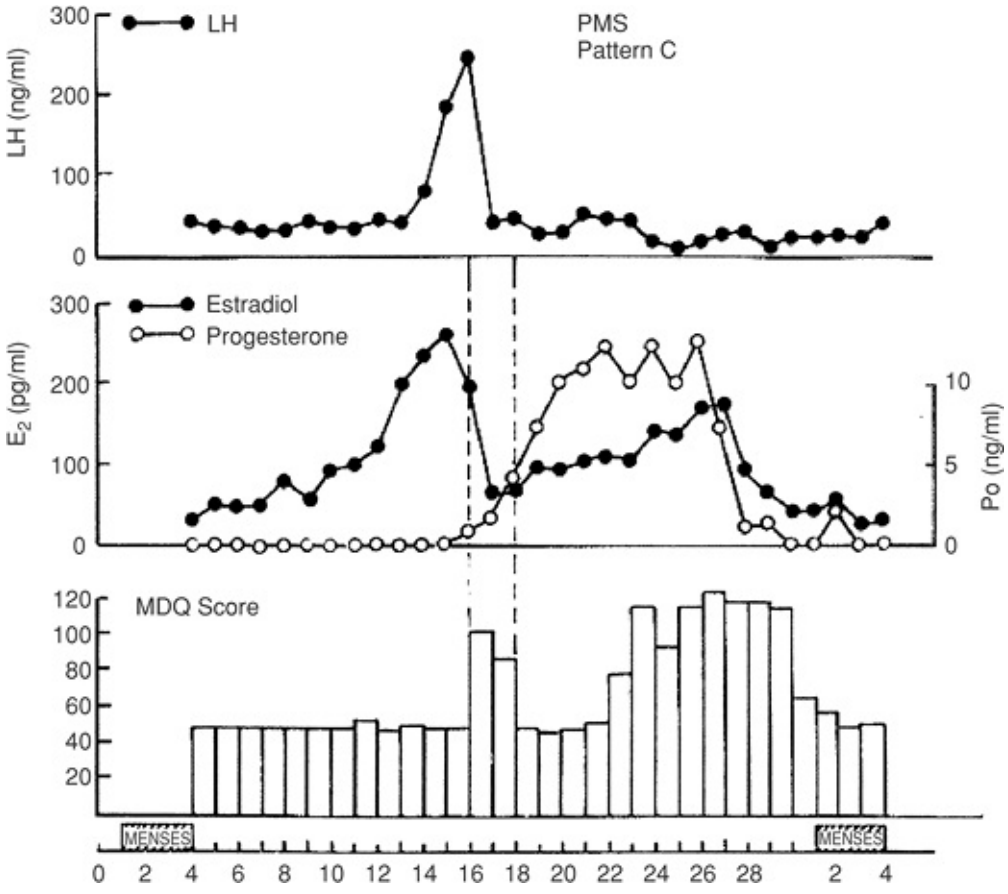

Figure 38.1 Circulating gonadotropin, estradiol, and progesterone concentrations correlated to symptom severity in a woman with midcycle and PMS symptoms—so-called pattern C PMS. (LH, luteinizing hormone; PMS, premenstrual syndrome; E_2, estradiol; Po, progesterone; MDQ, Menstrual Distress Questionnaire.) (From Reid RL. Premenstrual syndrome. In: Rebar RW, ed. *Female reproductive endocrinology*. Available at: *http://www.endotext.com*. Accessed January 16, 2003, with permission.)

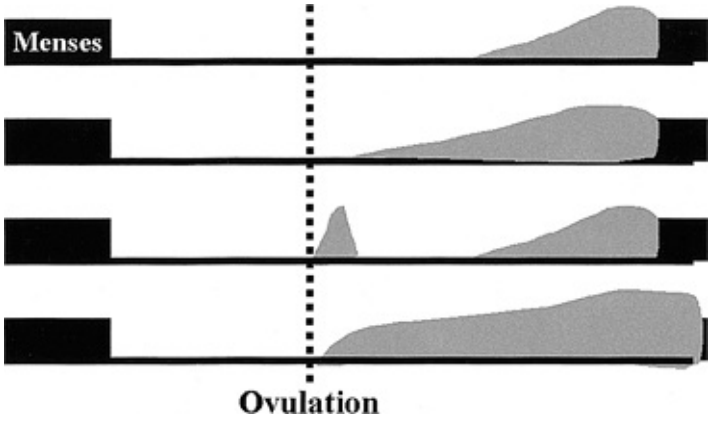

Figure 38.2 Four common patterns of PMS symptomatology in relation to the menstrual cycle. Note that in every case, symptoms commence after ovulation. (From Reid RL. Premenstrual syndrome. In: Rebar RW, ed. *Female reproductive endocrinology*. Available at: *http://www.endotext.com*. Accessed January 16, 2003, with permission.)

Blood Tests

Contrary to some claims, there is no blood test that will establish a diagnosis of PMS. Blood work is only helpful to rule out conditions such as anemia, leukemia, or thyroid dysfunction.

Etiology

Many theories have attempted to explain the diverse manifestations of PMS, but until recently, no single theory has received widespread acceptance. Many of the early theories lacked biologic plausibility and appeared to have emerged as a means to market specific therapeutic products. More recently, a theory that links gonadal steroid levels and central serotonergic activity has begun to emerge.

The current consensus seems to be that in some predisposed women, normal fluctuations in the gonadal hormones estrogen and progesterone trigger central

biochemical events related to PMS symptomatology. Of all the neurotransmitters studied to date, serotonin seems to be the most promising central target. It is likely that serotonin levels dip premenstrually in most women and that susceptible individuals will show varying degrees of psychiatric symptomatology. Many women report a menstrual or immediate postmenstrual state of mental well-being (sometimes bordering on euphoria) that may reflect a rebound surge of serotonin activity. The theoretical effects of gonadal hormones on serotonin activity (Fig. 38.5) form the basis for several current interventions for PMS and PMDD.

TABLE 38.2 Key Elements of a Prospective Symptom Record Used for the Diagnosis of Premenstrual Syndrome

1. Daily listing of symptoms
2. Ratings of symptom severity throughout the month
3. Timing of symptoms in relation to menstruation
4. Rating of baseline symptom severity during the follicular phase

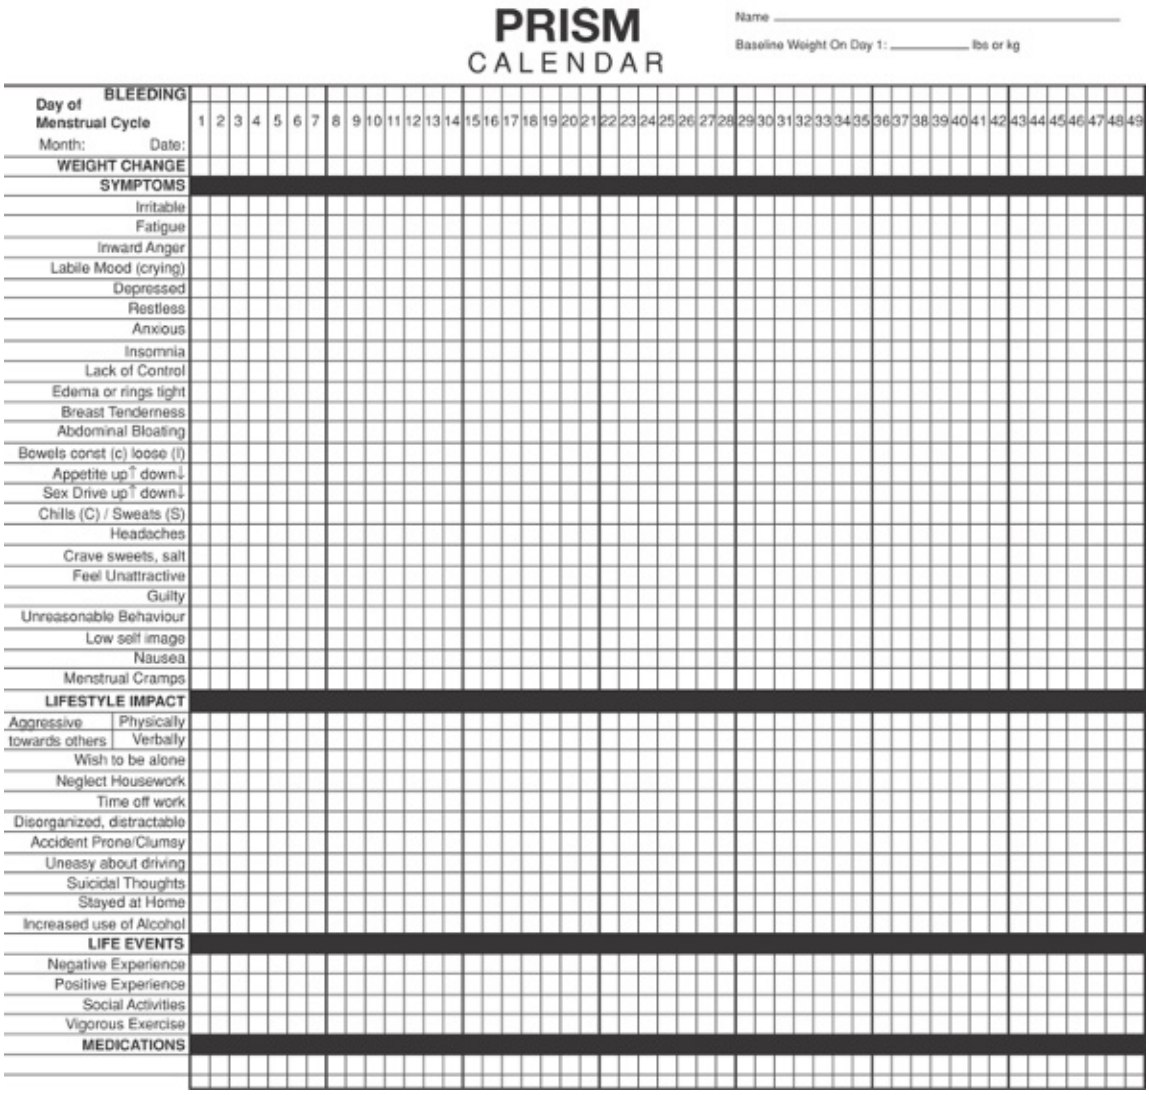

Figure 38.3 One example of a prospective record of the impact and severity of menstrual symptoms—the PRISM calendar. (From Reid RL. Premenstrual syndrome. In: Rebar RW, ed. *Female reproductive endocrinology*. Available at: *http://www.endotext.com*. Accessed January 16, 2003, with permission.)

Several lines of evidence from clinical medicine support this interrelationship between estrogen or lack of estrogen effect (perhaps mediated by progestin-induced depletion of estrogen receptors) and central serotonergic activity. The midcycle appearance of PMS symptoms in women with pattern C PMS coincides with the periovulatory fall in estradiol, whereas the reappearance and ever-increasing severity of symptoms in the late luteal phase may result from progesterone-induced depletion of central estrogen receptors coincident with the decline of estradiol leading up to menstruation (Fig. 38.1). Estrogen has been shown to

alleviate clinical depression in hypoestrogenic perimenopausal women in double-blind clinical trials. The addition of sequential progestin therapy to estrogen replacement triggers characteristic PMS-like mood disturbance in some susceptible postmenopausal women. Antiestrogens given for ovulation induction may, at times, provoke profound mood

disruption. Women with PMS show a surprisingly high frequency of premenstrual and menstrual hot flashes (85% of those with PMS vs. 15% of non-PMS controls) that are typical of those experienced by menopausal women. Selective serotonin reuptake inhibitors (SSRIs) have been shown to relieve hot flashes in breast cancer survivors who have been made menopausal by chemotherapy. In each of these circumstances, a decrease in exposure to estrogen has been linked to mood disturbance, and in each case, a decrease in serotonin activity (inferred from the response to SSRIs) appears to be the proximate cause.

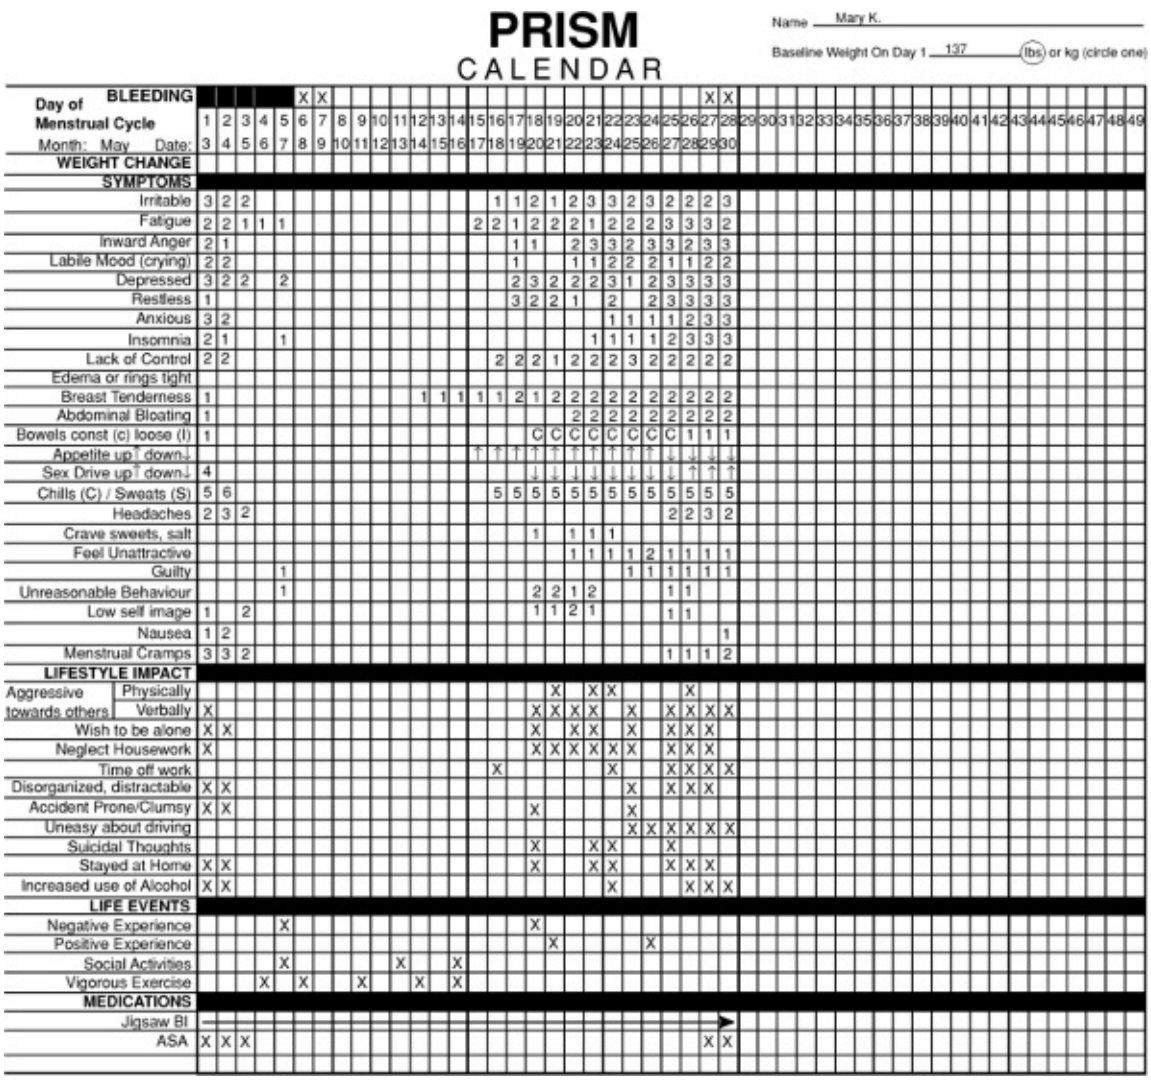

Figure 38.4 Arm's length assessment of a completed PRISM calendar reveals a pattern of symptoms consistent with PMS. (From Reid RL. Premenstrual syndrome. In: Rebar, RW, ed. *Female reproductive endocrinology*. Available at: *http://www.endotext.com*. Accessed January 16, 2003, with permission.)

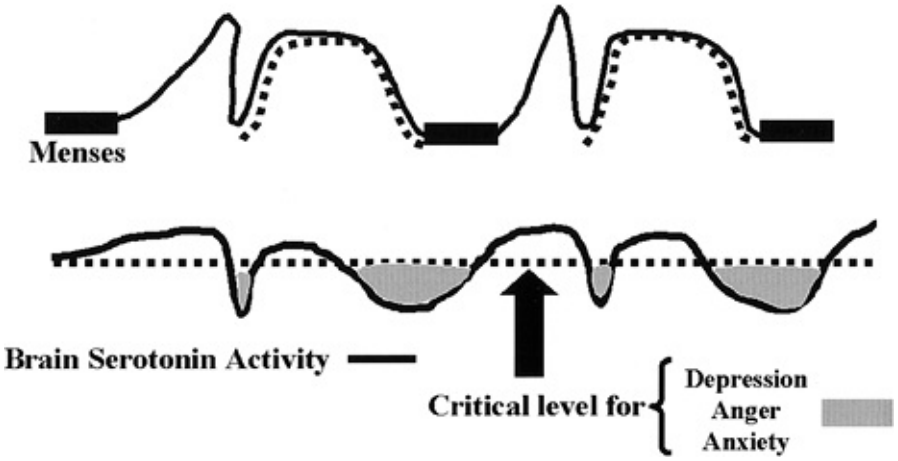

Figure 38.5 A hypothetical depiction of the interrelationship between gonadal steroid fluctuations and central changes in serotonin activity to explain the timing of symptoms in PMS. When serotonin levels or activity fall below an arbitrary level (that may be influenced by stress, heredity, or other factors), symptoms of anger, anxiety, or depression may emerge. (*Solid line*, estrogen; *dotted line*, progesterone.) (From Reid RL. Premenstrual syndrome. In: Rebar RW, ed. *Female reproductive endocrinology*. Available at: *http://www.endotext.com*. Accessed January 16, 2003, with permission.)

Therapy

Education and Counseling

Women who present with severe premenstrual complaints often benefit from reassurance that they are not "losing their minds" and that PMS is a real condition that affects many women of reproductive age. Although all the answers cannot be found with regard to PMS, reassurance can be provided that there is an available range of effective therapies, which is equally important information.

The prospective documentation of symptoms is as much a part of therapy as it is the key to diagnosis (Table 38.1). The use of a calendar record (listing the range of PMS symptoms) may provide much needed reassurance that other women experience similar symptoms. The completed chart may demonstrate to the patient for the first time the cyclicity of her symptoms, supporting a clear link to hormonal shifts of the menstrual cycle.

While it is useful for women with PMS to learn to anticipate times in the month when vulnerability to emotional upset and confrontation may be greatest, the strategy of making important decisions "only on the good days," as espoused in some PMS clinics, falls apart if premenstrual symptoms last for more than just a few days per month. For some women, premenstrual symptoms may last for a full 3 weeks, and advising them to restrict their important activities to the remaining days of the month is neither helpful nor warranted. Interventions aimed at reducing symptoms are more appropriate in this circumstance.

Lifestyle Modification

Communication Strategies

When an individual is suffering to a degree that requires more than simple counseling and reassurance, measures aimed at lifestyle modification should first be explored. Women with such symptoms should be encouraged to discuss the problem with those individuals who are central to their life, including their partner, other family members, or friends. Confrontations often can be avoided if an understanding partner or friend recognizes the cause for a woman's distress and defers discussion of the controversial subject until another time. Strategies for stress reduction can be helpful. Communication skills and assertiveness may be improved with counseling. Cognitive behavioral therapy has been shown to result in sustained improvement in premenstrual symptoms in small trials with highly motivated participants. Practically speaking, because such therapy requires skilled counselors and subjects who are willing to attend multiple intervention sessions, this approach has been limited in its clinical application.

Diet

While there have been many books written describing specific “PMS diets,” few of the recommendations contained therein are based on scientific fact. Several simple dietary measures may afford relief for women with PMS. Reduction of the intake of salt and refined carbohydrates may help to prevent edema and swelling in some women. Although a link between methylxanthine intake and premenstrual breast pain has been suggested, available data are not convincing. Nevertheless, a reduction in the intake of caffeine may prove useful in women where tension, anxiety, and insomnia predominate. Anecdotal evidence suggests that small, more frequent meals may alleviate mood swings in some women. Based on evidence that cellular uptake of glucose is impaired premenstrually, there is at least some theoretic basis for this dietary recommendation. Several lines of evidence indicate that there is a tendency toward increased consumption of alcohol premenstrually, and women should be cautioned that excessive use of alcohol frequently is an antecedent factor in relationship discord. Calcium supplementation to reduce symptoms has been shown to be marginally superior to placebo in a randomized placebo-controlled trial. Published data in regard to the efficacy of dietary supplementation with pyridoxine (vitamin B_6) have been contradictory; however, this medication in proper doses (100 mg daily) is, at worst, a safe placebo that may be used as one part of an overall management plan for women with distressing molimina. Patients should be cautioned that vitamin B_6 may not be helpful and that increasing the dose of pyridoxine in an effort to achieve complete relief of symptoms may lead to peripheral neuropathy. Pyridoxine should be discontinued if there is evidence of tingling or numbness of the extremities.

Exercise

Exercise is reported to reduce premenstrual molimina in women running in excess of 50 km per cycle. The effects of exercise in women with well-characterized PMS have not been rigorously evaluated. As part of an overall program of lifestyle modification, exercise may reduce stress by providing a time away from the home and by providing a useful outlet for

suffer from PMS report that exercise promotes relaxation and helps them sleep at night.

Medical Interventions

The primary factor directing the selection of therapy should be the intensity and impact of premenstrual symptoms. Symptoms that are causing major disruption to quality of life rarely respond to lifestyle modification alone, and efforts to push this approach often do nothing more than delay effective therapy. Conversely, minor symptoms or symptoms that are short lived each month seldom justify major medical interventions.

Attention should always initially be directed to symptoms for which simple, established treatments exist. For example, dysmenorrhea or menorrhagia may be satisfactorily relieved with prostaglandin synthetase inhibitors and/or oral contraceptives.

Mefenamic acid (500 mg three times daily) in the premenstrual and menstrual weeks has outperformed placebo for the treatment of PMS in some clinical trials. It is likely that many of the end-stage mediators of PMS symptomatology are prostaglandins, which indicates that this prostaglandin synthetase inhibitor may be working through a general inhibition of prostaglandin activity. Based on this, mefenamic acid is an ideal adjunct for any woman with coexisting dysmenorrhea and menorrhagia. In practice, however, its effectiveness for premenstrual symptomatology, particularly psychologic symptoms, seems quite variable. Mefenamic acid is contraindicated in women with known sensitivity to aspirin or in those at risk for peptic ulcers.

The routine use of diuretics in the treatment of PMS should be abandoned. Most women show only random weight fluctuations during the menstrual cycle despite the common sensation of bloating. In the absence of demonstrable weight gain, it is likely that this symptom may result from constipation or bowel wall edema rather than from an overall fluid accumulation. In rare cases, ingestion of salt and refined carbohydrates has been shown to result in true fluid retention. In cases where a consistent increase in weight can be documented or where edema is demonstrable, limitation of salt and refined carbohydrate intake should be attempted first. If such dietary restrictions fail to relieve premenstrual fluid accumulation, the use of a potassium-sparing diuretic such as spironolactone may be considered. Spironolactone's unique structure may have central actions, and this is thought to account for the fact that it offers relief of both physical and psychologic manifestations of PMS in controlled clinical trials.

Trials comparing oral contraceptive therapy with placebo have not shown a beneficial effect on mood in most circumstances. However, when contraception is required in a woman with PMS and coexisting dysmenorrhea or menorrhagia, the net effect of an oral contraceptive pill may be positive. Although oral contraceptives by no means guarantee relief from PMS, they may afford sufficient relief from associated physical symptoms so that for some women the remaining premenstrual manifestations become tolerable. When an oral contraceptive user presents with PMS, it is common to find that symptoms begin earlier in the cycle. A new oral contraceptive preparation containing a novel progestin with diuretic effects (drospirenone) has undergone the most rigorous testing in normal

women and women with strictly defined PMDD. Though the evidence supporting a role for fluid retention as an etiologic component of PMS is lacking, many women are distressed by feelings of bloating and edema. In controlled clinical trials, this new oral contraceptive has been shown to offer relief from both physical and psychologic manifestations of PMS with an improvement in health-related quality of life. Neither progestin therapy nor evening primrose oil has been shown to be efficacious for PMS in controlled clinical trials.

Premenstrual mastalgia, which affects up to 10% of women of reproductive age, may occur in isolation from other PMS symptoms and, as such, should be considered a moliminal symptom. Low-dose danazol (100 mg daily) or luteal phase–only danazol (200 mg daily) can bring about dramatic relief of mastalgia in most women; however, higher doses (400 mg daily) may be required to relieve other PMS symptoms. Mastalgia may also respond to tamoxifen (10 mg daily) but has not been shown to respond to diuretics, medroxyprogesterone acetate, or pyridoxine.

Some women report overriding symptoms of anxiety, tension, and insomnia in the premenstrual week. New short-acting anxiolytics or hypnotics such as alprazolam or triazolam, respectively, may be prescribed sparingly for such individuals. Buspirone has also proven useful in preliminary trials.

Estrogen withdrawal has been implicated in menstrually related migraines, and evidence indicates that estrogen supplementation commencing in the late luteal phase and continued through menstruation may alleviate headaches in some women. As discussed subsequently, if headaches are severe and are unrelieved by short-term estrogen supplementation, they often can be controlled by intramuscular or oral sumatriptan therapy or by medical ovarian suppression with gonadotropin-releasing hormone (GnRH) agonists and continuous combined hormone replacement therapy.

Antidepressant Therapy

A range of newer antidepressant medications that augment central serotonin activity (SSRIs or selective serotonin and norepinephrine reuptake inhibitors [SNRIs]) have been shown to alleviate severe PMS. The theoretic effect of these agents on serotonin levels throughout the menstrual cycle is depicted in schematic fashion in Figure 38.6. Since these agents will also relieve endogenous depression, a pretreatment diagnosis, achieved by prospective charting, is very important. Practically speaking, many women who attend

a gynecology clinic to seek relief from premenstrual symptoms express reservations about taking an antidepressant, particularly if a short-term end point (3 to 6 months away) is not likely. Long-term therapy may be required to control symptoms of PMS for women in their 30s until menopause. Rapid reappearance of PMS has been reported after cessation of SSRI therapy by premenopausal women.

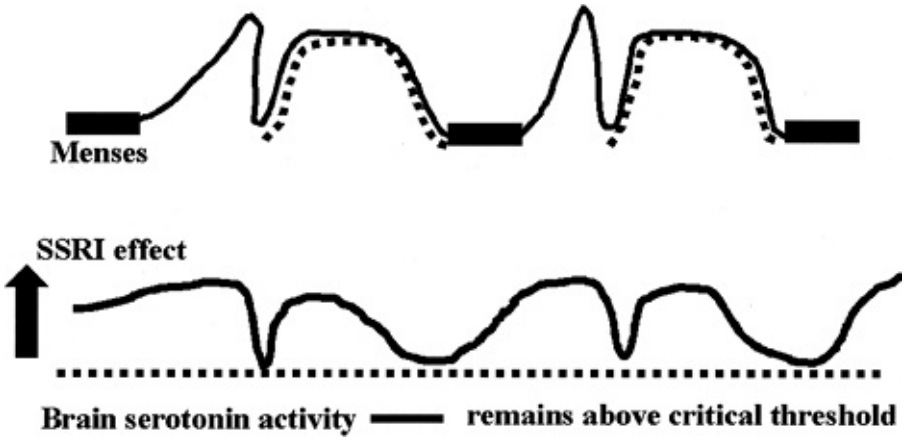

Figure 38.6 Hypothetical depiction of how drugs that elevate serotonin activity can alleviate PMS. (SSRI, selective serotonin reuptake inhibitor; *solid line*, estrogen; *dotted line*, progesterone.) (From Reid RL. Premenstrual syndrome. In: Rebar RW, ed. *Female reproductive endocrinology*. Available at: *http://www.endotext.com*. Accessed January 16, 2003, with permission.)

For patients in whom PMS psychiatric symptoms predominate, antidepressant therapy may provide excellent results. SSRIs such as fluoxetine, sertraline, paroxetine, fluvoxamine, and venlafaxine (an SNRI) have all been successfully employed.

Symptom profiles may help in selecting the most appropriate agent (i.e., fluoxetine in patients where fatigue and depression predominate; sertraline if insomnia, irritability, and anxiety are paramount). SSRIs have been associated with loss of libido and anorgasmia, which are particularly distressing to this patient population. Appropriate pretreatment counseling is essential.

Tricyclic antidepressants (TCAs) have not generally been effective with the exception of clomipramine, a TCA with strong serotonergic activity. Intolerance to the side effects of TCAs is common.

Most women who suffer from PMS would prefer to medicate themselves only during the symptomatic phase of the menstrual cycle. Studies have demonstrated that luteal phase therapy may be effective for many women with PMS. Practically speaking, a trial of SSRI therapy should be commenced with continuous use. After a woman has determined the optimal dosage to achieve the desired response, it is reasonable to test luteal phase–only therapy to determine if the benefit is maintained.

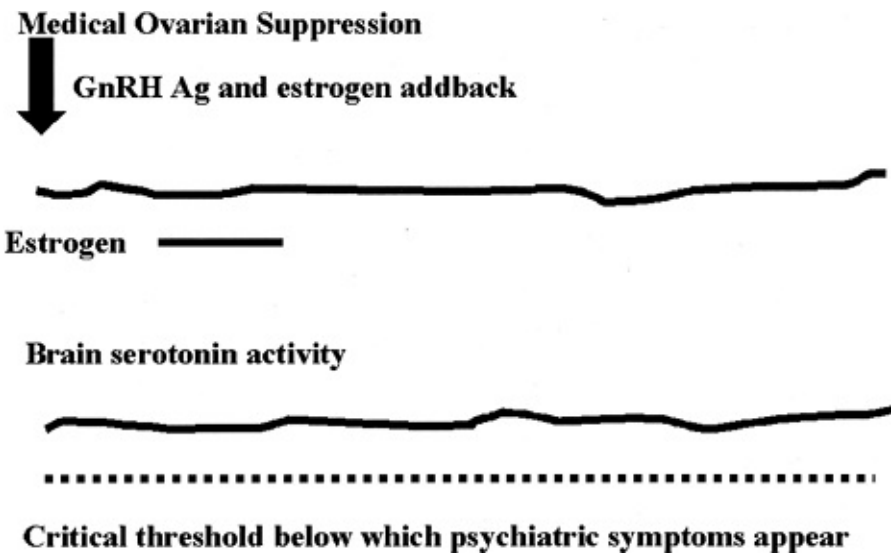

Figure 38.7 Hypothetical depiction of how medical or surgical elimination of ovarian steroid fluctuations can stabilize central serotonin activity and eliminate premenstrual syndrome. (GnRh Ag, gonadotropin-releasing hormone agonist analog.) (From Reid RL. Premenstrual syndrome. In: Rebar RW, ed. *Female reproductive endocrinology*. Available at: *http://www.endotext.com*. Accessed January 16, 2003, with permission.)

Medical Ovarian Suppression

Suppression of cyclic ovarian function may afford dramatic relief for the woman with severe and long-lasting symptoms (Fig. 38.7). In each case, therapy should be directed toward the suppression of cyclic ovarian activity while ensuring a constant low level of estrogen sufficient to prevent menopausal symptomatology and side effects.

Danazol at a dose of 200 mg twice daily has been successfully employed to relieve PMS. However, this therapy is seldom used due to the availability of GnRH agonists that when combined with estrogen add-back have many fewer side effects.

GnRH agonists effect rapid medical ovarian suppression, thereby inducing a state of "pseudomenopause" and affording relief from PMS. This approach is unsatisfactory in the long term not only because of the troublesome menopausal symptoms it evokes but also because it creates

an increased risk for osteoporosis and ischemic heart disease. When combined with continuous combined hormone replacement therapy, GnRH agonists afford excellent relief from premenstrual symptomatology without the attendant risks and symptoms resulting from hypoestrogenism. The major drawback to this therapeutic approach is the expense of medication and the need for the patient to take multiple medications on a long-term basis, as long as 10 to 15 years from diagnosis until menopause in some cases.

Though not established in well-designed clinical trials, there is abundant clinical experience with depomedroxyprogesterone acetate (DMPA) as a cheaper and less-complicated approach to medical ovarian suppression than the use of a GnRH agonist with

hormone therapy add-back. This therapy cannot be used by women who are trying to conceive and is sometimes unacceptable to those who desire contraception because of the irregular bleeding and gradual weight gain that sometimes accompanies its use.

Continuous combined oral contraceptives have recently been reported to reduce symptoms in women with PMDD—an effect that probably is related to elimination of the hormonal cyclicity that accompanies normal cyclic oral contraceptive exposure. This may ultimately prove to be one the simplest therapeutic approaches for women who desire contraception.

Surgical Therapy

Medical approaches should be exhausted prior to considering surgery for debilitating PMS, a fact emphasized in the American College of Obstetricians and Gynecologists Committee Opinion No. 155, *Premenstrual Syndrome*. Clinical trials have clearly shown surgical approaches such as hysterectomy and oophorectomy to be effective. For woman in whom there is unequivocal documentation that premenstrual symptoms are severe and disruptive to their lifestyle and relationships and in whom conservative medical therapies have failed (either due to lack of response, intolerable side effects, or prohibitive cost), the effect of medical ovarian suppression should be tested. At times this therapeutic approach (a GnRH agonist and continuous combined hormone replacement therapy) can be maintained until menopause with satisfactory symptom control. Some women, despite complete relief of symptoms, cannot afford or choose not to take this combination of medications for prolonged intervals (as long as 10–15 years from diagnosis until menopause in some cases).

In these specific circumstances a surgical option may be considered. In the situation where the family is complete and permanent contraception is desired, the pros and cons of oophorectomy for lasting relief from premenstrual symptomatology should be discussed with the patient. In many women, the progestin component of hormone replacement therapy, when given sequentially, may induce an apparent recrudescence of PMS-like symptoms and, when given continuously, may result in unwanted irregular bleeding. Hysterectomy at the time of oophorectomy is a consideration that allows subsequent hormone replacement with low-dose estrogen alone.

The risks of cancer of the endometrium, cervix, and ovary are nearly eliminated by hysterectomy and bilateral oophorectomy. Breast cancer risk is decreased following oophorectomy, and there is no evidence that low-dose estrogen replacement until the age of natural menopause increases the overall risk for breast cancer, as some women and their physicians fear.

Summary Points

- It is critical to make an accurate diagnosis of PMS based on four key areas: specific symptoms, severity, timing in relation to the menstrual cycle, and baseline level of symptoms in the follicular phase.
- The most useful diagnostic tool is prospective reporting of the nature of symptoms and their functional impact by self-report using

a calendar record.
- Initial therapeutic steps should include education, counseling, lifestyle modification, communication techniques, diet, and exercise.
- Medicinal efforts should begin with mefenamic acid and oral contraceptives, cyclically or continuously. If these agents are unsuccessful, low-dose danazol, SSRIs, DMPA, and GnRH agonists (depo) may prove useful.
- Surgical therapy (oophorectomy) is always the last resort, but when all other conservative therapeutic options have failed, randomized clinical trials have proven this to be effective in treating the symptoms in properly selected patients.

Androgen Excess Disorders

Richard S. Legro
Ricardo Azziz

Androgen excess, or hyperandrogenism, is a common, albeit heterogeneous, endocrine disorder of women. The clinical presentation of androgen excess may range from mild hirsutism, acne, or subtle ovulatory dysfunction to the rare patient with frank virilization and masculinization. Androgen excess disorders include the polycystic ovary syndrome (PCOS), nonclassic adrenal hyperplasia (NCAH), the hyperandrogenic insulin-resistant acanthosis nigricans (HAIR-AN) syndrome, and androgen-secreting neoplasms. Although the most recognizable clinical feature of androgen excess is hirsutism, it should be noted that not all patients with hirsutism have evidence of androgen excess, as in the patient with idiopathic hirsutism (IH). Likewise, not all patients with an androgen excess disorder have clinically evident hirsutism, to wit the Asian patient with PCOS. However, because of its frequent association with PCOS, clinically evident androgen excess (e.g., hirsutism) is a useful marker for the presence of metabolic abnormalities in these women, including insulin resistance and glucose intolerance resulting in an increased risk for type 2 diabetes mellitus (DM) and possibly also cardiovascular disease (CVD). With these new insights, the burden of care for the treating physician has increased beyond that of solely treating the presenting complaint to include the detection and, if possible, prevention of these metabolic consequences.

Normal Androgen Production and Metabolism

Androgen Production and Action

Androgens are C19 steroids (that is they contain 19 carbons) produced from circulating low-density lipoprotein (LDL) cholesterol (a C27 molecule). As in most metabolic pathways, the first step is rate limiting, that is, the conversion of cholesterol to the weak progestogen pregnenolone (a C21 steroid) by cytochrome P450scc (Fig. 39.1). The zona reticularis of the adrenal cortex, the theca, and possibly stroma of the ovaries secrete androgens produced through de novo synthesis from cholesterol. In addition, circulating steroid precursors can be metabolized further in these organs or in peripheral tissues, including the liver, adipose tissue stroma, and the pilosebaceous unit (PSU) in skin to more potent androgens (e.g., the conversion of testosterone to dihydrotestosterone [DHT]) and to estrogens via the action of

aromatase, or they can be inactivated and readied for excretion (Fig. 39.2). The origins of the principal circulating plasma androgens in pre- and postmenopausal women are summarized in Table 39.1. Androstenedione is the most important precursor of testosterone and DHT, while dehydroepiandrosterone (DHEA) accounts for only 5% and 13% of circulating testosterone in normal women. Overall, DHEA has little androgenic activity and is best viewed as a pro-androgen.

Androgens, either directly or through metabolites, can act systemically in a classic endocrine fashion or locally in a paracrine and intracrine fashion (e.g., in the PSU or in the ovarian follicle). Androgens exert their genomic effects through interaction with the androgen receptor, a member of the nuclear receptor superfamily. The unbound androgen receptor is a cytoplasmic protein, and on ligand binding, it translocates into the nucleus. In the nucleus, it influences the transcription of target genes through a complex process that includes interactions with other transcription factors and coactivators. As noted, androgens also can exert their effects indirectly, though metabolites such as the estrogens. Androgens, like other sex steroids, also exert

nongenomic effects through binding to membrane-bound steroid receptors as well as nonreceptor-mediated actions at the plasma membrane.

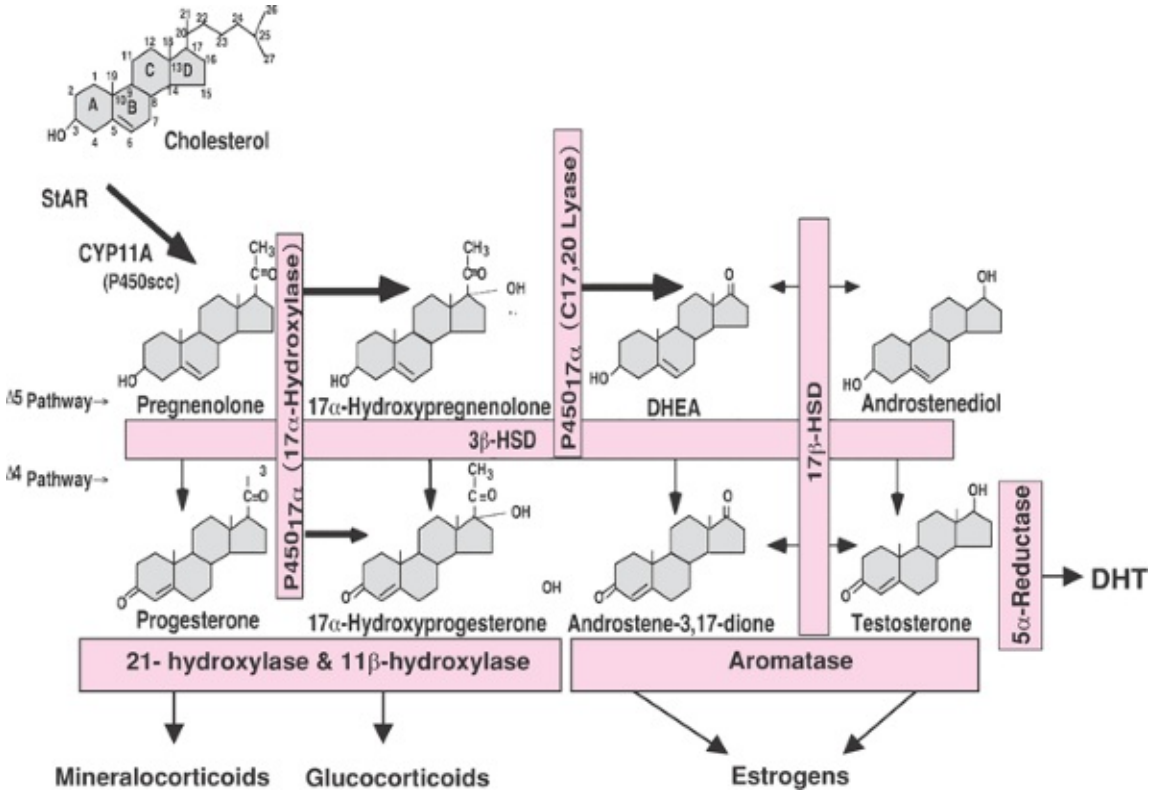

Figure 39.1 Pathways of androgen synthesis. The ovary, the testis, and the adrenal gland produce six common core steroids. The core Δ^5 steroids are pregnenolone, 17α-hydroxypregnenolone, and DHEA. The core Δ^4 steroids are progesterone, 17α-hydroxyprogesterone, and androstenedione (Androstene-3,17-dione). The core steroids are important precursors for the production of sex steroids, glucocorticoids, and mineralocorticoids.

Androgen Clearance

The clearance of androgens is accomplished by hepatic extraction and peripheral metabolism, which are highly dependent on the unbound portion of circulating steroid. Approximately 10% of testosterone and 50% of androstenedione are metabolized peripherally in women. Clearance of androgens by the hepatic splanchnic circulation involves mainly catabolism via 5α- and 5ß-reductase. Androgen metabolites are further conjugated by the liver (95% glucuronic and 5% sulfuric), facilitating their urinary excretion (Fig. 39.2). Some 15% of androgen sulfates are excreted in bile, of which 80% are reabsorbed in the gut. Peripheral metabolism of androgens also occurs in the various target tissues, including skin, muscle, brain, and adipose tissue. A-ring aromatization (via aromatase activity), 17ß-hydroxysteroid dehydrogenization (also known as 17ß-ketosteroid reductase), 3α- and 3ß-oxo-reduction, and 5α- and 5ß-A-ring reduction (via 5α- and 5ß-reductase) give rise to estrogens; to weaker metabolites such as 5α-androstane-3α,17ß-diol, androsterone, and etiocholanolone; or to more potent androgens such as DHT. Androgen metabolites are subsequently conjugated by the liver and excreted in the urine and bile. Measurement of these metabolites (e.g., 3α-androstanediol glucuronide) was proposed as a circulating marker of peripheral androgen excess, but its clinical use currently is negligible.

Bioavailability of Androgens

Androgens circulate in the body bound by a variety of proteins, including albumin, cortisol-binding globulin, acid α2-glycoprotein, and most importantly, sex hormone–binding globulin (SHBG, formerly known as testosterone or testosterone-estradiol–binding globulin [TeBG]). Because of its much higher concentration and total amount, albumin has a much greater overall binding capacity for androgens than SHBG. However, the affinity of androgens for SHBG is several orders of magnitude higher than that of albumin, and thus SHBG binds the largest portion of

circulating testosterone. Androgens bound to SHBG are essentially not bioavailable; alternatively, those androgens complexed to albumin are more readily available for tissue interaction due to the much lower affinity of this protein for these steroids relative to their affinity for the androgen receptor, representing a potentially functional androgen pool or reservoir. The liver produces SHBG, and production is stimulated by estrogen, particularly oral forms, and inhibited by androgens, and most importantly, insulin. These factors lead to lower levels of SHBG and higher

bioavailable androgens in males and patients with androgen excess disorders compared with those found in healthy women.

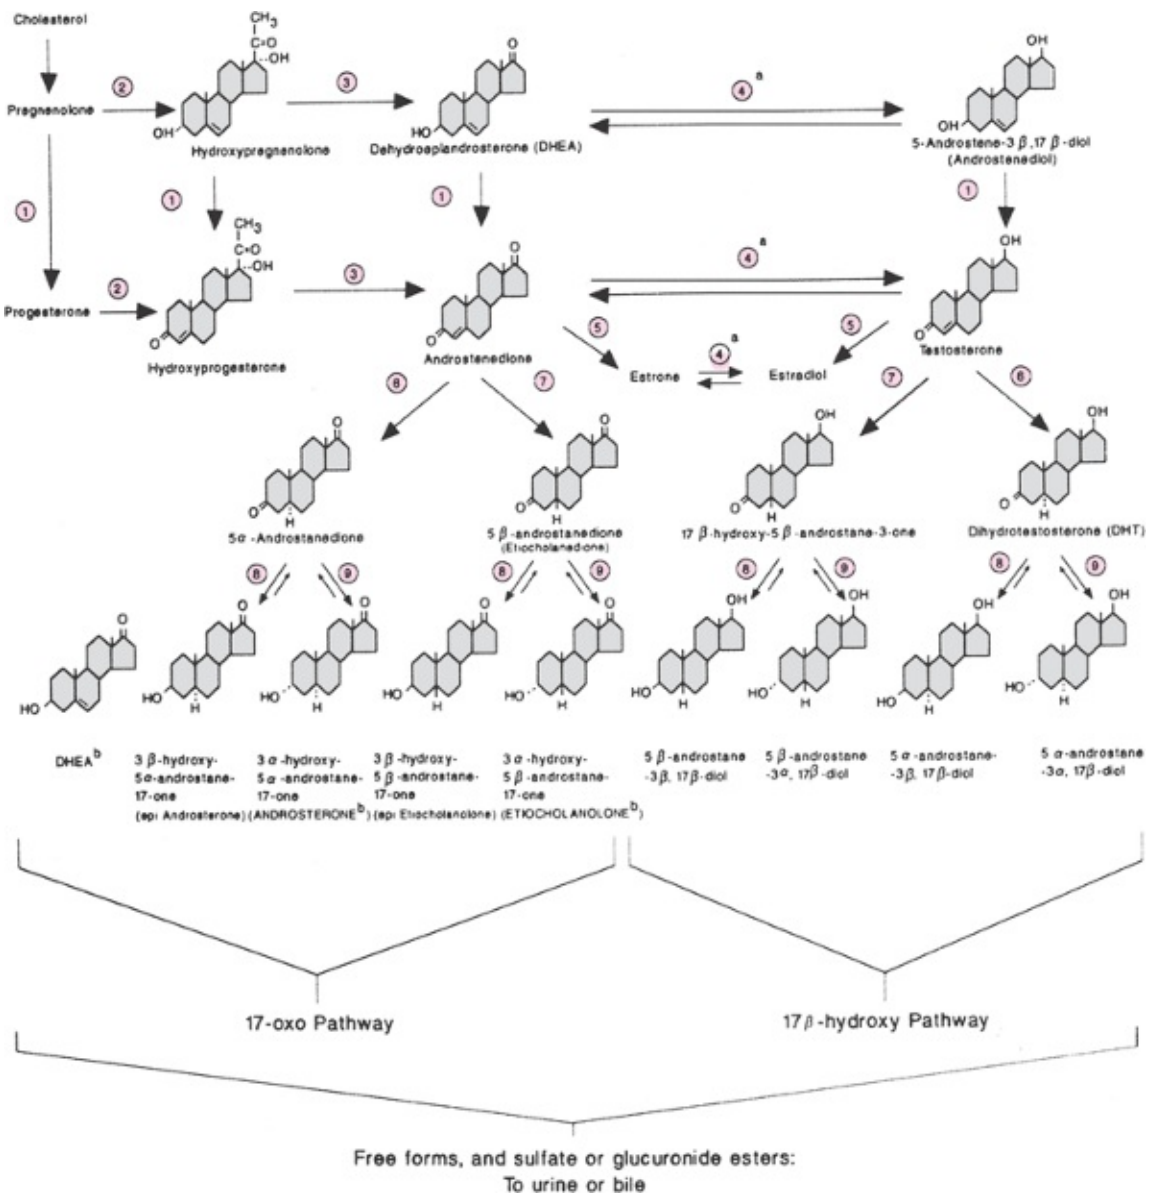

Figure 39.2 Principal pathways of androgen metabolism. Enzymes: *(1)* 3ß-hydroxysteroid dehydrogenase, *(2)* 17ß-hydroxylase, *(3)* 17,20-lyase (17,20-desmolase), *(4)* 17ß-hydroxysteroid dehydrogenase (17-keto reductase), *(5)* aromatase, *(6)* 5α-reductase, *(7)* 5ß-reductase, *(8)* 3ß-oxoreductase, and *(9)* 3α-oxoreductase. ([a] In the gonads, the 17ß-hydroxysteroid dehydrogenase reaction predominantly produces 17ß-dehydrogenated products (androstenediol and testosterone), while the reverse is true in peripheral tissues; [b] Aldosterone, etiocholanolone, and DHEA are the principal urinary metabolites of androgens.) Modified from Vermeulen A. Androgen secretion by adrenals and gonads. In: Mahesh VB, Greenblat RB, eds. *Hirsutism and virilism*. Boston: John Wright/PSG Inc., 1983:17.

As noted below, the production, metabolism, and circulating levels of androgens are affected, among other factors, by age, menopausal status, the presence of obesity, and medications that affect hepatic clearance.

Androgens, Age, and Menopause

The metabolism and circulating levels of androgens can be altered significantly by age. Most notably, adrenal androgen production clearly decreases with age, beginning in the premenopausal years. Serum dehydroepiandrosterone sulfate (DHEAS) concentrations decrease linearly with age and begin at about 20 years, independent of menopause. Decreased secretion of 17-hydroxyprogesterone, 17-hydroxypregnenolone, DHEA, and androstenedione also has been observed in postmenopausal women following acute adrenal stimulation. In normal postmenopausal women, plasma concentrations of androstenedione are about half that observed in premenopausal females, although there is no observable

difference in the clearance rate of this steroid between premenopausal and postmenopausal women. After menopause, androstenedione levels continue to gradually decrease with age. Testosterone levels are less affected by age and menopause, and it is clear that the ovary continues to produce a significant amount of testosterone in the postmenopause. Most of the decrease in circulating testosterone with age and menopause is explainable by the lower androstenedione levels.

Androgens and Obesity

In eumenorrheic obesity, the production rate (PR) and metabolic clearance rate (MCR) of ovarian- and adrenal-secreted androgens are increased, while circulating levels change only minimally. The increased MCR may be due to an obesity-related decrease in the plasma concentration of the carrier protein SHBG. Steroid sequestration by fat also may increase steroid clearance, leading to an extremely large pool of sex hormones in obese individuals. Adipose tissue metabolism of steroids, including aromatization and 17β-hydroxysteroid dehydrogenation, also contributes to the increased MCR of androgens, whereas alterations in hepatic conjugation and extraction also can be a contributing factor. The increased PR of androgens in obesity may simply be due to the operation of a servo-control mechanism compensating for the increased MCR. Alternatively, the increased ovarian and adrenal production noted in obesity may reflect changes in the intraglandular and/or circulating concentration of androgens themselves, or of estrogens, prolactin, growth hormone, and other growth factors, and most importantly, insulin. In addition, the accelerated turnover of androgens in obesity may increase tissue exposure to these steroids, potentially enhancing the effect of androgens in this condition. Although weight reduction improves the abnormalities noted in steroid levels, it is not known whether the elevated PR and MCR of androgens also normalize following weight reduction.

The increased production (or intake) of androgens, which can be altered by age and degree of obesity, is likely the most important determinant of clinically evident androgenicity. However, other factors such as the potency of the androgen produced (DHT > testosterone > androstenedione > DHEA), the amount of androgen that is free or weakly bound in serum (i.e., the amount bioavailable), the degree and type of central and peripheral metabolism (e.g., local or hepatic amounts of 5α-reductase, 17-hydroxysteroid dehydrogenase, or aromatase activities), or tissue sensitivity (e.g., local androgen receptor concentration) undoubtedly also play a role in determining and modifying the phenotype of androgen excess.

Signs and Symptoms of Androgen Excess

Androgen excess can result in various clinical signs and symptoms, including abnormalities of the PSU, such as hirsutism, acne, and androgenic alopecia, or dysfunction of the hypothalamic–pituitary–ovarian (i.e., ovulatory and menstrual dysfunction) or of the hypothalamic–pituitary–adrenal axes (adrenal androgen excess). If the androgen excess is very severe, virilization and/or masculinization also can be apparent. Changes in mood or sense of well-being with androgen excess may be related to neuroendocrine changes

stemming from abnormalities in the endocrine and metabolic axes and to the social and psychologic stigmata of androgen excess, such as hirsutism and infertility, and associated obesity.

Androgen Excess and the Pilosebaceous Unit

The PSU is the common skin structure that gives rise to both hair follicles and sebaceous glands, which are found everywhere on the body except the palms, soles, and lips. The density is greatest on the face and scalp (400 to 800 glands/cm^2) and lowest on the extremities (50 glands/cm^2). The number of PSUs does not generally increase after birth (about 5 million), but they can become more prominent through activation and differentiation. Generally, three phases of the hair growth cycle can be considered. The period of active growth is termed *anagen*, after which the hair follicle enters a resting or *catagen* phase, of varying lengths of time (Fig. 39.3). During this transition, the hair shaft separates from the dermal papillae at the base. The separated hair is then shed during the *telogen* phase. The period of anagen varies from 3 years on the scalp to 4 months on the face. For corresponding parts of the skin, men have longer anagen phases than women do, which may be partially due to their higher circulating androgen levels.

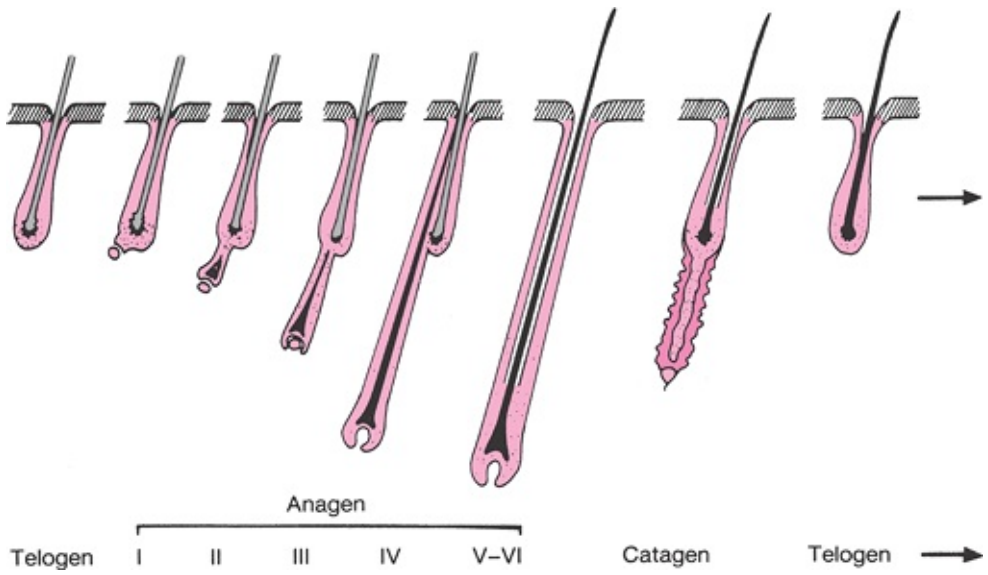

Figure 39.3 Diagram of cyclic hair follicles, a club hair (*white*) in old telogen and early anagen (I–IV) follicles, and a new hair (*black*) in new anagen (V–VI) follicles. (From Uno H. *Seminars in reproductive endocrinology*. Vol 4. New York: Thieme, 1986, with permission.)

The effects of androgens are most visible on the PSU. Androgens stimulate the transformation of fine, unpigmented vellus hairs to coarse, pigmented, thickened terminal hairs that generally measure >5 mm in length, a process called *terminalization*, in skin areas sensitive to the effects of androgens. The peripheral effects of androgens are determined primarily by the intracellular actions of the enzymes 17β-hydroxysteroid dehydrogenase (converting androstenedione to testosterone) and 5α-reductase (converting

testosterone to the more potent androgen DHT) and the androgen receptor content. Before puberty, body hair is primarily composed of fine, short, unpigmented vellus hairs. The increase in androgen production observed with pubertal development transforms some of these, mainly in androgen-sensitive areas of skin such as the axilla and the genital triangle, into the coarser, longer, pigmented terminal hairs observed in adults. It should be noted that not all skin areas are androgen sensitive. For example, the development of terminal hairs in body areas such as the eyebrows, eyelashes, and the temporal and occipital scalp is relatively androgen independent.

Excess androgen-dependent hair growth present in women can result in clinically evident hirsutism (see below). Paradoxically, androgens can exert opposite effects on the hair follicles of the scalp, causing conversion of terminal follicles to velluslike follicles, a process called *miniaturization*. This effect may lead to the development of androgenic alopecia in women (see below) or male-pattern baldness characterized by frontal and sagittal scalp hair loss. Androgens also can cause increased sebum production and abnormal keratinization of the PSU, contributing to the development of seborrhea and acne evident at puberty and in women with androgen excess. There are ethnic and genetic differences that can modify the effects of

androgens on skin, as demonstrated by the lesser degree of hirsutism present in Asian women with PCOS (Fig. 39.4).

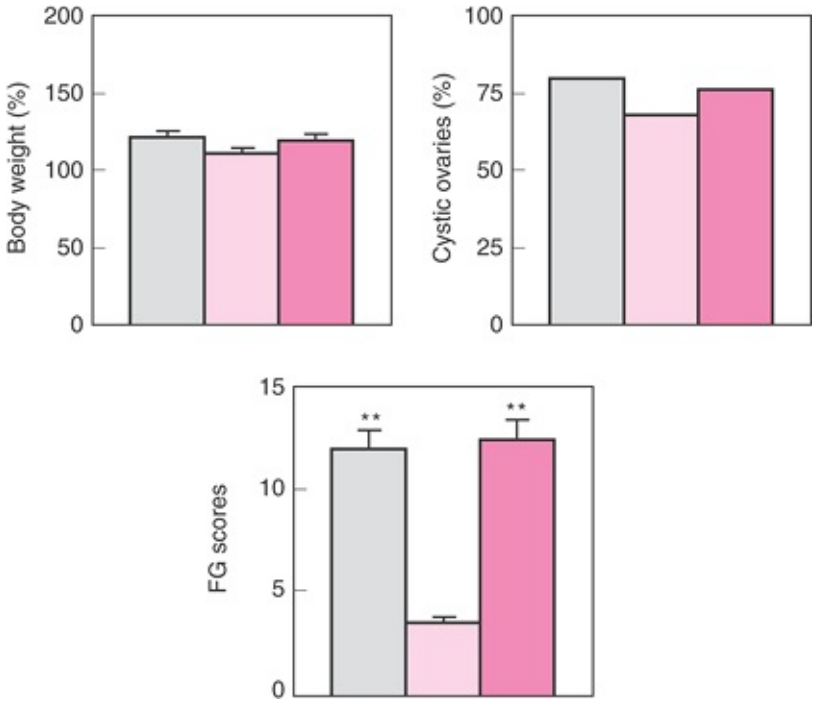

Figure 39.4 Features in PCOS women, 25 each from the United States, Italy, and Japan. Note the much lower prevalence of hirsutism among Japanese women. (FG, Ferriman-Gallwey.) (Reprinted from Carmina E, Koyama T, Chang L, et al. Does ethnicity influence the prevalence of adrenal hyperandrogenism and insulin resistance in polycystic ovary syndrome? *Am J Obstet Gynecol* 1992;167:1807–1812, with permission.)

Hirsutism

Hirsutism is the presence of terminal (coarse) hairs in females in a malelike pattern. Excessive growth of coarse hairs of the lower forearms and lower legs alone does not constitute hirsutism, although women suffering from hirsutism may note an increase in the pigmentation and growth rate of hairs on these body areas. Hirsutism should be viewed much as polycystic ovaries, as a sign rather than a diagnosis. Most commonly, hirsutism is associated with androgen excess. Although the term *idiopathic hirsutism* was coined to identify the presence of hirsutism without other identifiable cause or abnormality, this may actually reflect our limited ability to assess androgen action in the peripheral compartment or even in the circulation (see below).

The definition of hirsutism is somewhat variable. The most commonly used method of estimating the amount of terminal hair present in a malelike distribution in women is the visual scale first described by Ferriman and Gallwey in 1961. While these investigators originally assessed 11 body areas, today we use a modification of this scale (Fig. 39.5), which assesses 9 body areas (the modified Ferriman-Gallwey or mFG score). The cutoff value for defining hirsutism varies, with Ferriman using a score 5, Hatch and colleagues proposing a score of 8, and Knochenhauer and colleagues suggesting a score of 6.

In a study of 633 unselected women seen for a pre-employment physical, we determined that a value of 8 defined the upper 95th percentile of the distribution of the mFG scores. However, principal component and univariate analyses denoted two nearly distinct clusters that occurred above and below an mFG value of 2, with the bulk of the scores below. Overall, an mFG score of at least 3 was observed in 22.1% of all subjects (i.e., the upper quartile), and of these subjects, 69% complained of being hirsute, similar to the proportion of women with an mFG score of at least 8 who considered themselves to be hirsute (70%). This proportion was much greater than that of women with an mFG score below this value (16%). There were no significant differences between black and white women. Furthermore, in a study 228 women complaining of unwanted hair growth but who demonstrated minimal increases in mFG (≥5), approximately 50% demonstrated androgen excess. These data suggest the likelihood that even minimal increases in the mFG may denote an underlying endocrine abnormality.

Acne

The PSU, in addition to the hair follicle, also contains a sebaceous gland that produces an oily protective secretion known as sebum. The excessive production of sebum in response to androgen action may lead to oily skin, clogged hair follicles, folliculitis, and the development of acne. Elevations in serum androgen levels have been noted in patients with acne, particularly in those with concurrent hirsutism, although not all investigators agree. Although the persistence or appearance of acne in adulthood has been suggested to be more frequently associated with androgen excess, we observed evidence of hyperandrogenemia in the majority of 30 consecutive nonhirsute acneic patients regardless of age. Some investigators have observed that while serum androgen levels may be

relatively normal in acneic patients, the conversion of androgens to DHT via 5α-reductase was increased in the affected skin. These data

suggest that androgen suppression may be useful in treating acne in many of these patients, and it is clear that acne frequently improves following treatment with antiandrogens, oral contraceptives, or glucocorticoid suppression. Thus, empiric treatment with oral contraceptives, or even with judicious use of glucocorticoids, may be justified in acneic patients without other evidence of overt androgen excess.

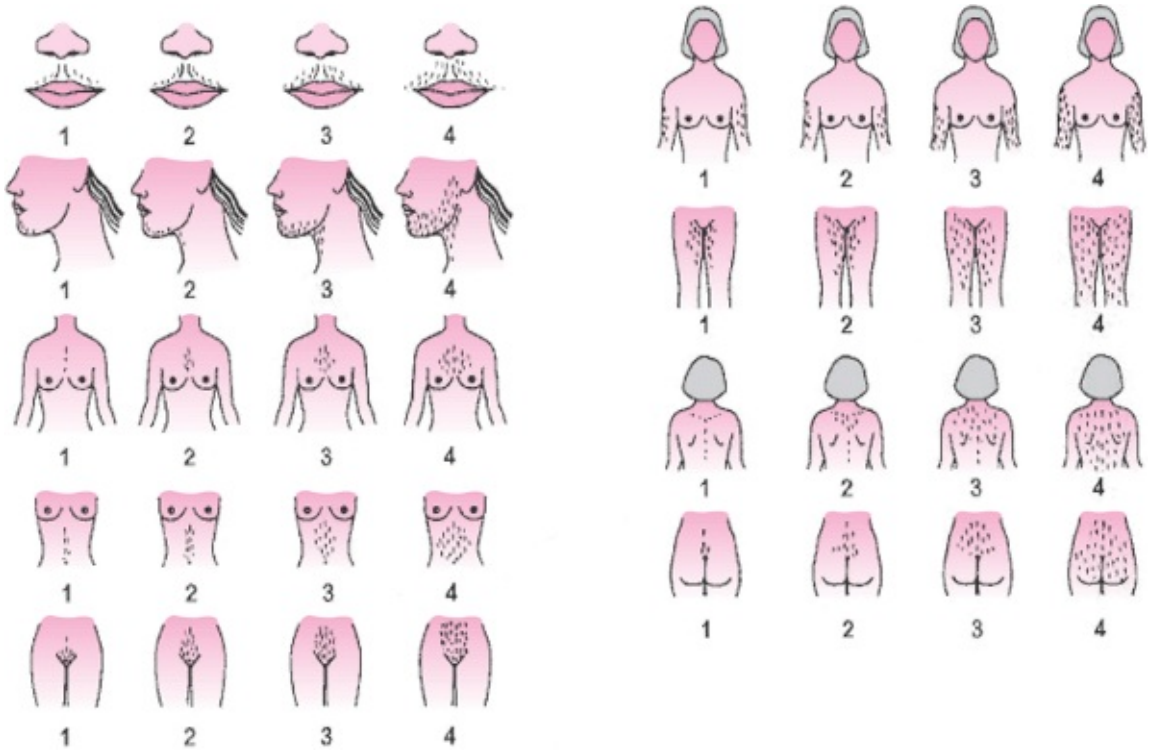

Figure 39.5 Modified Ferriman-Gallwey scale for assessing hirsutism. (Modified from Hatch R, Rosenfield RL, Kim MH, et al. *Am J Obstet Gynecol* 1981;140:815–830).

Androgenic Alopecia

Scalp hair loss as a consequence of androgen excess can take two forms. In severe cases, where massive androgen excess and virilization/masculinization is present, patients can demonstrate the typical pattern of balding found in men (i.e., premature male-pattern balding). More common, however, is the so-called androgenic (also termed *androgenetic*, as an inherited etiology often is suspected) alopecia of women (i.e., female-pattern balding). In female androgenic alopecia, a diffuse thinning of hair throughout the sagittal scalp is primarily noted, and approximately 40% of women with androgenic alopecia have some form of hyperandrogenemia. However, if only nonhirsute women with androgenic alopecia are considered, then only approximately 20% of these patients are found to be hyperandrogenemic.

Androgens and Hypothalamic-Pituitary-Ovarian Axis Dysfunction

Androgens, indirectly (e.g., possibly through conversion to estrogens) and directly, may alter the secretion of gonadotropins in women. For example, women with PCOS appear to have reduced hypothalamic sensitivity to progesterone that may be mediated by elevated androgens, since normal sensitivity can be restored with the androgen receptor blocker flutamide. Alternatively, other data suggests that in the absence of severe androgens excess, the direct effect of androgens on the hypothalamic–pituitary axis appears limited. For example, the infusion of the nonaromatizable androgen DHT to five women with PCOS did not alter the mean levels, pulsatile patterns, or sensitivity to gonadotropin-releasing hormone (GnRH) of luteinizing hormone (LH) or follicle-stimulating hormone (FSH). Overall, the mechanisms underlying the hypothalamic–pituitary dysfunction of PCOS and the potential role that androgens play in the same remains unclear. Finally, excessive androgens also may directly inhibit follicular development at the ovary, which may result in disrupted folliculogenesis and the accumulation of multiple small cysts within the ovarian cortex, the so-called “polycystic” ovary.

Androgens and Hypothalamic-Pituitary-Adrenal Axis Dysfunction

Adrenal androgen excess (i.e., elevated levels of DHEA and DHEAS and of the adrenal fraction of androstenedione) is a concomitant finding in many women with androgen excess. It should be noted that the age-associated decline in DHEAS levels is observable and similar in both control and PCOS women. Hence, estimates of the prevalence of adrenal androgen excess require consideration of age. In a study of 213 (27 black and 186 white) women with PCOS and 182 (88 black and 94 white) age-matched healthy eumenorrheic nonhirsute women, the authors observed that the prevalence of DHEAS excess was approximately 20% among white and 30% among black PCOS patients when using age and race-adjusted normative values.

It is possible that extra-adrenal androgens (e.g., ovarian) may alter adrenocortical steroidogenesis and androgen secretion. For example, various investigators have observed a 20% to 25% decrease in mean DHEAS levels following long-acting GnRH-α suppression in PCOS women with elevated levels of this adrenal androgen, although elevated adrenal androgen levels in these women rarely normalize with GnRH-α suppression. Vermesh and colleagues reported that a 2-hour infusion of testosterone in seven healthy women resulted in subtle inhibition of 21- and/or 11ß-hydroxylase activities but not in 17,20-lyase or 3ß-hydroxysteroid dehydrogenase activities. In turn, Azziz and colleagues prospectively studied the effect of 3 weeks of parenteral exogenous testosterone in seven healthy oophorectomized women. A significant change in the adrenal response to adrenocorticotrophic hormone (ACTH) stimulation was not observed, although an increase in the metabolism of DHEA to DHEAS was apparent. Thus, it appears that the secretion of adrenal androgens can be increased by extra-adrenal hyperandrogenemia, although the

clinical relevance of such an effect is unclear.

Virilization and Masculinization

Virilization includes the appearance of sagittal and frontal balding, clitoromegaly, and severe hirsutism. Furthermore, if androgen levels are extremely elevated for a substantial period of time, the features of virilization may be accompanied by masculinization of the body habitus, with atrophy of the breasts, an increase in muscle mass, a redistribution of body fat, and a deepening of the voice. Premenopausal patients with virilization of masculinization almost always are amenorrheic. In general, virilization or masculinization should raise the suspicion of an androgen-secreting neoplasms or classic (but not nonclassic) adrenal hyperplasia. Occasionally, girls suffering from a severe insulin resistance syndrome may exhibit a moderate degree of virilization. These situations will be discussed in the following section.

Polycystic Ovary Syndrome

By far, the most common cause of androgen excess is PCOS, accounting for the vast majority of these patients. When defined strictly, it appears to affect approximately 7% of unselected women in the developed world. There is no firm consensus as to the definition of PCOS, although criteria arising from a 1990 National Institutes of Health (NIH) conference on the subject have proven clinically and investigationally useful and identified PCOS as unexplained hyperandrogenic chronic anovulation (Table 39.2). Diagnostic criteria, sometimes called the *Rotterdam criteria*, were proposed by an expert panel in 2003 (Table 39.2) and modify the prior 1990 NIH criteria by incorporating ovarian size and morphology into the schema. It appears that the Rotterdam criteria increase the affected population by about 50% and include less severe forms of the syndrome. A more recent recommendation for defining PCOS proposed by a task force of the Androgen Excess Society attempts to bridge this difference (Table 39.2).

Clinical and Biochemical Features of Polycystic Ovary Syndrome

Approximately 70% to 80% of women with PCOS demonstrates frank elevations in circulating androgens, particularly free testosterone, and 25% to 50% will have elevated levels of the adrenal androgen metabolite DHEAS. Prolactin levels usually are normal, although they may be slightly elevated (generally <40 ng/mL) in a small fraction of patients. The LH/FSH ratio is >2 to 3:1 in approximately 60% of these patients. As noted previously, the ovaries of up to 90% of patients with PCOS usually contain

---

intermediate and atretic follicles measuring 2 to 5 mm in diameter, resulting in a polycystic appearance at sonography (Fig. 39.6). About 60% of PCOS patients are obese, although significant fractions are nonobese.

Figure 39.6 Transvaginal ultrasound visualization of a polycystic ovary. Note the string of subcapsular follicles measuring 3 to 6 mm in diameter, with increased central stroma mass.

Metabolic Features of Polycystic Ovary Syndrome

While not part of the diagnostic criteria, many PCOS women appear to be uniquely insulin resistant and hyperinsulinemic. Approximately 50% to 70% of PCOS patients demonstrate profound insulin resistance and secondary hyperinsulinemia, independent of body weight. In PCOS, insulin resistance usually refers to the impaired action of insulin in stimulating glucose transport and in inhibiting lipolysis in adipocytes, and studies of the action of insulin in adipocytes, myocytes, and other tissues in this disorder appear to suggest the presence of an intracellular defect of insulin signaling.

The compensatory hyperinsulinemia, resulting from the underlying insulin resistance, augments the stimulatory action of LH on the growth and androgen secretion of ovarian thecal cells while inhibiting the hepatic production of SHBG. In addition, treatment of PCOS patients with insulin sensitizers may lower circulating levels of LH, suggesting that insulin resistance, or more likely hyperinsulinemia, is in part responsible for the gonadotropic abnormalities observed in many women with PCOS, although not all agree. Since insulin also is a mitogenic hormone, the extremely elevated insulin levels may lead to hyperplasia of the basal layers of the epidermis, resulting in the development of acanthosis nigricans (a velvety, hyperpigmented change of the crease areas of the skin) (Fig. 39.7) and acrochordons (skin tags). Overall, insulin resistance and secondary hyperinsulinemia affects a large fraction of PCOS patients and may cause or augment the androgen excess of these patients.

Figure 39.7 Acanthosis nigricans on the nape of the neck: a sign of hyperinsulinemia.

Ovarian Morphology in Polycystic Ovary Syndrome

It should be noted that polycystic ovaries on sonography or at pathology are simply a sign of androgen excess and possibly PCOS. For example, this ovarian morphology frequently is seen in patients with adrenal hyperplasia (Table 39.3), and up to 25% of unselected women have polycystic ovaries on ultrasound, many of which are normoandrogenic regularly cycling. The classic polycystic ovary morphology on ultrasound has been described as containing multiple 2- to 8-mm subcapsular preantral follicles forming a “black pearl necklace” sign (Fig. 39.6). Hence, the appearance of polycystic ovaries, particularly on sonographic exam are considered to be a sign, albeit nondiagnostic, of androgen excess and PCOS. Finally, while polycystic ovaries are common in women with PCOS, their presence does not predict the metabolic or reproductive phenotype of these patients.

Polycystic Ovary Syndrome throughout the Life Span

Clinically evident PCOS tends to develop shortly after menarche and persists through most of the reproductive life. Nonetheless, some patients may present initially in the prepuberty with premature adrenarche, with affected girls displaying hyperinsulinemia, elevated DHEAS levels, and postmenarche oligomenorrhea. At the other end of the reproductive spectrum, both menstrual irregularity and hyperandrogenemia appear to normalize as PCOS women approach the perimenopause. However, mothers of women with PCOS have elevated testosterone levels compared with levels of controls, suggesting that mild elevations in androgens may persist into later life. Although the endocrine

and reproductive features of the disorder may improve with age, the associated metabolic abnormalities, particularly glucose intolerance, actually may worsen with age (see below).

TABLE 39.3 Syndromes or Disease Entities That Have Been

Associated with Polycystic Ovaries

Hyperandrogenism without Insulin Resistance
Steroidogenic enzyme deficiencies
- Congenital adrenal hyperplasia
- Aromatase deficiency

Androgen-secreting tumors
- Ovarian
- Adrenal

Exogenous androgens
- Anabolic steroids
- Transsexual hormone replacement

Other
- Acne
- IH

Hyperandrogenism and Insulin Resistance
Congenital
- Type A syndrome
- Type B syndrome
- Leprechaunism
- Lipoatrophic diabetes
- Rabson-Mendenhall syndrome
- PCOS

Acquired
- Cushing syndrome

Insulin Resistance
Glycogen storage diseases
Type 2 DM

Other
Central nervous system lesions
- Trauma/Lesions
- Hyperprolactinemia

Nonhormonal medications
- Valproate

Hereditary angioedema
Bulimia
Idiopathic (includes normoandrogenic women with cyclic menses)

IH, idiopathic hirsutism; PCOS, polycystic ovary syndrome; DM, diabetes mellitus.

Long-term Sequelae of Polycystic Ovary Syndrome

PCOS is associated with the development of a number of sequelae, including oligo-ovulatory infertility, dysfunctional uterine bleeding (DUB); an increased risk of endometrial malignancy secondary to the chronic euestrogenic oligo-ovulation; and an increased risk of glucose intolerance, gestational diabetes, type 2 DM, and possibly cardiovascular complications due to the associated metabolic dysfunction. The overall economic burden of PCOS in the premenopausal years has been conservatively estimated to amount to $4.3 billion yearly. In addition, PCOS is associated with an important negative impact on quality of life.

Infertility and Chronic Anovulation

One of the most common reasons that PCOS women present to the gynecologist is due to infertility secondary to chronic anovulation. These women in general are not absolutely infertile but are subfertile due to the infrequency and unpredictability of their ovulation, possibly due to an increased risk of pregnancy loss. As a general rule, PCOS women represent one of the most difficult groups in which to induce ovulation both successfully and safely. Many PCOS women are unresponsive or resistant to ovulation induction with clomiphene citrate and may have an inappropriate or exaggerated response to the administration of human menopausal gonadotropins (menotropins). In part, the abnormal response to ovulatory agents of PCOS patients relates to their degree of hyperinsulinemia and obesity as well as to abnormalities of the intraovarian hormonal milieu and the increased number of preantral follicles. Women with polycystic ovaries are at especially increased risks for developing the hyperstimulation syndrome—a syndrome of massive enlargement of the ovaries, development of rapid and symptomatic ascites, intravascular contraction, hypercoagulability, and systemic organ dysfunction—and having multiple gestations. Increasing obesity may blunt the risk for these complications. These complications generally occur following treatment with menotropins, although ovarian hyperstimulation has even been reported in women with PCOS conceiving a singleton pregnancy spontaneously or after clomiphene or pulsatile GnRH use.

Abnormalities of the Pilosebaceous Unit

The development of hirsutism, acne, or androgenic alopecia in PCOS has been attributed to the increased systemic and local production of androgens, as discussed previously. While insulin is essential for hair follicle growth in vitro, it is unclear whether the hyperinsulinemia of PCOS directly stimulates the terminalization of body hairs and the development of hirsutism.

Gynecologic Cancers

Many gynecologic cancers have been reported to be more common in women with PCOS, including those related to the ovary, breast, and endometrium. However, the best case of an association between PCOS and cancer can be made for endometrial cancer, as many risk factors for this cancer are present in the PCOS patient, although the epidemiologic evidence of an increased incidence is weak. Overall, current data suggests that PCOS patients do not have a significantly higher risk for breast or ovarian cancer than do matched controls, although prospective studies of large populations of PCOS and matched controls are still needed.

Type 2 Diabetes Mellitus

The inherent insulin resistance present in women with PCOS, aggravated by the high prevalence of obesity in these individuals, places them at increased risk for impaired glucose tolerance (IGT) and type 2 DM. About 30% to 40% of obese, reproductive-age PCOS women have been found to have IGT, and about 10% have frank type 2 DM based on a 2-hour glucose level >200 mg/dL. Of note is that only a small fraction of PCOS women with either IGT or type 2 DM display fasting hyperglycemia consistent with diabetes by the 1997 American Diabetes Association (ADA) criteria (fasting glucose ≥126 mg/dL) (Fig. 39.8). The conversion rate to glucose intolerance over time is low per year in the range of 3% to 5%, which suggests that rescreening every 3 to 5 years may be adequate to detect abnormalities. However, the level of insulin resistance found in PCOS women based on dynamic measures of insulin action has in other populations (i.e., children of parents with diabetes) been associated with a marked increased risk of developing type 2 DM.

Metabolic Syndrome and Cardiovascular Disease

Many of the studies suggesting an increased incidence of CVD are inferential based on risk-factor models, with little evidence of increased or premature onset of CVD events such as stroke or myocardial infarction. Patients with PCOS demonstrate a 1.4- to 3.5-fold increased prevalence of hypertension above that of controls. However, it should be noted that the prevalence of hypertension in PCOS is significantly greater in obese patients, and in one study, when the prevalence of hypertension was adjusted for BMI, the difference in risk between PCOS and age-matched controls was no longer significant. The mechanisms underlying the relationship between the insulin resistance/hyperinsulinemia and hypertension are unclear but may include sodium retention, overactivity of the sympathetic nervous system, impairment of membrane transport, and stimulation of vascular smooth muscle cells.

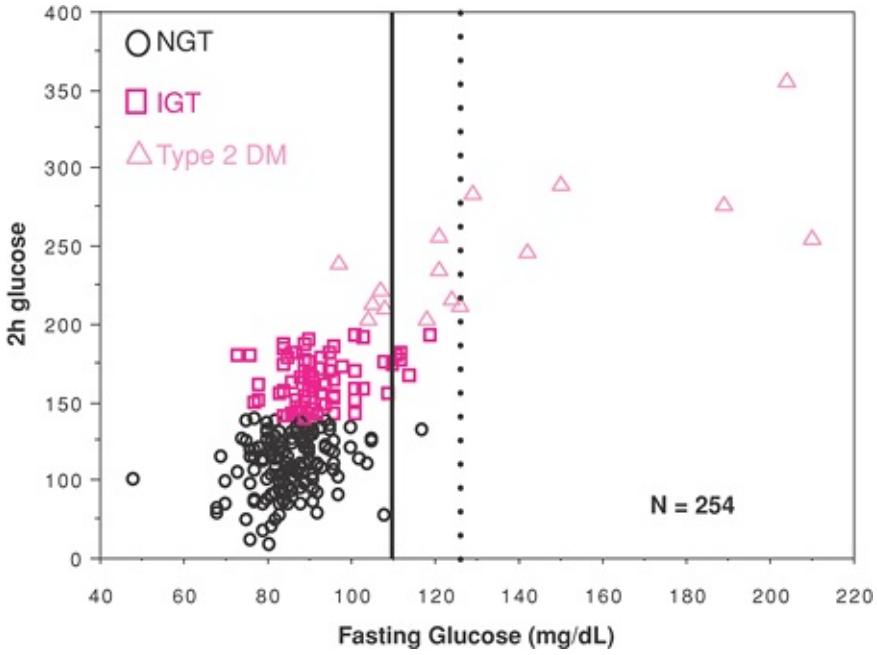

Figure 39.8 Scatterogram of fasting blood glucose levels versus 2-hour postchallenge glucose levels in 254 women with PCOS. Points on the graph are coded to reflect the WHO status based on postchallenge glucose levels: 140 to 199 mg/dL = IGT. The *dashed vertical line* is the threshold (110 mg/dL) for the diagnosis of impaired fasting glucose according to the 1997 ADA criteria, and the *solid vertical line* (126 mg/dL) is the threshold for the diagnosis of type 2 DM by the same criteria. (NGT, normal glucose tolerance; IGT, impaired glucose tolerance; DM, diabetes mellitus.) (Reprinted from Legro RS, Kunselman AR, Dodson WC, et al. Prevalence and predictors of risk for type 2 diabetes mellitus and impaired glucose tolerance in polycystic ovary syndrome: a prospective, controlled study in 254 affected women. *J Clin Endocrinol Metab* 1999;84:165–169, with permission.)

Other effects of hyperinsulinemia and insulin resistance include the development of an atherogenic plasma lipid profile due to insulin enhancement of synthesis of very low-density lipoproteins (VLDL) and hypertriglyceridemia. Insulin also causes the proliferation of smooth muscle cells and stimulation of collagen synthesis in small arterioles. These effects, in combination with insulin-induced growth factor elaboration and inhibition of regression of lipid plaques, contribute to the development of atherosclerosis and the resultant CVD. In fact, many PCOS women have significant dyslipidemia, with lower HDL, and higher triglyceride and LDL levels than age, sex, and weight-matched controls. PCOS women, at least in later life, also appear to have a higher risk of developing hypertension. Recent studies have documented other interim risk factors such as increased carotid artery intimal thickness or increased coronary artery calcification to suggest that these women have evidence of atherosclerotic disease at an earlier and more advanced stage than control women.

There are a number of features of PCOS that do not fully fit the definition of metabolic syndrome. For example, although dyslipidemia is part of metabolic syndrome, the elevation in LDL levels noted in PCOS is not one of the characteristic findings. As well,

although the risk of developing hypertension later in life appears to be higher in PCOS patients, hypertension is still relatively uncommon in women with PCOS of reproductive age.

Other Androgen Excess Disorders

Other major androgen excess disorders include the HAIR-AN syndrome; 21-hydroxylase (21-OH) deficient NCAH; and very rarely, ovarian or adrenal androgen-secreting neoplasms.

Hyperandrogenic Insulin-resistant Acanthosis Nigricans Syndrome

HAIR-AN syndrome is an inherited disorder of severe insulin resistance, distinct from PCOS, which actually includes many different genetic syndromes. Although single point mutations of the insulin receptor are rare among these patients, some patients with this syndrome actually may suffer from a form of the familial lipodystrophy syndrome. In the authors' experience, approximately 3% of hyperandrogenic women suffer from these disorders. These patients are diagnosed by having extremely high circulating levels of basal (>80 μU/mL) or glucose-stimulated (>300 to 500 μU/mL) levels, although exact diagnostic criteria are lacking, in part due to the heterogeneity of the syndrome. Patients can be severely hyperandrogenemic, with testosterone levels reminiscent of patients with androgen-secreting neoplasms, resulting in the development of severe hirsutism and even virilization. In addition to significant hirsutism, patients also develop the characteristic dermatologic finding of acanthosis nigricans (Fig. 39.7). Because of their high androgen levels, gonadotropin levels in these patients may be somewhat suppressed, resulting in persistent endometrial atrophy and amenorrhea despite the administration of a cyclic progestogen or an oral contraceptive.

Because of the mitogenic effect of insulin on ovarian theca cells, the ovaries of many patients with HAIR-AN syndrome will become hyperthecotic. On ultrasound and histology, the ovaries morphologically have a paucity of cortical cysts and demonstrate a thickened and enlarged theca/stroma compartment. In addition, these patients are at significant risk for dyslipidemia, type 2 DM, hypertension, and CVD. These patients can be particularly difficult to treat, although the selected use of long-acting GnRH analogs has been promising. Some patients may necessitate surgery, either ovarian wedge resection or oophorectomy. Concomitant insulin sensitizer use may lower both androgen and insulin levels.

Nonclassic Adrenal Hyperplasia

NCAH, also referred to as late-onset congenital adrenal hyperplasia, is a homozygous recessive disorder due to mutations in the CYP21 gene, resulting in an abnormal (or absent) cytochrome P450c21 with relatively deficient 21-OH activity. Overall, between 1% and 8% of women with androgen excess have 21-OH deficient NCAH depending on ethnicity, with the highest rates reported in Ashkenazi Jewish populations. Due to the lack of 21-

hydroxylation, the progestogenic precursors to cortisol, 17α-hydroxyprogesterone (17-HP), and to a certain degree 17-hydroxypregnenolone accumulate in excess. These steroids are then metabolized to C19 products, principally androstenedione and testosterone (Figs. 39.1, 39.2). However, clinically and biochemically, these patients are very difficult to distinguish from other hyperandrogenic patients, particularly patients with PCOS. Patients with NCAH may present only with persistent acne or may have moderate degrees of hirsutism and oligoamenorrhea, although frank virilization or even severe hirsutism is relatively rare. The levels of the exclusive adrenal androgen metabolite DHEAS are not any higher than those of other hyperandrogenic women.

Although the frequency is relatively low, all patients with unexplained androgen excess should be screened for NCAH due to CYP21 mutations, as this diagnosis has a different prognosis, a different treatment regimen, and requires genetic counseling regarding the risks of congenital transmission. The measurement of a basal 17-HP in the follicular phase *and* in the morning can be used to screen for this disorder, with a level of <2 ng/mL excluding the disorder with 90% certainty. In addition, these patients can be treated with corticosteroid replacement, although many of the patients who are diagnosed in adulthood tend to also demonstrate a PCOS-like pattern requiring additional ovarian suppression and androgen blockade, which is discussed later.

While theoretically it is possible that NCAH may be due to mutations in other genes determining steroidogenic enzymes, such CYP11B1 (encoding for P450c11a and 11β-hydroxylase activity) or HSD3B (for 3β-hydroxysteroid dehydrogenase), mutations in the genes coding for these enzymes are rarely noted in adult women presenting with androgen excess.

Androgen-Secreting Neoplasms

Androgen-secreting neoplasms are relatively rare, affecting between 1 in 300 and 1 in 1,000 hirsute patients. These tumors usually originate in the ovary and, rarely, the adrenal cortex. The most common androgen-producing tumor in a premenopausal woman is a Sertoli-Leydig cell tumor, with thecomas and hilus cell tumors being less frequent. Hilus cell tumors are often small and can be <1 cm in diameter, theoretically below the range of imaging visualization. Another rare neoplasm may be a granulosa cell tumor, 10% of which primarily secrete androgens instead of estrogens. Also, any large tumor within the body of the ovary (i.e., benign cystic teratomas, dysgerminomas, epithelial tumors) can produce androgens indirectly by causing hyperplasia of the surrounding normal stroma. Fortunately, the vast majority of ovarian androgen-secreting neoplasms are benign.

Alternatively, adrenal androgen-secreting tumors are generally malignant (i.e., due to adrenocortical carcinoma) and associated with a high mortality rate, although androgen-secreting adrenal adenomas also have been reported. Fortunately, adrenal androgen-secreting neoplasms are rare, with an estimated incidence of two cases per one million persons per year. The age of onset in adults peaks in the fifth decade. Virilization can accompany both

---

tumors primarily producing androgens and tumors primarily producing cortisol (Cushing

syndrome). A long history of symptoms, as in the case with an ovarian tumor, does not exclude the presence of an adrenocortical neoplasm.

The presence of androgen-secreting neoplasms should be suspected when the onset of androgenic symptoms is rapid and sudden, when androgen excess initially presents in later life, when they lead to virilization and masculinization, or are associated with cushingoid features. Nonetheless, it should be remembered that some of the younger patients with virilization suspected of having an androgen-secreting neoplasm actually suffer from the HAIR-AN syndrome. Suppression and stimulation tests can be misleading and are not encouraged for the diagnosis of these neoplasias. Overall, the single *best* predictor of an androgen-producing tumor is clinical presentation, not biochemical markers. For example, in a recent study, the authors noted that the positive predictive value of a repeat total T above 250 ng/dL was only 9%, as most women with total T levels above this cutoff have other abnormalities, such as the HAIR-AN syndrome or PCOS.

Rare Causes of Androgen Excess

Clinical signs of androgen excess also may result from the presence an ACTH-secreting tumor, due to either a pituitary adenoma (i.e., Cushing syndrome) or an extrapituitary (ectopic) source, although patients usually are also cushingoid. In one study of young women with Cushing syndrome, all had stigmata of hyperandrogenism (hirsutism, acne, or balding), but only 70% had oligomenorrhea. However, as Cushing syndrome has an extremely low prevalence in the population (one in a million) and screening tests do not have 100% sensitivity/specificity, routine screening of all women with androgen excess for Cushing syndrome is not indicated. Nonetheless, clinical signs more commonly found in Cushing syndrome, such as ecchymoses, proximal muscle weakness, centripetal reddened striae, facial rubor and swelling, and perhaps hypertension and glucose intolerance, should signal screening tests. Cortisol excess can be screened for with a 24-hour urine collection for free cortisol or an overnight dexamethasone suppression test.

Also in the differential of androgen excess in an adult female is the use or abuse of exogenous androgens, such as in a body builder or an excessive use of androgens in postmenopausal women. Severe hirsutism, and even virilization, that begins during pregnancy has its own unique differential, including benign ovarian sources such as hyperreactio luteinalis (i.e., gestational ovarian theca-lutein cysts) or luteomas, and extremely rare fetoplacental sources, such as aromatase deficiency resulting in androgen excess due to the placental inability to convert precursor androgens into estrogens. Finally, gonadal dysgenesis associated with an abnormal Y chromosome can present initially as peripubertal androgenization.

Idiopathic Hirsutism

Although IH is not properly an androgen excess disorder, it is included and should be considered in the differential diagnosis of androgen excess. Overall, approximately 5% to 15% of hirsute women will have the diagnosis of IH. The diagnosis of IH is by exclusion in a patient who is obviously hirsute, but in whom the circulating androgens and ovulatory function and morphology appear to be normal and no other disorders can be identified.

While some clinicians use regular menses as diagnostic of normal ovulatory function, it should be noted that approximately 40% of eumenorrheic hirsute women actually are anovulatory and hence do not suffer from IH. Although biochemically these patients do not have an obvious elevation in circulating androgen levels, it also is likely that many of these patients simply demonstrate degrees of hyperandrogenemia that may not be detectable with routine clinical androgen assays. Nonetheless, in some of these women, the 5α-reductase activity in the skin and hair follicle probably is overactive, leading to hirsutism in the face of normal circulating androgen levels.

Evaluation of Androgen Excess

History and Physical

The history and physical are essential to making a diagnosis of the underlying cause of androgen excess. History taking should focus on the onset and duration of the various stigmata of androgen excess, should include a thorough menstrual history, and offer a discussion of concomitant medications. The physical examination should carefully assess the patient for cushingoid features, acanthosis nigricans, balding, acne, and degree and type of body hair distribution. One commonly used scale to score the degree of excess hair growth is based on a modification of the Ferriman-Gallwey scale (Fig. 39.5). To determine the hirsutism score, nine body areas (upper lip, chin and neck, chest, abdomen above the umbilicus, abdomen below the umbilicus, thighs, upper back, lower back, and arms) are examined, and a score of 0 (no excess terminal hair growth seen) to 4 (terminal hair growth equivalent to that of a man) is assigned. The individual scores for each area assessed are summed to provide the overall mF-G score. As discussed previously, a score of 6 to 8 usually is used to denote the presence of hirsutism, although lesser scores in the face of patient complaints may be sufficient to warrant investigation.

Signs of virilization and masculinization should be sought, although their recognition usually is obvious. Clitoromegaly usually is defined as a clitoral index >35 mm^2, where the clitoral index is the product of the sagittal and transverse diameters of the glans of the clitoris in millimeters. In normal women, these clitoral diameters are in the range of 5 mm. Clitoromegaly can be suspected if the

---

clitoris is observed to protrude beyond the clitoral hood on external pelvic exam.

Evidence and risk factors for insulin resistance should be sought out, which is critical to the long-term health of the women affected. Family history of diabetes, present in about one third of women with PCOS and CVD, especially of first-degree relatives with premature onset heart disease (males <55 years of age and females <65 years), is an important part of the assessment. Lifestyle factors such as smoking, ethanol consumption, and diet and exercise histories should be recorded. Signs of insulin resistance on physical exam such as obesity, particularly with a centripetal fat distribution, and the presence of acanthosis nigricans and acrochordons should be recorded. Acanthosis nigricans is principally noted in most crural areas of the body, including the back of the neck, the axilla, underneath the breasts, and even on the vulva.

