Title: *Danforth's Obstetrics and Gynecology, 10th Edition*

Dedication

This hallmark 10th Edition of *Danforth's Obstetrics and Gynecology* is dedicated to our mentors and our teachers who have guided us to where we are; to our residents and students who have stimulated and prodded us; to our patients who have given us great gratification and inspiration; and to our families and friends who have given us love and support and make all that we do so meaningful.

Editors: Gibbs, Ronald S.; Karlan, Beth Y.; Haney, Arthur F.; Nygaard, Ingrid E.
Title: *Danforth's Obstetrics and Gynecology, 10th Edition*

Preface

Welcome to the hallmark 10th Edition *of Danforth's Obstetrics and Gynecology*. In the 42 years since the first edition of this text appeared, it has been widely recognized as a standard text book for practicing physicians, residents, medical students and nurses. Previous editions have been translated into several languages and the text has enjoyed wide readership over the face of the globe. As medical practice changes continually, we also have made important changes in the 10th Edition. Important new topics have been added including stillbirth, group *B streptococci* and a whole new section on pelvic reconstructive surgery. To add to the appeal of the text, we have added many two-color figures and there is an enlarged multi-color section. In the textbook's website, accessible to those who purchase the book, we will have the full text of the book including all figures and tables. Our objective throughout has been to provide in a single textbook, current cutting edge information on the practice of the breadth of obstetrics and gynecology. Our goal has been to provide this in a highly readable, user friendly and evidence-based fashion.

We are also happy to announce that with this 10th edition, we have a new editor, Dr. Ingrid Nygaard, Professor of Obstetrics and Gynecology in the Division of Urogynecology and Reconstructive Pelvic Surgery at the University of Utah. Dr. Nygaard replaced Dr. James R. Scott who had served as editor from the 5th through the 10th Editions—a record that will be long lasting. We also are most pleased to welcome new contributing authors, all experts in their fields, and returning contributing authors who have updated their previous chapters. With all of the pressures on faculty in academic departments these days, we know that writing a chapter for this text becomes a labor of love and demonstrates great commitment on the part of the authors to education and translating knowledge to the bedside.

We also wish to extend a heartfelt thanks to our administrative staff who labored extensively in the preparation of this text—Michelle Nelson at University of Colorado and Phyllis Lopez at Cedars Sinai Medical Center. Finally this book would not have been possible without the expertise and organization our trusty editors, Sonya Seigafuse and Ryan Shaw at Lippincott Williams & Wilkins. We wish all of our readers continued success and gratification in the practice of obstetrics and gynecology.

1

Prenatal Care

Vern L. Katz

The time period from the recognition of a pregnancy until delivery is one of the greatest physical and psychologic transitions that a woman undergoes in her lifetime. During these months, the obstetrician, family physician, or midwife serves a much larger role than just health care provider. The clinicians' role during this time is not only to assess the health of the mother and fetus, prescribe interventions, and try to influence behaviors but also to advise and help patients as they undergo this challenging psychologic passage. This chapter outlines the principles of prenatal care and addresses specific concerns of a woman's general health during gestation.

Prenatal care has consisted of adherence to ritual and taboo for generations. Greek authors suggested that Spartan women exercised in pregnancy to give birth to better warriors. Roman physicians argued that strong and violent movements induced rupture of membranes. In the early twentieth century, hanging clothing to dry on a clothesline was said to increase the risk of the umbilical cord wrapping around the baby's neck. In the United States, the first organized prenatal care programs began in 1901 with home nurse visits. The first prenatal clinic was established in 1911. The goal of early prenatal care was to diagnose and treat preeclampsia in order to decrease maternal mortality. It is not surprising that this focus on maternal and infant health occurred as a direct outgrowth of the woman suffrage movement.

The current emphasis on prenatal care stems from historic pronouncements and retrospective analyses concluding that women who receive prenatal care have less fetal, infant, and maternal morbidity and mortality. However, a conclusive scientific foundation is lacking for the content of prenatal care and the relationship of its components to good outcomes. As technology flourishes and resources dwindle, it has become increasingly important to obtain scientifically based evidence demonstrating which components of prenatal care are clinically appropriate, cost-effective, and deserving of preferential funding. At this time, the optimal content and delivery of prenatal care remains the subject of discussion and debate. Given the increasing number of tools of prenatal assessment, the current consensus is that the best prenatal care is individualized for the specific needs of the mother.

Prenatal care has two areas of emphasis. The first is directed at ensuring appropriate fetal growth and development. This is accomplished through counseling with regard to health

behaviors of the mother as well as physical and laboratory evaluations. The second area of emphasis is more complex and involves assessment of the physical and psychologic adaptations of the mother during her pregnancy. Most aspects of pathology occur when there is either insufficient maternal adaptation or too much. Preeclampsia and diabetes are good examples of such pathologies, respectively. The two areas of attention—maternal and fetal well-being—are obviously intertwined. For the clinician facing complex problems, it sometimes helps to untangle these two themes to better address diagnosis and therapy. An example is the pregnant woman diagnosed with cancer or the mother with epilepsy. The evaluation of risk:benefit ratio of tests and treatments must be seen looking at both maternal and fetal health. This chapter will emphasize normal changes in pregnancy, and later chapters will build on this discussion to focus on pathology.

Over the three trimesters of pregnancy, a woman must develop new aspects to her identity. Her self-image develops an additional sense of femininity beyond what was developed at puberty, and a maternal self-concept must develop as well. Reba Rubin, in her works on the maternal experience, describes a new mother's psychologic tasks as the woman grows into her new role. These tasks include:

- Accepting a new body image, which is often in conflict with accepted societal views of attractiveness
- Accepting the child who is growing inside her
- Reordering her identity with her mother, her friends, and the father of the pregnancy
- Symbolically finding acceptance and safety for her child (i.e., making a new home).

For many women with good social support, these tasks are anticipated and desired roles that bring a sense of fulfillment. For other women, some or all of these tasks are unanticipated and difficult. The obstetric provider, in multiple ways, helps the mother through these transitions while at the same time ensures the physical health of both patients (mother and fetus). Many aspects of prenatal care have grown from their original role of health promotion to ritualized traditions that have acquired symbolic value in helping women and their families adapt to these psychologic transitions. For example, studies have found that for women of average weight, the practice of weighing a woman during each visit has minimal medical value. Yet, if the nurse forgets to weigh a patient, that woman usually remarks quite quickly about having her weight taken. Another example is the routine ultrasound. This is now a demand ritual. At this visit, a mother will usually bring several female family members or friends to see the sonogram. The new mother not only uses the sonogram to bond with her child but also shows the baby to the other women around her for their acceptance. Throughout the world, cultures and subcultures view prenatal care differently, but most all hold it with respect. A woman might miss her annual Pap smear, but she rarely misses a prenatal visit.

Primary and Preconception Care

Philosophy

Care for preconception, pregnancy, and postpartum should be integrated and accessible, focus on the majority of personal health care needs, represent a sustained partnership between patient and provider, and occur within the context of family and community. For many women, pregnancy care occurs as a part of the continuum in a long-term relationship with the health care provider. The first visit may be a preconception visit or may occur after the woman is pregnant. If a woman is seen for a preconception visit, many issues need not be readdressed when she becomes pregnant.

Content of the Preconception Visit

The preconception visit is a focused visit for the woman who is planning to become or is considering becoming pregnant in the near future. The content of this interval visit includes a complete history; when appropriate, a complete physical examination; risk assessment and intervention; selected laboratory testing based on the patient's age and the results of the foregoing evaluation; ongoing management of medical conditions; and a plan of care. A purposeful discussion of contraception, sexually transmitted disease prevention, and timing of conception is appropriate. Timely administration of routine immunizations, educational counseling, and advice complete the visit.

Risk Assessment

A goal specific to the preconception interval visit is the systematic identification of potential risks to pregnancy and the implementation of early intervention as necessary. These risks fall into several categories, described in the following sections.

Unalterable Factors

Unalterable factors are preexisting factors that cannot be altered in any medical way by clinical intervention. These include the patient's height, age, reproductive history, ethnicity, educational level, socioeconomic status, genetic composition, and to some extent her body mass index (BMI). Genetic and family histories, although unalterable, may lend themselves to screening and evaluation. A detailed family history should be obtained, including inquiry of thromboembolic disease, recurrent miscarriage, neonatal or early infant death, congenital cardiac disease, mental retardation, or other major disease affecting health in family members.

Factors Benefiting from Early Intervention

Conditions that should or could be modified before pregnancy is attempted include poor nutrition; an underweight or obese BMI; and poorly controlled medical diseases such as diabetes mellitus, asthma, epilepsy, phenylketonuria, hypertension, and thyroid disease.

Some prescription medications that are known teratogens should be discontinued and appropriate substitutions made. These include medications such as isotretinoin (Accutane), warfarin sodium (Coumadin), certain anticonvulsants, and angiotensin-converting enzyme inhibitors. However, many medications are safe, such as medications for asthma and most antihistamines. Some medications such as antidepressants need to be evaluated for the

risk:benefit ratio.

Determining the status of a patient's immunity to rubella, varicella, and hepatitis is appropriate during the preconception visit. If needed, the influenza vaccine is safe. In high-risk populations or endemic geographic areas, patients should be assessed for active tuberculosis with skin testing and chest x-ray.

Social Risk Factors

Inquiry should be made regarding occupational hazards involving exposure to toxins such as lead, mercury and other heavy metals, pesticides, and organic solvents (both liquid and vapors). Hazards in the home, such as exposure to toxoplasmosis or toxic chemicals (asbestos, pesticides), are important to identify. If a woman uses well water, it should be assessed for acidity, lead, and copper.

Family violence is a particularly important household hazard. Nonjudgmental, open-ended evaluation should be applied. Judith MacFarland has recommended questions such as “Are you in a relationship in which you are being hit, kicked, slapped, or threatened?” “Do you feel threatened?”

“Have you been forced to do things against your will?” These questions should be asked again at the first prenatal visit. Some studies have suggested that a written questionnaire, in addition to oral questions, will allow for greater identification of domestic abuse. Approximately 20% of all pregnant women are battered during their pregnancy. About one half of women who are physically abused prior to pregnancy continue to be battered during pregnancy. For some women, the violence begins with pregnancy. All such patients require information regarding their immediate safety and referrals for counseling and support.

Risky Health Habits

The use of illicit drugs or abuse of alcohol represents a significant health hazard to pregnancy. Alcohol is a known teratogen. There is no consensus on the correlation between the quantity of alcohol consumed and the manifestation of adverse fetal effects. Therefore, the best advice to women who wish to become pregnant is to stop drinking. The T-A-C-E screen for alcohol abuse has been well studied. The letters stand for four questions asked in a nonjudgmental manner:

1. T—“How much do you drink to feel drunk?” (*tolerance*)
2. A—“Does your drinking *annoy* anyone?”
3. C—“Has anyone told you to *cut* down?”
4. E—“Do you drink in the morning to feel better?” (*eye-opener*).

Smoking cigarettes is associated with adverse pregnancy outcomes, including low birth weight, premature birth, and perinatal death. Smoking by both the pregnant woman and members of the household should be avoided during pregnancy and, preferably, not resumed postpartum. The relative risk of intrauterine growth restriction (IUGR) among

pregnant smokers has been calculated at 2.2 to 4.2. Because of the morbidity associated with smoking, various methods to assist women to quit smoking should be encouraged prior to pregnancy. Numerous interventions are available. Use of the transdermal nicotine patch in pregnancy is thought to be preferable to smoking. One benefit of using a nicotine patch is the elimination of exposure to other toxins such as carbon monoxide inhaled in cigarette smoke. Its theoretic risk is that it creates a constant blood level of nicotine, as opposed to the vacillations that occur with smoking. Depending on the timing of the prescription, it may be a very appropriate intervention. Similarly, all illicit drugs have the potential of harming the pregnancy.

Other behaviors that should be avoided are those that promote exposure to sexually transmitted and other infectious diseases. These include unprotected sexual intercourse in a nonmonogamous relationship and the sharing of needles between addicts.

Interventions

The final phase of the preconception visit involves specific interventions derived from the information obtained during the history, physical examination, and risk assessment phases. The specific interventions may include immunization against rubella, varicella, or hepatitis; changes in prescribed medications; behavior modification; genetic screening for such conditions as Tay–Sachs disease, cystic fibrosis, thalassemia, and sickle cell anemia; and nutritional and physical activity recommendations.

During the physical examination, evaluation of the thyroid and breasts is important. Signs or symptoms of thyroid disease should prompt laboratory evaluation with TSH and free T4. If a woman is 35 years of age or older, a screening mammogram should be ordered, since as much as two and a half years may pass before she will be able to have one (mammograms have significantly decreased sensitivity during pregnancy and for up to 6 months after lactation). If a woman has a family history of premenopausal breast cancer, a mammogram may be considered at younger ages. Additionally, if there is a body habitus or history suggestive of polycystic ovary disease, this condition should be evaluated (Chapter 38). If a Pap smear has not been done within a year, this test should be repeated at this time. Abnormalities of the Pap smear are more easily addressed prior to pregnancy. Additionally, it is valuable at this visit to examine the patient's skin. The incidence of melanoma is increasing faster than any other malignancy in the United States. The obstetrician has the unique opportunity to assess and teach at this visit regarding this cancer. An inquiry about periodontal disease and, when appropriate, assessment of dental hygiene is important. Periodontal disease is associated with a significant risk of preterm birth. Periodontal disease may be treated at any time in pregnancy but is best addressed preconception.