Weight should be corrected for height by using the body mass index (by dividing weight in kilograms by the square of the height in meters, i.e., kg/M^2). However, the pattern of fat distribution rather than body mass index seems to be most predictive of morbidity and mortality. In women, a central or abdominal distribution of adiposity fat (the so-called apple-shaped or android obesity) has been associated with an increased risk for CVD and with an increased index of death from all causes. Fat distribution is most easily assessed by using the waist circumference, with a value >35 inches being associated with an increased risk for diabetes and CVD. In women, the android pattern of obesity, as captured by the waist circumference, has been associated with abnormal lipid profiles and increased insulin resistance compared with those found in the gynecoid pattern.

The laboratory evaluation should have the objective of excluding related and specific disorders and, if necessary, providing confirmation of androgen excess. As well, the presence of metabolic abnormalities, particularly in patients with PCOS or the HAIR-AN syndrome, should be sought out.

Laboratory Evaluation for Androgen Excess

Specific related disorders of androgen excess that should be excluded are thyroid dysfunction, hyperprolactinemia, NCAH, HAIR-AN syndrome, and androgen-secreting tumors. Thyroid dysfunction and NCAH are ruled out by measuring a third-generation TSH and a basal 17-HP level, the latter measured in the follicular phase of the menstrual cycle. If the 17-HP level is >2 ng/mL, the patient should undergo an acute adrenal stimulation test to exclude 21-hydroxylase–deficient NCAH. If after 60 minutes the 17-HP level following ACTH administration is >10 ng/mL, the diagnosis of 21-OH–deficient NCAH is established.

As noted previously, hirsute women claiming to have regular menstrual cycles should be evaluated for ovulatory dysfunction, most simply by obtaining a serum progesterone in the luteal phase (days 20 to 24) of the menstrual cycle. If the patient has ovulatory dysfunction, as evidenced by either a luteal phase progesterone level <5 ng/mL in a eumenorrheic patient or because she has overt menstrual abnormalities, the diagnosis of PCOS should be entertained. In women with ovulatory dysfunction, serum prolactin and fasting insulin levels also should be obtained to exclude hyperprolactinemia and the HAIR-AN syndrome, respectively. Androgen-secreting neoplasms generally are excluded by the history and physical exam. Rarely will a 24-hour urine collection for free cortisol be required in a patient with features suggestive of Cushing syndrome.

The measurement of circulating androgen levels, including total and free testosterone, and DHEAS are useful primarily in the minimally or nonhirsute oligo-ovulatory patient to exclude the presence of androgen excess as the cause of the ovulatory dysfunction. However, these measurements have limited diagnostic utility in the patient who is frankly hirsute and have a low positive predictive value for adrenal or ovarian androgen-secreting neoplasms.

Inappropriate gonadotropin secretion has been one of the characteristic signs of PCOS, and many clinicians have used elevated LH to FSH ratios of 2:1 or 3:1 as diagnostic criteria for PCOS. Nonetheless, because up to 50% of PCOS patients may have a normal ratio and the LH

to FSH ratios tend to normalize with increasing body mass index, or alternatively with insulin sensitizer or oral contraceptive therapy, measuring gonadotropins is an insensitive marker of PCOS.

Laboratory Assessment for Metabolic Abnormalities

Metabolic abnormalities are common among women with PCOS and occur in all patients with the HAIR-AN syndrome. In patients with HAIR-AN syndrome, the presence of insulin resistance is obvious, although this may not be case in women with PCOS. Unfortunately, there are no accurate, inexpensive, or reproducible tests for assessing insulin sensitivity clinically. The standards are dynamic tests such as the euglycemic clamp and the frequently sampled intravenous glucose tolerance test. These assessments primarily determine insulin-mediated glucose uptake in the skeletal muscle, the primary tissue utilizing circulating insulin. Insulin-mediated glucose uptake, however, is just one aspect of insulin's protean actions. While these methods are the most accurate for determining decreased sensitivity to insulin (or insulin resistance), they are too laborious and expensive to use for the routine clinical evaluation of insulin resistance. For larger epidemiologic studies, detection of IR may be accomplished by using surrogate measures such as the homeostatic model assessment (HOMA) or the quantitative insulin sensitivity check index (QUICKI). However, these measures have limited value in the assessment of the individual patient.

Clinically, in PCOS, the standard 2-hour oral glucose tolerance test (OGTT), measuring both insulin and glucose,

---

yields the highest amount of information for a reasonable cost and risk, thus providing an assessment of both the degrees of hyperinsulinemia and glucose tolerance. However, considering the current variability in insulin assays, each laboratory should set its own normal range and establish a method for periodically reevaluating the acceptability of its results. Further, there are scant data that markers of insulin resistance identify women with androgen excess who are more likely to respond to specific therapies, such as treatment with insulin sensitizers, nor are they particularly useful in monitoring response of stigmata of PCOS to therapy (i.e., anovulation, hirsutism, etc.).

Given the high prevalence of abnormalities in glucose tolerance, PCOS and HAIR-AN syndrome patients should be screened for IGT or frank diabetes with an OGTT using a 75-g glucose load. Considering the World Health Organization (WHO) criteria, IGT is diagnosed by a normal fasting glucose (≤110 mg/dL) and a 2-hour glucose of between 140 mg/dL and 199 mg/dL, while frank diabetes is diagnosed by a fasting glucose ≥140 mg/dL *or* a 2-hour glucose during the OGTT ≥200 mg/dL. Abnormal OGTT results need to be repeated for confirmation. The development of glucose intolerance heralds ß-cell dysfunction with inadequate insulin secretion for the degree of reduced peripheral insulin sensitivity. The development of IGT is a clear risk factor for developing type 2 DM and also may be an independent risk factor for CVD, such as myocardial infarction and stroke. In addition, measuring insulin during the OGTT will provide an assessment of the degree of hyperinsulinemia, with a peak insulin of 80 to 150 µIU/mL denoting mild hyperinsulinemia,

insulin of 151 to 300 μIU/mL indicating moderate hyperinsulinemia, and insulin levels >300 μIU/mL indicating severe hyperinsulinemia.

Rather than relying on fasting levels of insulin and glucose of limited utility as discussed previously, the Expert Panel on the Detection, Evaluation, and Treatment on High Blood Cholesterol in Adults (Adult Treatment Panel III) defined metabolic syndrome as being an integrated phenotype of insulin resistance, which includes biometric and biochemical measures of centripetal obesity, hypertension, fasting hyperglycemia, and dyslipidemia (Table 39.4). Women with PCOS have been shown to have a high prevalence of this disorder, although it primarily is present in obese women (BMI >30 kg/m^2). Screening obese women with hyperandrogenism for metabolic syndrome is likely to have a high yield.

Radiologic Imaging in the Evaluation of the Patient with Androgen Excess

Routine ultrasound of the pelvis in patients with androgen excess is probably not indicated. Polycystic ovaries can be noted with many of the androgen excess disorders and remain nonspecific (Fig. 39.8). Nonetheless, the appearance of polycystic ovaries may be useful as a potential predictor for the development of ovarian hyperstimulation syndrome during ovulation induction. Furthermore, a transvaginal sonogram in obese individuals to properly examine the ovaries for pathologic masses may be appropriate. In cases where an androgen-secreting tumor is suspected, a computed tomography (CT) scan or magnetic resonance imaging (MRI) of the adrenals should be considered to exclude adrenal masses as small as 5 mm in diameter and to detect bilateral adrenal hyperplasia in the event of an ACTH-secreting tumor. However, about 2% of the population harbors a clinically insignificant adrenal adenoma (i.e., incidentaloma) such that the finding of such an adrenal mass is not diagnostic for an androgen-secreting adrenal tumor. Functional radiologic techniques such as selective venous catheterization or scintigraphy with ^{131}iodomethyl-norcholesterol are rarely used for the localization of such tumors.

TABLE 39.4 Criteria for the Metabolic Syndrome in Women[a]

Risk Factor	Cutoff
1. Abdominal obesity	Waist circumference >88 cm (>35 in)
2. Triglycerides	≥150 mg/dL
3. HDL-C	<50 mg/dL
4. Blood pressure	≥130/≥85
5. Fasting and/or 2-h glucose from a 75-g OGTT	110–126 mg/dL[b] and/or 2-h glucose 140–199 mg/dL[c]

HDL-C, high-density lipoprotein cholesterol; OGTT, oral glucose tolerance test.

[a]Three out of five qualify for the diagnosis.

[b]As recommended by the Third Report of the Expert Panel on the Detection, Evaluation, and Treatment on High Blood Cholesterol in Adults (Adult Treatment Panel III, or ATP III) of the National Cholesterol Education Program.

[c]As recommended by the American College of Obstetricians and Gynecologists (ACOG).

Treatment of Androgen Excess

Treatment of androgen excess tends to be symptom based. In general, four reasons for treatment can be considered, including (a) regulation of uterine bleeding, reducing the risk of endometrial hyperplasia and cancer, DUB, and secondary anemia; (b) the improvement of dermatologic abnormalities such as hirsutism, acne, or alopecia; (c) the amelioration and prevention of associated metabolic abnormalities, particularly diabetes and cardiovascular risk factors; and (d) the treatment of anovulatory infertility. Overall, avenues of treatment include the suppression of androgen production; the blockade of peripheral androgen action; the improvement of any associated insulin resistance and dyslipidemia; and topical, mechanical, or cosmetic measures for improving the dermatologic manifestations of these disorders (Fig. 39.9). The vast majority of patients with androgen excess will require and benefit the most from combination therapy. Unfortunately, there is a lack of large-scale randomized trials in these areas, and treatment frequently is guided by the often conflicting evidence of small trials of varying quality.

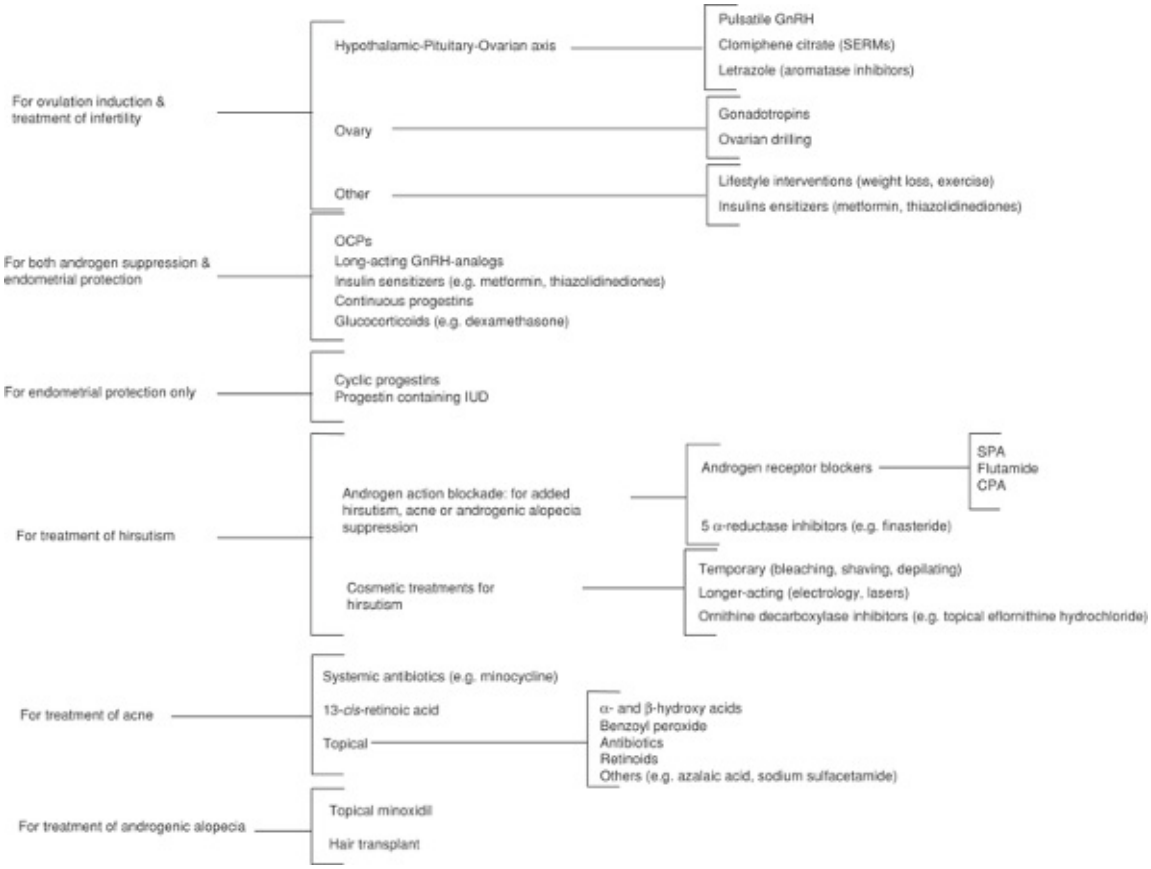

Figure 39.9 Treatment strategies in the patient with androgen excess. CPA, cyproterone acetate; GnRH, gonadotropin releasing hormone; OCPs, oral contraceptive pills; SERMs, selective estrogen receptor modulators; SPA, spronoledrone.

Regulation of Uterine Bleeding

In general, the regulation of uterine bleeding can be achieved with oral contraceptives; cyclic or continuous progestogens; and in some patients with PCOS, with insulin-sensitizing agents and rarely surgery. Experimentally, the antifungal agent ketoconazole also has the potential of inhibiting steroidogenesis, although its use primarily has been relegated to experimental protocols, as it has the potential of also inhibiting adrenocortical steroidogenesis.

Oral Contraceptives

Oral contraceptive medications generally act by suppressing circulating LH and FSH, leading to a decrease in ovarian androgen production. In addition, the estrogen in the birth control pill increases SHBG, thus decreasing free testosterone levels. Furthermore, the progestin in the birth control pill can lead to a beneficial antagonism of 5α-reductase activity and androgen binding to the androgen receptor. Finally, these medications also may decrease adrenal androgen production by a mechanism not yet clear. Oral contraceptives are very effective at regulating uterine bleeding and decreasing the associated risk of endometrial hyperplasia or carcinoma in the hyperandrogenic patient, regardless of etiology. It is preferable, although not critical, to select a pill containing a

progestin with low androgenic activity (e.g., norethindrone acetate, ethynodiol diacetate, desogesterol, gestodene, or norgestimate). There is some evidence that oral contraceptives can slightly worsen insulin resistance and glucose tolerance in PCOS women. However, there is no evidence that these effects of the oral contraceptive pill on glucose metabolism result in an increased risk for developing type 2 DM in the general population, and their use in androgen excess patients should not be limited by this concern.

Cyclic or Continuous Progestogens

Cyclic progestogen administration is useful to regulate uterine bleeding in androgen excess patients, particularly in the amenorrheic women. It is not known how many progestin-induced withdrawal bleeds per year are necessary to adequately prevent the development of endometrial cancer in the PCOS-women population, although extrapolating from the postmenopausal hormone replacement literature, monthly treatment for a minimum of 12 days or longer are optimal. Because progestogen administration occasionally can stimulate an ovulatory event and because not all these patients are completely anovulatory, it may be preferable to treat sexually active women with oral micronized progesterone, 100 mg to 200 mg twice daily.

Glucocorticoids

Glucocorticoid therapy may be beneficial in regulating menstrual bleeding in the patient with NCAH although have limited benefit in patients with PCOS. However, the authors have found that in NCAH, monotherapy is effective primarily in those women whose treatment is initiated in adolescence and that many patients will require combination therapy. The lowest effective dose of glucocorticoids should be used (e.g., dexamethasone 0.25 mg daily or every other day). Glucocorticoids should be administered with caution, as they have the potential of producing weight gain and cushingoid features and worsening existing insulin resistance. They also are associated with bone abnormalities, including osteoporosis.

Insulin-Sensitizing Agents

Drugs developed initially to treat type 2 DM have now also been utilized to treat PCOS. These include metformin, thiazolidinediones, and an experimental insulin sensitizer drug D-*chiro*-inositol. Other drugs, such as acarbose, have been studied as well in PCOS, with beneficial effects. However, it should be noted that none of these agents is currently Food and Drug Administration (FDA) approved for the treatment of PCOS or for related symptoms such as anovulation, hirsutism, or acne.

Metformin

Metformin was approved for the treatment of type 2 DM by the FDA in 1994 but was used clinically for close to 20 years before that in other parts of the world. Metformin is a biguanide that works primarily by suppressing hepatic gluconeogenesis, but it also improves insulin sensitivity peripherally. Gastrointestinal symptoms (diarrhea, nausea, vomiting,

abdominal bloating, flatulence, and anorexia) are the most common reactions to metformin, occurring in about 30% of treated women. There is a small risk of lactic acidosis among women taking this medication, which may be triggered by exposure to intravenous iodinated radiocontrast agents in susceptible individuals, although this adverse effect occurs primarily in patients with poorly controlled diabetes and impaired renal function. In small studies, metformin therapy has been found to improve uterine bleeding and menstrual function by about one third above baseline levels. More recent studies suggest that metformin alone is less likely to improve menstrual regularity without concomitant weight loss. While some benefit is noted, the overall improvement is modest.

Thiazolidinediones

Thiazolidinediones are peroxisome proliferator activating receptor (PPAR)-γ agonists and are thought to improve insulin sensitivity through a postreceptor mechanism. In a large multicenter trial, troglitazone has been shown to have a dose–response effect in improving ovulation and menstrual dysfunction in women with PCOS. This appears to be mediated through decreases in hyperinsulinemia and decreases in free testosterone levels. Troglitazone has subsequently been removed from the worldwide market due to the potential for inducing hepatotoxicity. Newer thiazolidinediones such as rosiglitazone and pioglitazone appear to be safer in terms of hepatotoxicity but also have been associated with embryotoxicity in animal studies (both are pregnancy category C). When using these drugs, liver function tests should be monitored on a regular basis. Limited studies support their effectiveness in PCOS, and there are conflicting data about the relative merits of each in head-to-head trials. Combination treatment with other insulin sensitizers, primarily metformin, has been shown to further improve insulin sensitivity and glycemic control in type 2 DM, although studies have not shown a similar benefit in women with PCOS.

Intrauterine Progestin-Releasing System

Recently, there have been some small studies to suggest that a progestin-releasing intrauterine device or intrauterine system (IUS) could be useful to treat menorrhagia and additionally may be useful to treat or reduce the risk of endometrial hyperplasia. Further studies are needed, but this may be a potentially useful therapy in select patients with PCOS.

Surgery

In patients with intractable uterine bleeding who have completed their childbearing, consideration may be given to either an endometrial ablation or more definitive surgical therapy with a hysterectomy. The long-term risk of endometrial cancer developing in isolated pockets of endometrium after ablation remains a theoretical concern without clear data. Ovulatory function may also improve following laparoscopic ovarian drilling procedures, although the long-term effect of these therapies on menstrual function is unclear, and these are traditionally performed for infertility, not for abnormal uterine bleeding.

Weight Loss and Lifestyle Modification

Multiple studies in hyperandrogenic or PCOS women have shown that weight loss can lower circulating androgen

levels and cause spontaneous resumption of menses. These changes have been reported with a weight loss as small as 5% of the initial weight. In patients with massive obesity, consideration may be given to surgical means of inducing weight loss, such as laparoscopic gastric bypass. Menstrual regularity in PCOS women has been noted to improve after gastric bypass surgery.

Treatment of Hirsutism and Androgen Excess-Associated Acne or Alopecia

The treatment of hirsutism can be complex and has been reviewed. Optimum therapy usually requires a combination of approaches, including suppression of circulating androgens (with oral contraceptives, insulin sensitizers, or even long-acting GnRH analogs or glucocorticoids), peripheral androgen blockade (with spironolactone, flutamide, cyproterone acetate, or finasteride), and the use of a topical hair growth inhibitor (eflornithine hydrochloride) or mechanical methods of hair reduction or destruction (electrology or lasers) as well as appropriate cosmetic measures (bleaching or chemical depilating). Acne in androgen excess patients usually can be treated with oral contraceptives, accompanied by topical or antibiotic therapies. The treatment of androgenic alopecia may require the use of androgen suppression in combination with androgen blockade and topical means of stimulating hair regrowth (e.g., minoxidil).

Most medical methods alone, while improving hirsutism, do not produce the dramatic and rapid results that many patients desire. In general, combination therapies appear to produce better results than single-agent approaches, response with medical therapies often takes 3 to 6 months to notice improvement, and adjunctive mechanical removal methods are often necessary. However, the majority of women appear to experience improvement in their hirsutism. Unfortunately, there are no universally accepted techniques for assessing the response of hirsutism to treatment. Some of the depilatory treatments utilized by patients are so effective that it is difficult to ever determine baseline hirsutism and response to treatment such that the patient's subjective assessment guides therapy.

Androgen Suppression

Women with documented hyperandrogenemia would theoretically benefit most from androgen suppression, although in actual practice, the clinical response to this type of therapy does not correlate with androgen levels. Suppression of ovarian androgen secretion has been achieved with oral contraceptives, progestins, or GnRH analogue treatment. Oral contraceptives improve hirsutism, although the response of hirsutism to this therapy alone generally is modest over the short run but may better in the long term (1 to 2 years). Extended cycle regimens may offer greater benefit given their longer treatment period in any given month. Treatment with a long-acting GnRH agonist may result in a greater

lowering of circulating androgens and, theoretically, a greater degree of hair growth suppression, although comparative trials against other agents and combined agent trials have yielded mixed results. It should be noted that a long-acting GnRH agonist given alone results in unacceptable bone loss. Glucocorticoid suppression of adrenal androgens also offers theoretical benefits, but deterioration in glucose tolerance is problematic for PCOS women, and long-term effects such as osteoporosis are significant concerns. Furthermore, glucocorticoid suppression produces only minimal improvements in hair growth in hirsute women.

Androgen Receptor Antagonists

Androgen receptor antagonists counteract the binding of testosterone and other androgens to the androgen receptor. Therefore, as a class, they are teratogenic and pose risk of feminization of the external genitalia in a male fetus in the event the patient conceives. Spironolactone, a diuretic and aldosterone antagonist, binds to the androgen receptor with 67% of the affinity of DHT. It has other mechanisms of action, including inhibition of ovarian and adrenal steroidogenesis, competition for androgen receptors in hair follicles, and direct inhibition of 5α-reductase activity. Hirsutism and even acne have been treated successfully with spironolactone. The usual dose for the treatment of hirsutism is 25 to 100 mg twice a day, and the dose should be titrated to minimize the potential for side effects. About 20% of the women will experience increased menstrual frequency, which is a reason for combining this therapy with an oral contraceptive. Other side effects include polyuria, orthostatic hypotension, nausea, dyspepsia, and fatigue. Because it can cause and exacerbate hyperkalemia, it should be used cautiously in patients with renal impairment and should not be combined with other potassium-sparing diuretics. The medication also has potential teratogenicity as an antiandrogen, although exposure has rarely resulted in ambiguous genitalia in male infants.

Flutamide is another nonsteroidal antiandrogen that has been shown to be effective against hirsutism. The most common side effect is dry skin; its use has rarely been associated with hepatitis. A dose of 250 mg per day is generally used. As there is a risk of teratogenicity with this compound, contraception should be used.

Cyproterone acetate, not available commercially in the United States, is a progestogen with antiandrogen properties. It frequently is combined in an oral contraceptive. However, an effective dose is 20–50 mg per day if treating hirsutism.

5α-Reductase Inhibitors

There are two forms of the enzyme 5α-reductase, type 1 predominantly found in the skin and type 2 predominantly found in the prostate and reproductive tissues. Both forms are found in the PSU and may contribute to the development of hirsutism, acne, and alopecia. Finasteride inhibits

---

both forms of 5α-reductase and is available as a 5-mg tablet for the treatment of prostate cancer and a 1-mg tablet for the treatment of male alopecia. It has been found to be effective for the treatment of hirsutism in women. Finasteride is tolerated better than

other antiandrogens but has the highest and clearest risk for teratogenicity in a male fetus, so adequate contraception must be used. Overall, randomized trials have found that spironolactone, flutamide, and finasteride to have similar efficacy in improving hirsutism (Fig. 39.10).

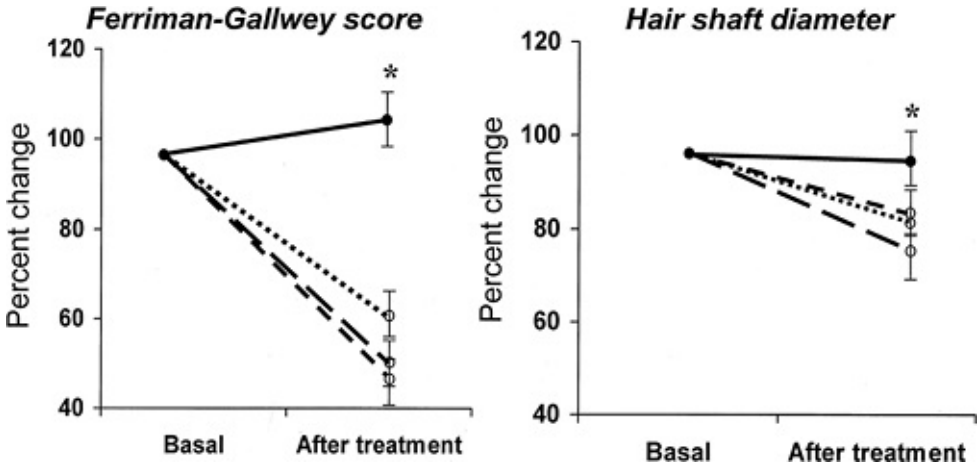

Figure 39.10 Spironolactone (100 mg per day), flutamide (250 mg per day), and finasteride (5 mg per day) were compared for the treatment of hirsutism in a randomized, double blind, placebo-controlled trial including 40 affected women. (OCPs, oral contraceptive pills; GnRH, gonadotropin-releasing hormone; SERMs, selective estrogen receptor modulators; SPA, spironolactone; CPA, cyproterone acetate.) (Modified from Moghetti P, Tosi F, Tosti A, et al. Comparison of spironolactone, flutamide, and finasteride efficacy in the treatment of hirsutism: a randomized, double blind, placebo-controlled trial. *J Clin Endocrinol Metab* 2000;85:89–94, with permission.)

Insulin-Sensitizing Agents and Lifestyle Modification

It is difficult to separate the effects of an improvement in insulin sensitivity from that of androgen suppression, as any improvement in insulin sensitivity can raise SHBG and thus lower bioavailable androgen. Given the long onset of action for improving hirsutism, longer periods of observation are needed. In the largest and longest randomized trial to date of these agents, troglitazone in a dose–response fashion was found to significantly improve hirsutism in PCOS women without lowering total testosterone, a benefit presumably achieved through the decrease in free testosterone. Weight loss in the obese patient also may, albeit modestly, benefit hirsutism. Increases in SHBG through improved insulin sensitivity from weight loss may lower bioavailable androgen levels. In one study, about 50% of these women who lost weight experienced improvement in their hirsutism. The combination of both metformin and lifestyle, however, has not been noted to significantly improve hirsutism in trials lasting up to 48 weeks.

Topical Hair Growth Suppression and Ornithine Decarboxylase

Inhibitors

Ornithine decarboxylase is necessary for the production of polyamines and is a sensitive and specific marker of androgen action in the prostate. Inhibition of this enzyme limits cell division and function, including that of the PSU. A potent inhibitor of this enzyme, eflornithine, has been found to be effective as a facial cream for the treatment of unwanted facial hair. It is available as a 13.9% cream of eflornithine hydrochloride and is applied to affected areas twice daily. In clinical trials, 32% of patients had marked improvement after 24 weeks compared with 8% of placebo-treated women, and the benefit was first noted at 8 weeks. It is pregnancy category C. It appears to be well tolerated, with only about 2% of patients developing skin irritation or other adverse reactions.

Mechanical and Cosmetic Means of Hair Reduction and Destruction

Mechanical hair removal (shaving, plucking, waxing, depilatory creams, electrolysis, and laser vaporization) can assist in controlling hirsutism and often is the first-line treatment used by women. Shaving, bleaching, or chemical depilation may be useful temporary treatments for unwanted hairs. Although shaving can lead to a blunt hair end that may feel “stubblelike,” it does not lead to a worsening of hirsutism. Depilating agents, while useful, can result in chronic skin irritation and worsening of hirsutism if used excessively or indiscriminately. The use of plucking and/or waxing in androgenized skin areas should be discouraged, as these techniques not only do not kill the hair follicles but also can induce folliculitis and trauma to the hair shaft with subsequent development of ingrown hairs and further skin damage.

Electrolysis (i.e., electroepilation) results in long-term hair destruction, albeit slowly. Side effects may include temporary skin irritation and, rarely, burning and scarring of the skin. Hair reduction via lasers also can be useful for selected patients. The main objective of laser therapy for hair removal is to selectively cause thermal damage of the hair follicle without destroying adjacent tissues, a process termed *selective photothermolysis*. Selective photothermolysis relies on the selective absorption of a brief radiation pulse to generate and confine heat at specific pigmented targets. Lasers that are useful in hair removal may be grouped into three categories based on the type of laser or light source that each employs: (a) red

---

light systems (694 nm ruby), (b) infrared light systems (755 nm alexandrite, 800 nm semiconductor diode, or 1,064 nm neodymium:yttrium-aluminum-garnet [Nd:YAG]), and (c) intense pulsed light (IPL) sources (590 to 1,200 nm). In general, laser hair removal is most successful in patients with Fitzpatrick skin colors I to IV who have dark-colored hairs. However, repeated therapies are necessary, and complete alopecia is rarely achieved. In general, treatment with the ruby, alexandrite, or diode lasers or the IPL results in similar success rates, although it appears to be somewhat lower for the Nd:YAG laser.

After laser-assisted hair removal, most patients experience erythema and edema lasting no more than 48 hours. Blistering or crusting may occur in 10% to 15% of patients. Temporary

hyperpigmentation occurs in 14% to 25% of patients, and hypopigmentation occurs in 10% to 17% of patients. Dyspigmentation is less common with the use of longer wavelengths, as in the alexandrite or diode lasers, and longer pulse durations. Overall, laser hair removal is a promising technique for the treatment of the hirsute patient. Nonetheless, most studies have been uncontrolled and have included fewer than 50 patients; none of the patients have been blinded; and all patients have used a variety of treatment protocols, equipment, skin types, and hair colors in the studies.

The Treatment of Associated Metabolic Abnormalities

The treatment of any associated metabolic abnormalities includes lifestyle alterations and weight reduction as well as the use of insulin sensitizers and possibly lipid-lowering agents. Multiple studies have shown that improving insulin sensitivity, through lifestyle modifications or by pharmacologic intervention, can result in lowered circulating androgens (primarily mediated through a reduction in bioavailable androgen) and an increase in the spontaneous ovulation and pregnancy rates. In addition, it is possible that a decrease in insulin resistance may reduce the risk that patients with PCOS will develop type 2 DM. In support of this, data from the Diabetes Prevention Program, which enrolled men and women at risk for diabetes, demonstrated that lifestyle interventions had a more profound effect at preventing the development of subsequent type 2 DM than did the sole use of metformin, although both interventions were superior to placebo. The beneficial effect of dietary modification and increased exercise similarly improved diabetes risk in the Finnish population. However, long-term studies documenting a decrease in such sequelae as endometrial cancer, type 2 DM, or CVD with improvements in insulin sensitivity are still lacking in the PCOS population.

The gold standard for improving insulin sensitivity in obese PCOS women should be weight loss, diet, and exercise. Obesity has become epidemic in our society and contributes substantially to reproductive and metabolic abnormalities in PCOS. Unfortunately, there are no effective treatments that result in permanent weight loss, and it is estimated that 90% to 95% of patients who experience a weight decrease will relapse. Furthermore, in markedly obese individuals, the only treatment that results in sustained and significant weight reduction is bariatric surgery. In addition to improving the endocrine aspects of PCOS, weight loss can decreased circulating insulin levels. Hypocaloric diets result in appropriate weight loss in women with hyperandrogenism, without clear evidence that any particular dietary composition benefits weight loss or reproductive or metabolic changes. There have been, unfortunately, few studies on the effect of exercise alone on insulin action in PCOS women, although it is reasonable to assume that exercise would have the same beneficial effects in PCOS women as in women with type 2 DM.

The Treatment of Hyperandrogenic Oligo-Ovulatory Infertility

A full discussion of the treatment of oligo-ovulatory infertility is beyond the scope of this chapter. In women with PCOS, there are a variety of methods available to improve ovulatory function that act through different mechanisms. Weight loss is often recommended as a preconception intervention. Ovulation induction for the treatment of

infertility related to androgen excess typically first includes the use of clomiphene citrate and then human gonadotropins (Table 39.5).The introduction of insulin-sensitizing agents and preliminary data supported a beneficial role of these agents as both first-line and adjuvant therapy. However, two recent large randomized blinded trials have shown no benefit on pregnancy rates when using the combination of clomiphene and metformin compared with clomiphene alone. Further, in a large NIH-supported trial, clomiphene was found to be markedly superior to metformin alone (Fig. 39.11). These trials have brought into question the role and efficacy of metformin for the treatment of infertility in women with PCOS.

Some clinicians advocate the use of metformin during early pregnancy to reduce the miscarriage rate, but the documentation for this claim is poor, based mainly on case series. Given the results of the recent randomized trials of metformin for the treatment of infertility, a word of caution is necessary before this medication is routinely used during pregnancy. Metformin is pregnancy category B, with no known human teratogenic risk or no known embryonic lethality in humans, which probably leads to an overconfidence in its benefits. There have been no reported abnormalities associated with its use during pregnancy in women with diabetes, to women with marked hyperandrogenism during pregnancy, or to the small number of PCOS women who have conceived during treatment.

The surgical destruction of the ovarian stroma/theca, by either wedge resection or ovarian drilling, has been reported to result in improved ovulatory and pregnancy rates in PCOS patients. In PCOS patients, ovarian drilling

may have a place in the therapy of those women who are clomiphene resistant, although the value of laparoscopic ovarian drilling as a primary treatment for subfertile patients with anovulation and PCOS is undetermined according to a Cochrane review. A number of recent randomized trials have shown that ovarian ablative procedures appear to be just as successful and with a lower multiple pregnancy rate. Therefore, these procedures may be eventually an effective second-line therapy for infertility after clomiphene. None of the various drilling techniques appear to offer obvious advantages, although excessive exposure to thermal energy can cause ovarian failure. In some cases, the results of the ovarian drilling may also be temporary. More importantly, such procedures do not address the underlying well-documented insulin resistance that accompanies the syndrome, and these abnormalities should be evaluated and treated.

Summary Points

- Androgen excess, or hyperandrogenism, is one of the most frequent, albeit heterogeneous, endocrine disorders of women; PCOS is the most common etiology of androgen excess and affects approximately 7% of unselected reproductive-age women.
- Androgen excess results in various clinical signs and symptoms, including abnormalities of the PSU (hirsutism, acne, and androgenic alopecia), those of the hypothalamic–pituitary–ovarian axis (i.e., ovulatory and menstrual dysfunction), and those of the hypothalamic–pituitary–adrenal axis (adrenal androgen excess). If the androgen excess is severe, virilization and/or masculinization also can be apparent.

- The vast majority of androgen excess is due to PCOS, with 21-OH–deficient NCAH, HAIR-AN syndrome, androgen-secreting neoplasms, and drug-induced hyperandrogenism generally accounting for <10% of such patients.
- Approximately 50% to 60% of patients with PCOS suffer from insulin resistance and hyperinsulinism, and they are at higher risk for the development of endometrial cancer, glucose intolerance, and type 2 DM as well as an adverse cardiovascular risk profile.
- The history and physical examination are essential to making a diagnosis of the underlying cause of androgen excess. The laboratory evaluation should have the objective of excluding related and specific disorders and, if necessary, providing confirmation of androgen excess. The presence of metabolic abnormalities, particularly in patients with PCOS or HAIR-AN syndrome also should be sought out.
- Treatment of androgen excess tends to be symptom based, with reasons for treatment including (a) regulation of uterine bleeding, reducing the risk of endometrial hyperplasia and cancer, DUB, and secondary anemia; (b) the improvement of dermatologic abnormalities such as hirsutism, acne, or alopecia; (c) the amelioration and prevention of associated metabolic abnormalities, particularly insulin resistance, hyperinsulinemia, and glucose intolerance; and (d) the treatment of anovulatory infertility (Fig. 39.9).
- Clomiphene citrate is the first-line therapy for infertility in women with hyperandrogenism and chronic anovulation.

Infertility

Kristen P. Wright
Julia V. Johnson

Infertility affects approximately 10% to 15% of couples and is a medical problem for 2.7 million women of reproductive age in the United States. Over the past few decades, successful treatments for virtually all causes of infertility have been developed, offering hope for couples with this medical condition. Unfortunately, many states continue to offer limited insurance coverage for infertility, minimizing effective diagnosis and treatment despite evidence that providing infertility care does not increase insurance costs. It is the goal of this chapter to identify the basic cost-effective diagnostic testing for couples with infertility that can allow the couple to rapidly move on to evidence-based therapeutic options. Prompt diagnosis and effective treatment will maximize the opportunity for conception while minimizing the cost of infertility care.

Infertility is defined as 1 year of unprotected intercourse without conception. Fecundability is the chance of conception in one menstrual cycle, and per cycle fecundity is commonly used to identify the success rate of an infertility treatment. It is expected that approximately 15% to 25% of healthy young couples will conceive in a single cycle, although clearly the chance of conception drops throughout the first year without contraception, selecting out the couples with infertility. The per cycle fecundity falls below 10% after 7 cycles, and only 3% of couples conceive during the 12th cycle. Although it is reasonable to wait a year to begin the infertility evaluation for young couples with no history suggestive of reproductive disorders, an earlier workup is indicated in couples with a positive history for a fertility-lowering disease or advancing maternal age. Decreased fecundity begins for women in their mid-30s, making it reasonable to begin the diagnostic evaluation and treatment of infertility for this age group following 6 months of unsuccessful attempts at pregnancy. When one or both members of the couple have a history suggestive of a disorder potentially altering reproduction, the diagnostic testing should begin immediately. Thus, it is critical for primary care providers and obstetrician–gynecologists to consider both the history and physical examination of both members of the couple as well as advanced maternal age when deciding the time to begin the infertility evaluation.

The increased diagnostic techniques and available treatments for infertility have raised the concern that infertility is a new disorder, increased by the exposure to environmental factors or high-risk behavior. Although the advancing age of the first pregnancy in our

society does increase the risk of infertility, the primary explanation for advancing infertility treatment is the increased awareness of this disorder by patients. It is now more socially acceptable for men and women to seek treatment for infertility and to expect providers to promptly proceed with diagnostic testing and effective treatment.

Evaluation: Initial Assessment

As with all medical problems, the first step in the evaluation of infertility is a thorough medical history and physical examination. Ovulatory dysfunction, tubal risk factors, uterine and cervical abnormalities, peritoneal factors, and male factors are often identified by history or physical exam at the initial visit. It is important for both members of the couple to be interviewed at this first visit.

The known causes of infertility and their incidence are listed in Table 40.1. The history should evaluate ovulatory dysfunction based on the age of menarche, cycle length, history of increased or decreased intervals between cycles, and symptoms of ovulation and hormone production such as mittelschmerz and premenstrual molimina. If ovulatory dysfunction is identified, an endocrine review of systems may assist in determining the etiology. Information regarding thyroid symptoms, androgen excess, marked weight fluctuations, and galactorrhea should be obtained. Decreased ovarian function, as indicated by shortened menstrual cycle length, new onset of irregular cycles, or hot flashes can indicate a contributing factor to infertility. The menstrual history also may point to other causes of infertility. Worsening dysmenorrhea, intermenstrual bleeding, and menorrhagia may point to gynecologic disease.

TABLE 40.1 Causes of Infertility and Their Approximate Frequencies

Main Causes

- Sperm defects or dysfunction, 30% (including spermatogenic failure [i.e., complete or virtually complete failure leading to azoospermia] in 1%–2%, seminal sperm antibodies in 5%, and varicocele in 1%–2%).
- Ovulation failure (amenorrhea or oligomenorrhea), 25% (including primary ovarian failure in 1%–2%).
- Tubal infective damage, 20%
- Unexplained infertility, 25%

Other Causes

- Endometriosis (causing tubal or ovarian structural damage), 5%

- Coital failure or infrequency, 5%
- Cervical mucus defects or dysfunction, 3%
- Uterine abnormalities (e.g., fibroids), rare as a true cause
- Genital tuberculosis, rare in developed countries
- General debilitating illnesses, rare

Risk factors for tubal damage have been shown to be excellent predictors of tubal factor infertility. A history of sexually transmitted diseases (STDs), pelvic inflammatory disease, pelvic surgery, ruptured appendix, septic abortion, endometriosis, and ectopic pregnancy can point to a heightened risk of tubal factor infertility. A history of uterine leiomyoma or uterine and cervical surgery also may impact fertility. Abdominal and pelvic exams can identify pelvic masses, cul-de-sac nodularity, irregular uterine contour, and fixed pelvic structures that are suggestive of tubal damage or peritoneal disease.

The history from the male partner is crucial, as sperm abnormalities account for 30% to 40% of infertility. STDs and other genitourinary infections, chemotherapy or radiation therapy, mumps during adolescence, testicular surgery or injury, and decreased ejaculatory function may herald male factor infertility. Chronic occupational exposure to extreme heat may alter sperm motility, while exposure to gametotoxic chemicals, such as nematocide dibromochloropropane, may affect sperm production. Several medications, including sulfasalazine; ketoconazole; alkylating agents such as cyclophosphamide and chlorambucil; and antiandrogens such as flutamide, cimetidine, cyproterone acetate, and spironolactone, are associated with decreased sperm production. Similarly, use of anabolic steroids for athletic performance can lead to decreased spermatogenesis. Cystic fibrosis (CF) is associated with bilateral absence of the vas deferens. An examination of the male partner, either by the obstetrician–gynecologist or an andrologist, is critical. Abnormal body habitus, lack of testicular descent, penile abnormalities, diminished size or abnormal consistency of the testes, and the presence of a varicocele may help to explain infertility.

Medical and family histories from both partners are important to identify factors that may complicate pregnancy. Preconceptual counseling typically is recommended for women with a history of diabetes, hypertension, obesity, heart disease, autoimmune diseases, thrombophilias, severe pulmonary disease, breast or gynecologic cancer, and infectious diseases such as HIV and hepatitis. Medications associated with fetal malformations, such as isotretinoin for severe cystic acne, should be discontinued. Carrier screening can be offered for inherited disorders such as CF, Tay–Sachs, thalassemia, and sickle cell anemia, based on the risk profile for each couple. A family history of genetic disorders such as fragile X and Down syndrome (trisomy 21) may indicate a need for genetic counseling. The American College of Obstetricians and Gynecologists (ACOG) now recommends offering all women prenatal diagnosis such as chorionic villus sampling or amniocentesis, and these optional tests may be discussed with women who are seeking fertility treatment. The availability of these tests should be emphasized to women over the age of 35, as they are at increased risk for conceiving a child with aneuploidy. The ACOG Technical Bulletin on preconceptional care is a valuable tool for all providers in their evaluation of couples with infertility.

The social and lifestyle history also is very important for the infertile couple. Smoking, alcohol abuse, and illicit drug use may have an adverse impact on the fertility of men and women. Smoking is particularly harmful, as it is associated with oocyte toxicity and an earlier age of menopause in women and decreased sperm motility and number in men. Excessive exercise and anorexia may adversely affect ovulation or sperm production. Exposure to potential teratogens such as lead should be excluded by the history. Although dietary alterations usually do not benefit the infertile couple, it is critical for women to begin taking at least 400 mcg of folic acid prior to conception, with many experts recommending doses up to 5 mg daily to optimally reduce the risk of neural tube defects. While moderate alcohol ingestion does not decrease fertility, women should avoid alcohol intake once they conceive. As victims of sexual and physical abuse may be markedly affected by the infertility testing and treatment required for infertility, it is important to identify these potential emotional barriers prior to the evaluation. Finally, infertility is remarkably stressful and can lead to social dysfunction or even dissolution of the couple's relationship. One of the key members of any infertility team is the counselor or psychologist who is experienced in helping couples deal with the stress. Appropriate referrals to this individual will be discussed in the Treatment section of this chapter, but it is selectively appropriate to involve this member of team from the start of the evaluation.

A thorough physical examination should be performed on both partners. Examination of the woman should

---

include a complete physical exam to assess medical conditions that may affect fertility and her health during pregnancy. A bimanual exam can identify the presence of uterine enlargement, limited uterine mobility, adnexal masses, or tenderness of the pelvic organs. A speculum exam and gonorrhea and *Chlamydia* cultures should be performed as appropriate. Examination of the male should be performed by a physician who is experienced in male factor infertility. This examination should include a complete physical exam with assessment of penile anatomy and testicular size and careful inspection of the abdomen, inguinal region, and genitalia for surgical scars or signs of trauma. The vas deferens and epididymis should be examined for evidence of obstruction, such as epididymal induration or fullness.

Evaluation: Testing

The amount of testing for most medical conditions has increased markedly over the past decade. By contrast, as our understanding of the mechanisms of infertility increases, the testing has simplified. Some traditional tests have been eliminated, as they have been shown not alter treatment decisions. The basic evaluation now includes only three tests—semen analysis, ovulation documentation, and uterine/tubal evaluation—that can be completed in 1 to 2 months. Although additional testing may be indicated in selected couples, once the cause of infertility is identified, the most cost-effective treatment can be undertaken. This lessens the couple's stress and minimizes the cost. Studies indicate that reproductive endocrinology and infertility subspecialists have minimized their infertility evaluation and “targeted” their evaluation. This section will examine the basic evaluation, the indications for expanded evaluation, and the justification for eliminating

many of the previous tests.

The semen analysis remains the primary evaluation of the male partner. This test clearly identifies subfertile men. The World Health Organization criteria in Table 40.2 are well established and were republished in 1999. The use of Kruger's strict morphology has been associated as an improved predictor of sperm function during in vitro fertilization (IVF) cycles and is now routinely used in many centers. Some centers employ a computer-assisted semen analysis (CASA). It is important that the laboratory is experienced in the assessment of semen, but the basic analysis is satisfactory for clinical care. If the initial semen analysis is abnormal, it is important to be certain that the specimen was adequately collected, without undue stress, not exposed extremes of temperature, and not contaminated by lubricants or soaps and that there has not been a severe illness within the past 3 months that might adversely impact sperm production. A repeat semen analysis is typically obtained to confirm an abnormal semen analysis. Although it is ideal to wait 90 to 108 days to evaluate recent production of sperm, this delay in the evaluation is not generally recommended, and collection within a month is acceptable.

TABLE 40.2 Semen Analysis: Minimal Standards of World Health Organization Criteria for Normal Semen Values

Parameter	*Values*
Ejaculate volume	≥2.0 mL
pH	7.2–7.8
Sperm density	≥20 million/mL
Total sperm count	≥40 million
Motility	≥50%
3 and 4 + forward progression	≥25%
Morphology	>30% normal forms
No significant sperm agglutination	

No significant pyospermia

No hyperviscosity

Although normal ovulation usually is assumed in women with regular menses and premenstrual moliminal symptoms, ovulation should be objectively confirmed. Only a single documented ovulation is required; there is no demonstrated value and significant frustration associated with months of repeat ovulation testing. There are three methods to evaluate ovulation. The classic method is a basal body temperature (BBT) chart. This method has a low cost, is fairly reliable, and documents the timing of ovulation. The daily BBT is obtained throughout the menstrual cycle, and the temperature should be taken first thing in the morning at the same time each day. Most women will have a temperature drop at the time ovulation, followed by a sustained temperature elevation of at least 0.4°F that coincides with the luteal phase of the menstrual cycle. It is important for the provider to evaluate this chart with the couple, as it often is difficult for them to interpret. A simpler but more costly method is the luteinizing hormone (LH) or ovulation predictor kit. Unlike the BBT chart, this method identifies the time of ovulation by identifying the LH surge 24 to 36 hours prior to release of the oocyte. This may be of value to patients whose lifestyles limit midcycle coitus. Finally, a midluteal (days 18 to 24) serum progesterone of >3 ng/mL indicates that ovulation has occurred. Although the timing of ovulation and the length of the follicular and luteal phases are not identified, this simple test unequivocally documents ovulation. Serial ultrasounds, cervical mucus examination, and endometrial biopsy also can suggest or confirm ovulation, although these tests are less frequently used because of reliability, discomfort, and cost.

For women over the age of 30, testing for decreased ovarian reserve should be added to the assessment of ovulation. The effect of advancing maternal age on fertility will be fully discussed later in the chapter, but there is no doubt that fertility begins to decrease in the mid-30s. Although the method of testing may change as our understanding of the menopausal transition increases, the classic test is a day 3 follicle-stimulating hormone (FSH) level. A normal value

for a day 3 FSH varies between laboratories, with current assays identifying decreased ovarian function with a level >10 to 15 IU/L. Although pregnancy can occur with elevated day 3 FSH levels, the chance of pregnancy is markedly reduced. Alternatively, a normal day 3 FSH should not falsely reassure women of the success of infertility treatment. This test primarily measures the number of oocytes remaining (i.e., ovarian reserve), not oocyte quality. The chance of pregnancy in the late 30s and 40s is reduced, compared with younger women, even with a normal day 3 FSH level.

Other forms of ovarian reserve testing such as the clomiphene citrate challenge test and antral follicle counts are used by some infertility specialists. The clomiphene challenge test involves measuring a day 3 FSH and estradiol level, followed by 100 mg per day of clomiphene citrate on cycle days 5 to 9 and a day 10 FSH. The clomiphene challenge test

may be a better predictor of decreased ovarian reserve for older women and those with unexplained infertility. An antral follicle count utilizes a high-resolution transvaginal ultrasound on day 3 of the menstrual cycle to count the number of follicles measuring between 2 and 10 mm in diameter. A count of <3 to 6 is associated with a poorer prognosis; however, considerable cycle-to-cycle variation exists within individuals and thus a single value should be interpreted with caution.

Following the semen analysis and ovulation monitoring, the basic investigation is completed by an evaluation of the uterus and fallopian tubes. There are several options for testing, but the primary method is the hysterosalpingogram (HSG). This test is mildly uncomfortable and has a 1.4% to 3.4% risk of postprocedure infection. However, it has the benefit of visualization of both the uterine cavity and the fallopian tubes. The test is performed in the early to midfollicular phase to avoid the altered tubal function following ovulation and to prevent potential radiation exposure to an early pregnancy. Slow introduction of dye into the cervical canal below the internal os by someone skilled in the technique allows the best visualization of the uterine cavity with minimal discomfort. If any abnormality of tubal architecture is identified, antibiotics, usually doxycycline 100 mg twice a day for 5 days, are typically advised. Oil-based dye has been associated with increased pregnancy rates for a few months following the HSG, but its persistence in obstructed tubes is problematic. Water-based dye can be used initially to assure tubal patency, followed by injection of oil-based dye as a therapeutic measure. If tubal patency does not need to be assessed, the woman can undergo uterine evaluation by using ultrasound with saline injection sonohysterography or office hysteroscopy. For women with known or strongly suspected tubal damage, moving promptly to operative laparoscopy and diagnostic hysteroscopy avoids the need for the HSG. Following the basic workup, the couple will benefit from consultation with the provider. If additional testing is necessary, this evaluation and potential treatment options can be discussed with the couple. If the infertility remains unexplained, the provider may advise moving directly to treatment. In the past, all couples underwent additional male factor testing, postcoital testing, timed endometrial biopsies, and laparoscopy/hysteroscopy before the infertility evaluation was considered complete. Although this additional testing may still be advised in selected cases, most couples benefit from rapid completion of testing and prompt initiation of effective therapy. The value of advanced testing for selected patients will be considered, but the basic workup is adequate to determine effective treatment options for most couples. Figure 40.1 demonstrates the basic infertility workup followed by more advanced evaluation.

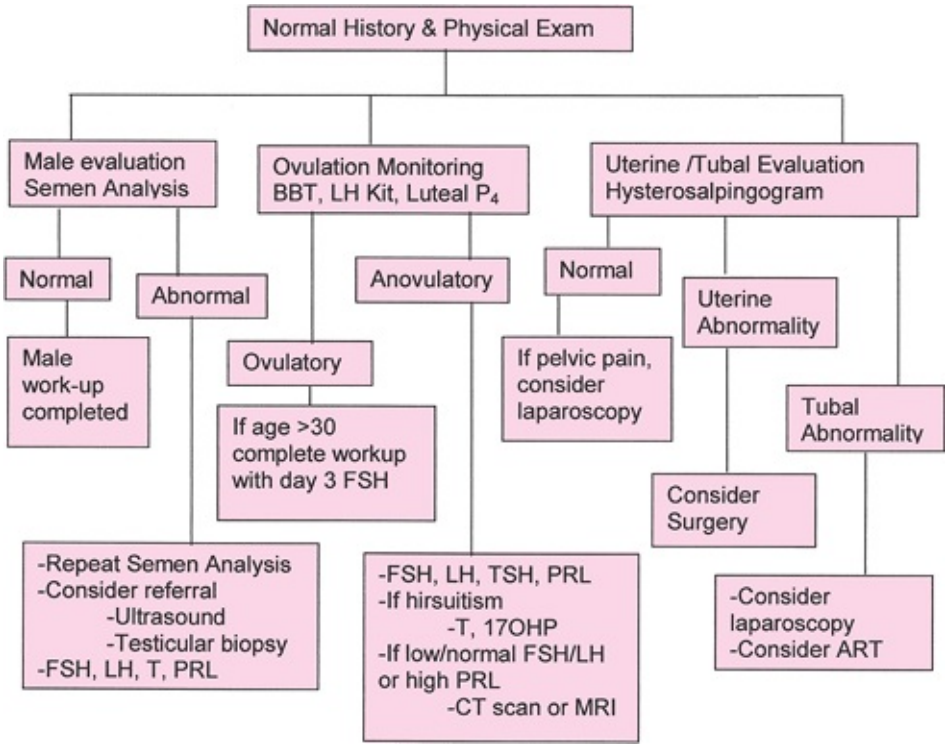

Figure 40.1 Basic workup for a couple with infertility. (BBT, basal body temperature; LH, luteinizing hormone; FSH, follicle-stimulating hormone; T, testosterone; PRL, prolactin; 17-OHP, 7-hydroxyprogesterone; CT, computed tomography; MRI, magnetic resonance imaging; ART, assisted reproductive technology.)

Evaluation: Advanced

Male Factor

If an abnormal semen analysis is identified, further workup may be indicated prior to moving on to treatment. If a history and physical exam have not yet been done, this may identify the cause of the abnormal test. Treatment of a varicocele via surgical ligation increases sperm motility, density, morphology, and possibly the pregnancy rate. Hormonal testing—testosterone, FSH, LH, and prolactin—is of value for identifying a hypothalamic, pituitary, testicular, or pharmacologic etiology for oligospermia or azoospermia. In general, a hormonal evaluation should be considered in all men with sperm counts <10 million/mL and/or low male libido. A fructose level and possible testicular biopsy can differentiate obstruction from testicular failure in men with azoospermia. If leukocytes are present in semen, bacterial cultures and antibiotic treatment are indicated. Unfortunately, most men with an abnormal semen analysis have idiopathic oligoasthenospermia. Although this is frustrating for the patient, very effective treatment options are available for unexplained male factor infertility.

The value of additional semen testing in men with a normal physical examination and hormonal testing prior to proceeding with therapy is controversial. Abnormalities in

seminal fluid have also been evaluated by antisperm antibody testing. The presence of antisperm antibodies may be assessed in men who are status postvasectomy reversal, in men with isolated asthenospermia despite normal sperm concentration, and when significant sperm agglutination is present. Some clinicians also routinely obtain antisperm antibodies for couples with unexplained infertility; however, the value of this test remains unproven. Antisperm antibodies are not necessary if intracytoplasmic sperm injection (ICSI) is planned.

The value of sperm function testing is controversial. Many assays have been developed in an attempt to evaluate sperm function, including hypoosmotic swelling, viability staining, sperm capacitation, and sperm penetration assays. Unfortunately, these tests have limited prognostic value and cannot consistently predict the effectiveness of selected treatments and currently are limited to experimental use.

Inherited and other medical problems can adversely affect fertility. Retrograde ejaculation can occur with diabetes and certain neurologic disorders and after pelvic surgery. The presence of sperm in the bladder can be determined by microscopic examination of a postejaculation urine sample and should be done if the volume of ejaculate is <1 mL. Most men with congenital bilateral absence of the vas deferens have a variant of CF, and these men should be screened for the common CF mutations. Genetic screening with karyotype and polymerase chain reaction (PCR) analysis of the Y chromosome should be offered to all men with nonobstructive severe oligospermia and azoospermia. Between 10% and 15% of men with azoospermia or severe oligospermia will have evidence of microdeletions on the Y chromosome. If microdeletions associated with oligospermia are present on the Y chromosome, it is important to inform men of the probability that this inherited condition will be passed on to male children. Klinefelter syndrome (46XXY) also can result in azoospermia and is diagnosed via karyotype.

Ovulation Dysfunction

Women with oligomenorrhea and amenorrhea should be evaluated for a hypothalamic, pituitary, ovarian, or adrenal etiology. The history and physical examination often will point to the cause of irregular menses. There is limited value in obtaining a BBT chart or LH predictor kit for women with markedly irregular menses. The most common causes of hypothalamic amenorrhea are due to weight loss (eating disorders) and excessive exercise. Rarely, Kallmann syndrome and hypothalamic lesions may be present. Pituitary etiologies include hyperprolactinemia, thyroid disease, Cushing disease, and Sheehan syndrome. Women with significant hyperprolactinemia or unexplained hypogonadotropic hypogonadism should undergo a computed tomography (CT) scan or magnetic resonance imaging (MRI) to determine if a hypothalamic lesion or pituitary adenoma is present. Ovarian dysfunction is most commonly due to anovulation with polycystic ovarian syndrome (PCOS) accounting for the majority of cases. PCOS is diagnosed with the presence of two of the three following criteria: (a) chronic anovulation or oligo-ovulation, (b) biochemical or clinical evidence of androgen excess, and (c) presence of polycystic ovaries on ultrasound. A less common etiology of ovulatory dysfunction is premature ovarian failure (POF), although decreased ovarian function occurs many years before menopause.

The classic laboratory testing for women with oligomenorrhea is a fasting prolactin, thyroid-stimulating hormone (TSH), and FSH. Women with hirsutism or acne should also have testosterone and 17-hydroxyprogesterone levels drawn to rule out ovarian neoplasm or late-onset adrenal hyperplasia. Women with suspected PCOS are known to be at increased risk for hyperlipidemia, insulin resistance, and adult-onset diabetes (type II); a lipid profile and fasting glucose are therefore recommended in these patients. The classic progestin challenge test, 10 mg of medroxyprogesterone acetate for 10 days, may be of some value, as women with hypoestrogenism typically will not have withdrawal bleeding due to progestins. Chapters 36 and 39 further discuss the evaluation of women with ovulatory dysfunction.

The use of the timed, luteal phase endometrial biopsy to assess for a minor ovulatory disturbance is no longer useful in clinical practice. Luteal phase defects appear to be a rare cause of infertility, and there are no reliable laboratory tests that can confirm this diagnosis. Additionally, the medications used for the treatment of unexplained infertility are

---

also used to correct luteal phase defects, making a precise diagnosis less critical. Women with a markedly shortened luteal phase by a BBT chart and normal hormonal workup may be treated empirically with medication such as progesterone, clomiphene citrate, or gonadotropins for correction of a presumed luteal phase defect.

Uterine/Tubal Factor

Women with a history of tubal disease or significant risk factors for pelvic adhesions, such as extensive pelvic surgery, a ruptured appendix, or pelvic inflammatory disease, may elect to avoid the HSG and proceed directly to laparoscopic surgery. Alternatively, these patients may elect to proceed with IVF.

The use of routine diagnostic laparoscopy following a normal HSG is not advised as a standard approach for tubal factor. Extensive peritubal adhesions in women with a negative history and normal HSG are rare. Endometriosis is the most common finding at laparoscopy for women with otherwise unexplained infertility. The effect of severe endometriosis on fertility is not questioned, but the link between mild to moderate endometriosis and infertility remains an enigma. Research does suggest decreased fertility in women with endometriosis who are undergoing donor insemination. One study demonstrated an increase in fertility following laparoscopic laser ablation of mild endometriosis, but the value of surgical therapy remains controversial. Women with debilitating pain related to possible endometriosis, such as dysmenorrhea and dyspareunia, may benefit from laparoscopic treatment.

In the past, evaluation of cervical mucus was a routine part of the evaluation for infertility. Although women with a history of cervical surgery such as conization or loop electroexcision may benefit from treatment that bypasses the cervix, the postcoital test was shown to have limited predictive value for future fertility.

The evaluation for infertility is now simplified in couples with negative histories and normal physical examinations. Although hormonal testing may be indicated for both men

and women and laparoscopy or hysteroscopy has a role in the evaluation of selected women, the basic workup should be limited to semen analysis, documenting ovulation, and uterine/tubal evaluation. The value of advanced male testing, endometrial biopsy, and postcoital test is limited. Until research can confirm that these tests have predictive value, they can be removed from the basic infertility evaluation.

Treatment

Once the cause of infertility is determined to the extent possible by current techniques, the health care provider can advise the couple regarding the most cost-effective treatment choices. Advances in infertility treatment offer virtually all couples a reasonable opportunity for pregnancy. It is critical for the provider to recognize the stress of infertility therapy and to actively involve a counselor or psychologist in the care of couples with infertility. There are limited data that suggest increased pregnancy rates with stress reduction, but the primary benefit is to maintain the well-being of infertile couples. RESOLVE, the national support organization for couples with infertility, is an excellent source of information and support for infertile men and women. As well, it is important for providers to encourage and support a couple's decision to pursue adoption or remain childfree. The remainder of this section highlights the treatment options for the male factor, ovulatory dysfunction, the uterine/tubal factor, unexplained infertility, and advanced maternal and paternal age.

Male Factor

The basic treatments for male factor infertility have improved over the past decade. Although donor sperm remains a viable option for many couples, intrauterine insemination (IUI) and IVF with ICSI now offer excellent opportunities for many couples. Surgery is the primary treatment for obstructive azoospermia secondary to previous vasectomy or injury. Additionally, surgical ligation of a varicocele improves sperm parameters and is a viable treatment option for selected men. Medical therapy for male factor infertility, with the exception of treatment for hypothalamic hypogonadism, has not been shown to be effective.

When there is a relatively mild oligoasthenospermia, IUI with the male partner's sperm offers a reasonable chance for pregnancy. Whole semen cannot be used for IUI due to the reactions to the prostaglandins and bacteria in the semen. IUI uses sperm washed in culture medium, often using a “swim-up” procedure to isolate motile sperm. A washed sample of at least 10 million motile sperm is necessary for this treatment to be effective. IUI often is combined with ovarian stimulation with timed ovulation, although the IUI also can be timed by using an ovulation predictor kit.

With more severe oligoasthenospermia or as a primary treatment for less severe male factor infertility, IVF offers the highest per cycle fecundity of any therapy. ICSI has increased the ability of sperm to fertilize oocytes in vitro, even with very low numbers of motile sperm. ICSI typically is recommended with severe oligospermia (<2 to 10 sperm/mL), severe asthenospermia (<5% to 10% motile sperm), or poor morphology (<4% normal forms by strict criteria). Fertilization rates are about 70%, similar to those seen with traditional

IVF procedures. Microsurgical epididymal sperm aspiration (MESA) or percutaneous epididymal sperm aspiration (PESA) obtain epididymal sperm for the treatment of obstructive azoospermia. Cases such as failed vasectomy reversal, postinflammatory obstruction, and congenital obstruction can be treated with MESA or PESA. MESA achieves better pregnancy rates than

---

PESA but requires microsurgical expertise and is associated with increased cost and greater postoperative discomfort. Testicular sperm extraction (TESE) can be used to obtain sperm with nonobstructive or severe obstructive azoospermia. Even men with the so-called Sertoli-cell-only syndrome (up to 40%) have successful sperm retrieval with TESE. It is important to cryopreserve excess retrieved spermatozoa to avoid unnecessary subsequent sperm-retrieval procedures. These procedures can also be performed prior to oocyte retrieval, which minimizes the logistic difficulties of coordinating the two procedures.

Concerns about the risks associated with IVF utilizing ICSI continue to be raised. The most comprehensive study to date demonstrates a modest increase in congenital anomalies in children born by ICSI as compared with standard IVF. However, the overall risk of major anomalies is low (4.2%). The prevalence of sex chromosome abnormalities also is higher in children conceived via ICSI (0.8% to 1.0%) compared with those observed in the IVF population (0.2%). It is not clear whether this increase in chromosomal abnormalities results from the ICSI procedure itself or if it reflects a direct effect of male factor infertility. Certainly, when a Y chromosome microdeletion is present, this defect will be passed on to any male offspring. IVF and IVF/ICSI also may be associated with a two- to threefold increased risk of rare imprinting disorders, such as Angelman syndrome and Beckwith-Wiedemann syndrome. Again, it is not clear if the increased incidence of these disorders is linked to the disorder or to the treatment of infertility. Fortunately, the overall prevalence of these disorders is quite low. There does not appear to be an increased risk of autosomal chromosomal structural defects associated with ICSI.

Ovulatory Dysfunction

Excellent treatment options are available for all causes of amenorrhea and anovulation. The ACOG Practice Bulletin on the management of infertility caused by ovulation dysfunction offers a well-written overview of these therapies. Hypothalamic hypogonadism due to weight loss or excessive exercise may be treated by a change in lifestyle, although this does not always result in correction of menstrual cyclicity. Ovulation can be accomplished with injectable gonadotropins in women with hypogonadotropic hypogonadism. A wide range of injectable human gonadotropins are now available, including human menopausal gonadotropins, purified urinary FSH, and recombinant FSH, which can be given intramuscularly or subcutaneously. The use of any of these products requires close monitoring, including ultrasound and estradiol levels, to minimize the risk of multiple gestation and the ovarian hyperstimulation syndrome. Human chorionic gonadotropin (hCG) is typically given when the dominant follicle diameter reaches 18 mm to mimic the LH surge and trigger ovulation. The risk of these medications will be further discussed in the section on Unexplained Infertility.

Women with hyperprolactinemia can be treated with dopamine-agonist therapy. Bromocriptine mesylate and cabergoline are oral agents that lower prolactin levels and routinely restore ovulation. Side effects, including headache, nausea, orthostatic hypotension, and dizziness, can be severe. Starting with a low dose and a slow, steady increase in the medication will minimize side effects. Bromocriptine can be started with half a tablet, 1.25 mg, at bedtime, increasing the dose weekly, if required to normalize prolactin levels, to a maximum of 2.5 mg twice daily. Cabergoline is taken only once or twice weekly at doses of 0.5 to 3.0 mg per week. Side effects are reported to be lower with cabergoline, although it is still important to gradually increase the dose of the medication. Once women achieve pregnancy, the dopamine agonist should be stopped, although there are no reports of harmful effects on the fetus when they are continued during pregnancy. There is no restriction to breast-feeding in women with hyperprolactinemia, assuming there is no worsening of symptoms after pregnancy.

Our understanding of the etiology of PCOS has undergone a rapid expansion over the past decade. The methods of inducing ovulation have expanded, although the standard treatments remain similar. Data from several small studies suggest that losing 5% to 10% of body weight can restore spontaneous ovulation in obese women with PCOS. Although long periods of time cannot be spent on unsuccessful attempts at weight loss, it is reasonable to start with this treatment option for obese women with PCOS. For slender women with PCOS or those who are unsuccessful with weight loss, many other options are available. The classic medication is clomiphene citrate. The usual dose starts with 50 mg, or one tablet, daily on cycle days 5 to 9 following spontaneous or progestin-induced menses. Ovulation should be confirmed by using BBT charts, ultrasound, or luteal progesterone levels. The maximal dose typically is 150 mg per day for 5 days, although higher doses (to 250 mg) for a longer period (to 8 days) have been utilized. In general, the higher the dose required for ovulation, the lower the pregnancy rate. Adding 0.5 mg of dexamethasone to clomiphene may increase the response in women with high adrenal androgen levels. Eight-five percent of women with PCOS will ovulate after taking clomiphene citrate. Side effects include hot flashes, headache, visual changes, breast tenderness, and bloating. Serious side effects are rare. A 10% chance of twins is the greatest risk, and the risk of higher-order multiple gestations is <1%. It is important for women to realize that not all women conceive, despite ovulating, with clomiphene citrate.

Three additional options for women with PCOS include surgical treatment, injectable human gonadotropins, and insulin-sensitizing agents. The classic ovarian wedge resection for the treatment of PCOS fell into disrepute due to a high incidence of postoperative adhesions. Laparoscopic cautery, diathermy, and laser treatment have been used in an attempt to induce spontaneous ovulation. The theory is

---

that a reduction in the androgen-producing ovarian cortex by the surgical destruction will allow ovulation to occur. Ten to 15 sites on each ovary are cauterized, and 70% to 80% of women ovulate following surgery. A significant advantage to this procedure is a decrease in the risk of multiple gestations. However, there are risks to ovarian diathermy, including increased adnexal adhesions and diminished ovarian reserve associated with ovarian destruction. This treatment is thus best reserved for the clomiphene-resistant patient.

Injectable gonadotropins effectively induce ovulation in women with PCOS. There is a need for close monitoring in order to minimize the risk of multiple gestation and ovarian hyperstimulation, which is greatest for women with PCOS. For women who do not ovulate with clomiphene, injectable gonadotropins usually are successful at inducing ovulation.

It is clear that women with PCOS are at increased risk for adult-onset diabetes and often have elevated fasting insulin levels despite a normal fasting glucose. Studies suggest that a large percentage of women with PCOS are insulin resistant and the use of insulin-sensitizing medications, such as metformin, will restore ovulatory menstrual cycles in a significant number of these women. However, recent evidence demonstrates that clomiphene is far superior to metformin with respect to achieving pregnancy, despite similar ovulation rates. Obese women with PCOS appear to benefit modestly from the combination of metformin and clomiphene when compared with clomiphene alone. Gastrointestinal side effects with metformin are common, and the safety of metformin in pregnancy has not been established. Future research on the use insulin-sensitizing agents to control obesity, hirsutism, and anovulation in women with PCOS will be of great interest to patients and providers alike.

Limited treatment options are available for women with POF. Women with hypergonadotropic hypogonadism secondary to a chromosomal abnormality, chemotherapy or radiation therapy, autoimmune disorder, or idiopathic loss of ovarian function do not respond to gonadotropins, as there typically are no functional follicles remaining. A spontaneous pregnancy rate of up to 20% is reported in women with idiopathic POF who are not on hormonal treatment; however, there are no studies demonstrating a benefit of ovulation induction in these women. Pharmacologic treatment with estrogen has been observed to lower elevated FSH levels in women with POF, which may restore down-regulated FSH receptors on the follicle, but data is insufficient to suggest this as a treatment for ovulation induction. Hormone replacement to prevent osteoporosis and minimize hypoestrogenic symptoms is the standard of care. Fortunately, donor oocytes can be offered as an option for these women. The generous contribution of oocytes by a donor undergoing gonadotropin stimulation and oocyte retrieval offers women with POF an opportunity for pregnancy. The choice to pursue adoption or the decision to remain childfree should also be discussed with these couples in a nonjudgmental fashion.

Uterine/Tubal Factor

Of women with infertility, 16% will have sonographic evidence of intracavitary lesions, usually either endometrial polyps or submucosal myomas. Studies demonstrate increased pregnancy rates in women undergoing hysteroscopic polypectomy or myomectomy, indicating that these lesions should be removed prior to attempting pregnancy. Hysteroscopic surgery is also recommended for women with intrauterine adhesions, or Asherman syndrome, and for removal of a uterine septum. The benefit of abdominal surgery—laparotomy or laparoscopy—for the removal of intramural or subserosal leiomyoma is less clear. Pregnancy rates appear to be lower in women with myomas >4 cm; however, myomectomy has not been shown to improve pregnancy rates in this population. This surgery also increases the risk of peritubal and periovarian adhesions and has a 30%

risk of recurrence that increases with time. Thus, routine removal of intramural or subserosal myomas prior to fertility treatment is not recommended.

The treatment of known tubal factor infertility depends on the severity of the disease. Proximal tubal blockage can be treated hysteroscopically, radiographically, or by microsurgical reanastomosis. A meta-analysis documented an intrauterine pregnancy rate of 50% in women undergoing surgery for proximal tubal blockage, with the highest success rates achieved with selective salpingography and transcervical cannulation. Laparoscopic removal of thin, avascular adhesions involving the tube and ovaries offers a reasonable chance for pregnancy, with a success rate up to 70% but with an ectopic pregnancy rate of 20%.

Women with significant symptoms, such as pelvic pain, secondary to adhesions or endometriosis, also benefit from laparoscopic surgery. However, removal of severe tubal adhesions and treatment of hydrosalpinges by neosalpingostomy offers a very limited benefit to future fertility. The per-cycle fecundity following extensive tubal surgery is only 2% to 4%. Repair of bilateral tubal damage—proximal and distal tubal adhesions—has the lowest chance of an intrauterine pregnancy and is not recommended. The success of IVF suggests this is a much superior treatment for women with severe tubal factor infertility. IVF offers a reasonable chance for pregnancy, lowers the risk of ectopic pregnancy, and avoids the prolonged delay required to determine the success of treatment. Studies suggest an increased pregnancy rate if large hydrosalpinges are either laparoscopically removed or clipped in the corneal region prior to IVF. Thus, tubal surgery, with removal or occlusion of the damaged fallopian tubes prior to IVF, increases the chance for successful infertility treatment.

Unexplained Infertility

Unexplained infertility is diagnosed in 15% to 25% of infertile couples. The failure to identify a specific etiology often

---

leads to significant distress, as the cause of infertility remains unknown. The good news is that treatment options for these couples allow a significant chance for pregnancy. For a young couple, one option may be no therapy. Approximately one half of couples who do not conceive in 1 year will do so within 2 years; up to 70% to 80% will conceive in 5 years. The primary benefit of treating unexplained infertility is to shorten the time to conception, a treatment of particular interest to couples in which the woman is >30 years old.

The three primary treatment options are clomiphene with IUI, injectable gonadotropins with IUI, and IVF. The benefit of IUI alone is so modest that it should not be used as a primary treatment for unexplained infertility. Adding clomiphene citrate to the IUI, 50 to 100 mg daily on cycle days 5 to 9, increases the per-cycle fecundity to 6% to 8% per cycle. However, this pregnancy rate declines by half in women 35 years and older with unexplained infertility and is probably no different from the natural cycle fecundity in this population. Thus, clomiphene and IUI should be reserved as a treatment for unexplained infertility only in women <35 years old. A large group study demonstrated a two- to threefold increase in pregnancy rate when controlled ovarian hyperstimulation occurred

with gonadotropin and IUI compared with insemination alone. Studies have reported a per-cycle fecundity rate of 10% to 18% with injectable gonadotropins and IUI; meta-analysis reports a 33% pregnancy rate with three cycles of gonadotropins and IUI. The pregnancy rate is increased with injectable gonadotropins alone, but the chance for pregnancy is doubled with the addition of an IUI.

The highest per-cycle fecundity is accomplished with IVF. The 2005 data collected by the Society for Assisted Reproductive Technology reported a delivery rate per retrieval of 37% per IVF cycle for women <35 years old. This success rate declines predictably with age and was only 10.5% for women 41 to 42 years old. Gamete interfallopian transfer (GIFT) and zygote intrafallopian transfer (ZIFT) also offer an excellent per-cycle fecundity of 27.4% and 29.6%; however, the cost and invasive nature of these procedures has limited their use. The widespread availability, simplicity, and cost-effectiveness of IVF has largely replaced these procedures. IVF, compared with clomiphene citrate or gonadotropin use, requires the greatest commitment of time, effort, and financial resources. But as is the case for couples with male factor or tubal factor infertility, IVF provides the highest per-cycle fecundity for couples with unexplained infertility.

Women with endometriosis are often placed in the unexplained infertility category. Debate continues regarding the effect of mild endometriosis on fertility. Laparoscopy can be bypassed if a woman is asymptomatic and has completed the evaluation, therefore allowing the couple to move on to treatment for unexplained infertility. If laparoscopy is elected and mild endometriosis is identified and removed, the treatment options are the same. As with unexplained infertility, the young couple with treated endometriosis may elect to have no infertility therapy. For women with known endometriosis, studies suggest an improved pregnancy outcome when using a gonadotropin-releasing hormone agonist for 3 to 6 months prior to proceeding with IVF.

Advanced Maternal Age

The age of first pregnancy has increased over the past several decades. In 1975, <20% of women attempted their first pregnancy between the ages of 35 to 39; in 1995, 44% of first pregnancies were attempted among this age group.

The Hutterites study published in the 1950s demonstrated the effect of age on fertility. In this population, the overall rate of infertility was 2.4%. After age 34, it rose to 11%; after age 40 to 33%; and after age 45 to 87%. The average woman did not conceive after age 40. Donor insemination studies in the United States and France confirm this age-related decline in fertility. Cycle fecundity clearly decreases with advancing age, likely beginning in the late 20s. The risk of infertility increases at least 10 to 15 years prior to menopause, as does the risk of spontaneous abortion and chromosomal anomalies of ongoing pregnancies. Unfortunately, many women expect normal fertility until shortly before menopause and are surprised by the realization that “natural infertility” begins many years before their last menstrual period.

Advanced Paternal Age

There has been recent attention from the medical community regarding the effect of paternal age on fertility. Studies demonstrate that males >35 years old are twice as likely to be infertile as men <25 years old. Among couples undergoing infertility treatments, the time necessary to achieve pregnancy increases significantly as men age, even when controlling for maternal age. There also have been reports of an association between advancing paternal age and disorders such as autism spectrum disorder and schizophrenia. Testosterone levels are known to decrease as men age at a rate of about 1% per year after the age of 30, although the effect of this on fertility, if any, is unknown. Finally, erectile dysfunction is associated with age-related biologic changes and can significantly impact a couple's chances of achieving pregnancy. Fortunately, medications such as sildenafil and tadalafil are available to overcome this problem.

What can health care providers do to prevent the issue of infertility from affecting their patients? Discussing the effect of aging on natural fertility with all patients during their reproductive years will provide useful information with which to make personal decisions. Although many women and couples do not pursue pregnancy until their lifestyle allows them to support and care for a child, awareness of age-related fertility decline is of great value. An active decision to remain childfree is better for women than

---

an unexpected outcome due to simply delaying conception based on misinformation. Once a woman of advanced maternal age decides to pursue pregnancy, information about the timing of intercourse during the cycle is of value. If history or exam suggests a potential cause of infertility (e.g., irregular menses or history of STD), the workup can begin immediately. The new basic workup can be accomplished in 1 to 2 months, allowing rapid diagnosis of the cause of infertility once a couple does not conceive within a year or earlier if the woman is over 35. Providing patients with information and rapid evaluation and treatment maximizes the chance that they will achieve their desired family.

It is now easier and faster for couples to determine the cause of infertility. The limited basic workup includes a semen analysis, ovulation monitoring, and uterine/tubal evaluation. For women >30 years old, a day 3 FSH or clomiphene challenge test is recommended to screen for decreased ovarian reserve. For selected couples, further male factor evaluation, hormonal testing, and laparoscopy can be considered. Treatment options for infertility now offer a variety of highly successful options for male factor infertility, ovulation dysfunction, uterine/tubal factor, and unexplained infertility.

Summary Points

- Infertility is a common problem in the United States, occurring in approximately 10% to 15% of couples.
- The basic workup for infertility should begin 1 year after discontinuance of contraception. The workup includes a semen analysis, documentation of ovulation, and uterine/tubal evaluation with an HSG.
- A thorough history and physical examination of both the man and woman may identify the etiology of infertility and direct further

testing to the most likely cause of infertility.
- Treatment for male factor infertility includes donor insemination, surgery, IUI, and IVF/ICSI.
- Treatment of hypothalamic dysfunction involves injectable gonadotropins. Hyperprolactinemia is treated successfully with dopamine agonists. PCOS can be treated with clomiphene citrate, surgery, injectable gonadotropins, and insulin-sensitizing medications. POF can be treated with donor oocytes.
- Uterine and tubal factor infertility may be treated surgically. Severe tubal factor infertility is most successfully treated with IVF.
- Unexplained infertility can be treated with clomiphene citrate/IUI, injectable gonadotropin/IUI, or IVF.
- Women with advanced maternal age are best served by rapid workup and treatment.

Endometriosis

Robert S. Schenken

Endometriosis is defined as the presence of endometrial glands and stroma outside the endometrial cavity and uterine musculature. The pelvis is the most common site of endometriosis, but endometriotic implants may occur nearly anywhere in the body. Although there are numerous theories to explain why women develop endometriosis, no one theory has been proven conclusively. Endometriosis is a common gynecologic problem in reproductive-age women who have pelvic pain, dyspareunia, or infertility. The management of endometriosis is controversial, but randomized clinical studies have substantiated some therapeutic approaches.

Pathogenesis

Several theories have been proposed to explain the histogenesis of endometriosis. The implantation theory proposes that endometrial tissue desquamated during menstruation passes through the fallopian tubes, where it gains access to and implants on pelvic structures. The incidence of retrograde menstruation is similar in women with and without endometriosis. Thus, the development of endometriosis could depend on the quantity of endometrial tissue reaching the peritoneal cavity, specific factors enhancing attachment of endometrial cells to the peritoneum and ovary, or the capacity of a woman's innate immune system to remove the refluxed menstrual debris.

The direct transplantation theory is the probable explanation for endometriosis that develops in episiotomy, cesarean section, and other scars following surgery. Endometriosis in locations outside the pelvis likely develops from dissemination of endometrial cells or tissue through lymphatic channels or blood vessels. The coelomic metaplasia theory proposes that the coelomic (peritoneal) cavity contains undifferentiated cells or cells capable of dedifferentiating into endometrial tissue. This theory is based on embryologic studies demonstrating that all pelvic organs, including the endometrium, are derived from the cells lining the coelomic cavity. The induction theory, an extension of the coelomic metaplasia theory, postulates that the refluxed endometrial debris releases a product that activates undifferentiated peritoneal cells to undergo metaplasia. There is no conclusive proof that the peritoneum can undergo spontaneous or induced metaplasia.

Anatomic alternations of the pelvis that increase tubal reflux of menstrual endometrium

increase a woman's chance of developing endometriosis. The incidence of endometriosis is increased in young women with genital tract obstructions that prevent expulsion of menses into the vagina and increase the likelihood of tubal reflux. Studies have suggested that deficient cellular immunity results in an inability to recognize the presence of endometrial tissue in abnormal locations. Decreased natural killer cell activity resulting in decreased cytotoxicity to autologous endometrium has been reported in women with endometriosis. The presence of increased concentrations of leukocytes and their cytokine products in peritoneal fluid of women with endometriosis may play a role in the initiation and growth of the ectopic implants. The immune system clearly has an important, albeit unclear, role in the pathogenesis of endometriosis. Other studies indicate that there are abnormalities of the eutopic endometrium in patients with endometriosis, including aberrant production of cytokines and growth factors. These characteristics may contribute to the establishment and maintenance of this disease.

The possibility of a familial tendency for endometriosis has been recognized for several decades. If a patient has endometriosis, a first-degree female relative has a 7% likelihood of being affected similarly. Studies are ongoing to determine the major susceptibility gene(s) involved.

Epidemiology

The true prevalence of endometriosis in the general population is unknown. Estimates of its prevalence are based on visualization of the pelvic organs. Pelvic endometriosis

is present in approximately 1% of women undergoing major surgery for all gynecologic indications, 6% to 43% of women undergoing sterilization, 12% to 32% when laparoscopy is performed to determine the cause of pelvic pain in reproductive-age women, and 21% to 48% of women undergoing laparoscopy for infertility. Endometriosis is found in 50% of teenagers undergoing laparoscopy for evaluation of chronic pelvic pain or dysmenorrhea.

The influence of age, socioeconomic status, and race on the prevalence of endometriosis remains controversial. The age at time of diagnosis is commonly 25 to 35 years, and endometriosis rarely is diagnosed in postmenopausal women. Many believe that endometriosis is more common in women of upper economic classes because they delay pregnancy, which is postulated to increase the risk of developing endometriosis. It is unknown whether this reflects a true increased incidence or results from greater access to medical care. Evidence indicates that blacks have a prevalence of endometriosis similar to that in whites when controlled for socioeconomic status.

Pathology

The most common sites of endometriosis, in decreasing order of frequency, are the ovaries, anterior and posterior cul-de-sac, posterior broad ligaments, uterosacral ligaments, uterus, fallopian tubes, sigmoid colon, appendix, and round ligaments. Other sites less commonly involved include the vagina, cervix, and rectovaginal septum. These latter lesions usually result from extension and invasion of posterior cul-de-sac implants. Uncommon locations include the inguinal canal, abdominal or perineal scars, ureters, urinary bladder, umbilicus,

kidney, lung, liver, diaphragm, vertebrae, and extremities.

Macroscopic Appearance

Endometriotic implants have a variety of appearances. Superficial lesions on the ovarian or peritoneal surface commonly are reddish maculae or nodules similar in consistency to normal endometrium. These implants vary from 1 mm to several centimeters in size. Collection of hemosiderin results in yellow-brown or black discoloration ("powder-burn" lesions). Nonpigmented disease appears as whitish opacified peritoneum, translucent blebs, or pinkish polyploid implants. Scarring with retraction of adjacent peritoneum and peritoneal pockets may occur.

Endometriosis also may appear as a deeply infiltrative disease. Tumorlike masses form from invasion, and diffuse fibrosis usually develops in the posterior cul-de-sac, pelvic sidewall, or posterior broad ligament and ovary and may extend deep into the retroperitoneal space, occasionally constricting the ureter. Lesions in the cul-de-sac may invade the rectovaginal septum. The rectosigmoid and small bowel may become adherent to these areas. Endometriotic foci on the ovarian surface may develop a fibrous enclosure and manifest cyst formation as a result of accumulation of fluid and blood. These endometriotic cysts (endometriomas) vary from several millimeters to over 10 cm in size. Bleeding with menses gives the cyst a dark red or bluish hemorrhagic color. The degradation of blood pigment over time results in thick, tarry contents, hence the term *chocolate cysts*. Occasionally, the content changes to a yellow straw color or clear fluid. Filmy or dense fibroid adhesions from these cysts to the pelvic sidewall and fallopian tubes are common and may obscure visualization of the cyst.

Microscopic Appearance

Endometriosis is histomorphologically similar to eutopic endometrium. The four major components of endometriotic implants are endometrial glands, endometrial stroma, fibrosis, and hemorrhage. The relative amount of each component is highly variable and dependent, in part, on the age and location of the lesions. Identifying the endometrial elements in individual implants requires an adequate tissue specimen, proper orientation, and often serial sections of the specimen.

The endometrial glands in ectopic implants lack uniform size and shape. The glands may show normal cyclic change with mitotic figures and pseudostratification in response to estrogen or vacuoles and intraluminal secretion in response to progesterone. The response to endogenous and exogenous hormones is inconsistent. This may imply differences in steroid hormone receptor content and function or a loss of the normal gland–stromal interaction. When glands are responsive, the epithelium becomes attenuated, and hemorrhage ensues at the time of menstruation.

The stromal cell morphologies of ectopic and eutopic endometrium are similar. Small arterioles, similar to the spiral arterioles of normal endometrium, usually are present in implants. Interstitial hemorrhage with accumulation of blood products and hemosiderin-laden macrophages is a frequent finding.

Malignant transformation of endometriosis is uncommon. In one literature review, the prevalence of endometriosis in mucinous, serous, endometrioid, and clear cell ovarian carcinoma was 1%, 5%, 19%, and 36%, respectively. However, this does not distinguish between whether the endometriosis was preexisting or dedifferentiated from cancer cells.

Fibrosis may occur in older endometriotic implants. This is very common in the lining of endometriomas, where the only histologic finding may be fibroblast proliferation and hemosiderin pigment deposition.

Symptoms

The common signs and symptoms of endometriosis are pelvic pain, dysmenorrhea, dyspareunia, abnormal uterine

---

bleeding, and infertility. The type and severity of symptoms are dependent on the extent of disease, the location, and the organs involved. Even limited amounts of disease may cause significant symptomatology.

Endometriosis is present in approximately one third of patients with chronic pelvic pain. The pain may be described as crampy, dull, or sharp and usually increases around menses. The discomfort may be unilateral or bilateral, and many patients complain of rectal pressure or low backache. Acute abdominal pain may result from hemorrhage secondary to a ruptured endometrioma.

Dysmenorrhea is a more frequent complaint than dyspareunia. There is some correlation between the extent of disease and the severity of pain. The morphologic appearance of an endometriotic implant appears to be unrelated to pain symptomatology. Dyspareunia is more common in women with invasive endometriotic nodules in the cul-de-sac, uterosacral ligaments, rectovaginal septum, and vagina.

Abnormal uterine bleeding occurs in up to one third of women with endometriosis with symptoms of oligomenorrhea, polymenorrhea, and midcycle or premenstrual spotting. The abnormal bleeding likely results from conditions associated with endometriosis: oligoanovulatory luteinized unruptured follicles, luteal phase defects, and other pathology such as uterine fibroids.

Endometriosis involving the gastrointestinal or urinary tracts and extrapelvic sites causes symptoms characteristic of the location of disease. Bladder involvement is associated with frequency and urgency. Invasion of the mucosa results in hematuria. Ureteral and rare cases of renal endometriosis occasionally cause flank pain or gross hematuria. Symptoms suggestive of gastrointestinal involvement include, in decreasing order of frequency, diarrhea, rectal bleeding, constipation, and dyschezia. All symptoms usually are exacerbated catamenially.

There are numerous case reports of extrapelvic endometriosis. Pulmonary endometriosis causes catamenial hemoptysis and dyspnea. Cutaneous lesions are associated with catamenial bleeding, tenderness, and swelling.

It is estimated that 25% to 50% of infertile women have endometriosis and that 30% to 50%

of women with endometriosis are infertile. Although the association of endometriosis and infertility is well recognized, the pathophysiologic mechanisms are poorly understood. Endometriomas and endometriosis with adhesions distort pelvic anatomy and impair tubal ovum pickup, which is an acceptable explanation for infertility. In less severe cases, there are several theories to explain the observed subfecundity (Table 41.1).

Research to explain the subfertility has focused on peritoneal fluid leukocytes and their cytokine products. Studies have suggested that constituents in the peritoneal fluid inhibit sperm function, fertilization, embryonic development, and implantation. The clinical significance of these findings has not been established.

TABLE 41.1 Proposed Mediators and Mechanisms of Infertility

Anatomic distortion and tubal obstruction
Anovulation, luteal phase defects, and hormonal abnormalities
Galactorrhea or hyperprolactinemia
Autoimmunity
Peritoneal leukocytes and the peritoneal inflammatory response
Peritoneal fluid prostaglandins
Peritoneal fluid cytokines
Embryo implantations defect and spontaneous abortions

Adamson GD, Pasta DJ. Surgical treatment of endometriosis-associated infertility: meta-analysis compared with survival analysis *Am J Obstet Gynecol* 1994;171:1488–1505, with permission.

Diagnosis

Endometriosis usually is diagnosed during the third and fourth decades of life. It has not been found in prepubertal girls and rarely is diagnosed in postmenopausal women unless they are taking replacement hormones. Endometriosis should be suspected in any woman having the classic symptoms of pelvic pain, dysmenorrhea, dyspareunia, abnormal menstrual bleeding, and infertility. These symptoms are present in other gynecologic disorders. No one constellation of signs or symptoms is pathognomonic of endometriosis. Many women with endometriosis are completely asymptomatic, and endometriosis should be considered in all reproductive-age women with infertility or an adnexal mass.

Physical findings in women with endometriosis are variable and dependent on the location and severity of disease (Table 41.2). Frequently, there are no obvious findings on pelvic

examination. When findings are present, the most common is tenderness when palpating the posterior fornix. Nodules of endometriosis on the uterosacral ligaments, enlarged ovaries as a result of endometriotic cysts, and a uterus fixed in the cul-de-sac by adhesions may be detected during a pelvic examination. Uterosacral implants are best palpated during a rectovaginal examination. On the other hand, some patients with these clinical findings turn out not to have endometriosis.

The optimal way to diagnose endometriosis is by direct visualization of the site of suspected involvement.

Because endometriosis is located primarily in the pelvis, laparoscopy is the preferred technique to make an accurate diagnosis. A double-puncture technique is necessary to adequately view all structures that may contain implants. Peritoneal fluid should be aspirated to see the entire cul-de-sac. Adhesions should be lysed to view the entire surface of the ovaries and the fossa ovarica. These sites are commonly involved with endometriosis when the ovary is adherent to the pelvic sidewall. Suspected endometriomas should be aspirated and resected to confirm the diagnosis. Biopsy and histologic study of any suspicious areas are helpful when the diagnosis is questionable, but often the visual diagnosis by the surgeon is more accurate than histologic sections of small peritoneal biopsies.

TABLE 41.2 Clinical Signs

Localized tenderness in the cul-de-sac or uterosacral ligament
Palpable tender nodules in the cull-de-sac, uterosacral ligament, or rectovaginal septum
Pain with uterine movement
Tender, enlarged adnexal masses
Fixation of adnexa or uterus in retroverted position

Transvaginal ultrasonography can be used to identify ovarian endometriomas, but it is of little utility to diagnose peritoneal implants. The use of other radiologic studies and blood tests to diagnose endometriosis rarely is required. Radioimmunoassay for the tumor marker CA-125 has been used, but the test is not sufficiently sensitive or specific, and patients having conditions other than endometriosis may have positive results.

Classification

A number of classifications have been developed for staging endometriosis. The most widely used system was introduced by the American Society for Reproductive Medicine

(ASRM) in 1979 and revised in 1985 and in 1996. This system assigns a point score for the size and location of endometriotic implants and associated adhesions. The new ASRM endometriosis classification for infertility includes the morphologic appearance of the implant. There is a form published by the ASRM to assist in the management of endometriosis in the presence of pelvic pain.

Endometriosis is classified as minimal, mild, moderate, and severe. Mild disease is characterized by superficial implants <5 cm^2 in aggregate scattered on the peritoneum and ovaries. Minimal or no adhesions are present. Moderate forms are characterized by multiple implants, both superficial and invasive. Peritubal and periovarian adhesions may be evident. Severe forms are characterized by multiple superficial and deep implants, including large ovarian endometriomas. Filmy and dense adhesions usually are present. However, no staging system has been validated to correlate with the symptoms of pain or infertility.

Treatment

The treatment of endometriosis is dependent on (a) the severity of symptoms, (b) the extent of disease, (c) the location of disease, (d) the patient's desire for pregnancy, and (e) the age of the patient. Treatment options are presented in Table 41.3.

TABLE 41.3 Treatment Options

Expectant Management
Medical therapy
- Progestins
- Levonorgestrel-releasing intrauterine device
- Danazol
- GnRH analogues
- Aromatase inhibitors

Surgical therapy (laparoscopy or laparotomy)
- Conservative: retains uterus and ovarian tissue
- Definitive: removal of uterus and possibly ovaries

Combination therapy
- Preoperative medical therapy
- Postoperative medical therapy

GnRH, gonadotropin-releasing hormone.

Expectant Management

Avoiding specific therapy is considered when patients have minimal or no symptoms and have suspected minimal or mild endometriosis. Patients in this category may benefit from nonsteroidal anti-inflammatory drugs (NSAIDs) and/or cyclic or continuous oral contraceptives to retard progression of the disease and protect against unwanted pregnancy. Minor pain may be controlled by NSAIDs and/or analgesics. Infertile women having suspected limited disease may be observed without treatment. One study suggests that surgical treatment of mild endometriosis results in higher pregnancy rates than expectant management. Another study with fewer subjects failed to confirm the benefit of laparoscopic surgery for infertile women with endometriosis. If pregnancy occurs, regression or complete resolution of the disease is common. Perimenopausal women may be managed expectantly even when the disease is advanced, because endometriotic implants usually regress in the absence of ovarian hormone production after menopause.

Medical Therapy

Endometriotic implant growth is highly dependent on ovarian steroids. Medical therapy attempts to “induce” pseudopregnancy or menopause, the two physiologic states believed to inhibit or delay progression of endometriosis by interrupting cyclic ovarian hormone production. Progestins alone or in combination with estrogen hormonally mimic pregnancy. Danazol and gonadotropin-releasing hormone (GnRH) analogues induce a state of pseudomenopause. Medical therapy has the following advantages over surgery: (a) avoidance of the surgical risks of damaging pelvic organs and causing postoperative

adhesions and (b) treatment of implants that are not visible at surgery. Disadvantages of medical therapy are the associated side effects, high recurrence rates following discontinuation of treatment, lack of an effect on endometrioma and adhesions, and inability to conceive because of medically induced anovulation. Medical therapy never has been shown to enhance fertility (Fig. 41.1). Thus, it is not appropriate for women with advanced stages of endometriosis and adhesions causing symptoms or women desiring pregnancy. The medications used most commonly to treat endometriosis are continuous oral contraceptives, progestins, danazol, and GnRH analogues. They should be considered after a definitive diagnosis of endometriosis has been made by direct visualization of the implants.

Progestins inhibit endometriotic tissue growth by a direct effect on the implants, causing initial decidualization and eventual pseudodecidual necrosis or atrophy. They also inhibit pituitary gonadotropin secretion and ovarian hormone production. Treatment may consist of medroxyprogesterone acetate (10 mg three times a day) or norethindrone acetate (5 mg daily for 2 weeks), increased by 2.5 mg per day every 2 weeks until a daily dose of 15.0 mg is reached. Depot medroxyprogesterone may also be given as an injection (150 mg intramuscularly or 104 mg subcutaneously every 3 months). Treatment usually is continued for at least 6 months. Side effects include irregular menstrual bleeding, nausea, breast tenderness, fluid retention, and depression. The effectiveness of continuous oral contraceptives or progestins in eliminating implants and the risk of recurrent endometriosis following treatment are not precisely known. Over 80% of women have partial or complete pain relief. Low-dose cyclic oral contraceptives are effective in relieving dysmenorrhea in

women with endometriosis, but they are less likely to relieve dyspareunia. Pregnancy rates in patients with less severe stages of disease are equivalent to those following expectant management. The levonorgestrel-releasing intrauterine device can decrease chronic pelvic pain and dysmenorrhea in women with endometriosis.

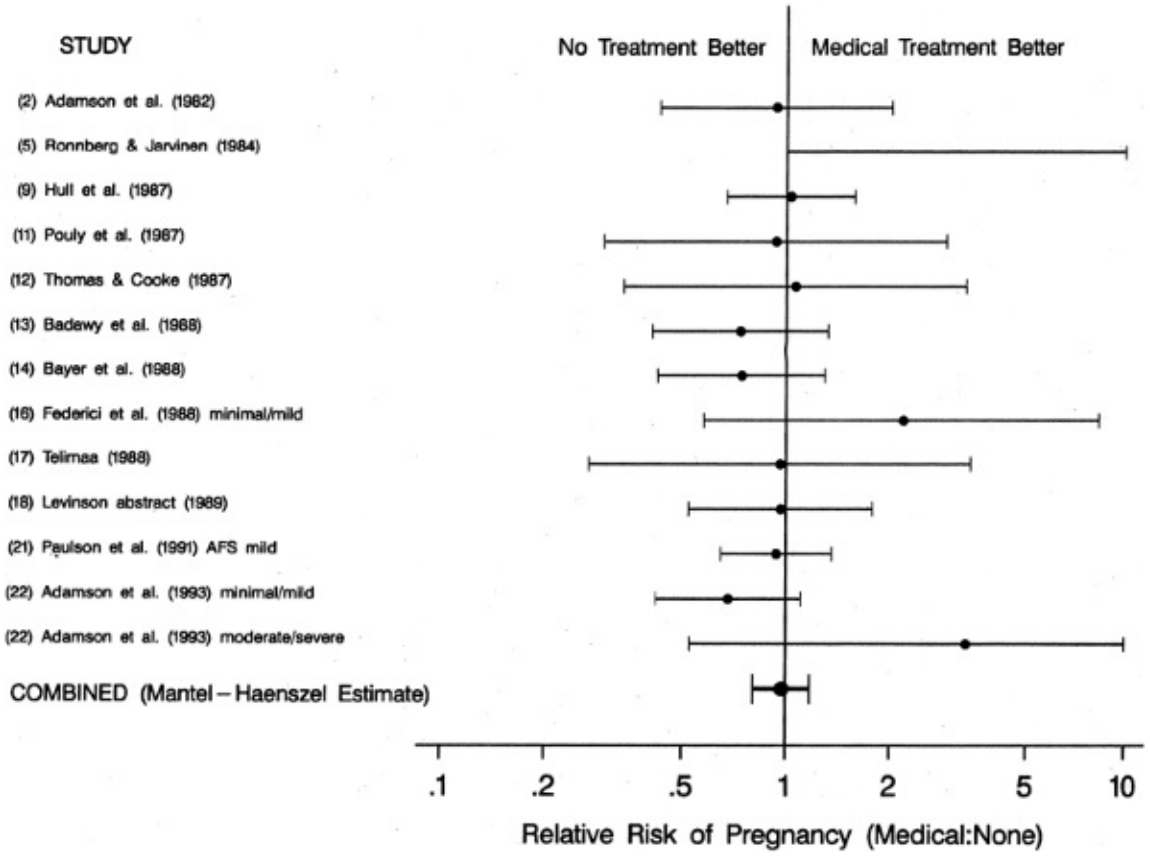

Figure 41.1 Meta-analysis of studies comparing medical treatment with no treatment. (AFS, American Fertility Society.)

Danazol is the isoxazole derivative of 17α-ethinyltestosterone and has the following three mechanisms of action: (a) inhibition of pituitary gonadotropin secretion, (b) direct inhibition of endometriotic implant growth, and (c) direct inhibition of steroidogenic enzymes. Danazol is given orally in divided doses, from 400 to 800 mg daily, generally for 6 months. Most women taking danazol have side effects, but only a small percentage of patients

discontinue the drug because of unwanted effects. Side effects, in decreasing order of frequency, include weight gain, muscle cramps, decreased breast size, acne, hirsutism, oily skin, decreased high-density lipoprotein levels, increased liver enzyme levels, hot flashes, mood changes, and depression. Danazol decreases the size of implants, especially in treating mild or moderate stages of disease. Endometriomas and adhesions do not respond well to danazol treatment. More than 80% of patients experience relief or improvement of pain symptoms within 2 months of treatment. Pregnancy rates following treatment approximate 40% and are independent of the disease severity. However, danazol is no more

effective than expectant management for treating infertility.

The GnRH analogues profoundly suppress ovarian estrogen production by inhibiting pituitary gonadotropin secretion. These medications are administered by nasal spray or depot injections. The usual dosage is 400.00 to 800.00 mg daily for nasal nafarelin, 3.60 mg for monthly subcutaneous goserelin, and 3.75 mg for monthly intramuscular leuprolide. Side effects of the hypoestrogenemia are common and include hot flashes, vaginal dryness, decreased libido, insomnia, breast tenderness, depression, headaches, and transient menstruation. In addition, GnRH analogue treatment for the recommended 6-month period decreases bone density and total body calcium, but most of the bone loss is reversible. Hypoestrogenic side effects and bone loss may be attenuated by “add-back” therapy consisting of progestin only, progestin plus bisphosphonate, or estrogen plus progestin (Table 41.4). The GnRH analogues effectively reduce the size of endometriotic implants, even with add-back therapy. Recurrence rates over 5 years range from 37% for patients with mild disease to 74% for severe disease. The GnRH analogues are as affective as other medical therapy in relieving pain symptoms, but they do not enhance fertility.

Aromatase inhibitors are a novel approach to inhibiting estrogen production in the endometriotic lesions themselves as well as in the ovary. The two most widely used aromatase inhibitors are anastrozole (1.0 mg) and letrozole (2.5 mg) daily. Aromatase inhibitors cause significant bone loss over time, and they should not be used alone, as they stimulate multiple ovarian follicular development. They have been used successfully in combination with daily progesterone (200.0 mg) or norethindrone acetate (2.5 mg), GnRH analogues, or oral contraceptives.

TABLE 41.4 Endometriosis Add-back Therapy

Norethindrone acetate	5–10 mg/d
Medroxyprogesterone acetate	20–30 mg/d or 100 mg/d
Conjugated estrogen	0.300–0.625 mg/d
Medroxyprogesterone acetate	5 mg/d
Micronized estradiol	1 mg/d
Medroxyprogesterone acetate	5 mg/d

Surgical Management

Surgery for endometriosis is considered conservative when the uterus and as much ovarian tissue as possible are preserved. Definitive surgery involves hysterectomy with or without removal of the fallopian tubes and ovaries.

Surgery is indicated when the symptoms are severe, incapacitating, or acute and when the disease is advanced. Surgery is preferred over medical therapy for advanced stages of disease with anatomic distortion of the pelvic organs, endometriotic cysts, or obstruction of the bowel or urinary tract. Women who are older than 35 years, infertile, or symptomatic following expectant or medical management should be treated surgically.

Laparoscopy is the preferred approach to perform conservative surgery. Treatment of endometriosis is possible during the initial laparoscopy, which is used to diagnose the condition. This offers the advantage of ablating the implants and adhesions while avoiding possible progression of disease or symptoms and the expense and side effects of medical therapy. Disadvantages include possible damage to the bowel and bladder, infection, and mechanical trauma that may result in adhesion formation.

Conservative surgery involves excision, fulguration, or laser ablation of endometriotic implants and removal of associated adhesions. The goal is to restore normal pelvic anatomy. Laparoscopic treatment offers advantages over laparotomy, including shorter hospitalization, anesthesia, and recuperation times. Laparotomy is advisable to deal with extensive adhesions or invasive endometriosis located near structures such as the uterine arteries, ureter, bladder, and bowel. Ancillary procedures include presacral neurectomy or uterosacral transection for interruption of sensory nerves innervating the pelvis to relieve midline pelvic pain. A Cochrane review of three trials involving destruction of pelvic nerve pathways concluded that there is insufficient evidence to recommend these procedures. Uterine suspension may be performed to avoid adhesion formation from the cul-de-sac to the posterior surface of the uterus, tubes, and ovaries.

Surgery effectively removes pathology and restores normal anatomy in most cases. The disease recurrence risk is estimated to be as much as 40% with 10 years of follow-up. Pain relief is achieved in 80% to 90% of patients. Presacral neurectomy provides additional pain relief, but its benefit is not lasting, and bladder dysfunction occasionally occurs after the procedure. The chance for pregnancy following surgery is related to the stage of disease and presence of other infertility factors. Approximate pregnancy rates after surgery in patients with mild, moderate, and severe endometriosis are 60%, 50%, and 40%, respectively. Surgery is preferred over expectant or medical management for infertile women with endometriosis (Fig. 41.2).

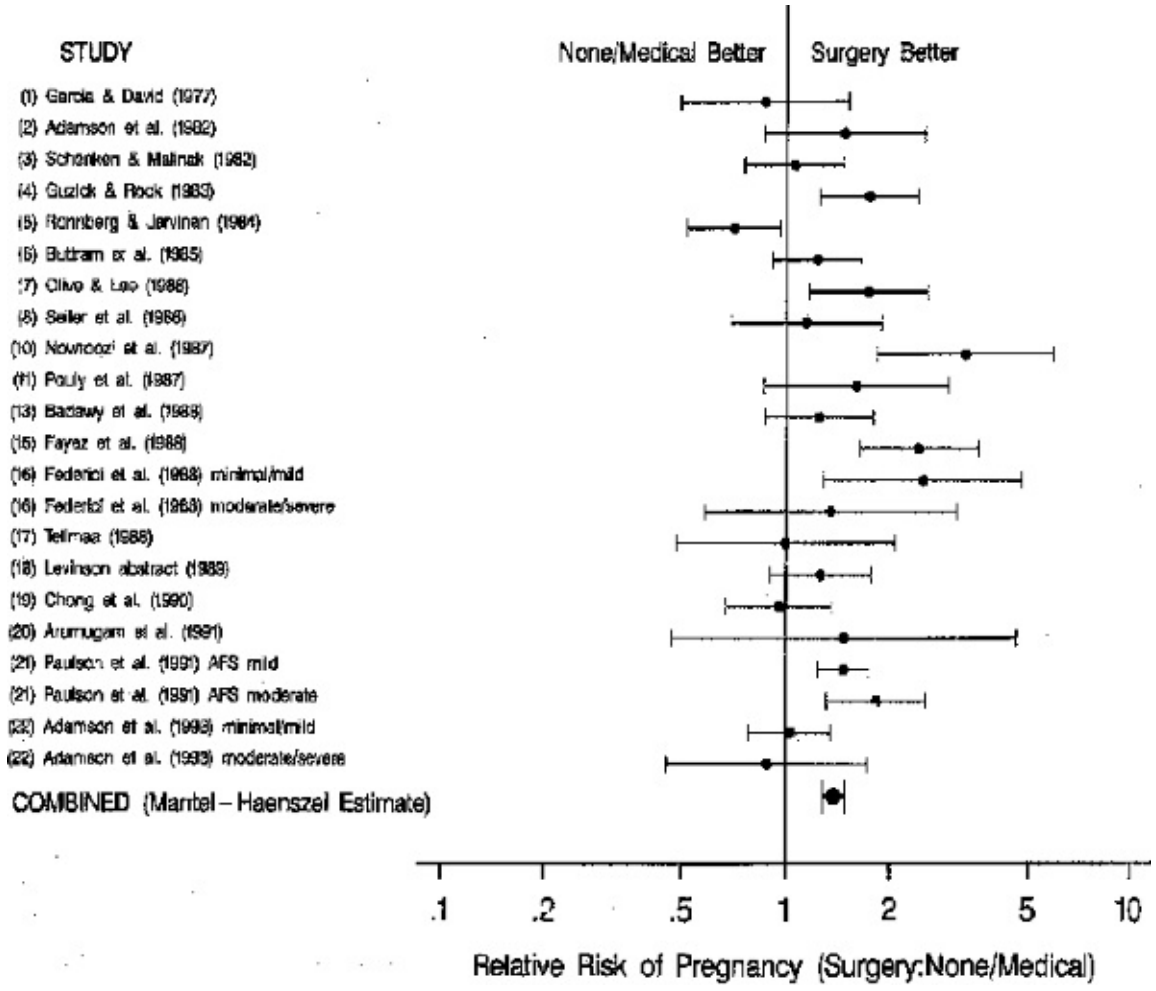

Figure 41.2 Meta-analysis of studies comparing surgical treatment (operative laparoscopy or laparotomy) with nonsurgical treatment (medical treatment or no treatment). (AFS, American Fertility Society.)

Definitive surgery for treatment of endometriosis is indicated when significant disease is present and pregnancy is not desired, when incapacitating symptoms persist following medical therapy or conservative surgery, and when coexisting pelvic pathology requires hysterectomy. The decision to perform hysterectomy is dependent primarily on the patient's interest in maintaining childbearing potential and the severity of her symptoms. The ovaries may be conserved in younger women to avoid the need for estrogen replacement therapy. Removal of both ovaries is appropriate when the ovaries are damaged extensively by endometriosis or when menopause is approaching. Endometriosis may recur even with castration, presumably from microscopic foci of disease not visible at surgery. Menopausal hormonal replacement is indicated when the ovaries are removed, even when surgery has not removed all endometriotic implants. The chance for symptomatic recurrence in these cases is small except when endometriosis involves the bowel.

Combination Medical and Surgical Therapy

Medical therapy is used before surgery to decrease the size of endometriotic implants and thus reduce the extent of surgery. When complete removal of implants is not possible or advisable, postoperative medical therapy is used to treat residual disease. Progestin, danazol, or GnRH analogues may be used in conjunction with conservative or definitive surgery. Preoperative medical therapy may decrease the amount of surgical dissection required to remove implants, but it does not prolong pain relief, increase pregnancy rates, or decrease recurrence rates. Postoperative treatment with

GnRH analogues will somewhat delay the recurrence of pelvic pain, but there is no evidence to support its use in infertile patients.

Summary Points

- The pathogenesis of endometriosis is poorly understood, but emerging evidence supports the causative role of retrograde menstruation and implantation of endometrial tissue.
- Endometriosis is common in women with pelvic pain and/or infertility.
- Laparoscopy is the optimal technique to diagnose pelvic endometriosis.
- In most cases, surgical therapy at the time of initial diagnosis effectively relieves pain and may enhance fertility.
- Alternatively, medical therapy with progestins, progestin-releasing intrauterine devices, danazol, or GnRH analogues will ameliorate pelvic pain, but they do not enhance fertility.
- Endometriosis is a recurrent disease, and definitive treatment with removal of pelvic organs may be necessary.

Menopause

Marcelle I. Cedars
Michele Evans

The ovary is unique in that the age associated with decline in function (to frank failure) appears to have remained constant despite the increase in longevity experienced by women over the last century. Because the loss of ovarian function has a profound impact on the hormonal milieu in women and on the subsequent risk for the development of disease via the loss of estrogen production, improving our understanding of reproductive aging is critical to care for all women.

Human follicles begin their development during the fourth gestational month. Approximately 1,000 to 2,000 germ cells migrate to the gonadal ridge and multiply, reaching a total of 5 to 7 million around the fifth month of intrauterine life. At this point, replication stops and follicle loss begins, declining to approximately 1 million by birth. In the human male, the dividing germ cells become quiescent and maintain their stem cell identity. In the female, between 12 and 18 weeks gestation, the germ cells enter meiosis and differentiate. Thus, all germ stem cells have differentiated prior to birth. In the adult woman, the germ cells may remain quiescent, be recruited for further development and ovulation, or undergo apoptosis. Over time, the population of oocytes will be depleted, without regeneration, through recruitment and apoptosis until fewer than a thousand oocytes exist and menopause ensues. Approximately 90% of women experience menopause during the early 50s. The other 10% of women experience menopause prior to 46 years of age (often termed *early menopause*), with 1% of women experiencing menopause at an age younger than 40 years (*premature menopause* or *premature ovarian failure* [POF]).

Menopause occurs at a median age of 51.4 years, with the age range in normal women being 42 to 58 years. The age of menopause appears to be determined largely by genetics and is due to exhaustion of the oocyte pool. Menopause and the years preceding it are characterized by hormonal changes, decline in reproductive potential, and increased risk for physical and psychologic changes.

The average age of menopause has remained constant throughout recorded history. It does not appear to be related significantly to race, parity, height, weight, socioeconomic status, or age at menarche. Evidence suggests that genetic and environmental factors influence the age of menopause, although the specific nature of these relationships is characterized

poorly. Given the strong association between age at menopause between mothers and daughters, this is likely a genetically determined trait. Environmental factors may not have a significant effect in themselves, but the interplay among environmental factors such as smoking (known to accelerate the age of menopause by 1.5 to 2.0 years), body mass index (BMI), alcohol use, and socioeconomic status and genetic risk may be important.

According to the 2000 census data, 35% of the population is age 45 or older and 21% are over 55 years of age. Currently, 7.3% are women 65 years or older (approximately 20 million women in the United States). Over 50 million women in the United States are in the menopausal transition or menopause.

Reproductive Stages

Reproductive aging is a continuum beginning in utero and ending with menopause. The stages along this continuum have been difficult to define. Numerous terms have been used clinically, to describe the end of this continuum, including *perimenopause*, *menopausal transition*, *climacteric*, *menopause*, and *postmenopause*. The Stages of Reproductive Aging Workshop (STRAW) was convened in July 2001 to address the lack of a pertinent reproductive staging system and to establish a nomenclature and guidelines as well as a consistent reproductive aging system for health practitioners, the medical research community, and the public.

The staging system takes into account menstrual cyclicity, endocrinology, and symptomatology, beginning with

menarche and ending with a woman's demise. The foundation of the staging system is the final menstrual period (FMP). Five stages precede the FMP and two follow it, for a total of seven stages. Stages -5 to -3 are called the *reproductive interval*, stages –2 to –1 are termed the *menopausal transition*, and stages +1 and +2 are known as the *postmenopause* (Fig. 42.1).

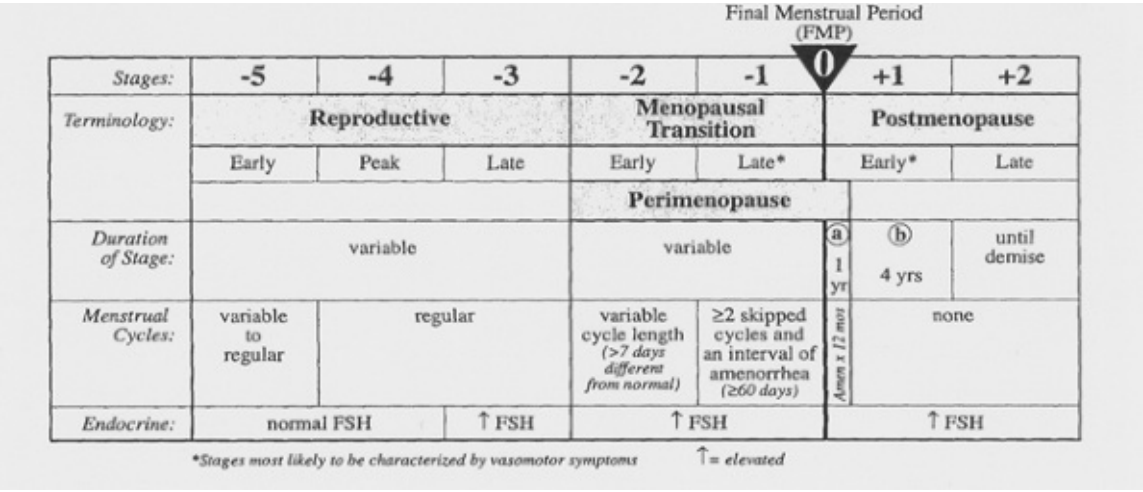

Figure 42.1 Stages of reproductive aging. (FSH, follicle-stimulating hormone; Amen, amenorrhea (From Soules MR, Sherman S, Parrott E, et al. Stages of Reproductive Aging Workshop (STRAW). *J Womens Health Gend Based Med* 2001;10:843–848, with

permission.)

The menopausal transition begins with variation in the menstrual cycle length (>7 days different from normal) in a woman with an elevated follicle-stimulating hormone (FSH) level. This stage ends with the FMP, which cannot be determined conclusively until after 12 months of amenorrhea. Early postmenopause is defined as the first 5 years following the FMP. Late postmenopause is variable in length, beginning 5 years after the FMP and ending with the woman's death.

Although this staging system is said to include endocrinologic aspects of ovarian aging, it still depends largely on menstrual cyclicity as a key indicator of ovarian aging. It does include measurement of FSH; however, by the time FSH is elevated, even with cyclic menstrual cycles, oocyte depletion already has proceeded to such an extent that fertility (as a marker of reproductive aging) is diminished significantly. As noted previously, evidence suggests that genetic and environmental factors influence both the age of menopause and the decline in fertility, although the specific nature of these relationships is characterized poorly. Premature menopause can be due to a failure to attain adequate follicle numbers in utero or to an accelerated depletion thereafter. Potentially, either of these factors could be affected by genetic and environmental risk. The timing of menopause has a consistent impact on overall health with respect to osteoporosis, cardiovascular disease (CVD), and cancer risk. Over the next decade, it is estimated that more than 40 million women will enter menopause.

Oocyte Depletion

As discussed previously, the leading theory regarding the onset of menopause relates to a critical threshold in oocyte number. Approximately 1,000 to 2,000 germ cells migrate to the gonadal ridge and multiply, reaching a total of 5 to 7 million around the fifth month of intrauterine life. At this point, replication stops and follicle loss begins, with a reduction to approximately 1 million by birth and 500,000 to 600,000 by menarche. As the number of oocytes in the reserve pool continues to decline, menstrual irregularity, followed by cessation, will occur. The theory that menopause is triggered primarily by ovarian aging is supported by the coincident occurrence of follicular depletion, elevated gonadotropin levels, and subsequent menstrual irregularity with ultimate cessation of bleeding.

A mathematical model that predicts the rate of follicular decline has been developed (Fig. 42.2). It utilizes existing data, which ultimately shows a biexponential decline, with an acceleration in oocyte loss when the remaining oocyte number equals approximately 25,000. In this model, the decline occurs at 37.5 years of age. At this point, the rate of follicular atresia accelerates. In the absence of this acceleration, the model suggests that menopause would be delayed until age 71. The cause of this accelerated depletion is not well defined. It is also clear that if the factor influencing the rate of decline is follicle number and not age, other factors that might account for a diminished follicle number (genetic risk and possible toxic exposure) would lead to an earlier rate of accelerated decline and an earlier age of menopause.

Coincident with the decline in the number of follicles in the ovary, there appears to be an increase in random genetic damage within these structures. Evidence for this comes from an observed increase in aneuploidy in the offspring of older mothers and the observation that in women over

40 years old, oocytes harvested for in vitro fertilization are karyotypically abnormal approximately 40% of the time. Further examples in nature, such as Turner syndrome, shed some light on the process of oocyte aging. Individuals with this syndrome are, by and large, born with dysgenetic gonads that are devoid of follicles. Ninety-five percent of these individuals are aborted spontaneously prior to birth. If one examines the ovaries of a 20-week abortus, a full complement of oocytes is present. Two factors have been isolated from the ovary: oocyte maturation inhibiting factor (OMI) and luteinizing inhibitor, which may control the rate of maturation of follicles. It has been suggested that individuals with dysgenetic gonads may fail to produce adequate OMI, thus allowing all follicles to progress prematurely toward maturity. The control mechanisms are conceptual rather than factual at this juncture, and new information will have to accumulate before the factors governing human oocyte atresia are elucidated more clearly.

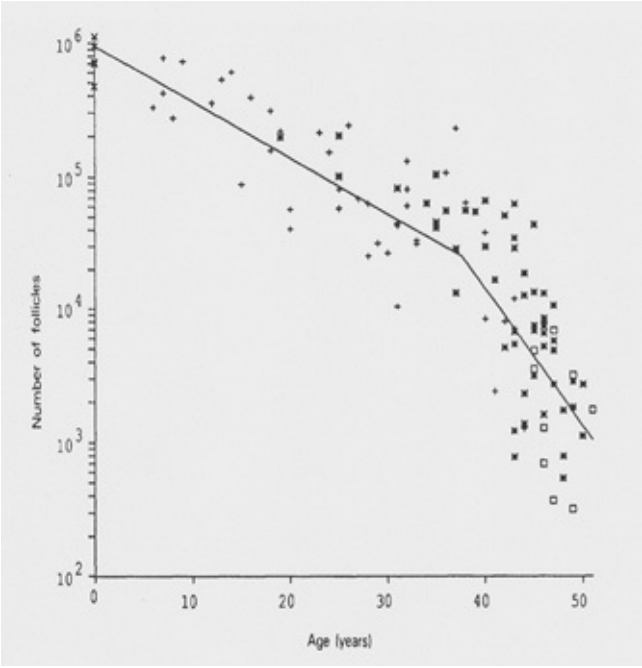

Figure 42.2 Biexponential model of declining follicle numbers in pairs of human ovaries from neonatal age to age 51. Data were obtained from the studies of Block in 1952 and 1953 (*x*, n = 6; +, n = 43), Richardson and others in 1987 (□, n = 9), and Gougeon (unpublished) (*, n = 52). (From Faddy MJ, Gosden RG, Gougeon A, et al. Accelerated disappearance of ovarian follicles in mid-life: implications for forecasting menopause. *Hum Reprod* 1992;7:1342–1346, with permission.)

Endocrinology

The entire endocrine system in women changes with advancing age. The somatotrophic axis begins to decline during the fourth decade, prior to the loss of ovarian function. This decline in growth hormone is accelerated during ovarian failure and may, itself, accelerate the ovarian failure. However, pituitary concentrations of growth hormone, as well as adrenocorticotropic hormone and thyroid-stimulating hormone, remain constant into the ninth decade. Although the thyroid gland undergoes progressive fibrosis with age and concentrations of T3 decline by 25% to 40%, elderly women remain clinically euthyroid. ß-cell function also undergoes degeneration with aging such that by age 65 years, 50% of subjects have an abnormal glucose tolerance test result. Frank diabetes is rare, however, occurring in only 7%. The female reproductive system, on the other hand, undergoes virtually complete failure at a relatively early age.

As noted previously, during the late fourth decade, FSH levels begin to rise even when cyclic menses continue. The most likely cause is a decrease in functional granulosa cells from the oocyte pool, with a decrease in inhibin B negative feedback allowing a monotropic rise in FSH. Early on, there also is a decline in luteal phase progesterone levels. As ovarian aging progresses, estradiol levels may be quite variable, with chaotic patterns and, occasionally, very high and very low levels. This dramatic variability may lead to an increase in symptomatology during the perimenopause (stages –2 to –1). As peripheral gonadotropin levels rise, luteinizing hormone (LH) pulsatile patterns become abnormal. There is an increase in pulse frequency with a decrease in opioid inhibition.

Estrogens

The main circulating estrogen during the reproductive years is 17-ß-estradiol. These levels are controlled by the developing follicle and resultant corpus luteum. Oophorectomy will reduce peripheral estradiol levels from 120 to 18 pg/mL, which suggests that more than 95% of circulating estradiol is derived from the ovary. Other sources include the peripheral conversion of testosterone and estrone. Very small amounts are secreted by the adrenal gland. Because the two-cell theory requires aromatization of androgens produced by the theca in the granulosa cell, follicular exhaustion is associated with gradual declines in estradiol concentrations.

The predominant estrogen in the postmenopausal woman is estrone, which has a biologic potency of approximately one third that of estradiol. Estrone is derived largely from peripheral conversion of androstenedione. Extraglandular aromatase is found in liver, fat, and some hypothalamic nuclei. This activity increases with aging and with a higher fat content (also an age-related change). Estrone and estradiol production rates during the postmenopause are 40 and 6 mg/day, respectively. This compares with 80 to 500 mg/day for estradiol during the reproductive years. Essentially, all the estradiol in the postmenopausal woman is derived from conversion of estrone.

Androgens

Dehydroepiandrosterone (DHEA) and its sulfated conjugate, DHEAS, have been shown to decrease with aging, along with adrenal corticotropin responsiveness. DHEAS levels decrease in both men and women. The decline is greater in women and may be due to the

deprivation. Ovarian failure, at any age, accelerates this decline. Evidence suggests that physiologic levels of DHEA may protect against neoplasia, enhance insulin action, protect against osteoporosis, increase immune competency, and offer some cardioprotection. Changes in DHEA levels also have been associated with alterations in body composition that, in themselves, appear to impact cardiac and breast cancer risk. DHEAS levels also may have an impact on “sense of mental well-being.”

Androstenedione is the predominant androgen during the reproductive years, and production declines from 1,500 to 800 pg/mL in postmenopausal women. The postmenopausal ovary contributes only 20% to the circulating androstenedione. Testosterone levels also decline after menopause although not to the same extent as estradiol levels. Postmenopausal testosterone is derived from the ovary (25%), the adrenal gland (25%), and extraglandular conversion from androstenedione (50%). The postmenopausal ovary produces a larger percentage of testosterone (50%) than does the premenopausal ovary.

Systemic Effects of Declining Ovarian Function

The decline in ovarian function brings about profound changes in secondary sexual organs. The endometrium becomes atrophic, and the uterus decreases in size. Evidence is accumulating in animal models that the uterus may be partially responsible for the initial decline in reproductive capacity. On the other hand, data from human oocyte donor programs have shown that transfer of ova from younger donors to menopausal recipients produces normal gestations and offspring. It should be noted that these women are stimulated with an artificial sequential overlapping regimen of estrogen and progesterone. This produces an endometrium that is indistinguishable from that of the premenopausal state. The author's data have shown high implantation rates in older women with a hormonally induced endometrium. Only those women who had received pelvic irradiation have responded poorly, suggesting an alteration of the uterine microvascular system.

The postmenopausal vagina, devoid of estrogen treatment, becomes smaller in both length and caliber. There is decreased elasticity of the vaginal wall, and the karyopyknotic index changes to show fewer superficial cells. The fallopian tubes contain both ciliated and secretory components. After age 60, cilia begin to disappear in the isthmic region, although they remain until a very old age in the ampulla and infundibulum. The mammary gland develops secretory potential at the time of puberty and maintains this function until menopause. Like other secondary sex organs, it is dependent on female sex steroids for its maintenance. With cessation of the production of estrogen and progesterone, glandular, ductal, and stromal involution occurs. The basement membrane thickens, and the luminal space becomes obliterated. Connective tissue of the lobule becomes indistinguishable from other types of connective tissue. There is an accumulation of adipose tissue in the breast, which occurs simultaneously with this involutional process.

Despite the involutional changes of the breast, 20% of patients with breast carcinoma are under the age of 50, with a median age of 55. There is evidence for a bimodal distribution

of breast carcinoma, with the first peak occurring at 45 years of age and the second at 65 years. The portion of estrogen receptor–positive breast cancers increases until ages 60 to 74 years. Therefore, a dichotomy appears to exist that ducts and glands, which are rapidly undergoing involution as the result of failing steroid production, become susceptible to malignant transformation while retaining a receptor molecule (E_2), which normally is self-induced.

Premature Ovarian Failure

Premature ovarian failure (POF) is a unique entity in which a woman undergoes changes consistent with menopause, such as amenorrhea, elevated FSH levels, and depletion of ovarian follicles, prior to the age of 40. POF occurs in 0.1% of women under 30 years of age and in 1% of women by age 40.

Genetic factors are thought to have a strong relationship with POF. There is a higher incidence of family history of early menopause and a suggestive increase in the family history of infertility as well as an increased incidence of familial cases of early menopause among patients with idiopathic POF. Twin studies have likewise noted a strong genetic component to the age of menopause. Although inheritance appears to be either X-linked or autosomal dominant sex limited, paternal transmission cannot be excluded. Women who have idiopathic early menopause (between the ages of 40 and 45) have a genetic pattern similar to those with POF. These observations support the hypothesis of common underlying genetic factors, which may lead to an early decrease in fertility, early menopause, and POF. Current recommendations advise testing of women with POF, or premature elevations of FSH, for the fragile X permutation (FMR-1). This knowledge may have impact on their own reproductive decisions and requires referral for genetic counseling given the multigenerational impact of this finding.

POF may not be the same as age-appropriate menopause, which results from the depletion of the primordial follicle pool, because POF may be reversible, with follicles in the ovary, estradiol production, and even pregnancies long after the diagnosis. When using ultrasonography to evaluate the follicles in women with POF compared with age-appropriate menopausal and young women on oral contraceptives (OCPs), the mean ovarian volumes were smaller in patients with POF compared with women on OCPs but not different from the women with

---

age-appropriate menopause. Approximately 40% of patients with POF had follicles in the ovary, albeit fewer than in the normal premenopausal women.

Menstrual Cycle

Prior to the menopausal transition, the average length of a menstrual cycle ranges from 21 to 35 days. The menopausal transition is defined partially by menstrual irregularity that occurs in response to changes within the ovary—specifically, a dramatic decline in follicle number (and granulosa cell content). As a result, inhibin B levels fall, decreasing negative feedback on FSH and causing a monotrophic rise in FSH. This early cycle rise in FSH may shorten the follicular phase due to accelerated folliculogenesis. Estradiol levels remain

relatively constant with age until the menopausal transition, when they initially rise in response to increased FSH levels. As the ovary fails, progesterone levels decline, leading to a shortened (or inadequate) luteal phase. Thus, an early sign of waning ovarian function may be a decreased intermenstrual interval. Precycle spotting may also signal deficiencies in progesterone production. These clinical signs of reproductive aging indicate a poor prognosis for those women still interested in reproduction. As the FMP approaches and the oocyte complement declines to a critical level, estradiol levels fall, leading to hot flashes, vaginal atrophy, and accelerated bone mineral density (BMD) loss. Also, as the FMP approaches, there is a steady trend toward an increased mean cycle length. In a woman's final 10 to 20 cycles, average cycle lengths characteristically are 40 to 42 days.

As menstrual irregularity increases during the menopausal transition, many women seek medical care. Treatment can be approached in several ways. After a complete history and physical examination, bleeding irregularities can be treated with different hormonal regimens, including OCPs, cyclic hormone replacement therapy (HRT), or progestin-only therapy. Many of these patients continue to ovulate, albeit irregularly, so the addition of cyclic progestin (without estrogen) may further increase cycle irregularity and does not offer contraceptive protection. Thus, treatment with OCPs or a combined, cyclic estrogen–progestin regimen is advisable.

There always is the risk of endometrial hyperplasia in this age group. Patients considered high risk (history of chronic anovulation or obesity or suspicious bleeding patterns such a watery, bloody discharge) should undergo endometrial sampling. Pelvic ultrasonography for measurement of endometrial stripe thickness is not a reliable predictor of risk in cycling women. For those who have a relatively new onset of bleeding irregularity (consistent with the menopausal transition in a previously ovulatory woman), initiation of hormonal treatment can be considered, with endometrial biopsy reserved only for those whose cycles fail to normalize after 3 months of therapy.

Postmenopausal bleeding always should be considered abnormal and must be evaluated accordingly. Bleeding can occur from the rectum, vagina, cervix, urethra, or uterus. A thorough history and physical examination is crucial. If the source of bleeding is uterine, a transvaginal ultrasonographic examination can be very helpful. If the endometrial stripe is thinner than 5 mm, the bleeding typically is the result of an atrophic endometrium. If the endometrium is 5 mm or thicker, it is imperative to perform a diagnostic test, either an endometrial biopsy or dilation and curettage, to sample the endometrium.

Menopausal Syndrome

Given the endocrinologic changes with aging, many symptoms associated with aging in women are due to estrogen deficiency, but the decline in adrenal androgens and growth hormone may contribute. Symptoms that definitely are a result of estrogen deprivation include vasomotor symptoms and urogenital atrophy. Osteoporosis is likely, largely due to estrogen deficiency, but this may be exacerbated by the relative growth hormone decline. The same may be said for the hormone-related changes of increasing atherosclerotic CVD and psychosocial symptoms including insomnia, fatigue, short-term memory loss, and depression. Both DHEAS and growth hormone may well have an impact on these age-

related symptoms.

Vasomotor Symptoms

Vasomotor instability in the form of a hot flash (flush) is one of the most consistent and bothersome symptoms that women face as they enter the menopausal transition and subsequent menopause. Hot flashes result from estrogen deficiency and a resetting of the hypothalamic thermoregulatory set point. They occur in 65% to 76% of women who undergo spontaneous menopause or surgical oophorectomy. Symptoms may begin during the menopausal transition, when estrogen levels may fluctuate dramatically from cycle to cycle and even day to day.

A hot flash usually is characterized by intense warmth, described as “heat or burning” that usually begins in the head, neck, and thorax and can spread in waves over the entire body. It may be preceded by pressure in the head and may be accompanied by heart palpitations. The hot flash usually is followed by an outbreak of sweating, followed by chills as the body's thermostat resets. The length of the episode varies from seconds to approximately 5 minutes, although episodes as long as 30 minutes have been described. The event frequency varies from a few per year to 30 per day.

For most women, the hot flashes commence prior to the FMP, although initially this may be perceived only as a sleep disturbance. In general, the episodes are noted more frequently at night, and the dysfunctional sleep pattern that follows may result in fatigue, irritability, loss of concentration, and depression, symptoms that often are elicited from

---

patients in the menopausal transition. More than 80% of women who experience hot flashes will experience them for longer than 1 year. Twenty-five percent of women complain of severe hot flashes. Without treatment, the symptoms usually subside slowly over 3 to 5 years. Investigators in a 25-year longitudinal study from Gothenburg, Sweden, with 1,462 participants found the prevalence of hot flashes to be at a maximum of 60% at 52 to 54 years of age. Interestingly, 9% of subjects still reported hot flashes at age 72.

The etiology of hot flashes seems to be the withdrawal of estrogen rather than the state of hypoestrogenism. For example, women with Turner syndrome who have not been treated with exogenous estrogen do not experience hot flashes. Those who are treated with estrogen, which is later withdrawn, will experience symptoms of vasomotor instability. Obese women seem to be less symptomatic than matched controls with a lower BMI. The explanation may be that obese women are less hypoestrogenic secondary to peripheral conversion of adrenal androgens into estrone or that obesity lowers sex hormone–binding globulin levels, allowing a greater proportion of their estrogen to remain unbound and able to act on target tissues. Studies of hot flashes with external monitoring of skin temperature and resistance have shown a frequency of approximately 54 plus or minus 10 minutes. This frequency has been shown to interrupt random eye movement sleep and potentially contributes to some of the psychosocial complaints. Hot flashes are correlated temporally with pulses of LH; however, exogenous LH does not induce a flash, suggesting that there is some central mediator leading simultaneously to hot flashes and LH pulses.

Several biochemical alterations are associated with the hot flash. During the actual

episode, there is evidence of a rise in plasma LH, epinephrine, corticotropin, cortisol, androstenedione, DHEA, ß-lipotropin, ß-endorphin, and growth hormone. Levels of estradiol, estrone, prolactin, thyroid-stimulating hormone, FSH, and norepinephrine are unchanged.

Treatment

Vasomotor symptoms are the most common indication for use of estrogen treatment in menopause and are also a Food and Drug Administration (FDA)-approved indication. Estrogen therapy, in either oral or transdermal form, has a greater than 95% efficacy for the treatment of hot flashes. Hot flash frequency is first notably reduced after 2 weeks of treatment, and the full effect of a certain dosage can be determined reliably after 4 weeks. Due to concerns over the risk–benefit analysis of HRT use, it is recommended that women be treated for vasomotor symptoms for short periods (1 to 4 years) and then gradually tapered because symptoms often recur when treatment is discontinued abruptly. For patients with contraindications to estrogen use, vasomotor symptoms can be treated, albeit less efficiently, with progestins, α2-adrenergic agonists (clonidine, methyldopa, lofexidine) and, possibly, antidepressants (selective serotonin reuptake inhibitors [SSRIs], venlafaxine hydrochloride [Effexor]). The SSRI/selective norepinephrine reuptake inhibitors (SSNIs) and gabapentin appear to show modest reduction in hot flashes when compared with placebo and should be utilized over herbal therapies that have not shown efficacy. Treatment side effects may, however, be a problem with these agents.

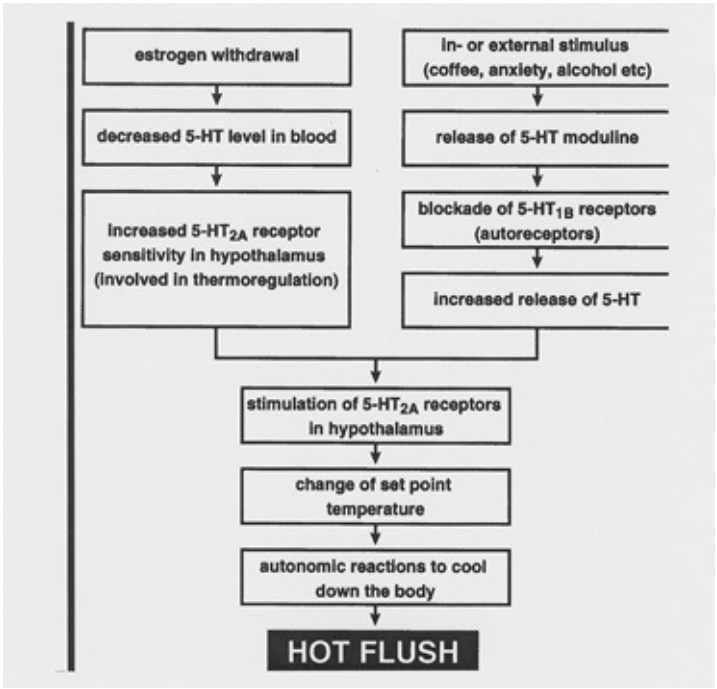

Figure 42.3 Possible mechanism by which a hot flush is induced. (5-HT, 5-hydroxytryptamine.) (From Berendsen HH. The role of serotonin in hot flushes. *Maturitas* 2000;36:155–164, with permission.)

The role of serotonin (5-hydroxytryptamine [5-HT]) in symptoms of menopause is being investigated increasingly. Serotonin levels fall with menopause, either naturally or surgically induced, and replacement estrogen is known to increase serotonergic tone. The $5\text{-}HT_{2A}$ receptor subtype is thought to underlie changes in thermogenesis. Stimulation of this receptor may lead to changes in the set point temperature, leading to autonomic changes that cool the body. An increased skin temperature and sweating may result. Thus, an involvement for the $5\text{-}HT_{2A}$ receptor in the etiology of hot flashes has been suggested. A theoretical model, illustrating a role for 5-HT in the mechanism of the hot flash, is shown in Figure 42.3.

Most studies using SSRIs for the treatment of vasomotor symptoms have been in patients with breast cancer. The differential between the antidepressant effects of these agents versus a direct effect on vasomotor symptoms may be more difficult to detect in this population.

Genitourinary Atrophy

Vagina

A decrease in circulating estrogen levels has deleterious effects on urogenital epithelium. Up to 50% of postmenopausal women experience symptoms of vaginal atrophy. The most common symptoms include dryness, irritation,

---

itching, burning, and dyspareunia. Atrophic vaginitis is associated with a rise in vaginal pH, which can lead to more frequent infections and worsening, irritative symptoms. A concurrent decrease in vaginal lubrication can lead to bleeding and decreased sexual comfort and pleasure.

Estrogen replacement therapy (ERT) is an effective treatment for vaginal atrophy. The systemic dosage necessary for vaginal protection is somewhat higher than needed for bone protection (see below), and thus, topical therapy by means of creams or vaginal rings may be advisable to limit systemic absorption. Unless systemic HRT is required for vasomotor instability, local estrogen therapy can be used effectively to treat urogenital atrophy. Vaginal estrogen cream or tablets can be used daily for approximately 2 to 3 weeks and then twice weekly after initial symptoms have improved and vaginal vascularization (hence, hormone uptake) has increased. Treatment usually is long term, as symptoms tend to recur when estrogen is discontinued. The twice-weekly estrogen regimen can be used without supplemental progestin and without an increase in endometrial thickness. The dosage should be kept low, however, because the well-vascularized vagina is extremely efficient in the absorption of steroids. The new low-dose vaginal ring also may be used without progestin protection of the endometrium.

Vaginal estrogen frequently will improve symptoms of urinary frequency, dysuria, urgency, and postvoid dribbling. A direct effect to improve urinary incontinence is less clear. Alternatives to estrogen include vaginal moisturizers and lubricants. There is no evidence to support the use of Agrimony, black cohosh, chaste tree, dong quai, witch hazel, or

phytoestrogens for the treatment of atrophic vaginitis.

Urinary Tract Infections

Urinary tract infections (UTIs) are common among women of all ages. Worldwide, an estimated 150 million UTIs occur annually. In the United States, UTIs account for more than $6 billion in health care costs. The incidence is highest in 18- to 24-year-old women at 17.5% and is 9% for women older than 50 years. In younger women, the major risk factors for recurrent UTI are sexual intercourse and spermicide exposure. In older, institutionalized women, the most important risk factors include urinary catheterization and functional status.

Healthy, postmenopausal women have different risk factors for recurrent UTI than those mentioned previously. Recurrent UTIs in healthy postmenopausal women are associated with urinary incontinence, cystocele, and increased postvoid residual volumes. Other significant risk factors include at least one episode of UTI prior to menopause, urogenital surgery, and reduced urinary flow. From the Heart and Estrogen/Progestin Replacement Study (HERS) of postmenopausal women with coronary heart disease (CHD), additional risk factors included diabetes, vaginal itching, and vaginal dryness.

Changes in the vaginal environment after menopause also may predispose a woman to UTI. These alterations include the absence of lactobacilli, elevated vaginal pH, and increased rate of vaginal colonization with Enterobacteriaceae. The intravaginal administration of estrogen has been shown to reduce the rate of recurrent UTI by normalizing the vaginal environment. Low-dose oral hormone therapy, with conjugated estrogen plus medroxyprogesterone acetate (MPA), does not reduce the frequency of UTIs in older women.

Urinary Incontinence

The prevalence of urinary incontinence in menopausal women is estimated to be in the range of 17% to 56%. Urinary incontinence is the eighth most prevalent chronic medical condition among U.S. women. Anatomic and physiologic alterations associated with aging and incontinence include thinning of the urethral mucosa, reversal of the proteoglycan-to-collagen ratio in the paraurethral connective tissue, decrease in urethral closure pressure, and changes in the normal urethrovesical angle.

Many risk factors have been associated with incontinence. Menopause often is considered to be one of these risk factors, especially because a prevalence peak in midlife has been reported by many authors. Epidemiologic studies generally have not found an increase in the prevalence of urinary incontinence in the menopausal transition.

A risk factor for incontinence is an increased BMI. This is an especially important factor because it is modifiable. Vaginal delivery is associated with transient postpartum incontinence as well as an increased risk of incontinence later in life. Interestingly, a study of nulliparous nuns, with mean age of 68, found that 50% of the nuns had urinary incontinence. Meta-analyses have found an association between hysterectomy and urinary incontinence, with an increase in incontinence of 60%. Considering that more than 600,000

hysterectomies are performed yearly in the United States and that approximately 40% of women have undergone hysterectomy by age 60, these results are quite relevant. Women should be counseled about this relationship prior to undergoing hysterectomy. Other significant risk factors include history of UTI and depression.

Treatment

Oral ERT has been shown to restore the genitourinary connective tissues to that of premenopausal women, but it seems to have little short-term clinical benefit in regard to urinary incontinence. Interestingly, oral estrogen replacement is associated consistently with an increased risk of incontinence in women aged 60 years and older in epidemiologic studies. This increase may reflect that women with more severe symptoms seek medical care and HRT more often than do asymptomatic women. It also is possible that the local levels of estrogen in these studies was too low to benefit fully the urogenital system, given the data

---

suggesting that higher systemic dosages may be needed for a vaginal effect.

Osteoporosis

Osteoporosis is a condition in which bone loss has been sufficient to allow mechanical fracture with limited stress. The likelihood of developing osteoporosis is dependent on the combination of peak bone density (stressing the importance of bone building in the young) and the rate of loss (accelerated with estrogen deficiency). Primary, or “senile,” osteoporosis usually affects women between the ages of 55 and 70 years. The most common sites include the vertebrae and the long bones of the arms and legs. Secondary osteoporosis is caused by a specific disease (such as hyperparathyroidism) or medication usage (glucocorticoids, thyroid hormone excess, anticonvulsants).

Menopausal bone loss begins before the FMP during stage -1. Postmenopausal osteoporosis causes over 1.3 million fractures annually. Most of the 250,000-plus hip fractures are due to primary osteoporosis. Excess mortality may exceed 20% within a year of a hip fracture, and because 75% of patients lose their independence, the social costs, not to mention the financial costs, are great.

Bone loss following natural menopause is approximately 1% to 2% per year, compared with 3.9% per year following oophorectomy. A woman's genetic background, lifestyle, dietary habits, and coexisting disease will impact the development of osteoporosis. Cigarette smoking, caffeine use, and alcohol consumption are associated with increased bone loss, while weight-bearing activity appears to slow it.

Approximately 30% of postmenopausal women have osteoporosis. The World Health Organization has defined osteoporosis as a hip BMD value, as measured by dual x-ray absorptiometry (DEXA), that is greater than 2.5 standard deviations below the adult peak (mean level for young, white women: t-score). Women with existing fractures, regardless of BMD, are also classified as osteoporotic. Both groups are at increased risk for fractures. Those patients with a low z-score (age-matched comparison) should be investigated for

secondary causes of osteoporosis.

Peak bone mass in women is achieved by the end of the third decade and is an important contributor to bone strength in later life. Adolescence is a critical period of rapid skeletal growth during which almost one half of the adult bone mass is accrued. Many factors contribute to a woman's peak skeletal mass, including heredity, diet, physical activity, and endocrine milieu. Hormones that may be a factor in peak bone mass attainment include insulin-like growth factor (IGF)-1, which regulates skeletal growth, and gonadotropins, which stimulate sex steroid production and epiphyseal maturation. Estrogen deficiency and amenorrhea can decrease peak bone mass, whereas weight-bearing exercise leads to an increase. Early influences, including birth weight and poor childhood growth, are linked directly to the risk of hip fracture. Independent predictors of low peak bone mass include low body weight, menarche at over 15 years of age, and physical inactivity as an adolescent. Early intervention during childhood and adolescence may reduce a woman's risk for osteoporosis in later life—this includes adequate calcium intake and education regarding diet, ideal weight, and physical activity.

Treatment

Hormone Replacement Therapy.

HRT has been used widely for the prevention of osteoporosis and is FDA approved for this indication. It is clear that HRT helps to prevent bone loss, as indicated by increased BMD. Whether these benefits translate into decreased fracture risk has been an important topic of research for the past decade. Observational studies have shown lower vertebral and nonvertebral fracture rates in women receiving estrogen compared with those not receiving this therapy. The addition of a progestin does not alter these results. However, observational studies may be biased, because women using HRT have better access to medical care and maintain healthier lifestyles in general.

Estrogen therapy acts via an inhibition of bone resorption. Although both BMD and fracture rate are improved with estrogen therapy, there is a rapid and progressive loss of bone mineral content after cessation of estrogen therapy. By 4 years after therapy, bone density is no different from that of patients who were never treated with estrogen.

Although estrogen is approved for prevention of osteoporosis, there is some evidence to support its usage in treatment. Dosages of 0.625 mg of conjugated estrogen and, more recently, as low as 0.300 mg have been shown to slow bone loss and provide adequate protection against the development of osteoporosis. Higher dosages may be required to treat existing disease.

Meta-analysis of randomized trials shows an overall 27% reduction in non-vertebral fractures in a pooled analysis, with the effect being greater in women under 60 years of age. The HERS trial showed no evidence of reduction in incidence of fractures or rate of height loss in older women with CHD not selected for osteoporosis. The Women's Health Initiative (WHI), the first randomized primary prevention trial studying the effects of postmenopausal HRT, showed a significant reduction in hip fracture (hazard ratio [HR] 0.66;

confidence interval [CI] 0.45 to 0.98). It seems clear that HRT must be taken indefinitely to preserve bone mass.

Calcitonin.

Calcitonin is a hormone normally secreted by the thyroid gland and responsible for calcium homeostasis. Calcitonin is now available as a nasal spray, specifically developed to decrease local side effects caused by the earlier subcutaneous injection. Intranasal calcitonin has been shown to improve spinal bone density and decrease the vertebral fracture rate in women with established osteoporosis. The increase in bone density appears to peak in

---

as little as 12 to 18 months. This may be due to down-regulation of the calcitonin receptors and the development of neutralizing antibodies. Although few studies have been performed and no data are available regarding calcitonin-related reductions in hip fracture, calcitonin does seem to be especially beneficial for women with a recent and still painful vertebral fracture. Unfortunately, it appears that some patients do not respond to this therapy, and those nonresponders cannot be identified prospectively.

Bisphosphonates.

Bisphosphonates are non-hormonal compounds, analogues of pyrophosphates that have an affinity for hydroxyapatite in bone. The basic molecular structure of bisphosphonates allows a large number of manipulations, producing different types of bisphosphonates that vary considerably in their potency. The first and least potent used clinically was etidronate. In succeeding order of development were pamidronate, alendronate, and risedronate, of which risedronate is the most potent of these compounds. Etidronate, if given continuously for more than 6 months, impairs mineralization of bone and may cause osteomalacia. There have been occasional reports of pamidronate also causing impairment of mineralization of bone. However, continuous administration of either alendronate or risedronate has not caused osteomalacia.

Alendronate has been evaluated more extensively than calcitonin and has a proven track record, reducing the risk of all major fracture types (vertebral and non-vertebral) in women with osteoporosis. In one study, risk of hip fracture was reduced by 53%, clinical vertebral fracture by 45%, and wrist fracture by 30%. For all fracture types, some reduction in fracture risk was evident within the first year of treatment. Bisphosphonates have only a modest effect on BMD early in the treatment course. Because alendronate is effective so quickly in reducing fracture risk, mechanisms other than increased BMD, such as changes in bone remodeling rates, may play a role in fracture reduction.

Alendronate has been shown to inhibit markers of bone remodeling and to increase BMD at the lumbar spine, hip, and in all other bones. Bone density increases with alendronate are greater than with calcitonin and are equal to that with HRT. The escape phenomenon seen with calcitonin is not seen with alendronate, which has the advantage of oral administration. The recommended daily dosage of 10 mg, however, must be taken according to a very strict dosing schedule (in the morning on an empty stomach, with the

patient required to remain upright for 30 minutes thereafter). The medication has very poor bioavailability (approximately 1%), so these restrictions must be followed precisely. Alendronate also has a propensity for irritation of the esophagus and stomach, especially in women with preexisting esophageal reflux or gastric or duodenal disease. A newer formulation allows for once-weekly or monthly administration, and development of a once-yearly intravenous formulation may further decrease side effects and administration difficulties.

Risedronate has been shown to reduce substantially the risk of both vertebral and nonvertebral fractures. Bone density is increased in early postmenopausal women as well as in those with established osteoporosis.

The remaining question concerning bisphosphonates has to do with the near-permanent changes in bone with the incorporation of this agent into the bone matrix. Although short-term fracture data appear favorable, the long-term effects of these agents and the ability of bone treated with bisphosphonates to heal (e.g., following hip fracture) are not known.

Raloxifene.

Raloxifene is the first of a new generation of compounds known as selective estrogen receptor modulators (SERMs) to have a treatment indication for osteoporosis. It is likely that there will be an explosion in the development of SERMs in the years to come. They may represent a new alternative for patients with breast cancer or for long-term use in all patients. These new agents act as selective estrogen receptor agonists on the bone and possibly the heart and antagonists of estrogen action on the breast and uterus. Effects on the brain are not well characterized and likely will vary among compounds (see below). Data on raloxifene suggests good preservation of bone density, albeit less than that seen with alendronate or HRT, and fracture data further supports a protective effect.

It is believed that the differential effect of estrogen agonists (estrogens) and estrogen antagonists (antiestrogens) is related to the transcriptional activation of specific estrogen-response elements. There appear to be two different domains of the estrogen receptor (AF-1 and AF-2) responsible for this transcriptional activation. Estrogen agonists and estrogen antagonists appear to act via different domains, resulting in their differential effects. Both appear to act to maintain bone density, at least partially, via regulation of the gene for transforming growth factor ß. It has further been suggested that there may be a raloxifene-response element, which is distinctly different from the estrogen-response element.

In women with osteoporosis, the 60-mg or 120-mg daily dose of raloxifene increases bone mass density in the spine and femoral neck and reduces the risk of vertebral fracture by 30% to 50% over no treatment. However, as with estrogen use, women receiving raloxifene have an increased risk of deep vein thrombosis compared with that seen in women receiving placebo.

Calcium and Vitamin D.

Calcium and vitamin D are important components of all three antiresorptive agents (calcitonin, bisphosphonates, SERMs). Decreased ability to absorb calcium among older

women is due, in part, to impaired vitamin D activation and effect. In addition, older women may have limited exposure to sunlight, and their dietary vitamin D intake may be lower than that of their younger counterparts. Daily calcium intake of

1,500 mg and 400 to 800 IU of vitamin D per day is probably sufficient to reduce the risk of fragility fractures by about 10%.

TABLE 42.1 Magnitude of Effect on Vertebral Fractures

Intervention	Number of Trials (patients)	Relative Risk (95% Confidence Interval)	P Value	Heterogeneity P Value
Calcium	5 (576)	0.77 (0.54–1.09)	.14	.40
Vitamin D	8 (1,130)	0.63 (0.45–0.88)	<.01	.16
Alendronate (5–40 mg)	8 (9,360)	0.52 (0.43–0.65)	<.01	.99
Etidronate (400 mg)	9 (1,076)	0.63 (0.44–0.92)	.02	.87
Risedronate	5 (2,604)	0.64 (0.54–0.77)	.01	.89
Calcitonin	1 (1,108)	0.79 (0.62–1.00)	.05	n/a
Raloxifene	1 (6,828)	0.60 (0.50–0.70)	.01	n/a

Osteoporosis Conclusions

Most current strategies regarding osteoporosis treatment have focused on identifying postmenopausal women who have low BMD and are already at increased risk for fracture. An evidence-based approach is to recommend appropriate calcium and vitamin D intake, smoking cessation, weight-bearing exercise, moderation in alcohol consumption, and fall prevention. If pharmacologic therapy is indicated, one of the above FDA-approved regimens should be instituted (Tables 42.1, 42.2). An alternative (complementary) approach to prevention is to focus on intervention beginning in childhood and adolescence, with attention to achieving maximal peak bone mass and minimizing premenopausal and postmenopausal bone loss.

TABLE 42.2 Magnitude of Effect on Nonvertebral Fractures

Intervention	Number of Trials (patients)	Relative Risk (95% Confidence Interval)	P Value	Heterogeneity P Value
Calcium	2 (222)	0.86 (0.43–1.72)	.66	.54
Vitamin D	6 (6,187)	0.77 (0.57–1.04)	.09	.09
Etidronate	7 (867)	0.99 (0.69–1.42)	.97	.94
Alendronate (5 mg)	8 (8,603)	0.87 (0.73–1.02)	.09	.31

Alendronate (10–40 mg)	6 (3,723)	0.51 (0.38–0.69)	<.01	.88
Raloxifene	2 (6,961)	0.91 (0.79–1.06)	.24	.43
Calcitonin	1 (1,245)	0.80 (0.59–1.09)	.16	n/a
Risedronate	7 (12,958)	0.73 (0.61–0.87)	<.01	.81
HRT	6 (3,986)	0.87 (0.71–1.08)	.10	.57
Fluoride	5 (950)	1.46 (0.92–2.32)	.11	.06

Cardiovascular Disease

CVD is the number one killer of both men and women in Western societies and is attributed primarily to age and lifestyle. Lifestyle modifications are well known to decrease the incidence of CVD. For women, CVD is largely a disease of postmenopause. Women will now spend more than one third of their lives beyond menopause, and preventive measures are paramount. A large body of observational evidence supports a protective effect of ERT on CVD. Observational data, however, are limited by the confounding variables of patient self-selection. Animal and in vitro studies, as well as assessment of surrogate markers in women, have shown a positive effect of estrogen and (less so) HRT against CVD development.

Approximately 2.5 million women in the United States are hospitalized each year for cardiovascular illness. CVD claims the lives of 500,000 women annually. One half of these deaths are due to CHD, making this the most frequent

cause of death among U.S. women. CVD can be separated into two categories: (a) CHD and (b) noncoronary CVD, such as stroke, valvular heart disease, peripheral vascular disease, congestive heart failure, and sudden death from cardiac causes.

A woman's risk of heart disease is far lower than a man's risk until after menopause. This change in incidence of heart disease may be related to advancing age, changes in hormonal milieu, or other unknown factors. CHD entails a worse prognosis for women than for men following either medical or surgical therapies. These sex discrepancies may reflect the older age, smaller body size, more frequent and severe coexisting illnesses of women, and perhaps a higher incidence of delayed or suboptimal care.

Chest pain or tachycardia may be overlooked as benign problems in women, seen instead as being potentially caused by depression, anxiety, or panic disorders. These misperceptions may lead to bias in evaluating women with chest pain, which also may have atypical clinical pictures compared with the more “classic” symptomatology in men. Chest pain, regardless of symptoms compatible with angina pectoris, warrants evaluation for CHD, regardless of sex.

If a woman seeks treatment for typical or atypical signs and symptoms of myocardial ischemia, a careful clinical history that includes assessment of cardiac risk factors should be taken. Electrocardiographic exercise testing is recommended for women who give a history typical of angina pectoris if the resting electrocardiogram findings are normal. When the resting electrocardiogram results are abnormal, the patient should be referred for either perfusion imaging studies or coronary arteriography. No screening test is of value for asymptomatic patients, even when risk factors are present.

Fewer symptomatic women than men undergo diagnostic coronary arteriography and therapeutic angioplasty or bypass surgery. Women who do undergo bypass surgery more often require emergency surgery and typically are sicker than men at the time of intervention. They have increased operative mortality rates and postoperative complications. It seems that women are referred for revascularization procedures at a later, more symptomatic stage of illness. Both coronary angioplasty and coronary bypass surgery have a comparable long-term survival for men and women who survive the initial hospital stay. ß-blockers and aspirin are equally efficacious in both sexes in preventing re-infarction after myocardial infarction.

Women should be encouraged to seek medical attention if they have any symptoms suggestive of myocardial ischemia. Physicians should emphasize the importance of modifiable risk factors for CHD, most notably weight management, fat restriction, increased physical activity, treatment of hypertension, and smoking cessation.

Randomized, controlled studies have failed to support a protective role for HRT. This is in conflict with earlier observational studies, studies utilizing surrogate markers, and animal studies. The differences may be due to the unbiased sample of subjects taking HRT in these newer studies and, hence, may be a more realistic reflection of the impact of HRT on CVD. However, other potential confounders may be present, even in these studies, such as the menopausal stage when treatment was begun, the particular HRT regimen selected, and the individual risk factors of each subject (although the results may be more reasonably generalized, this may not accurately reflect clinician practice).

The first reported trial evaluated HRT for secondary prevention. The HERS trial evaluated daily HRT (0.625 mg conjugated estrogen +2.500 mg MPA) in 2,763 postmenopausal women

with a mean age of 66.7 years and documented preexisting vascular disease. The study failed to demonstrate any overall difference in subsequent vascular events. This occurred despite improvements in lipid parameters in those patients receiving HRT. Although some have questioned the negative impact of the progestin in this trial, the Estrogen Replacement and Atherosclerosis (ERA) trial published in 2000 compared 3.2 years of treatment with estrogen, combined estrogen and progestin, and placebo. Study participants were postmenopausal women 42 to 80 years of age. This again was a secondary prevention trial and also failed to demonstrate a significant difference in the rate of progression of coronary atherosclerosis among the three groups. The importance of this study was the inclusion of an estrogen-only arm.

The WHI is the first large, randomized study to look at primary prevention. The same combined HRT regimen used in the HERS trial was evaluated. This study was stopped when interim analyses demonstrated an unacceptable risk profile for a drug in a prevention trial. There was an increase in the incidence in breast cancer (an increase of eight cases per 10,000 women), with no cardiovascular protection (and potentially increased cardiovascular risk). There was an increase in the absolute number of blood clots, strokes, and CHD. The risk of stroke and clot continued for the 5 years of study, while most of the CHD was limited to the first year of treatment. Whether these findings were related to the intrinsic properties of HRT, the oral administration route, or the unique regimen tested is not clear. There were, however, documented decreases in the risk of fracture and colon cancer. Ongoing reanalyses of the data from the WHI has begun to focus on the importance of patient age and time from menopause. Increasingly, data would seem to suggest that the initiation of hormone therapy, near the onset of menopause, not only is not harmful, but may offer cardiovascular advantage. Re-analysis of the Nurses' Health Study has likewise shown the importance of time from menopause to support the hypothesis that the vascular system may respond differently to estrogen based on the baseline atherosclerotic risk. Ongoing studies will assess earlier timing of estrogen treatment as well as differing routes of administration (oral vs. transdermal) in order to more fully address these issues.

Management of cardiovascular risk for women should parallel that for men. In other words, lifestyle modifications

---

should be made and antihypertensive therapy given as needed. If hyperlipidemia persists, statin therapy should be instituted. And, as noted previously, ß-blockers and aspirin should be given to prevent recurrent myocardial infarction. There is no evidence from well-designed prospective trials supporting a role for either ERT or HRT for the primary indication of cardiovascular protection.

Hormone Replacement

Introduction

Approximately 38% of U.S. women 50 to 74 years of age use HRT of some description. Of those surveyed, 59% of users had undergone a hysterectomy and 19.6% had a uterus. In 2000, Premarin (conjugated equine estrogen [CEE]) was the second most widely prescribed

drug in the United States, accounting for 46 million prescriptions and over $1 billion in sales. Historically, patients desiring hormone treatment for menopausal symptoms were supplemented initially with unopposed estrogen, regardless of the presence of a uterus. This therapy clearly was proven to increase a woman's risk of endometrial cancer, which was eliminated with the addition of either cyclic or continuous low-dose progestin. Women who have undergone hysterectomy can and should be treated with estrogen alone.

According to the FDA, approved indications for ERT-HRT include treatment of menopausal symptoms (e.g., hot flashes and genital tract atrophy) and the prevention of osteoporosis. During the past 30 years, it has become popular to prescribe ERT-HRT to prevent a range of chronic diseases, most notably heart disease. As above, evidence has been accumulating, which suggests that estrogen-progestin therapy for prevention of chronic diseases is not evidence based.

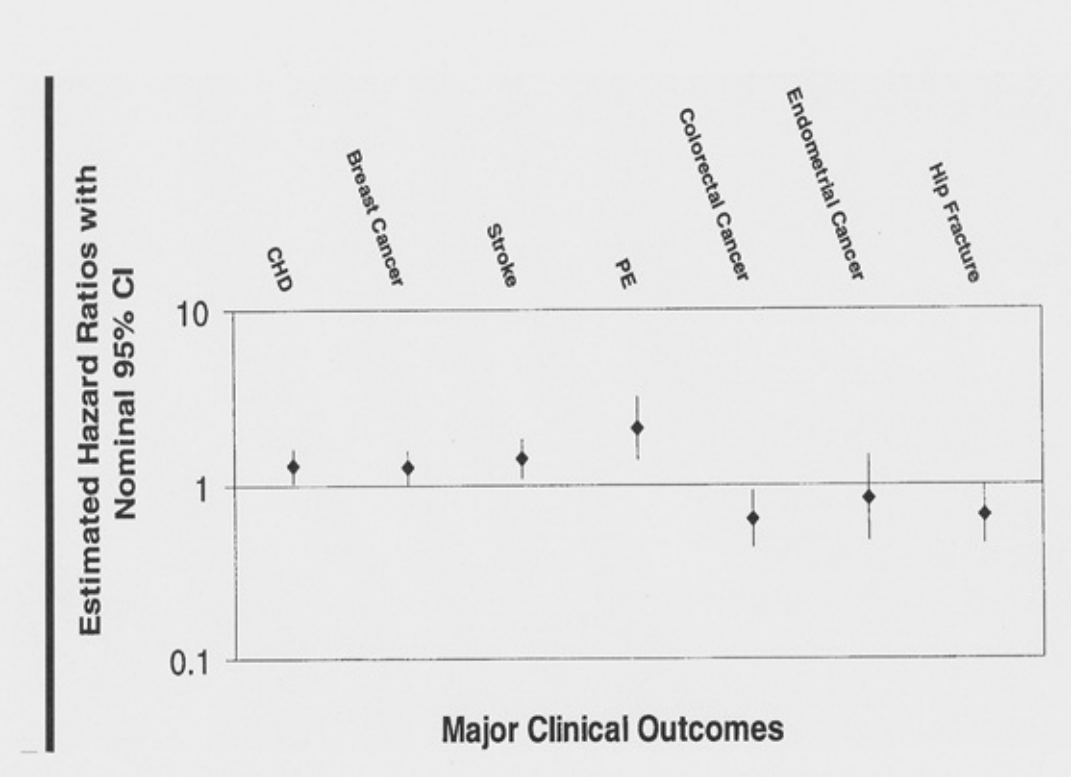

Figure 42.4 Estimated HRs for major clinical outcomes in the WHI trial of HRT. (CI, confidence interval; CHD, coronary heart disease; PE, pulmonary embolism.) (Writing Group for the Women's Health Initiative Investigators. From Grimes DA, Lobo RA. Perspectives on the Women's Health Initiative trial of hormone replacement therapy. *Obstet Gynecol* 2002;100:1344–1353, with permission.)

Benefits

With the publication of the WHI data, HRT risks and benefits have been examined critically (Fig. 42.4). HRT benefits include reduction in hot flash frequency and severity, improvement of atrophic vaginitis and UTIs, and prevention of osteoporosis and fractures.

Neither vasomotor symptoms nor vaginal atrophy were evaluated in the WHI, although likely occurrence was low because the participants were asymptomatic and not taking HRT when enrolled. The WHI results did support an additional benefit of decreased risk of colorectal cancer.

A variety of areas have been studied in postmenopausal women, including estrogen effects on depression and Alzheimer disease (AD). The cognitive benefits of HRT remain more controversial than benefits in other areas. A meta-analysis from 1998 incorporating all studies published between 1966 and 1997 suggests several mechanisms by which estrogen may affect cognition, including maintenance of neural circuits, favorable lipoprotein changes, prevention of cerebral ischemia, and promotion of serotonergic and cholinergic activity in the brain. It also is possible that cognition improves in estrogen users

during the menopausal transition because vasomotor symptoms improve, as there does not appear to be a clear benefit in asymptomatic women receiving HRT. The HERS data also support a cognitive benefit, concluding that the effects of HRT on emotional measures of quality of life depend on the presence of menopausal symptoms. The Seattle Midlife Women's Health Study showed that perceived memory functioning is more closely related to depressed mood, perceived stress, and perceived poor health than to age or reproductive stage.

AD is an enormous public health concern that intensifies as the population ages. In 1997, AD cases in the United States numbered 2.32 million, with 68% of individuals being female. In 1998, the annual number of new cases was 360,000. Interventions that could prevent this disease, or delay its onset, would have a major public health impact.

Women with high serum concentration of unbound (bioavailable) estradiol are less likely to develop cognitive impairment than women with low concentrations. Randomized trials studying estrogen use and AD are limited but suggest that estrogen users have a reduced risk of developing AD. However, there is no therapeutic benefit of estrogen usage in women with preexisting AD. Larger randomized trials are needed to evaluate the true significance of estrogen use and dementia. The WHI includes a memory study, and these results should be available in 2005. Recent animal data would suggest that the neuroprotective effect of HRT also may be dependent on the time from menopause (castration) when treatment is started, potentially explaining the unexpected negative finding in the WHI.

Risks

As more randomized trials of HRT are conducted, the risk profile has broadened. CHD was once a main off-label indication for HRT, and former guidelines from the American College of Physicians even suggested that HRT be considered for all women. The HERS trial and, more importantly, the WHI have shown that non-fatal cardiac events are increased in HRT users in the regimen tested. These studies have also reemphasized known risks of HRT, including pulmonary embolus, stroke, deep vein thrombosis, and gallbladder disease.

Controversies

Cardiovascular Disease

During the 1990s, HRT was prescribed increasingly to postmenopausal women for CHD prevention. Much of this enthusiasm was based on a meta-analysis published in 1992 that concluded, “there is extensive and consistent observational evidence that estrogen use reduces risks for CHD about 35%.” That same year, the American College of Physicians published guidelines recommending that all postmenopausal women should consider HRT. They emphasized that those who are at increased risk of CHD are especially likely to benefit. Further observational studies have supported this recommendation. For example, the Nurses' Health Study of 1996 confirmed a 40% to 60% reduction in cardiovascular events in women taking HRT.

The HERS was a randomized, blinded, secondary prevention clinical trial with results published in 1998. The study population was 2,763 postmenopausal women with documented CHD. The average age was 67, and all women had a uterus. Subjects were randomly assigned to receive either 0.625 mg CEE with 2.500 mg MPA daily or placebo. The average follow-up was 4.1 years. The investigators found that the women assigned to receive CEE plus MPA had a 50% increased risk of coronary events during the first year of the trial compared with that found in the placebo group. The risk was greatest during the first 4 months. The risk returned to baseline over the next 2 years and seemed to be lower in the hormone-treated group beginning in the third year of the study. The changes could have occurred by chance or may have been due to detrimental effects of the hormone replacement, the specific regimen studied, or the procoagulant effect associated with oral administration. An initial prothrombogenic effect was thought to be the cause of early morbidity, and there was some expectation that longer treatment would document an improved outcome. However, HERS II, which continued to follow this group (6.8 years of follow-up), failed to see a developing protective effect of HRT.

The WHI is the first randomized primary prevention trial studying the effects of a specific postmenopausal HRT regimen (the daily regimen of 0.625 mg CEE plus 2.500 mg MPA). In contrast to the HERS trial, these 50- to 79-year-old women were considered healthy, with only a small proportion (7.7%) of subjects having clinical signs or symptoms of CHD. The subjects were randomized to receive the HRT regimen or placebo if they had a uterus. Women without a uterus received either the estrogen alone or placebo. The planned duration of the trial was 8.5 years, but the estrogen-plus-progestin arm (16,608 women) was stopped after 5.2 years because of concerns regarding cardiovascular events and breast cancer. Data showed that “the test statistic for invasive breast cancer exceeded the stopping boundary for this adverse effect and the global index statistic supported risks exceeding benefits.” Estimated HRs for diseases other than breast cancer, including CHD, also were significant. The HR results were as follows: CHD, 1.29 (95% CI 1.02 to 1.63); breast cancer, 1.26 (1.00 to 1.59); stroke, 1.41 (1.07 to 1.85); pulmonary embolus, 2.13 (1.39 to 3.25); endometrial cancer, 0.83 (0.47 to 1.47); colorectal cancer, 0.63 (0.43 to 0.92); and hip fractures, 0.66 (0.45 to 0.98).

This important study suggests that breast cancer, nonfatal CHD events, stroke, and pulmonary embolus are all

significantly increased in the overall cohort, of women 50 to 79 years old using combined estrogen and progestin therapy. It showed that colorectal cancer and hip fracture risk are reduced significantly in the same group. Ultimately, the data suggest that the use of this combined HRT regimen for primary prevention of CHD is not justified.

In 2001, the American Heart Association published guidelines regarding HRT and CVD. While these recommendations were made prior to the publication of the WHI results, they currently remain in effect.

American Heart Association Recommendations

Secondary Prevention

- HRT should not be initiated for the secondary prevention of CVD.
- The decision to continue or stop HRT in women with CVD who have been undergoing long-term HRT should be based on established noncoronary benefits and risks and patient preference.
- If a woman develops an acute CVD event or is immobilized while undergoing HRT, it is prudent to consider thromboembolic prophylaxis while she is hospitalized to minimize risk of a venous thromboembolism associated with immobilization. Reinstitution of HRT should be based on established noncoronary benefits and risks as well as patient preference.

Primary Prevention

- Firm clinical recommendations for primary prevention await the results of ongoing randomized clinical trials.
- There are insufficient data to suggest that HRT should be initiated for the sole purpose of primary prevention of CVD.
- Initiation and continuation of HRT should be based on established noncoronary benefits and risks, possible coronary benefits and risks, and patient preference.

There is still some question about whether the WHI was really assessing “primary” prevention based on concern about the pre-existence of atherosclerotic disease. Enrollees were asymptomatic and older (mean age, 63 years) than the typical HRT-ERT user. Some vascular biologists have suggested that the early institution of HRT may inhibit the development of atherosclerotic plaque and that a delay in treatment for several years after menopause, after plaque formation is well established, would not only not offer benefit but might increase risk by destabilizing existing plaque, leading to plaque rupture and thrombosis. Although this thesis is consistent with animal studies, little human data are available to support or refute it. As noted previously, however, recent reanalyses of the WHI data suggest that time from menopause (length of estrogen deprivation) may in fact impact outcome with HRT treatment. Current ongoing trials of newly menopausal women

may help to answer these questions in order to better allow us to counsel our patients.

Breast Cancer

A woman's lifetime risk of breast cancer is 1 in 8. There are 192,000 new cases of breast cancer per year, accounting for 41,000 deaths per year. It is the second leading cause of cancer death after lung cancer and the leading cause of death among women ages 40 to 55.

The most compelling reason to believe that long-term use of postmenopausal estrogen increases the risk of breast cancer is the inherent biologic plausibility. Many of the risk factors associated with breast cancer are thought to be linked to increased duration of exposure to estrogen over a woman's lifetime. These risk factors include early menarche, late menopause, nulliparity, and older age at the birth of her first child. Oophorectomy can induce breast tumor regression, and early oophorectomy is protective against breast cancer, further supporting the notion that estrogen is involved. However, this remains controversial. All of these risk factors take ovarian function into account but not necessarily estrogen exposure, because the ovary is responsible for the formation of many other compounds that may influence the risk, such as progesterone and androgens.

The association of estrogen therapy and breast cancer remains controversial despite the publication of over 50 epidemiologic studies during the past 25 years. This subject is of great public health concern because of women's understandable fear of breast cancer and the complexity of the decision-making process regarding hormone therapy.

A re-analysis of the world's data on HRT-ERT and breast cancer was performed in 1997 by the Collaborative Group of Hormonal Factors in Breast Cancer. A team of epidemiologists invited all investigators who had previously studied the association of postmenopausal hormone use and the risk of breast cancer (51 studies) to submit their original data for a collaborative combined reanalysis, an undertaking more rigorous than a standard metaanalysis.

This analysis reached the following conclusions:

- Ever users of postmenopausal hormones had an overall increased relative risk of breast cancer of 1.14.
- Current users for 5 or more years had a relative risk of 1.35 (CI 1.21 to 1.49), and the risk increased with increasing duration of use.
- Current and recent users had evidence of having only localized disease (no metastatic disease), and ever users had less metastatic disease.
- There was no effect of a family history of breast cancer.
- There was no increase in relative risk in past users.
- The increase in relative risk in current and recent users was greatest in women with lower body weights.

The WHI has brought even greater attention to any relationship between breast cancer and

HRT use. The estrogen-progestin versus placebo arm of the study was stopped early, due primarily to an increase in breast cancer risk with a HR of 1.2. No similar effect was noted in the estrogen-only arm of the study, which is ongoing. Whether or not women in this category also will have an increased risk of breast cancer is unknown at this time. There is other epidemiologic evidence to suggest combined, continuous HRT may confer a higher risk of breast cancer than either cyclic estrogen-progestin regimens or those with estrogen only.

The comparison between the collaborative epidemiologic analysis described previously and the WHI is interesting (relative risk 1.35 vs. 1.26). Another relevant point the authors from the collaborative re-analysis make is that the quantitative effect of their conclusion is similar to the impact of raising the age of menopause. According to their calculations, current and recent hormone use was associated with a 2.3% increase in breast cancer risk per year, and the effect of age of menopause was equivalent to a 2.8% increase in risk per year of delay.

The presence of only localized disease, in the collaborative study, raises concern regarding screening bias and whether ERT-HRT treatment simply accelerated the detection of tumors already present. All of these studies that have examined the mortality rates of women who were taking estrogen at the time of breast cancer diagnosis have documented improved survival rates. This reflects earlier diagnosis in users, because the greater survival rate in current users is associated with a lower frequency of late-stage disease. There has been a suggestion that estrogen users develop better differentiated tumors and that the surveillance-detection bias is not the only explanation for better survival. This suggests that hormone treatment accelerated the growth of a malignant locus already in place, which appears clinically at a less virulent and aggressive stage. This data was somewhat contradicted in the Million Women Study, where current use increased not only cancer incidence but also cancer-related death. Past use, however, exhibited no increased risk of breast cancer, suggesting again that estrogen is not carcinogenic per se. There has been a great deal of controversy about the Million Women Study and those biases in an observational study, thus making interpretation difficult. There is strong suggestion in both the Million Women Study and the randomized WHI of an absolute risk of approximately 19 additional cancers per 1,000 women.

Selective Estrogen Receptor Modulators

The controversy regarding HRT-ERT has heightened the call for alternatives. The term *hormone/estrogen replacement* implies the replacement of the beneficial aspects of premenopausal estrogen. SERMs make up a class of compounds that act like estrogen agonists on some tissues and estrogen antagonists on others. SERMs act by causing dimerization and conformational changes in the estrogen receptor, altering the interaction with the promoter regions on DNA. These conformational changes further impact function through their interactions with coregulators and corepressors. This is illustrated in Figure 42.5.

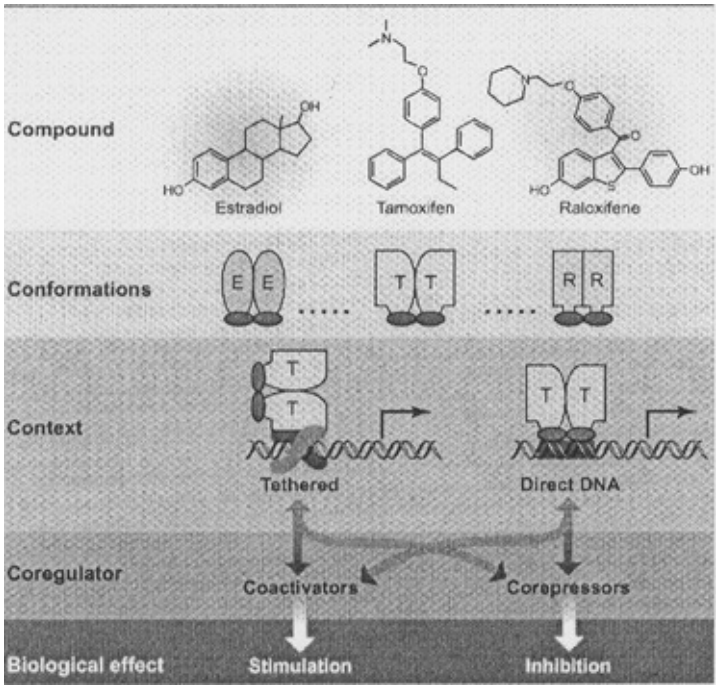

Figure 42.5 Differential SERM activity (stimulation and inhibition) is determined by the specific tissue, the endogenous milieu, and the impact of conformational changes on the interaction with regulatory sequences of DNA and coregulatory proteins (coactivators and corepressors). (*E*, estradiol; *T*, tamoxifen; *R*, raloxifene.) (From Katzenellenbogen BS, Katzenellenbogen JA. Defining the "S" in SERMs. *Science* 2002;295:2380–2381, with permission.)

The search for the "ideal" SERM, with positive (estrogenic) effects on the heart, bone, and brain and negative (antiestrogenic) effects on the breast and uterus, continues. Improved scientific knowledge regarding estrogen receptor function (more like a rheostat than an "on-off" switch), two receptor types (a and b), more than 50 transcription factors, over 20 modifying proteins, and different response elements should enhance the development of therapeutic agents for selective clinical applications.

The beneficial aspects of raloxifene, the most studied SERM, with respect to osteoporosis, already have been discussed. There are evolving data with respect to CVD. Both raloxifene and tamoxifen decrease total cholesterol and low-density lipoprotein levels. Neither has an effect on high-density lipoprotein or triglyceride levels. Interestingly, raloxifene is either neutral or decreases two inflammatory markers (homocysteine and C-reactive protein), which might participate in the increase in cardiovascular events seen with the institution of HRT-ERT.

The available data about SERMs and CVD are, again, based on surrogate markers. A prospective study, Raloxifene

Use in The Heart (RUTH), has recently reported its finding in 10,101 postmenopausal women with established CVD and/or multiple risk factors for CVD. Given evolving knowledge about the importance of timing with respect to estrogen treatment and CVD risk, it is perhaps not surprising that no benefit of raloxifene in this population was noted. There was, however,

an absolute risk reduction in invasive breast cancer of 1.2 cases in 1,000.

Limited data have suggested that SERMs may have a beneficial effect on cognition. Although raloxifene is known not to improve (and potentially worsen) vasomotor symptoms, there is some preliminary evidence to suggest a neuroprotective effect. The extent and mechanism of this effect is not well characterized and awaits further study.

There is no doubt that the available SERMs are antiestrogenic at the breast. Tamoxifen is used primarily in the United States for cancer chemoprevention and treatment. Raloxifene also appears to decrease the incidence of estrogen receptor-positive cancer development. The Study of Tamoxifen and Raloxifene (STAR) should yield direct information regarding the benefit of raloxifene in women at risk for breast cancer as the available data are derived from osteoporosis trials. Lastly, it should be remembered that both tamoxifen and raloxifene increase the risk of thromboembolic phenomena, and this may have an impact on cardiovascular risk.

Conclusion

The WHI did not address the effect of hormone treatment on hot flashes and vaginal atrophy. Clearly, there are alternatives for the treatment of osteoporosis and CVD that have less risk if CVD prevention is the sole reason for using HRT. Each woman should discuss with her health care provider the optimal treatment management to address her individual goals. This obviously would need to take into account medical and family history as well as symptomatology.

If HRT-ERT is selected by the patient, progestin should be used only for those women with a uterus. Furthermore, in developing an overall treatment strategy, physicians should utilize the full armamentarium of medications (conjugated estrogens, estradiol, MPA, norethindrone, micronized progesterone, and androgens), routes of administration (oral, vaginal, transdermal), and cyclic patterns (continuous, intermittent, monthly, quarterly) available, including low-dose aspirin and statins. Duration of hormone therapy would be an individual decision based on the original indication for treatment and its persistence. It can be recommended uniformly that menopausal women maintain appropriate nutrition, a healthy body weight, and regular exercise, including both weight-bearing aerobic exercise and muscle-strengthening exercise. This should be associated with moderation in alcohol intake and cessation of smoking.

Summary Points

- Estrogen production in women is related to follicular maturation, and the number of ovarian follicles is fixed, with declining numbers of follicles associated with hypoestrogenism.
- Declining ovarian estrogen production is associated with vasomotor instability, hot flashes, urogenital tract atrophy, and accelerated loss of BMD.
- Treatment of the symptoms associated with declining ovarian estrogen production is optimal with ERT in women without a uterus

and in estrogen with progestin regimens in women with a uterus.

- Although primary or secondary prevention of CVD has been suggested in observational studies, it has not been demonstrated in randomized treatment trials (HERS and WHI).
- The time of initiation of hormone therapy following menopause may be critical with respect to associated cardiovascular and neurologic risk.
- A small absolute increase in the risk of breast cancer has been associated with HRT.
- Decisions regarding the use of ERT-HRT should be individualized, based on the woman's goals of therapy, and reevaluated periodically to ensure that the risk–benefit analysis continues to favor hormone use.

Women's Sexuality and Sexual Dysfunction

Rosemary Basson

> *Sexual rights … include the right of all individuals … to (achieve) the highest attainable standard of health in relation to sexuality and to pursue a satisfying, safe and pleasurable sexual life.*
>
> —World Health Organization Working Definition, 2002

That sexual function is a legitimate aspect of medicine is clearly shown in the above declaration of sexual rights. National probability samples and clinical studies from many countries confirm that most men and women consider their sexual well-being as important. Nevertheless, studies suggest that fewer than one third of women who experience ongoing sexual problems have had these problems addressed by their physician. Moreover, the majority of women consider it appropriate for their physicians to take the initiative to inquire about sexual health, and a recent study of older minority women attending a primary care practice confirmed that significantly more would identify their sexual problems if the physician used an introduction such as “Many women after menopause have sexual problems, how about you?” Recent data show that regardless of any surgery-associated sexual changes, satisfaction with a hysterectomy increases if there is preoperative assessment of sexual function along with information about possible positive and negative effects on sexuality from a hysterectomy. In order to assess and manage common sexual dysfunctions, it is necessary for gynecologists and primary care physicians to understand women's variable sexual responses and some of the differences between men and women's sexuality.

Women's Sexual Response Cycle

There are different phases of sexual response, including desire, arousal, and orgasm followed by relaxation and well-being. However, particularly in women, these phases are not discreet, nor is their order invariable. Especially when in established relationships, women mostly initiate sex or accept their partner's invitation without any marked sense of sexual desire at that time. Qualitative research has clarified many of the reasons a woman instigates or accepts sexual engagement such as the enhancement of emotional closeness with her partner, finding herself responding to a romantic environment and, more

specifically, to erotic cues. Other reasons include wanting to feel better about herself, more normal, more loved, more committed to the relationship, to conceive, and sometimes for more nefarious reasons. Sexual desire, as typified by sexual fantasizing, positively anticipating sexual experiences, and spontaneously needing partnered sex or self-stimulation, has a broad spectrum of frequency across women. It is also clear that such overt desire is infrequent in many sexually functional and satisfied women.

The sexual response cycle, then, may or may not feature desire initially; rather, the woman may be motivated by other reasons, including wanting to be emotionally close to her partner such that she deliberately attends to sexual stimuli, and as a result of subsequent subjective arousal (excitement) and pleasure, feelings of sexual desire are triggered. Desire and arousal then coexist and compound each other, as shown in Figure 43.1. Provided that the duration of stimulation is sufficiently long and that she continues to attend to the stimuli and continues to feel pleasure, sexual satisfaction follows with one, many, or no discreet orgasms, thereby fulfilling her newly acquired sexual desire. Her original motivations and goals that encouraged her to be sexual initially will also be achieved. So, the response is circular with overlapping phases of variable order. Desire may follow arousal, and high arousal may follow the first orgasm. Desire, once triggered, can increase the motivation to attend to sexual stimuli and to accept or request

more intensely erotic forms of stimulation. Any initial or spontaneous desire also will augment the response at many sites in the circle. This circular response cycle also reflects male sexuality: however, data indicate that men begin with a sense of desire far more frequently than do women.