Folic acid as a supplement can reduce the occurrence and recurrence of neural tube defects and may reduce the risk of other birth defects as well. Women who have had a previous pregnancy affected by neural tube defects should take 4 mg of folic acid per day, starting 4 weeks prior to conception through the first trimester. For all other women of reproductive age who have the potential to become pregnant, 1 mg of folic acid should be prescribed. Unfortunately, prenatal vitamins contain only 0.4 to 0.8 mg.

Some patients purposely initiate a preconception visit to determine whether or not a

preexisting medical condition is an absolute contraindication to pregnancy. Pulmonary hypertension, for example, although rare, is associated with up to a 50% maternal mortality and a greater than 40% fetal mortality. It is possible to obtain epidemiologic studies that provide statistics on the morbidity and mortality for mother and fetus for most disease states. These cannot, however, provide specific data for any one patient with her own unique set of medical, demographic, and social variables. Many patients who make these inquiries will benefit by reading the relevant medical materials themselves and by obtaining more than one opinion. Consultation with other medical specialists may be necessary. For example, women with orthopedic problems often inquire about vaginal delivery. Another common concern is advanced

maternal age. Specific risks of increased rates of aneuploidy and miscarriage should be discussed. Women over age 40 have been found to have higher rates of low birth weight, fetal demise, preterm birth, and operative delivery.

It is also important to discuss how and when to discontinue contraceptive measures. Patients using medroxy-progesterone acetate (Depo-Provera) injections may experience a delay of several months in the return of regular ovulatory menstrual cycles. An intrauterine device (IUD) may be removed at any time in the cycle. It should be removed as soon as conception is considered, since removal during pregnancy (although preferable to leaving in place) is associated with a higher rate of pregnancy loss. Likewise, birth control pills and other hormone-based contraceptives should be discontinued prior to attempting conception. Many physicians believe that discontinuing the use of hormone-based contraceptives for one to two cycles allows better growth of the endometrium. Although definitive evidence is lacking, the thought is that this may be associated with better implantation of the fertilized egg. If a woman discontinues hormone-based contraception, she needs to be reminded that ovulation may occur in a variable time period after stopping the contraception. Thus, risky behaviors should be avoided at the time of discontinuation.

The patient should be advised to seek early prenatal care by making an appointment after missed menses or on confirmation of pregnancy by a home pregnancy test. Unfortunately, in the United States, only 75% of pregnant women receive prenatal care beginning in the first trimester. Ongoing barriers to prenatal care access include lack of money or insurance to pay for care, system undercapacity for appointments, and inadequate transportation.

Initial Prenatal Visit

This visit represents the first detailed assessment of the pregnant patient. The optimal timing of this visit may vary. For women who have not undergone the comprehensive preconception visit, prenatal visits should begin as soon as pregnancy is recognized. For these women, much of the content of the preconception visit will need to be addressed at this time—for example, screening for domestic abuse and alcohol use. All other women should be seen by about 8 menstrual weeks (6 weeks after conception) gestation. For all patients, the appropriate content of prenatal care and the first prenatal visit is contained in the antepartum record published by the American College of Obstetrics and Gynecology

(ACOG). Identifying data, a menstrual history, and a pregnancy history are obtained. Past medical, surgical, and social history are recorded, along with symptoms of pregnancy. The patient's current medications, including over-the-counter (OTC) and herbal supplements should be evaluated. A focused genetic screen, infection history, and risk status evaluation are performed or reconfirmed.

Diagnosis of Pregnancy

The two aspects of pregnancy diagnoses include confirmation of an intrauterine pregnancy and assessment of viability. Evaluation of the signs and symptoms associated with the presumptive diagnosis of pregnancy, while a useful adjunct, has been largely superseded by the widely available urine pregnancy test and ultrasound. The detection of greater than 35 mIU of human chorionic gonadotropin (hCG) in the first morning void has a very high specificity for pregnancy. OTC pregnancy tests can confirm a pregnancy prior to the missed period. Other tests for confirming the presence of pregnancy include a positive serum ß-hCG and demonstration of the fetal heart by either auscultation or ultrasound. Using a transvaginal probe, an intrauterine pregnancy may be confirmed (gestational sac–intradecidual sign) at the time a ß-hCG reaches 1,500 IU. Fetal cardiac activity should be seen by postconception week 3. Ultrasound imaging is not routinely indicated to diagnose pregnancy but is often used in the evaluation of a patient who is unsure of her last period, at increased risk for ectopic pregnancy, or showing signs of miscarriage. In conjunction with early quantitative serum ß-hCG assessments, these conditions can be clearly differentiated from a normal intrauterine pregnancy and timely therapy initiated (Chapter 5).

Gestational Age

The Nägele rule is commonly applied in calculating an estimated date of confinement (EDC). The clinician should remember that this is an approximate rule. Using the date of the patient's last menstrual period minus 3 months plus 1 week and 1 year, the rule is based on the assumptions that a normal gestation is 280 days and that all patients have 28-day menstrual cycles. Although several studies have found the average length of gestation for primiparous women to be 282 to 283 days, for convention, 280 days is the currently accepted average gestation. After adjustment for a patient's actual cycle length, natality statistics indicate that the majority of pregnancies deliver within 2 weeks before or after this estimated date. During prenatal care, the week of gestation can be obtained based on the calculated EDC. When the last menstrual period is unknown or the cycle is irregular, ultrasound measurements between the 14 and 20 weeks gestation provide an accurate determination of gestational age (Chapter 9). Care should be taken not to change the EDC unless the ultrasound differs by 10 or more days from the menstrual dates. Once dates are appropriately confirmed, continued alterations of EDC based on fetal size are problematic and ill advised.

Physical Examination

A targeted physical examination during the first prenatal visit includes special attention to the patient's BMI, blood pressure, thyroid, skin, breasts, and pelvis. On pelvic

examination, the cervix is inspected for anomalies and for the presence of condylomata, neoplasia, or infection. A Pap smear is performed, and cultures for gonorrhea and chlamydia are taken, if indicated. A small amount of bright red bleeding may occur after these manipulations, and the patient can be assured that this is normal. On bimanual examination, the cervix is palpated to assess consistency and length as well as to detect the presence of cervical motion tenderness. Size, position, and contour of the uterus are noted. The adnexa are palpated to assess for masses. The pelvic examination may include evaluation of the bony pelvis—specifically, the diagonal conjugate, the ischial spines, the sacral hollow, and the arch of the symphysis pubis. This evaluation need only be performed once during the pregnancy.

Laboratory Evaluation

Several laboratory tests are routinely done at the first prenatal visit.

Blood Tests

Hematologic testing includes a white blood cell count, hemoglobin, hematocrit, and platelet count. Full red cell indices are advised for women of Asian descent to evaluate for thalassemia, a serologic test for syphilis (RPR, rapid plasma reagin or VDRL), a rubella titer, a hepatitis B surface antigen, a blood group (ABO), and Rh type and antibody screen. HIV testing should be recommended to all pregnant patients and documented in the chart. Routine assessment for toxoplasmosis, cytomegalovirus, and varicella immunity is not necessary but may be obtained if indicated. The National Institutes of Health and ACOG recommend offering all white women testing for cystic fibrosis status. Women with histories suggestive of thrombophilia, or a personal or family history for thromboembolic disease, should be evaluated at this time. Women with a history suggestive of thyroid disease should also be evaluated. Although TSH is normally used to evaluate for thyroid disease, TSH may be affected by other pregnancy hormones and not accurately affect thyroid status. Thus, a free T4 should always be obtained when evaluating thyroid disease in pregnancy.

Appropriate screening for genetic carrier status, if not performed at the preconception visit, includes but is *not limited to* Tay–Sachs disease, Canavan disease in women of Jewish ancestry, α- and ß-thalassemia in women of Asian and Mediterranean descent, and sickle cell disease in women of African descent. Women with a suggestive history of mental retardation should be screened for fragile X syndrome.

Urine Tests

All women should have a clean-catch urine sent for culture. Asymptotic bacteriuria occurs in 5% to 8% of pregnant women. Urinary stasis is present during pregnancy secondary to physiologic changes in the urinary system, including decreased ureteral peristalsis and mechanical uterine compression of the ureter at the pelvic brim as pregnancy progresses. Bacteriuria combined with urinary stasis predisposes the patient to pyelonephritis, the most common nonobstetric cause for hospitalization during pregnancy. Urinary tract

infection is also associated with preterm labor, preterm premature rupture of the membranes, and preterm birth. Asymptomatic bacteriuria is identified by using microscopic urine analysis, urine culture (>100,000 colonies per milliliter), or a leukocyte esterase–nitrite dipstick on a clean-catch voided urine. Group B streptococcal (GBS) colonization of the urinary tract will not always induce a positive leukocyte esterase reaction. Thus, full urine culture at the first visit is indicated, even with negative leukocyte esterase.

Cultures and Infections

The use of routine genital tract cultures in pregnancy is controversial. While it is clear that chlamydia, gonorrhea, GBS disease, herpes infection, and potentially bacterial vaginosis can be detrimental to the ultimate health of the fetus or newborn, the indications for and timing of cultures for these infections are debated. The ACOG recommends assessment for chlamydiosis and gonorrhea at the first prenatal visit for high-risk patients. The high-risk patient is defined as less than 25 years of age with a past history or current evidence of any sexually transmitted disease, a new sexual partner within the preceding 3 months, or multiple sexual partners. Any abnormal discharge should be assessed with a wet prep or Gram stain. Symptomatic patients should be treated. Symptomatic bacterial vaginosis may be treated in the first trimester.

Tuberculosis skin testing in high-risk populations or in certain geographic areas should be done if the patient has not been vaccinated with BCG vaccine. BCG vaccinations are not given in the United States.

Discussions with the Patient

The first prenatal visit is a time for the caregiver and patient to exchange expectations, to answer questions, and to set the stage for what will occur throughout the rest of normal prenatal care. The timing and content of future visits and the timing and rationale behind further laboratory testing should be explained. The patient should be given educational resources and materials that are written at the appropriate reading level. She and her partner are encouraged to ask questions about what they will read and to share the concerns they have about the pregnancy. It is important to reinforce that there is no such thing as a meaningless, “dumb,” or trivial question. Emergency and routine phone numbers should be given to the patient in writing. Social services and community resources, such as Women,

---

Infants, and Children (WIC) programs, may be identified for the patient on an as-needed basis. Discussion regarding sexual activities, physical activities, and nutrition are usually initiated at this time. Instructions on safe and unsafe OTC medications (i.e., acetaminophen vs. ibuprofen) are also initiated. Instruction on the use of seat belts and domestic abuse is also recommended. For women with previous pregnancies, a discussion of issues and problems from that pregnancy and the past delivery experience should be entertained at this time. Many fears and tensions can be alleviated with simple discussions now and obviate anxieties that may linger and build over pregnancy. A note in the chart to

further discuss a particular point at a later time may also be helpful.

Finally, the patient should be made aware of the warning signs and symptoms of infection (fevers, chills, dysuria, and hematuria) or threatened pregnancy loss (bleeding, cramping, passage of tissue). Should any of these occur, the patient should seek immediate medical attention. At the completion of the first visit, the next prenatal appointment is made.

Routine Antepartum Surveillance

The rationale and guiding principles of prenatal care are listed in Table 1.1. It is at this point in the patients' care that individualization should occur. For women in high-risk categories—such as those with previous preterm birth, chronic medical diseases, family history of problems, and the like—an individualized frequency of visits should be established and documented. For example, a woman with a previous unexplained second-trimester loss that was suspicious but not diagnostic for incompetent cervix might be observed weekly between 17 and 24 weeks, or a woman with chronic hypertension might be seen every 2 weeks throughout the first and second trimesters. In contrast, a woman with previous uncomplicated pregnancies might be seen every 6 weeks in the first and second trimesters and every other week in the last 8 weeks. The traditional timing of 14 prenatal visits was established empirically in the 1930s and has never been validated. In the mid 1980s and 1990s, several randomized trials demonstrated that for low-risk women, 6 to 8 total prenatal visits were equally effective in achieving good pregnancy outcomes. A systematic review and the current standard of care allow for individualized scheduling of visits. Fourteen visits for a low-risk woman would be more than necessary. Table 1.2 lists the traditional timing of visits. From this outline, each woman's needs may be individualized and the prenatal course altered, based on necessary assessments and interventions. A U.S. Public Health Service report delineated the interventions and tests deemed minimally necessary in a normal pregnancy and the suggested the timing for each (Table 1.3).

TABLE 1.1 Rationale for Routine Prenatal Care

Prenatal care involves the following goals for pregnant women:

- to provide continuing, ongoing primary preventive health care
- to maintain or increase maternal health and the capability for self-care and to improve self-image before, during, and after pregnancy
- to reduce the risk of maternal mortality and morbidity as well as unnecessary pregnancy intervention

- to reduce the risks to health before subsequent pregnancies and beyond the childbearing years
- to promote the development of parenting skills, including breast-feeding.

The goals of prenatal care for the fetus are as follows:

- to reduce the risk of preterm birth, IUGR, retardation, and congenital anomalies
- to enhance fetal health and reduce the need for extended hospitalization after birth
- to promote healthy growth and development, immunization, and health supervision of the infant
- to reduce the risk of neurologic, developmental, and other morbidities
- to reduce the risk of child abuse and neglect, injuries, and preventable acute and chronic illness.

The goals of prenatal care for the family during pregnancy and the first year of an infant's life are the following:

- to promote family development and positive parent–infant interaction
- to reduce the number of unintended pregnancies
- to identify and treat behavioral disorders that can lead to child neglect and family violence.