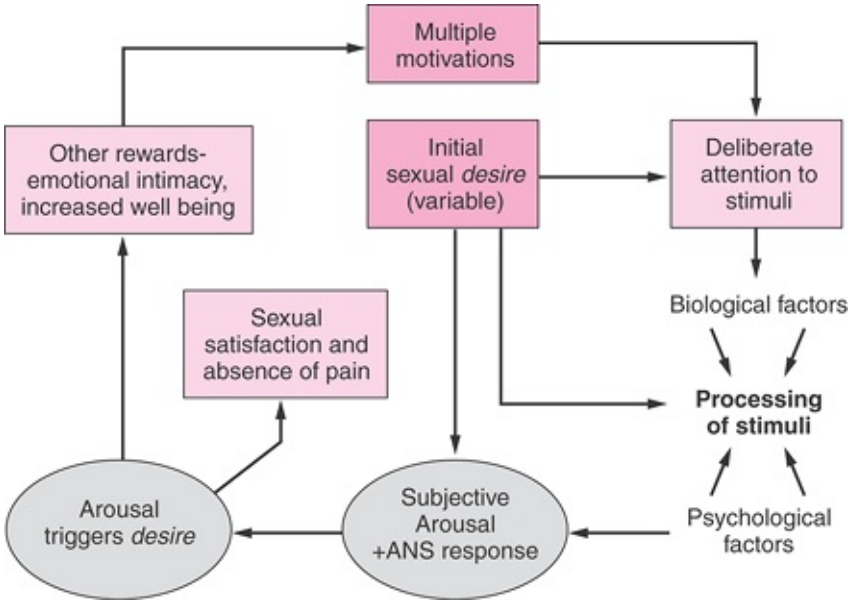

Figure 43.1 Circular response cycle of overlapping phases: desire may not be present initially but triggered instead during experience. The sexual and nonsexual outcome influences future sexual motivation. (ANS, autonomic nervous system.) (Adapted from Basson R. Female sexual response: the role of drugs in the management of sexual dysfunction. *Obstet Gynecol* 2001;98(2):350–352, with permission.)

Contained in the model shown in Figure 43.1 is the concept of arousability, meaning the ease with which the woman is aroused by sexual stimuli. This concept is important given the evidence that many factors modulate arousal, including feeling desired rather than feeling used, feeling accepted by the partner, finding the partner's behavior attractive, having a positive body image and positive mood, and having positive sexual experiences in the past as well as biologic factors such as testosterone, thyroid, and prolactin.

Complexities of Women's Sexual Arousal

The evidence-based conceptualization of women's sexual response shown in Figure 43.1 emphasizes subjective arousal rather than genital congestion per se. In the past, women's arousal was equated to vaginal lubrication and vulval swelling (as in the definitions of sexual disorders in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*). More accurately, lubrication is an epiphenomenon. Some lubrication is necessary when intravaginal stimulation is part of a couple's interaction, but neither lubrication nor genital swelling nor the degree of underlying congestion correlate well with subjective arousal on empirical testing. This has been demonstrated repeatedly during the past 30 years by using a tamponlike device (vaginal photoplethysmograph [VPP]) that measures increases in genital congestion while a woman watches an erotic video and rates her subjective excitement simultaneously with the measures of congestion. Women with chronic complaints of low arousal typically show VPP measures identical to control women while watching erotic videos but report no subjective excitement. Similarly, according to preliminary studies, there is little correlation between increases in clitoral volume, as measured by magnetic resonance imaging (MRI), or ultrasound-measured increases in clitoral blood flow and women's subjective arousal as they view erotica. Unlike penile erection in men, genital congestion in women does not robustly reinforce their subjective excitement.

Women's genital congestion appears to be automatic and nonselective. Women (but not men), when watching visual stimuli that were considered by healthy volunteers to be sexual but not erotic or arousing (videos of primates mating), had evidence of genital congestion in response to the stimulus. Both lesbian and heterosexual women show substantial genital response to both preferred and nonpreferred genders depicted in erotic videos. However, men show patterns of responding that correspond to their preferred gender.

Physiology of Women's Sexual Response

Physiology of Desire and Subjective Arousal

Feelings of sexual desire can be triggered by internal cues such as memories of sexual experiences or by external ones such as a romantic environment and are dependent on certain, and as yet not fully understood, biologic mechanisms. Multiple neurotransmitters, peptides, and hormones modulate desire and subjective arousal: noradrenalin, dopamine, melanocortin, oxytocin, and serotonin acting on some serotonin receptors are prosexual,

are inhibitory. There is complex interplay between the neurotransmitters and peptides and the sex hormones. There also is complex interplay between environmental and neuroendocrine factors. For instance, even in animal models, either dopamine or progesterone can act on receptors in the hypothalamus to cause an increase in sexual behavior in the oophorectomized estrogenized female rat. Of note, however, is that the presence of a male animal in an adjacent cage can cause an identical change in sexual behavior without the administration of either progesterone or dopamine. One corollary in women is that intensity of sexual response can be increased by raising serum testosterone levels in midlife women to those of younger women, by administering a dopaminergic drug such as bupropion, or by beginning a new relationship with a new partner. Animal experiments also demonstrate how the female assesses the context of potential sexual activity, relates it to past experience and therefore to expectation of reward, and adjusts her sexual behavior accordingly. In women, it is known that factors such as attitudes to sex, feelings for the partner, past sexual experiences, duration of relationship, and especially mental and emotional health more strongly modulate desire and arousability than do the biologic factors that have been investigated so far. It should be noted, however, that the data supporting the issues mentioned stem from nationally representative samples of women, not specifically from women with chronic disease, who may make up a large percentage of a gynecologist's practice. The disease itself and its treatment as well as its psychologic effects can all add to the interpersonal, personal, and contextual issues mentioned that impact on sexual response.

Physiology of Physical Sexual Arousal

Physical changes of sexual arousal include increases in blood pressure, heart rate, muscle tone, respiratory rate, and temperature in addition to genital swelling, increased vaginal lubrication, breast engorgement, nipple erection, increased skin sensitivity to sexual stimulation, and a characteristic mottling of the skin or “sexual flush” consisting of vasodilation over the face and chest. The response of the autonomic nervous system increasing blood flow to the vagina occurs within seconds of a visual sexual stimulus. There is increase in blood flow through the arterioles supplying the submucosal vaginal plexus, which increases the transudation of interstitial fluid from the capillaries across the epithelium and into the vaginal lumen. This rapid transit alters the electrolyte composition such that there is less potassium and more sodium than in the lubrication fluid in the unaroused state. There also is relaxation of smooth muscle cells around the blood spaces or sinusoids in the clitoral tissue. The latter includes the rami, shaft, and head of the clitoris as well as the extensions of clitoral tissue known as vestibular bulbs. As the clitoris becomes more swollen, the shaft elevates to lie near the symphysis pubis. The inner two thirds of the vagina lengthen and extend, elevating the uterus. It has been hypothesized that during intercourse, penile thrusting on the cervix might cause reflex contraction of the pelvic muscles, thereby facilitating the “ballooning” of the upper vagina, while the same muscle contraction constricts the lower vagina. This is described as a “cervical motor

reflex," whereby touch to the cervix reduces pressure in the upper portion of the vagina and increases pressure in the middle and lower portions with documented increased electromyographic activity in the levator ani. It is possible that the elevation of the uterus for sexual arousal is in part due to a further recently described reflex. Reduced uterine tone has been demonstrated in response to mechanical or electrical stimulation of the clitoris. It was apparent that clitoral stimulation abolished the background tonic uterine muscle contraction, such that uterine pressure declined. External changes include swelling and darkening of the labia minora. The increased congestion of the introitus actually narrows its diameter.

Neurotransmission of genital congestion is incompletely understood. Far more studies have been done to clarify male genital sexual physiology than female. The major neurotransmitter involved in clitoral engorgement is nitric oxide (NO), which is released from parasympathetic nerves along with vasointestinal polypeptide (VIP). Simultaneously, acetylcholine (Ach), which blocks noradrenergic vasoconstriction and promotes NO release from the endothelium, is released. Somatic, sympathetic, and parasympathetic nerve pathways are far less separate from each other than was formerly believed. There is documented communication between the NO containing cavernous nerve to the clitoris and the distal portion of the somatic dorsal nerve of the clitoris from the pudendal nerve. Recent work shows that input from the ganglia of the caudal sympathetic chain containing noradrenalin and perhaps neuropeptide Y produces, as one would expect, vasoconstriction by the way of α-adrenergic and peptidergic receptors. On the other hand, input from the hypogastric nerve (sympathetic) passing through ganglionic relay stations in the pelvic plexus can produce vasodilation and vulval congestion as well as the opposite. Of note is that an increase in sympathetic tone brought on by exercise, hyperventilation, or experimental ephedrine administration increases the physiologic arousal response of genital congestion. Similarly, in sexually functional women, the prior viewing of visual triggers that provoke anxiety increases the physiologic genital arousal response to subsequent erotic visual cues.

Neurology of Clitoral Sensitivity

The clitoris is the most sexually sensitive structure, but there is little research into the transmission of sexual sensation. Recent immunohistologic studies have confirmed neurotransmitters thought to be associated with sexual sensations (substance P and calcitonin gene-related peptide [CGRP]), concentrated directly under the epithelium of the glans. It is important to note that clitoral stimulation is usually enjoyable only if nonphysical and nongenital physical stimulation have previously occurred. Without

existing arousal, direct stimulation can be unpleasant, too intense, and even painful.

Physiology of Orgasm

The physiology of orgasm remains unclear. Definitions are not established but include "a psychic phenomenon, a sensation (cerebral, neuronal discharge) elicited by the accumulative effect on certain brain structures of appropriate stimuli originating in the

peripheral erogenous zones" or "the acme of sexual pleasure of rhythmic contraction of perineal/reproductive organs, cardiovascular, and respiratory changes, release of sexual tension." Given that men and women with complete spinal cord injury can experience orgasm, it currently is considered that orgasm primarily is a cerebral event. Recent positron emission tomography (PET) has shown women's orgasm to be mainly associated with profound decreases of cerebral blood flow in the neurocortex compared with control conditions (clitoral stimulation and imitation of orgasm), particularly in the left lateral orbitofrontal cortex, inferior temporal gyrus, and anterior temporal lobe. Measuring extracerebral markers of orgasm, such as rectal pressure variability, showed significant positive correlations between the rectal pressure variability and cerebral blood flow in the left deep cerebellar nuclei. Thus, it currently is proposed that decreased blood flow in the left lateral orbitofrontal cortex signifies removal of behavioral inhibition during orgasm and that deactivation of the temporal lobe is directly related to high sexual arousal. The deep cerebellar nuclei may be involved in motor activity—the orgasm-specific muscle contractions, but as well the cerebellum is now known to be involved in emotions and integrating sensory information. It also is possible that involvement of the ventral midbrain and right caudate nucleus is indicative of a role for dopamine in female sexual arousal and orgasm. The cerebral changes lead to reduction of inhibitory serotonergic tone from the nucleus paragigantocellularis to the so-called orgasm center in the lumbosacral cord.

The sexual stimulus eliciting orgasm may be to the genitalia but also may be to the breasts and nipples or from sexual fantasy or sexual dreams. Women with complete spinal cord injury above spinal cord level T10 can have orgasms from vibrostimulation of the cervix, possibly mediated by branches of the vagus nerve. Damage to the pelvic autonomic plexuses from radical hysterectomy, for instance, does not preclude orgasm. The necessary autonomic nerves probably travel with somatic fibers S2, S3, and S4. Branches from the sympathetic ganglia to the union of S2, S3, and S4 parasympathetic and somatic fibers proximal to the superior hypogastric plexus have been identified. Despite clinical impressions to the contrary, weakening of the pelvic floor from vaginal deliveries has not been scientifically proven to correlate with sexual dysfunction. In keeping with the known physiology of orgasm, the most common drugs that impede orgasm are the selective serotonin reuptake inhibitors (SSRIs).

Uterine contractions accompany orgasm, and a subset of women report altered orgasms after hysterectomy. The contractions of the pelvic floor muscles around the vagina during orgasm are variably perceived by women, and studies show the rhythmic contractions extend over many more seconds than the period of time during which women can feel their occurrence.

Physiology of Later Stages in Sexual Response: Relaxation and Well-being

There is little study of the neuropharmacology of the later stages in sexual response. The body gradually returns to its baseline state, and genital vasocongestion reverses. Any functional role of oxytocin or prolactin has yet to be established in humans. Increases in oxytocin with arousal have been inconsistently reported, and the more consistently

reported increases in prolactin after orgasm have not been shown to have functional implications.

Role of the Cervix

The role of the cervix in sexual function has been widely debated. It has a rich vascular and nerve supply such that its loss might negatively affect sexual pleasure and the physiology of genital arousal. The recent studies comparing vaginal and subtotal or total abdominal hysterectomies do not support a role for preservation of the cervix to enhance women's sexual function. Three studies were published in 2003. First, a prospective observational study of 145 women receiving abdominal hysterectomy, 89 receiving vaginal hysterectomy, and 76 receiving subtotal hysterectomy showed that there were no differences in sexual outcome among the three surgical methods. Second, a prospective randomized trial of 158 women having total abdominal hysterectomy and 161 having subtotal abdominal hysterectomy also showed no differences in sexual outcomes. The third was a retrospective study of 125 women undergoing classic intrafascial supracervical hysterectomy and 128 receiving total hysterectomy: no sexual benefits of CISH over total hysterectomy were reported. A subsequent randomized study of supracervical and total abdominal hysterectomy involving 135 women indicated similar sexual function during 2 years of follow-up. Another recent study included two control groups of women who did not undergo hysterectomy: one received minor gynecologic surgery, and the other was a healthy nonsurgical control group. Laparoscopic-assisted vaginal hysterectomy (total hysterectomy) was compared with laparoscopic subtotal hysterectomy. Both groups reported some improvement in sexual function, and both the surgical and normal control groups reported similar sexual complaints with similar frequencies as the hysterectomy groups. Similarly, hysterectomy would appear to be most often associated with improved sexual function. Detailed analysis of the small

---

percentage of women who report deteriorated sexual function after hysterectomy has not been done. It may well be that adverse effects cannot solely be attributed to hysterectomy given the above study, which included the two control groups.

Graefenberg Spot

An unknown proportion of women report that massaging the anterior vaginal wall approximately one third of the way up from the introitus causes increasingly intense sexual pleasure, arousal and may lead to orgasm. It currently is thought that it is the massaging of the periurethral erectile tissue (the equivalent of the corpus spongiosum around the male urethra in the penis) that underlies this phenomenon. There is no anatomical evidence of any structure to correspond to a specific “spot.”

Sex Hormones and Sexual Response

Androgens

The evidence for the role of testosterone in women's sexual response is mainly indirect.

Sudden loss of androgen can, in an unknown percentage of women, result in a syndrome whereby formerly useful sexual stimuli—mental, visual, or physical genital or nongenital or intercourse itself—all fail to arouse. Any former awareness of genital swelling, tingling, throbbing, and vaginal lubrication is now absent. Any former apparently spontaneous sexual thinking and desire also is lost. Clinicians report frequent association of chemotherapy-induced or surgical menopause with this syndrome. Nevertheless, other women with induced menopause report no sexual changes, and three recent prospective nonrandomized studies of women requiring hysterectomy for benign disease and electing to keep or not keep their ovaries show no deterioration in sexual function in those choosing oophorectomy. The indirect evidence is that supplementing postmenopausal estrogenized women diagnosed with hypoactive sexual desire, with testosterone such that their serum levels match or slightly exceed those of healthy young women, is associated with increased sexual response as well as increased desire.

Evidence correlating sexual function with serum androgen levels in either premenopausal or postmenopausal women with or without sexual dysfunction is lacking. There was minimal correlation between total testosterone and free androgen index (FAI) and sexual function in the study of 2,900 pre- and perimenopausal multiethnic North American women 42 to 52 years of age in the Study of Women's Health Across the Nation (SWAN). Similarly, measures of free and total testosterone failed to correlate with sexual function in a study of 1,021 Australian women 18 to 75 years of age. In that study, a low score for sexual response for those over 45 years was associated with higher odds of having a dehydroepiandrosterone sulphate (DHEAS) level below the tenth percentile for this age group. However, the majority of women with low DHEAS levels did not have reduced sexual function.

At this time, research is focusing on testosterone, which is produced intracellularly (i.e., within brain and other cells from ovarian and adrenal precursors). These precursors or “prohormones” include androstenedione and dehydroepiandrosterone (DHEA) from both the adrenals and ovaries (as well as DHEAS and androst-5-ene-3β, 17β-diol from the adrenal glands) and account for at least 50% of testosterone activity in younger women; the majority of testosterone activity in older, naturally menopausal women; and close to 100% in surgically menopausal women. From the third decade on, adrenal prohormone production progressively declines such that in the 50 to 60 year-old-age group, serum DHEAS has decreased by some 70% compared with peak values of the late 20s. How much individual variation there is is not yet known. It also is difficult to measure the cellular deprivation in an individual woman: <10% spills back into the bloodstream, so serum levels of testosterone reflect mainly gonadal production. To complicate the situation further, the assays available to date for free, bioavailable, and total testosterone are not designed for the female range and have proven very unreliable. Mass spectrometry methods or equilibrium dialysis for the measurement of free testosterone are recommended but are rarely available to clinicians and have often not been chosen by researchers. Currently, metabolites resulting from the breakdown of testosterone—wherever it has been produced—can be measured. These metabolites include androsterone glucuronide (ADT-G); androstane 3α, 17β-diol glucuronide (3α-diol-G); and androstane 3β, 17β-diol glucuronide (3β-diol-G). At this time, these are available only on research basis, and age-related values

in women with and without dysfunction are only now being established. Whether total androgen activity as measured by testosterone metabolites correlates with sexual function is currently under investigation. Also, the relative importance of total androgen activity needs to be compared with the importance of psychosocial variables, including the interpersonal relationship.

Estrogen

Any role of estrogen in sexual desire and arousability remains in question. One recent study showed sexual responsivity (a measure of desire and intensity of response) to be improved in Australian women receiving estrogen therapy, provided the estrogen serum estradiol levels reached between 650 and 758 pmol/L—approximately twice the level required to improve local symptoms of vaginal dryness. It is also unclear if the documented effect of supplemental testosterone to increase desire and arousability is via the androgen receptor or via the estrogen receptor after aromatization. One recent study suggests that benefit is via the androgen receptor, as the addition of an aromatase inhibitor did not reduce the benefit of supplemental testosterone. This was in a study of postmenopausal women receiving

---

transdermal estrogen therapy and additional testosterone to benefit loss of sexual desire. It also is possible that testosterone allows benefit mainly by reducing sex hormone–binding globulin (SHBG), thereby freeing estrogen to become more bioavailable.

Estrogen is necessary to maintain healthy vaginal epithelium, stromal cells, and smooth muscles of the muscularis as well as thickness of the vaginal rugae. Genes activated by estrogen and estrogen agonists include those that have a role in vascular response such as NO synthase and prostacyclin synthase. Estrogen's beneficial effects on lipids add to estrogen's potential vascular benefit.

The role of estrogen locally in genital tissue health requires further research. The pallor of vulvovaginal atrophy is sometimes obvious, but this does not necessarily correlate with symptoms of vaginal dryness and dyspareunia. Estrogen levels do directly correlate with the ratios between parabasal, intermediate, and superficial vaginal cells as in the maturation index. However, estrogen levels and duration of estrogen lack correlate poorly with sexual symptoms. The latter can occur perimenopausally and yet sometimes only decades postmenopause. Possibly, a confound is the permeability of vaginal epithelial cells; nerve endings containing CGRP are present in the vaginal epithelial cells and may modulate their permeability. It is of note that studies show that the prevalence of dyspareunia correlates with urinary incontinence, perceived stress, hostility, and depression as well as with vaginal dryness.

Low estrogen levels increase the pH of the vaginal lumen. There is evidence that vaginal and ectocervical cells acidify the lumen by the secretion protons across the apical plasma membrane. It is thought that this active proton secretion occurs throughout life but that it is up-regulated by estrogen. It was formerly thought that the low pH was maintained by hydrogen peroxide and protons secreted by Doderlein lactobacilli in the estrogen-replete tissues. Vaginal and urinary tract infections are more common when the pH increases, and

these infections undermine women's sexual self-confidence and contribute to dyspareunia.

Reduced sexual sensitivity of nongenital skin and the breast has received little scientific study. There is a small amount of research using pressure thresholds to demonstrate reduced vulval sensitivity postmenopause. Recently, both age and postmenopausal state have been associated with reduced vibratory sensation of the genital tract. It was also shown that age by itself affects peripheral nongenital sensation.

The pathophysiology underlying the complaint of “genital deadness,” giving rise to the syndrome known as genital arousal disorder, is unclear. Of women with this complaint, only a subgroup has demonstrably reduced genital vasocongestion in response to erotic visual stimulation. So, for some women, the genital structures are congesting apparently normally, yet their stimulation is no longer sexually arousing. Any role of reduced androgen activity awaits scientific study.

Estrogen production markedly decreases with menopause: ovarian production is minimal. The intracellular production of estrogen from testosterone, DHEA, DHEAS, and androstenedione depends on adrenal and ovarian production of these precursors, the numbers of fat cells (an important site of aromatization of testosterone to estradiol), and the activity of the appropriate steroidogenic enzymes to synthesize estrogen from the precursors in the tissue concerned. Therefore, in midlife and older women, the importance of local biosynthesis of sex hormones applies to estrogens as well as to androgens, although a reliable parameter of total estrogen activity comparable to the glucuronides identified for androgens has yet to be determined.

Estrogen-deplete states include not only post natural and surgical menopause but postpartum, in association with use of gonadotropin-releasing hormones (GnRH) agonists and some low-estrogen contraceptives, and is particularly marked in postmenopausal women receiving aromatase inhibitors for breast cancer.

Progesterone

Any role of progesterone in the sexual response of the human female remains to be clarified. Based on clinical experience, synthetic progestins may sometimes reduce sexual desire and arousability, and mood alteration may be partly responsible. Another confound is the increased SHBG when progestins are combined with estrogens in oral contraceptives. Progesterone, as opposed to progestins, has some anxiolytic properties such that increased well-being from improved sleep with associated increased sexual interest may benefit some postmenopausal women who are receiving nightly progesterone.

Dopamine

Dopamine is regarded as facilitory to sexual response and sexual desire. A small randomized controlled study of women who were not depressed but were diagnosed with hypoactive sexual desire disorder showed improvement in sexual response (but not in desire) in those receiving bupropion, a drug with both noradrenergic and dopaminergic activity. It is unknown how often anti-parkinsonian medications, which are dopaminergic, increase sexual desire in women. There is anecdotal report, but far more commonly,

women with Parkinson disease complain of low sexual desire (despite medication). Although at higher doses and chronic use cocaine impairs sexual function, an acute lower dose may increase sexual pleasure, which may be via its dopaminergic activity.

Prolactin

Women with hyperprolactinemia commonly present with menstrual irregularities, infertility, and galactorrhea rather than with sexual dysfunction. Nevertheless, studies have shown that hyperprolactinemic women without depression or other hormonal disorders report lower scores for sexual desire, response, and satisfaction than do controls.

Hyperprolactinemia is sometimes associated with primary hypothyroidism that can independently decrease sexual function or with hypopituitarism such that reductions in estrogens, androgens, and glucocorticoids as well as thyroxin can be relevant.

Sexual Dysfunction

Risk Factors

A number of factors have been shown to correlate with women's sexual function and satisfaction, the most robust correlations being with mental health, the sexual relationship, and partner sexual function.

Mental Health

Low desire and arousal is linked not only to clinical depression but to dysthymia with lack of mental well-being associated with low self-esteem and frequent anxious and depressed thoughts. Lack of emotional well-being was one of the stronger predictors of women's distress about sex in a recent North American probability sample. A history of past recurrent clinical depression has been found to be associated with reduced sexual arousal, sexual pleasure, and both physical and emotional dissatisfaction. This was true even when controlled for current mood, medications, marital status, and substance abuse. Unfortunately, antidepressants may further inhibit sexual response and desire, although for many women, treating their depression ameliorates their sexual difficulties. Of note, depressed women may masturbate more frequently when depressed.

Sexual Relationship

Extensive study of the psychosocial factors affecting the sexual response of 926 Swedish women 18 to 65 years of age has shown that satisfaction with the partner relationship is one of the two most prominent factors influencing presence or absence of dysfunction. Similar results stem from studies of midlife women, including those studied longitudinally across the menopause transition.

Partner's Sexual Function

The partner's sexual function was the second factor in the recent Swedish study that proved to have a robust association with women's sexual function and satisfaction. Other studies have corroborated these findings, and of note, for older women, the main reason to cease sexual activity is lack of a sexually functioning partner.

Personality Factors

There are clinical reports of women with orgasmic disorder being typically extremely uncomfortable in conditions where they are not in control of their circumstances or of their body's reactions. Characteristics including a marked fear of negative evaluation by others, marked self-criticism, increased somatization, and catastrophizing have been found in studies of women with vulvar vestibulitis syndrome (VVS). For the majority of women with vaginismus, there is a phobic quality to their fear of vaginal penetration, whereas other phobias are not reported to be increased beyond controls.

Duration of Partnership

Ease of response and heightened desire is typical of new relationships. Studies indicate that even after just 1 year, sexual desire declines in women but not in men, whereas desire for tenderness declines in men and rises in women. Clinically, it often is seen that the sexually symptomatic heterosexual woman in a longer-term committed relationship reports that her partner is not emotionally intimate with her—not willing to reveal his feelings, hopes, and fears.

Infertility

The goal-oriented approach to sex while trying to conceive, such that intercourse is scheduled and possibly desired by neither partner, can lead to sexual dysfunction. Emotional intimacy is disrupted by the stress of multiple tests and waiting for results. Women report that intense evaluation and need of assisted reproductive techniques can have negative effects on their self-image and body image as well as on their feelings of sexual self-worth. Unfortunately, these changes do not always reverse even with a successful pregnancy. Feelings of resentment are not uncommon given the fact that women receive multiple procedures and men typically undergo one semen analysis.

Drugs

Drugs with sexually negative effects include antidepressants, most typically the SSRIs, narcotics, GnRH agonists, low-estrogen contraceptives, aromatase inhibitors, antiandrogens, and β blockers (Table 43.1).

Chronic Illness

Chronic illness can alter sexual function and satisfaction in many ways, as shown in Table 43.2.

Radical Hysterectomy

Non–nerve-sparing surgery damages the autonomic nerves that innervate the blood vessels of the vaginal wall, thereby precluding lubrication, and the blood vessels supplying the vulvar and clitoral structures, thereby reducing their engorgement. Dissection of the sacrouterine ligament damages the hypogastric nerve, and severing of the cardinal ligaments disrupts the pelvic splanchnic nerves. Nerve-sparing radical hysterectomies have now been described, and recent outcome studies are encouraging. There is marked synergy between cancer of the cervix treated with non–nerve-sparing surgery and sexual abuse in causing sexual dysfunction. An absence of sexual satisfaction was reported by 20% of women reporting neither abuse nor cancer of the

cervix, by 31% of those who had been sexually abused but did not have cancer of the cervix, and by 28% of women with cancer of the cervix who had not been abused, and by 45% of women with comorbidity of abuse and cancer. Also, marked distress was reported by 18% of the women with neither abuse nor cancer, by 39% who had been abused but did not have cancer, by 23% with cancer but no abuse history, and by 44% of women with both abuse and cancer histories. Dyspareunia was extremely rare in women without cancer of the cervix, reported by 12% of those with cancer but by 30% of women with both cancer and past abuse.

TABLE 43.1 Medications Affecting Sexual Response

Drugs with negative sexual effects
Antihypertensives—β blockers, thiazides, serotonergic antidepressants, lithium
Antipsychotics
Narcotics
Benzodiazepines
Anticonvulsants
Oral contraceptives and oral estrogen therapy
GnRH agonists
Spironolactone
Cocaine
Alcohol
Drugs that appear to be prosexual:
Danazol
Levadopa
Amphetamines
Bupropion

TABLE 43.2 Overview of Medical and Psychosocial Effects of Chronic Illness on Sexual Function

- Biologic disruption of the sexual response: dyspareunia, infertility, changed anatomy of sexual organs
- Treatment of illness (e.g., chemotherapy-induced ovarian failure, non–nerve-sparing radical pelvic surgery)
- Limited mobility precluding intercourse, caressing her partner, masturbation
- Changed physical sensations such as hypersensitivity or insensitivity
- Angina or dyspnoea from sexual activity
- Fatigue, chronic pain, incontinence, stomas
- Negative psychologic consequences: feeling sexually unattractive and dependent, feeling that sex may be dangerous, or that illness is due to sexual activity.
- Accompanying depressive illness, preoccupation with illness, anger, shame, stress
- Partner's reaction to illness and to sexual dysfunction, role changes, inability to meet a partner, lack of privacy due to institutionalization
- Cultural nonacceptance of being sexual when ill

Endometriosis and Chronic Pelvic Inflammatory Disease

Gynecologic disease leading to dyspareunia such as chronic pelvic inflammatory disease or endometriosis may cause marked sexual distress.

Polycystic Ovary Syndrome

Polycystic ovary syndrome has been reported to be associated with low levels of sexual desire and response compared with controls despite the high androgen levels in this condition. Reducing the latter with treatment for the associated hirsutism improves sexual desire and response.

Recurrent Sexually Transmitted Infections

Understandably sexual motivation and ability to become aroused can be markedly reduced due to fear of spreading a sexually transmitted infection (STI) such as herpes or HIV. Along with explanation and discussion of the causes of the woman's lowered sexual motivation,

clear guidance regarding safer sexual practices is needed. A particular difficulty with recurrent herpes is viral shedding despite lack of skin lesions and uncertainty whether long-term antiviral therapy prevents this.

Vulval Dystrophies

The most common cause of vulval dystrophies is lichen sclerosis, and when this affects the clitoral hood and clitoris, loss of sexual sensitivity may be reported. Pain with clitoral stimulation may occur due to tethering of the clitoral hood, and pain with attempted entry of a penis, dildo, or finger may follow introital involvement.

Breast Cancer

Particularly after chemotherapy-induced premature menopause, sexual dysfunction following breast cancer is the most likely area of continued distress beyond 1 year of diagnosis. Surveys suggest that the most important predictors of sexual health are absence of vaginal dryness, presence of emotional well-being, positive body image, better quality of the relationship, and absence of partner sexual dysfunction. When the “medical menopause” is temporary from adjuvant GnRH agonist treatment, sexual dysfunction appears to be reversible. Whereas tamoxifen does not consistently alter sexual function, the recent increased use of aromatase inhibitors has led to increased numbers of women with dyspareunia related to the severe estrogen deficiency from the prevention of intracellular production of estrogen from adrenal (and any ovarian) precursors.

Diabetes

Both meta-analysis and a controlled study confirm strong links between depression and women's sexual dysfunction. By contrast, there is little correlation between sexual problems and age, body mass index, duration of diabetes, glycemic control, hormonal therapy, diabetic complications, or menopausal status. Although endothelial dysfunction is common in diabetes, only some studies report reduced lubrication. Reduced vulval engorgement to preclude effective stimulation has not been studied. The clinical impression that women with type 1 diabetes frequently develop orgasmic disorder is not well supported by scientific study. Dyspareunia is often due to inappropriate withholding of local estrogen postmenopause or from chronic candidiasis. The latter may predispose some women to VVS.

Lower Urinary Tract Symptoms

Lower urinary tract symptoms with and without prolapse have been shown to be correlated with increased prevalence of problematic desire, motivation, and response. Definitive surgery may or may not correct the sexual dysfunction and may create new dysfunction. Unfortunately, not all studies provide detailed preoperative assessment. Anterior suspension for stress incontinence can decrease sensation given that vaginal innervation is concentrated on the anterior and distal aspects of the vaginal wall. Dyspareunia

subsequent to Burch colposuspension and posterior colporrhaphy has been shown to increase from a preoperative rate of 8% to 20% postoperatively. However, there are data to show that dyspareunia is significantly improved after posterior colporrhaphy alone or with other vaginal surgery when a defect specific repair (without levator ani plication) is done. More study is needed on sexual function after tensionfree vaginal tape (TVT) procedures, but there are data to indicate significant decrease in sexual response. Researchers suggest that TVT decreases genital sensation and vaginal lubrication.

Pregnancy

Many factors affect a woman's sexuality while pregnant, including her physical changes and any medical restrictions as well as her own sexual value systems, folklore, and religious beliefs. There is no evidence that sexual activity including orgasm or intercourse increases the risk of pregnancy complications in the absence of preterm labor, antepartum bleeding, or incompetent cervix. Sexual problems may arise from interpersonal difficulties about the pregnancy or about the stressors that come along with it, including those physical, emotional, and economic. Studies show that sexual satisfaction is closely related to feeling happy about the pregnancy; understanding that in healthy pregnancy, sex and orgasm do not harm the fetus; having the partner share these opinions; and the woman continuing to feel attractive. Normal changes include a greater need for closeness, emotional support, and nurturing and a lessening of a need for orgasms or intercourse toward the later stages of pregnancy. A recent prospective Italian study of 450 women showed a reduction in desire and response for most in the first trimester but increased desire and orgasm satisfaction for a substantial minority in both the second and third trimesters. It is important that couples know there is much variation. Lack of sexual enjoyment was associated with aspects of maternal personality, depression, childhood experiences, relationship conflict, difficulties in conceiving, previous miscarriage, and fears of harming the fetus.

Postpartum

Reduced motivation for sexual activity stems from fatigue, fear of waking the baby, a decreased sense of attractiveness, and mood changes as well as ongoing physical difficulties including continued vaginal bleeding and discharge, perineal discomfort, hemorrhoids, sore breasts, and reduced vaginal lubrication (especially if breast-feeding). Some but not all studies show that women who breast-feed report less sexual activity and less sexual satisfaction than those who bottle-feed. Although women who deliver by cesarean section tend to resume intercourse earlier, there is no definite correlation between the method of delivery and sexual function and satisfaction. Similarly, there is minimal confirmation that presence or absence of episiotomy influences sexual function.

Definitions of Sexual Dysfunction

The current conceptualization of women's sexual response has led to revisions to the traditional definitions of sexual disorder as well as to awareness of the variability and plasticity of women's sexuality. Differences from the sexuality that is more typical of men are now taken into account. These include less frequent initial or spontaneous desire, the

importance of the ability to access desire during a sexual experience, and the relative lack of correlation between subjective sexual arousal/excitement and genital congestion as well as women's limited ability to detect the latter. Thus, the definitions of dysfunction are changing, and the currently recommended versions as first published in 2003 are shown in Table 43.3. An algorithm to aid diagnosis is shown in Figure 43.2. Women with sexual difficulty typically report a global muting of sexual response—little sexual desire or motivation, minimal arousal, and few orgasms. Given the overlap and variable order of the phases of desire, arousal, and orgasm, this comorbidity is not surprising. One exception is *female orgasmic disorder*, defined as experiencing high arousal but being unable to experience orgasmic release. Another exception is the woman with acquired chronic dyspareunia of short duration such that she still has ongoing desire and motivation, arousal, and orgasms. Unfortunately, given that most couples still continue to include the painful component of sex, namely intercourse, the woman's motivation and ability to respond often subside quickly.

TABLE 43.3 Definitions of Women's Sexual Dysfunctions Recommended by the International Consensus Committee Sponsored by the American Urological Association Foundation, 2003

Revised Definition of *Dysfunction*	Comments
Sexual desire/interest disorder: Absent or diminished feelings of sexual interest or desire, absent sexual thoughts or fantasies, *and* a lack of responsive desire. Motivations (here defined as reasons/incentives) for attempting to become sexually aroused are scarce or absent. The lack of interest is beyond a normative lessening with life cycle and relationship duration.	The evidence is that minimal spontaneous sexual thinking or desire for sex ahead of sexual experiences does not necessarily constitute disorder (given the data on women in sexually satisfactory established relationships). *Lack of desire triggered during the sexual encounter (i.e., "responsive" desire) is integral to the revised diagnosis.*
Combined arousal disorder:	

Absent or markedly reduced feelings of sexual arousal (sexual excitement and sexual pleasure) from any type of stimulation and absent or impaired genital sexual arousal (vulval swelling and lubrication).	There is no sexual excitement (in the mind) and no *awareness* of reflexive genital vasocongestion.
Subjective arousal disorder: Absent or markedly reduced feelings of sexual arousal (sexual excitement and sexual pleasure) from any type of stimulation. Vaginal lubrication and other signs of physical response still occur.	There is no sexual excitement (in the mind), but there is awareness of adequate lubrication.
Genital arousal disorder: Absent or impaired genital sexual arousal—minimal vulval swelling or vaginal lubrication from any type of sexual stimulation and reduced sexual sensations from caressing genitalia. Subjective sexual excitement still occurs from nongenital sexual stimuli.	*The presence of subjective arousal (sexual excitement) from nongenital stimuli (e.g., erotica, stimulating the partner, receiving breast stimulation, kissing)* is key to this revised diagnosis.
Female orgasmic disorder: Despite the self-report of high sexual arousal/excitement, there is either lack of orgasm, markedly diminished intensity of orgasmic sensations, or marked delay of orgasm from any kind of stimulation.	Women with arousal disorders frequently do not experience orgasm, but their correct diagnosis is one of an arousal disorder. Women who have orgasms from self-stimulation do not meet a diagnosis of orgasmic disorder.

Prevalence of Women's Sexual Dysfunction

The prevalence of women's sexual dysfunction is unclear for a number of reasons. Rates vary according to the population studied, the criteria used for dysfunction, whether the concerns are identified as constant or intermittent, their duration, and whether distress or being bothered by the symptoms was taken into account. To date, epidemiologic surveys have focused on traditional definitions of disorders that are modeled on male rather than female sexuality. Thus, such studies frequently report that 30% to 40% of women of all ages have “sexual desire disorder.” This is a remarkable occurrence of a “disease” in the general population—even in those of young age. Moreover, most surveys are not of carefully diagnosed disorder but consist in questionnaire assessment that more accurately reflects “problems” than diagnosed disorders. Often, only the past 4 weeks are assessed, and physicians know that women's sexuality is highly adaptive and that external factors such as a troubled life context or interpersonal relationship or severe stress can cause profound effects on the sexual response in the short term. When studies focus only on sexual problems lasting more than 6 months, prevalence figures reduce markedly. Less controversial is the definition of pain disorder. Chronic dyspareunia almost always causes distress that is either marked or moderate and affects 10% to 20% of women in general populations across all ages in most surveys. Vaginal dryness–associated dyspareunia may affect 30% to 50% of postmenopausal women. Prevalence of lack of subjective arousal/excitement is unclear, as most surveys have focused on lubrication. When the two are distinguished, prevalence rates match those of low desire. The number of women who have strictly defined orgasmic disorder also is unclear. Women typically report low desire, low subjective arousal/excitement, and infrequent orgasms.

Assessment of Sexual Dysfunction

Interview Assessment

Whenever possible, assessment of both partners—both alone and together—is recommended. Partner insights are helpful, and recommendations for changes in behavior—both sexual and nonsexual—are difficult if the second partner is not assessed and his or her opinion is not heard. Table 43.4 explains the assessment questions, and Table 43.5 provides a quick pneumonic.

Physical Exam

For general medical care, a physical examination that includes the genital and pelvic area is necessary. However, when the specific complaint is sexual dysfunction, the need

---

and timing of physical examination needs careful consideration. Examination can be essential and potentially diagnostic, as in chronic dyspareunia. It can be therapeutic, reassuring, and educational. Yet, genital examination can be irrelevant and confusing—for

instance, when the woman who can self-stimulate with full response and can insert tampons has never had dyspareunia and is complaining of lack of enjoyment or motivation to be sexual with her partner is told that "there is nothing wrong" after an assessment focused primarily on a physical exam. The examination might even be harmful, such as when it is attempted on the woman with phobic avoidance of vaginal entry typical of vaginismus who has not been given any guidance as to how to feel in control of such a situation and the examination is aborted, thus increasing her fears and sense of hopelessness. The physical exam is outlined in Table 43.6.

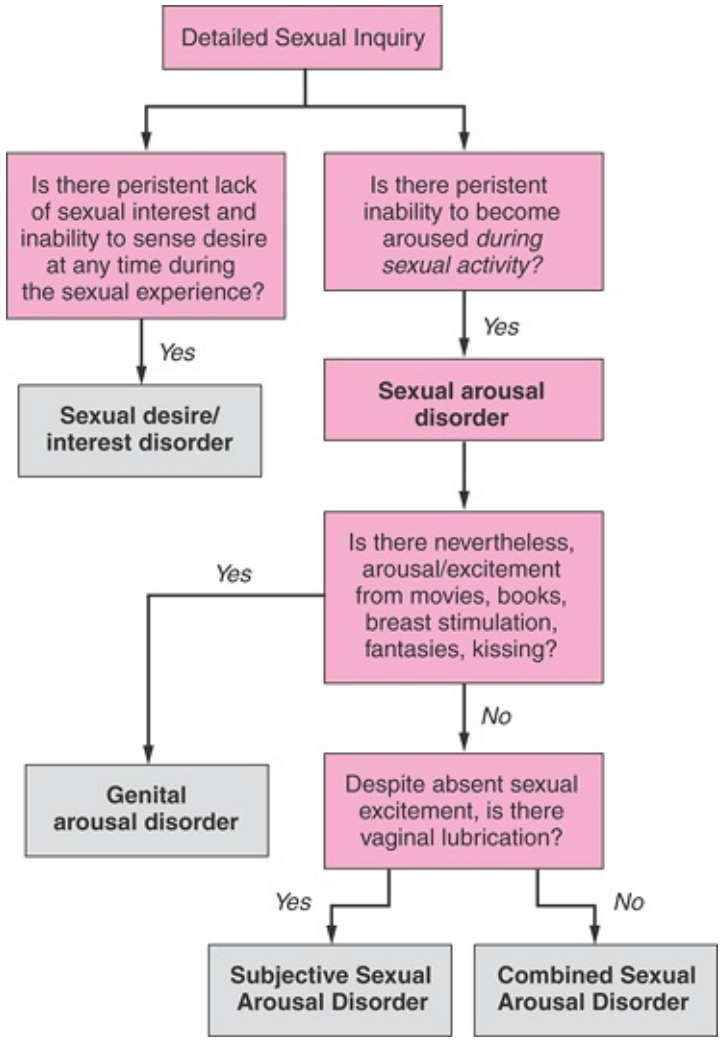

Figure 43.2 Algorithm to identify the subtype of arousal disorder.

Laboratory Investigations

Laboratory testing has only a small role in identifying causes of sexual dysfunction. Estrogen deficiency is best detected by history and examination; after menopause, the dominant estrogen is estrone, which is not detected by standard assays. As noted previously, serum levels of testosterone do not correlate with sexual function, and androgen metabolites as a measure of total androgen activity are not clinically available. Measurement of prolactin or thyrotropin level is warranted if there are relevant symptoms

or signs.

Management of Sexual Dysfunction

Evidence-based treatments are few, likely because sexual dysfunction usually is of multifactorial etiology, whereas randomized control trials usually are focused on one treatment modality. There is no clear distinction between assessment and therapy—as the woman considers and answers the various questions concerning the context of her sexual interactions, her relationship, her mood and self-image, and her feelings for her partner as well as her past experiences, she begins to see the logic of her situation, which in itself is therapeutic. Using the circular framework of women's sex response cycle, the following are assessed and addressed:

. Her various reasons or motivations to be sexual.

. Any apparently intrinsic desire—typical of a new relationship but commonly infrequent—for instance, perhaps just once a month in longer-term relationships.

. The degree of emotional intimacy, trust, respect, and attraction within the relationship.

. The sexual environment, including if it is sufficiently erotic, private, and free from interruption and undue fatigue.

. Adequacy of the sexual stimulation, including sufficient nonphysical and sufficient physical nongenital as well as sufficient nonpenetrative genital.

. Her thoughts and emotions when she is attempting to be sexual.

. Any biologic factors impairing her ability to be aroused, including depression, medication effect, or hormonal effect.

. Details of the outcome in terms of her emotional and physical satisfaction and freedom from pain or from untoward effects of partner dysfunction. If there is pain, its timing in terms of penile or dildo entry and movement, exacerbation with partner ejaculation, and postcoital pain or dysuria plus the woman's degree of arousal at the time of intercourse.

. Review of the physical findings.

Management of Low Motivation, Desire, and Subjective Arousal

Psychosexual Therapy

When the woman is unable to access desire and subjective arousal at any time during the sexual experience, the psychologic and biologic factors that may be impeding are addressed. These include her mood and self-image, her emotional closeness to the partner, and the attractiveness of her

---

partner's behavior in general as well as when sexual, the sexual context and her thoughts

and feelings while being sexual. Therapeutic techniques include cognitive behavioral therapy: the behaviors to be addressed are both sexual and nonsexual, including the interaction of the partners outside the bedroom. Ways to improve the sexual environment, the types of stimulation, the timing of sexual interaction, and possibly sexual technique may all be involved. Repetitive and catastrophizing thoughts are addressed and healthier thoughts suggested. Sex therapy focuses on both interpersonal issues as well as sexual technique and often includes “sensate focus” methods. Here, physical affection and sexual touch are “prescribed” on a regular basis for short periods of time (e.g., 10 minutes three times a week), moving from the nonsexual to sexual areas of the body, encouraging the partners to focus on the moment in order to guide the partner providing the stimulation to make it as pleasurable as possible, and taking turns in giving and receiving the stimulation rather than trying to do both at once. Touches to the breasts and genital area and intercourse are all precluded for the first number of sessions. Treatment is individualized for each couple. When sexual symptoms are thought to result from past events (sexual or nonsexual) in childhood and from low sexual self-image, short-term psychotherapy may be necessary. Outcome data are limited but are shown in Table 43.7.

TABLE 43.4 Assessment of Sexual Dysfunction

The following questions can be directed at the sexual couple.

Sexual problem in patient's own words	Clarify further with direct questions, giving options rather than leading questions, giving support and encouragement, acknowledgement of embarrassment, and reassurance that sexual problems are common.
Duration, consistency, priority	Are problems present in all situations, and which problem is most severe?
Context of sexual problems	Emotional intimacy with partner, activity/behavior just prior to sexual activity, privacy, birth control, risk of STDs, usefulness of sexual stimulation, sexual skills of partner, sexual communication, time of day/fatigue level.
Rest of each	

partner's sexual response	Check this currently and prior to the onset of the sexual problems.
Reaction of each partner	How each has reacted emotionally, sexually, behaviorally.
Previous help	Compliance with recommendations and effectiveness.
Reason for presenting now	What has precipitated this request for help?

The following questions are asked from each partner when seen alone.

Partner's own assessment of the situation	It sometimes is easier to say symptom severity (e.g., total lack of desire) in the partner's absence.
Sex response with self-stimulation	Also inquire regarding sexual thoughts and fantasies.
Past sexual experiences	Positive, negative aspects.
Developmental history	Relationships to others in the home while growing up. Losses, traumas, to whom (if anyone) were they close. Were they shown physical affection, love, respect?
Inquire regarding sexual, emotional, and physical abuse	Explain that abuse questions are routine and do not necessarily imply causation of the problems.

The following areas must also be assessed.

Physical health, including medications	Specifically ask regarding medications with known sexual side effects, including SSRIs, β blockers, antiandrogens, GnRH agonists, hormonal contraceptives.
Evaluation of mood	A significant correlation of sexual function and mood warrants routine screening for mood disorder.

STDs, sexually transmitted diseases; SSRIs, selective serotonin reuptake inhibitors; GnRH, gonadotropin-releasing hormone.
Items 3 to 5 of the single patient interview may sometimes be omitted (e.g., for a recent problem after decades of healthy sexual function).
Adapted with permission from Massachusetts Medical Society. Basson R. Clinical practice. Sexual desire and arousal disorders in women. Table 2, page 1500. *New Engl J Med* 2006;354:1497–1506.

TABLE 43.5 Quick Review of Assessment

Questions for all dysfunctions:
About—what happens; feelings, thoughts during
Both partners' sex response
Context—relationship, environment, culture, why now?
Depression? Mental health, including self-image
Experiences in the past (sexual and nonsexual)
Feelings for partner—when attempting to be sexual and generally

Adapted from Basson R. Recent conceptualization of women's sexual response. *Menopause Management*, May/June 2007;16(3):23. Available at:

http://www.menopausemgmt.com.

Limitations in the data are many, including different durations of therapy, different periods of follow-up, and different ways of evaluating the outcome.

TABLE 43.6 Physical Examination

General exam	Signs of systemic disease leading to low energy, low desire, low arousability (e.g., anemia, bradycardia, and slow relaxing reflexes of hypothyroidism); signs of connective tissue disease such as scleroderma or Sjogren syndrome, which are associated with vaginal dryness. Disabilities that might preclude movements involved in caressing a partner, self-stimulation, intercourse. Disfigurements/presence of stomas, catheters that may decrease sexual self-confidence leading to low desire, low arousability.
External genitalia	Sparsity of pubic hair, suggesting low adrenal androgens; vulval skin disorders, including lichen sclerosis, which may cause soreness with sexual stimulation. Cracks/fissures in the interlabial folds suggestive of chronic candidiasis, labial abnormalities that may cause embarrassment/sexual hesitancy (e.g., particularly long labia or asymmetry).
Introitus	Vulval disease involving introitus (e.g., pallor, friability, loss of elasticity, and moisture of vulval atrophy); lichen sclerosis; recurrent splitting of the posterior fourchette manifest as visible white lines perpendicular to fourchette edge; abnormalities of the hymen; adhesions of the labia minora; swellings in the area of the major vestibular glands; allodynia (pain sensation from touch stimulus) of the crease between the outer hymenal edge and the inner edge of the labia minora (typical of vulvar vestibulitis); presence of

	cystocele, rectocele, prolapse interfering with the woman's sexual self-image; inability to tighten and relax perivaginal muscles often associated with hypertonicity of pelvic muscles and midvaginal dyspareunia; abnormal vaginal discharge associated with burning dyspareunia.
Internal exam	Pelvic muscle tone, presence of tenderness, “trigger points” on palpitation of the deep levator ani due to underlying hypertonicity.
Full bimanual exam	Presence of nodules and/or tenderness in the cul-de-sac or vaginal fornix or along uterosacral ligaments; retroverted fixed uterus; pelvic tumor; fecal impaction as causes of deep dyspareunia; tenderness on palpitation of posterior bladder wall from anterior vaginal wall suggestive of bladder pathology.

Adapted with permission from Massachusetts Medical Society. Basson R. Clinical practice. Sexual desire and arousal disorders in women. Table 3, page 1501. *New Engl J Med* 2006;354:1497–1506.

Androgen Therapy

Supplemental testosterone has been prescribed to women for low sexual desire since the 1930s, mostly by using supraphysiologic doses and without ongoing safety and efficacy monitoring. Recently five industry-sponsored parallel group randomized controlled trials of six months' duration (four in surgically menopausal women and one in naturally menopausal women—all of whom were estrogen replete) showed benefit in some aspects of sexual desire and response from 350 µg but not 150 µg or 450 µg of transdermal testosterone daily. Clinical benefit in the nonresearch setting awaits to be seen.

TABLE 43.7 Outcome of Psychologic Therapy for Arousal, Desire, and Orgasm Disorders: Wait List Controls

Mode of Treatment	Level of Efficacy

Marital and sex therapy plus/minus orgasm consistency training[a]	Significant improvements in arousal when sex therapy plus orgasm consistency given versus sex therapy alone
Behavioral and sex therapy, including modified sensate focus therapy	Approximately 60% show significant improvement
Cognitive behavioral therapy	50%–74% show significant improvement
Directed masturbation and bibliotherapy	55%–82% became orgasmic
Combination of CBT, sensate focus, and directed masturbation	Increased orgasmic response and initiation of sexual activity in majority

CBT, cognitive behavior therapy.

[a]Orgasm consistency training: encouragement of self-stimulation, sensate focus therapy with partner, and coital techniques to facilitate clitoral stimulation.

Of note, the recruitment diagnosis was hypoactive sexual desire disorder, but the women reported improvements in sexual response in keeping with the known pervasive blunting of desire, motivation, and response that is typical for women. This short-term administration was not associated with significant increases in hirsutism, acne, or virilizing effects or lipid changes. However, the presumed androgen deficiency is of permanent duration and long-term safety-efficacy data are not available. Of particular concern are the associations of high endogenous testosterone with metabolic syndrome and breast cancer. The American Endocrine Society has recently recommended against widespread use of testosterone supplementation in women until further safety data are gathered. Another compounding factor is the current tendency to limit systemic estrogen to just a few years versus the need for concomitant systemic estrogen with any systemic testosterone. Prescribing the latter alone would be extremely nonphysiologic, raising the already high androgen-to-estrogen ratio of older women. This “normal” increase in the androgen–estrogen ratio has its clinical sequelae in terms of increased facial hair and male-type balding in many older women. Moreover, there

is no biochemical marker of women who are truly deficient in testosterone, as serum levels do not correlate with sexual function and no clinically proven method of determining total androgen activity is available. Studies are needed of women who are sexually motivated to be with their partner for reasons other than desire but who are distressed to find that their mind and body cannot be aroused by previously useful sexual stimuli. Such women were excluded from the recent randomized controlled trials, given the likelihood that they would have very infrequent sexual activity, which by itself precluded recruitment. Testosterone is not approved for treating women's sexual dysfunction in North America at this time but has been approved elsewhere, including some European countries and Australia.

Estrogen Therapy

Estrogen has not been shown to directly influence desire as in sexual thinking and fantasizing but can be associated with improved motivation to be sexual when its use allows painless intercourse and/or increased genital sexual sensitivity.

Nonhormonal Medications

No nonhormonal drugs are approved for use in treatment of sexual disorders. One study has shown that investigational use of bupropion improved response but not desire in women who were not clinically depressed but were diagnosed with hypoactive sexual desire disorder.

Management of Genital Arousal Disorder

Local estrogen can restore genital sexual sensitivity in some but not all women postmenopause. Recent research suggests that only a portion of women treated with estrogen but still retaining this disorder have demonstrably reduced vaginal congestion in response to erotic stimulation. This particular subgroup reported improvement from the investigational use of a phosphodiesterase inhibitor. It is possible that some women lose sexual sensitivity on the basis of androgen deficiency, but no data are available on the use of topical testosterone to the clitoral area, although this is sometimes prescribed.

Management of Orgasmic Disorder

Lifelong orgasmic disorder is more common than acquired orgasmic disorder and is frequently associated with obsessive self-observation and monitoring during the arousal phase, sometimes accompanied by anxiety and distracting negative and self-defeating thoughts. The assumption is that the woman may be so absorbed in monitoring her own and her partner's response and concerned about “failure” that she is unable to allow her natural reflexes to trigger an orgasm. Therefore, treatment is directed at increasing her understanding of the need not to monitor but rather to focus on her sexual thoughts and feelings and to take turns with her partner so as not to be distracted by concerns of the partner's well-being at that point in time. Also, it is important to ensure effective sexual technique. The only evidence-based therapy is encouragement of self-stimulation

accompanied by erotic fantasy. There are excellent self-help books available, some of which advocate the use of a vibrator. Once the woman has experienced orgasm with self-stimulation, she may or may not be able to teach this technique to her partner. At this point, issues of trust may surface, requiring more intense psychologic help.

Acquired orgasmic disorder may occur in association with relationship problems; depression; medications, especially SSRIs; or with chronic illness, especially neurologic disease such as multiple sclerosis. Although open-label trials and case series have suggested a number of pharmacologic agents that might improve the loss of arousal, desire, and orgasm commonly associated with serotonergic antidepressants, a recent Cochrane review did not identify a medication to counteract SSRI-associated orgasmic disorder in women but noted that bupropion was of promise in that two controlled trials showed benefit. Bupropion, mirtazapine, moclobemide, or reboxetine may impair orgasm less frequently than SSRIs.

Management of Dyspareunia

Definitive therapy of the cause of dyspareunia (e.g., endometriosis) is the general goal, but in the interim, encouragement of nonpenetrative sex is important for the preservation of the woman's sexual enjoyment and sexual self-image.

Vulvovaginal Atrophy

Local estrogen therapy is recommended for dyspareunia that is associated with vulval vaginal atrophy. Very low systemic absorption occurs from the use of a Silastic vaginal ring containing estradiol or from a mucoadhesive tablet placed once or twice a week in the vagina. The available selective estrogen receptor modulators (SERMs) are not estrogen agonists in the vagina, but one that is being trialed, namely lasofoxifene, has been reported to improve the dyspareunia of vulval vaginal atrophy. Similarly, tibolone, a synthetic steroid with tissue-specific action that is estrogenic, androgenic, and progestogenic has been shown to improve vaginal atrophy and associated dyspareunia. A recent trial comparing tibolone to transdermal estradiol plus norethindrone showed a marginally greater benefit from tibolone in terms of sexual response and desire. Long-term safety and efficacy data are awaited, and tibolone has recently been declined approval in North America. Interruption of the pelvic autonomic nerves reduces the vascular response to sexual stimulation. Thus, women with diabetes and those with multiple sclerosis might be helped by investigational use of a phosphodiesterase inhibitor, according to preliminary studies.

TABLE 43.8 Main Components of Treatment of Dyspareunia

1. Encourage/normalize nonpenetrative sex.

2. Medically address any specific pathology (e.g., recurrent tears of the posterior fourchette, vulvovaginal atrophy, lichen sclerosis, endometriosis, allodynia of VVS).
3. Consider physical methods: pelvic muscle physiotherapy +/- biofeedback to change pelvic muscle hypertonicity.
4. Address any associated anxiety, catastrophizing, self-blame, guilt, anger.
5. Address fertility issues, and arrange home or clinic insemination of partner's semen.

VVS, vulvar vestibulitis syndrome.

Vulvar Vestibulitis Syndrome

Of the two most common causes of dyspareunia, VVS and vulvovaginal atrophy, evidence-based therapy exists only for the latter. A recent National Institutes of Health (NIH) consensus report summarizes the many medical, psychologic approaches to VVS as well as partial or complete vestibulectomy. Conservative therapy includes prescription of chronic pain medication and encouragement of nonpenetrative sex, along with psychologic help to change the woman's reactions to internal as well as external stressors that are thought to influence this and many chronic pain syndromes. Other medical adjuncts include topical anti-inflammatory or local anesthetic medication to the sites of allodynia and pelvic muscle physiotherapy to correct the typical hypertonicity present in this syndrome. It is hoped that improved understanding of the different etiologic factors, including genetic predisposition, may allow scientifically based therapeutic options. The main components of treatment of dyspareunia are shown in Table 43.8.

Management of Vaginismus

Although its true prevalence is unknown, vaginismus often presents as an unconsummated relationship/marriage or infertility and is seen commonly in sexual medicine and many gynecology settings. Involvement of both partners in the nonconsummation is apparent to clinicians, but details and optimal management of the partner's sexual caution have not been published. Therapy involves a number of visits that may extend over a few weeks, but they often extend over many months. The woman learns more details regarding her anatomy and physiology and learns to do a “reverse Kegel” exercise to voluntarily open the introitus, preferably observing this in a mirror. This helps her change her former concept of “being penetrated” to one of being an active participant in the entry of an object and ultimately her partner's penis into her vagina. She is encouraged to self-touch daily as close to the introitus as possible either with her finger or the tip of an insert or tampon, and she is encouraged to envision being examined by opening the labia herself such that she and the physician can view her anatomy in a mirror. The diagnosis of vaginismus is confirmed by a careful introital exam, excluding pathology such as vestibulitis or hymenal

abnormality or tearing of the posterior fourchette. Often, the first examination is only partial and may involve no touching at all by the physician. More complete examination is done later. A series of vaginal inserts of increasing diameter usually is recommended. Attempts at intercourse are strictly discouraged while treatment progresses. At a later stage, the partner is encouraged to assist the woman with the placement of the insert. Then, penile-vulval stimulation is encouraged, and ultimately, the woman is encouraged to place her partner's well-lubricated penis into her introitus in a similar fashion to the insert placement. The underlying theme is that the woman is given a sense of control. Recent outcome studies do not confirm the original good prognosis stemming from the work of Masters and Johnson in the 1970s, and current research is focused on addressing the issues of caution in the male partner.

Sometimes, couples wish primarily to conceive rather than to have intercourse. Once the woman can tolerate placement of a small insert and is able to cooperate with a complete genital pelvic exam, she may choose to perform self-insemination of her partner's semen either at home or with a physician's assistance in the clinic.

Summary Points

- Women's sexual function is variable: a woman has many reasons to engage in sex; desire may follow rather than precede arousal; and orgasms may or may not be experienced in a satisfactory encounter.
- There is a minimum correlation between genital congestion (genital arousal) and sexual excitement (subjective sexual arousal).
- There is a robust correlation between women's sexual satisfaction and their feelings for their partner, their mental health, past sexual experiences, and duration of relationships.
- A minimum amount of estrogen activity is needed to allow sexual sensitivity of genital and nongenital areas. It is unclear why some postmenopausal women require supplementary estrogen and others do not.
- It is currently thought that a minimum of testosterone activity is needed for women's desire and response.
- Management of sexual dysfunction involves careful assessment of psychosexual and medical factors and construction of the woman's own sex response cycle. The mainstay of management is psychosexual therapy.

Chronic Pelvic Pain

Howard T. Sharp

Science has produced many drugs, therapies, and surgeries in an attempt to relieve the suffering associated with chronic pelvic pain (CPP). Unfortunately, only modest success has been achieved. This is likely in part due to the heterogeneity that exists in this ill-defined population of patients as well as our limited understanding of pain modulation. Often, when standard therapies fail or when no visible pathology can be identified, other specialties are consulted such as gastroenterology, urology, neurology, or psychiatry. Patients may eventually be referred to centers specializing in CPP or empiric pain management, wherein opioid therapy may be commenced without finding a specific cause for pain.

Along the course of therapy and referral, frustration is often a by-product of treating a supposed remediable pain state only to have pain persist. Clinically, part of the diagnostic challenge is to decipher whether (a) a defined pain state exists that has not yet been diagnosed or treated, (b) a defined pain state exists and has been identified correctly but happens to be present in an incidental form (e.g., asymptomatic endometriosis), and/or (c) a neuropathic pain processing state is present.

The focus of this chapter is to review several putative causes of pelvic pain that should be considered in patients who present with CPP and to review history taking, physical examination techniques, and treatment options.

Definitions

Allodynia: Pain due to a stimulus which does not normally provoke pain.*

Central pain: Pain initiated or caused by a primary lesion of dysfunction in the central nervous system.*

Chronic pelvic pain: Nonmenstrual pain of 6 months duration or greater, localized to the pelvis, anterior abdominal wall below the pelvis, or lower back, severe enough to result in functional disability or require medical or surgical treatment.

Dysesthesia: An unpleasant abnormal sensation, whether spontaneous or evoked.*

Endometriosis: The existence of two or more of the following outside of the

endometrium: (a) endometrial epithelium, (b) endometrial stroma, (c) endometrial glands, (d) hemosiderin-laden macrophages.

Hyperalgesia: An increased response to a stimulus which is normally painful.*

Myofascial pain syndrome: A heterogeneous pain-producing disorder characterized by localized, reproducible, hyperirritable trigger points within a muscle or its investing fascia.

Neuropathic pain: Pain initiated or caused by a primary lesion, dysfunction, or transitory perturbation in the peripheral or central nervous system.*

Neuralgia: Pain in the distribution of a nerve or nerves.*

Pain: An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of damage.*

Contemporary Pain Theories

Until the 1960s, pain was considered a sensory response to tissue damage. It is now widely accepted that pain has a reactive or emotional as well as sensory component that is influenced by genetic differences, past experiences, gender, anxiety, or expectation. The perception of and response to pain are believed to be determined by four simultaneous processes that include transduction (depolarization of a peripheral sensory nerve ending to generate an impulse), transmission (neural events to carry the impulse), modulation (neural events that control transmission neurons), and perception (event processing influenced by behavioral and emotional factors).

The theory most widely accepted to explain the mechanism whereby pain transmission occurs was described by Melzak and Wall as the gate control theory. This theory suggests that the modulation of nociception at the spinal cord is mediated by descending signals for high centers within the brain through neurotransmitters. It describes a bidirectional gate at the level of the spinal cord rather than merely unidirectional pain transmission as previously held by the Cartesian theory.

Putative Pelvic Pain States

Adhesions

Pelvic inflammatory disease (PID), endometriosis, inflammatory bowel disease, or prior surgery may cause adhesions; yet, in up to 50% of cases, there may be no significant antecedent event. Though adhesions are commonly found in patients with CPP, it may be difficult to assess whether they are contributing to pelvic pain or are merely incidental findings.

Several studies have raised questions about the benefit of treating adhesions surgically in patients with CPP. In a prospective study of patients undergoing second-look laparoscopy following laparotomy for reproductive surgery, 51% of patients developed de novo adhesions, thus raising the possibility that treating adhesions may lead to more adhesions.

There is evidence to suggest that the lysis of adhesions may not result in significant pain relief. Two randomized prospective studies have been conducted to evaluate the effect of adhesiolysis in patients with chronic pelvic or abdominal pain. Neither study has provided convincing evidence to support adhesiolysis as being beneficial for providing pain relief in patients with chronic pain. In the first study, patients in the treatment arm underwent adhesiolysis by minilaparotomy. At 9 to 12 months following surgery, there was no difference in McGill pain scales comparing the treatment group (N = 24) to controls (N = 24). After stratification, the authors acknowledged a trend toward a benefit in patients with well-vascularized or thick adhesions involving the intestinal tract, the pain hypothesis being symptoms of intermittent small bowel subileus. The second and larger study (N - 116) showed no difference in abdominal pain in the treatment and control groups at 1 year after surgery.

In a case-control study of 100 consecutive laparoscopies in patients with CPP compared with 88 patients used as controls who underwent laparoscopy for infertility, pelvic adhesions were more common in the control group (39% vs. 26%). In a study of 200 asymptomatic women undergoing laparoscopic sterilization, 14% of women were found to have pelvic adhesions. In a prospective cohort study of 102 women undergoing laparoscopy, wherein the surgeons were blinded as to the indications, that is, pain (64%), infertility (35%), previous abnormal findings (19%), and sterilization (15%), adhesion scores were no different in the CPP group compared with those found in controls.

In an uncontrolled prospective study of 30 women undergoing laparoscopic adhesiolysis for CPP with a mean follow-up interval of 8.2 months, there was an overall improvement of pain in 63%. There was a trend toward greater improvement in the group with CPP compared with the group with CPP syndrome. CPP syndrome was defined as patients having at least four of the following: (a) pain greater than 6 months duration, (b) previous treatments unsuccessful in relieving pain, (c) diminished physical activity (work, exercise, sex), (d) at least one vegetative sign of depression (sleep dysfunction, decreased appetite, psychomotor retardation), or (e) altered family role.

Based on these studies, the following should be considered: (a) adhesions can form after surgery, even if adhesiolysis was the main surgical objective; (b) adhesions may be present in patients who are asymptomatic with respect to pain; (c) adhesions may be incidental in patients who suffer from CPP; (d) while some case series have shown benefit to adhesiolysis, the randomized clinical trials of adhesiolysis in patients with chronic pelvic and/or abdominal pain have shown no treatment benefit; and (e) judgment is critical as to whether or not to perform surgery in patients who have had multiple laparoscopic procedures, weighing the risks and benefits.

Endometriosis

Endometriosis is one of the most enigmatic of gynecologic pain disorders. Not only is there little correlation between the extent of disease present and the degree of pain, but it is often found in asymptomatic women. The noted exception is deep infiltrating endometriosis in the rectovaginal septum, which has been shown to have a direct correlation to pain.

Endometriosis may have several appearances ranging from the more typical “powder burn,” blue-gray lesions to atypical lesions that may be clear, red, or white. Various explanations have been proposed to account for endometriosis-related pain, including inflammation, prostaglandin production, neuronal involvement, and adhesions. Data from conscious sedation laparoscopic pain-mapping have demonstrated areas of pain well beyond the visible endometriosis.

Symptoms associated with endometriosis include cyclic pelvic pain or dysmenorrhea. The pain associated with endometriosis may precede the menses, occur with menses, and continue after menses. Tenesmus may be associated with endometriosis involving the rectosigmoid colon. Other clinical manifestations may include dyspareunia or ovarian mass (endometrioma).

Conservative medical treatment is recommended as the initial therapy for endometriosis or presumed endometriosis. This may include the use of nonsteroidal anti-inflammatory drugs (NSAIDs), hormonal contraceptive

---

drugs, danazol, progestins, and gonadotropin-releasing hormone (GnRH) agonists. These medications may provide symptomatic relief and in some cases have been shown to reduce the size of endometriotic lesions and thus the stage. There are no convincing data to suggest that one form of medical suppressive therapy is superior to another. Usually, the agent with the lowest side effect profile is selected as first-line therapy, such as NSAIDs or hormonal contraceptive drugs.

Hormonal contraceptive drugs may be used in a cyclic (standard) or continuous fashion. Continuous use refers to delaying withdrawal menstruation for 3 to 6 months rather than allowing menses to occur during placebo administration. This usually allows the patient to avoid the dysmenorrhea that may occur with the cyclic regimen. If hormonal contraceptive drugs are not effective after 3 months, danazol (600 mg to 800 mg per day) or GnRH agonists may be used.

The use of danazol for endometriosis-associated pain was evaluated by Cochrane Database reviewers, wherein four trials were found with adequate study design for inclusion. The reviewers concluded that danazol is effective in treating the symptoms of endometriosis; however, its use is limited by the occurrence of androgenic side effects. GnRH agonists such as leuprolide or goserelin are generally used for 6 months if a favorable response is noted. The main concern about prolonged use of these agents is the loss of bone mineral density. The treatment window may be extended to 12 months or longer with the use of add-back therapy (addition of a progestin with or without estrogen).

Surgery is generally reserved for refractory cases. If surgery is to be performed, it should be tailored toward the patient's reproductive wishes. If the patient desires to preserve her childbearing capacity, endometriotic lesions may be destroyed or removed by vaporization or excision laparoscopically or by laparotomy. It is argued by some that vaporization may only treat the “tip of the iceberg” with the potential to leave deep infiltrating endometriosis behind. To date, there are no convincing data to recommend one laparoscopic therapy over the other. Unfortunately, a significant number of patients treated conservatively (without hysterectomy and bilateral salpingo-oophorectomy) will

develop returning symptoms 12 months postoperatively.

Laparoscopic surgery for the treatment of endometriosis-associated pain was reviewed in the Cochrane Database. Only one study was deemed adequate for evaluation; therefore, most of our current understanding stems from level 3 data (case series and opinions of experts). The review concluded that laparoscopic laser treatment of endometriosis was more effective than expectant treatment of endometriosis, but the reviewers included a caution about the interpretation of results due the lack of any corroborating studies. Hysterectomy with or without adnexectomy may be appropriate in cases where childbearing is no longer an issue.

Pelvic Inflammatory Disease

PID is a significant health problem (approximately 1 million cases per year) resulting in an expense of 3.5 billion dollars annually in the United States alone. It can clearly be a cause of acute pain, yet it also may be asymptomatic. The most likely mechanism for pain is from inflammation and distension of the fallopian tubes. A distended fluid-filled fallopian tube or hydrosalpinx will sometimes persist for months or years and may cause CPP. It is less clear why pain persists in patients with treated PID, who have subsequent normal-appearing reproductive organs, and are culture negative for causative microorganisms. It is theorized that the initial inflammatory insult may have started a cascade of signals within the pelvis, spinal cord, and brain, resulting in visceral neuropathic pain.

As many as 15% to 25% of patients with PID will go on to have CPP. There are no good studies addressing how to treat laparoscopy-negative, culture-negative patients with presumed persistent PID. The patient's partner should be treated as well to avoid reinfection. Persistent hydrosalpinx usually is treated surgically by salpingectomy.

Myofascial Pain

Myofascial pain syndrome (MFPS) may represent the largest group of unrecognized and undertreated acute and chronic medical problems in clinical practice. It is estimated to have a prevalence of 30% in patients suffering from pain in general medical clinics and as high as 85% to 93% in pain specialty clinics. Myofascial pain is common in patients with a history of trauma or multiple surgeries and is often overlooked as a cause for CPP. MFPS is a heterogeneous pain-producing disorder characterized by localized, reproducible, hyperirritable trigger points within a muscle or its investing fascia. Clinically, trigger points are tender when compressed, have characteristic referred pain patterns, referred tenderness, motor dysfunction, or autonomic dysfunction.

Abdominal wall myofascial pain is best detected by isolating the rectus abdominus muscles by having the patient flex her abdomen by lifting her feet or head and shoulders off the examination table while in the supine position. A one-finger search along the anterior abdominal wall is performed to identify painful trigger points. When localized, trigger points can be successfully treated with icing, stretching exercises, and injection with local anesthesia. One to 2 mL of a 50:50 mixture of 1.00% lidocaine and 0.25% bupivicaine may be injected into the muscle and fascia with a 22- or 25-gauge needle to achieve a diagnostic

and therapeutic block. Slocumb reported on the successful treatment of 89% of 131 CPP patients with trigger point injections. Most patients obtained relief within five injections. Physical therapy has also been successful in treating MFPS.

Pelvic Varicosity Pain Syndrome

Patients with pelvic varicosity pain syndrome (PVPS), formerly called *pelvic congestion syndrome*, typically complain of pelvic pain and aching that becomes progressively worse throughout the day. They also may complain of dyspareunia or postcoital aching. PVPS as a cause for CPP has been a controversial entity since it was first described. One reason for skepticism is the observation that some women who demonstrate dilated vessels at the time of surgery or during pregnancy are asymptomatic.

Beard and colleagues proposed a more objective method of diagnosing pelvic varicosities by using transcervical pelvic venography to measure vessel diameter, vessel tortuosity, and dye transit time, suggesting that vein diameter alone is not the only significant finding of PVPS. Subsequent studies by these authors propose diagnostic criteria for PVPS and pathophysiologic mechanisms for pain production. It has been postulated that pain from PVPS is caused by vasoactive nociceptive peptides such as substance P and calcitonin gene-related peptide. In a study by Reginald and associates of patients with venographically diagnosed PVPS injected with a potent vasoconstrictor (dihydroergotamine), a 35% reduction in vein diameter, decreased dye transit time, and up to 4 days of pain relief was demonstrated when compared with patients injected with placebo. The authors hypothesized that vasoconstriction allows clearance of nociceptive vasoactive peptides.

One randomized clinical trial showed benefit with the use of GnRH agonist therapy over medroxyprogesterone acetate in 30-mg daily doses. Ultimately, surgery may be necessary. In Beard's series of 36 patients treated with hysterectomy and bilateral salpingo-oophorectomy, 67% obtained complete relief of pelvic pain. Only 1 of the remaining 12 patients had significant pain.

Painful Bladder Syndrome

Painful bladder syndrome (PBS), formerly known as *interstitial cystitis*, is a chronic inflammatory condition of the bladder characterized by urgency, frequency, or pain in the absence of a urinary tract infection or malignancy. In some series, up to 85% of women with pelvic pain presenting to gynecologists have this condition.

The diagnosis of PBS is controversial but is often made by distending the bladder cystoscopically under anesthesia. Intravesical instillation of potassium chloride, which usually is nociceptive in the presence of PBS, has also been used diagnostically. Questionnaires can be used as well. Treatment usually is individualized and multimodal, including diet, exercise, smoking cessation, transcutaneous electrical nerve stimulation, bladder training, medications, bladder distention, or bladder instillation.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a common gastrointestinal disorder affecting approximately 15% of adults in the United States, yet only 25% of persons with questionnaire-detected IBS actually seek health care. It has been defined (Rome III criteria) as recurrent abdominal pain or discomfort (uncomfortable sensation not described as pain) that is present for at least 3 months, with onset at least 6 months previous and at least two of the following clinical features: (a) improvement with defecation, (b) onset associated with a change in frequency of stool, or (c) onset associated with a change in the form (appearance) of stools.

Theories to explain a putative mechanism for IBS include visceral hyperalgesia, infection, an imbalance of neurotransmitters, and psychologic factors. More recently, growing evidence suggests that these patients have a gastrointestinal sensory-reflex dysfunction as a common pathophysiologic mechanism that may be manifested by different forms depending on the specific pathways involved. This may explain why some individuals are more pain prone, while others may be more prone to have diarrhea or constipation.

Rectal and sigmoid balloon distention studies have shown a lower threshold for pain in patients with IBS compared with controls, referred to as visceral hypersensitivity. However, when balloon testing is performed, only 40% to 60% of patients with IBS report pain at levels of distention below the range of normal values; therefore, gut wall distension may not be the only stimulus to cause IBS.

Therapy for IBS involves treating symptoms, whether one is diarrhea prone or constipation prone. Diarrhea-prone patients respond better to loperamide, hyoscyamine, and desipramine, whereas constipation-prone patients respond better to fiber therapy, cisapride, or tegaserod (a 5HT-4 receptor antagonist). Patients with a pain predominance may be treated with tricyclic antidepressants, NSAIDs, anticholinergics, calcium channel blockers, and in some cases opioids.

Patients who have rectal bleeding, persistent occult fecal blood, or failure of medical therapy should be referred to a gastroenterologist to rule out malignancy or inflammatory bowel disease.

Ovarian Remnant Syndrome

Ovarian remnant syndrome may result from incomplete removal of ovarian tissue at the time of oophorectomy and can be associated with CPP in premenopausal women. Patients with this syndrome usually have a history of extensive endometriosis or pelvic inflammatory processes resulting in a technically difficult oophorectomy. Cyclic pelvic pain caused by ovarian remnant syndrome is most commonly associated with the development of ovarian follicles within hormonally active ovarian tissue. This diagnosis is suspected when serum levels of follicle-stimulating

---

hormone and luteinizing hormone are in the normal range. In women on hormone replacement therapy (HRT), assessing serum gonadotropin levels should be delayed until HRT has been discontinued for at least 10 days. Clomiphene citrate and GnRH agonists have been used to stimulate ovarian tissue, which assists in making an ultrasonographic diagnosis of ovarian remnant syndrome.

Surgical treatment usually requires extensive intraperitoneal adhesiolysis and retroperitoneal dissection to remove all ovarian tissue. In a series of eight patients treated surgically for ovarian remnant syndrome, three required large bowel resection, cystotomy occurred in three, a ureteroneocystostomy in one, and one required a small bowel resection. Outcome data regarding postoperative pain relief after surgical resection are limited to small case series, but cure rates as high as 90% are reported.

Residual Ovary Syndrome

Ovary retention syndrome (ORS) was originally described in 1958. It is characterized by the development of pain in one or both ovaries conserved at the time of hysterectomy, theoretically caused by perioophoritis with a thickened ovarian capsule. It has been postulated that pain is produced by the cyclical expansion of the ovary encased in adhesions.

The most common complaints in women with ORS are chronic lower abdominal pain, dyspareunia, and radiation of pain to the back or anterior thigh. A tender mass may be palpated on bimanual exam. This syndrome may occur in as many as 3% of women who have undergone hysterectomy with ovarian conservation. Treatment typically has been oophorectomy rather than lysis of adhesions, to avoid adhesion reformation. Care should be taken to avoid ureteral damage because retained ovaries are often positioned near the ureter. Outcome data are limited regarding pain relief after surgery for ORS, with case series reporting improvement in approximately 80% patients after oophorectomy.

Pain of Uterine Origin

In the United States, approximately 18% of hysterectomies are performed for CPP, with endometriosis cited as the most common indication. Carlson and colleagues demonstrated significant reduction in pain following hysterectomy for CPP of all causes. In patients with pelvic pain who underwent hysterectomy, 85% complained of frequently occurring pain preoperatively compared with 13% at 12 months postoperatively. In a prospective cohort study comparing surgical to nonsurgical treatment, 49% of medically managed patients with CPP had continued symptoms compared with 3% treated by hysterectomy. Moreover, 25% of patients in the nonsurgical group underwent hysterectomy within 1 year.

TABLE 44.1 Possible Causes of Pain of Uterine Origin

Adenomyosis

Intrauterine contraceptive device

PVPS, pelvic varicosity pain syndrome.

Stovall and associates reported a 78% success rate in patients undergoing hysterectomy for pelvic pain of presumed uterine origin. In this retrospective study, patients were excluded for nonuterine pain such as endometriosis. A prospective multicenter cohort of 308 women undergoing hysterectomy for CPP reported resolution of pain in 74% and improvement in 21%. Risk factors for continued pain included age 30 or younger, history of PID, and use of public assistance. These studies are helpful because they underscore the importance of investigating other nongynecologic causes for CPP, and they provide guidelines for preoperative counseling.

Hysterectomy may be indicated in the absence of pathology in patients who have concluded childbearing. Prior to performing a hysterectomy, conservative therapy should be attempted (hormonal contraceptives, NSAIDs, and induced amenorrhea), and the patient should be evaluated for urinary, gastrointestinal, musculoskeletal, and psychologic causes for pain. Possible causes of pain of uterine origin are listed in Table 44.1.

Psychologic Aspects of Chronic Pelvic Pain

Patients sometimes get the message that “your pain is all in your head.” Whether patients are actually told this or whether they hear this is irrelevant. This concept reflects what physicians were taught historically as the somatic model of pain, wherein there was a direct relationship between tissue damage and pain intensity. This model does not adequately account for the discrepancy between objective physical findings and the perception of pain severity. A more contemporary approach recognizes the central models of pain, which include the effect of peripheral nociception and central pathways that determine disability and distress.

The psychologic aspects of CPP can be significant. It is therefore worthwhile to distinguish between comorbid states such as depression, anxiety, and panic attacks. It often is helpful to obtain early consultation from a mental health care professional. Screening tests that may be administered by primary care physicians, such as the Beck Depression Inventory, Zung Depression Index, or the Patient

Health Questionnaire-2 (PHQ-2). The PHQ-2 screening questionnaire is especially easy to administer, as it is a validated questionnaire comprised of two questions.

Clinical depression associated with CPP often is related to sleep disturbance (insomnia or hypersomnia), loss of interest in pleasurable activities, guilt feelings, loss of energy, diminished concentration, appetite changes (decreased or increased), psychomotor changes, and possible suicidal ideation. The mainstays of therapy include the use of serotonin reuptake inhibitors, tricyclic antidepressants, and psychotherapy. Clinicians who prescribe these medications should be familiar with their side effects and contraindications as well as be aware of the diagnostic criteria for depression. Patients with suicidal ideation should be referred immediately to a crisis intervention unit.

History and Physical Exam

Taking a thorough patient history is one of the most helpful tools in the evaluation of patients with CPP. The *COLDERR* acronym may be used to gain a general understanding of the patient's history of present illness.

Character—What does the pain feels like? (sharp, dull, crampy, etc.)

Onset—Was the pain onset sudden or gradual? Is it cyclic or constant?

Location—Is the pain localized or diffuse?

Duration—How long has the pain been present, and how has it changed over time?

Exacerbation—What activities or movements make the pain worse?

Relief—What medication, activities, and positions make the pain better?

Radiation—Does the pain radiate anywhere (back, groin, flank, etc.)?

There are several important aspects of taking a detailed pain history and reviewing organ systems. Comprehensive history and physical examination forms are available through the International Pelvic Pain Society website, which can be downloaded at *http://www.pelvicpain.org*. Establishing whether the pain is cyclic or not is helpful is narrowing the list of possible causes (Table 44.2). If the patient has poor insight to the nature of her pain, a pain calendar may be used to prospectively chart her symptoms during the month.

Ulcer (duodenal, gastric)

IBS, irritable bowel syndrome.

Reviewing past surgeries is helpful to gain information about which organs can be eliminated from consideration and what effect surgery had on the patient's pain symptoms. It may help to establish a causal relationship between surgery and pain, which is common among patients with MFPS.

A thorough review of systems is important to exclude nongynecologic causes for CPP. Gastrointestinal complaints should be explored with specific questions about bowel frequency, consistency, and associated pain and to exclude a history of blood in the stool, which would alert the clinician to rule out neoplasm (Table 44.3). Likewise, urinary complaints such as dysuria, hematuria, nocturia, enuresis, and increased frequency should be probed for urologic causes of CPP (Table 44.4).

Physical Exam—Pain Directed

Observing a patient's gait, body language, and facial expression can provide valuable information. MFPS can both result in or be a result of musculoskeletal dysfunction as seen with abnormalities in gait, body posture, leg lengths, or

sacroiliac joint mobility. Such abnormalities warrant evaluation by a physiatrist or physical therapist.

PBS, painful bladder syndrome.

The abdominal wall should be examined while relaxed to evaluate for masses, tenderness, rebound tenderness, or guarding. An abdominal exam is performed on the flexed anterior abdominal wall to detect abdominal wall hernias and trigger points, as described in the Myofascial Pain section. Trigger points should be marked on the patient's skin with a soft pen tip and then mapped in the patient's chart for future comparison. Trigger points may also be found within the muscles of the back and buttocks.

A cotton-tipped applicator is useful in the examination of the vulvar vestibule to elicit possible allodynia, which is a feature of vulvar vestibulitis. Special attention should be made to examine the Bartholin ducts and Skene glands. On speculum exam, the vaginal fornices, or vaginal cuff in the posthysterectomy patient, can also be examined for tenderness by using a cotton-tipped applicator. Any cervical discharge should be noted, examined by microscopy, and cultured. The posterior vaginal fornix should be inspected visually to identify endometriosis. This is sometimes possible only with the aid of a tenaculum.

It is helpful to perform a unimanual examination prior to the bimanual examination to avoid “cross contamination” from anterior abdominal wall pain signals. This consists of examining the vagina, cervix, and pelvic floor muscles with a hand in the vagina, without using the abdominal hand. The pelvic floor muscles should be examined individually to include the levator ani group, coccygeus, obturator internus, and the piriformis muscles. The uterus, tubes, and ovaries should be examined for localized pain. The pelvis should then be examined by the bimanual technique.

The rectovaginal exam is particularly useful to evaluate nodular or infiltrating endometriosis. If there is no tenderness in the cul-de-sac or along the uterosacral ligaments yet endometriosis is strongly suspected, the patient should be reexamined during the menses.

Pain Management

Medical pain management may include the use of NSAIDs, anticonvulsant drugs, antidepressant drugs, and narcotics. Knowledge of drug interactions, contraindications, and side effects are important aspects of successful pain management.

Nonsteroidal Anti-inflammatory Drugs and Acetaminophen

NSAIDs usually are a safe category to start with, realizing that there are contraindications to these drugs, especially in patients with gastrointestinal disorders. The cyclooxygenase inhibitor-2 (COX-2) drugs have the advantage of having less adverse effects on the gastrointestinal tract (Table 44.5). In terms of efficacy, there is scant evidence to suggest the superiority of any individual NSAID with regard to either efficacy or safety.

TABLE 44.5 Oral Nonsteroidal Anti-inflammatory Drugs

Ibuprofen 400–800 mg q8h (maximum dose 2,400mg/d)
Naproxen sodium 250–500 mg q8h (maximum dose 1,500 mg/d)
Mefenamic acid 500 mg initially, then 250 mg q6h
Celecoxib 100–200 mg b.i.d.
Ketorolac 10 mg q6h (not to exceed 5 d)

Acetaminophen is a nonsalicylate that has the advantage of having no antiplatelet effects and causing no damage to the gastric mucosa. Doses of up to 4,000 mg daily usually are well tolerated; however, acute overdose can cause hepatic necrosis. Patients with liver disease or chronic alcoholism are at risk for hepatic necrosis. Acetaminophen has a potency similar to aspirin.

Analgesic Adjunct Medications

Analgesic adjunct medications encompass a number of drug categories used in the treatment of neuropathic pain, which include tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), and ion channel blockers. Table 44.6 lists some of these drugs, which have been studied in patients with chronic pain. Our current understanding of the use of these adjuvants in the treatment of CPP is based largely on studies conducted on patients with postherpetic neuralgia, diabetic peripheral neuropathy, and trigeminal

neuralgia. Several randomized clinical trials have been performed in these patient populations.

TABLE 44.6 Oral Analgesic Adjunct Medications

Drug Class	Drug	Dose
Antidepressants		
Tricyclic	Amitriptyline	65–100 mg/d
	Imipramine	100–200 mg/d
	Desipramine	100–200 mg/d
SSRI	Paroxetine	20–40 mg/d
	Fluoxetine	20–60 mg/d
	Citalopram	10–40 mg/d
SNRI	Venlafaxine	37.5–375.0 mg/d
	Duloxetine	20–60 mg/d
Ion channel blockers	Mexiletine	150–600 mg/d
	Carbamazepine	200–1,000 mg/d
	Phenytoin	300 mg/d
	Lamotrigine	400 mg/d
	Gabapentin	1,200–3,600 mg/d
	Pregabalin	50–300 mg/d
Analgesic	Tramadol	50–100 mg q6h

SSRI, selective serotonin reuptake inhibitor; SNRI, serotonin-norepinephrine reuptake inhibitor.

TABLE 44.7 Oral Narcotics

Drug	Dose
Intermediate potency	
Propoxyphene	65 mg q3–4h p.r.n
Codeine	15–60 mg q4–6h

High potency	
Hydrocodone	5–30 mg q4–6h
Oxycodone	5–30 mg q4–6h
High potency—long acting	
Methadone	5–20 mg q12h
Oxycodone SR	10–80 mg q12h

Narcotics

Narcotics are often thought of as being used for acute pain only; however, in some instances under careful supervision, patients with chronic pain may be candidates for narcotic therapy (Table 44.7). In keeping with the World Health Organization's pain-relief ladder, developed for cancer pain relief, it should be established that conservative therapies have been tried adequately and have failed. When narcotics are used, narcotic contracts are often helpful. Patients who demonstrate drug-abuse behavior are not candidates for narcotic therapy. If a patient repetitively loses her prescription, uses multiple physicians for filling narcotic prescriptions, or is routinely running out of narcotics early, she is not considered a narcotic candidate. Patients who use chronic narcotics should regularly report their numeric pain scores and should report on their ability to function. They should regularly be encouraged to wean off narcotics.

Narcotic Agreements

When long-term narcotic therapy is used for pain management, it is useful to have the patient enter into a pain agreement to prevent misunderstandings and to help both the physician and patient comply with the federal laws regarding controlled substances.

When the agreement is entered, it is understood that if the patient terminates the agreement, the physician will discontinue narcotic therapy but will taper off the medicine over a period of several days, as necessary, to avoid withdrawal symptoms. Also, a drug-dependence treatment program should be recommended if appropriate. By signing the narcotic agreement, the patient agrees not to use any illegal controlled substances and not share, sell, or trade medication with anyone.

Opioids, controlled stimulants, or antianxiety medication must not be obtained from any other doctor. The patient must agree to safeguard her pain medicine from loss or theft with knowledge that lost or stolen medicines will not be replaced. She should understand that

prescriptions will be made only at the time of an office visit or during regular office hours and that no refills will be available during evenings or on weekends. This is also helpful for covering physicians who receive calls for patients asking for narcotics. The pharmacy name, location, and telephone number are recorded, and a log of the dose, quantity, and prescription date is recorded in the patient's chart.

Conclusion

CPP is a complex entity, often without obvious visible pathology. A distinction should be made between putative causes of pelvic pain that will respond to specific treatment versus pelvic pain associated with incidental pathology, the treatment of which may result in failure to achieve pain relief and, in some cases, removal of otherwise normal organs. In refractory cases, appropriate consultation with other health care providers is often helpful. Treatment may take a more general and empiric course resulting in the use of analgesic adjunct medications and possibly the judicious use of narcotics.

Summary Points

- CPP is a complex entity, often without obvious visible pathology.
- Level I data suggest no benefit to adhesiolysis in patients with CPP.
- The extent of endometriosis present correlates poorly with the degree of pain, except for deep infiltrating endometriosis in the rectovaginal septum, which is associated with pain.
- PID may cause chronic pain because the initial inflammatory insult starts a cascade of signals between the pelvis, spinal cord, and brain, resulting in visceral neuropathic pain.
- MFPS, found in most people presenting to pain specialty clinics, is generally unrecognized and undertreated. Similarly, many women presenting to gynecologists with pelvic pain also have PBS.
- Hysterectomy effectively relieves pain of uterine origin in most women. Hysterectomy may be indicated in the absence of pathology in patients who have concluded childbearing and who have not responded to conservative therapy.
- Depression, anxiety, and panic attacks commonly exist as comorbid conditions in women with CPP.
- Chronic narcotic management may be indicated when more conservative therapies have been tried adequately and have failed. When narcotics are used, narcotic contracts are often helpful.

Perioperative Evaluation

Jeff Peipert
Sarah Hammil

> *One important key to success is self-confidence. An important key to self-confidence is preparation.*
>
> —Arthur Ashe

In this country, obstetrician–gynecologists are the primary surgeons for over 3.6 million pelvic operative procedures annually (Table 45.1). These procedural volumes, when combined with the many thousand minor office and obstetric procedures, are testimony to the enormous potential physical, psychologic, and economic impact of surgery and potentially preventable adverse events on women's health care. Importantly, nearly 50% of all adverse perioperative events are preventable. Risk prevention should be the ultimate goal of every surgeon. Assuming the role of primary care physician and surgical subspecialist for women, obstetrician–gynecologists should accept responsibility for developing, instituting, and completing all aspects of perioperative management. As an important step to improve quality of care, obstetrician–gynecologists should discuss nonsurgical options and understand appropriate surgical indications for pelvic disease processes.

Our primary goals should consist of prospective preoperative recognition, evaluation, and management of the significant clinical aspects of existing medical comorbidities and development of a flexible, multifaceted surgical skill set that increases the opportunity for safe completion of the procedure. Finally, pelvic surgeons should be capable of devising a postoperative care plan that further minimizes the risk of an adverse perioperative outcome, enhances the early recognition of acute perioperative problems, and lessens the risk and intensity of potentially catastrophic perioperative complications. This care plan should be formalized prior to entering the preanesthetic area or the operating suite, and its execution should contain enough clinical alternatives to ensure a successful result, regardless of the intraoperative findings or postoperative complications encountered.

The volumes of existing published literature on surgical alternatives and indications establish a clear message: “optimal” perioperative care is a moving target. Every treatment plan and intervention requires careful aim if the goals of improved quality and

optimal patient outcome are to be attained. Mastery of these perioperative planning processes only serves to improve the individual and collective quality of patient care. Proper implementation should result in decreased individual, regional, and national health care expenditures.

Surgical Indications and Consent for Surgery

The obstetrician–gynecologist should thoroughly evaluate a patient's reproductive tract complaints prior to entertaining the possibility of surgical management. In addition to evaluating the pelvic condition, it is vital to conduct a preoperative search for physical or psychologic comorbidities. Only when armed with this global information can the surgeon objectively present the risks, benefits, and alternatives and realistically relate the expected outcome of the entire spectrum of accepted medical and surgical options. Medical and noninvasive options for therapy should be considered prior to operative intervention. Following the failure of or mutual decision to bypass medical management, appropriate surgical management should be discussed. This information should be processed and presented to the patient (and other support persons when appropriate) clearly and respectfully, using understandable language that allows and facilitates an informed decision and consent process.

TABLE 45.1 Surgical Procedures in Obstetrics and Gynecology

Subspecialty Rank	Procedure	Number	National Rank
1.	Cesarean section	858,000	
2.	Tubal occlusion	681,000	2

Rutkow I. Surgical operation in the United States. *Arch Surg* 1997;132:983–990, with permission.

Although the preoperative diagnostic period may be deemed routine by the surgeon and staff, many women consider the prediagnostic interval to be the most stressful time of treatment. This psychologic stress contributes to difficulty in understanding the importance and results of diagnostic studies or results and potentially clouds the information covered during preoperative discussions. Decisions, options, and alternatives, as they relate to the potential need for postoperative therapy, can be lost. The preoperative use of illustrative drawings, pamphlets, videos, or other visual educational materials often can be of assistance in improving patient (and family) comprehension of medical alternatives, operative indications, associated risks, and expected treatment outcomes.

Typically, this preoperative encounter (or encounters) to discuss surgical options and obtain consent is best undertaken in a private setting, completed in a manner that is conducive of a two-way flow of communication. Eye contact, a caring touch, an unhurried approach, and other reassuring physician behaviors lower communication barriers and facilitate and support a patient's comprehension. The complexity of preoperative discussion and necessary time expenditure may vary dramatically with the surgical indications as well as with the medical alternatives to the proposed procedure. Regardless, the algorithm of care, surgical risks, and outcome expectations should be detailed, recognizing that modification may be required secondary to important or imperative patient desires (e.g., a patient desiring retention of ovaries or fertility). Regardless of the extent of preparation and best surgical technique, any unexpected or adverse intraoperative or postoperative event can alter dramatically the final surgical procedure and ultimate result. The apparently “simple” laparoscopic salpingo-oophorectomy may be complicated by uncontrolled bleeding, intestinal injury, or the finding of an ovarian malignancy. Postoperative myocardial infarction (MI), infection, or thromboembolism may occur. During an explanation of surgical risks, it is reasonable to discuss with the patient adverse events that occur at a frequency of 1% or more. All preoperative consent discussions should include discussion of the risk of death or permanent disability. The consent process also allows an opportunity for significant patient education, which has been shown to decrease the need for postoperative analgesia and improve postoperative outcomes. Unless the clinical situation is emergent or life threatening, these discussions are best undertaken at a time remote from the day of surgery. Timely entered, complete, and legible chart documentation should follow all of these discussions.

Before moving ahead with surgical intervention, the surgeon is faced with a number of other important procedural questions including the route (i.e., vaginal vs. abdominal vs. laparoscopic approach) as well as who should perform the procedure. Reported data confirm that even among subspecialists, individual surgical skills and outcomes of specific procedures can differ dramatically. These differences may relate to the surgeon's innate technical ability, the specifics of the individual's previous training and experience, patient selection, or factors unrelated to the physician. New training demands of subspecialties have altered the overall extent of residency surgical experience, resulting in fewer major operative procedures being completed per trainee. Coupled with the increasing ratio of physicians in practice to annual operative procedures and the increasing technical

procedural subspecialization, it is easily understood how difficult it is for the pelvic surgeon to obtain, maintain, or refine new surgical skills, even in the restricted subspecialty where the surgical focus is entirely on reproductive tract procedures. These factors lend credence to the adage “no one can be all things to all people,” and each physician must individualize the decision to operate, consult, or refer. Success of many procedures is related to increasing surgical experience, surgical volume, and expertise. Arguments against consultation or referral have little scientific merit and may not be in the patient's best interest. Although circumstances may prohibit actual patient referral, the ready availability of curbside, personal, telephone, and Internet consultation should encourage information dissemination, and utilization of available resources should improve patient care.

History and Physical Examination

> *Listen to women and they will tell you what's wrong with them.*
>
> —Charles E. Flowers

Every operative procedure requiring anesthesia should be viewed as a physiologic stress test. The intensity of the stress response varies in direct proportion to the extent of the

actual surgical procedure and is associated with a clinically and biochemically measurable adverse effect. Nearly every organ system is adversely affected by general anesthesia. General anesthesia results in 20% reduction in resting heat production and an increase in body surface heat loss. These two factors increase a patient's predisposition to hypothermia which causes an increased risk of adverse cardiac events, altered pulmonary reponse to hypercarbia and hypoxemia, impaired coagulation, and poor wound healing. The untoward anesthesia-related pulmonary effects of impaired oxygenation and altered lung mechanics are likely well tolerated by the 40 year old, but they may have catastrophic consequences in the elderly or in those with coexisting pulmonary disease. Most inhalational drugs directly create increased cardiac risk by altering myocardial oxygen supply and demand kinetics. Myocardial depression, increased arrhythmogenicity (as high as 27% incidence), and altered neural tone form the triad for predisposing women to adverse cardiovascular effects. Importantly, these risks are not lessened with spinal anesthesia compared with risks associated with general anesthesia. Reduction in renal blood supply (decreased by 30% to 70%), suppression of the immune system, ileus, and stress-related gastric ulceration represent but a few of the other quantitative adverse effects of anesthesia. Many of these effects can be correlated with the duration of operation, and every effort should be made to increase operative efficiency in an attempt to safely shorten the procedure and minimize risks.

Despite these anesthesia-enhanced risks, only a small percentage of operative deaths are attributable solely to anesthesia. Less than 18% of surgical mortality is directly attributable to the surgical procedure. The vast majority of surgical mortality (79%) can be related directly to problems created in great part from the patient's coexisting medical disease. This mortality risk further illustrates the need to undertake a diligent preoperative search

to identify and potentially modify the adverse effects of any significant coexisting medical condition.

The diagnostic power contained in a carefully obtained history and a thorough physical examination is enormous. The reproducible validity of this simple, easily obtainable evaluation is underscored when recognizing that as many as 98% of abnormalities found with preoperative laboratory and radiologic screening can be predicted by historical or physical findings.

Although studies relating to the pelvic process (i.e., urodynamics) frequently are necessary to delineate the need for surgery, attempts to obtain important historical information regarding diagnosed medical comorbidities and clinically silent medical disease are vital to direct additional preoperative evaluation. Review of pertinent medical records combined with initial direct questioning about previous hospitalizations, current treating physicians, concurrent diagnoses, use of prescribed and over-the-counter medications, and allergies will assist in the detection of coexisting medical disease. This information may be vital to the preoperative plan regarding the continuation (e.g., cardiac, hypertensive) or discontinuation (e.g., aspirin, oral contraceptives, anticoagulants) of medications. Over-the-counter and herbal medication usage can create the potential for additional untoward complications and should be evaluated in a nonjudgmental fashion (Table 45.2).

TABLE 45.2 Herbal Medicines: Possible Adverse Effects

Sympathomimetic effects:
Ephedra sinica (ma huang)
Panax ginseng (ginseng)
Glycyrrhiza glabra (licorice)
Hydrastis canadensis (goldenseal)
Potentiate bleeding:
Tanacetum parthenium (feverfew)
Allium sativum (garlic)
Ginkgo biloba (ginkgo)
Zingiber officinale (ginger)
Prolong sedative effects:
Valeriana officinalis (valerian)
Piper methysticum (kava kava)
Hypericum perforatum (St. John's wort)

An area that should not be overlooked is the importance of determining a patient's functional status. The functional status of any given patient, but particularly elderly patients, may be an important predictor of surgical risk. Functional status is defined as the capacity to perform activities of daily living and includes aspects of both social and cognitive functioning. Recent data reveals that these functional measures may be even more important than acute physiologic scores in predicting mortality in hospitalized patients. A patient's performance status can be determined adequately during a thorough review of systems while also giving the clinician an opportunity to diagnose previously undetected medical disease. Although intended to cover multiple systems, simple questions as to the patient's ability to walk a mile, climb two flights of stairs, or blow out a match from 12 inches away may suffice as a screen for significant cardiopulmonary disease. Various published functional status indices exist and can be useful tools to determine the degree of physiologic stress that a given patient can tolerate under routine circumstances. Historical information obtained by questionnaire can be considered valid; however, the presence or absence of significant symptoms should be confirmed by the clinician in the perioperative period.

A thorough multisystem physical examination is an essential part of every preoperative evaluation. Specific attention to the cardiopulmonary system assists in the detection of important coexisting disease that may alter outcome adversely and can also direct additional investigation. Every system carries some import, and abnormal findings allow

for appropriate morbidity-reducing, cost-effective adjustments in the perioperative plan.

Laboratory Investigation

The primary goal of preoperative laboratory preparation is to obtain results that allow reduction of those inherent risks related to the proposed procedural component as well as those risks associated with occult or recognized coexisting medical morbidities. It has become apparent that a “broadly cast net” preoperative laboratory screening strategy confers little patient benefit for the following reasons: (a) the majority of laboratory abnormalities can be predicted by findings noted in the history and physical examination, and it is rare to detect an unexpected abnormality; (b) the physiologic, psychologic, and economic costs associated with the evaluation of abnormal laboratory (including false-positive) studies bring little value and rarely influence clinical care; (c) as many as 60% of abnormal preoperative test results are not known or evaluated preoperatively, creating potential liability, and multiple reports suggest that nearly 70% of ordered preoperative laboratory tests are not indicated by facts obtained in the history and physical examination.

This information reiterates the importance of the history and physical examination and suggests that a directed preoperative laboratory testing strategy (Table 45.3) for routine procedures is both safe and cost-effective. All preoperative testing should be justified based on a specific sign, symptom, or diagnosis. Obviously, special studies such as tumor markers (e.g., CA-125) are appropriate during evaluation and management of women with pelvic malignancies, because they offer diagnostic assistance, facilitate decisions regarding

patient triage, are potentially prognostic, and are of significant value during postoperative management. Although care should be individualized, it has become apparent that directed preoperative laboratory testing forms a firm foundation for quality preoperative care for patients undergoing elective procedures.

Although advances in blood banking technology have lessened the risk of transfusion and favorably affected the outcomes of many surgical procedures, it is apparent that women do not need to have a type and cross match performed prior to the majority of obstetric or gynecologic surgical procedures. Although maximal surgical blood order schedules have been established, they should be validated at each institution. When deemed necessary, a type and screen allows for identification of specific antibodies and assures rapid availability (≤20 min) of red blood cell products. Individual decisions regarding blood bank strategies should be related to the patient's preoperative status (i.e., hemoglobin and hematocrit, blood volume), anticipated losses, and existing comorbidities that might carry an early transfusion trigger. Anemia is not uncommon among women undergoing pelvic surgery. Although it may constitute an indication (menorrhagia associated with leiomyomas) or result from an indication (cervical cancer), its presence should prompt an evaluation. As deemed appropriate, a preoperative search for other causes or losses should be undertaken. Additionally, preoperative discussions regarding procedure-associated blood loss and its attendant risks represent an important aspect of informed consent.

Critically ill patients may benefit from having their serum hemoglobin levels maintained at about 10 g/dL, but data suggest little effect of transfusion on survival in patients whose hemoglobin levels are between 8 and 10 g/dL. Aside from the special situations mentioned

above, the majority of women can safely undergo elective procedures without a type and screen.

Radiologic Investigation

Routine imaging studies can be obtained safely as directed by findings of the history and physical examination. The indications for a preoperative chest radiograph are relatively straightforward and should be limited to assessment for the presence of acute, progressive, or chronic changes of cardiac or pulmonary disease. Abnormalities found on preoperative chest radiographs are associated with an increased risk of perioperative pulmonary complications. Unfortunately, unnecessary chest radiographs and many additional, sometimes unnecessary, undirected diagnostic preoperative imaging studies are obtained frequently.

Diagnostic ultrasonographic examination, pelvic and abdominal computed tomography (CT), and magnetic resonance imaging studies are performed in patients with suspected or known gynecologic malignancies. These studies may suggest the benefit of preoperative triage to a subspecialist but rarely influence the surgical approach. Their results should not be considered binding, typically contribute little to clinical care, and often add significantly to health care costs. Although the radiologist's suggestions for additional studies are noted frequently, the astute pelvic surgeon should combine physical findings, patient symptoms, and laboratory results to develop the perioperative care plan.

Although proponents of preoperative “radiologic staging studies” suggest relative accuracy, the pelvic surgeon must recognize the subjective aspects of interpretation. In general, their routine use has not been associated with an alteration in perioperative clinical care. Although findings may alter approach, negative results do not exclude the finding of significant pathology. However, it appears that in specific situations, CT scans have a significant false-negative result rate (e.g., for the evaluation of extraovarian disease). Radiologic investigation adds little to clinical care in patients with endometrial cancer in the absence of physical findings. There is little clinical value for intravenous pyelography (IVP) to evaluate ureteral location or displacement, because it is not a substitute for intraoperative ureteral identification. In the absence of malignancy, hydronephrosis is likely related to displacement and is easily corrected or managed during the operative procedure.

A notable exception to the recommended “less is more” strategy toward preoperative radiologic investigation is an abnormal finding on a clinically indicated routine cancer screening study (e.g., mammography). In this case abnormal results may have a significant impact on clinical care, particularly in those women undergoing “elective pelvic procedures.”

Endoscopic Evaluation

There is little evidence to suggest the value of multiple endoscopic procedures prior to most routine gynecologic procedures. However, it is certainly appropriate to consider obtaining history-directed or disease-specific (e.g., inflammatory bowel disease, previous

colon cancer) or recommended cancer screening endoscopic procedures prior to elective procedures. For example, endoscopy performed prior to rectovaginal or vesicovaginal fistula repair may render significant and important information and cause the physician to alter the surgical approach or initiate referral.

Cardiac Disease

Preoperative assessment to detect undiagnosed heart disease and direct appropriate perioperative treatment of women with long-standing or newly diagnosed cardiac disease is of vital importance. The majority of inhalational anesthetics are myocardial depressants, modify neural tone, and are arrhythmogenic, creating cardiac risk even in the healthy patient. Nearly 50,000 perioperative MIs occur annually. Approximately 20,000 are fatal, and hundreds of thousands of related serious extracardiac complications occur, resulting in poor outcome. The prevalence of cardiovascular disease increases directly with increasing age, and within the aging population, serious cardiac events occur regularly. Gynecologic procedures represent a significant increase in the incidence of necessary major intra-abdominal procedures in the aging population, potentially increasing the absolute risk of cardiac morbidity. Although heart disease may not be readily apparent, the answers to carefully framed historical questions can assist in unmasking occult cardiac risk factors. Gynecologists should feel compelled to become familiar with the important aspects of perioperative cardiac care in order to improve individual patient outcome.

Proper preoperative cardiac assessment requires a systematic approach, typically undertaken in close coordination with qualified consultants. Attention to history, physical findings, and the effects of comorbid diseases forms the foundation for initial evaluation. These findings

assist in the direction of ordering ancillary cardiac studies, which can clarify risk and improve predictive power for perioperative morbidity associated with the proposed gynecologic surgery. They also allow institution of a sound plan for perioperative monitoring and management. A disease-specific approach is important, specifically addressing signs, current symptoms, and management of coronary artery disease (CAD), hypertension, heart failure, valvular heart disease, arrhythmias, pacemakers, pulmonary vascular disease, and type and extent of surgery.

General Considerations

Particular energy should be directed preoperatively to elicit historical or physical evidence of cardiac ischemia. Important elements include angina, a history of MI, past or current signs or symptoms suggesting congestive heart failure, unexplained palpitations, evidence of previous cardiac intervention, and renal impairment. Important aspects of noncardiac diseases that increase the incidence of cardiac risk factors, including diabetes mellitus, hypertension, hypercholesterolemia, family history of CAD, and obesity, should also be evaluated. Age >70 years, MI within the preceding 12 months, and evidence of congestive heart failure on physical examination significantly increase postoperative cardiac complications in patients undergoing gastrointestinal, urologic, and gynecologic surgery.

Concurrently, the pelvic surgeon should attempt to determine the patient's "functional capacity." The simple inability to walk three blocks or climb two flights of stairs portends a poor functional status and increased operative risk. Physical examination evaluating the patient's overall status is mandatory. This evaluation, coupled with pertinent laboratory and radiologic information and an electrocardiogram (ECG), provides a baseline estimate as to actual perioperative cardiac risk. Numerous schema from Goldman and others intended to quantify cardiac risks have been designed, reported, and verified in an attempt to quantitate perioperative cardiac risk. The American College of Cardiology–American Heart Association (ACC-AHA) published revised practice guidelines based on qualitative analysis. The guidelines define clinical risk stratification for noncardiac surgical procedures. Noncardiac procedures with high (>5%), intermediate (1% to 5%), and low (<1%) risk of cardiac morbidity or mortality have been categorized (Table 45.5).

TABLE 45.4 Cardiac Risk Stratification for Noncardiac Surgical Procedures

High (Reported Cardiac Risk Often >5%)
- Emergent major operations, particularly in the elderly
- Aortic and other major vascular
- Peripheral vascular
- Anticipated prolonged surgical procedures associated with large fluid shifts or blood loss or both

Intermediate (Reported Cardiac Risk Generally <5%)
- Carotid endarterectomy, head and neck
- Intraperitoneal and intrathoracic
- Orthopedic

Low (Reported Cardiac Risk Generally <1%)
- Endoscopic procedures
- Superficial procedure (i.e., dilation and curettage)
- Breast

From ACC/AHA guideline update for perioperative cardiovascular evaluation for noncardiac surgery—executive summary a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Update the 1996 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery). *Circulation* 2002;105:1257–1267, with permission.

In the perioperative setting, coronary artery bypass surgery or other invasive interventions

(i.e., coronary angioplasty) are appropriate only when they would otherwise be indicated for symptoms or to manage test-related cardiac disease not in the face of impending pelvic surgery. Specific disease states requiring strong consideration of presurgical revascularization include poorly controlled angina pectoris (despite maximal medical therapy), high-risk left main coronary artery stenosis (>50%), severe two- or three-vessel CAD (with involvement of the proximal left anterior descending artery) with >70% stenosis, easily induced myocardial ischemia on preoperative stress testing, and left ventricular systolic dysfunction at rest.

TABLE 45.5 Cardiac Conditions Associated with Endocarditis

Endocarditis Prophylaxis Recommended

High-risk category

Prosthetic cardiac valves, including bioprosthetic and homograft valves

Previous bacterial endocarditis

Complex cyanotic congenital heart disease (e.g., single-ventricle states, transposition of the great arteries, tetralogy of Fallot)

Surgically constructed systemic pulmonary shunts or conduits

Moderate-risk category

Most other genital cardiac malformations (other than those listed above and below)

Acquired valve dysfunction (e.g., rheumatic heart disease)

Hypertrophic cardiomyopathy

Mitral valve prolapse with valvular regurgitation, thickened leaflets, or both

Endocarditis Prophylaxis Not Recommended

Negligible-risk category (risk no greater than that of the general population)

Isolated secundum atrial septum defect

Surgical repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus (without residual beyond 6 months)

Previous coronary artery bypass graft surgery

Mitral valve prolapse without valve regurgitation

Physiologic, functional, or innocent heart murmurs

Previous Kawasaki syndrome without valve dysfunction

Previous rheumatic fever without valve dysfunction

Cardiac pacemakers (intravascular and epicardial) and

implanted defibrillators

Dajani AS, Taubert KA, Wilson W, et al. Prevention of bacterial endocarditis: recommendations by the American Heart Association. *JAMA* 1997;277:1795, with permission.

Cardiac Disease–Specific Approach

Coronary Artery Disease

CAD commonly occurs at a lower incidence in females than in males; however, diabetic women are risk equivalent to men. The mortality of an acute MI is greater for women and increases dramatically in the aged patient. Importantly, MIs occurring during the perioperative period carry a higher mortality risk than those occurring otherwise.

Many surgical patients have diagnosed CAD or risk factors for CAD. Women who are potential candidates for attempts at preoperative myocardial revascularization may benefit from noninvasive cardiac testing performed to determine the amount of myocardium in jeopardy, the patient's ischemic threshold, and the objective determination of ventricular function. Test results should be used to assist in stratifying prognostic information and determining the extent and benefit of perioperative surgical or medical intervention and postoperative monitoring.

Hypertension

As the training and practice of obstetricians–gynecologists increasingly stresses the importance of primary care, the preoperative evaluation and the management of hypertension have become a major focus on the gynecologic patient's problem list. Although the identification of early-stage hypertension should lead to the institution of appropriate medical therapy, the ACC-AHA guidelines suggest that those with stage II or milder hypertension (systolic blood pressure below 180 mm Hg and diastolic blood pressure below 110 mm Hg) are not at increased risk for perioperative cardiovascular complications. Surgical delay for medical treatment of women with stage I or II hypertension is not necessary or beneficial. However, elevated blood pressure in patients with stage III hypertension (systolic blood pressure 180 mm Hg or higher and a diastolic blood pressure 110 mm Hg or higher) should be controlled prior to surgery. The administration of ß-adrenergic blockers in this clinical situation results in rapid, effective control of severe blood pressure elevation. ß-adrenergic blockade also prevents perioperative hypo- or hypertension, either of which is associated with an increased risk of coronary ischemia. Regardless of actual measured systemic pressures, the ACC-AHA guidelines suggest that the blood pressure of patients with significant hypertension who require urgent surgery be controlled. The goal is to avoid the ischemic complications associated with perioperative blood pressure fluctuations that commonly occur in the surgical patient who has uncontrolled hypertension.

Heart Failure

Ventricular failure is an important predictor of and prognostic factor for perioperative cardiac morbidity. The initial attempt to identify women with ventricular dysfunction begins with a detailed history and organ-specific physical examination. Determination of ventricular status is mandatory in those with evidence or history of congestive heart failure, because the physiology of perioperative ventricular failure portends an ominous situation. Perioperative subspecialty consultation, pharmacologic manipulation to maximize cardiac oxygen supply–demand ratio, careful administration of intravenous fluids, and cardiac monitoring may benefit these patients. During preoperative investigation, gynecologic surgeons should not exclude the possibility of rare causes of cardiomyopathy, including hypertrophic obstructive cardiomyopathy, because their appropriate medical management decreases morbidity.

Echocardiography, to obtain an estimate of ventricular function and to rule out anatomic abnormalities, should be considered and may be necessary for the perioperative assessment for those women with suspected, known, or history of heart failure or cardiomyopathy.

Valvular Heart Disease

Although interpretation of the physical findings can be challenging, the gynecologic surgeon should attempt to identify significant heart murmurs. Echocardiography aids in defining the anatomic abnormality and in detailing the need and benefit of antibiotic endocarditis prophylaxis (Table 45.4). Failure to diagnose any significant valvular dysfunction or to administer appropriate antimicrobial prophylaxis increases the risk of a catastrophic perioperative consequence.

Aortic stenosis poses the greatest valvular risk for poor postoperative cardiac outcome. Cardiac morbidity in women with untreated aortic stenosis undergoing noncardiac surgery approaches 10%, sufficient to persuade every pelvic surgeon to diagnose this condition. ACC-AHA practice guidelines advise postponement of elective surgery in women with severe or symptomatic aortic stenosis until valve replacement (the accepted standard intervention) can be performed. In emergent situations, aortic valvuloplasty may be employed but has less certain success.

In general, surgical correction of mitral stenosis is not indicated prior to noncardiac surgery unless the severity would warrant treatment in a nonsurgical setting. If deemed necessary, balloon valvuloplasty is an appropriate corrective option for those with severe mitral stenosis. Mild to moderate mitral stenosis requires control of perioperative heart rate to reduce the risk of heart failure.

Significant aortic regurgitation requires attention to intravascular volume control and attempts at medical afterload reduction. In contrast to mitral stenosis, bradycardia should be avoided or aggressively treated to avoid left ventricular backfill.

Mitral regurgitation most commonly is associated with papillary muscle dysfunction and

mitral valve prolapse. Prior to surgical procedures, antimicrobial prophylaxis may be indicated for those with mitral valve prolapse and demonstrable clinical evidence of regurgitation or echocardiographic evidence of anatomic mitral valve leaflet abnormalities. Women with significant mitral regurgitation murmurs require careful monitoring of the left ventricular ejection fraction, because the low-resistance regurgitant valve predisposes perioperative patients to retrograde cardiac flow, resulting in pulmonary edema and high pulmonary artery pressures. Invasive perioperative cardiac monitoring may be necessary, as echocardiography tends to overestimate ejection fraction in patients with mitral regurgitation.

Patients with prosthetic mitral valves receiving systemic anticoagulants require intervention to lessen the risk of endocarditis and intracardiac coagulation. For patients at low, intermediate, and high risk of thromboembolism, the Seventh Consensus Conference on anticoagulation suggests that warfarin therapy should be stopped approximately 4 days before surgery, allowing the international normalized ratio (INR) to return to near-normal values. More specific recommendations based on an individual patient's category of risk were also outlined by the conference and are as follows:

. For patients with a low risk of thromboembolism who are undergoing an intervention that increases the risk of thrombosis, postoperative prophylaxis should be used consisting of low-dose unfractionated heparin (UFH) or a prophylactic dose of low-molecular-weight heparin (LMWH). Warfarin therapy should be restarted simultaneously. Alternatively, a low dose of UFH or a prophylactic dose of LMWH also can be used preoperatively.

.. Patients with an intermediate risk of thromboembolism should be covered preoperatively with a low dose of UFH or a prophylactic dose of LMWH while the INR is returning to normal. Postoperatively, therapy should be commenced with low-dose UFH or LMWH and concurrent warfarin therapy.

. For patients with a high risk of thromboembolism, therapy with full-dose UFH or full-dose LMWH should be instituted approximately 2 days preoperatively. UFH can be administered as a subcutaneous injection as an outpatient or as a continuous intravenous infusion after hospital admission in preparation for surgery and can be discontinued approximately 5 hours before surgery with the expectation that the anticoagulant effect will have worn off at the time of surgery. Alternatively, subcutaneous UFH or LMWH can be used preoperatively, discontinuing therapy 12 to 24 hours before surgery with the expectation that the anticoagulant effect will be very low or have worn off at the time of surgery. In these patients, therapy with low-dose UFH or LMWH should be commenced postoperatively.

Arrhythmias

Every gynecologic surgeon will encounter perioperative cardiac arrhythmias. The majority are considered benign, but their underlying etiology should be sought aggressively because undiagnosed cardiac ischemia may initially become clinically evident as a perioperative arrhythmia. Perioperative arrhythmias may worsen existing ischemia by increasing myocardial demand or decreasing cardiac efficiency. Pulmonary disease, metabolic

derangements, or drug toxicities are common causes. Monitoring and treatment is important, because an unstable arrhythmia such as atrial fibrillation occasionally may deteriorate into a life-threatening rhythm (i.e., ventricular fibrillation). In addition to conferring a therapeutic cardiac morbidity risk reduction in patients with CAD, ß-blockers may reduce arrhythmia-related perioperative morbidity and mortality.

Premature ventricular contractions occurring at a rate of fewer than 6 per minute are presumably “benign.” Even short and spontaneously converting runs of ventricular tachycardia may not predispose patients to perioperative death from MI. However, underlying coronary ischemia may be unmasked by the occurrence of these rhythms, making it imperative that the underlying etiology of a perioperative arrhythmia be ascertained, even if these are not treated by antiarrhythmic agents other than ß-blockade. Atrioventricular (AV) block, especially Mobitz type II or third-degree heart block, may increase operative risk. Patients with type I second-degree AV block, first-degree AV block, and left and right bundle branch blocks are usually asymptomatic, and their arrhythmias rarely contribute to postoperative morbidity and mortality. It is reasonable to consider early subspecialty consultation to diagnose and treat women who develop perioperative cardiac arrhythmias.

Patients with known or previously treated or untreated congenital heart disease or pulmonary vascular disease deserve close evaluation. Individuals with previous surgical correction of a ventricular septal defect, patent ductus arteriosis, or tetralogy of Fallot may be at increased operative cardiac risk, possibly due to decreased pulmonary vasculature reactivity to hypoxia.

Risk Stratification According to Type of Surgery

Although individually weighted, existing patient risk factors, the type and extent of operation, and the operative circumstances are important to delineate the risk of perioperative cardiac morbidity. Intuitively, the decision to operate and the choice of operation or operative approach should be made in an attempt to offer the most effective treatment while minimizing patient cardiac risk. Other medical conditions should be addressed to lessen any indirect impact on perioperative cardiac outcome.

Every surgical intervention should be based on acute or chronic patient-specific factors. Although emergent

---

surgical indications lessen available evaluation time, urgency does not absolve the responsibility to search diligently for significant risk factors. The young woman in shock with a ruptured ectopic pregnancy may provide the physician with only a brief opportunity for cardiac evaluation; however, cardiac risk factors are uncommon in this population, minimizing the necessity for or benefit of an extensive evaluation. The elderly patient with acute intestinal obstruction and strangulated bowel related to ovarian carcinoma may harbor significant cardiac risk factors but may require lifesaving surgery despite significant coronary risk and a high potential for morbidity.

Perhaps more problematic is evaluation of those patients who require diagnostic or therapeutic surgery for pelvic malignant neoplasms and who are discovered to have

cardiac disease during the presurgical evaluation. The clinical situation surrounding this or semiurgent gynecologic procedures may preclude the benefit of extensive intervention (i.e., coronary artery bypass grafting [CABG]). In this situation, consultation and maximal medical therapy can improve the patient's perioperative cardiac condition and lessen risks.

Perioperative evaluation of women undergoing elective pelvic surgery should consider the risk of an adverse cardiac event in relation to the extent of the necessary surgical procedure. The benefit of medical management of the gynecologic condition should always be considered carefully. A minimally invasive or a vaginal surgical approach carries less physiologic stress and less risk of associated cardiac morbidity when compared with more extensive intervention (e.g., an abdominal approach). Although it requires planning and technical flexibility, matching the patient's gynecologic and medical conditions to a proper surgical approach should be every surgeon's goal.

Risk Assessment and Treatment

The ultimate objective of preoperative cardiac risk assessment is to rule out serious CAD that requires cardiac intervention separate from the need for noncardiac surgery. Preoperative evaluation should be designed to recognize existing disease, expose occult underlying heart disease, and provide an opportunity for appropriate cardiac assessment.

Noninvasive Testing

ACC-AHA recommendations for those undergoing noncardiac surgery provide a short-cut to the appropriate application of noninvasive cardiac testing, which is indicated by two of three listed risk factors (Table 45.6). This testing schema assumes that the identification of a high-risk patient will identify those who would benefit from preoperative coronary revascularization or maximization of medical therapy. Either would contribute to improving the patient's long-term quantity and quality of life. Noninvasive studies include the 12-lead ECG, echocardiography, contrast ventriculography, radionuclide angiography, exercise stress testing, nonexercise stress testing, myocardial perfusion imaging, and dobutamine stress echocardiography. The ACC-AHA evaluation guidelines algorithm can be applied to all patients.

TABLE 45.6 Shortcut to Noninvasive Testing in Preoperative Patients If Any Two Factors Are Present

1. Intermediate clinical predictors are present (Canadian class 1 or 2 angina, prior MI based on history or pathologic Q waves, compensated or prior heart failure, or diabetes)
2. Poor functional capacity (<4 METs)
3. High surgical risk procedure (emergency major operations[a],

aortic repair or peripheral vascular surgery, prolonged surgical procedures with large fluid shifts or blood loss)

MI, myocardial infarction; METs, metabolic equivalents.
[a]Emergency major operations may require immediately proceeding to surgery without sufficient time for noninvasive testing or preoperative interventions.
Modified from Leppo JA, Dahlberg ST. The question: to test or not to test in preoperative cardiac risk evaluation. *J Nucl Cardiol* 1998;5:332–342, with permission. Copyright (c) 1998 by the American Society of Nuclear Cardiology.

In patients who are ambulatory, the noninvasive test of choice is exercise ECG testing, which can provide information about functional capacity as well as detect myocardial ischemia. In patients unable to perform adequate exercise, dipyridamole myocardial perfusion imaging and dobutamine echocardiography are the most commonly used modalities. In a meta-analysis of noninvasive studies, dobutamine stress echocardiography, ambulatory electrocardiography, radionucleotide ventriculography, and dipyridamole thallium scanning were found to have similar predictive value in predicting adverse cardiac outcome after vascular surgery. Patients in whom evidence of unstable angina or evidence of residual ischemia after MI is identified at the time of preoperative evaluation should be referred for coronary angiography. In general, the gynecologic surgeon should consider the role of noninvasive testing after consultation with qualified specialists to assist in the evaluation, interpret the results of noninvasive testing, and recommend intervention for those patients with cardiac risk factors.

Coronary Artery Bypass Graft-Specific Interventions

The decision to perform CABG versus maximizing medical therapy prior to noncardiac surgery should be based on potential risks versus the short- and long-term benefits of coronary revascularization. Eagle and colleagues, reporting on 3,368 patients (Coronary Artery Surgery Study database) with CAD, found that patients undergoing minimally invasive procedures have a cardiac-related mortality rate of <1%, regardless of previous CABG. In contrast, major surgical procedures including abdominal surgery carried a significantly higher risk of cardiac morbidity and

mortality for those patients with a history of CAD. When compared with patients having undergone prior coronary bypass surgery, medical treatment alone was highly correlated with an increased risk of perioperative MI or death. Among patients undergoing higher risk surgery, prior coronary artery bypass graft was associated with fewer postoperative deaths (1.7% versus 3.3%, $P = .03$) and myocardial infarctions (0.8% versus 2.7%, $P = .002$) compared with medically managed coronary disease.

The ACC-AHA Task Force has recommended that preoperative coronary revascularization

be employed in specific clinical situations: in those women with acceptable risks of coronary revascularization and a suitable amount of viable myocardium, those with left main coronary artery stenosis, those with three-vessel CAD in conjunction with left ventricular dysfunction, those with two-vessel disease involving severe proximal left anterior descending artery obstruction, and when intractable coronary ischemia persists despite maximal medical therapy.

These practice guidelines also suggest that the timing of coronary revascularization be weighed against the clinical urgency and extent of noncardiac surgical intervention. Patients requiring elective noncardiac procedures of intermediate or high surgical risk who have significantly abnormal coronary anatomy should be referred for surgical revascularization prior to noncardiac surgery. Those same patients undergoing low-risk noncardiac surgical procedures or patients with less severe coronary artery lesions should not undergo preoperative coronary artery revascularization.

Preoperative Prophylactic Coronary Intervention

The ACC-AHA Task Force has recommended that percutaneous transluminal coronary angioplasty (PTCA) be used in the perioperative setting in a manner identical to that proposed outside of the perioperative setting. Although debate exists as to the most appropriate interval from PTCA to the pelvic surgical procedure, delay for at least 2 to 4 weeks should be allowed to ensure healing and exclude restenosis of the treated vessel. However, extended delays of more than 6 to 8 weeks after PTCA may allow restenosis of the treated vessel and further increase the risk of perioperative ischemia.

If a coronary artery stent is placed, ACC-AHA recommendations suggest postponing surgery for to 2 to 4 weeks to allow stabilization and to exclude the risks of stent site stenosis. The 2-week delay allows completion of a full course of thienopyridine and aspirin therapy and lessens the risk of subsequent stent thrombosis. There is little evidence available to describe the perioperative effect of prophylactic coronary intervention months to years before noncardiac surgery; however, coronary restenosis is unlikely to occur within 8 to 12 months after prophylactic coronary intervention, with or without stent placement. Obviously, patients with previous cardiac intervention remain at risk to develop subsequent additional coronary artery lesions.

The Bypass Angioplasty Revascularization Investigation (BARI) compared the outcomes of noncardiac surgical procedures following CABG (250 patients) versus PTCA (251 patients) in 1,049 surgeries. The median time interval between the most recent coronary revascularization procedure and noncardiac surgery was 29 months. There were no significantly different outcomes when evaluating morbidity, in-hospital morbidity, and hospitalization costs, suggesting equivalence of revascularization procedures. However, the risk of cardiac death or MI was higher in patients undergoing noncardiac surgery with each successive year following revascularization (OR 1.3 per year; CI 0.96 to 1.9), emphasizing the need for thoughtful preoperative cardiac evaluation in this patient population.

Perioperative Medical Therapy

Recently, much attention has been paid to preoperative medical therapy with ß-blockers to decrease perioperative cardiac risk. Several meta-analyses have been published, some reaching conflicting results, but few randomized control trials have been published. The ACC-AHA recently published a guideline update on the use of ß-blockers to decrease perioperative cardiac risk. The current data suggest that there is likely a benefit in preoperative ß-blockade for high-risk patients undergoing noncardiac surgery. It has been suggested that preoperative ß-blockade reduces perioperative ischemia and may reduce perioperative MI and death. Major, intermediate, and minor clinical predictors of increased perioperative cardiac risk have been identified (Table 45.7). ß-Blockers are probably recommended for patients in whom preoperative assessment identifies coronary heart disease or high cardiac risk as defined by the presence of multiple clinical risk factors and who are undergoing intermediate or high-risk procedures as defined in these guidelines.

Patients who are already receiving ß-blockers to treat angina, symptomatic arrhythmias, or hypertension should have their medication continued at their current dose during the perioperative period. It has been suggested, but not definitively proven, that patients at high to intermediate cardiac risk undergoing noncardiac surgery may benefit from ß-blocker therapy started several days to weeks before surgery and titrated to a heart rate of 50 to 60 beats per minute. Definitive information regarding the ideal target population, agent, dose, and route for perioperative ß-blocker therapy are lacking. The best approach to how to medically protect patients from perioperative cardiac complication is still unknown. Therefore, a thoughtful approach with appropriate perioperative consultation is necessary for those patients at risk for cardiac complications undergoing intermediate- or high-risk surgery.

The potential effect of α-antagonist perioperative cardiac protection has also been evaluated. A randomized placebo-controlled multicenter trial study of mivazerol use during the perioperative period in 2,854 patients with known CAD or significant risk factors reported no difference in MI

incidence; however, the cardiac death rate was reduced by nearly 50%. For those undergoing treatment with placebo, the OR for cardiac death was 2.0 (95% CI 0.25 to 0.96) compared with that found with mivazerol. The Perioperative Ischemia Research Group also reported a significant reduction in perioperative cardiac ischemia in patients given high-dose perioperative mivazerol. This information suggests that the perioperative administration of α-antagonists may have a future role in cardiac protection.

TABLE 45.7 Clinical Predictors of Increased Perioperative Cardiovascular Risk (Myocardial Infarction, Heart Failure, Death)

Major

Unstable coronary syndromes

- Acute or recent MI[a] with evidence of important ischemic risk by clinical symptoms or noninvasive study
- Unstable or severe[b] angina (Canadian class III or IV)[c]

Decompensated heart failure
Significant arrhythmias

- High-grade AV block
- Symptomatic ventricular arrhythmias in the presence of underlying heart disease
- Supraventricular arrhythmias with uncontrolled ventricular rate

Severe valvular disease
Intermediate
Mild angina pectoris (Canadian class I or II)
Previous MI by history or pathological Q waves
Compensated or prior heart failureDiabetes mellitus (particularly insulin dependent)
Renal insufficiency
Minor
Advanced ageAbnormal ECG (left ventricular hypertrophy, left bundle branch block, ST-T abnormalities)
Rhythm other than sinus (e.g., atrial fibrillation)
Low functional capacity (e.g., inability to climb one flight of stairs with a bag of groceries)History of stroke
Uncontrolled systemic hypertension

MI, myocardial infarction; ECG, electrocardiogram.

[a]The American College of Cardiology National Database Library defines *recent MI* as greater than 7 days but less than or equal to 1 month (30 days); acute MI is within 7 days.

[b]May include “stable” angina in patients who are unusually sedentary.

[c]Campeau, L. Grading of Angina Pectoris. *Circulation* 1976; 54: 522–523, with permission.

Arrhythmias

The perioperative goal of cardiac arrhythmia or conduction disturbance management

relates to the need to prevent the deterioration of a given rhythm into one that is incompatible with life, to prevent cardiac ischemia, and to prevent thrombosis and endocarditis.

Electrophysiology studies with ablation of aberrant conduction foci may be necessary for women with demonstrable supraventricular arrhythmias. Advanced cardiac life support (ACLS) guidelines can be used for the pharmacologic treatment of perioperative supraventricular arrhythmias. Electrical or pharmacologic cardioversion may be necessary if patients are symptomatic or hemodynamic compromise is present. β-Adrenergic or calcium channel blockade also may be indicated for rate control in the absence of successful electrical cardioversion.

Depending on the extent of surgery, patients with atrial fibrillation receiving systemic anticoagulation require evaluation and, perhaps, presurgical reversal. Simple discontinuation of the oral anticoagulant (4 days prior) usually will suffice. However, fresh frozen plasma or parenteral vitamin K may be necessary to reverse anticoagulation and ensure hemostasis.

Frequent asymptomatic premature ventricular contractions or short runs of ventricular tachycardia may not require antiarrhythmic treatment, because they do not, in general, increase perioperative cardiac risk. Although other lesser arrhythmias do not require treatment, the gynecologist should be diligent in pursuing causes of new arrhythmias to rule out myocardial ischemia. Sustained ventricular tachycardia should be treated following ACLS guidelines using lidocaine, procainamide, or other agents such as amiodarone. Care of perioperative arrhythmias is likely optimized with close communication and consultation with appropriate internal medicine, cardiac, or critical care consultants.

Other Situations

Implanted Pacemakers and Implantable Cardiac Defibrillators

Occasionally, the gynecologic surgeon will encounter a surgical candidate with a pacemaker or implantable cardiac defibrillator. Lack of familiarity with the device and its function can cause perioperative anxiety, particularly when combined with the intraoperative use of electrocautery. General ACC-AHA recommendations include the following:

1. Patients should have the implanted device evaluated before and after surgical procedures to determine the underlying rhythm, program settings, and battery status. If the pacemaker is programmed in a rate-responsive mode, the device should be inactivated during surgery.
2. If patient is pacemaker dependent, the pacing threshold should be determined and evaluated appropriately.
3. Implantable cardiac defibrillators should be turned off during surgery and on again after recovery from anesthesia.

Pulmonary Artery Catheters

Invasive cardiac monitoring, including the use of a pulmonary artery catheter, provides instantaneous information, which may contribute to successful postoperative decision making. Unfortunately, the risks of catheter insertion and malfunction are significant, and the rate of

complications are operator dependent. Additionally, information generated from pulmonary artery catheterization is sometimes esoteric, and decisions based on the cardiac function data are limited by some degree of observer subjectivity. Evidence does not support the routine perioperative use of a pulmonary artery catheter; however, placement should be considered in specific high-risk patient subsets. It may have particular benefit in those in whom the gynecologic disease (e.g., ovarian cancer) or the surgical procedure (e.g., exenteration) is associated with large fluid shifts in those with a compromised medical condition.

Surveillance for Perioperative Myocardial Infarction

A significant proportion of perioperative MIs are silent but carry a higher mortality rate (40% to 70%) than those occurring in a nonsurgical setting. Electrocardiography, cardiac-specific biomarkers, echocardiography, and radioisotope studies have all been proposed and used for detection of postoperative MIs. Although many of these studies used alone or in combination are effective, false-positive findings are common. The measurement of creatinine phosphokinase myocardial bands alone is less diagnostic of MI than the evaluation of serum troponin levels. Guidelines call for standard surveillance in low-risk patients without documented CAD and normal preoperative ECG or serum biomarker findings. However, patients with high or intermediate clinical risks who have known or suspected CAD and are undergoing high- or intermediate-risk procedures are followed appropriately with an ECG obtained in the recovery room and on the first two postoperative mornings, combined with a cardiac troponin level obtained 24 hours postoperatively and on day 4 or at hospital discharge, whichever comes first. If infarction occurs, rapid reperfusion of the myocardium is the cornerstone of therapy. Unfortunately, thromboembolic therapy cannot be used in the immediate postoperative setting, leaving medical therapy (to maximize cardiac oxygen supply–demand ratio), angiography, and revascularization as the only available therapeutic interventions.

New-Onset Arrhythmia and Conduction Disorders

Any arrhythmia occurring perioperatively should be addressed immediately to determine its etiology and managed according to ACLS guidelines. Tachyarrhythmias should prompt the immediate assessment of potential contributing factors including hypotension, hypoxia, or metabolic derangements. An ECG with rhythm strip should assist in identifying the exact features of the arrhythmia. Narrow-complex regular arrhythmias are likely due to AV node reentry tachycardia or supraventricular tachycardia. Vagal maneuvers should be employed initially. Pharmacologic management consists of administering adenosine or AV nodal blockade using ß-blockers, calcium channel blockers, or class I-A or I-C antiarrhythmic

agents.

Atrial fibrillation and flutter are unstable rhythms, which often produce a rapid ventricular response. Initial management should be aimed at control of ventricular rate by AV node blockade. Evaluation of the underlying etiology is paramount, and the use of cardioversion should not be entertained until the underlying etiology (e.g., hypothyroidism, hypokalemia, hypomagnesemia) has been found and corrected.

Infrequent premature ventricular contractions do not require treatment; however, long runs of ventricular tachycardia may require antiarrhythmic therapy, particularly if symptoms or hemodynamic compromise occurs. In general, ventricular arrhythmias should be treated according to ACLS guidelines in conjunction with appropriate cardiology or internal medicine consultation. Cardiac pacing should be considered when warranted by hemodynamic compromise, symptoms including chest pain, or pulmonary edema.

The pelvic surgeon assumes great responsibility for perioperative care of the patient with cardiac risks. Although performing the best-suited procedure for the gynecologic condition is imperative, an understanding of the factors that influence overall results, the appropriate intervention, and the timely use of consultants should maximize operative outcome.

Perioperative Pulmonary Evaluation

Postoperative pulmonary complications (PPCs) commonly occur following abdominal or pelvic surgery. Pulmonary dysfunction occurs in as many as 80% of patients, and clinically significant PPCs include atelectasis, bronchospasm, the need for prolonged ventilatory support, pneumonia, and worsening pulmonary function due to exacerbation of an underlying problem. The combination of general anesthesia and abdominal surgery results in a morbid alteration of pulmonary physiology, with effects that are compounded by postoperative immobilization, narcotics, or inadequate pain relief.

Patient-Related Risk Factors

All patients, even those without underlying known pulmonary disease, remain at significant risk following general endotracheal anesthesia and abdominal surgery. Numerous comorbidities have been linked to the risk of developing PPC (Table 45.8). Although the physiologic and economic costs are significant, the ability to qualitatively or quantitatively evaluate or modulate pulmonary risks unfortunately is not as straightforward as the identification or modulation of cardiac risks.

Tobacco abuse is a risk factor for PPC, even without clinically apparent pulmonary disease. When compared with nonsmokers, the relative risk of PPC for smokers increases as much as fourfold following abdominal surgery. Although difficult to achieve, prolonged smoking cessation

---

reduces the risk of PPC by nearly 50%. Unfortunately, many of the physiologic effects of smoking are long lasting, and little benefit is gained unless smoking is stopped at least 8 weeks prior to surgery. Cessation for periods briefer than 8 weeks may increase the risk of

From Smetana GW. Preoperative pulmonary evaluation. *N Engl J Med* 1999;340:937–944, with permission.

A patient who is unable to exercise is at increased risk for PPC following abdominal surgery. The inability to climb a flight of stairs or blow out a match at 6 inches (equals a forced expiratory volume [FEV] <1.76 L) suggests a very high pulmonary risk. The Goldman cardiac risk index and the American Society of Anesthesiologists classification reasonably predict pulmonary risk but not necessarily the severity of PPC. Clinically evident chronic obstructive pulmonary disease (COPD) has been associated with a four- to fivefold relative risk of PPC in patients undergoing surgery. Despite common belief, age and obesity, when controlling for other existing comorbidities, do not contribute significantly to the development of PPC.

Active asthma, when severe, can be among the most difficult respiratory conditions to manage, although its presence does not necessarily herald an increase in perioperative bronchospasm if appropriate prophylaxis is administered. Preoperative improvement of small airway patency, as evidenced by freedom from wheezing and a peak flow >80% of predicted value, may minimize pulmonary risk in these patients. A short course of oral steroids may assist in achieving this preoperative goal. Even though history and physical examination may detect those at risk for PPC, no spirometric or other test detects those patients whose abdominal surgery should be canceled. Most patients can undergo surgery, even if at high risk.

Although the optimal reduction regimen is unknown, the realization that postoperative pneumonia is extremely morbid and occasionally lethal in even a healthy patient demands adequate attention to perioperative pulmonary management.

Procedure-Related Pulmonary Risk Factors

Limitation of surgery to the lower abdomen greatly reduces the extent of pulmonary dysfunction and the risk of developing PPC. Upper abdominal incisions increase this risk by as much as 40% in general surgery patients. A laparoscopic approach significantly reduces the risk of PPC by as much as 33%.

The type of anesthesia, anesthetic pharmaceutical agent, and length of surgery play important roles in patient risk. Although reports have shown mixed results, spinal conduction anesthesia (spinal or epidural anesthesia) offers pain relief, improves pulmonary mechanics, and may significantly reduce the chance of PPC when compared with general endotracheal anesthesia.

Preoperative Evaluation

Using findings from the history and physical examination, one can select the majority of patients who are at risk for developing PPC. It has been suggested previously that

preoperative pulmonary function testing should be used in patients who have significant pulmonary risk factors or in those undergoing high-risk surgical procedures, particularly if requiring abdominal or thoracic incisions. Preoperative spirometry neither identifies high-risk patients who would escape clinical detection or those patients whose risk of proceeding to surgery is prohibitive. Pulmonary function testing (PFT) should not be used to deny surgery if the reason for the surgery is compelling.

Although not considered a standard part of routine preoperative evaluation, preoperative PFT may be indicated in specific patient subsets. PFT can be helpful in cases when the history and physical examination does not explain a patient's exercise intolerance or dyspnea. PFT may also be useful if it is unclear whether a patient with severe asthma or COPD is at her best baseline function. Some have recommended that perioperative P_aCO_2 monitoring can assist in the management of those who are chronic CO_2 retainers. Although hypercarbia is a significant risk for PPC, no validated published studies suggest a CO_2 threshold that prohibits surgery. Baseline CO_2 determination may be useful for postoperative ventilator management.

Risk-Reduction Strategies

The inability to quantify pulmonary risk highlights the importance for the gynecologist to develop clinical acumen in an effort to reduce pulmonary complications. Several risk-reduction strategies have been proposed (Table 45.9). Attention to maneuvers that enhance postsurgical lung expansion combined with adequate pain control to reduce splinting and subsequent atelectasis are the vital components of good postoperative

pulmonary care. Preoperative education engages the patient in her care, increases her willingness and active participation, and assists in overcoming a major psychologic obstacle to postoperative pulmonary health. The potential benefits of incentive spirometry, chest physiotherapy, and inhalational nebulizer treatments should be explained and understood preoperatively.

TABLE 45.9 Postoperative Pulmonary Complication Risk-reduction Strategies

Preoperative
- Encourage cessation of cigarette smoking for at least 8 weeks prior to surgery.
- Treat airflow obstruction in patients with chronic obstructive pulmonary disease or asthma.
- Administer antibiotics and delay surgery if respiratory infection is present.
- Begin patient education regarding lung expansion maneuvers.

Intraoperative
- Limit duration of surgery to <3 h.
- Use spinal or epidural anesthesia.[a]
- Avoid use of pancuronium.
- Use laparoscopic procedures when possible.
- Substitute less ambitious procedure for upper abdominal or thoracic surgery when possible.

Postoperative
- Use deep breathing exercises or incentive spirometry.
- Use continuous positive airway pressure.
- Use epidural analgesia.[a]
- Use intercostal nerve blocks.[a]

[a]This strategy is recommended, although variable efficacy has been reported in the literature.
From Smetana GW. Preoperative Pulmonary Evaluation *New Engl J Med* 1999; 340:937–944, with permission.

Renal Disease

The anatomic relation of the urinary tract to the reproductive organs places it at risk for

extrinsic (disease-related) or iatrogenic complications. Although intraoperative technique should be designed to decrease injury risk, perioperative renal insufficiency or failure is among the most foreboding postoperative complications faced by the gynecologic surgeon. The overall risk of urinary tract injury is procedure related and is not uncommon (≤2%). Preoperative urologic studies may reveal congenital anatomic or other abnormalities and a rare renal cancer. Importantly, radiographic evidence of ureteral deviation, displacement, or hydronephrosis should not be considered a substitute for good operative technique and cannot be equated with lessening the risk of injury. The 3% incidence of serious adverse events associated with IVP and its lack of cost-effectiveness (approximately 833 IVPs are necessary to potentially prevent 1 ureteral injury) draw attention to its inappropriate routine use.

Total cessation of renal function (i.e., bilateral ureteral obstruction) results in a daily increase of 1 to 2 mg/dL in serum creatinine. Although the postoperative dynamics of measured serum creatinine are complex, lesser degrees of elevation (i.e., >0.3 mg/dL per day) should raise suspicion for a unilateral ureteral injury.

Although overt oliguric renal failure rapidly becomes clinically obvious, lesser degrees of renal insufficiency may occur silently. Although all patients are at risk, the geriatric patient is at particular risk of perioperative renal insufficiency secondary to an age-related decrease in glomerular filtration rate; a decrease in urinary concentrating ability; and narrowed limits for sodium, potassium, and acid excretion. This population should be monitored carefully to maintain euvolemia and minimize the electrolyte load found in many medications.

Research has detailed the predominant biochemical and physiologic changes occurring in the patient with acute renal failure. Recognizing the important effects of medullary hypoxia, tubular cell injury, and alterations associated with diuretics and electrolytes assists in understanding the mechanisms of disease; however, the clinical usefulness of this new information has yet to make a significant impact on daily practice. Thus, the classic approach of evaluating intrinsic renal, prerenal, or postrenal etiologies of

---

perioperative renal failure remains useful. Prerenal azotemia results from any condition that prevents adequate blood flow to the renal unit. Hypovolemia, renal artery atherosclerotic disease, and pharmacologic etiologies (e.g., a combination of angiotensin-converting enzymes [ACE] inhibitors and diuretics) interfere with normal renal perfusion. Hypovolemia may occur as a result of intrinsic cardiac failure; general anesthesia; excessive blood loss; pre-, intra-, or postoperative volume contraction; or physiologic vasodilation (e.g., as in septic shock). Most postoperative causes of prerenal azotemia are reversible with the correction of intravascular volume deficits, minimizing the effect of left ventricular dysfunction or the reversal of anesthesia.

Postrenal failure, which can be related to outflow tract obstruction at any level of the renal collecting system, carries significant importance following pelvic surgery. Functional obstruction due to a neurogenic bladder or the inability to void spontaneously may be related to existing deficits or postsurgical changes. Urethral catheterization typically reverses this problem. Postobstructive oliguria related to causes proximal to the bladder

requires significant ureteral obstruction. Although this situation can occur with bilateral renal calculi, bilateral or unilateral obstruction can occur after prolapse surgery and is most frequently encountered with advanced carcinoma of the cervix or in idiopathic retroperitoneal fibrosis. Renal ultrasonography is an easily obtained and low-risk diagnostic study. Acute management of most causes of postrenal failure involve appropriate diversion of the urinary units, either by transvesical ureteral stenting or percutaneous nephrostomy, to preserve existing renal function.

Lastly, intrinsic renal dysfunction may be due to acute tubular necrosis, interstitial nephritis, and acute glomerulonephritis. Intrinsic renal failure most often is due to renal parenchymal ischemia or the effects of nephrotoxic agents, including aminoglycoside antibiotics, vancomycin, amphotericin B, and cisplatin. Radiocontrast agents and heme pigments are two agents commonly associated with acute tubular necrosis. The former may have intrinsic parenchymal effects and create a diuresis that aggravates existing volume deficits. Interstitial nephritis associated with an allergic drug reaction, autoimmune diseases, infiltrative diseases, and infectious agents represents another form of intrinsic renal failure. When present, withdrawal of the offending agent usually results in reversal; however, glucocorticoid administration may hasten recovery. Finally, acute glomerular nephritis, rare in the gynecologic patient, may also be responsible for intrinsic renal failure and should be entertained in the differential diagnosis of postoperative renal insufficiency, particularly in the absence of other causes.

Diagnosis, Morbidity, and Mortality

The initial diagnostic evaluation of women with perioperative renal insufficiency requires a systematic method of investigation. Intraoperative suspicion and assessment with cystoscopy (or cystotomy) and methylene blue or indigo carmine dye injection is an important initial step. Postoperative hypovolemia may be obvious. However, volume status determination may be difficult when based on history, physical examination, and quantitation of perioperative input and output data. The urinalysis in those with prerenal azotemia shows a high osmolality (>500 mOsm/kg), a fractional sodium excretion of <1%, and proteinuria. Elevated serum blood urea nitrogen out of proportion to creatinine (>20-to-1 ratio) is strongly indicative of prerenal azotemia. Renal azotemia often is associated with minimal proteinuria; however, urine osmolality will be <350 mOsm/kg, and fractional excretion of sodium will be >1%. The surgeon's degree of suspicion based on operative findings and events is an important aspect of assessment to exclude postrenal azotemia, particularly when the procedure required a difficult pelvic dissection, repair of prolapsed pelvic organs, or treatment of a malignancy. Renal ultrasonography can quickly determine the extent of unilateral or bilateral hydronephrosis and eliminate the possibility of clinically significant ureteral ligation or kinking. If an ultrasonograph is not diagnostic, an IVP may answer important questions, although the administration of contrast may worsen the clinical condition of a patient with intrinsic renal insufficiency.

Nonoliguric and oliguric renal insufficiency can occur in the postoperative patient, and physicians should not assume that “adequate” urine production indicates intact renal function. Importantly, oliguric renal failure portends a worse prognosis than nonoliguric

renal failure. Using low-dose dopamine to increase renal perfusion (and convert an oliguric problem to a nonoliguric situation) has no proven efficacy and thus should not be utilized, as it creates a propensity for cardiac arrhythmias and alters blood supply to other vital organs.

The morbidity and mortality of renal failure in the postoperative patient is five times higher than that of individuals treated medically. These adverse outcomes are probably related to many factors, from perioperative ischemic insults to the volume depletion and other changes associated with contrast used for preoperative testing (i.e., IVP, CT) or mechanical bowel preparation. Common predisposing comorbid illnesses, including diabetes mellitus, hypertension, and cardiopulmonary insufficiency, carry their own inherent risks for causing renal insufficiency. Medications such as ACE inhibitors and nonsteroidal anti-inflammatory drugs, used frequently in the perioperative patient, also increase risk.

Methods to promote perioperative renal protection include practicing good surgical technique, limiting the use of nephrotoxic agents, maximizing cardiopulmonary function by paying attention to intraoperative blood and volume losses, and replacing intravascular losses. Although invasive monitoring to guide fluid replacement may be helpful, its use and the administration of pharmacologic

---

agents (dopamine, mannitol, furosemide) or other interventions has not been conclusively proven beneficial. Women with chronic renal insufficiency are at risk for acute renal insufficiency during the perioperative period. Preoperative internal medicine or nephrology consultation should be considered in an attempt to optimize volume, use dialysis strategically, and manage coexisting morbidities.

Management

Dialysis is the cornerstone of perioperative management of renal insufficiency once postrenal obstructions are relieved. Specialists should be consulted to treat acidemia, recalcitrant hyperkalemia, symptomatic volume overload, or impending cardiovascular failure. All medication dosages and schedules should be reviewed regularly to maximize efficacy and minimize toxicity.

In conclusion, although perioperative renal failure represents a significant danger to the operative patient, insufficient scientific data exist to identify patients at risk and to develop guidelines for postoperative renal surveillance and management. The surgical community awaits a more specific definition of renal failure; additional research regarding renal protection strategies; and better, less invasive treatments for patients with perioperative renal insufficiency.

Wounds and Incisions

Once surgery has been deemed appropriate therapy, selecting the operative approach is possibly the most important initial surgical decision. Choice of approach is related primarily to physician bias and comfort, which is related to previous teaching and

experience. However, surgical indications, disease process, previous abdominal incision (and resultant adhesions), patient preference, and existing medical comorbidity should be considered carefully prior to solving this sometimes complex problem. Adequate intraoperative exposure must be a primary consideration. Although a vertical lower midline incision should be the first consideration, some, particularly those with a large body mass index, may be best managed with an upper abdominal incision, avoiding trauma to the infection-prone panniculus. A panniculectomy may be necessary or appropriate. It is evident that many, if not most, gynecologic (even oncologic) and obstetric procedures can be completed safely through a more cosmetic transverse lower abdominal approach. The transverse approach may offer the additional advantage of less pain and diminished postoperative pulmonary dysfunction. Although the Pfannenstiel incision, when combined with a table-stabilized self-retaining retractor, will often suffice, preoperative consideration of a Maylard (rectus muscle splitting) incision or intraoperative conversion to a Cherney (rectus splitting–incision at pubic insertion) may be necessary. To avoid increased risk of hernias, care should be taken to avoid placing the incision perpendicular to a previous incision. Placing the long axis of the incision in the direction of maximal skin tension creates the most aesthetically pleasing scar.

A more contemporary approach to numerous gynecologic procedures involves laparoscopy. Many, if not most, routine procedures and a significant proportion of complex procedures used for the management of benign or malignant disease can be safely completed laparoscopically, with less physiologic stress, less pain, and a more rapid return to normal activity. Although there are many correct answers to surgical incision placement, performing an incomplete procedure because of a compromised incision is an unacceptable alternative and should be avoided by immediate conversion to a more accommodating approach (e.g., hand-assisted laparoscopy or an open operation).

Operative laparoscopy and abdominal approach are associated with additional inherent surgical risks, so they should not replace vaginal surgery. Although laparoscopy may be complementary to “convert” abdominal procedures and to complete (extensive) operations, stand-alone vaginal surgery should remain an important arm of the obstetrician–gynecologist's surgical repertoire because it results in less morbidity. Vaginal surgery will suffice for many, if not most, gynecologic procedures. Although lesser invasive (laparoscopic or vaginal) surgical approaches are associated with diminished physiologic stress, their use does not negate the need for appropriate preoperative evaluation, preparation, and management.

Wound Preparation

Although many rituals of preoperative skin preparation exist, only a few add documented value to patient care. Preoperative hair removal is not deemed necessary; however, if performed, clipper removal at a time close to surgery avoids microinjury and is associated with a lower risk of wound infection than is razor preparation.

Routine preoperative skin antisepsis is necessary to minimize the infectious potential of normal flora as well as of pathogens. Bacterial concentrations in moist body areas (i.e., perineum) reach $10^6/cm^2$ of tissue and are greater than those in drier (abdomen) areas,

reaching $10^3/cm^2$ of tissue. These areas also harbor different ratios of aerobic to anaerobic bacteria. Preparation solutions differ significantly in the immediate or late (>3 hours) mean bacterial reduction. Manufacturer recommendations should be used to guide the length of time that the solution remains on the skin prior to the incision (i.e. ≥5 minutes for provodine iodine; ≥2 minutes for chlorhexidine).

Surgical Technique

Creating an abdominal incision with a single bold knife stroke through the skin and subcutaneous tissue avoids a stair-step effect in the subcutaneous tissues. The use of multiple knife blades to create the incision offers little benefit and contributes to expense. Avoiding the creation of

subcutaneous dead space is important, as dead space increases the risk of wound infection and poor wound outcome, even when closed. The use of electrical or laser coagulation techniques to create an incision saves little time and adds little value. Their use creates “devitalized” tissue, which may contribute to an adverse wound environment and increase the risk of surgical site infection, resulting in poor wound outcomes. Surgical technique may be of specific impact in those already at high risk because of thick (≥3.0 cm) subcutaneous tissues.

The rationale for proper suture selection rests on the need for tensile strength, the duration of retained tensile strength, and the biologic effects on the involved tissue (Table 45.10). In general, the suture's chemical composition is more important than the physical configuration, although braided and multifilament sutures may potentiate infection. When compared with other absorbable materials, polyglycolic acid suture is associated with less inflammation and decreased pain, and in animal models, it lessens the risk of infection. The incorporation of permanent suture material creates an increased risk (approximately 10%) of chronic wound problems (i.e., pain, wound sinus); however, their use is associated with a lessened risk of developing a fascial hernia. Vascular pedicle ligation can be accomplished safely by using short-term absorbable sutures because the risk of bleeding is minimal 96 hours after ligation. Prior evidence suggested that there is little clinical benefit to be gained from peritoneal closure; however, newer studies regarding the closure of the peritoneum at the time of cesarean section suggests that there may be a benefit to closure with respect to decreased formation of significant intra-abdominal adhesions.

TABLE 45.10 Suture Material

Type	Tensile Strength	Knot Security	Tissu React

Nonabsorbable			
Natural			
Silk	2	3	4
Cotton	2	2	2
Linen	2	2	2
Manufactured			
Steel	4	4	—
Polyamide (nylon)	3	3	1

Polyolefin (Prolene)	3	2	1
Polybutester (Novafil)	3	2	—
Polytetrafluororoethlene (PTFE)	3	2	—
Absorbable			
Catgut	1	2	3
Chromic	1	3	3
Polyglycolic acid	2	2	1
Polydioxanone sulfate (PDS)	3	2	1
Polygluconate (Maxon)	3	2	1
Glycolide caprolactine (Monocryl)	2	2	1

Polygalactin 910 (Rapid)	1	1	1
Glycolide/Dioxanone/Trimetheline carbonate (Brosyn)	3	1	1

4 = most, 1 = least.

Suture size selection should be based on specific needs. Excluding fascial closure, there is little rationale for using suture larger than 2–0. Additional wound suture material increases the inflammatory response and may predispose to infection, and the tensile strength of a 2–0 absorbable suture is adequate for nearly all pedicle ligations.

Although it seems basic, correct suture-tying techniques can contribute to surgical outcome. Complex knots (e.g., surgeon's) impart greater tensile strength than multiple simple square knots. Avoiding excess knots minimizes the amount of suture material, lessens inflammatory response, and potentially decreases the risk of poor wound outcome. Although all knots should be secure, tightly tied fascial sutures strangulate the incorporated tissues, increase ischemia, and lessen wound strength. Although good surgical technique always has been tied to attempts to prevent adhesion formation, the development of hyaluronic acid products for adhesion prevention has opened new avenues.

The astute surgeon recognizes the different tissue-related healing curves and selects a suture designed to promote good outcome. Although short-term wound results are important, the risk of late problems (e.g., hernia) can be minimized with appropriate closure technique. A suture length–to–wound length ratio of >4 decreases the risk of hernia formation and can be accomplished by placing sutures at least 1.5 cm from the fascial edge and 1.5 cm apart.

Subcutaneous tissue closure is typically only recommended in patients in whom the subcutaneous tissue depth is >2 cm. If closure is required, small minimally reactive sutures should be chosen. Closed suction and subcutaneous drain placement are of little apparent benefit, and drains increase the risk of surgical site infection.

The best method or material for epithelial approximation should be related to the potential time, cost, need for return visits, and cosmetic results.

Gastrointestinal Care

Perioperative management of the gastrointestinal tract during pelvic surgery focuses on the following three aspects: (a) avoidance of operative injury and reduction of subsequent complications, (b) the role of early feeding, and (c) the appropriate diagnosis and management of patients with liver disease.

Excluding the need to address important aspects of coexisting intestinal diseases (e.g., inflammatory bowel disease) and issues related to cancer screening, gastrointestinal

preparation values the decisions related to the incorporation of bowel preparation. Mechanical intestinal preparation offers a number of potential benefits (Table 45.11) and currently is a common practice before abdominal surgery in both gynecologic and general surgical procedures. Despite this trend, at present, no evidence exists to recommend its routine use in the prevention of perioperative infection or bowel injury. Suboptimal preparation may actually increase the risk of contamination, yet most pelvic surgeons are inclined to use a mechanical bowel preparation when the risk of manipulation or injury is substantial. If a preoperative bowel preparation is thought to be necessary, several regimens are available and choice of regimen should be tailored to the individual patient. Care should be taken when prescribing preparations with high electrolyte concentrations to patients with a history of or risk factors for renal insufficiency.

Early Oral Feeding and Nasogastric Suction

Nasogastric suction often has been incorporated into the postoperative care of women who are undergoing difficult pelvic operations. Reports not only question its use but deny its benefit as it relates to symptomatic relief, lessened risk of ileus, need for reinsertion, and protection of intestinal anastomosis. Regardless of procedure, fewer than 10% of patients require nasogastric suction, and it appears to be of little benefit to the other 90%. Importantly, early oral feeding is well tolerated, does not increase the risk of ileus or symptoms, and may shorten hospital stay.

TABLE 45.11 Mechanical Bowel Preparation Potential Benefits

Removes fecal material.
Lowers bacterial load.
Improves handling.
Reduces spillage, contamination.
Lessens risk of mechanical disruption.
Facilitates intraoperative palpation.
Allows intraoperative colonoscopy.
Aids laparoscopic handling

Liver Disease

The preoperative detection of liver disease may not be easy, because serum liver enzymes may not be elevated in patients with late-stage disease. However, the historical and physical findings of significant alcohol intake or exposure to hepatotoxins should raise suspicion. Physical evidence of malnutrition, signs of hepatic encephalopathy, or jaundice usually signify advanced disease. Laboratory evidence of hepatic dysfunction includes a 10-fold increase in serum transaminase levels, abnormal coagulation study results, elevated

total bilirubin values, and low serum albumin levels. Classic surgical risk indices have been based on the Child classification, initially detailed in the 1960s to determine risks associated with surgical management of those with esophageal varices. These indices have been applied to the risks in those with liver disease who are undergoing abdominal surgery.

Perioperative management of women with hepatic disease requires particular attention to drugs (and to their dosing and scheduling) that are metabolized by the liver. For example, patients receiving benzodiazepines and narcotics are at risk for drug accumulation and overdosage due to poor hepatic clearance.

Patients with acute liver disease should not undergo elective surgery until stabilization of liver dysfunction has been secured. Those with chronic liver disease and hepatic encephalopathy may require subspecialty consultation in an attempt to stabilize liver function.

Infection

Perioperative surgical site infection occurs in the practice of every gynecologic surgeon. Knowledge of prophylactic measures and the optimal treatment regimen for those with active or acquired infection are expected of every pelvic surgeon. Numerous factors including obesity, diabetes, use of steroids, excessive blood loss, and even length of preoperative hospitalization are all risk factors for infectious perioperative morbidity (Table 45.12). Although addressing each of them is beyond the scope of this chapter, numerous technical methods can modulate these risks. Proper use of prophylactic antibiotics lessens infectious risks in many pelvic procedures. Numerous antibiotics and regimens are efficacious. In most situations, a properly administered single dose is as effective as most multiple-dose

---

regimens. However, in longer procedures (i.e., ≥3 hours) when the duration of the procedure is longer than the half-life of the chosen drug or if blood loss exceeds 1,500 mL, repeat dosing improves its benefit. The use of antibiotics prophylactically can result in patient hypersensitivity and the development of resistant strains of bacteria. Although careful thought is never to be discouraged, the potential benefit of controlling operative site infection with antibiotic prophylaxis usually outweighs other patient risks. A first-generation cephalosporin has been recommended for perioperative prophylaxis, recognizing the lack of enterococcus coverage. Patients allergic to penicillin have an 8% risk of cross reactivity with cephalosporins, but anaphylaxis risk is estimated at 0.0001% to 0.1% in non–penicillin-allergic patients to 0.02% in penicillin-allergic patients. Doxycycline or metronidazole represents an excellent alternative in patients undergoing abdominal or vaginal hysterectomy. Although the benefit of antibiotic prophylaxis has not been definitively demonstrated in patients undergoing laparoscopy-assisted hysterectomy, it would seem prudent to use these drugs, as recent American College of Obstetricians and Gynecologists (ACOG) guidelines recommend their use in vaginal hysterectomy. The recommendation of prophylaxis for other procedures varies (Table 45.13). Specific prophylaxis for those women at risk for endocarditis is imperative (Table 45.14).

Treatment for Existing Infection

Prophylactic drugs are administered to patients in the absence of preoperative evidence of active infection. However, gynecologic patients with an obvious infection prior to surgery should receive an antibiotic treatment regimen appropriate for the type of infection. For example, patients with tuboovarian abscess should be treated with a broad-spectrum antibiotic regimen covering gram-positive, gram-negative, and anaerobic bacteria.

Postoperatively, antibiotics should be given for documented infection. It is clear that most postoperative febrile illness is not related to a documented infection. When postoperative fever, leukocytosis, and clinical picture suggest postoperative infection, an examination to identify potential sources should be performed. Source-directed therapy is appropriate. Adjunctive procedures, including CT or ultrasonographically guided drainage, may hasten recovery in patients with fluid collections or abscesses. In general, patients should receive adequate, broad-spectrum antibiotic treatment prior to surgical intervention.

Thromboembolism

Thromboembolic phenomena, including deep venous thrombosis (DVT) and pulmonary embolism (PE), are inevitable following gynecologic surgery. A 1988 meta-analysis estimated a 6% to 7% proximal DVT risk and a 0.5% to 0.8% fatal PE risk in unprotected patients over 40 years of age undergoing abdominal surgery. This risk increases the level of

anxiety in most surgeons because of the difficulty of diagnosing venous thromboembolism (VTE) and the potential catastrophic outcome of PE.

The impact and importance of postoperative thromboembolic prophylaxis is no longer a question. In a survey by the American College of Surgeons, approximately 96% of surgeons claimed that they regularly used antiembolic prophylaxis. However, patient poll and chart review suggest that only one third of patients received adequate prophylaxis.

All gynecologic patients should be considered at risk for venous emboli. Approximately 50% of thromboembolic events following surgical procedures occur postdischarge, fostering a belief that such events are rare. Additionally, surgeons have been anxious about the potential side effects of prophylaxis, because low-dose UFH or LMWH administration has been associated with postoperative bleeding and wound hematomas. The infrequent occurrence of heparin-induced thrombocytopenia has also created some anxiety regarding prophylaxis. Finally, the initial or primary cost of thromboprophylaxis has deterred some from its use, although prophylaxis has been shown to be cost-effective. Thromboembolic phenomena can be clinically silent, whereas complications related to prophylaxis are not easily missed by the gynecologic surgeon or the patient. Furthermore, according to the Rochester Epidemiology Project and other studies, the incidence of PE and DVT is increasing as women age.

The Agency for Healthcare Research and Quality recently published a report containing a systematic review ranking patient safety interventions based on the strength of the evidence supporting more widespread implementation of these procedures. The highest-ranked safety practice was the “appropriate use of prophylaxis to prevent VTE in patients at risk.” This recommendation was based on overwhelming evidence that thromboprophylaxis reduces adverse patient outcomes while, at the same time, decreasing overall costs.

Despite these common misperceptions, principles of good gynecologic perioperative care demand careful attention to the role and benefit of thromboprophylaxis. The American College of Chest Physicians published guidelines regarding perioperative thromboprophylaxis. Risk factor stratification (Table 45.15) allows delineation of low-risk, moderate-risk, high-risk, and highest-risk categories, with coincident risk of developing DVT, clinical PE, and fatal PE.

A report suggested that the frequency of DVT following gynecologic procedures was approximately 16% (a range of 4% to 38%). Fatal PE was reported in only 0.4% of the pooled sample. The cited risks for postoperative thromboembolic event included age >40, history of venous embolism, surgery for cancer, and an abdominal surgical procedure. It was suggested that gynecologic oncology patients were at particularly high risk, fulfilling Virchow's triad of advanced age, cancer, and the hypocoagulable state; venostasis related to pelvic mass compression; vascular injury due to lymph node dissection; postoperative immobility; and the thrombogenic effect of chemotherapy. Importantly, the authors noted a 75% reduction in fatal PE (from 0.4% to 0.1%) with the use of appropriate thromboprophylaxis. The strongest evidence presented for thromboprophylaxis was a relative risk reduction of 64% with use of low-dose UFH (reductive from 20% of patients to 7%). A dose response was suggested. Patients undergoing procedures for gynecologic cancers

derived less protection from the twice daily administration of low-dose UFH than patients undergoing other noncardiac procedures. It would appear that dosing three times a day is more appropriate. Although of concern, the potential risk of bleeding complications was not reproducible. Importantly, aspirin use was deemed insufficient for thromboprophylaxis.

The Seventh American College of Chest Physicians Conference on Antithrombotic and Thrombolytic Therapy recently released evidence-based guidelines regarding the perioperative prevention of VTE. For gynecologic surgery patients undergoing brief procedures of lasting <30 minutes for benign disease, the use of specific prophylaxis other than early and persistent mobilization is not recommended. For patients undergoing laparoscopic gynecologic procedures, in whom additional VTE risk

factors are present, the use of thromboprophylaxis with one or more of the following is recommended: low-dose UFH, LMWH, intermittent pneumatic compression (IPC), or graduated compression stockings (GCS).

TABLE 45.15 Levels of Thromboembolism Risk in Surgical Pati without Prophylaxis

Level of Risk	DVT (%)		PE (%)		Successfu Preventic Strategie
	Calf	Proximal	Clinical	Fatal	
Low risk	2	0.4	0.2	<0.01	No specif prophylax early and “aggressi mobilizat
Minor surgery in patients <40 y with no additional risk factors					
Moderate risk	10–20	2–4	1–2	0.1–0.4	LDUH (q1 LMWH (≤3,400 U daily), GC or IPC
Minor surgery in					

patients with additional risk factors					
Surgery in patients age 40–60 y with no additional risk factors					
High risk	20–40	4–8	2–4	0.4–1.0	LDUH (q8 LMWH (>3,400 U daily), or
Surgery in patients >60 y, or age 40–60 with additional risk factors (prior VTE, cancer, molecular hypercoagulability)					
Highest risk	40–80	10–20	4–10	0.2–5.0	LMWH (>3,400 U daily), fondapar oral VKAs (INR, 2–3 IPC/GCS LDUH/LM
Surgery in patients with multiple risk factors (age >40 y, cancer, prior VTE) Hip or knee arthroplasty, HFS Major trauma; SCI					

DVT, deep vein thrombosis; PE, pulmonary embolism; LDUH, low-c unfractionated heparin; LMWH, low-molecular-weight heparin; G graduated compression stockings; IPC, intermittent pneumatic

compression; VTE, venous thromboembolism; VKAs, vitamin K antagonists; INR, international normalized ratio; HFS, hip fractur surgery; SCI, spinal cord injury.
Modified from *Geerts WH, Pineo GF, Heit JA, et al*. Prevention of venous thromboembolism: the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy. *Chest* 2004;126:338S–4

Thromboprophylaxis with one of the above agents should be used in all patients undergoing major gynecologic surgery. For those undergoing major gynecologic surgery for benign disease without additional risk factors, low-dose UFH, 5,000 U twice daily, is recommended. Alternatives to this regimen include once-daily prophylaxis with LMWH, ≤3,400 U per day, or IPC started just before surgery and used continuously until the patient is ambulating. For patients undergoing extensive surgery for malignancy, and for patients with additional VTE risk factors, routine prophylaxis with low-dose UFH, 5,000 U three times a day, or higher doses of LMWH (i.e., >3,400 U per day) is recommended. Alternative considerations include IPC alone continued until hospital discharge, or a combination of low-dose UFH or LMWH plus mechanical prophylaxis with GCS or IPC.

For patients undergoing major gynecologic procedures, prophylaxis should be continued until discharge from the hospital. For patients who are at particularly high risk, including those who have undergone cancer surgery and are >60 years of age or have previously experienced VTE, continuing prophylaxis for 2 to 4 weeks after hospital discharge has been suggested.

Neurologic Complications

Avoiding serious perioperative neurologic sequelae, including stroke, seizure, altered mental status, and operation-associated nerve injury, is a vital aspect of perioperative management. Most general anesthetics adversely affect central nervous system (CNS) function. Even short-term anesthetic use impairs psychomotor performance for 5 hours and sleep patterns for 24 hours or more. Women at risk for cerebrovascular disease (as evidenced by transient ischemic attacks, peripheral vascular disease, or other events) may require specific preoperative evaluation and neurologic consultation. Although an asymptomatic carotid bruit may signal the need for imaging studies or consultation, it does not, by itself, increase perioperative risk. Presurgical neurologic and radiologic evaluation, extracranial carotid endarterectomy, systemic anticoagulation, and platelet inhibition are some of the potential perioperative risk-sparing procedures to be considered. Particular attention should

be paid to avoiding perioperative hypotension in patients with a history of arterial disease who are at increased risk for thrombolic events. The overall risk of recurrent stroke approaches 3.0%, but fortunately, the risk of stroke is 0.2% to 0.7% in those with no such history.

Cerebral blood flow is unstable and brain metabolism is depressed for 6 to 8 weeks

following a completed stroke, making it prudent to avoid any significant elective operations during this interval. The risk of a second infarct may approach 20%, and the mortality rate is high (approximately 25%). Preoperative CNS scanning may assist in determining the time of resolution of the initial infarct, when operative procedures are less likely to result in repeated infarct. Emergency procedures in those at risk for CNS infarct should be completed in a perioperative environment that maintains an elevated blood pressure and avoids events that may increase the risk of CNS hypoperfusion.

Vertebral basilar ischemic episodes are associated with a lower perioperative stroke risk than is carotid ischemia. Although perioperative neurologic evaluation may be appropriate, these patients usually are managed medically, with minimal surgical risks.

Operative Neurologic Deficits

Nearly 2% of gynecologic procedures are associated with postoperative lower extremity neurologic deficits, regardless of attention paid to preoperative care or positioning. Multiple nerves are at risk, regardless of positioning, surgical duration, or approach. Mechanisms of nerve injury include prolonged compression (e.g., femoral nerve), excessive traction, stretch (e.g., sciatic nerve), or transection (e.g., lateral femoral cutaneous nerve). Regardless of the extent of injury, attention to positioning, or retractor placement, these problems occur and are managed by evaluation and rehabilitation. Fortunately, most resolve. Attention to minimizing hip flexion and external rotation potentially lessens the risk of traction injury. Ilioinguinal and iliohypogastric nerve injuries can be diagnosed with relief after local infiltration of nerve block or excision.

Summary Points

- The primary goal of the pelvic surgeon involves prospective preoperative recognition, evaluation, and management of existing medical comorbidities. Every pelvic surgeon should commit to the development of operative techniques that form a surgical skill set geared to the safe completion of indicated surgical procedures.
- Appropriate consultation should be sought if the level of qualification does not fit the necessary procedure.
- A thorough, multisystem physical examination is an essential part of the preoperative evaluation to detect important coexisting disease. The suspicion or diagnosis of coexistent morbidities that have not been diagnosed previously requires preoperative investigation. Laboratory and radiologic investigation should be conducted patiently and procedures directed in a safe, cost-effective manner.
- Coexisting or occult cardiac disease represents a significant contributor to perioperative morbidity. Particular attention to the detection, evaluation, and management of cardiac risk factors including CAD, hypertension, congestive heart failure, valvular disease, arrhythmias, and hypercholesterolemia is imperative.

Particular attention to ACLS guidelines is important. Perioperative assistance by personnel experienced in cardiac care should be invoked when necessary.

- Perioperative pulmonary care is an important concern. The procedure should be designed to minimize pulmonary risks when possible. Preoperative and postoperative attention to pulmonary toilet may render the best possible outcome.
- Perioperative renal failure is associated with high morbidity and mortality. No intervention, including prophylactic low-dose dopamine, mannitol, or furosemide therapy, has been shown to be of any benefit in reducing the incidence of perioperative renal insufficiency.
- The optimal surgical incision is chosen according to the procedure done, existing comorbidity, disease process, and patient preference. Appropriate preoperative skin antisepsis is necessary and, in combination with intravenous antimicrobial agents, will decrease the incidence of wound infection. Good surgical technique is mandatory for wound health and maximizing patient outcome.
- Classically, bowel preparation (mechanical, with or without antibiotic) is undertaken prior to many gynecologic procedures, but this practice is not currently supported by evidence. Nasogastric suction has not been shown to lessen the risk of ileus, and only 10% of patients require insertion of a nasogastric tube postoperatively. Most patients can be managed without nasogastric suction.
- Proper use of prophylactic antibiotics lessens infectious risks in many pelvic procedures. Single-agent broad-spectrum antibiotic use, such as cephalosporin, doxycycline, or metronidazole, appears to be safe and effective for women who are undergoing abdominal or vaginal hysterectomy.
- The American College of Chest Physicians has published guidelines regarding perioperative thromboprophylaxis. Patients at low risk should be mobilized aggressively postoperatively. Those at moderate and high risk should use pneumatic compression hose or pharmaceutical methods. Patients at highest risk may also benefit from combined mechanical and pharmaceutical prophylaxis.
- Approximately 2% of gynecologic procedures are associated with postoperative lower extremity neurologic deficits. Special attention should be paid to patient positioning, surgical duration, proper use of surgical retractors to prevent excessive traction and stretch, and careful operative techniques.

Laparoscopic Surgery

Joseph S. Sanfilippo
Lisa M. Roberts

Endoscopic (minimally invasive) surgery originated in 1847; the pioneering work of Sir James Y. Simpson of Edinburgh, Scotland, introduced chloroform narcosis. The first endoscopic evaluation of the abdominal cavity utilized a dog model in 1901 and was undertaken by Kelling. In 1911, Jacobaeus reported the first laparoscopic procedure in the human. Cold illumination fiber optics by Semm followed in 1963 and then the surgical area evolved rapidly. The first laparoscopic appendectomy was performed in 1980 and the first cholecystectomy in 1985.

This relatively new aspect of endoscopic surgery has far-reaching and ever-increasing innovative aspects. Advances in hysteroscopic surgery have altered the approach to uterine leiomyomas. Currently, the spectrum of laparoscopy includes radical hysterectomies and node sampling. The technical advances, including new instrumentation, are within the scope of this chapter. There appears to be a continuous state of evolution and more far-reaching new and improved instrumentation within the discipline of minimally invasive surgery.

Laparoscopy

Patient Positioning

Proper patient positioning is paramount to avoid injuries. The surgeon should position the patient so as to prevent any excessive pressure on the lower extremities. Use of intermittent pneumatic compression devices is becoming more commonplace in order to prevent thromboembolic events. Surgeons must also be aware of nerve injuries that can result from improper placement of the lower extremities in stirrups. The lithotomy position with access to steep Trendelenburg is oftentimes utilized. The physician should discuss with the anesthesia team decisions regarding whether the arms should be extended or “tucked” along the sides of the patient. The latter requires particular attention to prevent any trauma to the hands and fingers when the table is maneuvered. Plastic “sleds” can be utilized to secure the upper extremities in obese patients.

With the patient in the low lithotomy position and the legs supported in stirrups, the

buttocks should protrude slightly from the lower edge of the table. The lateral aspect of the knee should be protected with padding in the stirrup to prevent peroneal nerve injury. The knees should be kept in slight flexion to minimize stretching of the sciatic nerves and to provide increased stability in the Trendelenburg position. With respect to positioning of the arms, care should be taken not to stretch or traumatize the brachial plexus.

It has been advocated that an angle of 145 degrees between the abdomen and the lower extremity (thigh) is ideal, providing the surgeon with adequate space for instrumentation. The typical patient positioning for endoscopic surgery is noted in Figure 46.1.

Equipment

The array of instruments designed to facilitate operative laparoscopic procedures continues to evolve. This section describes a number of instruments.

Viewing System

The video equipment should include a three-chip camera, a processor, a 300-watt xenon light source with fiber-optic cable, a high-resolution monitor, and a video recorder. The three-chip camera provides a sharper, brighter image with higher resolution than the older single-chip cameras (Fig. 46.2). Three-chip cameras can deliver over 600 lines of resolution; therefore, the video monitor's horizontal resolution should be greater to maximize image quality. Fiber light cables should be inspected for broken fibers and replaced if a significant number of fibers are broken, because damaged fibers will result in suboptimal light delivery.

Figure 46.1 Patient positioning for laparoscopic surgery.

Operating Table

An operating room table that allows 30 degrees of flexion (Trendelenburg position) is ideal for visualization of the deep pelvis. Shoulder braces (Stierlen-Maquet Shoulder Braces, Siemens Medical Systems, Englewood, CO) placed at the acromioclavicular joints and the

arms placed at the patient's sides will minimize nerve injuries.

Insufflator

For most procedures, the pneumoperitoneum may be maintained with an insufflator that flows at a rate of 2 to 7 L per minute. High-flow insufflators that achieve up to 30 L per minute are available and will maintain the pneumoperitoneum during procedures with frequent changes in instruments that allow escape of large amounts of carbon dioxide (CO_2), such as during tissue morcellation.

Figure 46.2 Autoclavable Goldtip videolaparoscope with camera processor and xenon light source (Olympus, Melville, NY).

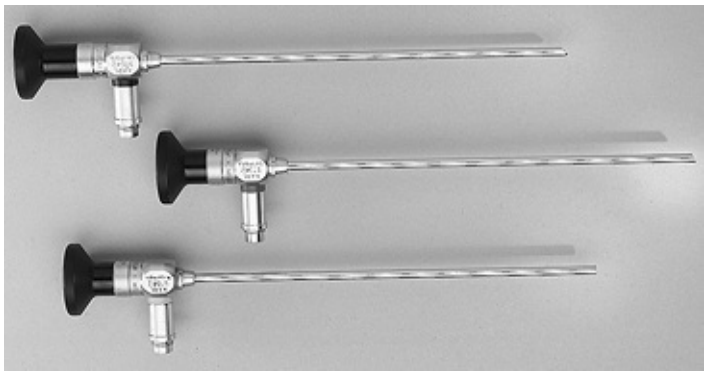

Figure 46.3 Five-millimeter laparoscopes (Karl Storz Endoscopy–America, Culver City, CA).

Carbon Dioxide Warmer

There is evidence that warmed CO_2 is less irritating to the peritoneal surface and,

therefore, may cause fewer postoperative adhesions. CO_2 warmers are available commercially.

Laparoscopes

Laparoscopes are telescopes that vary in size from 2 to 10 mm. Viewing angles are available in 0-, 30-, 45-, and 70-degree increments. The choice is operator dependent. Most diagnostic laparoscopes do not contain an operating channel. Operative laparoscopes, with a smaller fiber diameter, contain a channel through which instruments or a laser (Figs. 46.3, 46.4) can be used.

Trocars

Trocars come in a variety of sizes, materials, and designs. Sizes range from 3 to 15 mm. Reusable metal trocars have the advantage of cost efficiency, but they may actually be more dangerous if the tips are not kept sharp (Figs. 46.5,46.6,46.7). Disposable trocars are utilized in most operating rooms; they decrease the risk of injury during insertion compared with reusuable instrumentation that may require increased force during insertion (Fig. 46.8). Some trocars are designed to stretch the fascia so that fascial closure is not necessary. Others have been designed to allow visualization of tissue layer separation with the laparoscope during insertion. Advocates assert that this type of trocar decreases bowel and vascular injuries. There are no objective data supportive of a reduction in risk for any trocar. The trocar chosen should be based on the surgeon's preference. Hasson-type trocars have a blunt end for placement in open laparoscopy (Figs. 46.9, 46.10).

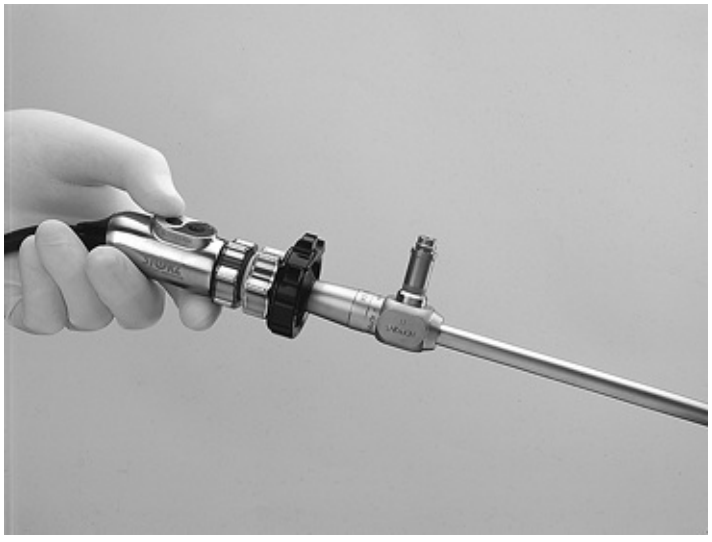

Figure 46.4 Ten-millimeter laparoscope (Karl Storz Endoscopy–America, Culver City, CA).

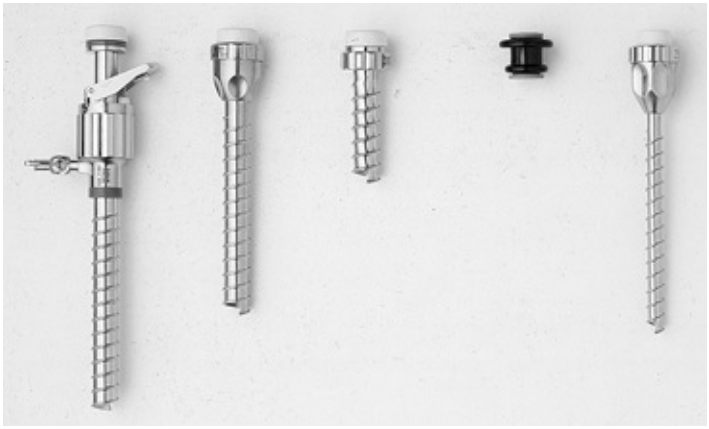

Figure 46.5 Five- and ten-millimeter trocars (Karl Storz Endoscopy–America, Culver City, CA).

Operating Instruments

A standard laparoscopy set should include the following:

- Trocars
- Bipolar forceps (Figs. 46.11, 46.12)
- Atraumatic grasping forceps (Figs. 46.13,46.14,46.15)
- Biopsy forceps (Fig. 46.16)
- Blunt probe
- Blunt sawtooth scissors (Fig. 46.17)
- Pointed Metzenbaum scissors (Fig. 46.18)

Staplers

Endoscopic staplers that simultaneously ligate and divide tissue are available. In gynecologic procedures, they are used most commonly on the infundibulopelvic ligament, round ligament, fallopian tubes, and utero-ovarian ligaments in laparoscopically assisted vaginal hysterectomies. They also may be used when excising endometriosis from the bowel (Fig. 46.33).

Harmonic Scalpel

The active blade of the Harmonic Scalpel (Ethicon Endosurgery Inc., Cincinnati, OH) vibrates at a rate of 55,000 cycles per second, resulting in coagulation and

tissue separation. The scalpel is available as a 5- or 10-mm “hook,” “ball” dissector, spatula, or opposing jaws. Although electrical energy is not used, the tissue still becomes heated, and a 2-mm lateral energy spread that can cause thermal injury may be encountered.