Content of Subsequent Prenatal Visits

The two components of each prenatal visit are the assessments of fetal growth and health and the evaluation of maternal well-being. Maternal health is assessed first with the taking of an interval history, risk assessment and identification, and intervention as necessary. Fetal assessment is via physical examination and inquiry of fetal movements. It is important that the assessments be recorded in an ongoing database. The final aspect of the visit is education, advice, and support of the patient and her family.

TABLE 1.2 The Traditional Timing and Number of Prenatal Visits

Preconception:	Up to 1 year before conception
First prenatal:	6 to 8 weeks after missed menses
Monthly:	Up to 28 weeks
Bimonthly:	Up to 36 weeks
Weekly:	Until delivery

This schedule is modified and individualized for the needs of each woman, 6 prenatal visits may be sufficient for most low-risk women, whereas 20 or more may be necessary for some high-risk women.

TABLE 1.3 Timing of Prenatal Care Based on Specific Intervent (in weeks)

	First Visit	6-8[a]	16-18	26-28	32	36	38	39

GDM, gestational diabetes mellitus; HIV, human immunodeficienc virus.
[a] If the patient had a preconception visit, some elements will be omitted.
[b] If Rh negative, rescreen at 26 to 28 weeks.

Interval History

Each prenatal visit begins with information gathering. Patients should be asked questions about their general health (see Concerns and Questions Particular to Pregnancy later in the chapter), their diet, sleeping patterns, and fetal movement. Questions regarding warning signs such as bleeding, contractions, leaking of fluid, headache, or visual disturbances are also appropriate. Importantly, patients should be given the opportunity to raise their own questions and concerns at each visit, with open-ended inquiries.

Physical Examination

The patient's weight is measured, and total weight gain and trends are evaluated (see Nutrition later in the chapter). The blood pressure is taken and trends are assessed for possible pregnancy-induced hypertension. As blood pressure tends to decrease during the second trimester, increases of 30 mm Hg systolic or 15 mm Hg diastolic over first-trimester pressures are considered abnormal and warrant further evaluation.

The fundal height is measured with a tape from the top of the symphysis pubis, over the uterine curve, to the top of the fundus (Figs. 1.1, 1.2). This technique places an emphasis on change in growth patterns rather than the absolute measurement in centimeters, which can vary between patients. In women who are obese, periodic ultrasound assessments of fetal growth may be necessary. Gestational age is approximately equal to fundal height in centimeters from 16 to 36 weeks gestation. Measurements that are more than 2 cm smaller than expected for week of gestation are suspicious for oligohydramnios, IUGR, fetal anomaly, abnormal fetal lie, or premature fetal descent into the pelvis. Conversely, larger than expected measurements may indicate multiple gestation, polyhydramnios, fetal macrosomia, or

leiomyomata. These concerns can be resolved with ultrasound examination.

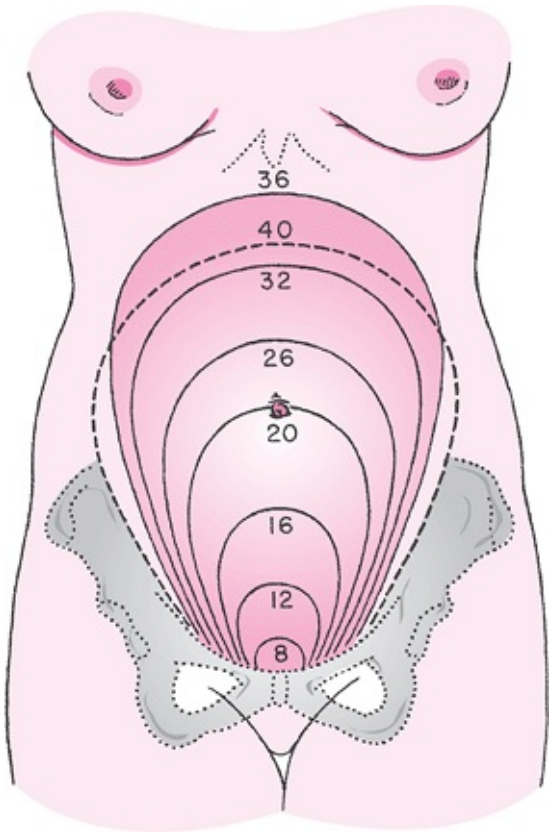

Figure 1.1 The height of the fundus at comparable gestational dates varies among patients. Those shown are the most common. A convenient rule of thumb is that at 20 weeks gestation, the fundus is at or slightly above the umbilicus.

Fetal heart rate is auscultated, with care taken to differentiate fetal from maternal rates.

The normal fetal heart rate throughout pregnancy is between 110 and 160 beats per minute.

Fetal position has been traditionally evaluated with the use of Leopold maneuvers. These are initiated at midpregnancy, when fetal body parts are more clearly identified. The maneuvers consist of four parts; the first three are performed with the examiner standing to one side of the patient and facing her head and the last with the examiner facing the patient's feet.

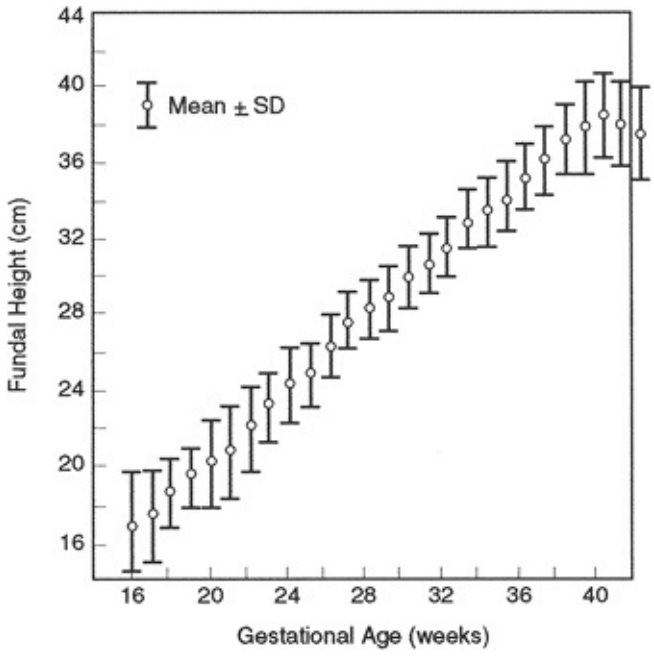

Figure 1.2 Fundal heights versus gestational age.

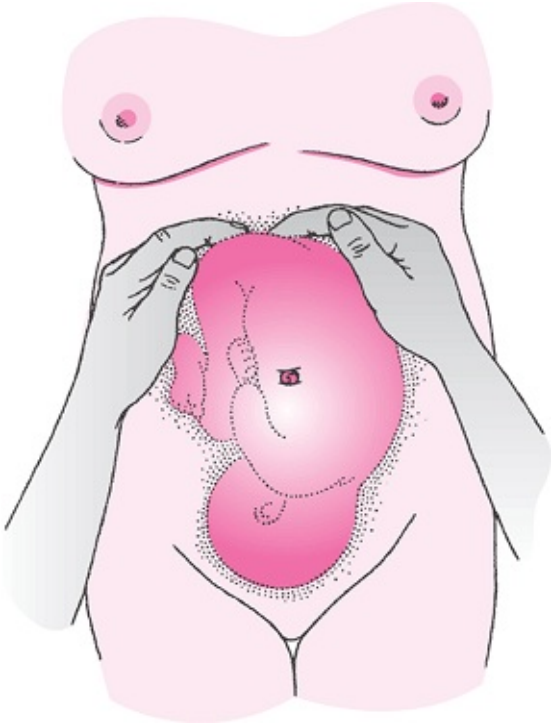

Figure 1.3 The first Leopold maneuver reveals what fetal part occupies the fundus.

- The first maneuver answers the question, “What fetal part occupies the fundus?” (Fig. 1.3). The examiner palpates the fundal area and differentiates between the irregular, firm breech and the round, hard head.
- The second maneuver answers the question, “On which side is the fetal back?” (Fig. 1.4). The palms of the hands

are placed on either side of the abdomen. On one side, the linear continuous ridge of the back is felt; on the other side, compressible areas and nodular parts are found.

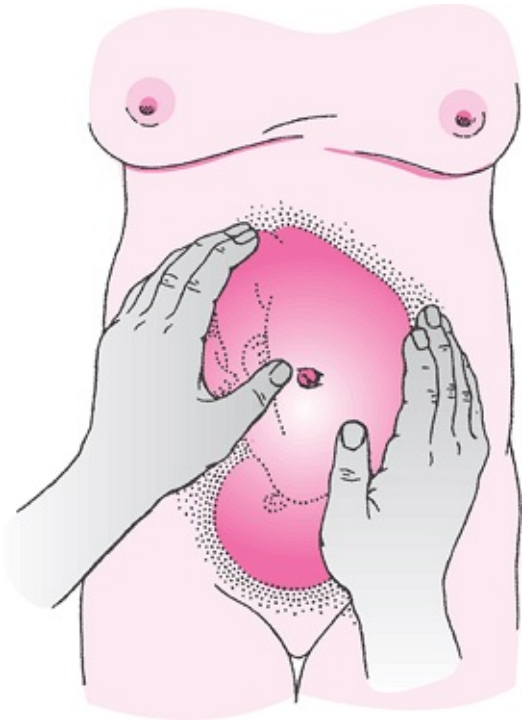

Figure 1.4 The second Leopold maneuver reveals the position of the fetal back.

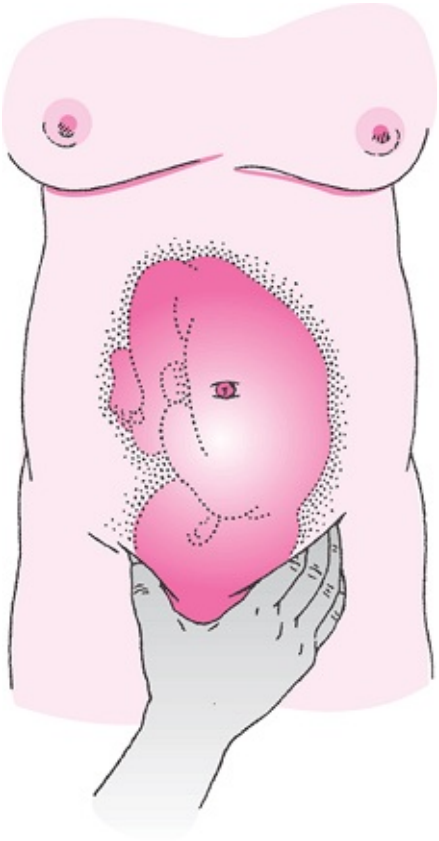

Figure 1.5 The third Leopold maneuver reveals what fetal part lies over the pelvic inlet.

- The third maneuver answers the question, “What fetal part lies over the pelvic inlet?” (Fig. 1.5). A single examining hand is placed just above the symphysis. The fetal part that overrides the symphysis is grasped between the thumb and third finger. If the head is unengaged, it is readily recognized as a round, hard object that frequently can be displaced upward. After engagement, the back of the head or a shoulder is felt as a relatively fixed, knoblike part. In breech presentations, the irregular, nodular breech is felt in direct continuity with the fetal back.
- The fourth maneuver answers the question, “On which side is the cephalic prominence?” (Figs. 1.6, 1.7). This maneuver can be performed only when the head is engaged; if the head is floating, the maneuver is inapplicable. The examiner faces the patient's feet and places a hand on either side of the uterus, just above the pelvic inlet. When pressure is exerted in the direction of the inlet, one hand can descend farther than the other. The part of the fetus that prevents the deep descent of one hand is called the *cephalic prominence*.

The routine examination is completed by evaluating the patient for edema. A finding of new-onset edema of the face and hands in association with proteinuria and elevated blood pressure is consistent with preeclampsia. Dependent pitting edema of the ankles and legs in the absence of other findings is normal in late pregnancy. It responds well to resting, with the legs elevated, and therefore is usually absent on rising in the morning. Another treatment for edema is immersion in a bathtub or swimming pool. Sudden weight gain in

the third trimester to a large extent reflects an increase in edema. The amount of weight gain that is pathologic is not known. However, more than 5 lb in a week is generally considered problematic. Routine examination of the cervix is not necessary unless the patient is at risk for cervical incompetence or is being evaluated for preterm labor.

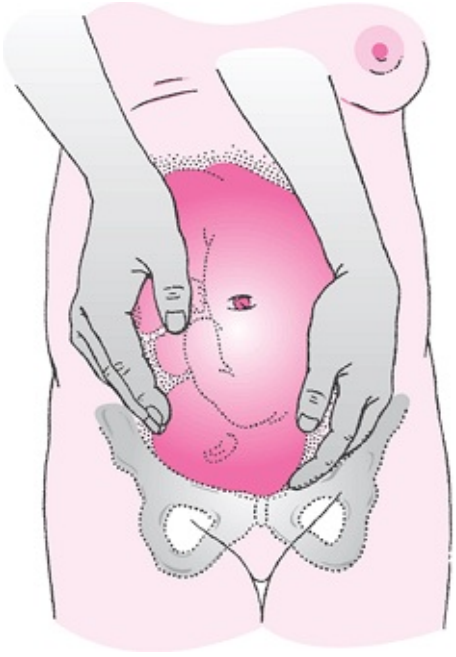

Figure 1.6 The fourth Leopold maneuver reveals the position of the cephalic prominence. In a flexion attitude, the cephalic prominence is on the same side as the small parts.

Laboratory Evaluation

Several laboratory evaluations are offered to all patients after the initial prenatal labs. These include screening for

aneuploidy, which may be done at 11 to 13 weeks or at 16 to 20 weeks (Chapters 6, 7), screening for gestational diabetes mellitus (GBM) with a glucose challenge, and screening for maternal antibodies to fetal blood type.