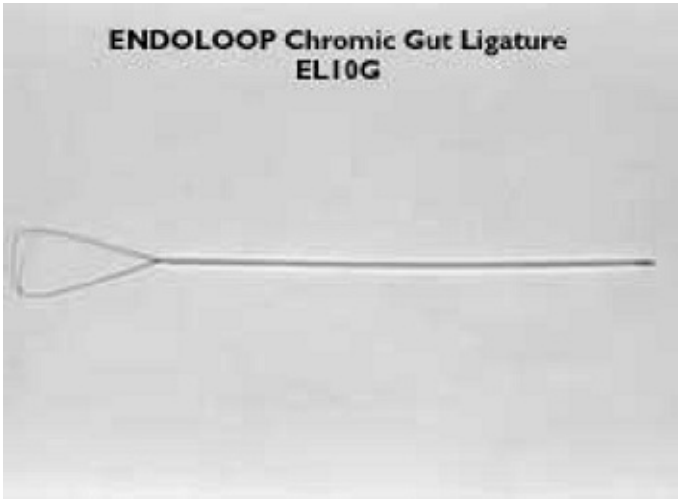

Figure 46.32 Surgitite endoscopic suture ligature (U.S. Surgical, Norwalk, CT).

Electrosurgery

Unipolar electrosurgical instruments are used to cut and coagulate tissue. Cutting occurs when there is sufficient voltage (at least 200 V) between the electrode and the tissue to produce an electric arc. This arc concentrates the current to points along the tissue, resulting in a cutting effect. In contrast to cutting current, coagulation is produced through instrument contact with the tissue. Contact allows heating of the tissue followed by irreversible cellular damage, vaporization of intracellular water, coagulation, and contraction of blood vessels and surrounding tissue. Electrosurgical burns may occur due to insulation failure, direct coupling (activated electrode makes unintended contact with another metal object in the area of the surgical field), or capacitive coupling (induction of stray current to a surrounding conductor through the intact insulation of an active electrode).

Bipolar electrosurgical instruments contain the electrical current between an active and return electrode, usually the two blades of forceps. The flow of alternating current is passed between the two electrodes rather than passing through the patient to a grounding pad. In comparison to monopolar current, bipolar elctectrocautery eliminates the risk of capacitive coupling and stray current.

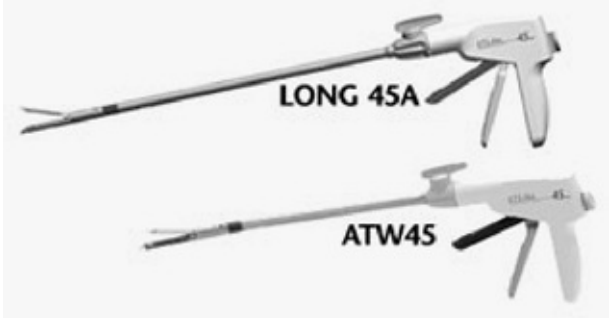

Figure 46.33 Stapling device (U.S. Surgical, Norwalk, CT).

Laser

Lasers offer an alternative method of cutting and vaporizing tissue. The CO_2 laser with a depth of penetration of 1 mm allows the surgeon some security when working around bowel, ureters, and large blood vessels. In addition, a CO_2 laser will not traverse through water, thus irrigation fluid may be used as a backstop. The Coherent 5000L (Coherent Laser, Palo Alto, CA) laser offers high-power density over a short period of time, minimizing thermal damage to surrounding tissue. This laser uses a 13C isotope of CO_2 with an 11.1-mm wavelength beam. The wavelength of the CO_2 purge gas in the operating channel of the laparoscope is 10.6 mm. Because the wavelengths are different, there is no absorption of the laser beam by the purge gas, keeping the power density ten times more than at similar settings with other standard laser beams with 10.6-mm wavelengths. The 1.5-mm spot size is maintained at all power settings, offering precision, minimal surrounding tissue damage, and less charring.

Fiber lasers (potassium titanyl phosphate [KTP], argon, and neodymium-doped yttrium aluminium garnet [Nd:YAG]) are introduced through small channels of the operating laparoscope or through ancillary trocars. The KTP and argon lasers may be used for cutting and coagulating. As the tip of the fiber approaches the tissue, the power density increases and the laser is used for cutting. As the tip is moved away from the tissue, the spot size increases and power density decreases rapidly. The clinical applications for the YAG laser are more limited. The YAG laser coagulates well, but it does not cut well unless a sapphire tip is used to increase the power density.

Uterine Manipulators

A comparative survey of uterine manipulators has been done, each of which has advantages and disadvantages.

The Clermont-Ferrand manipulator (Storz Endoskope, Tuttlingen, Germany) allows movement +140 degrees, is reusable, and requires cervical dilation to a Hegar dilator no. 9.

The Hohl manipulator movement ranges up to 130 degrees, and is minimally traumatic. (Endoworid Gyn, Karl Sturz, Ltd. Tuttlingen, Germany).

The Endopath (Ethicon Ethosurgery Inc., Cincinnati, OH) allows movement range of +130 degrees and is disposable, and the pneumoperitoneum is maintained with difficulty.

The RUMI System with the KOH Colpotomizer (Cooper Surgical, Shelton, CT) has a snap drum that rotates around a 140-degree arch, allows good delineation

of the vaginal fornices, and can be used with the harmonic scalpel. The disadvantage is

that it is not always easy to place the device, especially with a narrow vagina. Elevation of the uterus is restricted.

The Histerophore uterine manipulator levers the lateral fornices free, facilitating uterine pedicle formation, and is reusable and easy to assemble (Karl Sturz, Tuttlingen, Germany). The range of motion is less than other manipulators.

The Vcare manipulator (ConMed Corporation, Utica, NY) provides for optimal exposure of the vaginal fornices, maintains the pneumoperitoneum, and allows for easy uterine manipulation. It is disposable and cannot be used as a laser backstop.

The Total laparoscopic hysterectomy uterine manipulator allows for movement in the range of +130 degrees, is reusable, and provides for good presentation of the vaginal fornices. The one disadvantage is restricted movement of the external device over the internal rod.

Handoscopy

Hand-assisted laparoscopy, or "handoscopy," has received some attention, mainly in the field of solid organ and bowel surgery. This involves making a small incision that is large enough to squeeze a hand through with a seal to prevent loss of CO_2. To date, the only gynecologic procedure where this device has been used is in rectal resection for deep fibrotic endometriosis. The main advantage of handoscopy is that it allows the surgeon to regain the tactile feel of tissues lost in standard laparoscopies. The disadvantage is that the incision needs to be carefully closed to prevent hernia, and it requires a longer recovery interval, albeit less than if the procedure were performed open.

Physiologic Effects of the Pneumoperitoneum

The respiratory, hemodynamic, and renal consequences of the pneumoperitoneum are substantial but usually are well tolerated by the healthy patient. These changes may be severely problematic in the patient whose cardiopulmonary or renal system is compromised.

Respiratory Changes

Ventilation during laparoscopic surgery is altered by the increased intra-abdominal pressure (IAP) of the pneumoperitoneum. The airway pressure required for adequate ventilation consequently is increased. Thoracic compliance, diaphragmatic excursion, and functional residual capacity are all decreased. Studies have shown that the increase in IAP alone reduces compliance by 30%; this may be decreased by another 20% when the patient is placed in a Trendelenburg position.

In addition to mechanical changes, the CO_2 pneumoperitoneum produces changes in acid-base balance. Because CO_2 is absorbed rapidly from the peritoneal cavity, the minute volume must be increased as indicated by the end-tidal CO_2 to prevent respiratory acidosis (Table 46.1).

TABLE 46.1 Ventilatory Effects of Carbon Dioxide Pneumoperitoneum

1. Hypercapnia with subsequent acidosis
2. Increased airway pressure
3. Decreased functional residual capacity
4. Decreased thoracic compliance
5. Decreased diaphragmatic excursion

Hemodynamic Changes

Circulatory changes seen during laparoscopic surgery are the result of the mechanical compressive effects of the increased IAP and its associated hormonal changes (Table 46.2). Catecholamines, angiotensin, and vasopressin are all increased, resulting in increased systemic vascular resistance. An increase in systemic vascular resistance results in an increase in mean arterial pressure and a decrease in cardiac index. The increased IAP also causes increased intrathoracic pressure, with resultant increases in central venous pressure, pulmonary capillary wedge pressure, and pulmonary vascular resistance.

Renal Blood Flow Changes

Animal studies have shown an increase in renal vascular resistance and a decrease in renal perfusion and glomerular filtration rate secondary to increased IAP. A subsequent decrease in urine output may be observed and may continue to remain low 1 hour after release of the pneumoperitoneum (Table 46.3).

Compromised Patient

The multiple cardiopulmonary and renal changes observed during CO_2 laparoscopy are well tolerated by the healthy patient. Extreme caution must be taken when performing gaseous laparoscopy in patients with compromised respiratory function, ischemic heart disease, congestive heart failure, and renal dysfunction. These compromised states may even be considered relative contraindications to pneumoperitoneum laparoscopy. The lowest IAP that allows

adequate visualization should be used to minimize increases in intrathoracic pressure. An alternative consideration would be to use an abdominal wall lift method (elevating the ventral abdominal wall by an inflatable balloon or fan retractor), eliminating the

consequences of CO_2 in the peritoneum. The use of alternative gases such as argon, nitrous oxide, helium, and room air for pneumoperitoneum has been considered. CO_2's advantages over these gases include higher solubility and therefore possibly fewer deleterious effects in the event of gas embolism, the ability to use cautery in its presence, and its low cost. It is the surgeon's responsibility to take a careful history and perform appropriate preoperative diagnostic testing when determining a patient's candidacy for laparoscopic surgery.

Anatomy of the Anterior Abdominal Wall

Knowledge of the anterior abdominal wall vascular anatomy will reduce vascular complications associated with trocar placement. Of particular concern are the superior and

inferior epigastric vessels. The superior epigastric artery, one of the terminal branches of the internal thoracic artery, enters the rectus sheath first and then the rectus muscle coursing near its lateral border. This artery and its adjacent vein often can be visualized by transillumination of the abdominal wall with the laparoscope.

Visualization of the ventral abdominal wall laparoscopically will often locate the deep inferior epigastric vessels. The artery, a branch of the external iliac, and its accompanying vein course along the abdominal wall peritoneum just lateral to the rectus muscle until midway between the symphysis pubis and umbilicus, where it blends into the body of the rectus muscle. These vessels may be seen medial to the insertion of the round ligament at the deep inguinal ring. Therefore, placement of the trocar lateral to the deep inguinal ring and lateral border of the rectus muscle will avoid injury to these vessels.

If placement of the trocar is too far laterally, branches of the superficial circumflex iliac vessels may be injured. Again, transillumination of the anterior abdominal wall by using the laparoscope will assist in avoiding these vessels.

As a general guideline, the superficial and inferior epigastric vessels are located approximately 5.5 cm from the midline. The superficial circumflex iliac vessels are approximately 7 cm from the midline. Theoretically, a “safe area” would be 8 cm above the symphysis pubis and 8 cm from the midline. If transillumination is not effective due to a thick abdominal wall, the surgeon may consider insertion of a spinal needle through the abdominal wall at the selected trocar insertion site. If no bleeding is observed after removal of the needle, the location is likely safe for trocar placement.

Obtaining Intra-Abdominal Access

For most laparoscopic surgeons, obtaining access to the peritoneal cavity is the most anxiety-provoking step of the entire endoscopic procedure. There are a number of ways to obtain intra-abdominal access for trocar placement and establishment of a pneumoperitoneum. None of the available methods preclude the possibility of complications from trocar or needle insertion. In general, these methods of entry can be classified as either open or closed.

An open entry uses the technique first described by Hasson. It remains a very popular method of entry into the abdominal cavity. An incision into the peritoneal cavity through all anterior abdominal wall layers at the umbilicus is made carefully. A blunt-tipped trocar is placed through the incision into the abdominal cavity. Insufflation is conducted through this trocar sleeve. This technique may reduce vascular injuries due to sharp trocar or needle placement, but the possibility of bowel injury still exits if there are abdominal wall adhesions.

The closed entry may be performed with or without the use of a Veress needle to insufflate CO_2. Placement of the sharp trocar through the umbilicus without prior insufflation in general has lost favor due to the higher risk of bowel and vascular injuries.

Insufflation of CO_2 through a Veress needle is the most common method of gas instillation, although some would argue that the open technique should become the method of choice.

One technique of access by using a Veress needle is performed in the following manner:

. A vertical incision through the skin corresponding to the size of the trocar is made either within the umbilicus or at the base. This is because the distance between skin and peritoneum on the anterior abdominal wall is shortest at the base of the umbilicus. In addition, the peritoneum is firmly attached, which will prevent tracking through the subcutaneous tissue and subsequent retroperitoneal insufflation.

.. The Veress needle is inspected for sharpness and a functioning spring mechanism to extend the protective sheath in the absence of pressure.

. The anterior abdominal wall inferior to the umbilicus is grasped with the non-dominant hand, and the umbilicus is moved in the caudad direction, further displacing it below the bifurcation of the aorta. Alternatively, the incision may be elevated by grasping the edges of the edges of the umbilical incision with two Alice clamps and lifting.

. The tip of the Veress needle is held in the dominant hand between the thumb and forefinger while the ulnar palm rests on the patient's abdomen. The needle is inserted carefully at a 90-degree angle, through the base of the umbilicus, millimeter by millimeter, until a click is heard and resistance is no longer felt, identifying intra-abdominal placement.

. A saline-filled 10-cc syringe is attached to the Veress needle and aspirated, inspecting for blood or bowel contents. If only bubbles are visible, saline is injected and observed to fall from the trough on the needle into the peritoneal cavity.

. The syringe is removed, the insufflation tubing (with CO_2 turned on low flow) is attached, and the initial IAP is observed. If the pressure is >10 mm Hg, the needle should be removed quickly to avoid retroperitoneal insufflation, which further displaces the peritoneum from its attachment to the anterior abdominal wall. A second needle placement attempt is then made.

'. Once intraperitoneal placement is confirmed, a CO_2 pneumoperitoneum is obtained. Insufflation up to an IAP of 20 to 25 mm Hg, as initially described by Reich and others, remains one accepted method. This temporary increase in IAP increases the distance between abdominal viscera and the anterior abdominal wall (in the absence of adhesions) during primary sharp trocar placement through the umbilicus. It is also extremely beneficial for surgeons with small hands, who may find it difficult to grasp and further elevate the abdominal wall if the initial pressure is <20 mm Hg.

. The end of the sharp trocar is held in the palm of the dominant hand, with the forefinger extended along the shaft as close to the sharp tip as possible. The tip is inserted through the umbilical incision until the fascia at the base of the umbilicus is felt. Insertion is carried through at a near–90-degree angle until the tip is felt to pass through the peritoneum. The trocar is then directed toward the pelvis to minimize risk of vascular or bowel injury.

. After placement of the primary trocar, the intra-abdominal placement is confirmed visually and the IAP is reduced to 12 to 15 mm Hg.

Alternative methods for obtaining pneumoperitoneum have been described and are useful in cases in which adhesions at or near the umbilicus are suspected. The most common method is insertion of the Veress needle in the left upper quadrant, followed by placement of a 5-mm trocar and laparoscope. Others have performed insufflation after inserting a Veress needle transfundally or through the posterior cul-de-sac into the intra-abdominal cavity.

There are no prospective randomized studies comparing the safety and efficacy of open-entry with closed-entry techniques. The incidence of injuries is so low that a very large study population would be required to show any statistical difference. Randomized studies comparing the Veress needle with the direct trocar insertion technique favor the Veress needle. The vast majority of surgeons agree that the method used should be that with which the surgeon has the most experience and is, therefore, most comfortable.

Laparoscopic Procedures

Ectopic Pregnancy

Through earlier diagnosis, ultrasonography has significantly reduced the morbidity and mortality associated with ectopic pregnancies. In 98% of cases after the fifth week of pregnancy (when human chorionic gonadotropin [hCG] levels are >1,000), transvaginal ultrasonography can reliably visualize a normal gestational sac. The absence of an intrauterine sac above this level should alert the physician to a high likelihood of ectopic pregnancy. With the advent of methotrexate use, the total number of ectopic pregnancies treated surgically has decreased. Laparoscopy remains a standard for surgical management in the stable patient.

While obtaining informed consent, the surgeon must discuss management alternatives. Should the pregnancy alone be removed, leaving the fallopian tube in place, or should a salpingectomy be performed? Assuming that the pregnancy can be aborted without significant bleeding from the fallopian tube, this decision should be based on the status of the contralateral ovary and tube. If the contralateral tube and ovary are normal in appearance, without adhesions, then a salpingectomy or salpingostomy may be performed with a subsequent intrauterine pregnancy rate of 85% and a repeat ectopic rate of 10%. If the contralateral tube is impaired, then the subsequent intrauterine pregnancy rate is 46% and repeat ectopic rate is 52%. In this situation, the affected fallopian tube should be removed.

Technique for Salpingostomy or Salpingectomy

Laparoscopic access is obtained as described previously. In addition to the umbilical port, two 5-mm lower abdominal ports are indicated, left and right. A suction-irrigator is used to aspirate the hemoperitoneum, if present. The pregnancy is identified within the fallopian tube, usually within the ampullary portion. The tube is stabilized with a Babcock or atraumatic grasper. There is considerable debate regarding the use of dilute vasopressin prior to making the incision on the antimesenteric side of the tube overlying the

pregnancy. Clinicians must understand that the use of vasopressin has the potential for delayed bleeding postoperatively. An incision parallel to the axis of the tube is now made on the antimesenteric side. This may be performed by using a spoon, knife, or hook monopolar electrocautery, set at 50 to 80 W to minimize bleeding. An effort should be made to minimize tubal epithelium trauma. The suction-irrigator is used to “aquadissect” the attachments between the pregnancy and tube, thus aborting the pregnancy into the pelvis. Alternatively, the pregnancy may be grasped by

using atraumatic graspers and pulled from its attachment. It is then removed from the abdomen.

TABLE 46.4 Ultrasonographic Criteria for Malignant Ovarian Tumors

Size >5 cm
High (solid) echogenicity
Internal septations
Irregular border
Papillary intracystic formations
Ascites

If significant bleeding is encountered or the pregnancy does not dissect freely, a salpingectomy may need to be performed. Again, the fallopian tube is grasped with an atraumatic grasper and lifted. Transection of the involved tube is performed. Transection should be done after complete desiccation by using cautery or may be performed after suture ligation (a window is created within the mesosalpinx inferior to the ligation site). The mesosalpinx, immediately inferior to the fallopian tube, is then desiccated by using bipolar cautery and transected, freeing the tube and pregnancy from its anatomic attachments.

Adnexal Mass

Laparoscopic management of adnexal masses is gaining widespread acceptance, but some aspects still conjure considerable debate. The patient's age, transvaginal sonographic findings, and to some extent CA-125 level (if indicated based on patient's age) will determine if a laparoscopic approach rather than laparotomy is acceptable. Ultrasonographic criteria for malignant and benign tumors are presented in Tables 46.4 and 46.5. CA-125 levels are most useful in postmenopausal women; a level of 35 U/mL in postmenopausal women carries a sensitivity of 81% and specificity of 91% for malignancy. If

the level is >50, then the sensitivity remains essentially the same and the specificity increases to 97%. In premenopausal women, sensitivity remains 60% as the level increases, but specificity increases from 73% at a level of 35 to 95% at a level of 100.

A primary concern for those advocating laparotomy over laparoscopy for management of suspicious adnexal masses is the potential increased risk of cyst rupture during laparoscopic surgery. Preoperative or intraoperative rupture changes a stage Ia ovarian carcinoma to a stage Ic. Studies have shown that intraoperative iatrogenic rupture of the tumor capsule does not adversely affect survival, but survival is negatively influenced by spontaneous or preoperative rupture. The American College of Obstetricians and Gynecologists (ACOG) guidelines for intraoperative management of adnexal masses are presented in Table 46.6. As a general rule, if malignancy is highly suspected, then complete surgical staging procedure should be performed. If a laparoscopy is performed initially and malignancy subsequently is identified histologically, the staging procedure should be completed within 1 week.

Obtain peritoneal washings
Explore the upper abdomen
Obtain biopsy specimens from any abnormal areas
Look for external excrescences
Perform laparotomy for any question of malignancy or if mass

is removed inadequately
Use frozen sections for cytologic analysis; perform laparotomy if malignant

Technique for Ovarian Cystectomy

After obtaining intraperitoneal access and placement of trocars, the utero-ovarian ligament is grasped to stabilize the ovary. The ovarian cortex overlying the cyst is incised very superficially so as not to rupture the cyst. This may be performed using a CO_2 laser set at 5 to 10 W, a monopolar electrode (knife, hook, spoon) set at 30 to 50 W of cutting current, or scissors. The edge of the cut ovarian cortex is grasped with a biopsy forceps and elevated. The suction-irrigator is placed gently at the opening between cortex and cyst wall. Aquadissection is performed by using Ringer's lactate. A blunt grasper is introduced within the space, and the cyst is shelled out from its attachment to the cortex. The incision is made longer as necessary. The cyst is placed within an impermeable sac introduced through the umbilical port or through a culdotomy incision. For larger cysts, a zip-lock type sandwich bag may be gas sterilized and placed through the 10- to 12-mm umbilical port. The sac is then removed either through the umbilicus or transvaginally. A spinal needle may be used to aspirate the contents of the cyst within the sac prior to removal to decrease its volume. A minimal access to management of large ovarian cysts can minimize spillage; work from Singapore has suggested a combination of laparoscopic-guided aspiration followed by extra-abdominal excision of the ovarian cyst.

Technique for Oophorectomy

The first step in an oophorectomy procedure is always identification of the adjacent ureter. The ureter is most easily located at the pelvic brim near the bifurcation of the common iliac. Its retroperitoneal course may then be followed and location relative to the infundibulopelvic ligament noted. Once certain of the ureteral location, the infundibulopelvic ligament is grasped gently, elevated, and brought medially by using an atraumatic grasper. The ligament is then desiccated at its attachment to the ovary by using bipolar cautery. It is then transected. Alternatively, an opening through the peritoneum inferior to the ligament may be created by using scissors. Suture ligatures may then be placed and tied. After transection of the infundibulopelvic ligament, the utero-ovarian ligament is desiccated and transected. Desiccation of the mesovarium is followed by transection, completely freeing the ovary. The ovary is then placed in an impermeable sac and removed as described previously.

Tubal Sterilization

Surgical occlusion of the fallopian tubes is the most common method of contraception in developing countries. The techniques have evolved from a laparotomy to minilaparotomy to a laparoscopic approach including excision, electrosurgical desiccation by using bipolar

cautery, and application of clips or rings.

A Pomeroy tubal ligation can be easily performed laparoscopically by grasping the fallopian tube at its isthmic portion and placing a chromic endoloop suture around a segment of tube. The knuckle of tube may then be excised.

Two clips are approved by the Food and Drug Administration for tubal occlusion, the Hulka-Clemens clip and the Filshie clip. Both clips are placed at the proximal isthmus after the tube has been placed on stretch. The clip should be applied at 90 degrees to the long axis of the tube and advanced until the hinge reaches the tube, incorporating the mesosalpinx at its tip.

The Falope ring is placed on the ampullary portion of the fallopian tube by grasping the tube with the applicator and drawing the tube inside the applicator. A 1- to 2-cm segment of tube is drawn into the ring.

Although sterilization failure rates are lowest with unipolar cautery, most are performed by using bipolar cautery because of safety concerns. Bipolar desiccation is performed correctly with an in-line ammeter (indicating complete desiccation), current set at 25 W, and desiccation of three contiguous areas of the isthmus incorporating the blood supply from the mesosalpinx.

The results of the U.S. Collaborative Review of Sterilization found that all methods of tubal occlusion are very effective, although failure rates were higher than expected. The Hulka-Clemens clip and bipolar methods carry the highest failure rates, likely due to improper application technique.

Myomectomy

Women with symptomatic leiomyomas who wish to retain their reproductive potential or their uteri are candidates for myomectomy. Most of these procedures are still performed abdominally, because laparoscopic myomectomy is one of the more difficult laparoscopic procedures. There is controversy as to whether a laparoscopic closure of the myometrium is comparable to a closure achieved in an open procedure. In general, a laparoscopic approach should not be selected if leiomyomas are larger than 5 to 8 cm, are multiple, or embedded deep within the myometrium. If a laparoscopic approach is chosen, the patient should be informed of the potential increased risk of spontaneous uterine rupture prior to labor and of recurrence (33% after 27 months). Additionally, since the surgeon cannot palpate the uterus, smaller intramural fibroids that may have been detected at the time of a open myomectomy will not be detected. This results in a higher rate of relatively prompt *recurrence* of fibroids which is more accurately termed *persistence*.

Most myomectomies can be performed with three trocar sites. One 10-mm trocar is placed umbilically, and 5-mm trocars are placed in the lower left and right abdomen. A vertical incision is made in the myometrium overlying the myoma by using a spoon electrode (or other electrosurgical instrument) set at 60 to 80 W of cutting current to minimize bleeding. The incision is continued through the myometrium to the surface of the myoma, identifying the plane between the pseudocapsule and fibroid. The myoma is grasped with a 5-mm single-toothed tenaculum or corkscrew, and traction is applied. The plane between the

fibroid and pseudocapsule is entered and adhesions released with a combination of blunt and sharp dissection. The suction-irrigator works well here for blunt dissection. The adhesive attachments are desiccated by using bipolar forceps prior to their transection to minimize bleeding. These adhesions may also be vaporized by using the CO_2 laser. The process is continued until the base of the myoma is reached, where the remaining attachments are desiccated by using bipolar cautery. The myoma is freed and placed in the posterior cul-de-sac for later retrieval. Hemostasis of the myometrium is achieved. A multilayer closure is now performed by using single interrupted sutures placed and tied laparoscopically. Alternatively, if the operator is not skilled in laparoscopic suturing or if there is concern regarding obtaining a maximally tight closure, a small laparotomy incision may be made and the suturing performed abdominally. A uterine manipulator placed within the uterus can help to elevate the uterine incision to the laparotomy incision and make suturing through a smaller incision easier. The myoma is now removed from the abdomen. If a small laparotomy incision has been made, the myoma may be removed through this incision. Morcellation by using a scalpel or scissors may be necessary if the myoma is larger than the incision. If the entire procedure has been performed laparoscopically, the myoma may be removed

---

by using a morcellator introduced through the umbilical incision and visualized with a 5-mm laparoscope placed in one of the lower trocar sleeves. Alternatively, a culdotomy incision can be made and the myoma removed vaginally. The culdotomy incision may then be closed vaginally or laparoscopically.

Hysterectomy

The advanced surgical skills required to perform a laparoscopic hysterectomy and the economic factors involved have limited the acceptance of this procedure in gynecologic practice. The laparoscopic hysterectomy or laparoscopically assisted vaginal hysterectomy was never intended to replace the vaginal hysterectomy. The primary role of this procedure is to reduce the number of abdominal hysterectomies performed. Of all hysterectomies performed in the United States, 70% are performed abdominally. A review of the data from the Health Insurance Commission Medicare in Australia showed a decrease in the incidence of abdominal hysterectomy from 70% in 1991 to 1992 to 57% in 1994 to 1995 after the introduction of laparoscopically assisted hysterectomies in private hospitals. The ACOG has agreed on the indications listed in Table 46.7 for laparoscopically assisted vaginal hysterectomy (there has been no comment on total laparoscopic hysterectomies, but the same indications inherently would apply).

Several randomized controlled trials comparing laparoscopically assisted vaginal hysterectomies with abdominal hysterectomies reported that the former are associated with significantly less postoperative pain, shorter hospital stays, and faster return to work and normal activities but possibly longer operative times.

Technique for Total Laparoscopic Hysterectomy

As noted previously, a uterine manipulator (e.g., RUMI System), a vaginal extender (e.g.,

KOH Cup Vaginal Fornices Delineator), and a pneumo-occluder (Colpo-Pneumo Occluder; all products from Cooper Surgical, Shelton, CT) or similar instruments are put in place at the beginning of the procedure. A 10-mm reusable trocar is introduced through the umbilicus after pneumoperitoneum is obtained as described previously. Five-millimeter trocars are introduced into the lower left and right abdomen under direct visualization. The course of the ureters is identified retroperitoneally. If the ovaries are to be removed, the infundibulopelvic ligament is isolated, desiccated, and transected as described previously for oophorectomy. If ovaries are to remain, then the round ligament, fallopian tube, and utero-ovarian ligaments are desiccated by using bipolar forceps and transected approximately 1 cm from their uterine attachments. The anterior leaves of the broad ligament are incised bilaterally to meet in the midline, releasing the bladder peritoneal attachment to the lower uterine segment. The harmonic scalpel with the hook attachment works well to minimize oozing. The bladder is gently pushed inferiorly over the vaginal metal colpodelineator. Using scissors, the posterior broad ligaments are incised downward to the insertion of the uterosacral ligaments, allowing lateral retraction of the ureters. The uterine arteries are identified within the broad ligament, and the surrounding loose, areolar tissue is skeletonized in a blunt fashion. The uterine arteries are then desiccated completely by placing the bipolar forceps at right angles to the lower uterine segment on either side, above the level of the vaginal metal colpodelineator. The uterus should take on a bluish hue if complete desiccation has been achieved. The desiccated arteries are transected, freeing the cardinal ligament attachment.

TABLE 46.7 Indications for Laparoscopically Assisted Vaginal Hysterectomy

Prior pelvic surgery requiring lysis of adhesions
Endometriosis requiring treatment or lysis of adhesions or both
Pelvic inflammatory disease requiring lysis of adhesions
Ligation of infundibulopelvic ligaments for ovarian removal allowing completion by vaginal hysterectomy
Pelvic mass
Limited uterine mobility
Narrow pubic arch
Constricted vagina with no prolapse

The vaginal pneumo-occluder balloon is then insufflated prior to the colpotomy incision. The vaginal metal colpodelineator is emphasized by pushing the uterus cranially. The harmonic scalpel with hook electrode is used to make a circumferential incision over the metal ring, releasing the cervicovaginal attachment. The occluder balloon is deflated, and the uterus is brought into the vagina and now serves as the pneumo-occluder. Hemostasis

of the vaginal cuff is achieved. The cuff is sutured and closed laparoscopically, incorporating the uterosacral ligaments for pelvic support. The uterus is then removed through the vagina.

Endometriosis

Surgical treatment of endometriosis usually is performed for pain or infertility. There are no randomized controlled trials comparing excision, vaporization, fulguration, and desiccation of endometriotic lesions. Although each method of destruction has its proponents, the authors prefer excision of deep fibrotic endometriosis and vaporization of superficial implants. The only definitive cure for endometriosis is surgical resection or complete destruction of the endometriotic lesion. Surgical management does not include bilateral salpingo-oophorectomy. Removal of the ovaries will not necessarily ensure relief of symptoms. Estrogen, in addition to that produced by the ovaries, also is produced by peripheral conversion of androgens in the presence of aromatase. Aberrant aromatase expression has been identified in some endometriotic implants, suggesting local production of estradiol within them. This may

---

explain the reason for failures or “recurrences” after bilateral salpingo-oophorectomy or only superficial destruction of the implant.

Ovarian endometriomas should be treated by cystectomy rather than drainage and coagulation, as evidenced by the results of a randomized clinical trial. Often, these ovaries are adherent to the pelvic sidewall, adjacent bowel, or the opposing ovary. During adhesiolysis, the endometrioma often is ruptured, spilling its thick, chocolatelike fluid into the cul-de-sac. The thick fluid should be aspirated and the opening to the endometrioma identified. If necessary, the opening is enlarged until the thick endometrioma cyst wall is identified. Using a biopsy forceps (single-toothed grasper), the cyst wall is grasped and peeled from its attachment to the ovarian cortex. Once hemostasis is achieved, the cortex usually does not require suture closure.

Complications

Information regarding entry access injuries is provided in a review reflecting the Physician Insurers Association of America (PIAA). They noted that entry access injuries occurred in between 5 per 10,000 and 3 per 1,000 patients undergoing laparoscopic surgery. Bowel, rectal, and retroperitoneal vascular injuries accounted for 76% of all injuries incurred in the process of establishing a primary port. The PIAA reported that approximately 50% of bowel injuries were unrecognized for 24 hours or longer following the laparoscopic surgical procedure. A delay in recognition, age over 59 years, and major vascular injuries were independent factors associated with death. Inevitably, as more and more procedures are adapted for laparoscopy, the complication rate will likely increase but remain comparable or lower than for the corresponding procedures done by open techniques.

In a Canadian Task Force study, the overall complication rate for all laparoscopic procedures was 0.65%; for operative laparoscopy it was 0.80%. The American Association of Gynecologic Laparoscopists has noted similar results (1.45 complications per 1,000

procedures).

In a review of 32,205 gynecologic laparoscopic procedures in a Finnish study, 130 major complications were noted. The total complication rate was reported as 4.0 per 1,000 and, more specifically, 0.6 per 1,000 diagnostic laparoscopies, 0.5 per 1,000 sterilizations, and 12.6 per 1,000 operative laparoscopies. Intestinal injuries were reported in 0.7 per 1,000 procedures, incisional hernias in 0.3, urinary tract injuries in 2.5, and major vascular injuries in 0.1. Overall, laparoscopically assisted vaginal hysterectomy was associated with the highest complication rate at 2.3%, with ureteral injuries occurring in 1.0% of women undergoing the procedure.

Gas and air emboli have been reported with both laparoscopic and hysteroscopic procedures. Oxygen saturation monitoring, as well as end-tidal carbon dioxide and, more recently, capnography and mass spectrometry, are designed to provide early diagnosis. If an embolus occurs, it frequently is accompanied by cardiac arrhythmia and cardiac arrest. It is beyond the scope of this chapter to provide detailed information regarding cardiopulmonary resuscitation.

Ureteral injury, as noted previously, has been reported in association with minimally invasive surgery. Oftentimes, it is not recognized at the time of the initial procedure. The diagnosis should be considered when a patient exhibits postoperative fever, hematuria, flank pain, or evidence of peritonitis. Initial treatment with ureteral stenting on occasion is inadequate, resulting in subsequent ureteroneocystostomy. With respect to bladder injury, if one suspects such, distension of the bladder with methylene blue can identify a defect. If there is suspicion of ureteral injury, intravenous administration of indigo carmine frequently proves helpful in identifying the defect.

Other minimally invasive surgery–associated complications have included spleen laceration. The injury was reported in four patients, and predisposition included splenomegaly, with injury occurring primarily during trocar insertion. This was associated with a laparoscopic salpingoplasty. However, this complication is extremely rare.

Death, although extremely rare following minimally invasive surgical procedures, has been reported. It is more commonly associated with unrecognized trauma to the intestinal tract with ensuing sequelae. It also has been reported in association with major vascular trauma.

Summary Points

- Endoscopic surgery has replaced open surgery for many commonly performed gynecologic procedures, such as tubal sterilization, excision of unruptured tubal pregnancies, ablation of peritoneal endometriosis, and simple ovarian cystectomy.
- Endoscopically assisted vaginal hysterectomy with removal of the adnexal structures demonstrates the potential for this technology.
- Endoscopic procedures have several advantages. They can be performed on an ambulatory basis, require shorter recovery times, cause less postoperative pain, and improve the cosmetic impact of

incisions.
- Endoscopic procedures require specialized equipment and a high degree of technical skill.

Hysteroscopic Surgery

R. Stan Williams

Although hysteroscopy has been described since the early 1800s, widespread use by practicing gynecologists did not occur until the 1980s. With improvements in optics, video systems, instrumentation, and distension media, there has been an increased acceptance of hysteroscopy as the gold standard in the evaluation of the uterine cavity and treatment of intracavitary pathology.

Hysteroscopy is used most commonly for evaluation of abnormal uterine bleeding, but it also is used frequently for evaluation of the endometrial cavity in patients with recurrent pregnancy loss and infertility, particularly when intracavitary pathology is suspected. Many studies have shown that blind dilation and curettage may miss up to 60% of endometrial pathology, such as endometrial polyps and submucous leiomyoma, although with increasing expertise in ultrasonographic techniques such as the saline sonohysterogram, endometrial pathology often can be identified prior to performing diagnostic and therapeutic operative hysteroscopy. Alternatively, many practitioners perform office hysteroscopy with small-diameter hysteroscopes, which do not require significant dilation of the cervix, can provide direct visualization of the endometrial cavity, and facilitate a directed biopsy of suspected endometrial lesions or better characterization of suspected intracavitary pathology.

Operative hysteroscopy requires larger-diameter instrumentation and is best performed under anesthesia in the outpatient operating room because of the need for significant cervical dilation and more extensive instrumentation. Hysteroscopic surgery allows a variety of intrauterine surgical procedures such as myomectomy, polypectomy, resection of a uterine septum, endometrial ablation by a variety of techniques, correction of intrauterine synechiae, cannulation of proximal tubal occlusion, and placement of intraluminal coils to occlude the tube for permanent sterilization.

Instrumentation

Hysteroscopy can be used both as a primary diagnostic tool and as a more definitive operative technique. Diagnostic hysteroscopy can be performed either in an office setting or in the outpatient operating room and requires only small 3.6-mm to 5-mm hysteroscopes. These hysteroscopes may be either flexible or rigid. A small channel often is provided for a biopsy instrument, but these are rather delicate, and significant surgical

procedures will require larger-diameter hysteroscopes.

The flexible hysteroscope is used often for office hysteroscopy because it can be inserted through a narrow cervical os and can negotiate the cervical canal by using a deflecting lever to guide the instrument under direct vision. The flexible hysteroscope is available in two diameters, 3.6 mm and 4.9 mm, both with a zero-degree optical view. The larger-diameter endoscope also provides a 2.2-mm diameter instrument channel, which allows for directed biopsies of endometrial pathology. The larger instrument provides better optics than the smaller flexible hysteroscope but is still somewhat optically inferior to a 4-mm rigid scope.

Small rigid diagnostic hysteroscopes are 4 to 5 mm in diameter and have only a single channel for installation of a distending medium. If a low-viscosity liquid distension medium is used, then a continuous flow sheath that is 5.5 mm in diameter is used, allowing for the continuous simultaneous inflow and outflow of the medium, thus flushing any blood or mucus from the cavity and providing an optimal view.

Rigid hysteroscopes are available with 0-, 12-, 15-, 30-, and 70-degree optical views. For diagnostic procedures, 30-degree endoscopes are primarily used in order to easily see the entire endometrial cavity, which can be done simply by rotating the telescope 360 degrees.

Operative procedures

most commonly require the 12- or 15-degree telescopes so that the operative component of the instrumentation can be visualized fully during the procedure.

The operative hysteroscope uses a 4-mm rigid telescope within a 7- to 8-mm operative sheath, which can be configured to either provide a port for the insertion of accessory instruments (scissors, biopsy forceps, catheters, etc.) or a resectoscope with a working element for the resectoscope electrodes. Older models of operative hysteroscopes included only a single channel for installation of distension medium. Adequate egress of fluid usually is not possible with these hysteroscopes, because the only available exits are the fallopian tubes or around the hysteroscope through a patulous or overdilated cervix. Use of these single-channel hysteroscopes should be limited to high-viscosity distension media. Most commonly, operative hysteroscopy is performed with a continuous flow sheath allowing for input of the distension medium through a middle channel and egress of a low-viscosity distension medium through an outer evacuation channel. This provides for constant inflow-to-outflow exchange of media, washing of the uterine cavity, and removal of blood and debris.

Infusion of low-viscosity fluids can be accomplished either by the force of gravity or with infusion pumps. Suction tubing attached to the outflow port can be directed to wall suction or allowed to drain by gravity. Low-viscosity fluid pumps have been designed to operate in pressure ranges of 0 to 80 mm Hg. They can deliver fluid at a rate necessary to maintain a preset pressure with a maximum flow rate of 300 mL per minute, although the upper limit of flow through the outflow ports for most hysteroscopes is 250 mL per minute. Outflow usually is adjusted to be significantly lower than the maximum to allow adequate visualization, free from blood and debris; maintain adequate uterine distension; and minimize the amount of fluid needed to complete the procedure. Fluid management

systems are available that not only control the inflow pressure but also continuously measure the fluid deficit.

Alternatively, inflow of the distension medium can be controlled by gravity. The height of the infusion bag above the patient controls the maximum intrauterine pressure. Every 1 foot of height above the patient that the bag of distension medium is placed will deliver approximately 25 mm Hg of pressure to the endometrial cavity. This system is then regulated by the amount of outflow to maximize visualization while maintaining adequate uterine pressure. Because pressure of inflow is constant, changes in intrauterine pressure, and thus distension, are affected by alterations of the rate of the outflow. Use of standard suction containers to collect the outflow will make fluid measurement and calculation of any fluid deficit straightforward.

Modern operative hysteroscopy requires a video camera and video monitor for adequate operative visualization. A halogen or xenon light source providing 150 to 300 W of incandescent light is used and attached to the hysteroscope by a fiber optic light cable. The light cable should be inspected frequently to ensure that a significant number of the internal fibers have not broken and that the light cable is capable of delivering an adequate amount of light through the hysteroscope. Most chip cameras have the capability to adjust gain and can be integrated with the light source for automatic light balance.

For documentation of findings and recording of procedures, video capture units may be used. Most commonly, VCRs are used to videotape pertinent portions of the procedure. Also available are video capture units for taking still pictures or storing digital images on a computer hard disk or CD. DVD recorders also may be used to capture digital videos.

Energy for operative hysteroscopy can be delivered either with the neodymium-doped yttrium aluminium garnet (Nd:YAG) laser or with electrosurgical generators with either unipolar or bipolar electrodes. Other lasers, such as the carbon dioxide (CO_2) laser, are not used in hysteroscopy because of their failure to penetrate fluid and because of the generation of smoke if CO_2 is used as the distension medium. The Nd:YAG laser can be delivered through a flexible quartz fiber passed through the instrument channel of the operating hysteroscope, and its wavelength penetrates through the liquid distension medium used in hysteroscopy. The extent of tissue necrosis can be up to a depth of 4 to 5 mm. Varying the distance of the fiber tip and incident angle can regulate the extent of thermal damage. It is rendered ineffective at distances >2 cm or as the incident angle deviates more than 90 degrees. This laser is often used to perform endometrial ablation, using power outputs of 50 W by dragging the fiber over endometrial surfaces.

Electrosurgery through a standard resectoscope typically utilizes a monopolar electrode, with the electrical probe serving as the source electrode and the return plate on the patient as the return electrode. The resectoscope can be used with either cut or coagulation output settings on the electrosurgical generator or a blend of the two. When used in the cutting mode, a high-frequency sine wave is delivered that creates extremely high current density, instantly superheating cellular water to vaporization, causing cellular architecture to explode, and resulting in tissue cutting. In the coagulation mode, delivery of high-frequency energy is interrupted by periods of modulation. This alternation of frequency and interruption results in wider zones of tissue coagulation and damage,

resulting in coagulation and sealing of blood vessels. A variety of electrode tips are available, including a cutting loop for excision of tissue, a rollerball or bar for coagulation and ablation, and a knife electrode for incision.

Bipolar electrical generators (Versapoint, Gynecare Inc., Somerville, NJ) have recently been developed. Electrodes have been designed in several configurations, producing variable tissue effects. A ball tip can be used for vaporization with limited tissue desiccation, a spring tip for vaporizing larger amounts of tissue, and a twizzle tip for resecting and

---

morcellating tissue. These tips have both active and return electrodes and require an electrolyte-containing medium such as saline. In contrast, when using a monopolar resectoscope, a non-electrolyte distension medium such as glycine must be used.

Distension Media

Four basic types of distension media are used for hysteroscopy. The first type, CO_2, is used primarily for diagnostic hysteroscopy in an office setting. Secondly, a high-viscosity medium such as Hyskon is used primarily with inflow only–type hysteroscopes. The third and fourth types are both low-viscosity solutions that are used with continuous-flow hysteroscopes, electrolyte solutions, and non-electrolyte solutions. The choice between an electrolyte and non-electrolyte solution will depend on the use of monopolar versus bipolar electrocautery.

For diagnostic procedures in the office, some physicians choose CO_2 as the distension medium. CO_2 use requires a hysteroflator that delivers the gas at preset intrauterine pressures and has regulated flow rates. CO_2 may be used with either a small diagnostic rigid hysteroscope or a flexible hysteroscope and does not require a return channel for continuous flow, because the CO_2 gas will escape from the cervix or through patent fallopian tubes into the peritoneal cavity, where it is absorbed. Starting pressures for CO_2 are usually between 50 and 75 mm Hg. If adequate distension is not achieved, it may be necessary to increase the intrauterine pressure to a maximum of 100 mg Hg or a maximal flow of 100 mL per minute. Higher pressures or flow rates may produce a gas embolus, and rare fatalities have been reported. CO_2 will give an ideal view of the endometrial cavity that is not bleeding, because light reflection is identical to that of room air. However, any blood or mucus within the endometrial cavity will require changing to a liquid medium. Many physicians are routinely using low-viscosity solutions for office-based diagnostic procedures by using a large syringe as the delivery system. Since these procedures only take a few minutes to perform, larger volumes are not needed. Distention of the uterus can be controlled by varying the pressure on the syringe.

For many years, prior to the evolution of hysteroscopes that accommodate continuous flow, 32% high-molecular-weight dextran-70 (Hyskon) was commonly used as a liquid distension medium for operative hysteroscopy. Its nonmiscibility with blood allows its use when either blood or mucus is present in the endometrial cavity or bleeding is anticipated. Hyskon is compatible with either the Nd:YAG laser or electric cautery devices. When using Hyskon as the distension medium, its delivery requires significant constant pressure to

overcome the resistance of a high-viscosity fluid flowing through the tubing and a standard diagnostic sheath. The major disadvantage of Hyskon is the difficulty in cleaning the solution from the instruments and stopcocks. If the instrumentation is not thoroughly cleaned, the dextran crystallizes and results in clouding of the hysteroscope lens and freezing of stopcocks. Rarely, patients may have an anaphylactic reaction to the dextran. Intravascular absorption of Hyskon results in a proportional 10-fold increase of intravascular volume, and if the absorbed volume is large, there may be accompanying cardiovascular overload and pulmonary edema. Careful monitoring of the amount of Hyskon intravasated during the procedure is mandatory, and absorption of 100 to 200 mL of Hyskon should warrant termination of the procedure. Because the molecular weight of Hyskon exceeds that which can pass into the circulation from the peritoneal cavity, spill through the fallopian tubes is inconsequential.

Operative hysteroscopy most commonly uses low-viscosity solutions, which can be either electrolyte solutions or non-electrolyte solutions. If monopolar resectoscopes are used, non-electrolyte solutions are required so that the flow of energy will be directed from the electrode tip into the tissue and not allowed to “short circuit” through an electrolyte-containing medium throughout the entire uterus. The electrolyte-free solutions that are used most often for operative hysteroscopy include 1.5% glycine, sorbitol, 5.0% mannitol, and dextrose in water. Significant intravasation of distension medium may occur with resectoscope use. As tissue is resected, venous channels within the endometrium and myometrium are opened, and the pressure of the distension medium will result in the absorption of these solutions. The primary complications associated with non-electrolyte low-viscosity solutions include fluid overload and hyponatremia. Fluid overload may result in pulmonary edema, and severe hyponatremia may result in neurologic sequelae such as confusion, seizures, and even death. Intraoperative monitoring of inflow and outflow must be performed every 5 to 10 minutes throughout the procedure, and a discrepancy between 500 and 1,000 mL with non-electrolyte solutions should warrant termination of the procedure. Glycine use has also been reported to cause hyperammonemia because of its conversion from glycine to ammonia by the liver.

Electrolyte solutions such as normal saline or lactated Ringer's solution are used with bipolar electrical devices or for continuous-flow diagnostic hysteroscopy. Because bipolar devices contain both the active and return electrodes at the electrode tip, electrolytes are needed to complete the electrical circuit. The primary complication associated with electrolyte solutions is fluid overload, and a discrepancy of 1,500 to 2,000 mL during the procedure warrants termination of the procedure.

During operative hysteroscopy with significant operating time and use of large amounts of distension medium, the anesthesiologist should keep intravascular fluid replacement to a minimum to avoid fluid overload. Anesthesia personnel should also monitor the patient carefully for electrolyte abnormalities when using non-electrolyte solutions and anaphylactic shock under anesthesia when using Hyskon.

General Technique

Hysteroscopy can be difficult to perform during the luteal phase because of the abundance of endometrial tissue. Performing hysteroscopy during the early to middle follicular phase should ensure adequate visualization of the uterine cavity. Alternatively, the endometrium can be suppressed with 2 to 4 weeks of progestin therapy, or hysteroscopy may be performed at any time in a patient taking oral contraceptives because of the dominant atrophy effect of progestin. Gonadotropin-releasing hormone (GnRH) analogues have most commonly been used to prepare the endometrium for endometrial ablation. At least 4 weeks of preoperative treatment are required for GnRH analogs such as leuprolide acetate (Depo-Lupron), because these medications are initially agonists and will actually increase estrogen output for the first 7 to 14 days before subsequent down-regulation of the pituitary ovarian axis and subsequent endometrial atrophy.

The cervix should be dilated no larger than the outer diameter of the hysteroscope that will be used. With many of the larger operative hysteroscopes, this will require dilation of the cervix to at least the diameter of a 20-French Hank dilator or a 9/10-French Hegar dilator. Care should be taken to avoid cervical lacerations and uterine perforation during cervical dilation. Preoperative treatment with intravaginal misoprostol can soften the cervix for easier dilation and may prevent cervical lacerations.

With insertion of the hysteroscope, the cervical canal can be visualized and the hysteroscope guided into the endometrial cavity under direct vision. If overdilation of the cervix has occurred and the distension medium cannot be retained within the endometrial cavity, an additional tenaculum may be placed on the posterior lip of the cervix or a special four-pronged tenaculum can be used to compress the cervix around the hysteroscope. The cervical canal and internal os will appear off center within the field of view when using offset-angle lenses. When the angle of the lens is oriented to look downward, the internal os will appear at the 12 o'clock position. If the telescope is inverted and the lens is pointed upward, the os will appear in the 6 o'clock position. The latter position is useful for viewing a retroverted uterus. The surgeon should always maintain the camera position in a straight up-and-down orientation so that the view on the screen corresponds anatomically to the patient's position. As the hysteroscope is rotated to visualize the entire endometrial cavity, one hand should be kept on the camera to prevent its rotation; otherwise, the view on the monitor will be oriented improperly.

With insertion of the hysteroscope, the cervical canal should be visualized and the endometrial cavity entered carefully through the internal os. If adequate visualization is prevented by blood and mucus, continuous flow of the distension medium should be maintained for 30 to 60 seconds to wash out blood and debris. If the field of view still appears red, the hysteroscope should be pulled back 1 to 2 cm, as it is a common mistake to insert the hysteroscope too far, and the lens may be obscured by abutting the uterine fundus. Visualization can also be compromised by inadequate distension of the uterine cavity because of insufficient intrauterine pressure. The fluid delivery devices should be checked to ensure adequate pressure. If a gravity system is being used, the height of the bag above the patient should be extended. Careful adjustment of the outflow should be made to clear any ongoing bleeding and debris without decreasing intrauterine pressure or using extremely large volumes of distension medium.

The entire endometrial cavity should be inspected carefully, including the identification of both tubal ostia, the fundus, and the anterior and posterior portions of the uterine wall. Video documentation of the intraoperative findings is useful. If operative techniques are to be used during the hysteroscopy, inflow and outflow should be measured carefully and reported to the surgeon every 5 to 10 minutes. If significant bleeding or a long operative time is anticipated, vascular constriction through the paracervical injection of a dilute pitressin solution may be used. Care should be taken to avoid intravascular injection of pitressin because reports of fatalities have been reported when that occurs.

Endometrial Ablation

Approximately 35% of gynecologic complaints concern menorrhagia, and it is estimated that 60% of these women ultimately will be treated with hysterectomy. Endometrial ablation originally was developed as an alternative treatment for patients who are medically too unstable for the surgical stress of hysterectomy. Since its original development in the 1980s, however, patient selection criteria have now expanded, and hysteroscopic endometrial ablation is viewed by many as an alternative to hysterectomy, even in healthy patients. Prior to consideration of hysteroscopic endometrial ablation, endometrial pathology needs to be excluded with either a combination of endometrial biopsy to rule out hyperplasia or carcinoma and transvaginal ultrasonography with saline infusion to rule out polyps or submucous myomas. Alternatively, office diagnostic hysteroscopy could be performed with directed biopsies.

Because the goal of an endometrial ablation is destruction of the functional layer of endometrium with the artificial creation of intrauterine synechiae, many experts feel that preoperative preparation of the endometrium with a GnRH agonist or continuous progestin will maximize the chance of adequate scar formation within the endometrial cavity. As an alternative, some authors perform a mechanical preparation of the endometrium by using a sharp curette or suction curettage immediately prior to endometrial ablation. This technique has the advantage of being able to immediately perform the procedure without a lengthy preoperative medical suppression of the endometrium. The

disadvantage of a mechanical preparation, however, is the possibility of inadequate visualization during the procedure because of bleeding and the possibility of a compromised outcome secondary to inadequate destruction of the endometrial basalis.

TABLE 47.1 Global Endometrial Ablation Devices

Device	Method	Cervical Dilation (millimeters)	Cavity Limit (centimeters)	T (m
	Thermal			

ThermaChoice	balloon	5.0	4.0–10.0
Hydro ThermAblator	Circulated hot water	8.0	<10.5
Her Option	Cryotherapy	5.0	<10.0
NovaSure	Radio frequency	8.0	6.0–10.0
MEA	Microwave energy	8.5	6.0–14.0

MEA, microwave endometrial ablation.

Endometrial ablation was originally described with either the Nd:YAG laser or the hysteroscopic resectoscope by using either a wire loop or rollerball technique. The Nd:YAG laser system uses a 600-m bare fiber with power settings of 55 to 70 W. The Nd:YAG laser penetrates 4 to 5 mm into the endometrium, destroying not only the superficial endometrial layers but also the endometrial basalis and superficial myometrium. A touching technique was described originally, dragging the fiber against the endometrium and thus destroying the endometrium and superficial myometrium by vaporization and necrosis. Alternatively, a nontouch technique with the higher power setting has been described in which the fiber is held perpendicular to the endometrium without touching the surface, achieving a deep coagulation effect. Results of the two techniques appear comparable.

Due to the expense of laser ablation, electrosurgical ablation is performed more commonly. Most resectoscopes use monopolar electrodes, necessitating a non-electrolyte low-viscosity medium. Hysteroscopic resection of the endometrium has been described by using a loop electrode to excise strips of endometrium, although the incidence of uterine perforation is reportedly higher with this technique when compared with a rollerball or laser ablation. Most commonly, a rollerball technique is used. With a roller electrode, a blend 1 setting with 70 to 140 W of power is used, depending on the width and thickness of the electrode. This current will allow consistent penetration and destruction of the uterine tissue. Care must be taken to ensure adequate ablation of the uterine cornu and to avoid destruction of the endocervical canal to prevent cervical stenosis.

Extensive studies of the outcome following endometrial ablation have been published. Approximately 80% to 90% of women will have a significant reduction of their menorrhagia and will be satisfied with the outcome, including approximately 25% to 40% of women

experiencing amenorrhea postoperatively.

Complications of endometrial ablation include a 10% hysterectomy rate because of dissatisfaction with the outcome of surgery. In addition to the immediate postoperative complications previously discussed, there also have been reports of isolated endometrial carcinoma in areas of the uterus not adequately ablated and symptomatic hematometra developing in loculated areas of inadequate ablation. Although most women are sterile after this procedure, intrauterine pregnancies can occur, and patients should be counseled to use adequate contraception.

Global endometrial ablation is now widely used, and a variety of devices have been developed (Table 47.1). Compared with resectoscopic techniques, global ablation has shorter operative times and can be used with local anesthesia. Device malfunction is more common with the global devices. Amenorrhea rates are similar to those seen with the resectoscope, and patient satisfaction rates are >95%. The one device that uses a hysteroscope is the Hydro ThermAblator (Boston Scientific, San Diego, CA). A sheath with an outer diameter of 7.8 mm, with two lumens, fits over a 3-mm hysteroscope. Heated fluid circulates under a low pressure of 55 mm Hg, which is a pressure below fallopian tube opening pressure. After 10 minutes at 90°C and a 1-minute cool-down phase, the procedure is complete. One advantage of this system over the other global systems is visualization of the endometrial cavity.

Hysteroscopic Septum Resection

A septate uterus is the most common congenital uterine malformation associated with recurrent reproductive failure and obstetric complications. The appearances of a septate uterus and bicornuate uterus are extremely similar on hysterosalpingogram, and the distinction must be made by demonstrating a normal external fundal contour with a uterine septum as opposed to the presence of two uterine horns in a bicornuate uterus. The uterine septum may be thin or broad and may varying in length, from an exaggerated arcuate appearance to total division of the uterine corpus, possibly including the cervix (Fig. 47.1). Indications for hysteroscopic resection of a uterine septum

include repeated first- or second-trimester losses, a history of premature labor and delivery, and possibly concurrent infertility.

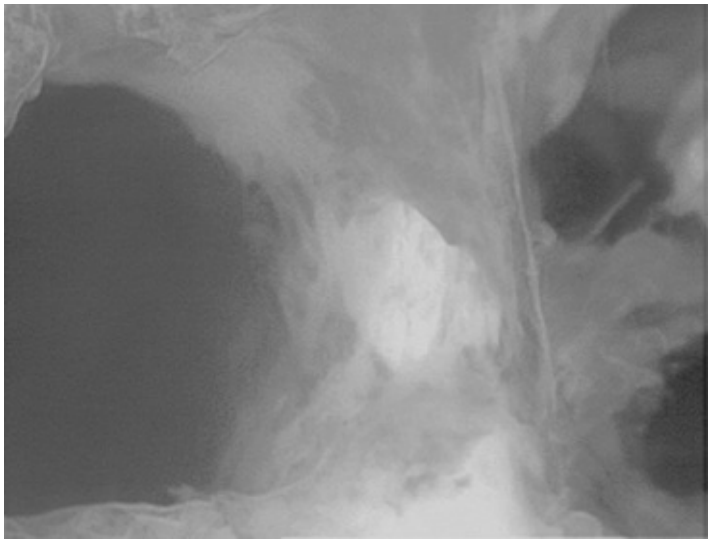

Figure 47.1 Hysteroscopic view of a uterine septum extending down to the lower uterine segment before division.

The hysteroscopic approach to the division of the uterine septum is performed almost exclusively today rather than the transabdominal resection or incision of the septum performed prior to the 1970s. The hysteroscopic approach allows for ambulatory treatment of this disorder, and because the uterine wall has not been incised, cesarean delivery is not indicated postoperatively.

After adequate documentation of the diagnosis of a septate uterus and the exclusion of concurrent causes of pregnancy wastage, the surgery should be scheduled during the early follicular phase to allow adequate visualization of the septum. The use of GnRH analogues or other drugs to induce endometrial suppression may result in the iatrogenic formation of postoperative intrauterine scar formation unless postoperative estrogen replacement is given. Semi-rigid scissors are most commonly used to divide uterine septa (Fig. 47.2). The uterine septum is typically avascular, and cautery is rarely necessary. Under direct visualization, the septum is incised at its midpoint. As the incision is carried toward the fundus, the septal tissue normally retracts anteriorly and posteriorly into the myometrium, and resection of tissue usually is not necessary. When the uterine cavity is symmetric, or when normal myometrial tissue is identified by bleeding, the dissection should stop (Fig. 47.3). It is also useful to perform concurrent laparoscopy to both visualize the normal fundal contour before dividing the septum as well as to guide the direction and extent of the dissection hysteroscopically.

The septum also can be divided with either fiber-optic lasers or cutting loop resectoscopes. The disadvantages of these techniques include additional instrumentation and further complications in the event that uterine perforation occurs. When perforation occurs with hysteroscopic scissors, bleeding is unlikely and damage to surrounding structures is rare. When uterine perforation has occurred while using an electrical cutting loop or laser fiber, the risk of damage to the surrounding bowel is increased. There also is concern that these modalities may damage surrounding normal myometrial and endometrial tissue.

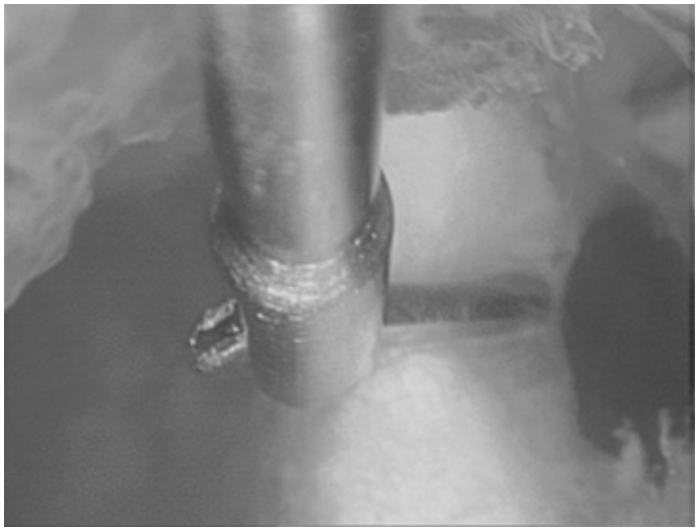

Figure 47.2 The uterine septum is being divided by hysteroscopic rigid scissors.

Although some surgeons routinely administer high-dose estrogen therapy for 30 days postoperatively, randomized studies have shown no benefit when used in normally cycling women. Similarly, an intrauterine splinting device such as a pediatric Foley catheter has been advocated by some authors but usually is not needed because of the rapid re-epithelialization of the endometrial cavity postoperatively.

Normal reproductive outcome following the division of a uterine septum is reported to be between 70% and 85% term delivery rate in patients with prior recurrent spontaneous abortions. Pregnancy outcome is equal with all three methods of septum division.

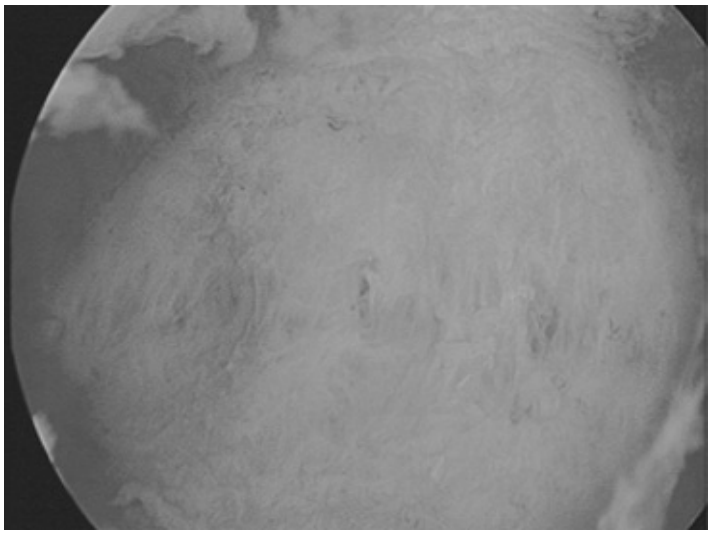

Figure 47.3 The uterine septum has been resected completely, and a contour of the fundus is normal, with normal myometrial tissue visible.

Hysteroscopic Myomectomy

Uterine leiomyomas are the most common benign tumors of the uterus, and submucous and intracavitary myomas are common causes of menorrhagia and abnormal uterine bleeding. Submucous myomas also are associated with recurrent pregnancy loss and infertility. The evaluation of abnormal uterine bleeding and menorrhagia should include either a diagnostic hysteroscopy or a saline infusion sonohysterography to diagnose submucous myomas. Blind procedures such as endometrial biopsy and dilation and curettage will commonly miss these tumors. Most submucous myomas do not have a pedicle but project into the endometrial cavity with a broad base. Myomas that have >50% of their volume projecting into the cavity and are <3 to 4 cm in size can be approached adequately for resection hysteroscopically. It often is useful to pretreat patients with a GnRH analogue prior to a hysteroscopic myomectomy to shrink the myoma as well as to thin the endometrium. If the patient is anemic from menorrhagia, GnRH-agonist pretreatment also will allow her a period of amenorrhea and permit her hemoglobin level to normalize.

The resectoscope with a loop electrode is used commonly to shave the myoma until it is flush with the endometrial cavity. Power settings of 100 to 120 W are used. With unipolar devices, a non-electrolyte solution must to be used as the distension medium. The loop should be advanced past the myoma, and resection of strips of tissue is accomplished by pulling the loop toward the operator (Fig. 47.4). This technique will minimize the risk of uterine perforation. It frequently is necessary to remove the chips of tissue when they become so numerous as to obscure the surgical view. After removal of the resectoscope, the outflow of the medium will remove the chips, or alternatively, a uterine polyp forceps can be used to blindly remove them. Even if all the tissue fragments are not removed, they will be expelled from the uterus with the next menstrual period.

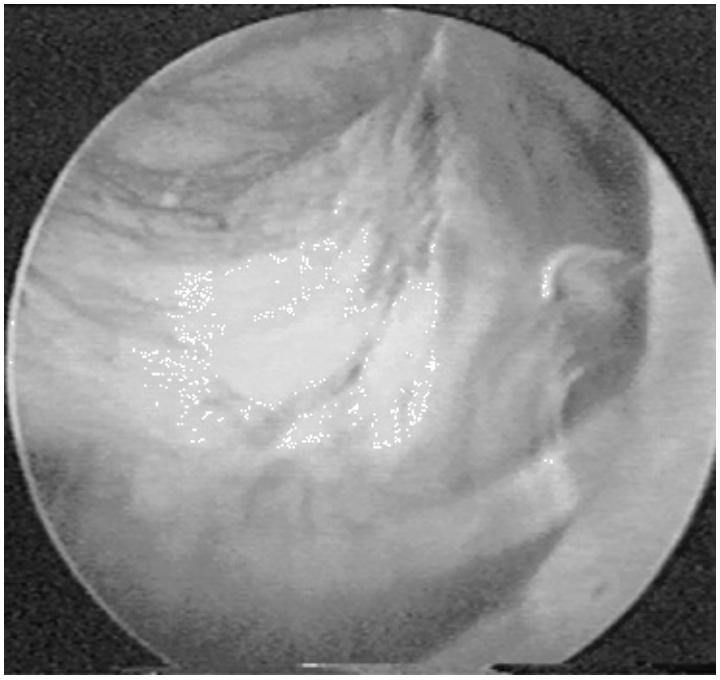

Figure 47.4 A submucous myoma is being resected with a resectoscope loop electrode.

It may be useful to reduce intraoperative bleeding and reduce intravasation of distension medium by injecting a dilute solution of pitressin (20 U per 100 cc of injectable saline) paracervically prior to the endometrial resection to achieve vascular constriction. Care should be taken to avoid intravascular injection of this solution because deaths have been reported. A total of 5 to 10 cc usually is sufficient. Intraoperatively, small bleeding vessels may be coagulated with the loop electrode by using 40 W of coagulation current.

Bipolar systems can be utilized, which cause vaporization of tissue. Because these devices use a bipolar electrode, an electrolyte solution is needed as the distension medium. This system requires its own generator and will not work with other electrical generators such as Valleylab's generator. The advantage of these systems is the prevention of multiple tissue fragment generation as the technique vaporizes tissue. If pathologic diagnosis is desired, the tips can be used to isolate and remove a portion of tissue to be sent to the pathology department.

When performed for menorrhagia, success rates of hysteroscopic myomectomy have been reported in approximately 80% of women. Conception rates have been reported between 43% and 63% following hysteroscopic myomectomy in previously infertile women.

Hysteroscopic Polypectomy

Endometrial polyps are diagnosed in approximately 20% of women with abnormal uterine bleeding. This diagnosis usually requires either direct visualization of the polyp with a diagnostic hysteroscope or the visualization of a polyp by using saline infusion sonohysterography. Hysteroscopically, endometrial polyps generally are more often pedunculated than submucous myomas and have a softer, fleshier appearance without the presence of blood vessels on the surface (Fig. 47.5).

Depending on the size of the endometrial polyp, it may be removed by one of several techniques. With a small pedunculated polyp, grasping the polyp stalk with a hysteroscopic grasper and rotating of the grasper to remove the polyp can be performed easily (Fig. 47.6). With larger polyps or polyps with a larger base, a cutting loop resectoscope should be used. By resecting the base of the polyp with the loop electrode, the polyp subsequently can be removed intact with grasping forceps. If a small portion of the base remains, it can be destroyed with the loop electrode. Care should be taken not to destroy adjacent normal endometrial tissue to prevent postoperative adhesion formation.

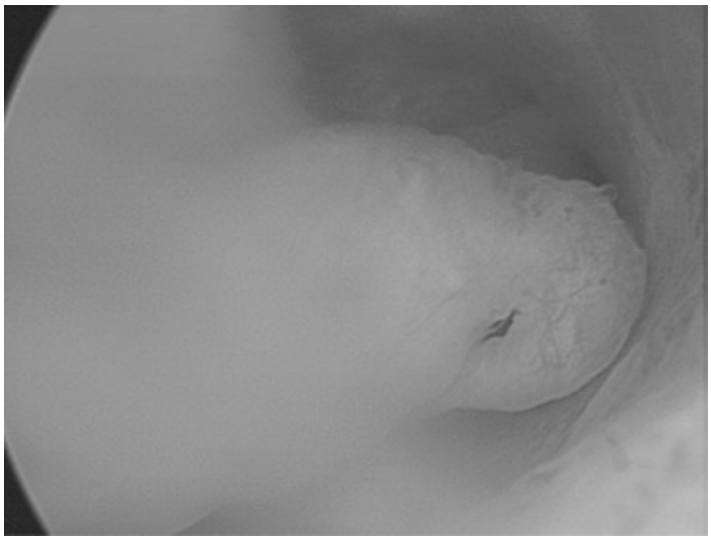

Figure 47.5 An endometrial polyp is seen hysteroscopically as a soft, fleshy growth.

Asherman Syndrome

Intrauterine adhesions or synechiae, known as Asherman syndrome, may develop when opposing endometrial surfaces are damaged and heal as a coalescing adhesion. This typically occurs when inflammation or infection persists after spontaneous first-trimester abortion and when estrogen production is low. Patients who have had late postpartum curettages for retained placental fragments are at high risk for the development of Asherman syndrome (Fig. 47.7). In the postpartum period, estrogens of placental origin are metabolized rapidly and ovarian suppression continues for several weeks. With the absence of estrogen, the endometrium will fail to proliferate and re-epithelialize damaged areas of endometrium following a curettage. Any concurrent inflammation or infection will increase the risk of intrauterine synechiae. Patients who have had elective abortions or postabortal curettages for any reason are also at risk for the development of intrauterine adhesions. The patient with Asherman syndrome may have amenorrhea if the extent of the adhesions is severe, but it more commonly manifests with normal menses or mild hypomenorrhea with recurrent spontaneous abortion or infertility. The diagnosis of Asherman syndrome can be made by hysterosalpingogram, saline infusion sonohysterography, or direct visualization with diagnostic hysteroscopy.

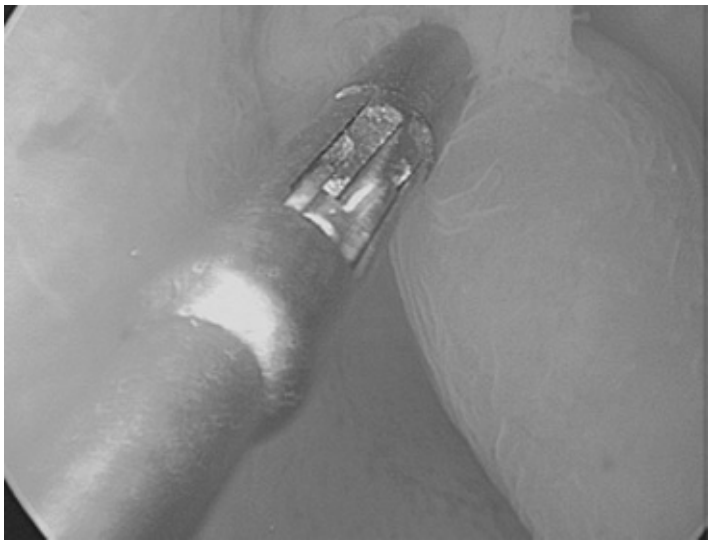

Figure 47.6 A rigid grasper is placed through the hysteroscope to grasp the base of an endometrial polyp for removal.

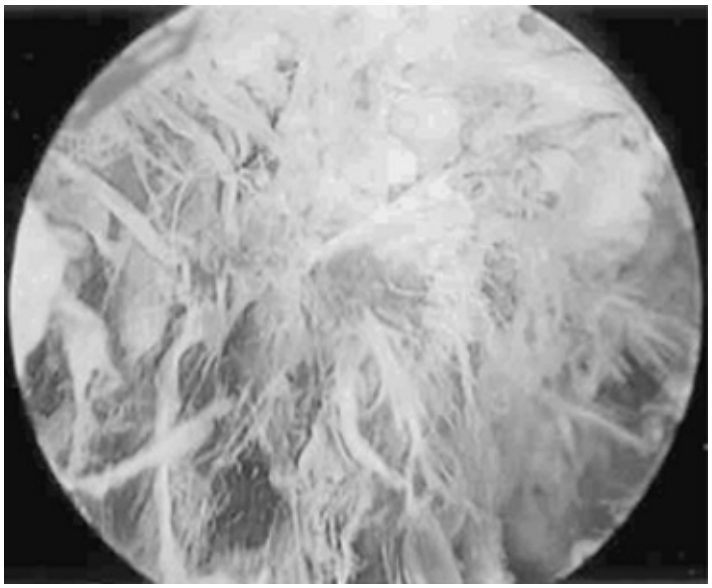

Figure 47.7 The hysteroscopic appearance of a retained placental fragment 1 month postpartum.

Intrauterine adhesions should be lysed with hysteroscopic scissors under direct visualization. This procedure is straightforward with mild to moderate cases of Asherman syndrome but can be very complicated in severe cases with complete obliteration of the endometrial cavity. In difficult cases, concurrent laparoscopy can be useful to guide the hysteroscope. Pockets of normal endometrium are used as guides to the lysis of thick adhesion bands. Both cornu of the uterus ultimately should be visualized, and the uterine contour should be relatively normal at the end of the procedure.

Postoperatively, most practitioners will place patients with Asherman syndrome on high-

dose estrogen replacement using conjugate estrogens such as Premarin 2.5 mg twice daily, or its equivalent, for 30 days to help induce proliferation of any remaining endometrium to re-epithelialize the previous site of adhesions. Stenting of the uterus with a pediatric Foley catheter that is balloon filled with approximately 3 cc of saline for 1 week postoperatively also will prevent the damaged endometrial surfaces from coming immediately into contact with one another. With this foreign body in place, antibiotics should be used to prevent infection.

Proximal Tubal Cannulation

Approximately 20% of tubal occlusion occurs in the intramural portion of the fallopian tube at the uterotubal

junction. Pathologically, proximal occlusion may be caused by debris plugs or fibrosis from inflammation, intraluminal endometriosis, or salpingitis isthmica nodosa. The diagnosis of proximal tubal occlusion often is made by hysterosalpingography. However, a definitive diagnosis cannot be made with this technique because uterine muscle spasm falsely suggesting proximal tubal occlusion may be a consequence of the procedure itself. If pathologic proximal tubal occlusion is suspected, selective injection of contrast medium into the fallopian tubes may be performed either fluoroscopically or via hysteroscopy with concurrent laparoscopy. The latter technique has the advantage of simultaneously inspecting the distal portion of fallopian tube for damage. If the patient has both a proximal and a distal occlusion, the tubes are not candidates for surgical correction, and in vitro fertilization should be recommended. If selective injection of one or both of the fallopian tubes does demonstrate proximal tubal occlusion, then hysteroscopic cannulation of the fallopian tube can be performed immediately.

Hysteroscopically, a flexible guide wire, 0.3 to 0.8 mm in outer diameter, is guided into the uterine cornu. The softness of this guide wire usually allows it to penetrate the occlusion while staying within the tubal lumen. When the guide wire is seen in the proximal portion of the fallopian tube laparoscopically, a soft Teflon catheter of 1.3-mm outer diameter is pressed over the guide wire until this is also within the proximal portion of fallopian tube. The guide wire can then be removed and methylene blue injected through the Teflon catheter to confirm tubal patency.

Approximately 80% of proximal tubal occlusions can be cannulated successfully. Complications include perforation of the guide wire through the proximal portion of fallopian tube, but this rarely results in troublesome bleeding or infection. Intrauterine pregnancy rates have been reported at approximately 30% to 40% following proximal tubal cannulation.

Hysteroscopic Sterilization

The Food and Drug Administration (FDA) has approved the Essure procedure (Conceptus, San Carlos, CA) for hysteroscopic sterilization. This procedure has been used in over 50,000 women worldwide, with only 64 pregnancies being reported over 4 years. Most pregnancies appear to be related to the luteal phase or from failure to assure that the tubes were

successfully occluded prior to stopping additional birth control.

Essure is a disposable delivery system with polyethylene fibers (PET) wound in and around a stainless steel core. An outer coil of nitinol is deployed to anchor the device across the uterotubal junction. Over a period of 3 months, the PET fibers stimulate fibrous tissue ingrowth, which results in tubal occlusion. This is a nonreversible sterilization method, and documentation of tubal occlusion by hysterosalpingogram 3 months after the procedure is required before stopping backup contraception. Bilateral tubal placement rates are reported to be 90%, with a 3% expulsion rate and a 1% tubal perforation rate. This procedure can be performed under local anesthesia in the office and avoids the risks of general anesthesia.

Summary Points

- The development of good hysteroscopy skills is important to gynecologists so that they may use the diagnostic and operative advantages that these techniques offer.
- Careful attention to the surgical technique and particularly the distension medium employed is important in order to perform hysteroscopy safely.
- Diagnostic hysteroscopy is the gold standard for evaluation of the endometrial cavity.
- Operative hysteroscopy offers an outpatient surgical approach to many uterine problems, including submucous and intracavitary leiomyomata, endometrial polyps, intrauterine synechiae, uterine septa, and proximal tubal occlusion.
- Endometrial ablation offers women an alternative to hysterectomy for the management of abnormal uterine bleeding or menorrhagia.

Epidemiology, Pathophysiology, and Evaluation of Pelvic Organ Support

John O. L. DeLancey

Pelvic organ prolapse is a condition that has been known to affect women since the earliest medical records 4,500 years ago. Attempts to correct this condition helped to define the specialty of obstetrics and gynecology. Although it is often discussed as a purely mechanical phenomenon, prolapse is associated with significant functional problems. Stress urinary incontinence, micturition difficulties, and problems with defecation are all associated with prolapse. These functional derangements are not simply results of altered support of the bladder and rectum but have to do with the innervation and musculature of the urinary and intestinal tracts as well. This chapter reviews the structural and functional aspects of prolapse necessary to understand and manage these conditions and describes current clinical evaluation of women who have pelvic organ prolapse.

The Pelvic Floor and the Nature of Genital Prolapse

The pelvis lies at the bottom of the abdominopelvic cavity, and the pelvic floor closes the canal within the bony pelvis (Fig. 48.1). If the body cavity were a box containing the abdominal and pelvic organs, the pelvic floor would form the bottom of the box. It is the structure that carries the load. Its structural role can best be appreciated by considering a surgeon's hand placed through an abdominal incision that pushes caudally on the pelvic organs. All of the elements that prevent this hand from passing through the pelvic canal constitute the pelvic floor. In addition to this supportive role, the pelvic floor must accommodate conception and parturition while also controlling storage and evacuation of urine and feces. To understand the pelvic floor and genital prolapse, it is necessary to understand the mechanical strategies that evolution has put in place to prevent downward descent of the pelvic organs as well as the process by which genital prolapse occurs. As Victory Bonney pointed out, the phenomenon of prolapse is similar to the maneuver that a scrub nurse uses to evert the in-turned finger of a surgical glove (Fig. 48.2). Compressing the air within the glove drives the invaginated finger outward in much the same way that increases in abdominal pressure force the vagina and the uterus to prolapse. It is not the weight of the uterus that is important in the development of prolapse but rather the forces placed on the pelvic floor by increases in abdominal pressure.

Two mechanical principles explain how the pelvic floor prevents prolapse (Fig. 48.2). First, the uterus and vagina are attached to the walls of the pelvis by a series of ligaments and fascial structures that suspend the organs from the pelvic sidewalls. Second, the levator ani muscles constrict the lumina of these organs, forming an occlusive layer

on which the pelvic organs may rest. It is a combination of these two factors—suspension of the genital tract by the ligaments and fasciae and closure of the pelvic floor by the levator ani—that holds the vagina over the levator ani muscles and forms a flap-valve closure. This flap-valve mechanism is instrumental in keeping the posterior cul-de-sac closed and preventing the development of an enterocele. Failure of this mechanism is common in women. The following sections describe how often it occurs, what changes are involved, and how to evaluate women who present with complaints of prolapse.

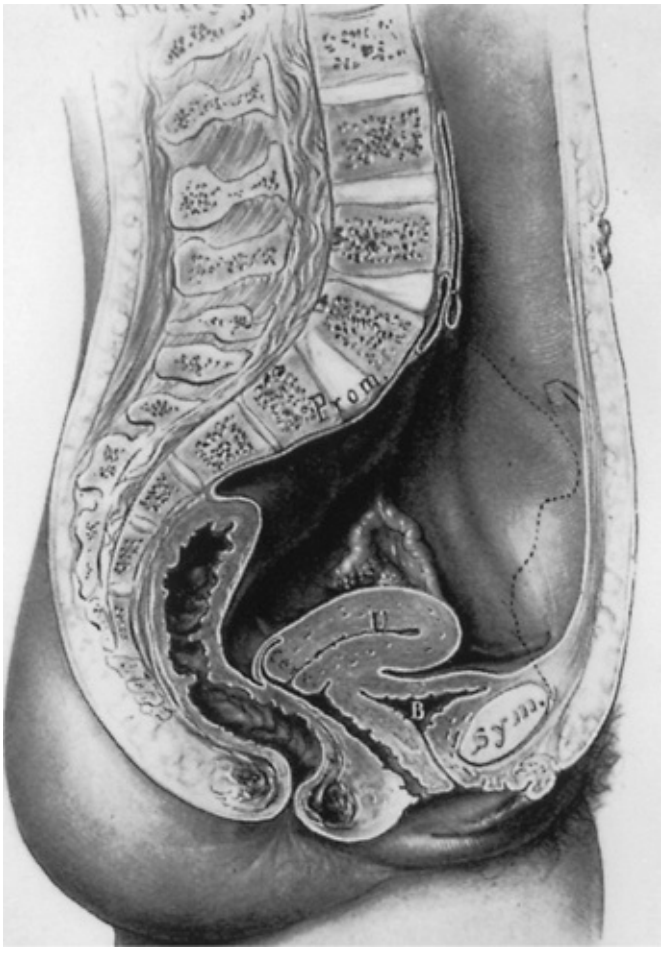

Figure 48.1 Sagittal section of the abdomen and pelvis shows the relation of the pelvic floor to the abdominal cavity. (From Kelly HA. *Gynecology*. Baltimore: Appleton and Co, 1928:64, with permission.)

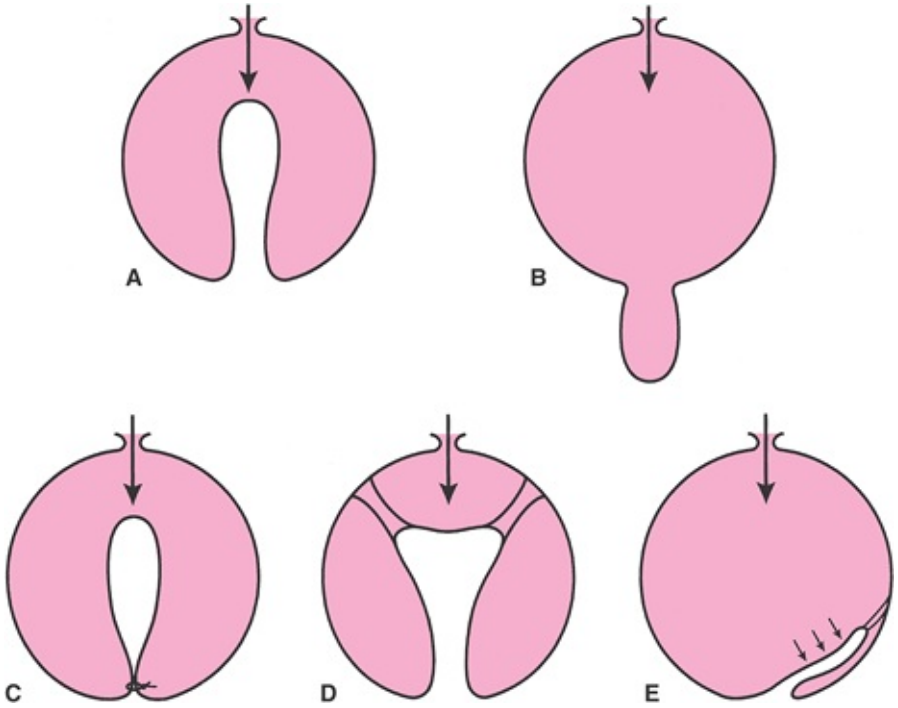

Figure 48.2 A: Diagrammatic representation of the vagina within the abdomen shows how increases in abdominal pressure (*arrow*) force the vagina to prolapse. **B:** This prolapse may be prevented by **(C)** constricting the lower portion of the vagina, **(D)** suspending the vagina from the pelvic walls, and **(E)** forming a flap-valve closure, wherein the vagina is pinned against surrounding structures.

Epidemiology of Surgically Managed Pelvic Organ Prolapse

Prevalence and Age of Occurrence

Pelvic organ prolapse is the pelvic floor disorder that most often requires surgery (Fig. 48.3), followed by surgeries for stress incontinence and fecal incontinence. Based on national hospital discharge data, it is known that approximately 200,000 American women undergo procedures for pelvic organ prolapse, while 80,000 operations per year are done for stress urinary incontinence and approximately 2,000 are for fecal incontinence. In 1997, the National Hospital Discharge Survey information indicated that this is approximately 22.7 operations per 10,000 women. The mean age of these women is in their mid-50s. The annual direct cost of treating pelvic organ prolapse is slightly in excess of $1 billion annually.

The effect of age on pelvic organ prolapse surgery has been studied in health maintenance organization populations. Olsen found that among 149,554 women over the

age of 25 who were members of Kaiser Permanente Northwest Health Maintenance Organization, 384 women had surgical treatment for either pelvic organ prolapse or urinary incontinence or both in 1 year. They documented that a woman's lifetime risk for needing a single operation by age 80 was 11.1%. Among this group of women, there was a great

variety in the types and sizes of prolapse (Table 48.1). Repeat operations were remarkably common occurring in 29.2% of patients.

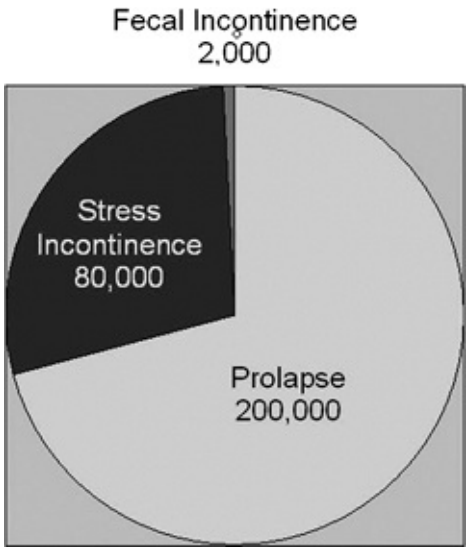

Figure 48.3 Operations for pelvic floor dysfunction.

In contrast to these data concerning surgical procedures required for pelvic floor dysfunction, studies of symptomatic women in the population offer a somewhat different picture. In a study of members of a group health plan (Kaiser Permanente Southern California) where 4,458 women were selected to represent the population, the prevalence of pelvic floor symptoms was as follows: pelvic organ prolapse, 7%; stress urinary incontinence, 15%; overactive bladder, 13%; and anal incontinence (including flatal incontinence), 25%. Overall, 37% of these women had symptoms of pelvic floor disorder. The difference between the number of operations and the occurrence of symptoms relates to the severity of the problem. For example, many women have relatively mild symptoms of stress or fecal incontinence and may not consider it a particular problem and do not seek surgical correction, while more women with symptomatic prolapse have their problem addressed surgically.

TABLE 48.1 Preoperative Prolapse Severity according to Operative Site

	Anterior Compartment (n[%])	Posterior Compartment (n[%])	Apex (n[%])	Worst grade (n[%])
No prolapse	36 (9.4%)	61 (15.9%)	80 (20.8%)	14 (3.6%)

Grade 1	81 (21.1%)	73 (19.0%)	20 (5.2%)	54 (14.1%)
Grade 2	124 (32.3%)	92 (24.0%)	63 (16.4%)	173 (45.1%)
Grade 3	41 (10.7%)	21 (5.5%)	26 (6.8%)	61 (15.9%)
Not assigned	34 (8.9%)	25 (6.5%)	27 (7.0%)	59 (15.4%)
Not documented	68 (17.7%)	112 (29.2%)	168 (43.8%)	23 (6.0%)

TABLE 48.2 Risk Factors for Pelvic Organ Prolapse

Definite
Advancing age
Vaginal delivery
Probable
Heritable issues

- Race or ethnic origin
- Family history of pelvic organ prolapse
- Connective tissue disorders

Obstetric factors associated with difficult birth

- Forceps delivery
- Prolonged second stage of labor
- Infant birth weight >4,500 g

Increased abdominal pressure

- Occupations entailing heavy lifting
- Constipation
- Obesity

Shape or orientation of bony pelvis
Previous hysterectomy
Hypothesized
Young age at first delivery
Pregnancy in the absence of vaginal delivery
Selective estrogen receptor modulators

Because of the increase in pelvic organ prolapse at advancing age, it is expected that the demand for services related to pelvic floor disorders can be expected to double in the next decades, justifying the need for all obstetrician and gynecologists to be experienced in its diagnosis and management.

Risk Factors

There are multiple risk factors for pelvic organ prolapse, defined as being definite, probable, or hypothesized (Table 48.2).

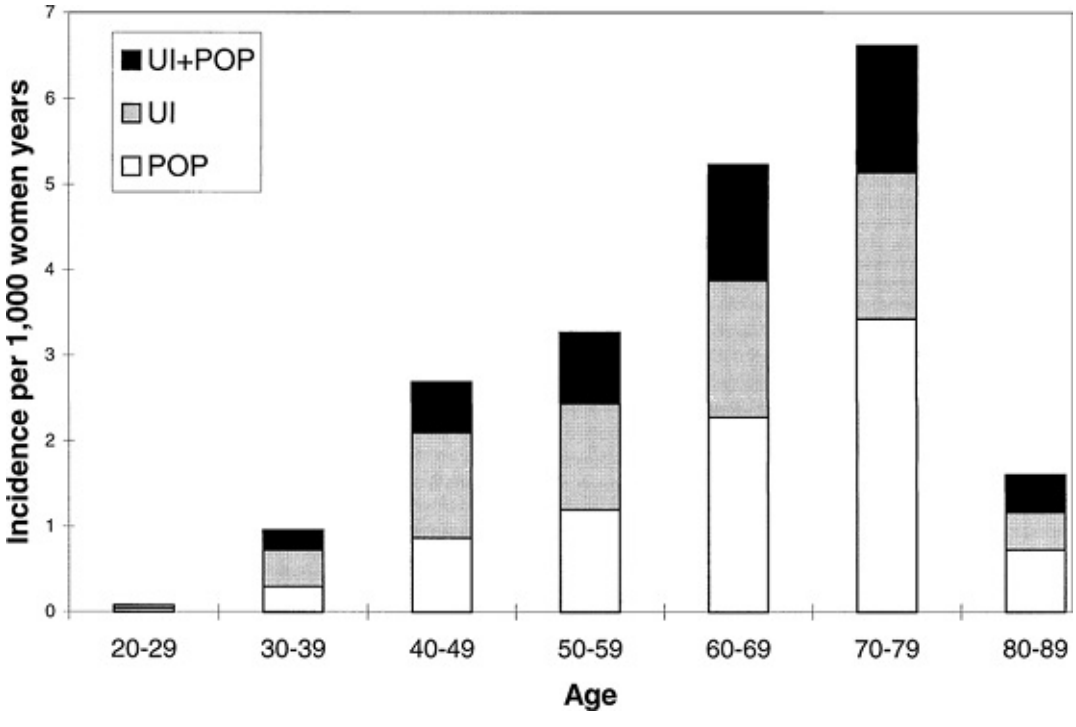

Figure 48.4 Age-specific incidence of surgery for pelvic organ prolapse or urinary incontinence. (*UI*, urinary incontinence; *POP*, pelvic organ prolapse.) (From Olsen AL, Smith VJ, Bergstrom JO, et al. Epidemiology of surgically managed pelvic organ prolapse and urinary incontinence. *Obstet Gynecol* 1997;89:501, with permission.)

Factors Associated with Definite Occurrence

Age

The role of advancing age in the increased occurrence of pelvic organ prolapse is obvious (Fig. 48.4). Although prolapse can occur in young women and women soon after childbirth, the number of women treated for pelvic organ prolapse increases with advancing years. Because the available information comes from counts of surgical procedures performed, there is a decrease in data for very elderly, perhaps because surgery is less likely to be performed in these women who have in increased operative risk.