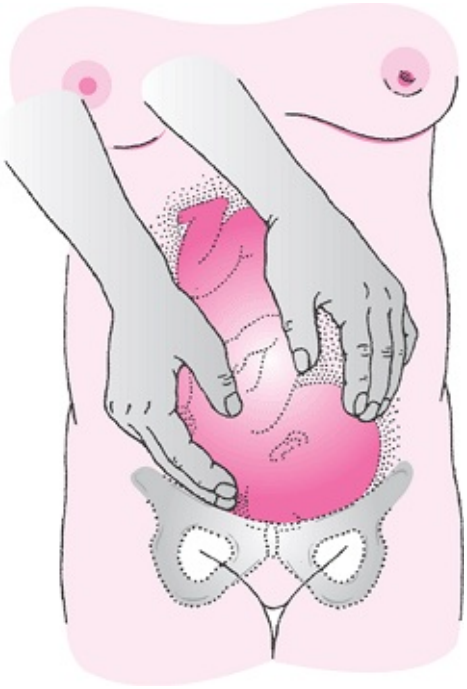

Figure 1.7 In the fourth Leopold maneuver, in an extension attitude, the cephalic prominence is on the same side as the back.

Maternal Serum Screening Tests

Screening with maternal serum alpha-fetoprotein (MSAFP) was originally adopted in the mid 1980s to detect fetal neural tube defects and fetal ventral wall defects. Further evaluation of maternal serum levels noted associations with aneuploidy. Several serum markers have been established as independent markers for fetal chromosome abnormalities. Different acolytes are used at different times in gestation, in conjunction with ultrasound evaluation. These are detailed in Chapters 6 and 7. During pregnancy, AFP is produced in sequence by the fetal yolk sac; the fetal gastrointestinal tract; and finally, the fetal liver. Its peak concentration in fetal serum occurs at the end of the first trimester. Transfer of AFP to the maternal serum occurs via the placenta and transamniotically. MSAFP levels are reported as multiples of the median from the database of the individual laboratory. Elevated maternal serum and amniotic fluid levels of AFP detect 85% of open neural tube defects (open spina bifida and anencephaly). Other causes for elevated MSAFP levels include omphalocele, gastroschisis, multiple gestation, fetal demise, incorrect dates, and adverse pregnancy outcomes. Patients with abnormal MSAFP levels require evaluation with targeted fetal ultrasonography (Chapters 6, 7, 9). Maternal serum markers and ultrasound evaluation should be offered to all women regardless of age; however, local availability and timing of initial maternal presentation to the health care system will influence the best test to offer each patient. First-trimester screening has a sensitivity of 80% to 85% for the detection of aneuploidy in women over age 35. The quad screen at 16 to 20 weeks has a slightly lower sensitivity. Many couples will decline serum screening but desire ultrasound evaluation of the pregnancy. Ultrasound has at best a 50% sensitivity to identify fetuses at risk for trisomy 21 and 90% sensitivity to predict more dimples

aneuploidy.

Screening for Gestational Diabetes

The 1-hour, 50-g oral glucose screen is used to detect glucose intolerance in pregnancy. Following an abnormal screen, a 3-hour glucose tolerance test, commencing with a fasting blood sugar, followed by a 100-g glucola, is currently recommended. Two or more abnormal values on this test are considered diagnostic of GDM. GDM is discussed in greater detail in Chapter 15.

Some clinicians feel that only women with risk factors (Table 1.4) should be screened. Proponents of universal screening argue that screening only those patients with risk factors will detect no more than half of patients with glucose intolerance. Opponents argue that the inconvenience and expense of testing are not necessary in patients without these risk factors, because the incidence of frank GDM in this population is so low. Most clinicians in the United States have adopted universal screening.

TABLE 1.4 Risk Factors for Gestational Diabetes Mellitus

- Maternal age greater than 30 years
- Previous macrosomic, malformed, or stillborn infant
- GDM in a previous pregnancy
- Family history of diabetes
- Maternal obesity
- Persistent glucosuria
- Chronic use of certain drugs such as β-sympathomimetics or corticosteroids

GDM, gestational diabetes mellitus.

Universal screening is offered to all patients between 26 and 28 weeks gestation. Selective screening based on risks may be performed earlier and repeated as needed if negative at earlier gestations. A patient may be tested in the fasting or nonfasting state. One hour after administration of a 50-g glucose load, the patient's blood is drawn. A patient with a glucose value greater than 140 mg/dL of serum is a candidate for a 3-hour, 100-g glucose tolerance test. If the value exceeds 180 mg/dL, most clinicians will not proceed with the 100-g test but rather will assign the woman a diagnosis of GDM. Women who are at high risk, such as those with a previous history of GDM or polycystic ovary syndrome, should have a cutoff of 130 mg/dL by which to proceed to the 100-g full test. The sensitivity of a serum glucose of 140 mg is 80% in predicting GDM, and women at significantly increased risk benefit from a higher sensitivity.

The significance of GDM lies not in an increased risk of fetal loss but in the risk of excessive fetal growth with its attendant birth-related morbidities. In addition, women with GDM have a 60% likelihood of developing overt diabetes mellitus within 16 years.

Rescreening for Rh Antibodies and Other Irregular Antibodies

All Rh-negative women who are unsensitized at the beginning of pregnancy should be retested at approximately 26 to 28 weeks gestation. If the antibody screen remains negative, the mother should receive Rh_0(D) immune globulin 300 mcg at 28 weeks to prevent isoimmunization in the third trimester. Approximately 1% of Rh-negative women will become sensitized if not given Rh immune globulins. Any woman with a positive indirect Coombs (antibody screen) in early pregnancy should be followed with serial antibody screens (Chapter 17).

Screening for Bacterial Vaginosis

Bacterial vaginosis (BV) is a condition in which the normal flora of the vagina (specifically lactobacilli) are reduced in number and replaced by an overgrowth of anaerobic organisms. Studies have linked BV with an increased incidence of preterm labor, endometritis, and premature rupture of the

---

membranes. A simple and effective screen performed late in the second trimester consists of a pelvic examination and wet mount to detect BV. A Gram stain is an alternative diagnostic tool. The treatment for women who are positive for BV includes either metronidazole (Flagyl) or clindamycin (Cleocin). Both are safe in pregnancy. Because BV is often asymptomatic, a test of cure may be appropriate. Routine screening is not recommended, as studies have not shown that screening and treatment decrease preterm labor and delivery. However, symptomatic women, women with cerclage, or women with preterm dilated cervices should be screened and treated.

Screening for Group B Streptococcus

GBS are part of the normal vaginal, genitourinary, and gastrointestinal tract flora in up to 30% of healthy women. GBS have been implicated in amnionitis, endometritis, pyelonephritis, and wound infection in the mother. Vertical transmission during pregnancy, labor, and delivery may result in generalized sepsis in the newborn and related long-term morbidity or neonatal death.

Prevention strategies have focused on detection of the bacteria in the mother and prophylaxis to decrease the incidence of early-onset GBS disease in the newborn.

The recommended strategy involves routine anogenital cultures of all pregnant women at 35 to 37 weeks gestation. Cultures are obtained from the lower third of the vagina and perianal area. Cervical cultures are not reliable, and a speculum is not necessary to obtain an adequate culture sample. Culture-positive women are treated during labor with antibiotic prophylaxis to prevent fetal–neonatal GBS infection. Women with a positive urine culture for GBS at any time in pregnancy should be given antibiotic prophylaxis in labor.

These women do not need to be recultured. Treatment is with penicillin or ampicillin. Women with penicillin allergies may receive a cephalosporin or clindamycin. However, up to 15% of GBS colonies will be resistant to clindamycin. Thus, in the penicillin-allergic patient who cannot take cephalosporins, a sensitivity should be obtained at the time of anogenital cultures.

Testing Based on Symptoms or Clinical Risk Assessment

A part of prenatal care of the normal patient consists of ongoing risk assessment and intervention or referral if a risk is identified. Several clinical signs or symptoms warrant further evaluation. Symptoms suggestive of urinary tract infections should prompt examination of a clean-catch urine specimen and cultures when appropriate. High-risk behaviors, identified during the course of a pregnancy, should prompt a test (or retest) for HIV infection and sexually transmitted diseases (STDs) or performance of a urinary drug screen. Repeated testing of hemoglobin should be done if the patient is symptomatic or at nutritional risk for anemia.

Other testing, performed on an as-needed basis, includes ultrasound to detect abnormal fetal growth, antepartum fetal monitoring to assess fetal oxygenation status, or comprehensive targeted ultrasound examinations. A more thorough discussion of antepartum fetal monitoring can be found in Chapter 10.

Routine Ultrasound

Most clinicians will obtain a detailed anatomic fetal evaluation in the mid second trimester by ultrasound (Chapter 9). This ultrasound helps document fetal age and fetal well-being as well as placental position. The fetal evaluation by ultrasound should be performed before 20 weeks so that appropriate referrals and consultation can be obtained if abnormalities are discovered.

Discussion with Patients and Families: Answering Questions

Patients need the opportunity to engage in dialogue with their health care provider and to feel confident that their concerns are heard. Patients and families will often interact with a nurse or triage person in a physician's office. These individuals need to be trained in careful assessment and evaluation. The value of information that ancillary personnel can provide cannot be overemphasized.

The prenatal visits are a time to stress the involvement of the entire family in the pregnancy process, including the role of the father and siblings. Therefore, an important part of the prenatal visit is discussion with the patient, her partner, or her family, both to exchange questions and answers and to provide reassurance and education. The exact content of these discussions will vary from visit to visit. Reaffirming the importance of appropriate social behaviors, such as smoking cessation, is beneficial, as are periodic evaluations of the social support systems and help in the home, both now and after the birth of the infant.

Ongoing risk assessment requires that the patient be educated about the signs and

symptoms of preterm labor and preeclampsia. The list of warning signs for which an emergent telephone call is warranted includes the following:

- Vaginal bleeding
- Leaking of fluid from the vagina
- Rhythmic cramping pains of more than six per hour
- Abdominal pain of a prolonged or increasing nature
- Fever or chills
- Burning with urination
- Prolonged vomiting with inability to hold down liquids or solids for more than 24 hours
- Severe continuous headache, visual changes, or generalized edema
- A pronounced decrease in the frequency or intensity of fetal movements.

Concerns and Questions Particular to Pregnancy

Pregnancy is a time of change, expectation, and anticipation. It may also be a time of heightened anxiety,

---

emotionality, concern, and uncertainty. Many symptoms that the nonpregnant patient might view as minor may indicate a cause for alarm during pregnancy. The provision of direct, concise, and accurate information in a compassionate and reassuring manner will assuage many of these worries and provide direction for day-to-day activities.

One of the roles of clinicians is to judge whether the symptoms a mother asks about and whether the physical findings measured are physiologic or pathologic. These judgments are most easily made and most easily explained to the patient and her family in the context of a few basic maternal physiologic adaptations. The first major maternal adaptation is cardiovascular. The maternal cardiovascular system must deliver enough nutrition and oxygen to the fetoplacental unit to ensure healthy development while at the same time not compromise the mother. During times of maternal activity when blood would normally be shunted from the viscera (including the uterus) to exercising muscles, there must be enough cardiovascular reserve to perfuse the uterus. This is accomplished through a series of steps that begin before the missed menses. Rising levels of progesterone induce increasing venous compliance. To maintain cardiac output, blood volume is increased. Blood volume reaches approximately 140% of normal by the early third trimester. Since only 25% of body water is intravascular, there is a compensatory increase in total body water. The clinician usually has to explain this to the woman who asks why at 8 weeks pregnant she already has to change pant size. The increased blood volume produces increased renal blood flow and increased glomerular filtration. Most medications are excreted much more quickly in pregnancy and level-dependent medications such as antiepileptics need to be adjusted. Blood vessel responsiveness to catecholamines and other pressors is reduced to inhibit shunting of circulation away from the growing uterus during stress, which leads to a generalized lower arterial and venous pressure. An additional effect of the relaxation of

smooth muscle by progesterone is the greater ability of the uterus to grow and stretch without the usual compensatory contractions. However, most other smooth muscle in the body is also affected, particularly in the gastrointestinal system.

The following sets of topics and problems are centered on the most frequently asked questions and most important areas of concern.

Nutrition and Weight Gain

The objectives of nutritional assessment and counseling are to develop, in concert with the patient, an analysis of maternal nutritional risk, a goal for total weight gain, and a diet plan that will fit the patient's lifestyle and is ethnically sensitive.

The principle of good nutrition is that there is a positive linear relationship between maternal weight gain and newborn weight and that prepregnant maternal BMI can affect fetal weight independently of the amount gained by the mother during pregnancy. Together, initial weight and weight gain have an impact on IUGR and low birth weight. However, for a woman of normal weight and normal nutrition, the relationship between poor weight gain and fetal growth restriction may be an association, not a cause and effect. Importantly, excess maternal weight gain is also directly proportional to adverse perinatal outcome.

The BMI is a calculation that relates the patient's weight to her height, thereby providing a more accurate indirect estimate of the patient's body fat distribution than can be obtained by weight alone. The BMI is calculated by dividing weight in kilograms by height in meters squared. If pounds and inches are used, the quotient is multiplied by 700. The BMI of a patient is categorized as underweight, normal weight, overweight, or obese.

Maternal Weight Gain

Although dependent on many factors, the ideal weight gain during pregnancy can be simplified into three recommendations based on the prepregnant BMI (for singleton pregnancies). Women with a prepregnant BMI <19.8 should gain between 30 and 40 lb. Women with a normal BMI of 19.8 to 26 should gain between 25 and 35 lb. Women with a high BMI, between 26.1 and 29, should gain 15 to 25 lb. Women who are obese should aim for a 15 lb weight gain (Fig. 1.8). The optimal weight gain for women with twins with a normal BMI is approximately 40 lb or 10 to 15 lb more than for a singleton.

Figure 1.9 illustrates the components of weight gain in a normal pregnancy. During the first and second trimesters, most of the weight gained reflects maternal changes, primarily an increase in total body water, while fetal growth is most rapid in the last trimester, with the fetus more than tripling its weight. Many women will not gain significant weight until the middle of the second trimester. Patients may be reassured that this is a normal pattern as long as weight begins to increase by 20 to 22 weeks. Poor weight gain is often a reflection of a patient not expanding her intravascular volume. This is associated with low birth weight and greater complications in pregnancy. Having patients “eat more” does not usually help. In contrast, weight gain greater than 30 lb in a singleton pregnancy will remain as extra weight after delivery. Excess weight gain is also associated with preterm

delivery; low birth weight; and in some women, a higher incidence of macrosomia. Recent studies have noted that adolescent women have the highest rate of excess weight gain in pregnancy, and several authors have suggested that this may be due to poor counseling of this age group.

Maternal Diet

While weight gain is an important gauge of caloric intake, the quality of the diet and the frequency of meals

may also affect patient and fetal well-being. A diet should be balanced by containing foods from all of the basic food groups. Specifics of a diet will vary considerably according to patient preference, family eating patterns, and cultural and ethnic background. Women should be instructed not to diet during pregnancy in terms of decreasing calories, but the issues of dietary requirements should be addressed.

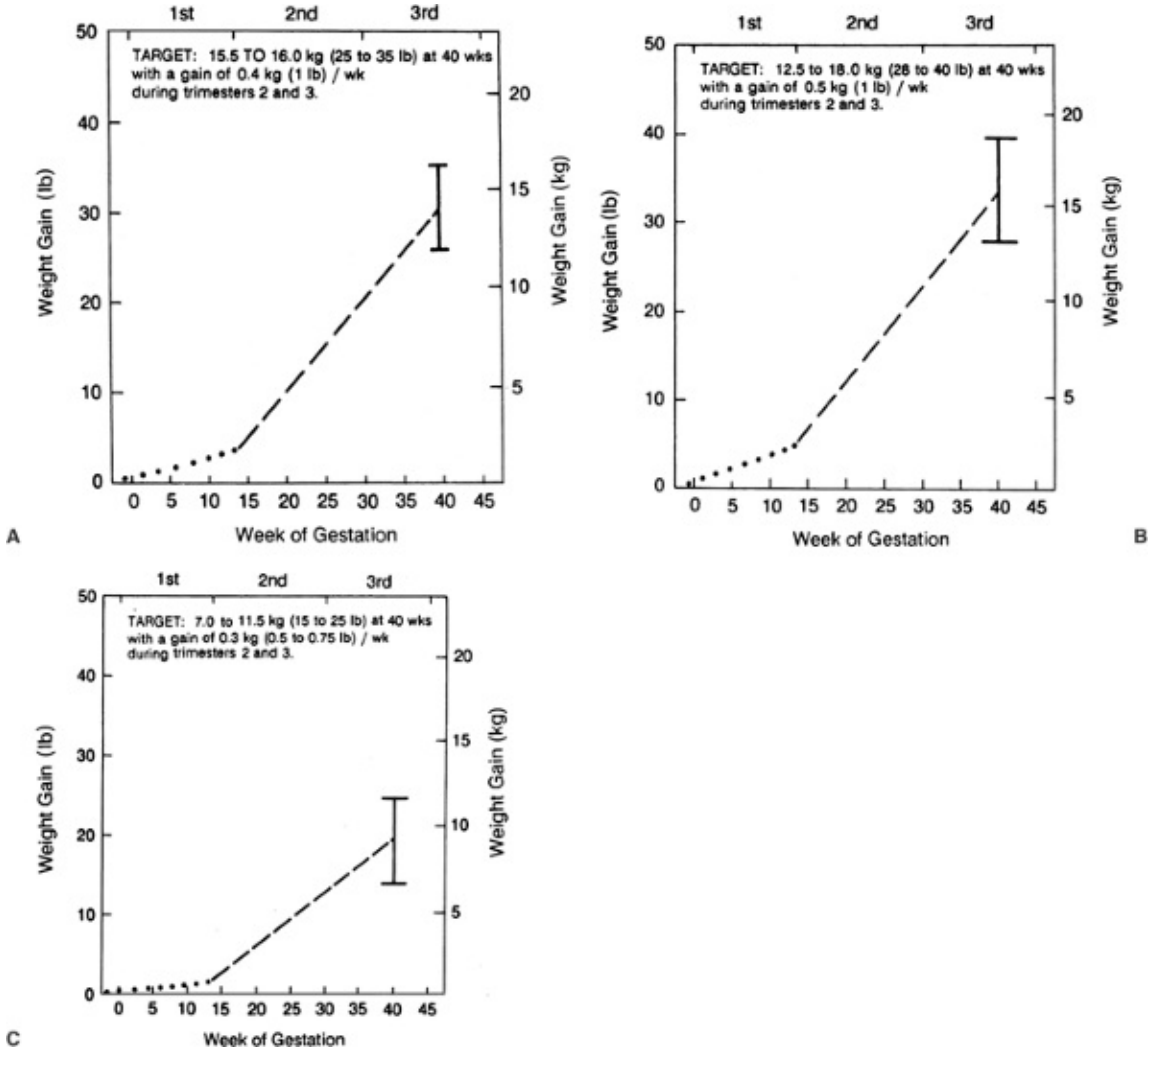

Figure 1.8 Target weight gains for normal-weight women with a BMI of 19.8 to 26.0, underweight women with a BMI of less than 19.8, and overweight women with a BMI of more than 26.0 to 29.0. **A:** A 1.60 kg (3.50 lb) gain in the first trimester and the remaining gain at a rate of 0.44 kg (0.97 lb) per week are assumed. **B:** A 2.30 kg (5.0 lb)

gain in the first trimester and the remaining gain at a rate of 0.49 kg (1.1 lb) per week are assumed. **C:** A 0.9 kg (2.00 lb) gain in the first trimester and the remaining gain at a rate of 0.3 kg (0.67 lb) per week are assumed.

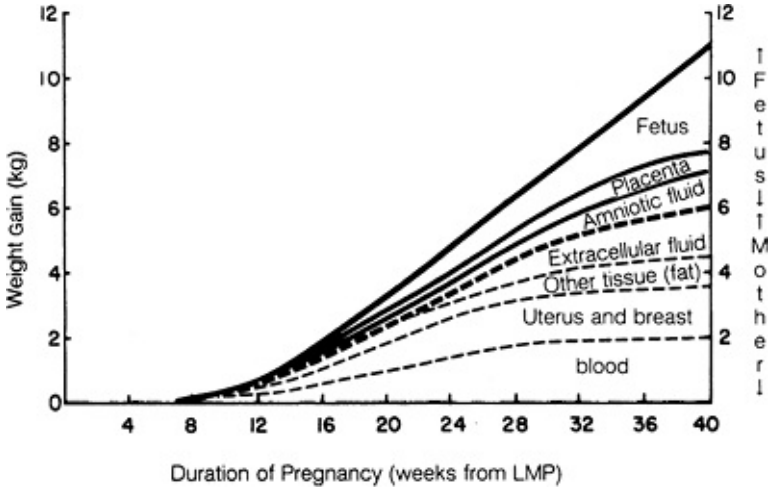

Figure 1.9 Pattern and components of weight gain during pregnancy. (LMP, last menstrual period.) (From Pitkin RM. Nutritional support in obstetrics and gynecology. *Clin Obstet Gynecol* 1976;19:489, with permission.)

Increased nutritional requirements during pregnancy reflect the needs of the fetus for growth as well as maternal physiologic needs. To meet the overall increasing energy needs, the average woman must consume an additional 300 kcal per day beyond her baseline needs. The appropriate daily caloric content of a diet required to supply energy needs and achieve appropriate weight gain can be estimated by multiplying the patient's optimal body weight in kilograms by 35 kcal and adding 300 kcal to the total (Table 1.5).

TABLE 1.5 Recommended Dietary Allowances for Women of Re Age and for Pregnant and Lactating Women

Nutrient	Nonpregnant Women	Pregnant Women	Increase (%)	Lactating Women	Sou
Energy	2,200 kcal	2,500 kcal	+14	2,640 kcal	Pro car
					Me

Protein	50 mg	60 mg	+20	65 g	pou dai
Fat-soluble vitamins

Iodine	105 mg	175 mg	+17	200 mg	Iod sea
Selenium	55 mg	65 mg	+18	75 mg	Sea live

Vitamin and Mineral Supplementation

Multivitamin supplements are not routinely necessary in a woman eating a well-balanced diet. However, 800 to 1,000 mg of supplemental folic acid daily is necessary because the

requirement cannot be met with food alone. Additional folate and sometimes B_{12} may be necessary for women with a hemoglobinopathy or MTHFR mutation, for women on antiseizure medications, or for women with a history of neural tube defects. Vitamin D supplementation is appropriate. Most women will have low levels of vitamin D, particularly women in northern latitudes and women in their mid thirties.

Mineral supplementation is also not needed in healthy women. The exception is iron. The iron requirements of pregnancy total about 1 g. Due to the monthly menses, most women have less than optimal iron stores during their reproductive years. Therefore, supplementation with 30 mg of elemental iron is recommended in the second and third trimesters to prevent anemia and to meet this requirement. One tablet of iron salts per day, ingested between meals or at bedtime, is sufficient to meet this requirement. Women with iron deficiency anemia require 60 to 120 mg of elemental ferrous iron per day. Additional zinc (15 mg) and copper (2 mg) are then needed, as iron inhibits the absorption of these ions. Iron is better absorbed in the ferrous state and with an acid pH. For women taking H2 blockers and proton pump inhibitors, taking the iron with orange juice or in a citric acid compound may be helpful.

Pregnancy is a time in which the mother usually experiences bone loss of calcium. Calcium supplementation is not necessary in women with a diet that includes adequate dairy foods. Unfortunately, many women will not meet their dietary needs for calcium. Absent this, calcium supplementation may be used on an as-needed basis to meet the recommended dietary allowance (RDA) of 1,200 to 1,500 mg per day during pregnancy and 2,000 mg per day with lactation. Women with twins may be given 2,000 mg daily. Women in their mid thirties should also receive increased dosing. Calcium is best absorbed in an acidic pH, similar to iron. To absorb calcium, adequate vitamin D is needed. Many women have insufficient vitamin D. Calcium supplements that contain vitamin D are desirable.

Zinc is a trace mineral. A zinc deficiency may be teratogenic in humans, although this has not yet been conclusively demonstrated. Zinc levels in amniotic fluid correlate with antimicrobial activity, suggesting that zinc plays a role in protecting against intrauterine infection. Low dietary intake of zinc has been associated with IUGR, although it does not cause IUGR. The RDA for zinc during pregnancy

---

is increased from 15 to 20 mg per day. Iodine deficiency can be associated in the most severe forms with cretinism—congenital hypothyroid. Most table salt contains iodine. For women who do not eat iodized salt, this can become a concern.

Other Dietary Considerations

Vegetarianism

Lacto-ovo vegetarians should have no particular nutritional deficiency, with the possible exceptions of iron and zinc, which may be supplemented. The strict vegan, however, must design a diet of sufficient vegetable proteins to provide all of the essential amino acids normally found in animal protein. Due to the decreased protein density of most vegetables,

this may cause an unusually high weight gain. Supplementation of zinc, vitamin B_{12}, and iron is necessary.

Food Restriction

Dieting and fasting on a chronic basis in an otherwise healthy woman can result in suboptimal fetal growth. Eating disorders such as bulimia and anorexia nervosa reflect extreme forms of food restriction and malnutrition. There are limited data about these disorders in pregnancy, but anorexics in particular place their fetus at risk. Bulimic women may suffer from electrolyte imbalance and a deficit of trace minerals.

Many pregnant women in the United States are not eating an optimal diet due to poverty and inadequate resources to purchase food. It is appropriate to inquire about resources in impoverished women and to refer these patients to groups such as WIC and to appropriate agencies providing food stamps.

Pica

Pica is the compulsive ingestion of nonfood substances with little or no nutrient value. The practice most commonly involves ice, clay (geophagia), or starch (amylophagia). Although pica is most commonly recognized during pregnancy, it is not specific to the gravid state. Neither the cause nor the medical implications of pica are well understood. It is unusual for pica to cause significant harm if the diet is otherwise nutritionally adequate.

Phenylketonuria

Women with phenylketonuria who are not on a phenylalanine-controlled diet are at increased risk of bearing fetuses with microcephaly, growth retardation, and mental retardation. The goal of dietary management is to minimize these adverse fetal outcomes by reducing the maternal serum phenylalanine levels to <20 mg/dL before and during the pregnancy. At the first prenatal visit, every pregnant woman should be asked if she was on a special diet as a child.

Megadose Vitamins

The misuse of megadose nutrients can be categorized as a fad type of dietary manipulation. Water-soluble vitamins such as vitamin C cannot be consumed in harmful quantities because they are readily excreted in the urine. However, a problem occurs with fat-soluble vitamin A. There is an association between high doses of supplemental vitamin A and birth defects similar to those seen with isotretinoin. Although the minimum teratogenic dose in humans has not been identified, it may be a little as 10,000 IU per day. Beta-carotene is a provitamin of vitamin A, but it does not produce similar toxicity. Most prenatal vitamins contain less than 5,000 IU of vitamin A and, until further data are available, this should be considered the maximum safe supplemental dose.