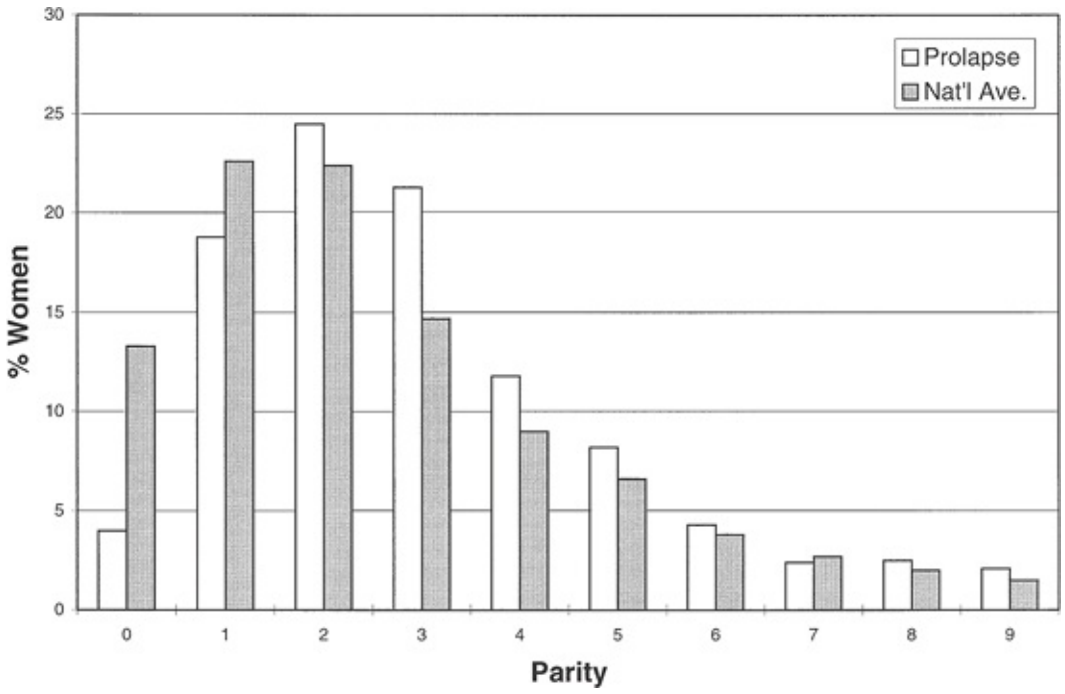

Figure 48.5 Parity information for women who were operated on for pelvic organ prolapse compared with that of the national average. (Nat'l Ave., national average.) (From Timonen S, Nuoranne E, Meyer B. Genital prolapse: etiological factors. *Ann Chir Gynaecol Fenn* 1968;57:363, with permission.)

Vaginal Delivery

Of the pelvic floor disorders, pelvic organ prolapse is the one that is most strongly associated with vaginal delivery. In studying a longitudinally followed cohort of women, the Oxford Family Planning Study reported that there was increasing relative risk for developing prolapse with increasing vaginal parity, as shown in Figure 48.5. Although the likelihood of developing stress incontinence is also related to parity, this association is weaker (relative risk 2.4) than that of prolapse and advanced parity. The strength of this relationship depends to some extent on how one defines

prolapse. This strong association is found for women who require surgery.

Specific features of vaginal birth also influence whether or not a woman develops prolapse later in life. Several factors that can be grouped together as descriptors of “difficult” vaginal delivery are associated with increased occurrence of prolapse: forceps delivery, prolonged second stage of labor, and large infant birth weight have been associated with pelvic organ prolapse. Unfortunately, because of the overlapping nature of these different factors, it is difficult to determine which are causal and which are associated. Forceps delivery is often used when there has been a prolonged second stage of labor, and both of these factors are increased in infants of large size.

The role of childbirth in causing damage to the levator ani muscle, which is both associated with vaginal delivery and with pelvic organ prolapse, is probably the mediating mechanism in these injuries. This will be discussed later in the chapter in somewhat more detail.

Factors Associated Probable Occurrence

Heritable Issues

Although there are incontrovertible data concerning the relationship between advancing age and vaginal delivery in causing pelvic organ prolapse, there are a number of factors that have supportive evidence indicating their relationship to increased risk for developing pelvic organ prolapse but for which data are less well established. For example, some data suggest that race may play a role in modulating the likelihood that a woman may develop prolapse. In the 1997 National Discharge Summary, the surgery rate for whites (19.6 in 10,000) is approximately three times greater than it is for blacks (6.4 in 10,000). Other published data have indicated that Hispanic and Asian women appear to have an increased risk of developing pelvic organ prolapse when compared with white individuals, with modest increased risks of 1.20 among Hispanics and 2.20 in Asian women and decreased risk of 0.63 for black women.

Prolapse seems to also occur more often in some families than others. Women who report that their mother had pelvic organ prolapse have an odds ratio of 3.0 for having prolapse compared with those without a family history, and women with a sister who have prolapse have an odds ratio of 2.4. This is likely related to heritable changes in pelvic floor tissues. There is information that women with prolapse have a decrease in type I collagen and an increase in type 3 collagen compared with women who do not have prolapse. In addition, circumstantial evidence suggests that patients with Marfan syndrome or Ehlers-Danlos syndrome may have an increase in prolapse occurrence. However, the overall number of women with these syndromes who have prolapse is only a tiny fraction of women presenting with this prolapse. Further evidence of genetic factors is emerging from new investigations of elastin homeostasis in knock out mice.

Increased Abdominal Pressure

The structural supports of the pelvic organs are subjected to the forces created by gravity and increases in abdominal pressure. There is evidence that chronic or significant increases in abdominal pressure may be related to increased occurrence of prolapse. Women who have pelvic organ prolapse are more likely to report straining at stool as a young adult than women without prolapse, and women with stage II or greater pelvic organ prolapse are also known to have an increased risk of reporting constipation compared with women who do not have prolapse. Because difficult defecation can be a symptom of prolapse, it is somewhat difficult to prove that it is causal. In addition, women who do more physically stressful occupations have a threefold odds ratio for developing prolapse compared with professional or managerial women.

Hypothesized Factors for Occurrence

Several other factors that increase the risk of prolapse have been suggested, although they are less well established. Obesity, for example, seems to have a modest increase in risk for having prolapse; however, these studies have not had substantial number of patients with clinically evident prolapse (that below the hymeneal ring). Case-control information about women with definite prolapse and definite normal support has not found a difference in body mass index (BMI). There are several authors who have called attention to differences in shape and orientation of the bony pelvis between patients with prolapse and nonprolapse controls. Ironically, these seem to have to do with the upper dimensions of the pelvis, so the biomechanical reason for this is less well known.

There has long been speculation that a previous hysterectomy might alter the chance that women will develop pelvic organ prolapse. In the Oxford Family Planning cohort, women who had previously undergone hysterectomy developed prolapse at a rate of 29 in 1,000 woman-years versus 16 in 1,000 woman-years for the entire cohort. However, the gap between previous hysterectomy and prolapse is quite long, being approximately 20 years, so there must be caution in making implications about the relationship between hysterectomy and prolapse. In addition, prolapse may in some ways be part of an indication for surgery although not listed in a way that retrospective review can discern, thereby potentially confounding these analyses.

A number of other factors such as young age at first delivery, pregnancy in the absence of vaginal delivery, and selective estrogen receptor modulators have also been suggested as potentially influencing prolapse, yet definitive data concerning these issues at the present time validated by independent studies has not been available.

Anatomy and Pathophysiology of the Pelvic Floor

Connective Tissue Supports

Anterior and Apical Anatomy

The topmost layer of the pelvic floor is a combination of the pelvic viscera and their

connections to the pelvic walls and will be referred to as the viscerofascial layer. Although it is common to speak of the fasciae and ligaments as separate from the pelvic organs, unless these fibrous structures have something to attach to (e.g., the pelvic organs), they have no structural integrity of the support unit.

The uterus and vagina are attached to the pelvic walls by the fibrous tissue referred to as the endopelvic fascia. It forms a sheetlike mesentery that is continuous from the uterine artery to the point at which the vagina fuses with the levator ani muscles as it passes through the urogenital hiatus. The parametria are tissues that connect the uterus, and the paracolpium are those that attach to the vagina. Although given regional names, they are one continuous entity. The parametria comprise the cardinal and uterosacral ligaments. These are two different elements of the same tissue (Fig. 48.6). The uterosacral ligaments are the visible and palpable medial margin of the cardinal–uterosacral ligament complex. As is true of the remainder of the parametria, they contain smooth muscle, nerves, and blood vessels and are not the same type of tissue seen in the fascia of the rectus abdominus muscle, which is dense regular connective tissue.

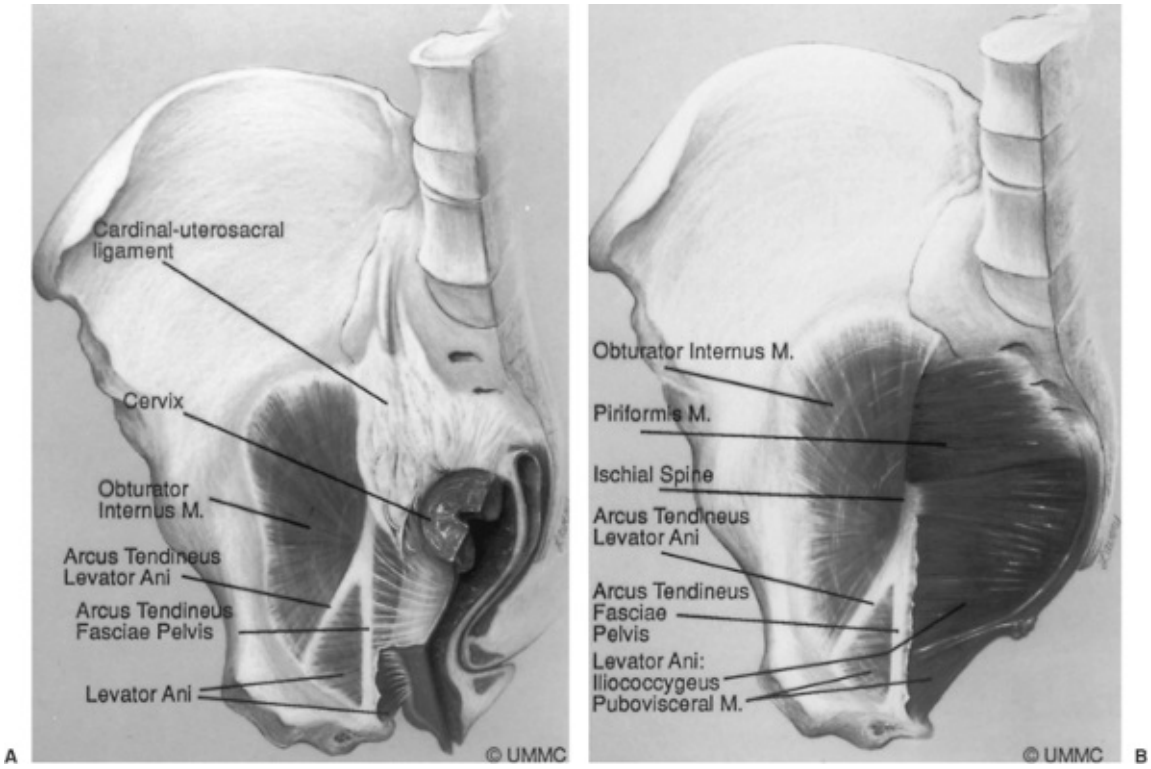

Figure 48.6 Sagittal section of the pelvis shows the support structures of the genital tract. **A:** The bladder, urethra, and uterine corpus (above the cervix) have been removed. **B:** All of the pelvic organs have been removed to show the levator ani muscles. (M., muscle.)

Opposite the external cervical os, the sheet of tissue that attaches the genital tract to the pelvic wall arbitrarily changes name from the parametrium to the paracolpium. The paracolpium has two portions (Fig. 48.7). The upper portion (i.e., level I) consists of a relatively long sheet of tissue that suspends the vagina by attaching it to the pelvic wall in

an area similar to that of the cardinal-uterosacral ligament complex. It is this portion that prevents the upper vagina from prolapsing after the uterus has been removed.

In the midportion of the vagina, the paracolpium attaches the vagina laterally and more directly to the pelvic walls (i.e., level II). This stretches the vagina transversely between these two lateral attachments (Fig. 48.7B). This arrangement has functional significance. The structural layer that supports the bladder (i.e., pubocervical fascia) is composed of the anterior vaginal wall and its attachment through the endopelvic fascia to the pelvic wall. The term *fascia* is used commonly, but this is not a layer separate from the vagina. *Fibromuscular layer of the vagina*, which

contains both smooth muscle and connective tissue, is the term that has been proposed for this layer. These terms are used interchangeably in the remainder of the text because the surgeon generally refers to this layer as fascia. Similarly, the posterior vaginal fibromuscular layer and its connection to the pelvic walls form the restraining layer that prevents the rectum from protruding forward. In the distal vagina (i.e., level III), the vaginal wall is attached directly to surrounding structures without any intervening paracolpium.

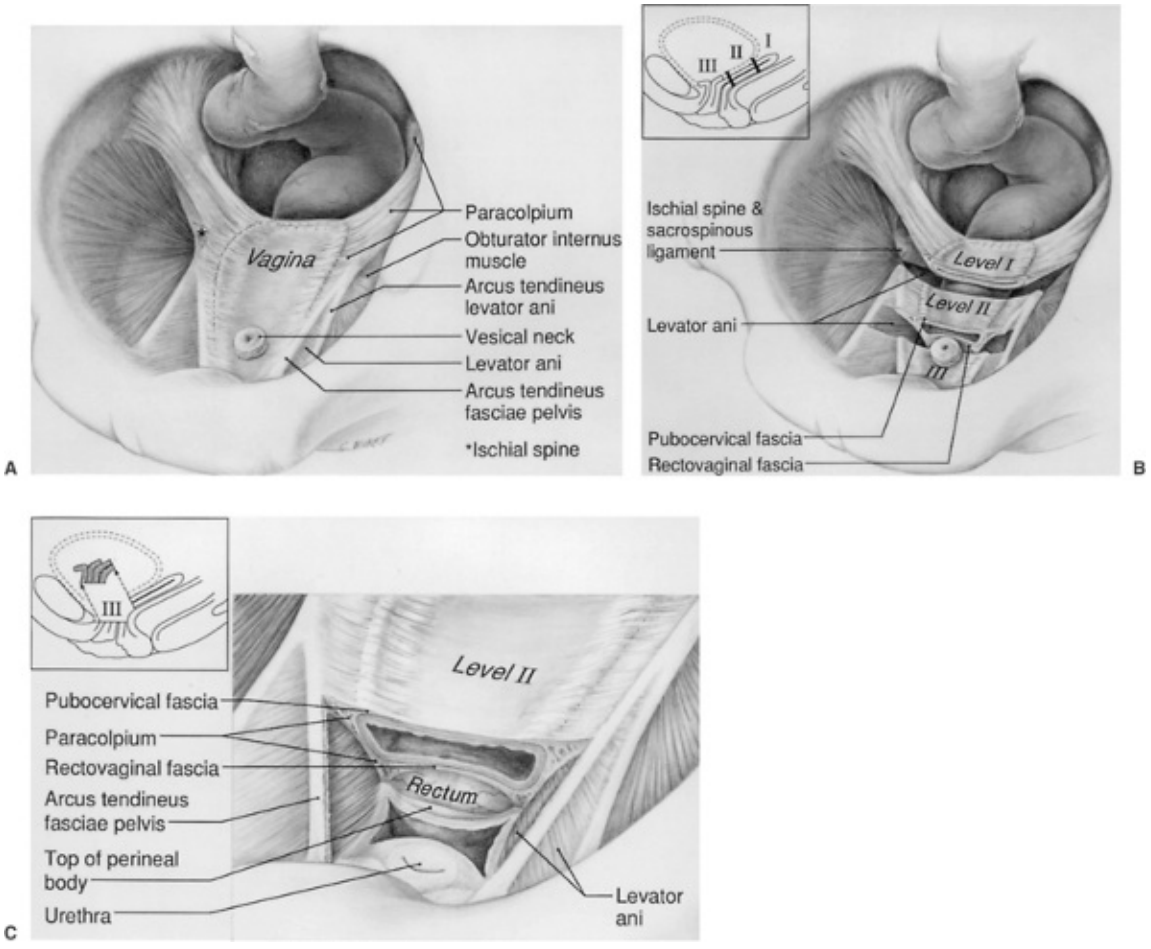

Figure 48.7 Support structures of the vagina after hysterectomy. The bladder has been removed to expose the vagina. **A:** The paracolpium. **B:** The different levels of support structures. **C:** The details of the pubocervical and rectovaginal fasciae after a wedge of vagina and urethra has been removed **(inset)**. (From DeLancey JOL. Anatomic

aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol* 1992;166:1717, with permission.)

The support that lies under the urethra has special importance for urinary incontinence. The endopelvic fascia in this region is better developed and is tougher than the tissues of the upper vagina in the area under the bladder. This provides better support for the vesical neck than for the bladder. This layer of suburethral endopelvic fascia attaches laterally to the arcus tendineus fasciae pelvis and also to the medial border of the levator ani muscles. Loss of this normal support of the urethra at the vesical neck is responsible for stress incontinence of urine.

Mechanism of Anterior/Apical Support

Structural support of the upper vaginal wall and uterus is intimately related. Loss of anterior vaginal wall support and uterine descent typically are part of the same process. This can be seen in the strong correlation between the degree of anterior vaginal wall/bladder descent (cystocele) and the degree of apical descent present in women. An understanding of the structural mechanics of that interaction

can be seen in Figure 48.8. From a conceptual standpoint, the bladder can be considered to rest on a trapezoidal-shaped region of the anterior vaginal wall, as seen in the diagram. The lateral margins of this trapezoid lie at the arcus tendineus fascia pelvis, with the top held in place by the apical supports and the bottom attached at the pubic bones.

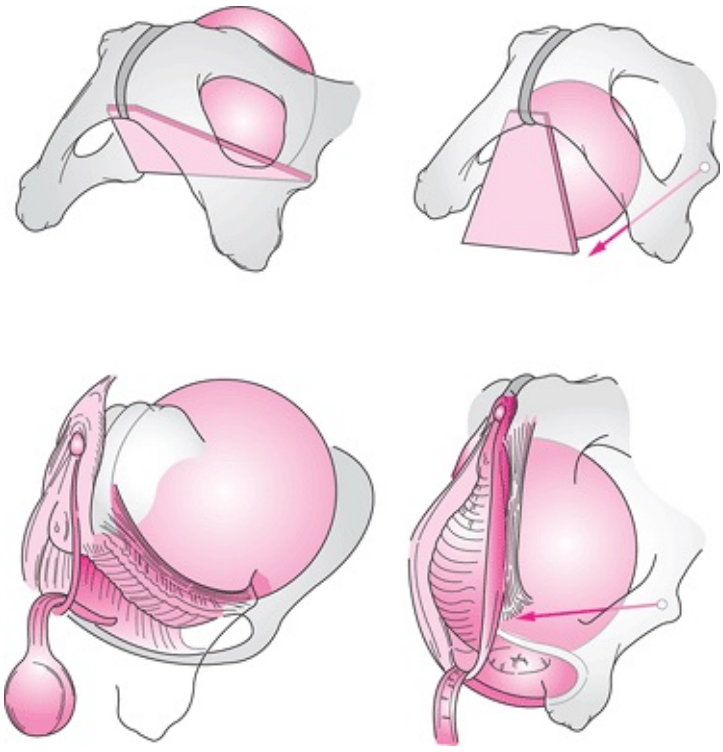

Figure 48.8 Conceptual diagram showing the mechanical effect of detachment of the arcus tendineus fascia pelvis from the ischial spine. **Top:** The trapezoidal plane of the

pubocervical fascia. The attachments to the pubis and the ischial spines are intact **(left)**. The connection to the spine has been lost, allowing the fascial plane to swing downward **(right)**. **Bottom:** The anterior vaginal wall as would be seen with a weighted speculum in place. Normal anterior vaginal wall support **(left)**. The effect of dorsal detachment of the arcus from the ischial spine **(right)**. (Copyright © DeLancey.)

With loss of apical support, this supportive layer rotates downward with prolapse of the bladder. This leads to a separation between the sidewall structures at the arcus tendineus and the edge of the pubocervical fascia in what has been referred to as a paravaginal defect. At present, it is not known whether this process directly involves detachment from the ischial spine or failure of the cardinal uterosacral complex or both.

Data indicating the strength of this relationship is presented in Figure 48.9A. They represent measurements taken from magnetic resonance imaging (MRI) scans made at maximal Valsalva. The most dependent point of the bladder and the location of the uterine cervix were marked in women with varying degrees of pelvic organ support, ranging from normal support to prolapse. The correlation between bladder descent and descent of the cervix is strong, with half of the variation in bladder descent being explained by descent of the apex. Increased anterior vaginal length is responsible for an additional 30% of cystocele size with other less well-understood factors responsible for the remaining contribution to anterior wall descent.

Posterior Support Anatomy

The anatomical structures involved in posterior vaginal wall support are shown in Figure 48.10. The upper portion of the posterior vaginal wall is suspended by the dorsal component of the cardinal–uterosacral ligament complex. The posterior arcus tendineus fascia pelvis can be seen to extend from this upper margin to the perineal body below. It is the connective tissue at the lateral vaginal wall and is not a separate structure from the vagina itself. Distally, the vagina and arcus fuse with structures of the perineal body.

The perineal body unites the perineal membrane from one side of the pelvis with the other side (Fig. 48.11). It is the connection of the two perineal membranes in the midline that provides structural continuity to this supportive apparatus. As long as the connection is intact, it can resist downward descent of the perineum. If this connection is broken (Fig. 48.11B), then this structural continuity is lost. The anal sphincter complex closes the rectum.

Figure 48.12 shows a simplified version of the structural mechanics of this region. Although it does not capture all of the intricacies of this support system, it provides a useful depiction of the major elements in posterior vaginal wall support. In panel A, the borders of the posterior compartment are shown with the perineal body and anal sphincter at the bottom, the levator plate formed by the decussation of the levator muscles in the midline dorsally, and the posterior vaginal wall on the ventral side. The levator muscles are responsible for holding the posterior compartment in the normal location where the posterior vaginal wall is held against the anterior wall (panel C). In panel B, it can be seen

what happens when the levators do not adequately close the pelvic floor. In this instance, high pressures within the rectum are not counterbalanced by contact with the anterior vaginal wall, and the connective tissue supports must come into play in order to resist this downward descent.

Pathophysiology of Posterior Compartment Problems

The clinical implications of the mentioned anatomical relationships can be understood by considering the different elements of posterior vaginal wall support. The posterior wall above the perineal membrane may be considered to have the form of a square ship sail that is held above and below (Fig. 48.12B). The upward forces provided by the apical supports of the posterior vaginal wall suspend it and hold it over the levator plate formed by the dorsal decussation of the levator ani muscles behind the rectum. Distally, the posterior wall is attached to the cranial margin of the perineal body. The perineal body gains its structural support laterally from attachments to the ischiopubic rami through the perineal membrane. It is the connection of the two perineal membranes by the midline tissue of the

---

perineal body that establishes the structural integrity of this complex. If this connection is lost, as seen in Figure 48.11, then downward descent of the rectum can occur. Failure of the levators to hold the pelvic floor closed is also a critical element of this support system.

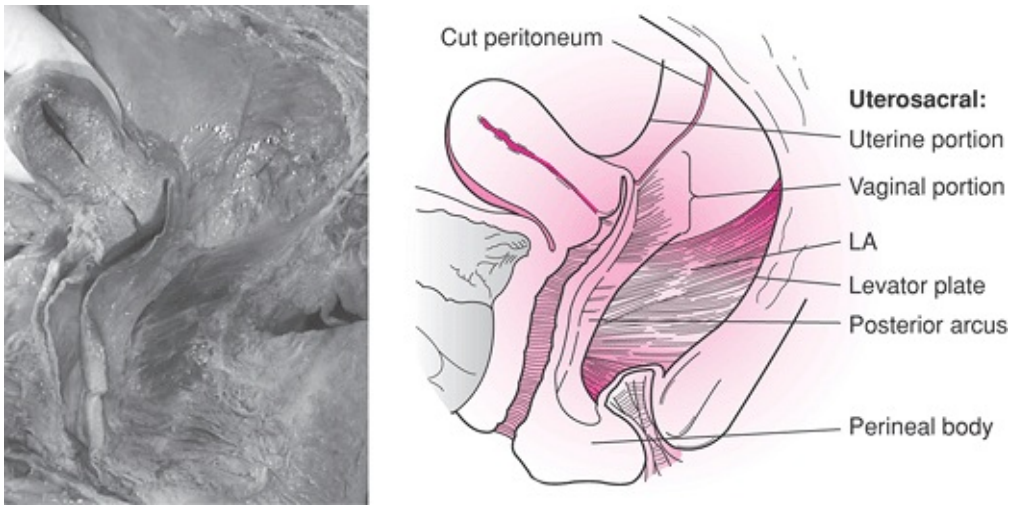

Figure 48.10 Dissection and illustration of posterior compartment anatomy seen in midline sagittal section of a cadaver with normal pelvic organ support from a 56-year-old multipara, showing structural relationships after the rectum has been removed. Note apical connections of the upper posterior vaginal wall to the inside of the pelvic wall in a retroperitoneal position. These lie below the peritoneum and are dorsal and caudal to what is traditionally referred to as the uterosacral ligament. These structures are continuous with the posterior arcus tendineus. At the distal end of the vagina, the vaginal wall merges into the top of the perineal body. The lateral and dorsal margins of the compartment are formed by the levator ani muscles *(LA)* and the levator plate. The asterisk *(*)* denotes the region of the sacrospinous ligament overlain by the coccygeus muscle. (Copyright © DeLancey.)

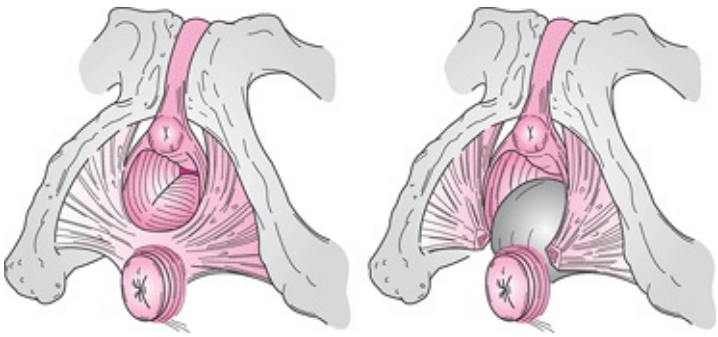

Figure 48.11 Intact perineal body *(*)* uniting the perineal membranes *(PM)* **(left)** and perineal body disruption **(right)**.

Loss of connection between the two sides results in the formation of a rectocele low in the vagina at the level of the perineal body. Failure of the upper supports is associated with enterocele and high rectocele. When the apical failure is most severe, vaginal vault eversion occurs.

Levator Ani Muscles

For many years, damage to the levator ani muscle has been suggested as a causal factor in development of pelvic organ prolapse. Recent data in a case-control study shows that women with prolapse have major defects in their levator ani muscles much more frequently than do women who have normal support. The tonic and constantly modulated contraction of the levator ani muscles supports the pelvic organs. By closing the pelvic floor, they protect the connective tissues from excessive force that would lead to their failure. It is this load-sharing relationship between the connective tissue supports and the levator ani muscles that is disturbed in women who develop prolapse.

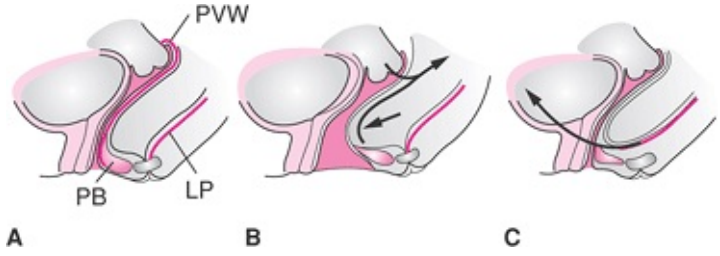

Figure 48.12 A: Normal borders of the posterior compartment including the posterior vaginal wall *(PVW)*, the perineal body *(PB)*, and the levator plate *(LP)*. **B:** Under load, the posterior wall apical suspension (*arrow*) resists downward displacement of the posterior vaginal wall and its attachment of the perineal body. **C:** Action of the levator ani to keep the genital hiatus closed, in which state the posterior wall is in contact with the anterior wall (note that this is not the case in **B**), preventing posterior wall prolapse. (Copyright © DeLancey.)

The levator ani muscles lie below the pelvic organs (Fig. 48.6B). They span the opening within the bony pelvis,

providing a “floor” to support the abdominal and pelvic organs. They have two major divisions: a medial pubovisceral and puborectal component and a lateral iliococcygeal portion.

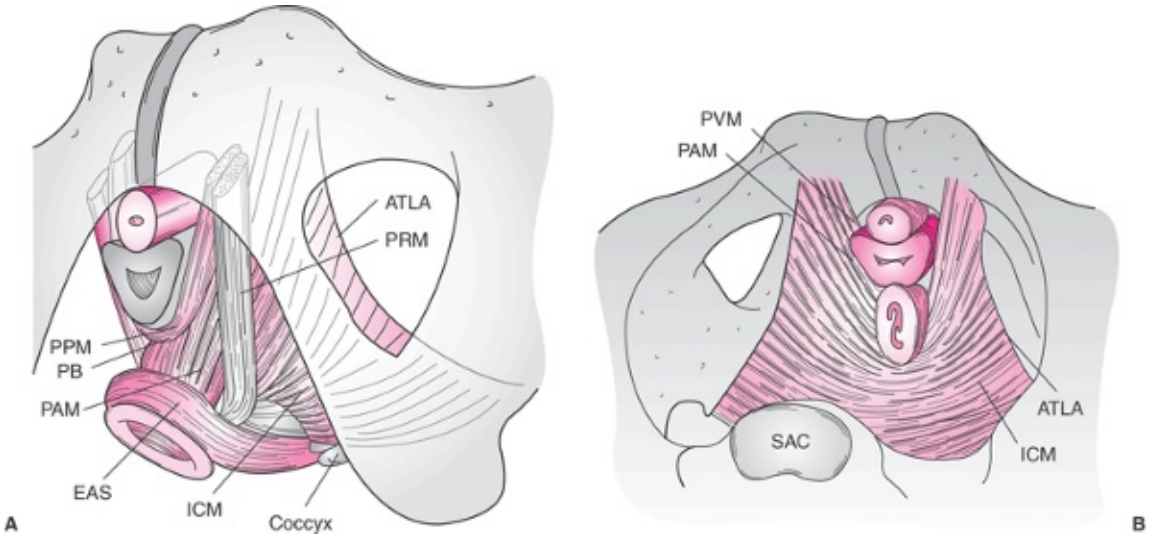

Figure 48.13 A: Schematic view of the levator ani muscles from below after the vulvar structures and perineal membrane have been removed, showing the arcus tendineus levator ani *(ATLA)*, external anal sphincter *(EAS)*, puboanal muscle *(PAM)*, perineal body *(PB)* uniting the two ends of the puboperineal muscle *(PPM)*, iliococcygeal muscle *(ICM)*, and puborectal muscle *(PRM)*. Note that the urethra and vagina have been transected just above the hymenal ring. © DeLancey.) **B:** The levator ani muscle seen from above looking over the sacral promontory *(SAC)*, showing the pubovaginal muscle *(PVM)*. (*PAM*, puboanal muscle; *ATLA*, arcus tendineus levator ani; *ICM*, iliococcygeal muscle.) (Copyright © DeLancey.)

The medial portion of the levator ani muscles originates from the pubic bones and attaches to the vagina, perineal body, and rectum, with only a few insignificant fibers ending in the coccyx (Fig. 48.13). Therefore, the term *pubovisceral muscle* has replaced the former term *pubococcygeal muscle*. This strong, robust, fatigue-resistant striated muscle starts on the inner surface of the pubic bone and has fibers that attach to near the midline and passes behind the rectum, to return to the pubic bone on the other side. It attaches to the vagina (pubovaginal) and perineal body (puboperineal) and sends fibers toward the anus (puboanal). The normal resting tone of this muscle squeezes the rectum, vagina, and urethra closed by compressing them against the pubic bone. The puborectalis muscle originates lateral to the pubovisceral muscle and forms a sling behind the rectum at the anorectal angle. Arising from the lateral pelvic walls (at the tendineus arch of the levator ani muscles) is the iliococcygeal muscle that forms a horizontal shelf on which the upper pelvic organs rest.

Levator Ani Muscle Damage and Pelvic Organ Prolapse

Recent studies have proven the long hypothesized link between levator ani muscle impairment and pelvic organ prolapse. The advent of modern imaging has permitted the detailed structure of the levator ani muscle to be seen in women with pelvic organ

prolapse and in normal asymptomatic controls. The degree of damage visible varies from one woman to the next and so different degrees of damage have been studied and related to the occurrence of prolapse (Fig. 48.14). Defects were classified as none, with no visible defect; minor, with less than half of the muscle damaged; and major, with more than half of the muscle damaged. In a case-control study that compared asymptomatic healthy volunteers with age- and race-matched controls, women with prolapse had major defects more often than control women (Fig. 48.15). Major defects occurred in 55.0% of women with prolapse but in only 15.6% of asymptomatic controls; an odds ratio of 7.3.

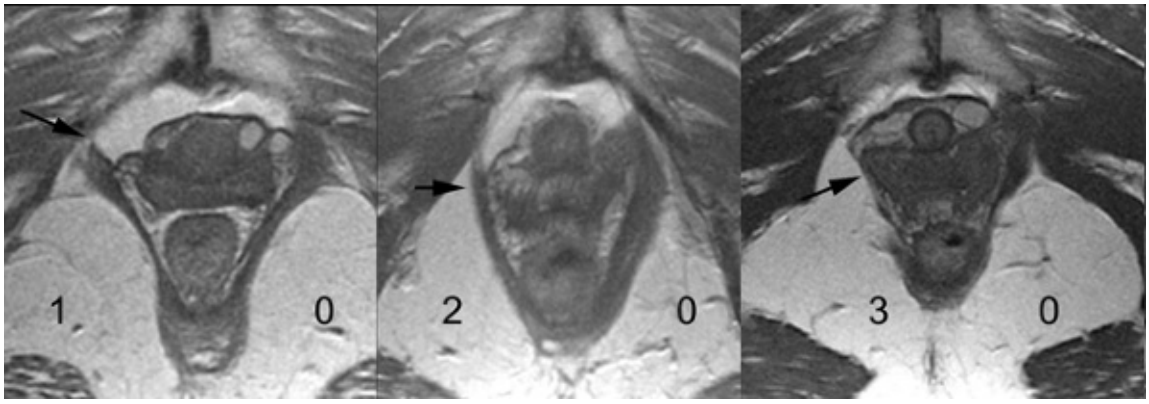

Figure 48.14 Examples of different grades of the pubovisceral portion of the levator ani muscle defects. Subjects with unilateral defects are chosen to contrast different defect severity with normal muscle showing grade 1, 2, and 3 defects contrasted with normal muscle (0) on the contralateral side.

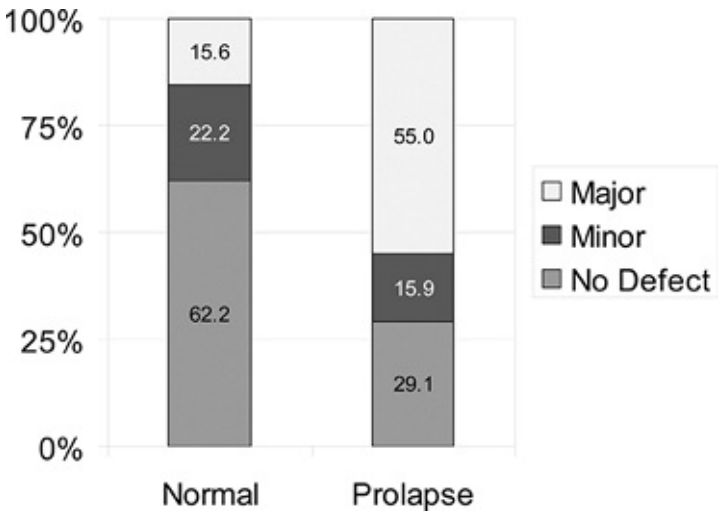

Figure 48.15 Percentages of cases and controls with no defects, minor defects, and major defects; P _.001. (DeLancey JOL. Levator ani impairment in prolapse. *Obstet Gynecol* 2007.)

Muscle function can be assessed by measuring vaginal closure force. This parameter assesses the forces created by the pelvic floor muscle and connective tissue that maintain vaginal closure. It can be studied at rest, reflecting tonic muscle activity plus connective tissue elastic forces and during a maximal contraction that assesses the increased force a woman can generate by voluntary contraction. Figure 48.16 shows data from a case-control study demonstrating that women with defects had approximately 40% less force during maximal contraction compared with women who had no defect in both the prolapse and the normal support groups. The women with prolapse had a 40% lower maximum contraction force for each defect level than the normal women.

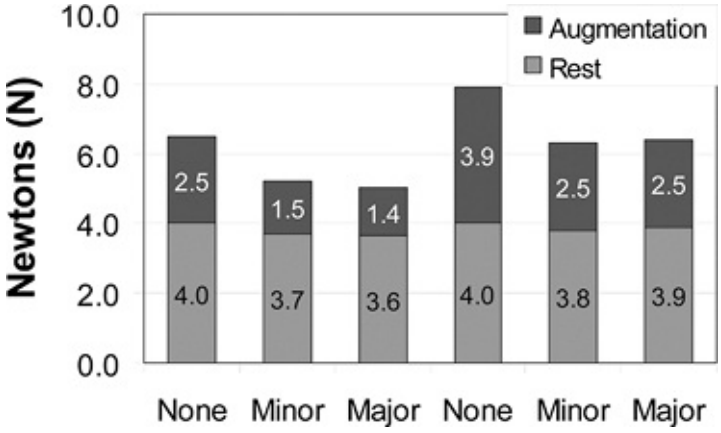

Figure 48.16 Vaginal closure force and augmentation of vaginal closure force with maximum pelvic floor muscle contraction stratified by cases and controls and by levator ani muscle defect status. Means are shown in the columns, and standard error bars are shown. Resting vaginal closure force did not differ by case and control cohorts or by levator ani defect status. (DeLancey JOL. Levator ani impairment in prolapse. *Obstet Gynecol* 2007.)

Levator Ani Muscle Damage during Birth

Injury from Vaginal Birth

Vaginal birth is a primary source of levator ani muscle impairment. Approximately 10% to 15% of women who deliver vaginally will develop a visible defect in the levator ani muscle, with 90% occurring in the pubovisceral portion of the levator ani muscle. Women who have new stress incontinence after their first birth are twice as likely to have sustained this type of injury. These injuries are visible in both MRI and ultrasound. Compared with women who did not develop a defect, women who did develop a defect were, on average, 3 years older and had second-stage lengths that were more than an hour longer. Increased odds ratios were found for forceps (14.7), anal sphincter rupture (8.1), and episiotomy (3.1). Vacuum, oxytocin, and epidural use did not differ between the groups.

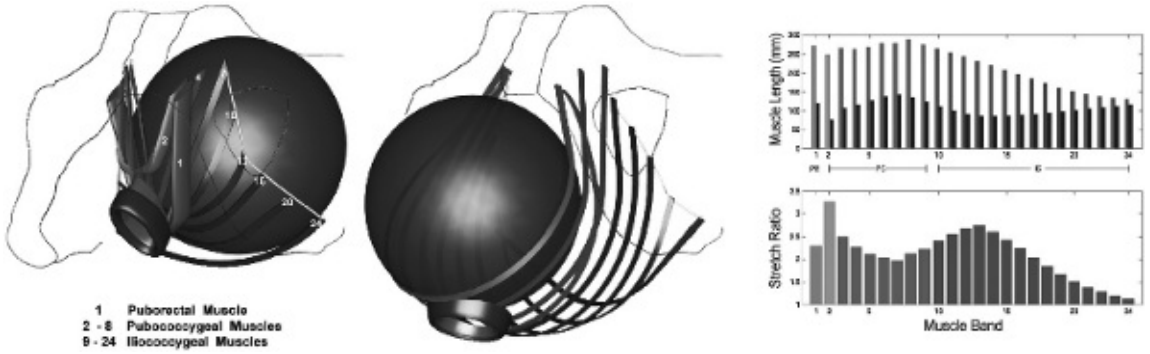

Figure 48.17 Bowling-ball model. **Left:** Computer model of selected levator ani muscle bands before birth, with muscle fibers numbered and the muscle groups identified. **Middle:** Muscle band lengthening present at the end of the second stage of labor. **Right:** Graphic representation of the original and final muscle **(top)** and the stretch ratio **(bottom)**, indicating the degree to which each muscle band must lengthen to accommodate a normal sized fetal head. Note that the pubococcygeal muscle fascicles labeled *PC2* undergo the greatest degree of stretch and would be the most vulnerable to stretch-induced injury. (From Lien KC, Mooney B, DeLancey JO, et al. Levator ani muscle stretch induced by simulated vaginal birth. *Obstet Gynecol* 2004;103:31–40. Copyright © Biomechanics Research Laboratory 2005.) (See Color Plate)

Mechanisms of Levator Ani Muscle Injury

Recent computer models have suggested that some muscle damage during the second stage of labor may come from overstretching, because those parts of the muscle that are stretched the most are those parts that are seen to be injured. Using a computer model of the levator ani muscle based on anatomy from a normal woman, the degree to which individual muscle bands are stretched could be studied (Fig. 48.17). This analysis revealed that the muscle injured most often, the pubovisceral (pubococcygeal) portion, was the portion of the muscle that underwent the greatest degree of stretch; the second area of observed injury, the iliococcygeal muscle, was the second-most stretched muscle. Furthermore, when the portion of the muscle at risk was identified in cross sections cut in the same orientation as axial MRI scans, the pattern of predicted injury matched the injury seen in MRI (Fig. 48.17).

There have also been several studies based on electrodiagnostic techniques, demonstrating that birth causes changes in mean motor unit duration after vaginal birth as well as changes in pudendal terminal motor latency. Abnormal tests have been seen in women with both prolapse and stress incontinence. Although the pudendal nerve innervates the voluntary urethral and anal sphincters, it does not innervate the levator ani muscles, which receive their own nerve supply from the sacral plexus. At present, it is not clear whether the visible levator defects are from neurologic or stretch injury.

Clinical Implications of Levator Ani Muscle Injury

Interaction between the Muscles and Fasciae

The interaction between the pelvic floor muscles and ligaments is critical to proper function. As long as the pelvic floor musculature functions normally, the pelvic floor is closed and the ligaments and fasciae are under no tension. The levator ani closes the vagina by creating a high-pressure zone similar to the high-pressure zones created by the urethral and anal sphincter muscles. The muscles and ligaments must resist the downward force applied on the pelvic floor by the superincumbent abdominal organs as well as the forces that arise from increases in abdominal pressure during cough and sneeze or from inertial loads placed on them (e.g., when landing from a jump). Although the ligaments can sustain these loads for short periods, if the pelvic floor muscles do not close the pelvic floor, then it is more likely that the connective tissue will become damaged and eventually fail to hold the vagina in place.

This normal-load sharing between the adaptive action of the muscles and the energy-efficient action of static connective tissues is part of the elegant load-bearing design of the pelvic floor. When injury to one of these two components occurs, the other must carry the increased demands placed on it. When the muscle is injured, the connective tissue is subjected to increased load. If this load exceeds the strength of the pelvic tissues, they may be stretched or broken and prolapse may result. This forms a causal chain of events by which pelvic muscle injury may influence pelvic organ prolapse or urinary incontinence. In addition, there is accumulating evidence that women who are operated on for pelvic organ prolapse or urinary incontinence have higher postoperative failure rates if they have levator ani muscle impairment assessed by biopsy or muscle function testing than do women who have normal muscles.

Nerves

Anatomy

There are two main nerves that supply the pelvic floor relative to pelvic organ prolapse. One is the pudendal nerve that supplies the urethral and anal sphincters and perineal muscles, and the other is the nerve to the levator ani that innervates the major musculature supporting the pelvic floor. These are distinct nerves with differing origins, courses, and insertions. The nerve to the levator originates from S3 to S5 foramina, runs inside of the pelvis on the cranial surface of the levator ani muscle, and provides the innervation to all the subdivisions of the muscle (Fig. 48.13). The pudendal nerve originates from S2 to S4 foramina and runs through the Alcock canal, which is caudal to the levator ani muscles. The pudendal nerve has three branches: the clitoral, perineal, and inferior hemorrhoidal that innervate the clitoris; the perineal musculature and inner perineal skin; and the external anal sphincter, respectively.

Neural Injury and Pelvic Floor Dysfunction

A unifying neurogenic hypothesis has been well established as a contributor to pelvic floor dysfunction. Although there is a significant body of literature regarding neurogenic causes of fecal and urinary incontinence, there is comparatively little exploring the relation between nerve damage and prolapse. Prospective study of perineal descent on defecography and pudendal nerve terminal motor latency failed to show any relationship between pudendal nerve damage and increased degree of perineal descent. Two studies where prolapse patients were included did not show a difference in the pudendal nerve terminal motor latencies in patients with prolapse. However, electromyographical studies of women with pelvic floor dysfunction, including prolapse and incontinence, found changes consistent with motor unit loss or failure of central activation. This is an active field of research, and there are likely to be more insights into the important role of nerve injury in the coming years.

Diagnosis and Classification

Determining the type and severity of prolapse in any given patient is a skill that should be acquired through practice and careful observation. Characterizing the degree of support loss as normal or abnormal depends on comparisons with the findings in normal multiparous women in the examiner's experience. Therefore, it is helpful to perform the same examination on a sufficient number of asymptomatic patients without prolapse to become familiar with the range of normal support. In performing an examination to determine the type and severity of prolapse, the practitioner has two important points to consider:

- Examination must be made with the patient straining forcefully enough that the prolapse is at its greatest.
- The examiner must examine each element of support independently.

If a patient is not able to strain sufficiently in the lithotomy position so that the prolapse is at its largest, examination in the standing position may be necessary. This is a critical point, because it is only when the prolapse can be seen in its fullest extent that all of its various elements can be assessed. For example, a large cystocele may be seen initially when the patient strains. It may be only with continued effort by the patient that an enterocele and prolapse of the vaginal apex can be demonstrated. To make sure that all aspects of the prolapse can be evaluated, the patient should be asked how large her prolapse is at its largest, and the physician should persist in the examination until that size is achieved. Once the prolapse is visible, the elements of the vagina and pelvic organs that have prolapsed can be evaluated.

Once the prolapse is maximally developed, the physician should begin by identifying how much the anterior wall, cervix, and posterior wall have prolapsed. The

anterior and posterior walls should be examined separately by retracting the opposite wall with the posterior half of a vaginal speculum. A stepwise, site-specific examination is important, because a large cystocele, for example, may hold a potential rectocele in place and therefore hide it. If a rectocele is not recognized preoperatively, its repair may be overlooked and the defect can become symptomatic postoperatively. These observations

have been confirmed on dynamic colpoproctography imaging studies of the pelvic floor, with contrast placed in the bladder and rectum while the patient strains in the standing position. If the patient has a full bladder when imaging is performed, a rectocele can be obstructed and will not be evident until the patient empties her bladder.

Care must also be taken to assess how much of the loss of support is from a defect of the apical (level I) support. It is not uncommon to correct the apical defects and find that much of what was considered a cystocele and rectocele has been corrected. Examination while under anesthesia is used to evaluate pelvic masses, but it is not the optimal time to identify defects caused by prolapse because of the patient's inability to perform the Valsalva maneuver and because of loss of normal levator tone.

Examination: Patterns of Pelvic Organ Support Failure

Anterior Vaginal Wall

Examination of the anterior vaginal wall should establish the status of urethral support as well as bladder support. The urethra is fused with the lower 3 to 4 cm of the vaginal wall, and abnormal support in this region is properly referred to as a *urethrocele* (Fig. 48.18). Defective support of the upper portion of the vagina is called a *cystocele* because the bladder lies adjacent to this portion of the vaginal wall (Fig. 48.19). The urethrovesical crease, normally visible on examination, forms the line of demarcation between these two areas of support (Fig. 48.20). When support of the entire anterior wall is defective, the term *cystourethrocele* is used.

The anterior vaginal wall should be above the hymenal ring during straining. Descent of the lower anterior vaginal wall to the level of the hymenal ring during straining is characteristic of a urethrocele and is seen often in patients with stress urinary incontinence. This is due to loss of urethral support and corresponds to the loss of the posterior urethrovesical angle on radiographic studies of patients with stress incontinence. The lower anterior vaginal wall is mobile in all women and may move significantly in continent multiparas. Therefore, motion of this region does not establish stress incontinence but rather indicates the degree to which the support of the urethra has failed. Descent below the hymenal ring is definitely abnormal and

indicates a cystourethrocele whether or not stress incontinence is present.

Figure 48.19 Distension cystourethrocele caused by midline failure of the pubocervical fascia. (Copyright © DeLancey, 1993.)

Figure 48.20 Angulation in the anterior vaginal wall, called the *urethrovesical crease* (*arrow*), indicates the location of the urethrovesical junction. (Copyright © DeLancey, 1993.)

The anterior vaginal wall above the urethrovesical crease usually lies in a flat plane at about a 45-degree angle from the horizontal (Fig. 48.20). Descent below the level of the hymenal ring is significant. This descent can be caused by one of three entities:

- separation of the paravaginal attachment of the pubocervical fascia from the white line due to detachment from the ischial spine
- loss of the vagina's attachment to the cervix
- tearing in the pubocervical fascia that results in herniation of the bladder through this layer.

Uterus and Vaginal Apex

The vagina and cervix are fused with one another, and prolapse of the uterine cervix is associated invariably with prolapse of the upper vagina as well. When the uterus descends below its normal level, the term *uterovaginal prolapse* is appropriate, although *uterine prolapse* commonly is used. In patients in whom the uterus has been removed, descent of the vaginal apex below its normal position in the pelvis is referred to as *prolapse of the vaginal apex*, and when the vagina turns entirely inside out, the term *vaginal eversion* is used.

The location of the cervix customarily is used to gauge the severity of uterine prolapse (Fig. 48.21). Its position relative to the hymenal ring should be noted while the prolapse is at its greatest. If the cervix is not visible because of a cystocele or rectocele, then its

location may be palpated while having the patient strain. When the cervix descends to within 1 cm of the hymenal ring, there is a significant loss of support. In instances in which the uterus is not necessarily going to be removed, uterine support should be tested before it is assumed that the uterus is well supported. This can be done by grasping the cervix with a tenaculum or ring forceps and applying traction until it stops descending. Occult prolapse, in which the cervix comes below the hymenal ring, can be detected in this way.

Figure 48.21 Uterine prolapse with the cervix extending 3 cm below the hymen. (Copyright © DeLancey, 1993.)

In addition to determining how far the cervix descends, its length should be measured. Cervical elongation is frequent in individuals with prolapse, and the uterine corpus often may lie in its normal location. Awareness of cervical elongation preoperatively will allow the surgeon to proceed expeditiously with the hysterectomy rather than hoping with every pedicle that the uterine arteries will soon appear.

Posterior Vaginal Wall

The posterior vaginal wall is the site of both rectoceles and enteroceles. Evaluation and correction of these two problems challenge even the most experienced gynecologic surgeon, and they are probably the most difficult to understand of all pelvic support defects. Because dyspareunia can follow repair, correction of asymptomatic posterior wall defects is not without risk. On the other hand, having a rectocele or enterocele develop after vaginal hysterectomy

and anterior colporrhaphy is an undesirable outcome, and careful consideration of the

support of the posterior vaginal wall is important.

Three questions should be asked by the physician when examining the posterior wall.

- Is it supported normally?
- If not, is it a true rectocele or a pseudorectocele?
- Is an enterocele present?

A rectocele is present when the anterior rectal wall and overlying vagina protrude below the hymenal ring. An enterocele exists when the cul-de-sac becomes distended with the intestine and bulges the posterior vaginal wall outward. There are also occasions in which the posterior wall appears to bulge into the vagina, not because of poor support of the rectal wall but because of a deficiency in the perineal body. This has been referred to by Nichols and Randall as a pseudorectocele and can be differentiated easily from a true rectocele because the anterior rectal wall contour is normal on rectal examination. Another type of pseudorectocele may be suspected when there is apical descent of the upper vagina or cervix and apparent loss of posterior support. However, often when the normal apical support is restored (by temporarily supporting it with ring forceps in the office or after surgical repair of the apical descent), a suspected rectocele is not evident. This is important to determine preoperatively, because loss of tone of the levator ani muscle and anal sphincter muscle with muscle paralyzing agents during anesthesia make it harder to establish the existence of a true rectocele.

Enterocele

There is always a cul-de-sac between the upper vagina and the rectum. This allows a culdocentesis to be performed and a colpotomy to be made through the posterior vaginal wall at the beginning of a vaginal hysterectomy. The peritoneal pouch normally extends 3 to 4 cm beyond the junction of the vagina and cervix. Therefore, the absence of an enterocele in normal women must be explained by factors that keep the cul-de-sac closed rather than by the absence of a peritoneal space between the upper vagina and rectum. It is the suspension of the upper vagina near the sacrum in a position where it may rest over the rectum and intact levator plate that keeps this space closed.

There are two types of enterocele: pulsion enterocele and traction enterocele. A pulsion enterocele exists when the cul-de-sac is distended and appears as a bulging mass that is inflated by increases in abdominal pressure. This may occur with either the vaginal apex or uterus well suspended, in which case the cervix or vaginal apex is at a normal level and the enterocele dissects between the vagina and the rectum. When an enterocele is associated with prolapse of the uterus or vaginal apex, then the prolapse and enterocele occur together.

A traction enterocele represents a situation in which prolapse of the uterus pulls the cul-de-sac peritoneum down with it but there is no bulging or distension of the cul-de-sac when abdominal pressure rises. This condition usually is found at the time of vaginal hysterectomy when the cervix has prolapsed. It represents a potential enterocele rather than an actual enterocele because there is no bulging mass separate from the uterus.

Unlike uterine prolapse, which is obvious because of the protrusion of the easily recognized uterine cervix, enteroceles and rectoceles rarely are evident on examination. Therefore, the key to detecting an enterocele lies in actively looking for it whenever a patient who has prolapse is examined. Detection of an enterocele is performed best in the awake, straining patient by noting a mass of small intestine between the rectum and vagina; it may not be suspected in a supine individual at rest.

Anatomically, an enterocele extends from the apex of the vagina downward, whereas a rectocele typically begins in the lower portion of the vagina. An enterocele sometimes is evident as a bulge that overrides the more caudal rectocele (Fig. 48.22). Careful inspection of the posterior vaginal wall with a speculum retracting the anterior wall sometimes can suggest that an enterocele is present. The key to detecting a pulsion enterocele lies in palpating the small bowel between the vagina and rectum during rectovaginal examination, with the patient straining so that the prolapse is protruding. To do this, an index finger is placed in the rectum, and a thumb is placed in the

vagina. Then, with the patient straining, the rectovaginal space may be palpated to detect the bulge of the enterocele and the presence of small bowel, omentum, or large bowel.

Figure 48.22 "Double hump" sign of an enterocele overriding a rectocele. (Copyright © DeLancey, 1993.)

Rectocele

The hallmark of a typical rectocele is the formation of a pocket that allows the anterior rectal wall to balloon downward through the introitus. When a rectal examination is

performed with the prolapse fully developed, a rectocele exists if there is an extension of the rectal lumen below the axis of the anus (Fig. 48.23). This not only provides the diagnosis but also illustrates the mechanism by which rectoceles create their symptoms. As long as the anterior rectal wall has a smooth contour and no sacculation, even though it may be more mobile than normal, stool will pass through the anus. However, when a pocket develops as the patient strains, stool becomes trapped in it, and difficulty with evacuation can occur.

Prolapse Subsequent to Hysterectomy

Special consideration should be given to patients who have prolapse after hysterectomy to assess whether or not prolapse of the vaginal apex is present. When the uterus is in situ, the cervix calls attention to the poor support of the cervix and upper vagina. In instances of posthysterectomy vaginal prolapse, descent of the vaginal apex is more easily missed. If it is overlooked and an anteroposterior colporrhaphy is not accompanied by suspension of the vaginal apex, the colporrhaphy will fail to cure the apical prolapse and the problem is not corrected. Overlooking apical support loss also can lead to overly aggressive excision of vaginal tissues during anteroposterior colporrhaphy and a shortened vagina. Examination of patients who have previously had a hysterectomy should include a specific effort to determine the location of the vaginal apex when the prolapse is at its largest. The apex is identified by the vaginal scar at the hysterectomy site (Fig. 48.24). Vaginal prolapse is present when the hysterectomy scar lies below the level of the hymenal ring. If the apex descends to within the lower one third of the vagina with straining, a significant deficit in support of the apex is present and the vagina should be resuspended during repair.

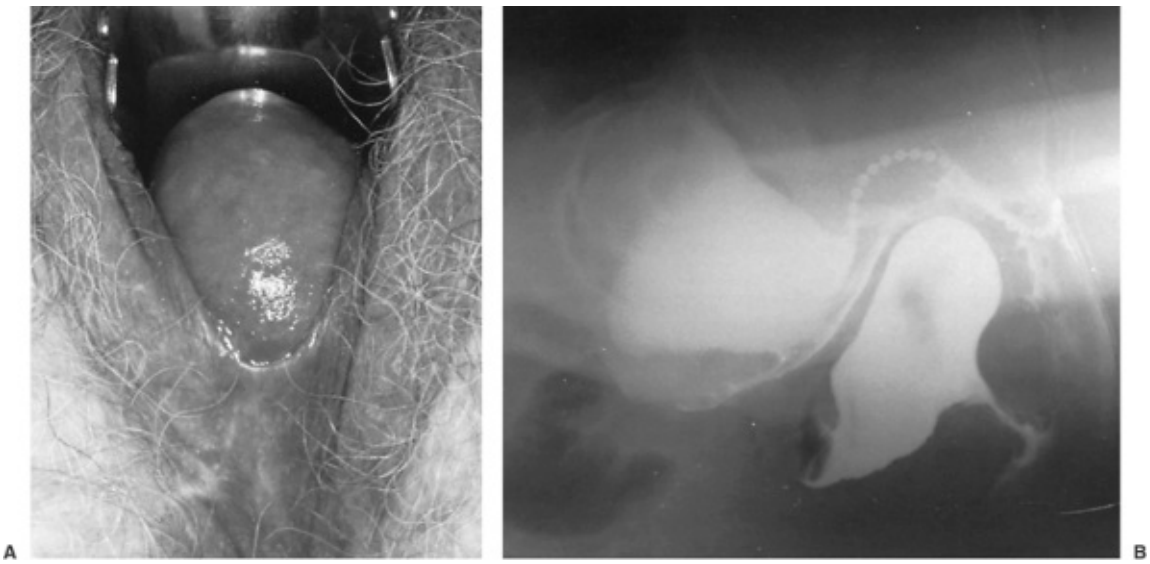

Figure 48.23 A: Pelvic examination shows a rectocele. **B:** Lateral bead chain cystourethrogram with the patient supine and with contrast in the vagina and rectum shows a protruding rectocele. (Copyright © DeLancey, 1993.)

Evaluation of Pelvic Organ Prolapse

Pelvic Organ Prolapse Classification

Several classification systems have been used to describe the sizes and types of pelvic organ prolapse in a woman. Because many of these systems use similar words to indicate different degrees of prolapse, confusion has arisen concerning the size of prolapse. For example, grade 2 uterine prolapse in some systems indicates that the cervix descends halfway between its normal position and the introitus. In other classifications, grade 2 can mean that one half of the uterus is outside the introitus. A system that

standardizes terminology has been adopted by several groups, including the International Continence Society, the American Urogynecologic Society, and the Society of Gynecologic Surgeons. This standardized terminology (pelvic organ prolapse quantification, or POP-Q) provides a system that can describe the type of prolapse as well as quantify the degree of prolapse in each area. Although this standardized system seems somewhat cumbersome when described in writing, in actual practice it is quite simple. The following section first considers the measurements that describe the type and size of prolapse and then discusses the measurements concerned with the changes in the urogenital hiatus in the levator ani muscles through which the prolapse descends.

Figure 48.24 Eversion of the vagina after hysterectomy. Note that the vaginal apex, indicated by the puckered scar where the cervix had been removed, lies below the hymenal ring. (Copyright © DeLancey, 1993.)

Measurements Describing Prolapse Type and Size

To describe the nature of a woman's prolapse, it is necessary to do the following: (a) document what part or parts of the genital tract have prolapsed, and (b) indicate how far down each part of the vaginal wall or cervix has descended.

Prolapse description must include a consideration of anterior vaginal wall descent, posterior wall descent, and uterine descent (or prolapse of the vaginal apex after hysterectomy). Furthermore, because different parts of the anterior wall might suffer support damage, the system provides for determining the status of each level of vaginal support. For example, the distal anterior vaginal wall adjacent to the urethra may be well supported, while the portion of the vagina under the bladder may prolapse. This system addresses the need to make individual assessments of different parts of the vaginal wall.

The three levels of vaginal support (Fig. 48.7) must be assessed, corresponding to the different anatomic regions of vaginal support:

- Level I: support of the vaginal apex and uterus
- Level II: support of the bladder and rectum
- Level III: support of the urethra and perineal body.

In levels II and III, the anterior and posterior vaginal wall are considered separately, while in level I, the cervix (or vaginal apex) and posterior fornix must be assessed.

To understand the POP-Q classification system, refer to Figure 48.25. The size and type of prolapse are measured by determining the location of a series of points on the anterior and posterior vaginal walls relative to the hymenal ring. Points at each of the three levels are measured. Positive numbers reflect measurements of the vaginal points that have prolapsed below the level of the hymen, and negative numbers reflect measurements above the hymen. It should be noted that this descriptive scheme does not distinguish between rectocele and enterocele but simply provides a way to quantify the amount of vaginal wall descent in each specific area. Additional examination and written comments concerning these important differences should be made.

A summary of the measurements obtained during the POP-Q examination is noted in Table 48.3.

. Vaginal points (vaginal profile): patient straining maximally

A. Level I: apex and cervix, points C and D (D is omitted if patient has had a hysterectomy)

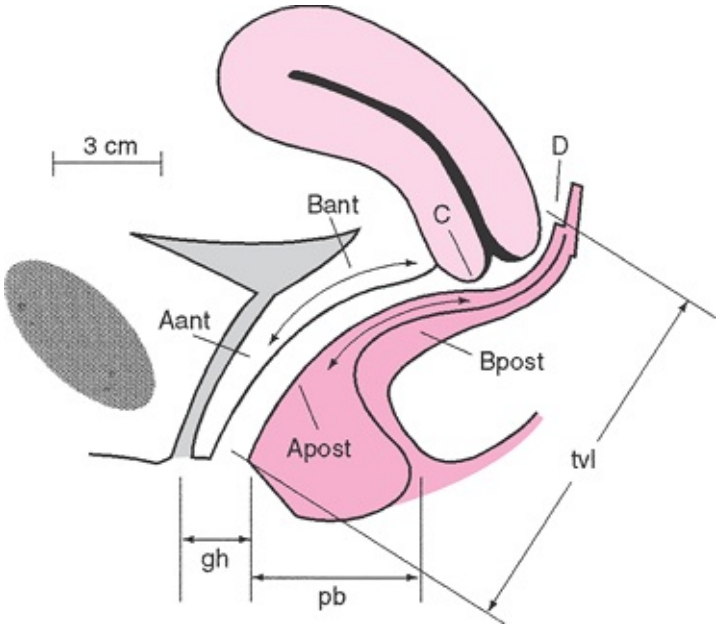

Figure 48.25 Six sites (points A_{ant}, B_{ant}, C, D, B_{post}, and A_{post}), genital hiatus *(gh)*, perineal body *(pb)*, and total vaginal length *(tvl)* used for pelvic organ support quantitation.

TABLE 48.3 Stages of Pelvic Organ Prolapse based on Measurement of Specific Sites

Stage 0	No prolapse is demonstrated. Points A_{ant}, A_{post}, B_{ant}, B_{post} are all at –3 cm and either point C or D is between – total vaginal length (tvl) cm and –(tvl-2) cm (i.e., the quantitation value for point C or D is ≤- [tvl-2] cm)
Stage I	The criteria for stage 0 are not met, but the most distal portion of the prolapse is >1 cm above the level of the hymen (i.e., its quatitation value is > -1 cm)
	The most distal portion of the prolapse is between

Stage II	1 cm above and 1 cm below the plane of the hymenal ring (i.e., its quantitation value is ≥ -1 cm but ≤ +1 cm)
Stage III	The most distal portion of the prolapse is >1 cm below the plane of the hymen but protrudes no farther than 2 cm less than the tvl in centimeters (i.e., quantitation value is > +1 cm but < + [tvl-2] cm)
Stage IV	Essentially complete eversion of the total length of the lower genital tract is demonstrated. The distal portion of the prolapse protrudes to at least (tvl-2) cm (i.e., its quantitation value is < -1 cm)

Tvl, total vaginal length.

B. Level II: midvaginal points

1. Anterior wall: B_a or B_{ant}
2. Posterior wall: B_p or B_{post}

C. Level III: distal vagina (perineum and urethrovesical neck)

1. Anterior wall: A_a or A_{ant}
2. Posterior wall: A_p or A_{post}
3. External measurements: obtained with patient at rest and again straining

A. Genital hiatus: length, gh

B. Perineal body: length, pb

. Internal digital measurements: obtained with patient at rest with vaginal apex restored to normal position

A. Total vaginal length: tvl

To measure the lower third of vaginal support (level III), the location of a pair of points that normally lies 3 cm above the hymenal ring is assessed. Points measured at level III are called *points A*. One can imagine marking these vaginal points 3 cm above the hymen with a marker and then recording the position of these points in relation to the hymen with the subject straining maximally. Anteriorly, this corresponds to the approximate location of the urethrovesical junction, and this measurement assesses urethral descent (A_a or A_{ant}). Posteriorly, this region is normally occupied by the tissues of the perineal body (A_p or A_{post}).

By definition, the highest possible position of either point A_{ant} or A_{post} is 3 cm above the hymen (-3), and the lowest position is 3 cm below the hymen (+3).

To assess midvaginal support (level II), the most dependent part of the vaginal wall above point A_{ant} is used. This point is called B_a, or B_{ant}, on the anterior wall and B_p, or B_{post}, on the posterior wall. Therefore, this is not a fixed point along the surface of the vagina but rather is marked at whatever location is the most caudal (distal) portion of that vaginal segment at maximal prolapse protrusion. In a normally supported vagina, this will be the same as point A_{ant}, whereas it will be the same as point C in a woman with procidentia. The same is true for the posterior vaginal wall at point B_{post}. Point C corresponds to the most distal portion of the uterine cervix or of the hysterectomy scar in the vagina in those patients who have had the uterus removed. Point D denotes the posterior fornix (that point at which the posterior vaginal wall changes direction). In addition to the positions of these points, the total length of the vagina is noted. Once these data have been gathered, a simple line diagram can be constructed by plotting these points relative to the hymen to provide a graphic representation of the prolapse (Fig. 48.26).

So far, each element of the prolapse has been considered separately. It is also possible to give an overall description to the size of the prolapse by looking at the most dependent part of the protruding vagina or uterus. In this way, different stages—stage 0 through stage IV—can be defined; a description of these is shown in Table 48.3. A briefer version of the original description of the POP-Q staging system has been summarized as well.

The choice of the term *stage* here is somewhat unfortunate, because most women with stage I and II support are anatomically normal. The implication that they have a stage of prolapse is incorrect. Hopefully, this problem with terminology will be corrected in the future.

Pelvic Floor Measurements

In normal women, the levator ani muscles close the pelvic floor. In women with pelvic organ prolapse, the urogenital hiatus within the levator ani muscles is the opening through which the vagina prolapses. This hiatus is enlarged

in women with pelvic organ prolapse. The size of the urogenital hiatus and thickness of the perineal body can easily be measured to describe the changes that have occurred in the pelvic floor. The anteroposterior diameter of the genital hiatus extends from the arch of the pubic bone to the front of the perineal body, while the thickness of the perineal body is measured from the anterior margin of the perineal body to the center of the anal verge. The urogenital hiatus is held closed by the constant activity of the levator ani muscles, and the diameter of this opening enlarges in many women with prolapse.

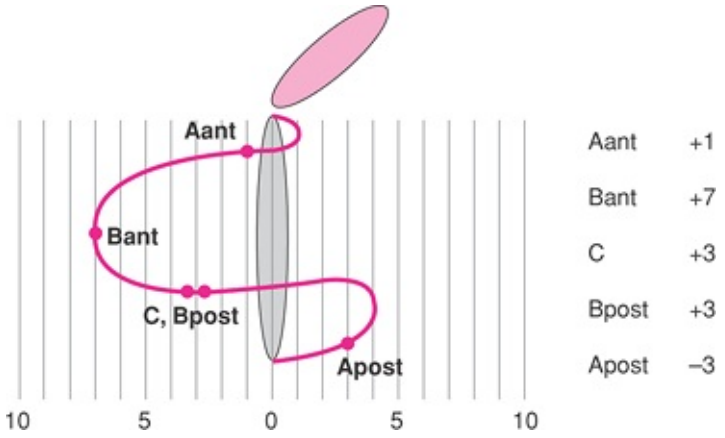

Figure 48.26 Diagram of prolapse sites. (From Viereck V, Peschers U, Singer M, et al. Metrische Quantifizierung des weiblichen Genitalprolapses: eine sinnvolle Neuerung in der Prolapsdiagnostik? *Geburtshilfe Frauenheilkd* 1997;57:177, with permission.)

This classification system is detailed and specific. It requires careful examination and assessment. Although at first it seems quite detailed, it is simply the quantitative documentation of the individual defects that experienced surgeons always have found necessary to assess. Some clinicians will not find it expedient to measure each of these sites, but intelligent, detailed analysis of each site of support is important to plan properly any repair for pelvic organ prolapse.

Symptoms

All types of prolapse have several symptoms in common. Once the vagina prolapses below the introitus, it becomes the structural layer between the high pressures in the abdominal space and the relatively low atmospheric pressure. The downward force that this pressure differential creates puts tension on the fasciae and ligaments that support the vagina and uterus. This results in a dragging sensation where the tissues connect to the pelvic wall, usually identified by patients as occurring in the groin, and in sacral backache caused by traction on the uterosacral ligaments. This type of discomfort resolves when the patient lies down and the downward pressure is reduced. In addition, exposure of the moist vaginal walls leads to a sensation of perineal wetness that may be confused with urinary incontinence, and it also can give rise to ulceration of the vaginal wall. Most patients have an underlying sense of insecurity that is difficult for them to describe and is often expressed as a feeling that “something is just not right.” Sometimes, patients who feel the cervix or vagina protruding have fears that they have a cancer and may be relieved to find that the condition is related to prolapse. Although patients may find it difficult to put their symptoms into words, the symptoms can cause significant distress and should not be ignored.

Anterior Wall Prolapse

The symptoms of cystourethrocele are varied, and the two primary ones are paradoxical. On the one hand, loss of support of the urethra and the lower vaginal wall is associated with stress urinary incontinence, whereas loss of support of the upper anterior vaginal wall and bladder base can cause difficulty in emptying the bladder. This inability to empty the bladder completely is probably related to voiding by the Valsalva maneuver. If there is a detrusor contraction, there should be no reason for a woman with a cystocele not to empty her bladder, and many women with a significant cystocele have normal postvoid residual urine volumes. When a woman strains to void, however, the cystocele simply gets bigger, and no impulse is provided for urine to flow through the urethra.

In addition to these functional symptoms, many patients with a cystourethrocele complain of urinary urgency and frequency. This probably arises from stretching of the bladder base that accompanies its prolapse through the vaginal introitus; it is often less pronounced at night when patients are supine.

Patients have a varying amount of support loss under the urethra or bladder, and symptoms vary along the spectrum from incontinence to urinary retention. As is true for other forms of prolapse, it is important to correlate a patient's symptoms with the physical findings so that these problems can be addressed.

Prolapse of the Uterus, Prolapse of the Vaginal Apex, or Enterocele

Few specific symptoms are related to prolapse of the uterus, prolapse of the vaginal apex, or enterocele. Patients with these conditions usually complain of the generalized symptoms of prolapse mentioned previously. Some have urgency and frequency, probably related to pressure of the prolapse on the bladder base, but this is variable. In addition, patients with large, thin enteroceles occasionally have a sense of impending rupture. Although this is an uncommon problem, it should not be overlooked.

Summary Points

- Annually, approximately 200,000 American women have surgery for pelvic organ prolapse.
- The main risk factors for pelvic organ prolapse are age, vaginal delivery, race, and family history.
- The combination of two mechanical factors—suspension of the genital tract by the ligaments and fasciae and closure of the pelvic floor by the levator ani—holds the vagina over the levator ani muscles and forms a flap-valve closure, preventing prolapse.
- The levator ani muscles and the connective tissues in the pelvic floor act together to share the load. When the muscle is injured, the connective tissue is subjected to increased load. If this load exceeds the strength of the pelvic tissues, they may be stretched or broken, and prolapse may result.
- The degree of anterior vaginal wall/bladder descent (cystocele)

correlates strongly with the degree of apical descent because the structural support of the two is intimately related.

- Approximately 10% to 15% of women who deliver vaginally develop a visible defect in the levator ani muscle.
- Women with prolapse have major defects in their levator ani muscles much more frequently than do women who have normal support: 55% versus 15%, respectively (odds ratio 7.3).
- The two main nerves that supply the pelvic floor relative to pelvic organ prolapse are the pudendal nerve (originating from S2 to S4) that supplies the urethral sphincter, anal sphincter, and perineal muscles and the nerve to the levator ani (originating from S3 to S4) that innervates the major musculature that supports the pelvic floor.

Operative Management of Pelvic Organ Prolapse

Kris Strohbehn
Holly E. Richter

Pelvic organ prolapse (POP) is a common condition affecting women. While many women live with varying degrees of POP without treatment, it is estimated that over 200,000 surgical procedures are performed in the United States annually to treat this condition. More than 1 in 10 women will have surgical treatment of prolapse and/or urinary incontinence by the time they reach 80 years of age. The repairs are not always successful, and 1 in 3 women who undergo surgery for urinary incontinence or prolapse need to undergo a subsequent procedure. The risk factors, anatomic changes, and demographics of POP are covered in Chapter 48.

Despite the fact that up to 50% of women over the age of 50 have physical findings consistent with some degree of POP, fewer than 20% seek treatment for this condition. This may be due to a number of reasons including lack of symptoms, embarrassment, or misperceptions about available treatment options for this condition. Recent estimates predict an increased demand for prolapse surgery by 45% in the next 30 years. To effectively use financial resources in the surgical management of POP, it is imperative to perform surgeries that are evidence based to improve outcomes and minimize recurrences. The authors believe that nonsurgical options, including observation or a trial of a pessary, are of low risk to patients and should be considered first, if acceptable to the patient.

This chapter will review different surgical options for treating POP, including transvaginal repairs, open abdominal repairs, laparoscopic repairs, and new percutaneous needle or trocar repair kits as well as a combination of these procedures. Each of these surgical approaches to treat POP may use native ligaments and tissues for repair. Alternatively, some surgeons utilize biologic grafts for selected repairs, including xenografts, allografts, and autologous grafts. Finally, synthetic graft materials are frequently utilized via transvaginal, laparoscopic, and open abdominal repairs. A brief discussion of these options and the pros and cons of each will be included in this chapter.

Preoperative Considerations

A careful preoperative evaluation of patients with POP is crucial in determining whether surgical repair is the right treatment choice for an individual and if so, which procedure is

most appropriate. The decision to operate for POP should be based on the degree of POP symptom bother that a patient is experiencing. Consideration of the patient's postrepair goals and their risks should be addressed prior to surgery. Symptom-based scoring questionnaires have been introduced and validated to assess the impact of POP on quality of life. There are a wide complex of symptoms associated with POP, including urinary incontinence, voiding dysfunction, anal incontinence, defecatory dysfunction, sexual dysfunction, and prolapse symptoms, that are also commonly reported in women without POP. However, it is more common for subjects to have symptoms when the prolapse extends to or beyond the hymen.

Determination of a patient's bother prior to considering surgical approach is useful to assess whether or not surgery

offers hope of alleviating her symptoms. In determining bother, it can be helpful to ask the patient if her prolapse is preventing her from doing things that she would like to do. For example, if an individual has stopped exercising because of POP, this may have great impact on her overall health. In the authors' practice, a simple but nonvalidated scoring system is used to assess bother for specific symptoms (Table 49.1). A more in-depth validated assessment of impact on quality of life has been introduced by Barber and colleagues and is validated for subscales of colorectal function, urinary incontinence, and prolapse. Whether or not a validated scoring system is used, making the effort to determine bother is useful in determining preoperative goals and postoperative outcomes.

A. YOUR SYMPTOMS THIS WEEK . . .

1. Do you have urinary symptoms (e.g., leaking urine or some other urinating problem)?
   _____ Yes _____ No (0)
   If Yes, Are these symptoms . . . ?
   ☐ Mild (1) ☐ Moderate (2) ☐ Severe (3)
2. Do you have bowel symptoms (e.g., leaking stool, constipation, other problems defecating)?
   _____ Yes _____ No (0)
   If Yes, Are these symptoms . . . ?
   ☐ Mild (1) ☐ Moderate (2) ☐ Severe (3)
3. Do you have prolapse symptoms (e.g., tissue bulging or protruding at or beyond the opening of the vagina)?
   _____ Yes _____ No (0)
   If Yes, Are these symptoms . . . ?
   ☐ Mild (1) ☐ Moderate (2) ☐ Severe (3)

B. DO THESE URINARY/BOWEL/PROLAPSE SYMPTOMS BOTHER YOU?

Some people will have mild symptoms and consider them very bothersome. Other people will have moderate or severe symptoms and will not consider them very bothersome. How bothersome have your symptoms been over the past week in regard to each of the following areas of your life?

1. Going out in public . . .
   ☐ Symptoms not at all bothersome (0) ☐ Symptoms slightly bothersome (1) ☐ Symptoms very bothersome (2) ☐ Symptoms extremely bothersome (3)
2. Thinking about my general health . . .
   ☐ Symptoms not at all bothersome (0) ☐ Symptoms slightly bothersome (1) ☐ Symptoms very bothersome (2) ☐ Symptoms extremely bothersome (3)
3. Relating with my self-image or my spouse/partner . . .
   ☐ Symptoms not at all bothersome (0) ☐ Symptoms slightly bothersome (1) ☐ Symptoms very bothersome (2) ☐ Symptoms extremely bothersome (3)
4. Feelings about my physical appearance . . .
   ☐ Symptoms not at all bothersome (0) ☐ Symptoms slightly bothersome (1) ☐ Symptoms very bothersome (2) ☐ Symptoms extremely bothersome (3)

Adapted from Hullfish KL, Bovbjerg VE, Steers WD. Patient-centered goals for pelvic floor dysfunction surgery: long-term follow-up. *Am J Obstet Gynecol* 2004;191(1):201–205.

TABLE 49.1 Bother Score to Assess Pre- and Postoperative Bother from Pelvic Organ Prolapse

Setting realistic expectations and goals with the patient prior to prolapse repair is important. As part of the discussion prior to surgery, a review of possible outcomes (good and bad) should be reviewed with honesty and, if possible, with the surgeon's individual outcome data. The discussion should include potential negative impact on sexual function and visceral functions, such as bladder and bowel continence and evacuation after anatomic correction of prolapse. If a patient is bothered by prolapse but is without symptoms of urinary incontinence, she will be

understandably upset with her outcome if she develops de novo urinary incontinence. By the same token, someone who has mild urinary incontinence preoperatively who develops de novo urinary retention postoperatively may have elected to live with her mild incontinence compared with the voiding dysfunction she now suffers with.

A review of an individual's prior abdominal and pelvic surgeries is imperative to planning a prolapse procedure. If a patient has had several laparotomies, is morbidly obese, or there is a suspicion for severe abdominopelvic adhesions, the surgeon should consider a vaginal repair. At a minimum, preparation for possible change in the planned repair may be in order, especially if inadvertent enterotomy occurs intraoperatively. If a patient has failed prior prolapse surgeries with native tissue repairs, then consideration of a mesh-augmented or other graft repair should be entertained.

Other considerations regarding the approach to repair include surgeon experience, patient age, other comorbidities, and pelvic muscle strength. Assessment of individual surgeon outcomes may help to determine which prolapse repairs are best suited for an individual's practice. A focus on outcomes in practices for procedures is being mandated with adoption of the National Surgery Quality Improvement Program (NSQIP).

As part of the focus on excellent outcomes, prophylactic antibiotics should be considered prior to any POP procedure, especially in cases where the vaginal epithelium is disrupted. Within 60 minutes of the incision start, 1 g of cefazolin or a similar broad-coverage antibiotic is administered intravenously. The American College of Obstetrics and Gynecology (ACOG) practice bulletin guidelines are helpful for decisions regarding prophylaxis. Prophylaxis for deep venous thrombosis should be considered for any pelvic surgery that is anticipated to take longer than 30 minutes, and the authors employ intermittent pneumatic compression stockings in such cases.

The age of the patient may help to direct which surgical approach is suitable. Many experienced surgeons advocate vaginal repairs for older patients, but using age cutoffs alone may be inappropriate. It is common knowledge that there are 80-year-old women who are more active and in better health than some 50-year-old women. As a generalization, it makes sense to consider a quicker, less invasive repair such as a

transvaginal repair or colpectomy with colpocleisis for a frail, inactive patient. This makes sense to reduce morbidity, as inactive individuals are less likely to place stress on the repair. However, the lower morbidity may be at the cost of lower success due to potential diminished strength of the native tissues that may be inherent in frail or elderly patients.

The selection of repair may also depend on whether the levator ani muscles will appropriately protect the ligaments. If a patient is unable to contract her levator muscles, there is likely to be more load on her native ligaments, with possible added risks of failure over time. If it is apparent that there is no protection of the connective tissue support from the pelvic musculature, the choice of a synthetic graft to compensate for lack of muscular support seems sensible.

Planning a prolapse repair requires consideration of the impact of the function of the pelvic organs in addition to anatomic support. Urodynamic evaluation has been recommended by some, even if urinary incontinence is not a symptom of the patient. Urodynamic evaluation may assist in identifying occult urinary incontinence in women with prolapse who leak with a full bladder when the prolapse is reduced. Pessary or barrier testing has also been used to try to assess risks for occult stress urinary incontinence. In the recently published CARE trial, a prophylactic Burch procedure was effective at reducing the risk of stress urinary incontinence among women without preoperative symptoms of such incontinence who underwent mesh sacral colpopexy for the treatment of prolapse. The reduction in risk of stress urinary incontinence did not result in a higher rate of voiding dysfunction or bladder storage symptoms. There are no data available regarding midurethral sling procedures as a prophylactic procedure.

Operative Repairs

The aims of surgical management of POP are to:

- Reduce the prolapse
- Improve symptoms of POP, the lower urinary tract, and bowel
- Restore or improve sexual functioning (except after colpocleisis), and correct coexisting pelvic pathology.

As mentioned previously, the surgical approach for POP includes vaginal, abdominal, and laparoscopic routes. Anatomic studies have demonstrated different levels of support, and POP may result from a single or combination of support defects (Fig. 49.1). Surgical management may therefore involve a combination of repairs including the anterior vaginal wall, vaginal apex, and posterior vaginal wall.

The surgical route is typically chosen based on the type and severity of prolapse, combined with the surgeon's training and expertise as well as patient functional level and preference, rather than on primary consideration of surgical outcome. Surgical procedures for POP can be categorized into three groups: restorative procedures that use the patient's endogenous support structures to restore normal anatomy; compensatory procedures that augment defective support structures with autologous, allogenic, or synthetic graft material; and obliterative procedures that stricture the vagina. These categories are somewhat arbitrary

and not entirely exclusive. For example, graft material may be used to replace support that is deficient or to reinforce repairs. Graft use in abdominal sacral colpopexy (ASC) substitutes for the cardinal and uterosacral ligaments that would normally support the vaginal apex. When vaginal function is

desired by the patient, restorative or compensatory procedures are utilized, whereas an obliterative procedure may be utilized when there is no desire to retain sexual function of the vagina.

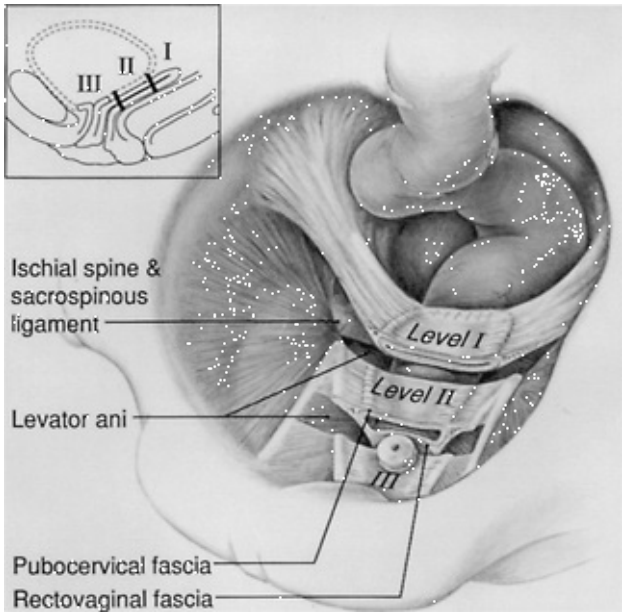

Figure 49.1 The different levels of vaginal support structures after hysterectomy. (Reproduced with permission from DeLancey JOL. Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol* 1992;166:1717.)

Whether to repair all defects seen is controversial, especially if the patient is asymptomatic. Restorative repairs may be less successful than compensatory repairs in patients with generally “poor tissue,” and at times, one defect repair may exert more tension on the repair of another defect. Each case should be individualized based on the patient's presentation, expectations, the specific anatomical defects noted (preoperatively and, at times, intraoperatively), and on the presence or absence of lower urinary and bowel dysfunction symptoms.

The following sections will describe surgical approaches of prolapse in the anterior, apical, and posterior vaginal components. Vaginal, abdominal, and laparoscopic approaches will be reviewed for each compartment.

Vaginal Approaches

Anterior Compartment

Surgical management of the anterior compartment continues to be a challenge for all pelvic surgeons. In most published series, the anterior wall is the most common site of objective failure with different surgical approaches to POP.

Anterior Colporrhaphy

Anatomic correction of an anterior defect or cystocele will generally relieve symptoms of protrusion and pressure and will usually improve micturition function when abnormal micturition is associated temporally with the defect and if there is no associated neuropathy. If a single, well-defined midline defect is recognized, excision of the weak vaginal wall and an imbricating closure of the defect may be performed. However, recent magnetic resonance imaging (MRI) and anatomic measurement studies indicate that at least one third of the descent of cystoceles is due to loss of apical support, so it is important to determine whether the apex needs to be suspended as well. Most central anterior defects require a more extensive dissection of the vesicovaginal space. In the case where the cuff is well suspended, the authors typically grasp the vaginal epithelium vertically with two Allis clamps cephalad to the urethrovesical junction and incise with the knife. With the use of a Metzenbaum or comparable scissors, the vaginal epithelial and subepithelial layers are separated from the fibromuscular layer out to a point lateral to the defect up to the cuff or cervix; this is followed by midline plication of this tissue with either a running or interrupted delayed absorbable suture such as polyglactin (Vicryl, Ethicon, Somerville, NJ) or no.1 polydioxanone (PDS, Ethicon, Somerville, NJ), excision of excess epithelium, and closure. The repair is similar at the time of concomitant vaginal hysterectomy or apical cuff suspension except that the dissection proceeds in a cephalad to caudad fashion. It appears of great importance to ensure that the continuum of repaired fibromuscular tissue to a well-supported vaginal apex be maintained.

Recurrence rates of traditional fibromuscular connective tissue plication anterior repairs vary in the literature from 5% to 90%; however, studies define recurrence in numerous ways from minimal prolapse to stage III descent. The clinical significance of recurrent asymptomatic cystoceles (stage I and some stage II) is debatable because many of these do not progress to larger defects. The authors' interpretation of the literature is that when traditional anterior repairs are performed with patients with a pelvic organ prolapse quantitation (POP-Q) system of measurement of stage II or greater cystoceles (frequently concurrently with other procedures), a recurrence rate of stage II or greater prolapse of up to 20% to 40% is not uncommon. Many studies do not define how the subjects were evaluated postoperatively and vary in respect to patient populations, type and severity of defects, presence of concurrent defects, surgical technique, and follow-up time and length. Some studies have suggested higher recurrence rates when these repairs are performed concurrently with sacrospinous suspensions and hypothesize that this type of apical suspension may predispose the repair anterior wall to greater pressure transmission. Other possibilities of the higher failure rates in these studies are the fact that the patients having concurrent repairs may be more likely to have more complicated forms of prolapse or, possibly, more defective “pelvic floors” than other groups of patients.

The addition of adjunctive graft materials has been employed in the past decade to try to

improve success rates. Two randomized trials suggest modest improvement in success after 1 year when polyglactin mesh (Vicryl, Ethicon, Somerville, NJ) was placed over the midline plication compared with standard repair. However, most

surgeons have abandoned this type of mesh because of subsequent failures. Other graft materials that are discussed later in this chapter may have more promise, but long-term outcome data are lacking. Fascial autologous grafts, allografts, xenografts, and newer synthetics are presently used by many surgeons with variable short-term success and, thus far, little data on adverse effects and success after 3 years. These have been used in several ways in the anterior compartment, including placement of smaller grafts to bolster suture lines and larger grafts for complete substitution of the entire anterior support plate from the pubis to the arcus to the vaginal apex.

Vaginal Paravaginal Repair

The paravaginal or “lateral defect” repair described first by White and reintroduced by Richardson and Edmonds involves reattachment of the anterior lateral vaginal sulcus to the obturator internus fascia and, at times, muscle at the level of the arcus tendineus fascia pelvis (ATFP) or “white line.” The paravaginal repair reattaches the anterolateral vaginal sulcus to the pubococcygeus and obturator internus muscles and fascia at the level of the ATFP. The original transvaginal repair used bilateral incisions along the lateral vaginal sulci to expose the arcus tendineus. Three or four sutures were then placed from the ischial spine along the ATFP to suspend the vaginal muscularis and adventitia bilaterally.

Subsequently, use of a midline incision was described that facilitated the concurrent repair of central anterior defects. The typical vaginal paravaginal procedure involves the “three point closure” with incorporation of the detached edge of the pubocervical connective tissue into the ATFP and the anterior vaginal wall with a series of four to six nonabsorbable sutures (Prolene, Ethicon, Somerville, NJ) 1.5 cm apart, initiated approximately 1 cm anterior to the ischial spine. The sutures are tied sequentially, beginning with the one closest to the spine and ending periurethrally. Cystoscopy should be performed to ensure ureteral patency and inadvertent stitch placement into the bladder. This often is performed with a reinforcement of the midline pubocervical connective tissue with trimming of the vaginal epithelium (if necessary) and closure. The procedure has been described with the use of a Capio suturing device as well (Microvasive Endoscopy, Natick, MA).

Observational outcome studies have reported good success (80% to 95%); however, long-term data on durability and function is lacking. Previous work has shown that most subjects with anterolateral detachments almost always have separation of the upper vaginal fornices from the arcus tendineus immediately adjacent to the ischial spine. Thus, it is important to resuspend those specific areas.

It is the authors' opinion that it is difficult to achieve optimal results when vaginal paravaginal repair is used in combination with traditional central repairs because of the creation of tension on opposing suture lines. A repair that removes a weakened central vaginal wall may decrease the side-to-side dimensions of the anterior vaginal wall, making

it difficult to suspend its lateral points more laterally. When large central defects are coexistent with lateral defects, one option is an extensive central repair accompanied by a good apical support procedure. This changes the shape of the vagina to a more cylindrical structure. Another choice is placement of a graft material to span the entire anterior rhomboid-shaped plate, thus augmenting anterior paravaginal tissue strength. The graft with tension adjusted may be anchored to the arcus tendineus along with the adjacent vaginal wall from the level of the pubic rami to the ischial spine. The new synthetic graft kits utilize this principle, as described later.

Although most reports indicate that repair of anterior defects with all of these procedures relieves symptoms that are directly related to prolapse, there is very little data on patient satisfaction and quality-of-life improvement over time. Such studies are much needed. There are no randomized trials that compare outcomes after anterior colporrhaphy versus vaginal paravaginal repair.

Posterior Compartment

There is no consensus on what defines a rectocele or posterior vaginal wall prolapse by physical examination or the use of diagnostic imaging modalities. However, early descriptions of the traditional posterior colporrhaphy in the early 1800s addressed perineal tears sustained at vaginal delivery. The support of the rectum and posterior vagina includes the pelvic floor musculature, connective tissue, Denonvilliers (pararectal) fascia (which is the fibromuscular layer of the posterior vaginal wall), and its lateral attachments to the lateral pelvic floor (levator) musculature and its fascia. This lateral attachment site, the fascia levator ani, fuses with the ATFP at the mid to upper vaginal level and continues to the level of the ischial spine. Less dense, areolar, connective tissue surrounds the rectum and vagina and may supply some fixation of these structures as well. Richardson hypothesized, based on careful cadaveric dissections, that most rectoceles were due to discrete tears in the Denonvilliers fascia at its lateral, apical, and perineal attachments and centrally within the fascia itself. He described perineal detachment along with a defect in the perineal membrane as a perineal rectocele, which is most commonly associated with complaints of difficulty with defecation. The apical attachment defects are generally associated with enteroceles and occasionally sigmoidoceles.

Once a decision is made to perform surgical repair of the posterior compartment based on symptoms, type, and location of defects, an appropriate approach should be decided on, and the patient should be made aware of what outcome she should expect and of potential adverse effects such as pain and sexual dysfunction. If the patient has defecatory dysfunction with a rectocele and has symptoms of constipation, pain with defecation, fecal or flatal incontinence, or any signs of levator spasm or analismus, appropriate evaluation and conservative management of

---

concurrent problems should be initiated prior to repair of the rectocele.

Specific types of repairs include the traditional posterior colporrhaphy, the defect-directed repair, replacement of fascia with graft materials, transanal repairs, and abdominal approaches by laparotomy or laparoscopy. An elegant review by Cundiff and Fenner has

recently summarized data on the evaluation and treatment of women with rectocele, with a focus on associated defecatory and sexual dysfunction. Surgical outcomes with available objective and subjective measures were also reported.

Traditional Posterior Colporrhaphy

The first description of the posterior colporrhaphy was by Jeffcoate in 1959 and involved plication of the pubococcygeus muscles across the anterior rectum as well as perineal body reconstruction. Since that time, the technique has been modified in attempts to preserve sexual function. Typically, a midline incision is extended from the perineal body to the vaginal apex or to the cephalad border of a small or distal rectocele. The Denonvilliers fascia is mobilized from the vaginal epithelium, leaving as much of this tissue attached laterally to the levator fascia as possible.

After obvious defects in the rectal muscularis are repaired, the fascia is then plicated in the midline with interrupted or continuous sutures (Fig. 49.2). The authors prefer delayed absorbable suture, no. 1–0 or no. 0 polydioxanone, for this plication. Permanent nonbraided suture material may be used as well. In our experience, braided permanent suture material is subject to a greater incidence of stitch infection and formation of granulation tissue. The vaginal epithelium is trimmed and closed with absorbable sutures.