Women Who Have Had Bariatric Surgery

Women with gastric bypass and gastric stapling have an increased risk of nutritional problems. Calcium and iron are best absorbed in an acidic pH, and thus extra supplementation is recommended for these women in combination with an acid such as citric acid and vitamin D. Because many women with bariatric surgeries can eat only small meals, such supplements need to be spread out, and counseling regarding adequate protein intake is recommended as well. B_{12} absorption is promoted by an acidic environment in the stomach and by the binding of intrinsic factor made in the stomach. Thus, women with gastric bypass will develop B_{12} deficiency if they do not receive either parenteral B_{12} supplementation or the B_{12} formulation that is absorbed in the mouth. It is recommend that B_{12} levels are checked in women who have had bariatric surgery at the first visit and providing appropriate supplementation 500 mcg per day. Vitamin B deficiencies in the mother have been associated with both fetal anomalies, miscarriage, and failure to thrive in the infant.

Caffeine

Caffeine is contained in numerous foodstuffs such as coffee, tea, chocolate, and cola beverages. A naturally occurring substance, it is the most widely used psychoactive drug in the United States. It is a central nervous system stimulant and is physically and psychologically addictive. Withdrawal symptoms include nausea, lethargy, malaise, and headache. The only evidence for teratogenic effects of caffeine comes from animal studies using doses not compatible with human consumption. Several large human studies have failed to show that caffeine has deleterious effects on the fetus when ingested in low amounts. However, it is associated with an increased risk of miscarriage when taken in greater than the equivalent of three cups of coffee. Caffeine intake of the equivalent of two to three cups is thus discouraged. Adverse maternal effects of caffeine include insomnia, acid indigestion, reflux, and urinary frequency. As these problems are already exaggerated in pregnancy, moderation in the consumption of caffeine is advisable.

Seafood

High levels of seafood intake are associated with high levels of mercury in umbilical cord blood samples as well as in maternal blood and tissue samples. Mercury is a treratogen and a neural toxin in the developing fetus and child. Current recommendations are to limit seafood to two servings per week of seafood such as light (not albacore) canned tuna, salmon, or shrimp. Avoid swordfish, shark, mackerel, and tilefish, which are particularly high in mercury. The older and bigger the fish, the higher the levels of mercury.

Nausea and Vomiting

Recurrent nausea and vomiting during the first trimester occurs in over one half of pregnancies. While the term *morning sickness* is well known, it is a misnomer, as these symptoms can occur at any time throughout the day or night. Symptoms usually begin in weeks 6 to 8, peak during weeks 12 to 14, and are significantly resolved by week 22. The

etiology of this problem is not clear. Hormonal as well as emotional factors have been investigated without consistent results. Symptoms can be mild or so severe that the patient becomes dehydrated and risks electrolyte imbalance and caloric malnutrition. Nonpharmacologic measures often suffice and may completely relieve the symptoms in some women. These include avoidance of fatty or spicy foods; eating small, more frequent meals, thus keeping something in the stomach; and inhaling peppermint oil vapors. Randomized trials have validated the effectiveness of fresh ginger—which may be made into a tea, candies, or compounded—in decreasing nausea and vomiting. Several studies have evaluated vitamin B_6, 25 mg two to three times a day, and found this helpful in eliminating nausea and vomiting. The use of the Nguyen pressure point on the wrist is also suggested to be helpful. Motion sickness bands on the wrists employ this technique.

In more severe cases of emesis, various pharmacologic agents have been used with varying success. These include a variety of antihistamines, doxylamine, promethazine, metoclopramide, trimethobenzamide, methylprednisolone, and serotonin 5-Ht3 antagonists such as ordansetron. Because supplemental vitamin and mineral preparations may exacerbate symptoms of nausea, they should be stopped until the symptoms have resolved. Women and their families may be reassured that minimal weight gain in the first 18 weeks is common. Hyperthyroid disease will exacerbate nausea and vomiting, and if signs of thyroid disease are present, free T4 levels should be obtained and treatment initiated. Some studies have found *Helicobacter pylori* infection in women with more severe hyperemesis and resolution or decrease in symptoms with treatment.

Ptyalism

Ptyalism is the increased production of saliva, sometimes induced by the consumption of starch. There is no cure, although reducing carbohydrate intake may be helpful. The problem is often self-limiting. It is not uncommon in pregnancy and is not associated with adverse outcome.

Heartburn

Heartburn is usually caused by reflux esophagitis from both mechanical factors (the enlarging uterus displacing the stomach above the esophageal sphincter) and hormonal factors (progesterone causing a relative relaxation of the esophageal sphincter). Treatment consists of eliminating acidic and spicy foods, decreasing the amount of food and liquid at each meal, limiting food and liquid intake before bedtime, sleeping in a semi-Fowler position or propped up on pillows, and use of antacids. Liquid forms of antacids and H2-receptor inhibitors provide the most consistent relief of symptoms. Patients should be cautioned that antacids containing aluminum may cause constipation, while diarrhea may be associated with use of those containing magnesium. Proton pump inhibitors are sometimes necessary in severe cases. In women with chronic antacid use, careful attention should be given to iron and calcium absorption.

Constipation, Diarrhea and Gas

Progesterone-induced relaxation of the intestinal smooth muscle slows peristalsis and increases bowel transit time. Dietary management of this common condition includes increased fluids and liberal intake of high-fiber foods. Iron salts may exacerbate the problem. OTC products containing psyllium draw fluid into the intestine and promote a more rapid transit time. Enemas and strong cathartics should be avoided. Many women develop very different bowel patterns during pregnancy. Extra gas and loose stools are not uncommon symptoms. As long as there are no signs of underlying diseases such as parasites or inflammatory bowel disease, the patient may be reassured.

Exercise

Exercise is a routine part of many women's daily activities. For a normal pregnancy, a low-impact exercise regimen may be continued throughout pregnancy. Additionally, studies also show that women may increase their levels of fitness during pregnancy without problems. There are no data to indicate that pregnant women must decrease the intensity of their exercise or lower their target heart rates. However, physiologic changes of pregnancy may alter the effect of various exercises on the body or may limit the body's ability to perform certain types of exercise. Body position as a modulator of cardiac output is particularly important in the third trimester, when either motionless standing or the supine position can result in decreased venous return and cardiac output. In some instances, this will result in hypotension or syncope.

Both oxygen uptake and baseline oxygen consumption are increased during pregnancy. Deep breathing is more difficult, particularly in later pregnancy, due to uterine size and decreased diaphragmatic excursion. These changes combine to make less oxygen available for aerobic activity, thereby decreasing maximum exercise performance.

Exercise is not a means of weight control in pregnancy. Women who seek to exercise to keep from gaining weight or losing their prepregnancy shape should be counseled regarding normal pregnancy body changes.

Data regarding the fetal response to maternal exercise are reassuring. Moderate (submaximal) exercise has never been shown to increase maternal core body temperature and thus fetal temperature. Studies of the fetus following submaximal maternal exercise (65% to 70% aerobic capacity) have not shown any associated changes in the fetal heart rate. Exercise-induced effects on the fetus, including malformations, increased miscarriage rates, retardation, or growth restriction, have not been demonstrated in human pregnancies. Women who exercise strenuously throughout pregnancy, such as elite athletes, may deliver infants as much as 300 to 400 g smaller in weight than women who do not exercise as strenuously. This, however, is not considered deleterious.

Women who exercise regularly before pregnancy may be encouraged to continue. They may be counseled that performance capacity tends to fall, but this is not a sign that they should forgo regular moderate exercise. Indeed, exercise may relieve stress, diminish anxiety, and increase self-esteem. Some studies have also shown that women who exercise regularly have shorter labors. For most women with GDM, regular exercise has been shown to be helpful for glucose control.

Specific exercise regimens should be individualized, and patients who have not been physically active prior to pregnancy are advised to proceed slowly. General recommendations are contained in Table 1.6

Varicosities and Hemorrhoids

Varicosities most often occur in the lower extremities and may be seen in the vulva as well. Contributing factors include genetic predisposition, advanced maternal age, increased parity, and prolonged standing. Manifestations can range from mild cosmetic effects to chronic pain and superficial thrombophlebitis. Treatment includes avoidance of garments that constrict at the knee and upper leg, support stockings, and increased periods of rest with the legs elevated. If superficial thrombophlebitis develops, it is reasonable to evaluate for the presence of thrombophilias. If a thrombophilia is present, an empiric 5- to 7-day course of low-molecular-weight heparin in a low dose to help alleviate symptoms is often given. The presence of a silent deep vein thrombosis is also checked.

Hemorrhoids, which are varicosities of the rectal veins, are due to mechanical compression by the enlarging uterus as well as from constipation and straining at stool. Treatment includes OTC preparations, witch hazel, topical preparations, cool sitz baths, and stool softeners. If thrombosis of a hemorrhoid occurs, the clot can be excised to relieve pain and swelling.

TABLE 1.6 Recommendations for Exercise in Pregnancy

- Exercise should be regular rather than sporadic and intermittent.
- Exercise should be stopped if signs and symptoms of oxygen deprivation occur, such as extreme fatigue, dizziness, or extreme shortness of breath.
- To avoid becoming overheated, pregnant women should exercise in a cool area, stay well hydrated, and wear appropriate clothing.
- Exercise that requires prolonged time in the supine position should be avoided during the second and third trimesters.
- The form of exercise chosen should not be one with significant risk of trauma (especially to the abdomen) or falls.
- Caloric intake should be increased in direct proportion to the additional energy requirements of exercise.

Contraindications

Relative contraindications to exercise during pregnancy include the following:

- Evidence of IUGR
- Persistent vaginal bleeding
- Incompetent cervix or cervical cerclage placement
- Risk factors for preterm labor
- Rupture of membranes
- Pregnancy-induced hypertension
- Chronic medical conditions that might be adversely impacted by vigorous exercise.

Fatigue

Pregnant women will usually have an increased sense of fatigue during pregnancy. This is a normal symptom. A sense of breathlessness is also normal because of the progesterone stimulation of the respiratory centers. However, a significant increase in fatigue or breathlessness should alert the clinician to possible pathology.

Syncope

Venous pooling in the lower extremities increases as the pregnancy progresses. This can lead to dizziness or lightheadedness, especially after standing upright abruptly or for long periods of time. Other causes of syncope include dehydration, hypoglycemia, and the shunting of blood flow to the stomach after eating a large meal. Syncope during exercise is a sign of overexertion. In general, syncopal episodes resolve rapidly and should be managed acutely, just as in a nonpregnant patient. Syncope in the supine position is avoidable by resting in the lateral recumbent position, right or left, thereby relieving uterine compression of the vena cava. Some women will suffer from

excessive syncope throughout gestation. The serotonin antagonist paroxetine has been prescribed in this situation. Consideration should be given for women with recurrent severe syncope to be evaluated for maternal tachyarrhythmias with a Holter monitor.

Sleep Disturbances, Restless Leg Syndrome, and Leg Cramps

Most women will develop alterations from their normal sleep patterns during pregnancy. More frequent urination, more common gastric reflux, and physical discomfort with the growing pregnancy all contribute to poorer sleep. Some authors have described more common snoring (up to 30%), less rapid eye movement (REM) sleep, and much more vivid dreams. Antihistamines are usually recommended as a first-line sleeping aid, if necessary. Restless leg syndrome (RLS) is also a common complaint for pregnant women (approximately 25% of women may develop RLS during pregnancy). Women with RLS

experience the need to move the legs and calves, parasthesias in the lower extremities, and worsening of symptoms at night. This syndrome has been associated with iron deficiency, and thus treatment with iron supplementation may decrease symptoms. Almost half of all pregnant women suffer from recurrent painful spasms of the muscles of the lower extremities, especially the calves. Leg cramps are more frequent at night and usually occur during the third trimester. Various prophylactic and therapeutic options have been suggested—most notably, calcium lactate and high-potassium foods such as banana, kiwi, or cantaloupe—but there are no data from controlled trials to show benefit over placebo for any of these. Massage, heat, and stretching the affected muscle(s) relieves the cramps when they occur.

Backache

Most pregnant women experience lower backaches as pregnancy progresses. These are usually alleviated by minimizing the amount of time spent standing, increasing rest, wearing a specially designed support belt over the lower abdomen, and taking an analgesic such as acetaminophen. Exercises to increase muscular strength of the back and abdomen are sometimes helpful. Shoes with good support and avoidance of high heels that exaggerate the lordotic posture are essential. Increasingly severe or abrupt-onset back pain requires orthopedic consultation. Rhythmic cramping pains originating in the back may be a sign of preterm labor that necessitates appropriate evaluation.

Round Ligament Pain

Round ligament pain most frequently occurs during the second trimester when women report sharp, bilateral, or unilateral groin pain. It has been called *round ligament pain*, although it is not known if round ligament stretch is the true etiology. The pain may be increased with sudden movement or change in position. Resolution of unremitting ligament pain is sometimes achieved by having the patient assume a position on the hands and knees and lower the head to the floor while keeping the buttocks in the air.

Headache

Generalized headaches are not uncommon during the first trimester of pregnancy. Muscle tension headaches may occur intermittently. The frequency and intensity of migraine headaches may increase or decrease during pregnancy. Headaches during the second and third trimesters are not an expected symptom of pregnancy. Pathologic headaches that occur with preeclampsia are discussed in Chapter 16.

Emotional Changes

Pregnancy is a time of significant psychological stress. Changes in hormonal levels; changes in relationships to partners, family, and friends; and changes in body image all lead to increased psychological stress. Increased levels of placental corticotropin-releasing hormone toward the end of pregnancy also affect the maternal hypothalamic–pituitary axis and other brain loci involved in stress responses. There is a corresponding shift in most

women toward primary process. Dreams become more vivid and dramatic. Emotional lability is common. It is very helpful to counsel the pregnant woman and her partner about these normal changes. Women with social stressors or those with a history of depression may develop signs of atypical depression, necessitating counseling and medications. Elevated stress and anxiety has been associated with an increased incidence of adverse pregnancy outcomes.

Sexual Relations

Coital activity during normal pregnancy need not be restricted. The couple can be counseled regarding changing positions to achieve better comfort. Deep penetration may be more uncomfortable as pregnancy progresses. It is common for women to have changes in sexual desire over the course of gestation. Many women achieve orgasm easier during pregnancy; however, libido often decreases in the first and third trimesters. Nipple stimulation, vaginal penetration, and orgasm can cause uterine contractions secondary to the release of prostaglandins and oxytocin. However, there are no proven adverse effects on the fetus or the onset of labor. The question of the effect of coitus in women at risk for preterm labor or early spontaneous pregnancy loss remains unanswered. Couples at risk may prefer to avoid sexual relations to minimize any feelings of guilt or responsibility if a problem occurs subsequently.

There are two concrete interdictions to coitus during pregnancy. The first is that intercourse should not occur

---

after membrane rupture or in the presence of known placenta previa. The second is that forceful introduction of air into the vagina should be avoided because of the risk of fatal air embolism.

Employment

Most patients are able to continue to work throughout their pregnancy. In general, work activities that increase the risk of falls or trauma, especially to the abdomen, should be avoided. Hazardous toxic or chemical exposures should be identified early and avoided. Strenuous physical activity, including repetitive lifting and prolonged standing for more than 5 hours, has been associated with a greater rate of adverse outcomes, and work routines should be modified accordingly.

Urinary Frequency

Patients often experience urinary frequency during the first 3 months of pregnancy, as the enlarging uterus compresses the bladder, and again during the last weeks, as the fetal head descends into the pelvis. If frequency occurs in conjunction with dysuria, hematuria, or urgency/hesitancy, the patient should be evaluated for a urinary tract infection.

Skin Changes

Hair growth has variable patterns in pregnancy, although many women experience

increased growth during pregnancy and hair loss postpartum. Skin commonly darkens over the face and the median ventral line of the abdomen in many women. Any nevi that change color should be excised.

Leukorrhea

An increase in the amount of vaginal discharge is physiologic and expected during pregnancy. Discharge accompanied by itching or burning or a malodorous discharge should be evaluated and treated accordingly. Douching has no place in the treatment or management of leukorrhea in pregnancy. Increased watery discharge may precede preterm labor and should be evaluated.

X-rays/Ionizing Radiation

The adverse effects on the fetus of ionizing radiation are dose dependent. While there is no single diagnostic procedure that results in a dose of radiation high enough to threaten the fetus or embryo, cumulative exposures or multiple procedures should be avoided, especially during the first trimester when the fetus is at highest risk for possible anomalies. Patients may undergo dental x-rays as needed, provided that the abdomen is fully covered by a lead apron. Studies using radioactive isotopes are best avoided. As in all diagnostic procedures, the risks and the potential benefits must be evaluated and individualized for each patient. Exposure to video display terminals is safe in pregnancy.

Travel

Most issues concerning travel involve the comfort of the mother. When prolonged sitting is involved, the patient should try to stretch her legs and walk for 10 minutes every 2 hours to decrease the risk of thrombosis that can occur secondary to the hypercoagulable pregnancy state and mechanical compression of venous blood flow from the extremities. Dependent edema may also be more pronounced after prolonged sitting. If the patient will be away from home for a significant period of time, she should take a copy of her medical record with her. Pregnant women can and should always wear seat belts when riding in a car. Travel in a pressurized airplane presents no additional risk to pregnant women. In traveling abroad, especially to underdeveloped countries, the usual precautions should be taken regarding ingestion of unpurified drinking water and uncooked fruits and vegetables.

Immunizations

Four immunizations using vaccines containing live viruses are relatively contraindicated during pregnancy. These are measles, mumps, rubella, and yellow fever. However, in certain circumstances, risk/benefit assessment may lead to receiving the immunizations. The risks for the fetus from the administration of rabies vaccine are unknown, and each case must be considered individually since the indications for prophylaxis are not altered by pregnancy. Tetanus toxoid, if needed, is acceptable in pregnancy. Flu vaccine is recommended for pregnant women. Women who are receiving hepatitis B vaccine may continue receiving it during pregnancy. Immune globulin for acute exposures to hepatitis A

also is considered safe.

Preparing for Childbirth

Prenatal Education Classes

Few empiric studies have examined the impact of prepared childbirth education on perinatal outcomes, but such education is generally believed to be helpful and valuable. The landmark volume *Birth of a Child* by Grantley Dick-Read, published in 1958, changed the modern face of childbirth education. Formal childbirth classes evolved rapidly in a multiplicity of settings. The goals of these classes are to educate and to answer questions in an environment conducive to the woman's new state of being so that both the patient and her partner have the opportunity to decrease their anxiety level and increase their knowledge. Classes are designed to be an empowering experience, helping the parent(s) become a part of the process rather than the

---

object of the actions of others. The content of childbirth classes varies but usually includes topics such as normal labor and delivery, anesthesia, breathing and concentration techniques, obstetric complications and interventions, and obstetric operations. Many instructors encourage patients to formulate a “birth plan” and to put this in writing and share it with the clinician. This can facilitate communication between the parents themselves and between patient and caregiver.

Certain decisions are best considered and made prior to delivery. These include issues such as breast-feeding, postpartum contraception, return to work, and circumcision of a male infant. It is helpful if parents are given information in a nonjudgmental, nonthreatening environment so that they may make appropriate, well-considered, and informed decisions. Discussion regarding breast-feeding bears further emphasis. Several authors have noted that in most populations, antenatal discussions regarding breast-feeding increases the incidence and success of this very important aspect of childbearing.

Signs of Labor

The final element in preparing for childbirth is knowledge of when labor is occurring and when it is appropriate to notify the health care provider. Patients should be given a 24-hour phone number to call for assistance. A course of action should be made clear to the patient and her partner. As has been reinforced throughout pregnancy, any warning signs of potential adverse outcomes mandate an immediate telephone call.

Conclusion

The future of effective and efficient prenatal care in the United States depends largely on access, the ability to demonstrate clear benefit for patients, and the incorporation of evidence-based data and practices that have well-defined outcomes and use cost-effective methods.

Of equal importance to the content of prenatal care is the manner in which it is delivered.

A crucial determinant of effective prenatal care is the clinician-patient relationship. Virtues of trust, honesty, and ethical treatment are integral to achieving the goal of prenatal care, which emphasizes allowing patients to be active in their health care. The skill of a caregiver can prevent the alienating experience of a bad outcome, but caregivers who look for a solution to their own powerlessness in the domination of patients or the domination of natural processes can make good outcomes alienating experiences for their patients. Caregivers must be aware of cultural diversity and assess the care they give, not in terms of their own needs or the needs of a profession or a medical organization but in terms of those who have entrusted them with care.

Summary Points

- Pregnancy is a normal physiologic event in a woman's life, and most pregnancies are normal. Pregnancy is a time of significant psychological transitions that are experienced in varied ways by each mother.
- The preconception visit is a focused visit that allows systematic identification of potential risks and the implementation of early interventions.
- The appropriate content of the first prenatal visit and subsequent prenatal care is contained in formalized published forms.
- A firm scientific foundation for the content and timing of prenatal care visits and the relationship of such care to maternal and newborn outcomes is under continued review.
- Pregnancy is a time of change, expectation, anticipation, concern, and uncertainty for many women and their families; the provision of direct, concise, and accurate information in a compassionate and reassuring manner by the clinician is therapeutic.
- Each prenatal visit should evaluate and address interval history, maternal changes, fetal growth, specific interventions, and general patient concerns.

Normal Labor

Physiology

The course of normal human labor and delivery comprises a complex relationship between several dynamic parameters, including uterine contractions, cervical dilation, fetal descent, and elapsed time. Once the diagnosis of labor is made correctly, one can apply empiric models of progress in labor to identify labor abnormalities and apply effective interventions.

The onset of labor in humans occurs around 280 days, or 40 weeks, from the first day of a patient's last menstrual period (LMP). Because the estimated date of confinement (EDC), or “due date,” is associated with much anticipation and planning on the part of patients, care must be taken to educate the patient about the uncertainties inherent in setting the EDC as well as to ensure that the assignment of the due date is based on accurate medical data, insofar as this is possible. Individual variation accounts for a range for the onset of labor that spans 2 weeks on either side of the best estimated EDC; spontaneous labor between 38 and 42 weeks is considered normal. It is then the responsibility of the health care provider, when estimating a date of confinement, to take an accurate menstrual and contraceptive history in order to avoid assigning an incorrect date. If the patient's cycle length is anything other than 28 days, the EDC must be adjusted accordingly, as much of the variation in cycle length is associated with the follicular, or preovulatory, phase. If conception occurs while the patient is using, or had recently been using, hormonal contraception, the date of ovulation may again be something other than 14 days after the LMP. If so, early ultrasound may be warranted in order to date the pregnancy more accurately and avoid mis-timing of medical interventions. While such attention to detail may seem insignificant at the time, many interventions including unnecessary tocolysis and

unindicated induction of labor may result from an inaccurately dated pregnancy.

The physiology of normal labor in humans remains incompletely understood. Evidence from sheep models suggests that the causative event in labor onset is a fall in maternal serum progesterone, concomitant with a rise in estrogens, all triggered by fetal adrenal cortisol production. However, a dramatic decrease in serum progesterone at term is not seen in humans, and an intact fetal hypothalamic-pituitary-adrenal axis does not seem necessary for labor to occur, as observed in pregnancies complicated by fetal anencephaly where the average delivery date is 39 6/7 weeks. Research in murine models suggests a role for prostaglandin synthesis in the onset of labor, although such data are again limited by interspecies differences. It is likely that the human uterus, a muscular organ with significant resting tone outside of pregnancy, is under negative inhibition during the bulk of pregnancy, and only near term is that negative inhibition lifted, thus enabling coordinated uterine contractions to occur. Because

of the relatively poor understanding of the physiology of human labor, effective treatments for preterm labor and for induction of labor have remained elusive.

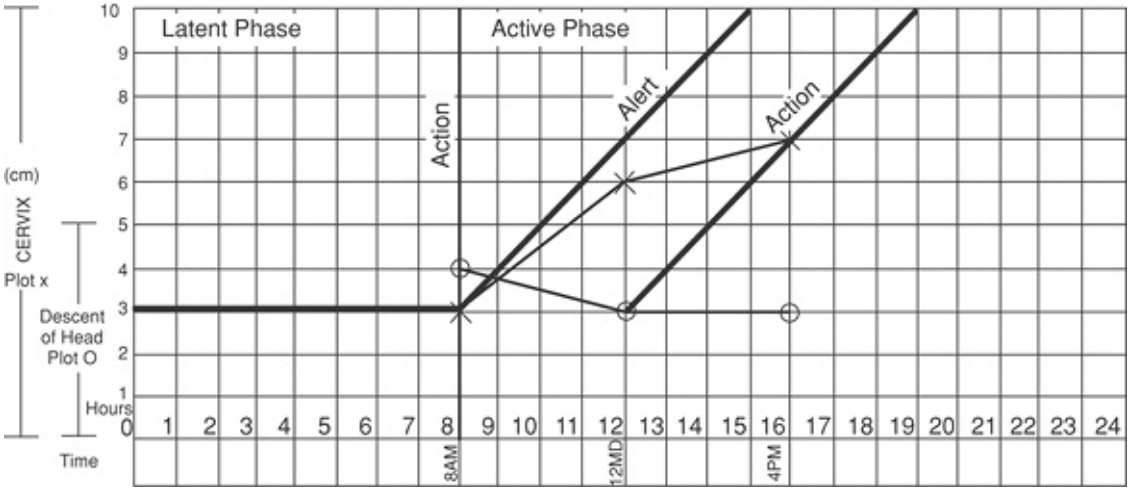

Figure 2.1 Flow sheet for following labor progress. (From Chua S, Arulkumaran S. Poor prognosis in labor, including augmentation, malpositions and malpresentations. In: James DK, Steer PJ, Weiner CP, et al., eds. *High risk pregnancy*, 2nd ed. London: Harcourt Brace, 1999:1105, with permission.)

Stages of Labor

Clinically recognizable labor is typically divided into three stages, each with statistically derived normative rates and durations. Many of these labor values were elucidated by Emanuel Friedman, who in the 1950s published his studies of hundreds of normal and abnormal labors and plotted cervical dilation and fetal descent against time. The resulting graphic labor curve was used to recognize individual labor patterns that deviated from normal and to guide the nature and timing of interventions. A more recent evaluation of

labor and delivery patterns takes into account changes in both medical management of labor (including higher induction rates, more use of oxytocin and regional anesthesia, and higher rates of continuous fetal monitoring) and in patient characteristics (including increased body mass index [BMI] and decreased smoking rates, both of which have contributed to an increase in fetal size) and suggests a significantly longer duration of the active phase of labor among the contemporary population. Regardless, the very practice of tracking labor in a formal fashion appears to improve labor outcome. In a World Health Organization study of 35,484 women, use of a “labor curve” or partogram (Fig. 2.1) and an agreed on labor management protocol was associated with a reduction in the percentage of prolonged labors, the proportion of labors requiring augmentation, and postpartum sepsis.