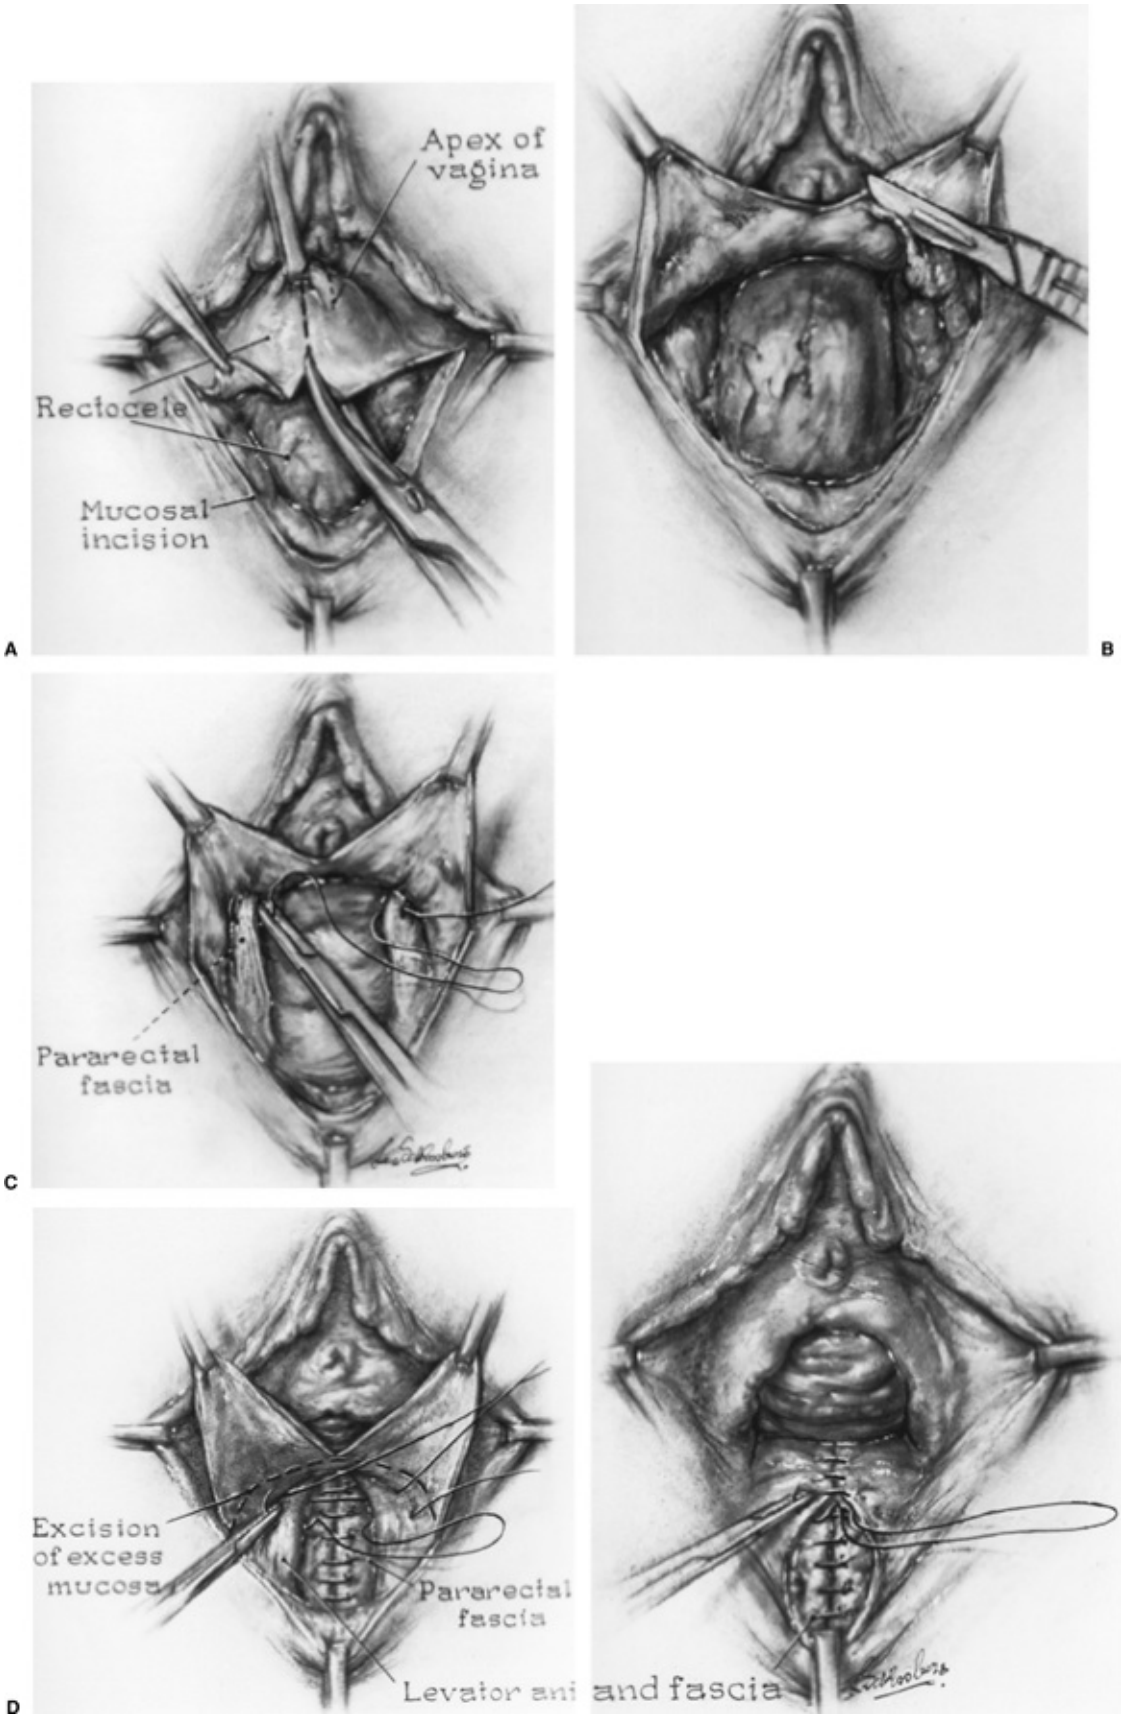

Figure 49.2 A: To begin the posterior colporraphy, a transverse incision is made in the perineal body, and a vertical incision is extended toward the vaginal apex. **B:** The perirectal musculo-connective tissue is mobilized from the epithelium. **C:** The perirectal musculo-connective tissue is sutured, beginning above the site of the rectocele. **D:** The inner surface of the levator ani are approximated as necessary and redundant epithelium excised. **E:** the vaginal epithelium, superficial perineal muscles

and skin are closed. (Reproduced with permission from Mattingly RF, Thompson JD, eds. *Te Linde's Operative Gynecology*, 6th ed. Philadelphia: JB Lippincott Co, 1985:578.)

When there is a defective perineal body or perineal membrane, reconstruction is performed after accompanying posterior colporrhaphy. The superficial muscles of the perineum and bulbocavernous fascia are plicated in the midline by using delayed absorbable suture, and the skin closed as in an episiotomy repair. Detachments of the inferior portion of the Denonvilliers fibromuscular connective tissue from the perineal body are also corrected. Plication of the puborectalis muscles concurrently with these procedures is performed by some surgeons in all or selected cases, but because this has been associated with a high incidence of sexual dysfunction, the authors do not recommend that it be performed routinely. However, puborectalis plication will be performed in selected patients with severe prolapse accompanied by a large genital hiatus with palpable levator weakness or inability to contract pelvic floor muscles. Sutures are carefully placed through the puborectalis muscles at least 3 cm or greater posterior to their insertion on the pubic rami, thereby decreasing the tension of the plication. For those women who desire sexual function with findings of an enlarged hiatus and weakened puborectalis muscles, there is an attempt to plicate the muscles far enough posteriorly to easily allow two fingers through the vaginal introitus and reconstruct the distal posterior vagina and perineum so that there will not be a ledge or ridge at the site of the puborectalis plication. Outcome data on such procedures is inadequate to make conclusions regarding its efficacy; however, it is the authors' opinion that pelvic floor defects producing an enlarged genital hiatus are common reasons for failure of support procedures and that puborectalis plication may decrease the incidence of such failures.

Reported anatomic cure rates for traditional posterior colporrhaphy have ranged from 76% to 90% with variable follow-up. Most studies show a benefit to ease of defecation if patients are using preoperative splinting; however, overall defecatory dysfunction (defined as constipation) is usually not relieved in the majority of the subjects. These repairs, per se, also appear to be of little to no benefit to fecal incontinence. It is not surprising that the repairs are not particularly effective for defecatory dysfunction related to disorders of constipation or for fecal incontinence since the etiology of these problems are multifactorial. De novo dyspareunia is reported to occur in up to 25% of sexually active patients who have traditional posterior colporrhaphy and is not always associated with levator plication

procedures. Potential causes for dyspareunia other than vaginal strictures or introital tightness include scarring with immobility of the vaginal wall, levator spasm, and neuralgias associated with sutures and/or dissection. Dyspareunia may also occur when a Burch colposuspension procedure (or other procedures that cause anterior displacement of the vaginal canal) is combined with a posterior repair. Careful surgical technique and appropriate choice of procedure should decrease the incidence of postoperative dyspareunia.

Defect-specific Posterior Colporrhaphy

Defect or site-specific posterior repairs are restorative procedures by which the posterior defects described by Richardson are corrected. These repairs begin by midline posterior vaginal incision through the epithelium and then separation of the epithelium from the fibromuscular wall (Fig. 49.3). After irrigation for better exposure, a finger is inserted in the rectum to better define defects of the rectal wall and in the fibromuscular connective tissue layer that has been dissected from the vaginal wall subepithelium. The specific defects are closed with either interrupted or running sutures (the authors prefer the delayed absorbable type). Defect closure is accomplished in such a way to minimize tension on the surrounding tissue and may involve vertical, horizontal, or oblique approximation. When there is separation of the fibromuscular tissue from the perineum, the upper anterior rectum, or a well-supported cervix or vaginal cuff, it is important to reapproximate these connections. Repairs of coexistent perineal and apical support defects are important. The goal of the surgery is to re-establish an intact plane of connective tissue that positions the rectum against the pelvic floor and obliterates any potential space between a well-supported cervix or vaginal cuff and the cephalad edge of the tissue plane and upper rectum. The technique should minimize tension and avoid potential strictures, which may be more likely to occur with traditional posterior colporrhaphy.

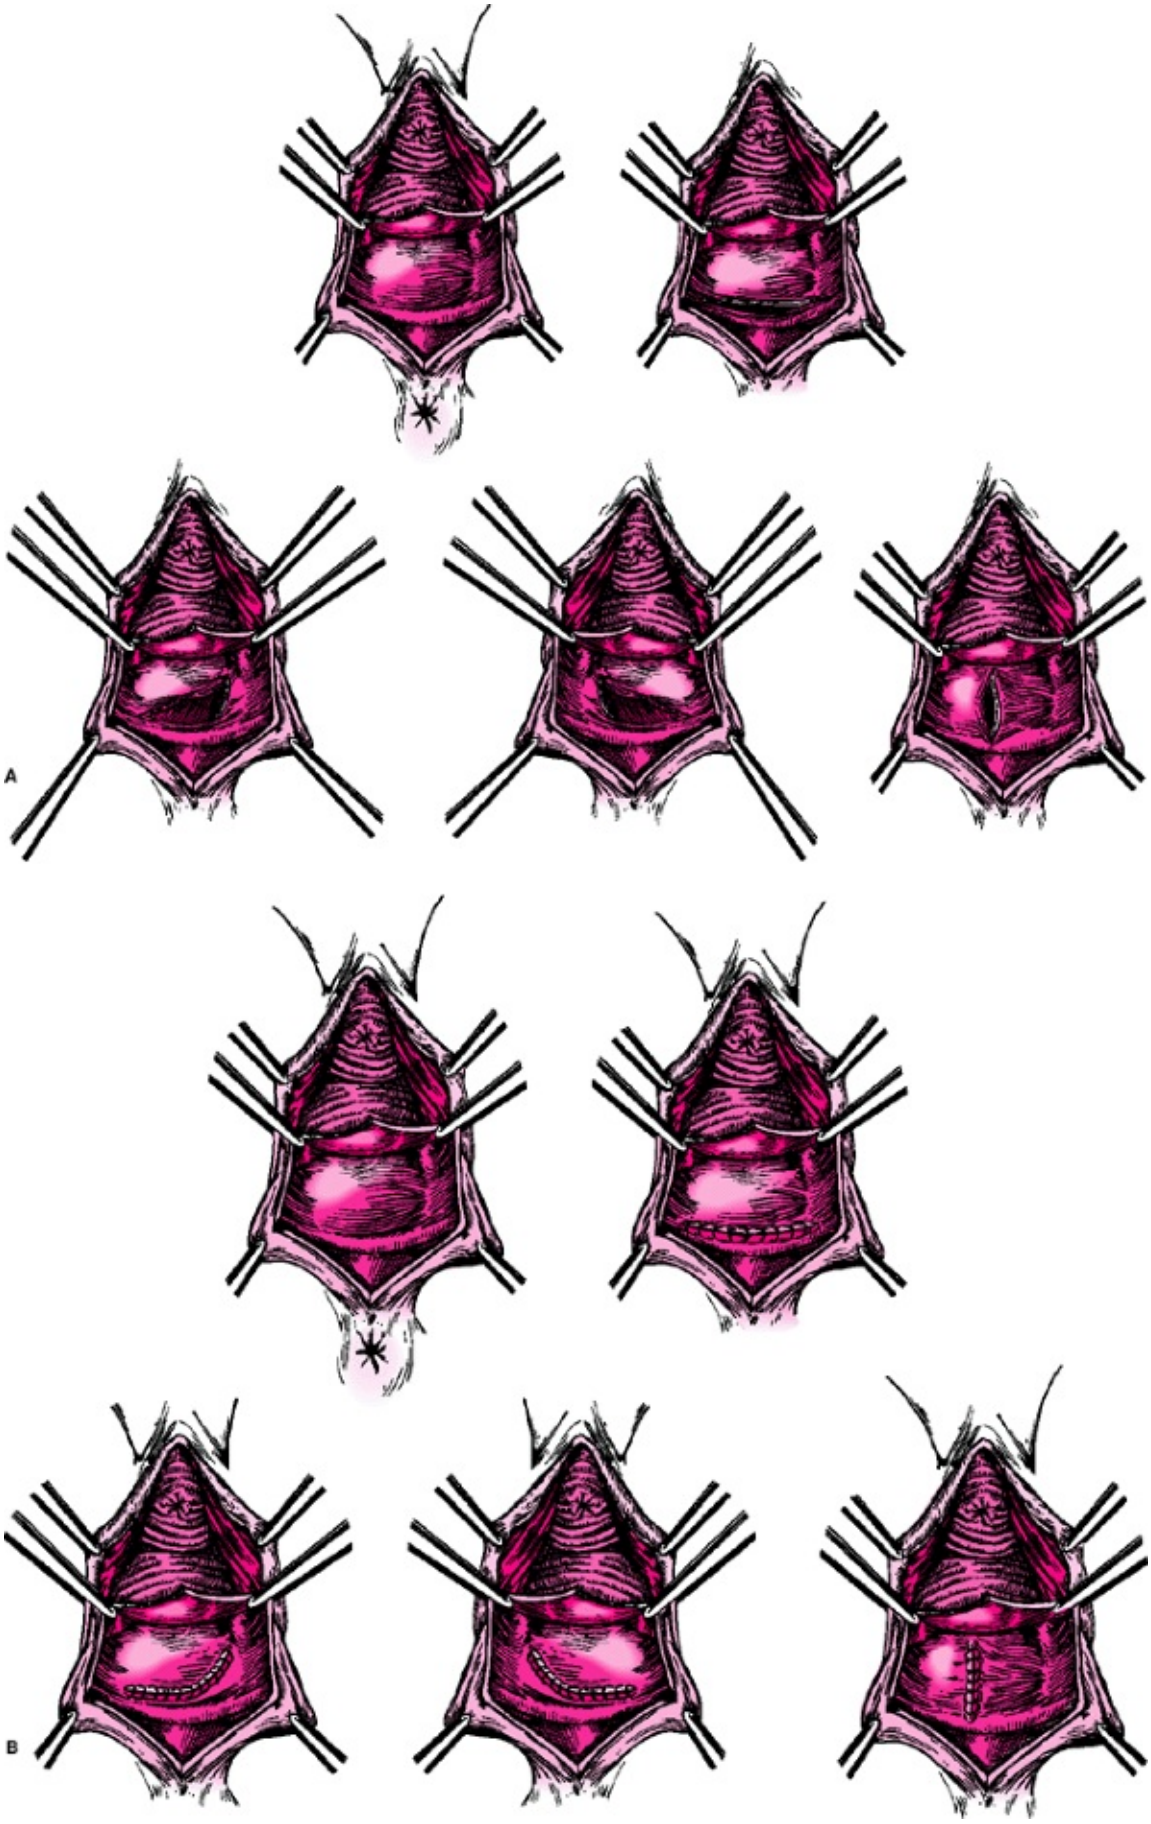

Figure 49.3 A: Musculo-connective tissue defects. **B:** Musculo-connective tissue repair.

Just as in anterior compartment procedures, the placement of graft materials to improve the success of posterior compartment repairs has been employed. Kohli and Miklos describe the use of a dermal allograft to augment

defect-directed repairs whereby the graft is sutured to the levator fascia on both sides of the defect to cover the rectovaginal plane. One concern about this technique is that in patients with relatively thin vaginal walls, removal of the fibromuscular tissue may devascularize the epithelium and make it more subject to erosion over the graft material. To improve the quality of vaginal epithelium in women with vaginal atrophy, patients in the authors' practice use vaginal for 4 to 8 weeks preoperatively. The initial surgical dissection is deep to the fibromuscular layer. Access to the lateral levator fascia is generally easily accomplished with a division of the Denonvilliers fascia at its incorporation into the posterior vaginal wall or, if the lateral attachment is not present, with combined sharp and blunt dissection to expose the paralevator fascia. This levator fascia on each side as well as any remaining lateral Denonvilliers fascia and occasionally muscle is incorporated into the edge of the graft with sutures. The posterior cephalad edge of the graft is attached to the anterior rectum at its sigmoid junction, and the anterior cephalad edge is attached to a well-suspended vaginal cuff. The caudad edge is incorporated in an appropriate repair of the perineal area. With short-term, mean follow-up of 12 to 30 months, overall results reveal good anatomic cure rates of 89% to 100% with cadaveric dermis, autologous dermis, polyglactin mesh, and polypropylene mesh. Improvement in obstipation has also been reported. Although the numbers of subjects assessed have been relatively low, de novo dyspareunia rates have been between 0% and 7%.

Transanal Rectocele Repair

The aim of transanal rectocele repair, usually performed by colorectal surgeons rather than gynecologists, is to remove or plicate redundant rectal mucosa, to decrease the size of the rectal vault, and to plicate the rectal muscularis, rectovaginal adventitia, and septum. Since the vaginal

epithelium is not incised or excised, this probably accounts for the procedure's reported lack of adverse affects on sexual function in contrast to the vaginal approach to posterior repair. Two randomized trials and several case series from transanal repairs with mean follow-up of 12 to 52 months report anatomic cure rates of 70% to 98%, improved constipation and fecal incontinence, and less need for vaginal digitation to expel stool. Complications included infections and rectovaginal fistulas, which were surprisingly rare in the reported series. From the gynecologic perspective, transanal posterior repair only makes sense when the procedure is performed for defecatory dysfunction and not for prolapse of the posterior vaginal wall. It is unclear whether the transanal approach with defect excision and repair improves defecatory dysfunction better than a defect-specific transperineal or transvaginal approach with imbrication of tissues to correct palpable weakness in the rectal wall and its adjacent connective tissues.

Apical Compartment

Apical vaginal prolapse encompasses the findings of uterine prolapse with or without enterocele and vaginal vault prolapse but typically with enterocele. Defects in apical support include the loss of cardinal–uterosacral support with resultant cervical–uterine or vaginal cuff descent; the detachment of the fibromuscular vagina from the anterior rectum with resultant enterocele or, at times, sigmoidocele into the rectovaginal space; and tears or attenuation of the upper fibromuscular tissue usually posthysterectomy, leading to a central apical descent that frequently presents as a ballooning defect. Often, these defects occur concurrently. The general principles of the repair should include management of the specific apical defects: (a) if present, the attenuated part of the upper vaginal wall (fibromuscular defect) should either be repaired or covered by graft material; (b) the vaginal cuff, or in some instances the cervix, should be suspended without excessive tension; and (c) any defect in the attachment of the upper vagina to the rectum at or below its sigmoid junction should be corrected. Enterocele repairs may include (a) removal of the peritoneal sac with closure of the peritoneal defect and then closure of the fascial and/or fibromuscular defect below it, (b) dissection and then reduction of the peritoneal sac and closure of the defect, or (c) obliteration of the peritoneal sac from within with transabdominal Halban- or Moschowitz-type procedures or transvaginal McCall or Halban procedures. Historically, the “standard” for the treatment for symptomatic uterine prolapse has been hysterectomy, which is performed vaginally or abdominally in combination with an apical suspension procedure and repair of coexisting defects.

Apical support procedures that have been described for use when the uterus or cervix is to be kept in place include the Manchester-Fothergill procedure, described later, and the Gilliam procedure, which suspended the uterus with the round ligaments. The latter has been abandoned due to high rates of failure. In addition, fixation of the cervix to the sacrospinous ligament, uterosacral ligament plication, and fixation of mesh from the cervix to the sacrum (mesh sacral hysteropexy) have been described. Adequate outcome data on such uterine-sparing procedures are not yet available. One randomized trial in Europe compared Gortex sacral hysteropexy to vaginal hysterectomy with uterosacral ligament suspension without mesh. The authors found higher failure rate and reoperation rate among the group who had uterine conservation with mesh sacral hysteropexy.

When the cervix is absent, it is the authors' opinion that in addition to repair of fibromuscular defects, both fibromuscular planes anterior and posterior to the vaginal cuff should be attached to whatever suspension is employed.

Enterocele Repair

Enterocele repair usually is performed in the setting of concomitant procedures for prolapse, more often as related to posterior compartment repair and apical repair. Whether by vaginal, abdominal, or laparoscopic access, the enterocele repair is traditionally performed by sharply dissecting the peritoneal sac from the rectum and bladder. A purse-string suture can be used to close the peritoneum as high (cephalad) as possible; whether excision of the peritoneum itself is necessary has not been determined. Care must be taken to identify and avoid the ureters during peritoneal closure. More important than closing the enterocele sac is approximating the anterior to the posterior

fibromuscular connective tissue of the vagina. Suspension of the vaginal apex is almost always necessary except in those rare cases when the enterocele occurs in the presence of adequate apical support.

Sacrospinous Ligament Suspension

The fixation of the vaginal apex to the sacrospinous ligament, the tendineus component of the coccygeus muscle, was first described in mid 20th century. Traditionally, access is extraperitoneal via the rectovaginal space with penetration of the pararectal (Denonvilliers fascia) at the level of the ischial spine to expose the muscle and ligament. The rectum and surrounding connective tissue typically are swept medially with blunt dissection, and visualization of the ligament prior to suture placement can be facilitated with the use of Breisky Navratil retractors. The authors typically use a delayed absorbable suture material such as polydioxanone placed with a Miya hook or free needle such that a long suture can be brought through the ligament, grasped, and cut, resulting in two sutures to incorporate into the vaginal apex (Fig. 49.4). Bilateral sacrospinous ligament suspensions have also been advocated; however, they may create a greater degree of tension on the sutures and at times create a band of apical vagina across the rectum at the level of the suspension. The advantages of the sacrospinous fixation procedure include (a) its transvaginal extraperitoneal approach, (b) resultant posterior vaginal deflection, and (c) the fact that it is a relatively durable repair if performed correctly. Reported success for apical support has

been good at approximately 97%, with follow-up times ranging from 1 month to 11 years. There have been subsequent reports of high rates of anterior vaginal prolapse. It is debatable as to whether this observation is due to the procedure and its exaggerated posterior vaginal deflection or due to other inherent factors for anterior prolapse in those subjects having the procedures. Other disadvantages cited by critics include relative difficulty in adequately exposing the ligament; an unnatural lateral vaginal deflection toward the fixation site; an inability to perform without excessive tension when the vaginal length is compromised, as may be the case in repeat procedures; potential risk for sciatic nerve or pudendal nerve or vessel injury; and occasional need to shorten or narrow the upper vagina when a fibromuscular defect involves much of the apical area. Additionally, some patients experience buttock pain that has been ascribed to entrapment of the nerve to the levator ani. Some of these problems are not unique to this procedure.

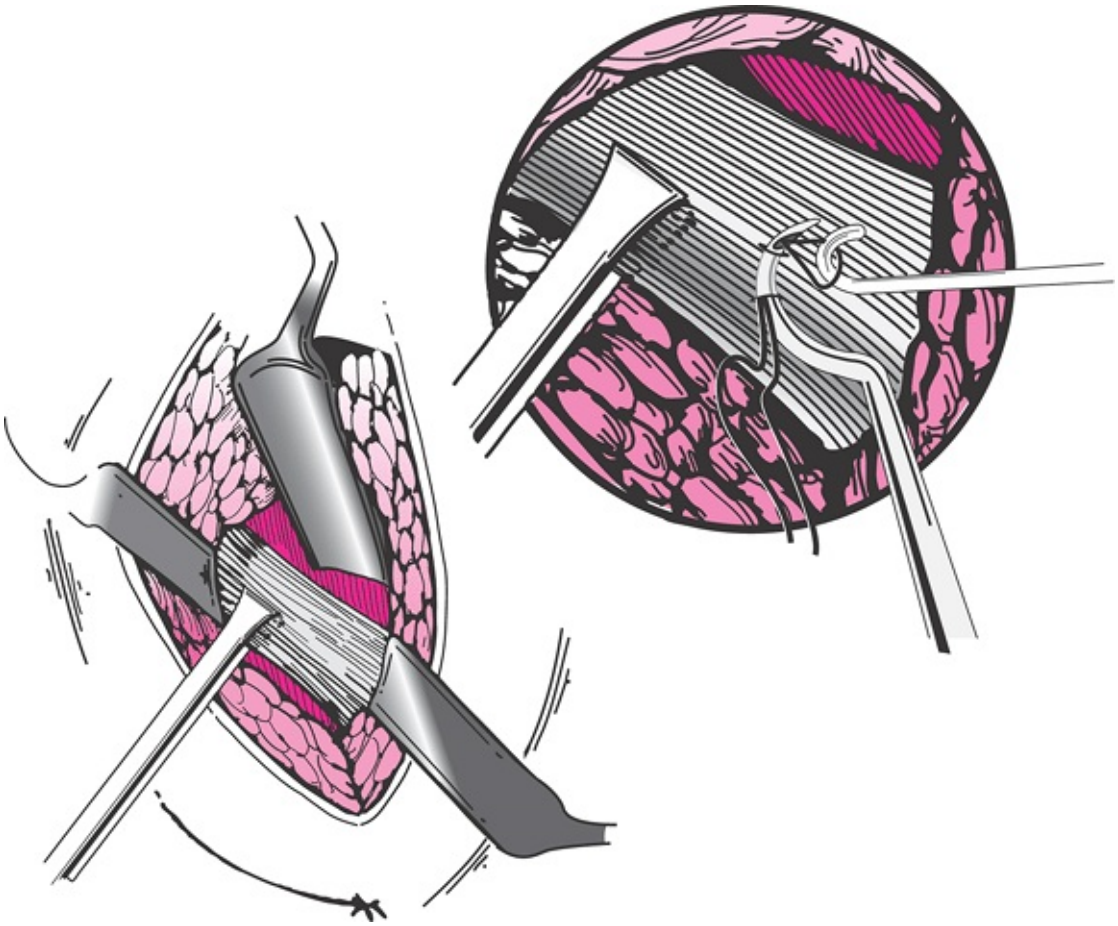

Figure 49.4 Penetration of the sacrospinous ligament. The right pararectal space has been entered, and the ischial spine palpated and identified. The use of 2 Breisky retractors can be helpful to hold the rectum medially and the cardinal ligament anteriorally. The coccygeus muscle-sacrospinous ligament complex running posteriomedially from the ischial spine to the sacrococcygeal area is exposed and grasped with a long-handled Allis or Babcock clamp as shown or delineated with the use of a notched half speculum. The tip of the ligature carrier is pushed under and upward through the ligament-muscle complex approximately 2 cm medial to the ischial spine. The suture is grasped with a nerve hook and held as the ligature carrier is removed.

Iliococcygeal Vaginal Suspension

The iliococcygeal vaginal suspension involves bilateral attachment of the vaginal apex to the iliococcygeus muscle and fascia. Extraperitoneal access is achieved via the posterior vagina. Briefly, the dissection of the area to the ischial spine is approached from a midline posterior vaginal wall incision by using the ischial spine as a landmark for identifying the sacrospinous ligament and the anterior iliococcygeal fascia and caudad to it. A no. 1 polydioxanone suture is placed through the fascia and attached to the vaginal apex as a pulley stitch. This procedure is more easily performed bilaterally than the sacrospinous suspension and should be considered particularly in the setting of a shortened vagina. Risk of major vessel, nerve, or ureteral injury should be relatively low compared with injury

found in other transvaginal suspensions.

Uterosacral Ligament Vaginal Vault Suspension

Surgical variations of the uterosacral ligament suspension originally described by McCall have been used prophylactically at hysterectomy or therapeutically for vaginal apical suspension. The original McCall culdoplasty begins with the placement of several rows (on average, three rows, with each row superior to the previous) of nonabsorbable suture ("internal" McCall sutures) starting at the left uterosacral ligament approximately 2 cm above its cut edge and reefing across the redundant cul-de-sac to the right uterosacral ligament. Prior to tying, three "external" absorbable sutures are placed incorporating the posterior vaginal epithelium, uterosacral ligaments, and the contralateral vaginal epithelium in a mirror image to the first pass through the vagina. Multiple rows are placed each superior to the last to move the cuff to the highest point on the uterosacral ligament. In 2000, Shull and colleagues described a therapeutic procedure in which the vaginal t apex is suspended to the uterosacral ligaments above the level of the ischial spines and reported excellent success rates in a large observational study. Once access to the posterior cul-de-sac has been attained, the uterosacral ligament remnant can usually be found adjacent to the pelvic side wall peritoneum just cephalad to the palpable ischial spine. Shull described placement of up to three sutures in each ligament and incorporated into the anterior and posterior fibromuscular layer of the vagina. Other surgeons suspend the right and left vaginal apex to the ipsilateral uterosacral ligament, leaving the cul-de-sac open to avoid impinging on the rectum and adversely affecting bowel function.

The most common serious complication has been ureteral obstruction secondary to ureteral kinking or incorporation of a ureter in a suspension stitch. This has been shown to occur in up to 11% of cases. Therefore, intraoperative cystoscopy with documentation of ureteral patency after administration of indigo carmine dye is recommended. Aronson and associates emphasize placement of the sutures deep toward the sacrum, along the posterior segment of the ligament, rather than cephalad. In the lithotomy position, this caution may reduce risks of ureteral injury. Their series had a low rate of injury.

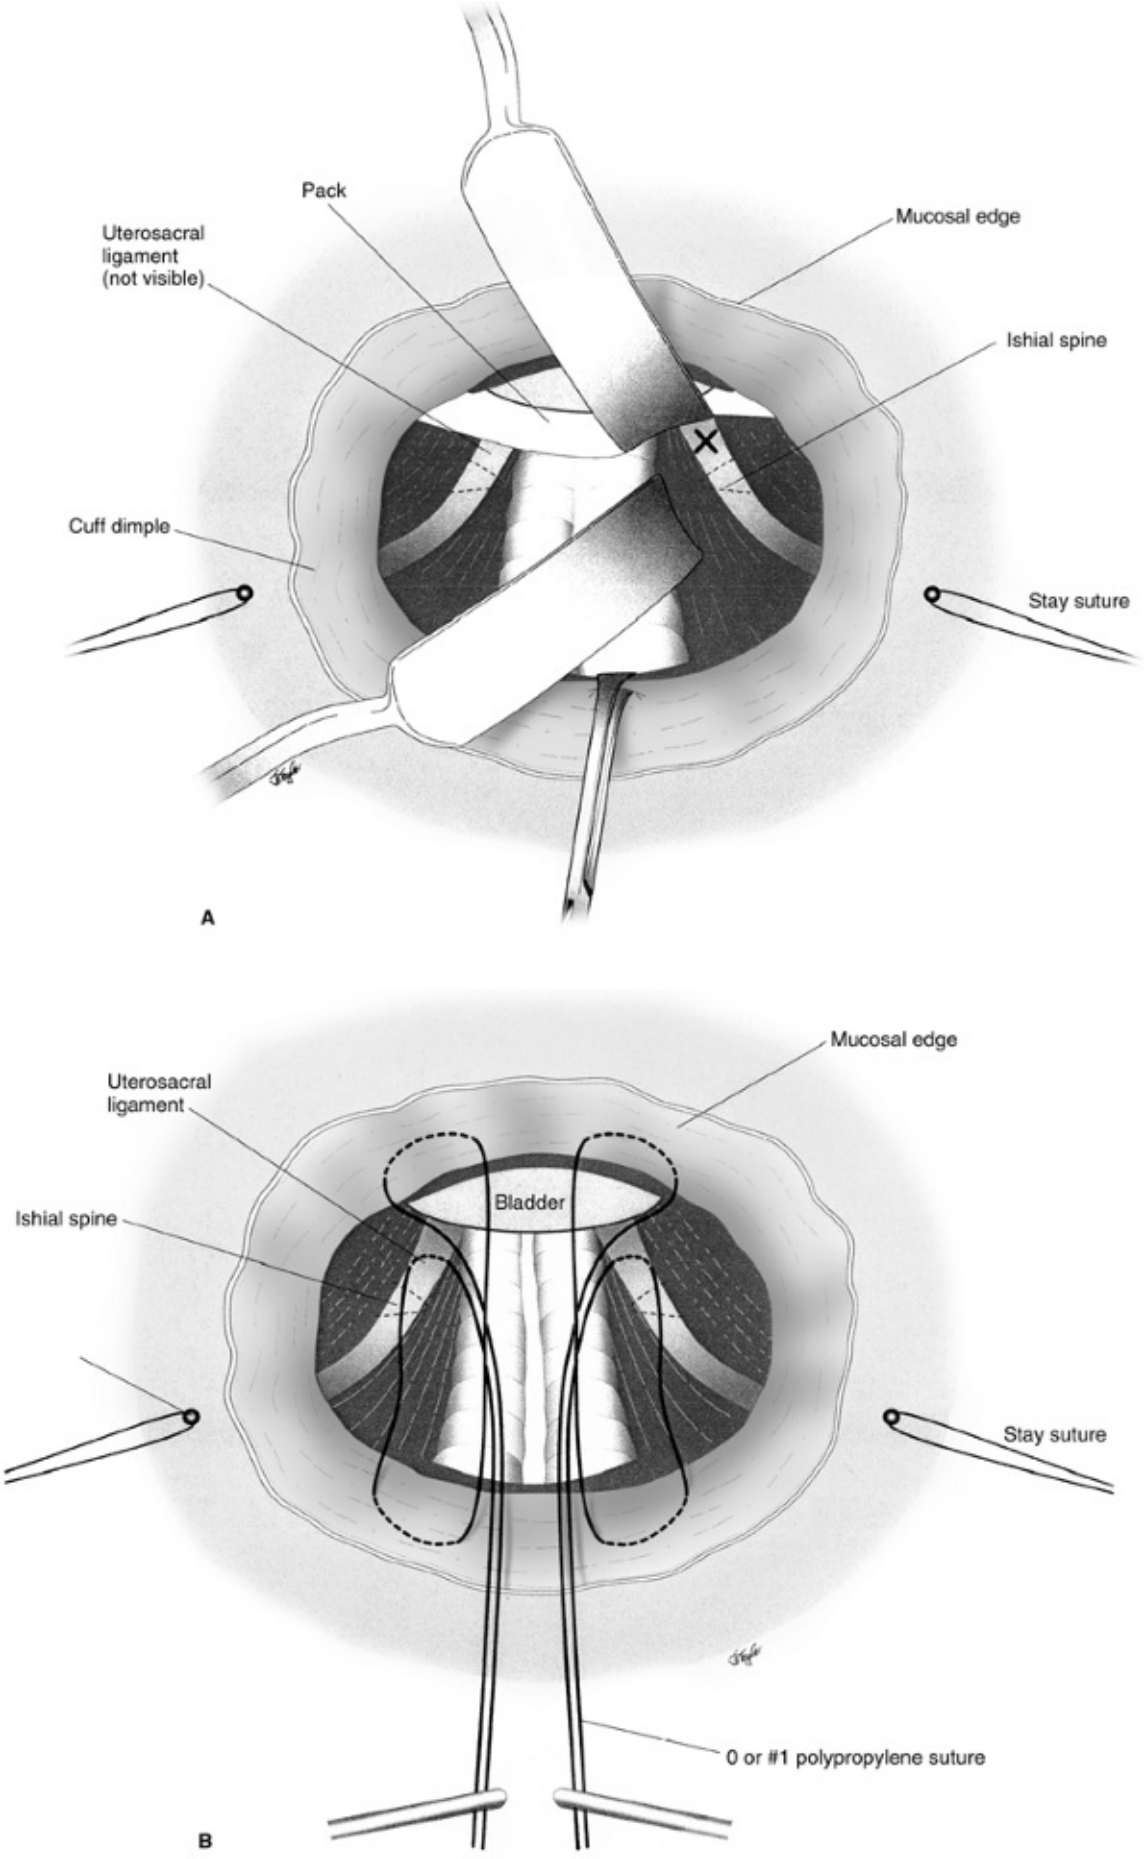

Figure 49.5 Diagrams illustrating open vaginal apex with a modification of the high uterosacral vaginal suspension described by Shull, whereby single monofilament permanent sutures are placed through the residual uterosacral remnants cephalad to

and at the same posterior level of the iscial spines. **(A)** exposure of site to suture placement on lateral pelvic sidewall. **(B)** Suture placement through ligament and then through the posterior and anterior paravaginal tissue where they may be locked to enable pulley action to the ligaments when tied. (Reproduced with permission from Berek JS. *Berek and Novak's Gynecology*, 14th ed. Philadelphia: Lippincott Williams & Wilkins, 2007.)

The authors have employed a modification of Shull's technique to minimize complications of ureteral kinking and injury and the number of sutures and knots present at the vaginal apex. It is thought that, at times, multiple sutures may increase the incidence of tissue devascularization and necrosis—thus, failure of the suspension. Exposure is accomplished through the vaginal cuff after hysterectomy, a transverse incision at the vaginal cuff in cases of vaginal vault prolapse or descent, and rarely through a posterior colpotomy when uterine or cervical conservation is desired. Attenuated areas of the apical vaginal wall are excised. The pelvic side wall, lateral to the sigmoid colon, is exposed by using Breisky Navratil retractors and a pack to

hold the small bowel cephalad and to place the sigmoid colon and side wall peritoneum on stretch (Fig. 49.5A). After palpation of the ischial spine, single permanent sutures of no. 0 or no. 1 polypropylene are placed through the peritoneum and adjacent uterosacral ligament approximately 1 cm cephalad to and at the same posterior level as the ischial spines. Traction on the sutures and palpation of the site should reveal good purchase of the ligamentous structures. The sutures are tagged for use after repair of defects of the anterior compartment. The peritoneum is dissected off the vaginal fibromuscular wall posterior to the vaginal cuff. The suspension sutures are then secured with large bites into the posterior vaginal fibromuscular tissue and anterior fibromuscular tissue and then locked in place in order to well approximate anterior to posterior connective tissue and to fix the suture to the vaginal apex so that it may be pulleyed up to the ligament (Fig. 49.5B). If a rectovaginal enterocele is present, it is dissected and reduced, and the defect is closed approximating the prerectal fascia or anterior rectal wall to the posterior fibromuscular vaginal tissue just caudad to the suspension sutures. Absorbable cuff closure sutures are placed at each cuff angle (usually no. 0 polyglactin), and one to two bites are taken to approximate anterior-to-posterior vaginal cuff over the suspension suture sites. When indicated, plication of the central cuff anterior to the posterior fibromuscular tissue with a box stitch is also performed. These sutures are secured after the suspension (pulley) sutures are tied, then cuff closure is completed from each side with the absorbable sutures in a running fashion. Cystoscopy is performed to document ureteral patency. Ureteral compromise has been noted in only 2 of 150 cases performed. The authors have also found adequate support of POP-Q point C and D in all 88 subjects evaluated 24 months postoperatively by an unbiased observer.

Manchester-Fothergill Procedure

There are several options to preserve the uterus with prolapse repairs at the apex,

including shortening the uterosacral ligaments as a vaginal, open, or laparoscopic approach and mesh or other biomaterial suspension of the cervix to the sacrum. The Manchester-Fothergill procedure, first performed in 1888, is primarily of historic interest but continues to be done in some parts of the world. For this procedure, the vaginal wall is dissected off of the cervix around its circumference. The elongated cervix is

amputated and then the cardinal ligaments are ligated and sutured over the anterior cervical stump. The procedure is summarized by Skiadas and associates and, for the interested reader, includes photographs of the procedural steps.

Abdominal Approaches

Anterior Compartment

Anterior Abdominal Colporrhaphy

A high central defect may also be corrected via a transabdominal approach by dissecting between the base of the bladder and the upper one third of the anterior vaginal wall. The defective tissue may then be wedged out and the defect closed with running or interrupted sutures. This may be of use when performing a transabdominal procedure for apical suspension.

Paravaginal Repair

The paravaginal or “lateral defect” repair described first by White and reintroduced by Richardson and Edmonds involves reattachment of the anterior lateral vaginal sulcus to the obturator internus fascia and, at times, muscle at the level of the ATFP. It usually is performed as a bilateral procedure. The procedure, in a sense, restores normal anatomy; however, since it is not practical to rebuild the defective endopelvic–fascial bridge to the pelvic sidewall, it attaches the vaginal wall itself. Previous work has shown that most subjects with anterolateral detachments almost always have separation of the upper vaginal fornices from the arcus tendineus immediately adjacent to the ischial spine. Thus, it is important to resuspend those specific areas.

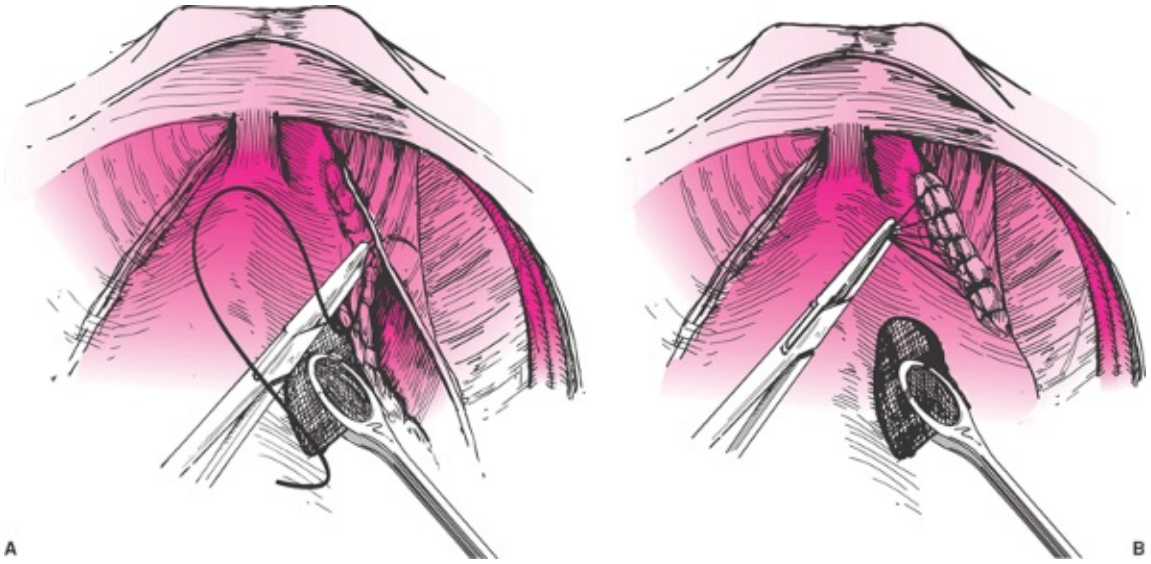

Figure 49.6 Open paravaginal defect repair. The paravaginal musculo-connective tissue was separated from the arcus tendineus fascia pelvis from the inferior pubic ramus to the ischial spine. **(A)** With a finger elevating the vagina, a full thickness bite of pubocervical connective tissue and partial vaginal wall are incorporated into the arcus **(B)** Completed procedure.

After entry into the retropubic space, careful blunt dissection is performed to mobilize the bladder, urethra, and paravaginal tissue. A Foley catheter helps to delineate the urethrovesical junction. The ATFP is identified along the obturator internus muscle from the inferior pubic ramus to the ischial spine as the bladder is reflected medially with a sponge stick. The nondominant hand is placed in the vagina to elevate the lateral superior vaginal sulcus, and a permanent suture is used to reattach the vaginal sulcus with its overlying fibromuscular connective tissue to the ATFP. The first stitch is usually placed 1.0 cm caudal to the ischial spine, with subsequent sutures placed 1.0 to 1.5 cm apart. The procedure is performed bilaterally as needed (Fig. 49.6). After all of the sutures are placed, they are tied and cystoscopy is performed.

Posterior Compartment

Mesh Abdominal Sacral Colpoperineopexy

When ASC is planned for apical vaginal prolapse and a concomitant rectocele is present, some have advocated extending the posterior graft arm down the posterior vaginal wall to correct the defect. Cundiff and coworkers described the technique of sacral colpoperineopexy to replace the normal vaginal suspensory ligaments and to augment or replace the posterior fibromuscular plane with graft material that runs from the sacrum to the perineal body. Its purpose is to both correct the posterior compartment defects and to suspend the perineal body, thus preventing descent and opening of the genital hiatus. It has been performed transabdominally or as a combined abdominal

and vaginal procedure with both Mersilene mesh and dermal allografts. Mesh erosion occurred frequently when the vagina was open (40% with transvaginal placement of mesh and 16% with transvaginal placement of sutures).

Apical Compartment

Uterosacral Ligament Suspension

Abdominal uterosacral colposuspension has been used prophylactically after hysterectomy and therapeutically for apical prolapse with cardinal–uterosacral defects. It can be performed through laparotomy incision or by laparoscopic techniques. For the therapeutic procedure, a no. 1 polypropylene or delayed absorbable suture is placed cephalad and at the same level posterior as the ischial spines, which may be palpated transabdominally or with a vaginal finger to push a vaginal fornix to the spine. The authors' technique has been to place one or two permanent sutures through one ligament, then, after reefing across the cul-de-sac peritoneum at the sigmoid border, through the contralateral ligament, then through the fibromuscular tissue just anterior to the vaginal cuff from each end of the suture, creating a box-type configuration. Tying the suture suspends the vaginal cuff and obliterates any enterocele defect. Another technique employs separate sutures placed at the same level into each uterosacral ligament and anchored to the ipsilateral side of the anterior and posterior vaginal cuff—similar to transvaginal procedures performed. If a uterus is in place, it can be tracked superiorly to more clearly delineate the ligamentous structure; if a cuff is present, an end-to-end anastomosis (EEA) sizer can likewise be utilized. Cystoscopy is performed after the procedure to document ureteral patency. The authors are unaware of outcome data on large series of subjects who have undergone such procedures.

Abdominal Sacral Colpopexy

ASC uses graft material attached to the anterior and posterior vaginal apex and suspended to the anterior longitudinal ligament of the sacrum. Different graft configurations and materials have been utilized, and numerous other modifications exist, including the extent to which the anterior and posterior vagina are attached to the graft, different graft and suture materials, peritoneal closure over the graft, and obliteration of the cul-de-sac for treatment or prevention of enterocele. Cure rates range from 78% to 100% for apical prolapse; when cure is defined as no postoperative prolapse, the range widens from 56% to 100%.

The peritoneum overlying the vaginal apex is removed and macroporous polypropylene mesh, fashioned in a Y configuration (or two separate layers), is affixed to the posterior vaginal apex at the rectovaginal junction and to the anterior vaginal apex at the bladder reflection. Two permanent sutures are then used to affix the mesh to the anterior longitudinal sacral ligament (Fig. 49.7). No overt tension is placed on the vagina while attaching the mesh to the anterior sacral ligament. The authors reperitonealize over the mesh. In the setting of a deep cul-de-sac, Halban culdoplasty sutures with no. 1 polydioxanone are placed. Cystoscopy is performed at the end of the procedure.

The most common complications associated with performing a sacral colpopexy include bleeding and graft erosion. Intraoperative hemorrhage that occurs when lacerated sacral veins retract into the sacrum can be difficult to control; the use of hemostatic sutures, pressure, and bone wax has been found to help manage this potential complication. Other options for management of bleeding of presacral veins include applying sterile thumbtacks into the bone to tamponade the veins. It is helpful to apply bone wax under the rim of the tack. More recently, a technique has been described by several authors where a small 1-cm piece of rectus abdominus muscle is harvested and placed over the bleeding veins and then electrocautery is applied. The authors have used this technique with excellent success and find it preferable to other options, as it reduces risks of creating new bleeding sites. Synthetic graft material holds the highest risk of infection or erosion, although these complications have been reported with all types of graft material. As with small bowel obstruction, mesh erosion or infection has been reported years after the index surgery. While mesh erosion usually can be treated successfully with a relatively minor transvaginal excision of the exposed mesh, the entire graft occasionally must be removed with high levels of potential surgical morbidity. The risk of erosion ranges from approximately 3.5% to 9.0%. Other complications associated with the procedure are those associated with laparotomy, including postoperative ileus, small bowel obstruction, and the development of intra-abdominal adhesions.

Laparoscopic Approaches

Laparoscopic approaches to treat POP were first introduced in 1992. The decision to use a laparoscopic approach must be partly directed by the surgeon's skill, but the authors' goal with laparoscopic repairs is to try to perform the same procedure that would be performed via an open approach. It is common for pioneers in laparoscopic procedures to change the overall technique for established open laparotomy procedures. Any change in technique, however, such as introducing anchoring screws or changing suturing locations or mesh applications may change the outcome. Outcomes may not be comparable and should ideally be tested with randomized trials. To date, there are no such trials available, and thus the high success rates reported with an open sacral colpopexy may not be recognized with a laparoscopic approach. There is one randomized trial comparing laparoscopic rectopexy with open rectopexy with favorable outcomes and earlier hospital discharges in the laparoscopic cohort.

For positioning in laparoscopic repairs, the table height should be adjusted as low as possible during laparoscopic

suturing. This allows for the surgeons' shoulders to be in a more normal resting position. The patient is positioned in low lithotomy with adjustable boot-type stirrups (Fig. 49.8). Lithotomy positioning is important to allow access to the urethra, vagina, and rectum.

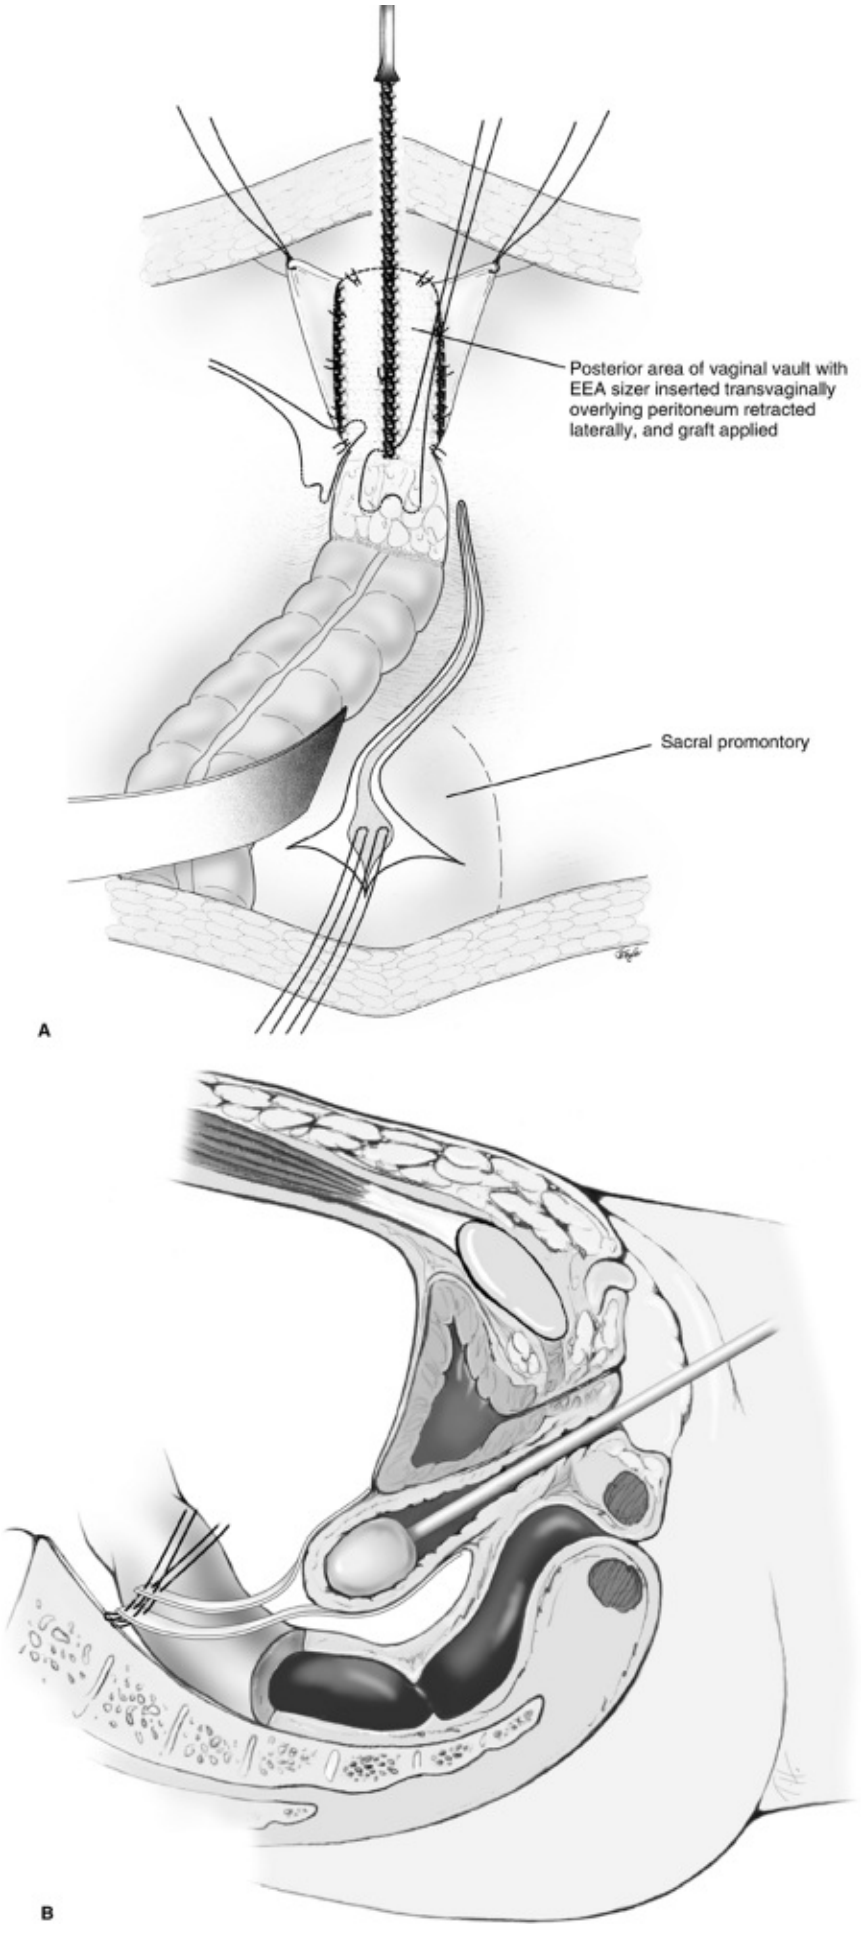

Figure 49.7 Sacrocolpopexy. **(A)** Illustration of (i) graft attachment to the posterior area of prolapsed vagina to or below the recto-sigmoid junction after the overlying

peritoneum has been dissected and flapped laterally (ii) exposure of the presacral space with permanent suture placement through the anterior sacral ligament. A second graft is placed anteriorly. **(B)** Attachment of both grafts to the sacrum without tension. Closure of the cul-de-sac peritoneum and graft reperitonealization is performed per surgeon preference. EEA, end-to-end anastomosis sizer. (Reproduced with permission from Berek JS. *Berek and Novak's Gynecology*, 14th ed. Philadelphia: Lippincott Williams & Wilkins, 2007.)

The location of trocar placement for complex laparoscopic surgery is important to optimize suturing. The authors use three 5-mm ports and one 10-mm port (Fig. 49.9). One 5-mm port is placed at the umbilicus. The 10-mm port is placed on the primary surgeon's side and is the port of entry for the needles and suture. If both surgeons are introducing and tying needles, two lateral 10-mm ports can be used. An alternative to using a 10-mm port is to use a 5-mm port. By back-loading the suture, a 5-mm port can be utilized rather than a 10-mm port, but the authors find this approach too time-consuming because this requires removal and reinsertion of the port with each suture. Two accessory 5-mm ports are placed, including one lateral port on the assistant's side and the other either on the operating surgeon's side or in the midline. This port allows the operating surgeon to retrieve sutures and grasp tissues.

Anterior Compartment

Laparoscopic Paravaginal Defect Repair

A paravaginal repair can be performed as an open procedure, a transvaginal approach, or via the laparoscope. Purported advantages of an abdominal approach include lack of disruption of the neurovascular supply at the anterior vagina, but this concern remains theoretical. The authors find that the laparoscopic paravaginal repair is technically more challenging than other laparoscopic repairs,

including laparoscopic sacral colpopexy. The difficulties with laparoscopic paravaginal repairs stem partly from the limitations of the bony pelvis angles coupled with long laparoscopic suturing instruments. These confines make suturing more challenging than open paravaginal repairs or laparoscopic mesh sacral colpopexy.

The authors perform paravaginal repairs with an intraperitoneal laparoscopic approach. Once the ports are placed, the peritoneum above the dome of the bladder is incised in the midline. A transverse incision is carried bilaterally to the obliterated umbilical artery. Filling the bladder retrograde can be helpful in determining the proper plane. The three-dimensional shape of the bladder dome can be difficult to appreciate with two-dimensional imaging. The tendency for the dissection to drift in a posterior direction should be avoided to avoid bladder dome injury. Once the proper plane is identified, the dissection is carried through the loose adventia easily. As the peritoneal incision is established, the insufflating gas often distends this space well and helps to delineate the structures. Dissection can

proceed bluntly or sharply. Care is taken to avoid anterolateral dissection in the region of the obturator canal. Once the space of Retzius is exposed (from the anterior pubovesical attachments adjacent to the pubic symphysis to the posterolateral ischial spine), the extent of the defect is assessed. Using a vaginal finger to elevate the vaginal at the defect, interrupted sutures are place from the lateral ATFP to the fibromuscular layer of the vagina medially. Sometimes, there is not much supportive ATFP left overlying the obturator internus muscle and fascia. In this case, there usually is strong connective tissue adjacent to the ischial spine. Alternatively, sutures can be placed in the obturator internus fascia. Approximately four to five interrupted no. 2–0 braided polyester (Ethibond, Ethicon, Somerville, NJ) or other permanent suture are placed on each side. The authors tie the sutures with an extracorporeal knot. The medial bite is more anterior, and the lateral bite is posterior and cephalad to help provide both lateral and apical

support. Once the sutures are placed and tied, irrigation is performed. After assuring hemostasis, a Burch retropubic urethropexy can also be placed laparoscopically. The data suggest that the stress incontinence outcomes may not be as good with a laparoscopic Burch approach when compared with that achieved by an open approach.

Figure 49.8 Laparoscopic positioning for pelvic support defects. The arms at both padded and then tucked at the sides. The legs are wrapped with knee-high intermittent pneumatic compression stockings and positioned in adjustable hydraulic boot stirrups. The table height is adjusted to its lowest position and the legs are positioned low so that the thighs will not inhibit the laparoscopic instruments.

Once the space of Retzius is irrigated, the authors close the space with peritoneal closure. Some centers leave this space open, but this closure is preferred to prevent herniation of bowel. A purse-string closure of the peritoneum is run by using a monofilament delayed absorbable suture.

Posterior Compartment

Laparoscopic Mesh Sacral Colpoperineopexy

As described previously for open ASC, some centers have advocated laparoscopic attachment of the perineal body to laparoscopically placed sacral colpopexy mesh. There has been a higher rate of mesh erosion reported when comparing historical controls, although true comparison studies are lacking. The technique described includes opening the posterior vagina, affixing mesh to the perineal body, and then retrieving the mesh via laparoscopy to attach to the sacrum.

Apical Compartment

Laparoscopic resuspension of the vaginal apex can be performed by shortening the uterosacral ligaments or with sacral colpopexy. The choice of suture and technique can be very similar to that described for open or vaginal repairs.

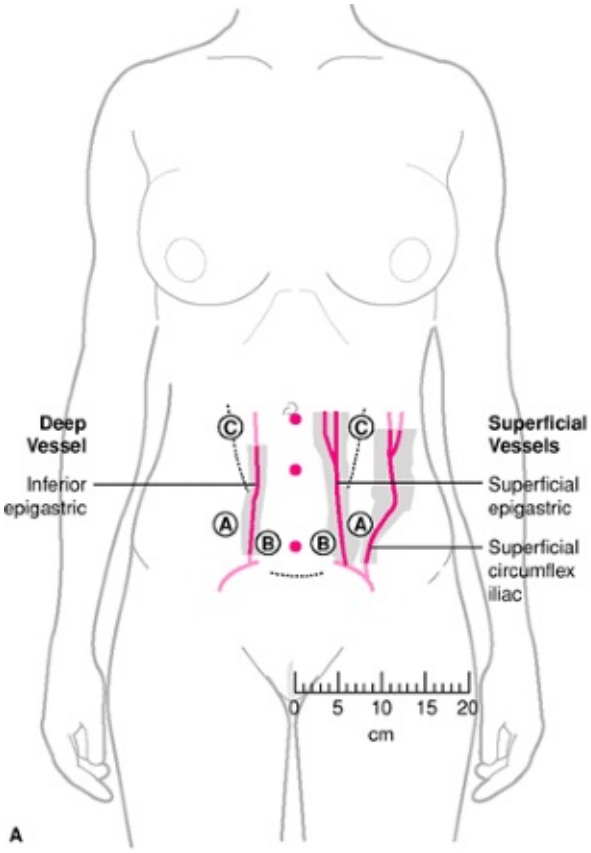
Laparoscopic Mesh Sacral Colpopexy

Mesh sacral colpopexy via the laparoscope requires a skilled laparoscopist who is facile at laparoscopic suturing. The overall technique is similar to that of an open procedure.

Positioning is as described previously, but left lateral tilt is often helpful to rotate the rectosigmoid away from the sacral promontory. Dissection begins at the sacral promontory after first assuring that there are no pelvic or abdominal abnormalities that need to be addressed on laparoscopic survey. The avascular spaces are utilized to sharply or bluntly expose the anterior longitudinal ligament of the sacral promontory. The authors choose to start at the promontory, as this is the region that is at most risk for bleeding. At this step, if uncontrollable bleeding ensues due to iliac, middle sacral, or presacral bleeding, conversion to laparotomy should rapidly be considered. Weislander and colleagues recently reviewed the presacral vascular anatomy. The vascular structures of most concern include (a) the left iliac vein, which is not protected by the artery as it is on the right side; (b) the middle sacral vessels; and (c) the presacral venous plexus. By isolating the deeper dissection to the sacral promontory rather than attempting to expose the anterior longitudinal ligament at lower levels, injury to the presacral veins is unlikely.

The right ureter, iliac vessels, and colon should be identified prior to incision. The peritoneum over the sacral promontory is elevated and incised with scissors. Alternatively, electrodissection (or a harmonic scalpel) can be utilized, but the authors prefer to reduce risks of thermal damage by using sharp dissection. The peritoneal incision is carried into the pelvis, lateral to the rectum but medial to

the right ureter. Once the peritoneal incision is completed, it can be valuable to run a suture along the medial side of the peritoneum and sometimes through epiploica. The suture can then retract the rectum medially out of the field by exiting it through a separate small stab incision. The suture ends are retrieved through the stab incision in the skin by using a fascial closure device. The suture can then be against the anterior abdominal wall (which is protected by a moistened sponge) on mild tension using a hemostat.



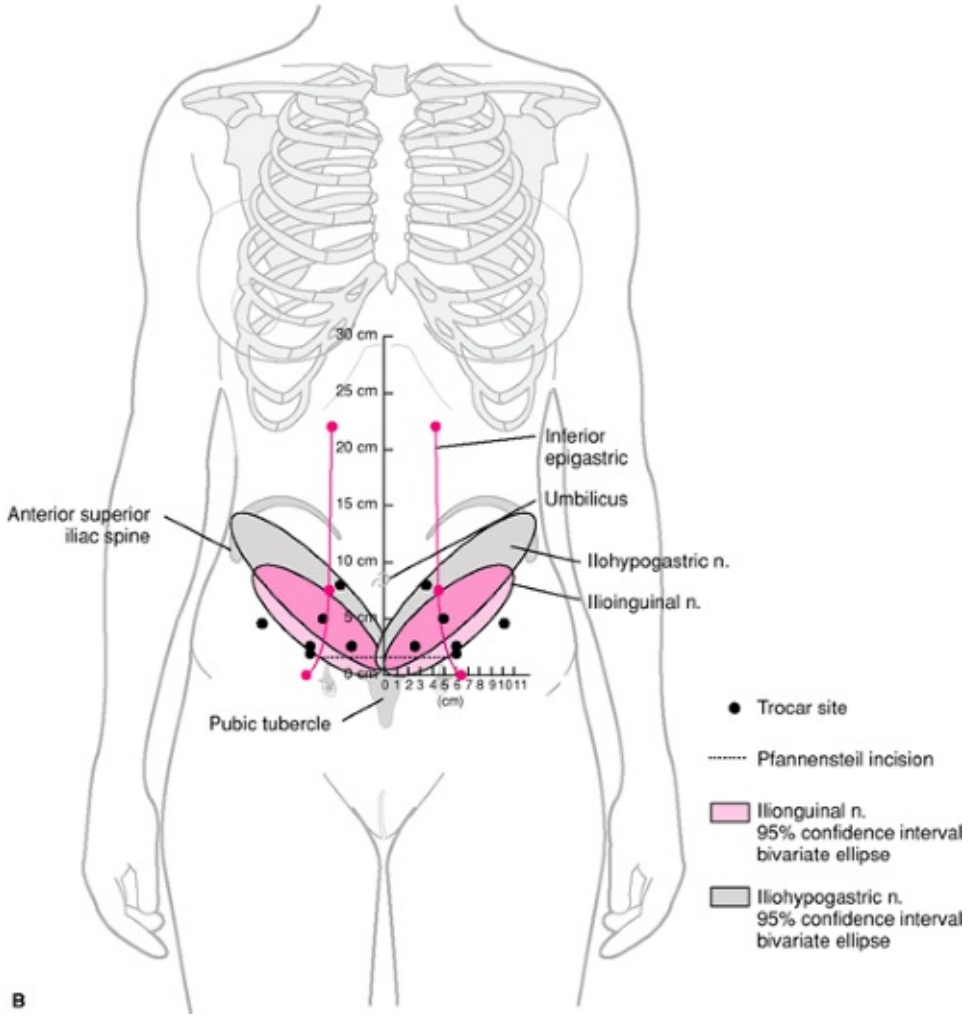


Figure 49.9 Laparoscopic port placement options for pelvic support defects. **A:** The position of the lateral ports should be at or above the level of the anterior superior

iliac spines to avoid injury to the ilioinguinal and iliohypogastric nerves. (Reproduced with permission from Whiteside JL, Barber M, Walters M, et al. Anatomy of ilioinguinal and iliohypogastric nerves in relation to trocar placement and low transverse incisions. *Am J Obstet Gynecol* 2003;189(6):1574–1578.) **B:** The inferior epigastric vessels should be identified bilaterally as they initiate just cephalad and lateral to the junction of the round ligament and the obliterated umbilical artery; identification at this location facilitates location of the more cephalad vessels by tracing them upward. The superior epigastric vessels can often be identified by transillumination in thin patients. (Reproduced with permission from Hurd WW, Bude RO, DeLancey JO, et al. The location of abdominal wall blood vessels in relationship to abdominal landmarks apparent at laparoscopy. *Am J Obstet Gynecol* 1994;171(3):642–646.)

Next, dissection of the rectovaginal is initiated. With a probe in the vagina and another in the rectum, the proper plane can be established. The authors utilize EEA sizers, with a small sizer placed in the rectum and a large placed in the vagina. This space is dissected prior to the anterior vesicovaginal space to avoid obstructing the view if there is bleeding at the anterior site. Sharp dissection is utilized, and the dissection can often proceed down to the lower half of the posterior vagina via the rectovaginal space. Care should be taken to avoid straying laterally with the dissection to avoid bleeding.

The vesicovaginal space is then dissected in a similar fashion and with careful attention to be sure that the bladder is dissected away anteriorly. If the plane of dissection is difficult to develop, then retrograde filling of the bladder can be helpful.

The authors utilize two leaves of polypropylene macropore mesh fashioned from a 10 ×15 cm piece (Gynemesh, Ethicon, Somerville, NJ). Occasionally, a larger-length piece is desired to be able to reach from low on the posterior vagina to the sacral promontory. The first leaf of mesh is attached to the posterior vagina. By manipulating the vaginal probe so that the tip of the probe is directed toward the rectum, the most distal suture can be placed far down the rectovaginal septum. The mesh is then threaded over the suture and guided into the pelvis and tied in place. At least six permanent monofilament no. 2–0 polypropylene (Prolene, Ethicon, Somerville, NJ) or Gortex (W. L. Gore & Associates, Flagstaff, AZ) sutures are then placed through the mesh and into the vaginal wall to secure it. (Fig. 49.10).

A second leaf of mesh is then attached to the anterior vagina in a similar fashion. If a concomitant hysterectomy has been performed, then the sutures attaching the mesh should not be placed near the cuff closure to avoid future mesh erosion.

At this point, both leaves of the mesh are brought back to the sacral promontory, and a determination of the appropriate tension is made. Ideally, there should be little tension on the mesh so that it follows the curve of the sacrum to some extent. The authors adjust the tension by finding a location on the mesh that will allow the mesh to be slack with pressure on the EEA vaginal probe but with tension taken up slightly with the probe removed. Two permanent no. 2–0 sutures are passed through the mesh and then through the anterior longitudinal ligament at the sacral promontory.

The authors prefer extracorporeal knot tying, as it has been found that this approach is faster than intracorporeal knot tying. There are disadvantages to extracorporeal knot tying, however, in that there is more leakage of the insufflation gas. Therefore, a properly functioning and self-sealing trocar is imperative.

Laparoscopic Uterosacral Ligament Suspension

While uterosacral ligament suspension is commonly performed via a vaginal approach, purported advantages of the laparoscopic approach to uterosacral ligament suspension include direct visualization of the ureters and bowel. Additionally, lysis of adhesions can be performed with improved visualization. Disadvantages include greater risks for bowel injury with port placement, greater discomfort, and the potential for more adhesions.

Trocar placement is similar to that described previously for laparoscopic mesh sacral colpopexy. After survey of

---

the abdomen and pelvis, identification of both ureters is imperative. The uterosacral ligaments normally attach from the upper vagina and cervix back to the lateral sacrum at the S2–3 level. The uterosacral suspension sutures are placed in the proximal third of the ligament, where it is broader. Care must be taken to identify the ipsilateral ureter and rectum prior to and during placement of the sutures. The first suture of no. 2–0 polypropylene or braided polyester is placed through the middle segment of the ligament and then into the ipsilateral vaginal cuff. A second suture is placed in the more proximal (sacral) portion of the ligament and into the medial ipsilateral cuff (Fig. 49.11). Injury to the rectum is avoided by placing a small EEA sizer and mapping out the location of the rectum prior to placing the sutures. The contralateral sutures are placed in a similar fashion. At times, it is helpful to incise the peritoneum medial to the ureter but lateral to the rectum to be sure that these structures are not at risk.

Once the sutures are tied, cystourethroscopy should be performed to assure normal bladder integrity and ureteral patency, as described elsewhere.

Obliterative Procedures

In selected patients, an obliterative procedure may be offered rather than a reconstructive procedure. The success

---

---

of obliterative procedures has been reported to be in the 90% to 95% range, with variable follow-up. However, obliterative procedures usually are reserved for patients with significant comorbidities who are not interested in retaining a vagina for sexual relations. There is an approximate 10% risk of regret following colpocleisis procedures, thus counseling of options and discussing potential future life changes, including loss of a current partner, and/or gaining a new partner, is important. An excellent review of colpocleisis was recently written by Fitzgerald and associates in 2006.

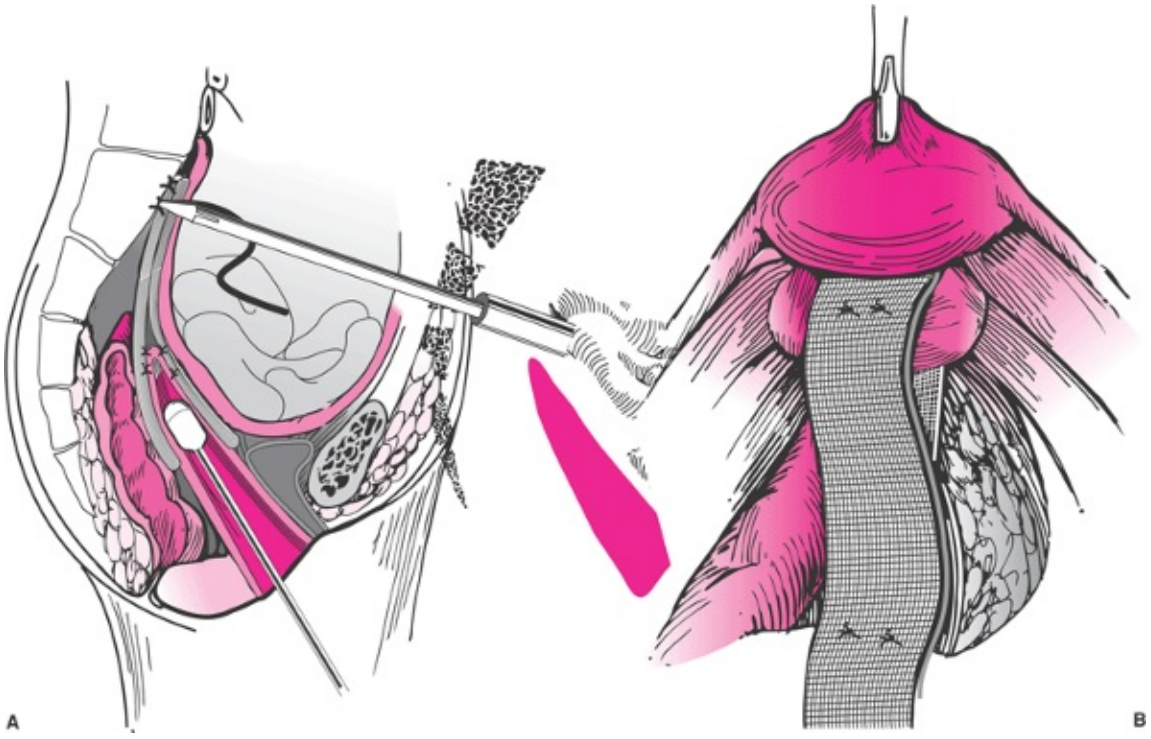

Figure 49.10 Laparoscopic mesh sacral colpopexy. **A:** Sagittal view with two leaves of macropore polypropylene mesh attached from the anterior and posterior vaginal apex to the anterior longitudinal ligament of sacral promontory with several permanent sutures. **B:** View from laparoscope with mesh attachments to sacral promontory.

Two uterosacral ligament permanent sutures are placed through the deep portion of the ligament and to the ipsilateral vaginal cuff. **A:** Placement of right uterosacral ligament suspension suture to lateral vagina. Care is taken to avoid the ureter laterally and the rectum medially. **B:** Four uterosacral ligament sutures have been tied, resuspending the vagina over the rectum.

Total Colpectomy with Colpocleisis

Total colpectomy (vaginectomy) is an option among patients who have posthysterectomy vaginal vault prolapse or in selected patients in which vaginal hysterectomy is combined with total colpectomy. Total colpectomy combined with vaginal hysterectomy is associated with higher morbidity, including transfusion risks, infection risks, and ureteral injury risks, than that found with colpectomy alone.

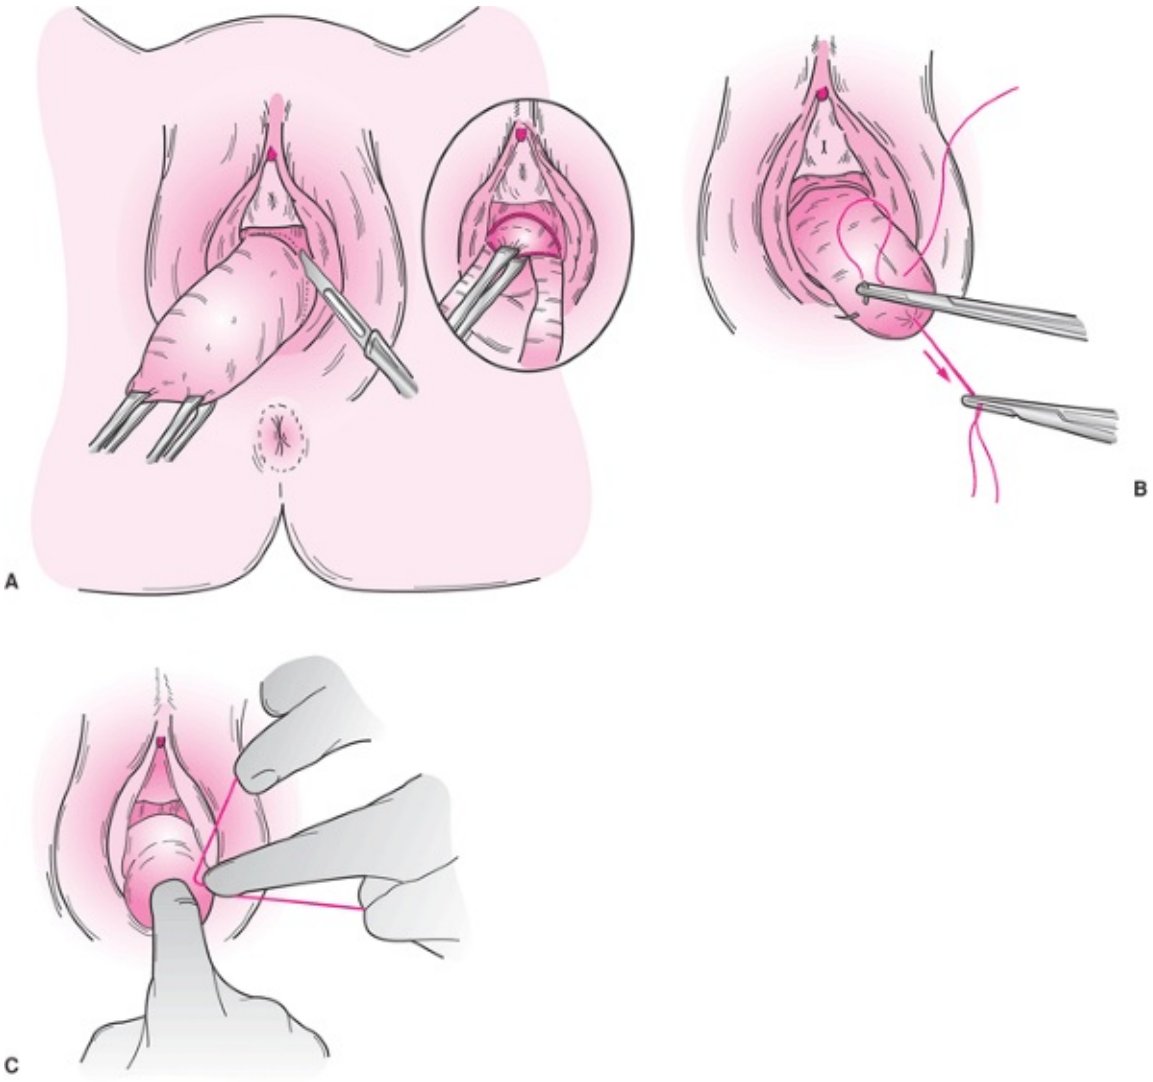

Figure 49.12 Total colpocleisis after colpectomy. **A:** The vaginal epithelium is removed in four quadrants with care to leave the distal 2 cm of vagina above the hymenal remnants. **B, C:** A pursestring closure is started at the apex, with sequential purstring closure progressing distally. (Reproduced with permission from DeLancey JOL, Morley GW. Total colpocleisis for vaginal eversion. *Am J Obstet Gynecol* 1997;176(6):1228–1235.)

Colpectomy is initiated by mapping out the region of vaginal epithelium that is to be denuded. The authors feel that it is important to leave a 1- to 2-cm margin of distal vagina to assure that the axis outlet of the bladder is not adversely altered. The vagina is marked

into quadrants to facilitate dissection (Fig. 49.12A). The subepithelium may be infiltrated with a vasoconstrictive agent such as dilute vasopressin (the authors utilize 20 U diluted in 100 cc of normal saline) or epinephrine. Alternatively, colpectomy under local anesthetic has been described by Miklos

and Kohli. Prior to injecting a vasoconstrictive agent, communication with the anesthesiologist is important to assure that the patient's comorbidities do not preclude its use.

The authors begin the dissection in one of the two posterior quadrants first to take advantage of better exposure by avoiding blood obscuring the operative field if the anterior quadrants are started first. The dissection begins at the apex of the vagina if the prolapse is extensive and then proceeds to the distal vagina. After initially scoring the epithelium with a scalpel, the epithelium is undermined with Metzenbaum scissors. It often is helpful to use countertraction with a finger from the nondominant hand behind the vagina. The proper plane can then be dissected with pressure applied from this finger against the vagina (Fig. 49.12B). Countertraction can be applied by an assistant with a smooth or Russian forceps. As dissection continues out to the distal vagina, the epithelium is completely removed. Similar excision is performed in all four quadrants.

Once all four quadrants are denuded, a purse-string closure of the fibromuscular layer of the vagina is initiated at the apex (Fig. 49.12C). Care must be taken to avoid taking bites that are too deep during the purse-string closure, as the bladder and bowel are at risk of injury. The authors generally use no. 2–0 polyglactin or polydioxanone delayed absorbable suture. Sequential purse-string closure is performed with each subsequent suture placed approximately 1 cm distal to the last. As the closure reaches the distal cut edge of the vaginal epithelium, the vagina is closed from front to back with interrupted no. 2–0 polyglactin suture. The authors leave the medial 1 to 2 cm open to leave room to perform an aggressive posterior colpoperineorrhaphy, as described previously. To provide extra support at the distal vagina and perineum, the puborectalis muscle across the space between the distal vagina and the rectum is plicated. The concerns for dyspareunia described previously with puborectalis muscle plication sutures are not an issue after colpocleisis.

The authors place a midurethral synthetic sling (retropubic or transobturator) in selected individuals who demonstrate stress urinary incontinence on cough stress testing. It is important to leave the distal vagina intact to be able to preserve the landmarks of the bladder neck and midurethra.

Partial Colpectomy with LeFort Colpocleisis

Partial colpectomy and colpocleisis was first performed by Neugebauer in 1867 but first published by LeFort in 1877. This procedure antedates hysterectomy and was a procedure to treat advanced prolapse without the added morbidity that accompanies hysterectomy. There have been many modifications to the initial descriptions of the procedure, and several have been named after surgeons who have described the modifications. Most of the modifications have changed the shape or amount of vaginal epithelium removed.

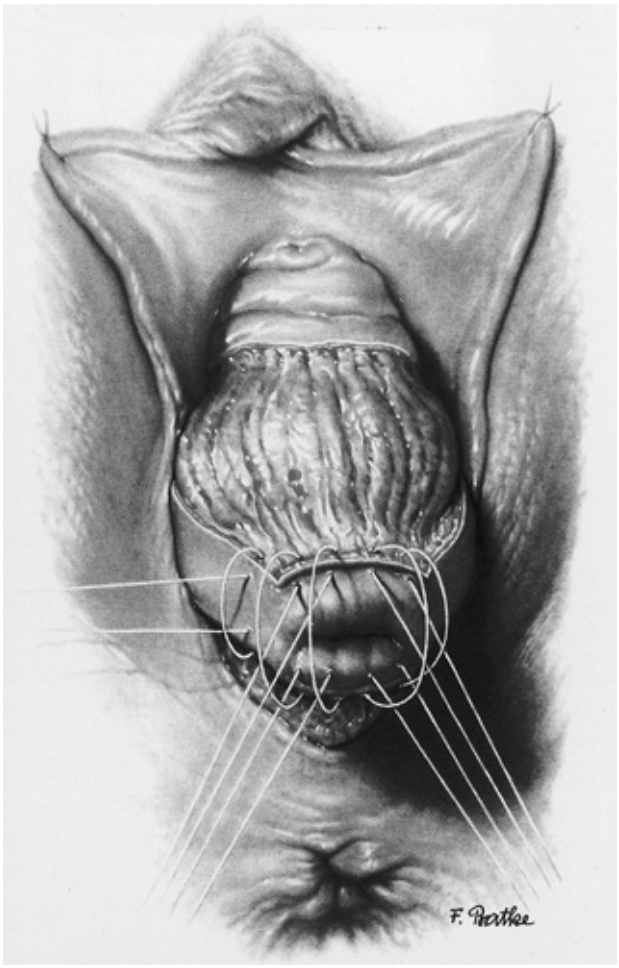

Figure 49.13 Partial colpectomy with colpocleisis. Trapezoids of anterior and posterior vagina are excised. The apex is closed with interrupted delayed absorbable suture, leaving channels laterally for drainage of the cervix and uterus. (Reproduced with permission from Reiffenstuhl G, Platzer W, Knapstein PG, eds. Vaginal operations: Surgical Anatomy and Technique, 2nd ed. Baltimore: Williams & Wilkins 1996:167.)

Anterior and posterior trapezoids of vaginal epithelium are excised (Fig. 49.13). As with other vaginal surgeries, the authors prefer to start with the posterior dissection first to prevent blood running down into the posterior operative field. A dilute vasopressin solution or local anesthetic with epinephrine may be helpful for hemostasis and to establish dissection planes. The vaginal epithelium is left intact from the cervix and along two lateral tracts to allow drainage from the uterus and cervix. The vaginal excision is also usually left intact for 1 to 2 cm above the hymenal remnants to prevent change in the urethral axis.

Once the trapezoids are excised, closure begins at the cervicovaginal junction. The anterior vagina is reapproximated to the posterior vagina with interrupted no. 2–0 polyglactin or polydioxanone suture. This effectively reduces the cervix by imbricating it above the vaginal closure line. Similar rows of suture are continued, closing anterior to posterior fibromuscular layers of the vagina. At the lateral edges, the sutures bring the anterior and posterior vagina together at the epithelium to make lateral channels

the cervix (Fig. 49.13). Similar to the total colpectomy with colpocleisis, the authors recommend leaving room distally to perform an aggressive posterior colpoperineorrhaphy. As described previously, plication of the puborectalis muscle across the midline is performed because dyspareunia is not a concern. Room is left at the distal anterior vagina as well, to prevent axis change at the bladder neck that can occur if the distal anterior vagina is sewed to the posterior vagina. If urethral hypermobility is a concern, sometimes a Kelly plication of the urethra can be considered. If stress urinary incontinence is documented, a midurethral sling may be considered.

Other Technology

Percutaneous Kits

New technologies have recently and rapidly been marketed to treat POP (Table 49.2). Most of these technologies have been derived from the success of the midurethral mesh slings, originally described with the tensionfree vaginal tape (TVT) procedure (Gynecare, Somerville, NJ). Despite very different placement and mechanisms of action than the original TVT, these surgical devices have been approved under the Food and Drug Administration (FDA) 510(k) mechanism. They are categorized as class II devices, and for this reason, clinical outcome, safety, and efficacy studies are not required before device implementation. Until there is safety and efficacy data available, these devices should be used with caution and with appropriate patient counseling.

The kits utilize polypropylene macropore mesh coupled to percutaneous needles. The mesh is inserted via vaginal incisions and retrieved through percutaneous needles placed through perineal skin sites. A vaginal incision is made in the compartment to be augmented with mesh. Percutaneous lateral needles are then placed via different sites and directed to the vaginal incision. The needles are used to retrieve small extension arms of mesh that are pulled back through the percutaneous sites.

TABLE 49.2 Permanent Synthetic Percutaneous Mesh Kits (U.S. Market)

Vaginal Support Defect	Procedures
Anterior vagina	Perigee (American Medical Systems, Minnetonka, MN) Avaulta (anterior) (C. R. Bard, Cranston, RI)

	Prolift (anterior) (Gynecare, Somerville, NJ)
Posterior vagina	Apogee Avaulta (posterior) Prolift (posterior)
Apical prolapse	Apogee Avaulta (posterior) Prolift (posterior)
Prolapse all segments	Perigee combined with Apogee Avaulta (anterior and posterior) Prolift (complete)

Anterior prolapse kits primarily access the anterior wall through percutaneous lateral sites that pierce the medial anterior and posterior margins of the obturator foramen. Placement is designed to have the mesh arms pierce the ATFP. Posterior prolapse kits tend to access the vaginal incisions through the ischiorectal fossa. The posterior kits often use posterior needle placement through or near the sacrospinous ligament to provide apical support. Ostensible advantages of macropore mesh (with pore size of at least 75 μm) are that the loose weave promotes fibroblast integration into the mesh and that the macrophages can permeate the mesh to reduce infection. The concept with the kits is to provide tensionfree mesh supports at the anterior vagina, apex, and posterior compartments. To date, there is limited safety data and limited follow-up. Mesh erosion is reported in the 0% to 18% of patients. There are no comparison trials with traditional repairs. Altman and colleagues recently published a registry of all subjects undergoing transvaginal mesh repairs in Sweden over a 6-month study period. They found a serious perioperative complication rate of 4.4%, dominated by visceral injury. There are not follow-up data regarding erosion risks, dyspareunia, or pain.

Biologic Grafts

Xenografts

Xenografts are biologic materials harvested from other species. Xenografts have been used in other surgical subspecialties for decades. The market for biomaterials is rapidly changing, and thus a list of available product has not been included. Tissues utilized commonly include porcine small intestinal submucosa and bovine pericardium. One concern regarding xenografts is the potential for latency of animal zoonoses. The FDA does have strict guidelines regarding knowledge of the animal herd, screening for bovine spongiform encephalopathy, feed source, and vaccination status. Evidence-based data regarding different products are limited. One randomized multicenter trial by Meschia and

associates compared porcine dermal graft to augment anterior colporrhaphy. They found lower recurrence rates with the graft-augmented repair. Studies to date on posterior colporrhaphy have not shown benefit with augmented repair, and in one randomized trial (Paraiso and coworkers), there was a higher recurrence rate when xenograft augmentation was utilized. Xenograft extrusion has been reported in some series.

Allografts

Human allografts are tissues harvested from cadavers. Fascia lata is commonly marketed for POP and has been used

---

in the orthopedic field for years. Human dermal products and human-derived dura mater are also available commercially for POP. Allograft material is screened for infection, including HIV, hepatitis B and C, and T-cell lymphocyte virus type 1. FDA guidelines require irradiation and freeze-drying. While under FDA control, there was a recall in 2005 of cadaveric human tissue from Biomedical Tissues Services, Ltd, that may not have been procured with appropriate screening. Even with adequate testing, there may be a small risk of HIV or prion transmission. Allografts used for pubovaginal sling procedures have had variable results. Autolysis and evidence for graft versus host reaction has been identified histologically on some products. Several authors have suggested that the preparation of the tissue may be a factor in its long-term integrity after implantation. Tissue preparation, including freezing, irradiating, and the storage medium, may affect durability and integrity. There are limited data on allograft tissues for prolapse. Flynn and colleagues describe favorable results using cadaveric fascia lata allograft for ASC with follow-up of 6 to 12 months. Another series by Gregory and associates found unfavorable results compared with those found with mesh, but they used fascia that was freeze-dried and irradiated.

Autologous Grafts

Autologous fascia lata and rectus abdominus fascia have also been utilized to augment prolapse repairs at the anterior, posterior, and apical compartments. The disadvantages of autologous grafts include perioperative morbidity associated with harvesting tissue, infection or pain at harvest site, incisional hernia, and unsatisfactory cosmesis. There is little comparison data available on outcomes in the literature.

Conclusion

Surgical treatment of POP is common. Surgical approaches to treat POP are varied, both with respect to the approach (vaginal, abdominal, and laparoscopic) as well as the materials used (native ligaments and other biomaterials). Selection of a procedure for an individual should be strategized based on her risks, comorbidities, and prior surgical history. Obliterative procedures may be best for selected individuals when penetrative vaginal intercourse is still desired. In the three randomized studies included in a 2005 Cochrane review, abdominal mesh sacral colpopexy has lower rates of failure, dyspareunia, and reoperation compared with rates associated with vaginal suspension. Nonetheless, there may be higher rates of adhesions and serious morbidity with abdominal approaches.

Recurrent prolapse and complications associated with traditional repairs have led investigators and biomedical companies to seek alternatives that are less invasive, quicker, and perhaps more durable. Their primary focus has been on the marketability. The surgical treatment of POP is rapidly changing due to rapid introduction of synthetics and biomaterials and new ways to introduce them. Unfortunately, most of these materials and techniques have come to market without safety and efficacy data, and their use in patients should be used cautiously until more data is available.

Summary Points

- POP is a prevalent condition that may manifest with a variety of symptoms and not necessarily reflective of the specific prolapse defect.
- The goal of surgical management of POP is to restore normal vaginal anatomy; improve symptoms of POP, the lower urinary tract, and bowel; restore or improve sexual functioning; and correct coexisting pelvic pathology.
- The goal of surgical intervention needs to be individualized to the patient and is dependent on patient physical activity level, desire for sexual function, and medical status.
- A variety of surgical approaches exist, including open abdominal and transvaginal, and outcomes from these different approaches may vary widely depending on the surgeon, operative materials, and technique utilized as well as patient factors.
- New operative approaches utilizing synthetic graft material need to be studied in a prospective robust fashion in order to get the information with which to more fully counsel patients about short- and long-term complications and outcomes.