The first stage of labor consists of the time between the onset of regular contractions associated with cervical change and the occurrence of complete cervical dilation. The first stage is further divided into latent and active phases. Although the distinction between the two phases can be difficult to make, the latent phase of labor is characterized by a slower rate of cervical dilation despite strong, regular uterine contractions. The latent phase can normally last up to 14 hours in multigravid patients and up to 20 hours in nulligravidas. In the active phase of labor, there is a more rapid change in cervical dilation. Patients may move extremely rapidly through active labor, although the lower limit of normal for cervical change is about 1 cm per hour for nulliparous women.

In the majority of patients, the transition between the latent and active phases occurs at some time between 3 and 5 cm of cervical dilation, although it is possible, particularly in multigravid patients, to see a patient who is 5-cm dilated and still in the latent phase of labor. It is also critical for the clinician to accurately distinguish between latent phase labor, during which incremental cervical change is occurring (although slowly), and dysfunctional uterine contractions, a condition characterized by no change in cervical dilation despite strong, painful uterine contractions. Such dysfunctional contractions do not constitute labor, and treating them as such may lead to unnecessary intervention.

The second stage of labor is defined as the interval between complete cervical dilation and delivery of the baby. This stage is characterized by descent of the fetal presenting part; maternal sensation of pelvic pressure as this descent progresses; and maternal expulsive efforts, which in concert with uterine contractions effect delivery of the baby. The duration of the second stage varies with parity, ethnicity, fetal size, and the presence or absence of regional anesthesia and can range from only minutes to as much as 3 hours.

Finally, the third stage of labor comprises that time period between delivery of the baby and delivery of the placenta and may take up to 30 minutes, although usually is much shorter.

Mechanics of Labor

Human labor differs from that of other mammals, not only with regard to physiology but also in the way in which the

---

fetus moves through and out of the birth canal. The mechanism of human labor is

complicated by two main evolutionary changes: increased brain size and changes in pelvic shape due to bipedal posture. Both present challenges to the "fit" between the fetal skull and the maternal pelvic outlet. Whereas labor complications in other mammals are mostly related to malpresentations, labor dystocia in humans may occur simply due to fetal head position or subtle differences in the shape of the maternal pelvis. Therefore, it is critical for the obstetrician to understand the anatomy of the pelvis as well as how to assess the presentation, lie, and position of the fetus.

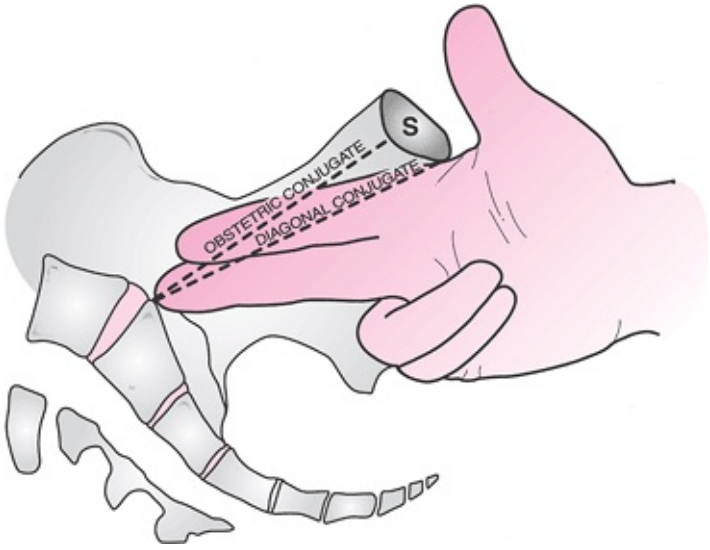

Figure 2.2 The pelvic inlet AP diameter is estimated from the diagonal conjugate.

Pelvimetry

Clinical assessment of the pelvis involves manual evaluation of the pelvic inlet, midpelvis, and outlet (Figs. 2.2, 2.3).

- *Pelvic inlet*—The transverse diameter of the pelvic inlet averages 13 cm. It cannot be measured clinically, but a narrow transverse inlet is a very rare cause of abnormal labor progress. The anteroposterior (AP) diameter of the inlet is more important. It is estimated clinically by determining the distance between the lower margin of the symphysis pubis and the sacral promontory. This value is known as the *diagonal conjugate*. The obstetric conjugate—or true AP diameter—is 1.5 to 2.0 cm shorter. The pelvic inlet is an adequate size for a normal fetus if the diagonal conjugate is 12 cm or greater.

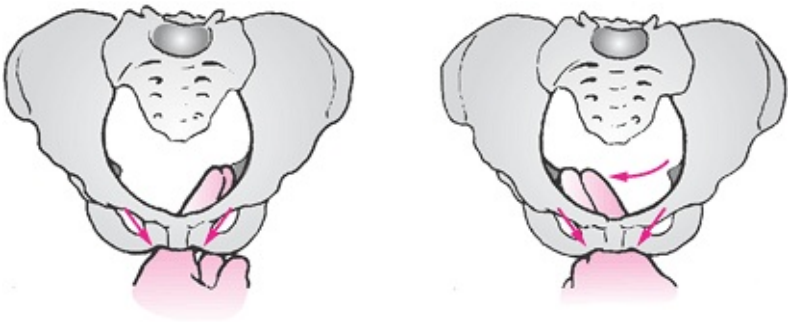

Figure 2.3 The transverse diameter of the midpelvis is estimated by evaluating the distance between the ischial spines.

- *Midpelvis*—The specific diameters of the midpelvis cannot be measured clinically. Contraction of the midpelvis is suspected if the ischial spines are quite prominent (or the sacrosciatic notch is less than two fingerbreadths wide), the pubic arch is narrow, the pelvic sidewalls converge, or the sacral concavity is quite shallow.
- *Pelvic outlet*—The transverse diameter of the pelvic outlet should be greater than 8 cm. This diameter can be estimated by placing a fist on the perineum to measure the distance between the ischial tuberosities.

Consideration of these measurements allows assignment to one of the various pelvic types and thus an appreciation of how and where labor may be stalled if the pelvis is not favorable for childbirth. Careful evaluation of the midpelvis is most important, as those women found to have a contracted midpelvis are poor candidates for forceps-assisted vaginal delivery. However, because the fetal skull has the ability to mold, and because overall fetal size is variable, borderline pelvimetry is not a contraindication to a trial of labor.

Fetal Orientation

Clinicians who provide care for women in the third trimester of pregnancy should assess the orientation of the fetus at each visit. Early detection of abnormal fetal orientation can increase the success of interventions to correct this; for example, the chance of successful external cephalic version of a breech fetus is greater if the version is performed prior to the onset of labor.

The fetal lie is the relationship between the sagittal plane of the fetus and the mother. The vast majority of patients in labor have a longitudinal fetal lie, although risk factors including multiparity and uterine or fetal anomalies may increase the rate of transverse or oblique lie. Fetal presentation refers to the part of the fetus that is closest to the pelvic inlet. Most often, the fetus is in cephalic presentation,

and of those, the majority are in a vertex (posterior fontanel as the presenting landmark) presentation. Other presentations include brow and face. Breech presentation is classified into several subcategories: complete (hips and knees flexed), frank (hips flexed, knees

extended), and incomplete or footling (one or both lower extremities presenting). Finally, fetal position describes the relationship of a presenting part to the maternal pelvis. For purposes of describing fetal position, the point of reference in a vertex presentation is the occiput; for a breech, it is the sacrum; and in face presentations, it is the chin (or mentum). The reference point is described in its relationship to the maternal pelvis. Thus, with a vertex presentation, the occiput on the maternal left side of the pelvis, and the fetal sagittal suture transverse in the pelvis, the position is left occiput transverse, abbreviated as LOT.

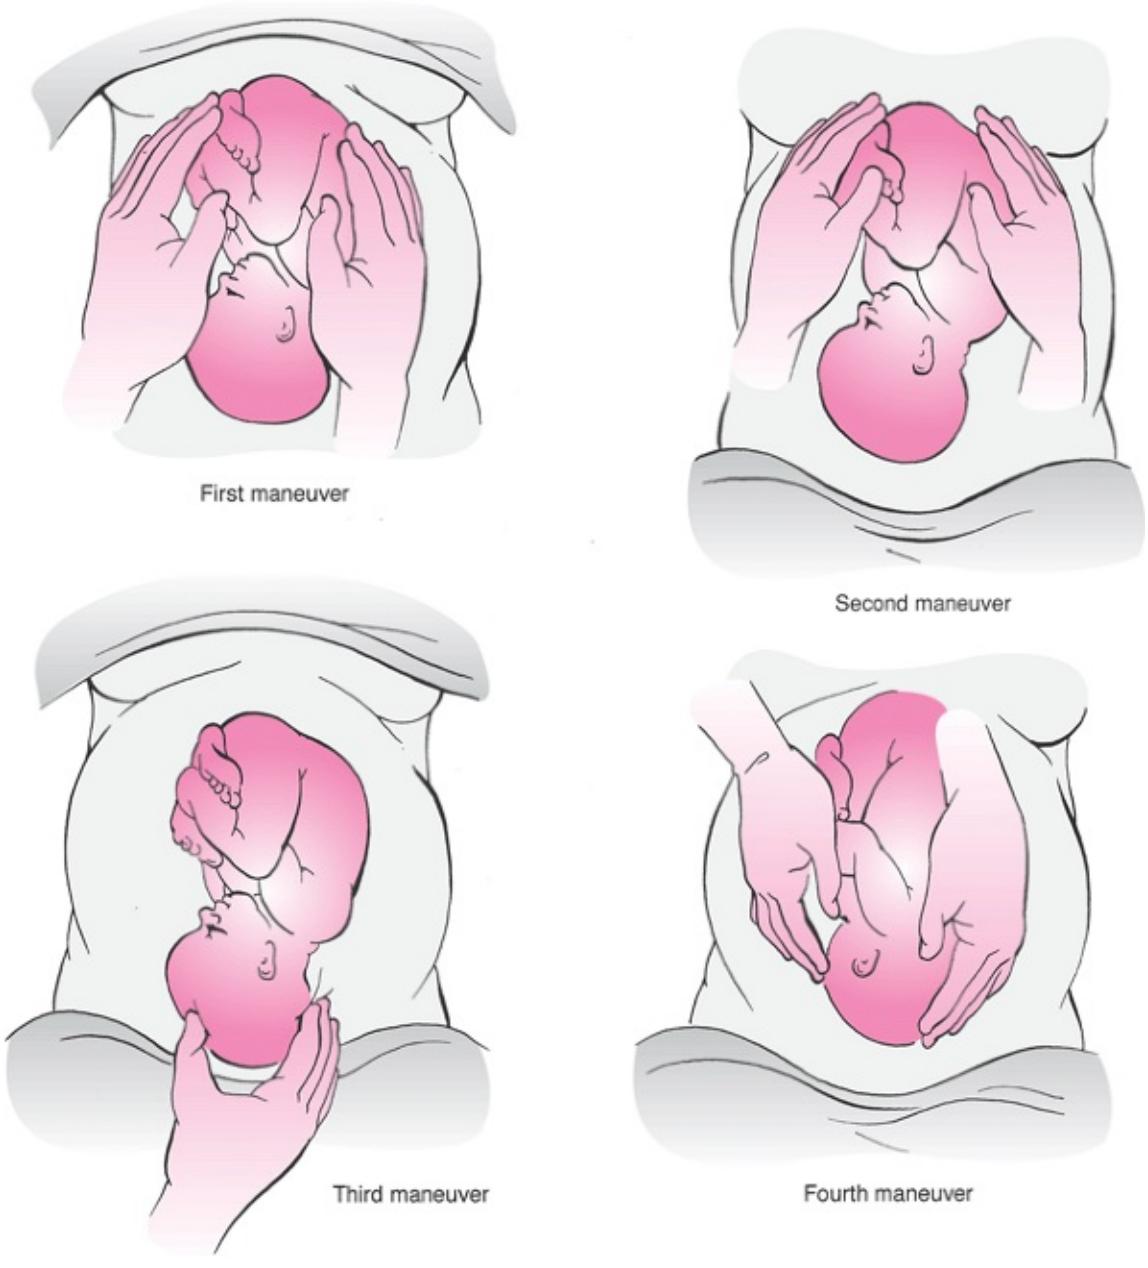

Figure 2.4 Leopold maneuvers. **First maneuver:** The uterine contour is outlined; the fundus is palpated, allowing identification of the fetal parts. **Second maneuver:** By palpation of the sides of the maternal abdomen, the location of the fetal back is determined. **Third maneuver:** The presenting part is grasped, identified, and evaluated for engagement. **Fourth maneuver:** With palpation toward the pelvis, the identity of the presenting part is confirmed, and flexion or extension of the fetal head

is evaluated.

The clinician can often determine fetal lie and presentation by manual palpation of the gravid uterus. This process was formalized in four discrete maneuvers described by Leopold in the late 19th century (Fig. 2.4). Fetal position generally cannot be determined by external examination but rather by vaginal examination and direct palpation of the fetus during active labor or by ultrasound investigation.

Cardinal Movements of Labor

From the perspective of the fetus, labor involves movement progressively downward through the pelvis by the following cardinal movements, described for a vertex presentation (Fig. 2.5).

- *Engagement* occurs days to weeks prior to labor for primigravidas and at the onset of labor for multigravidas.

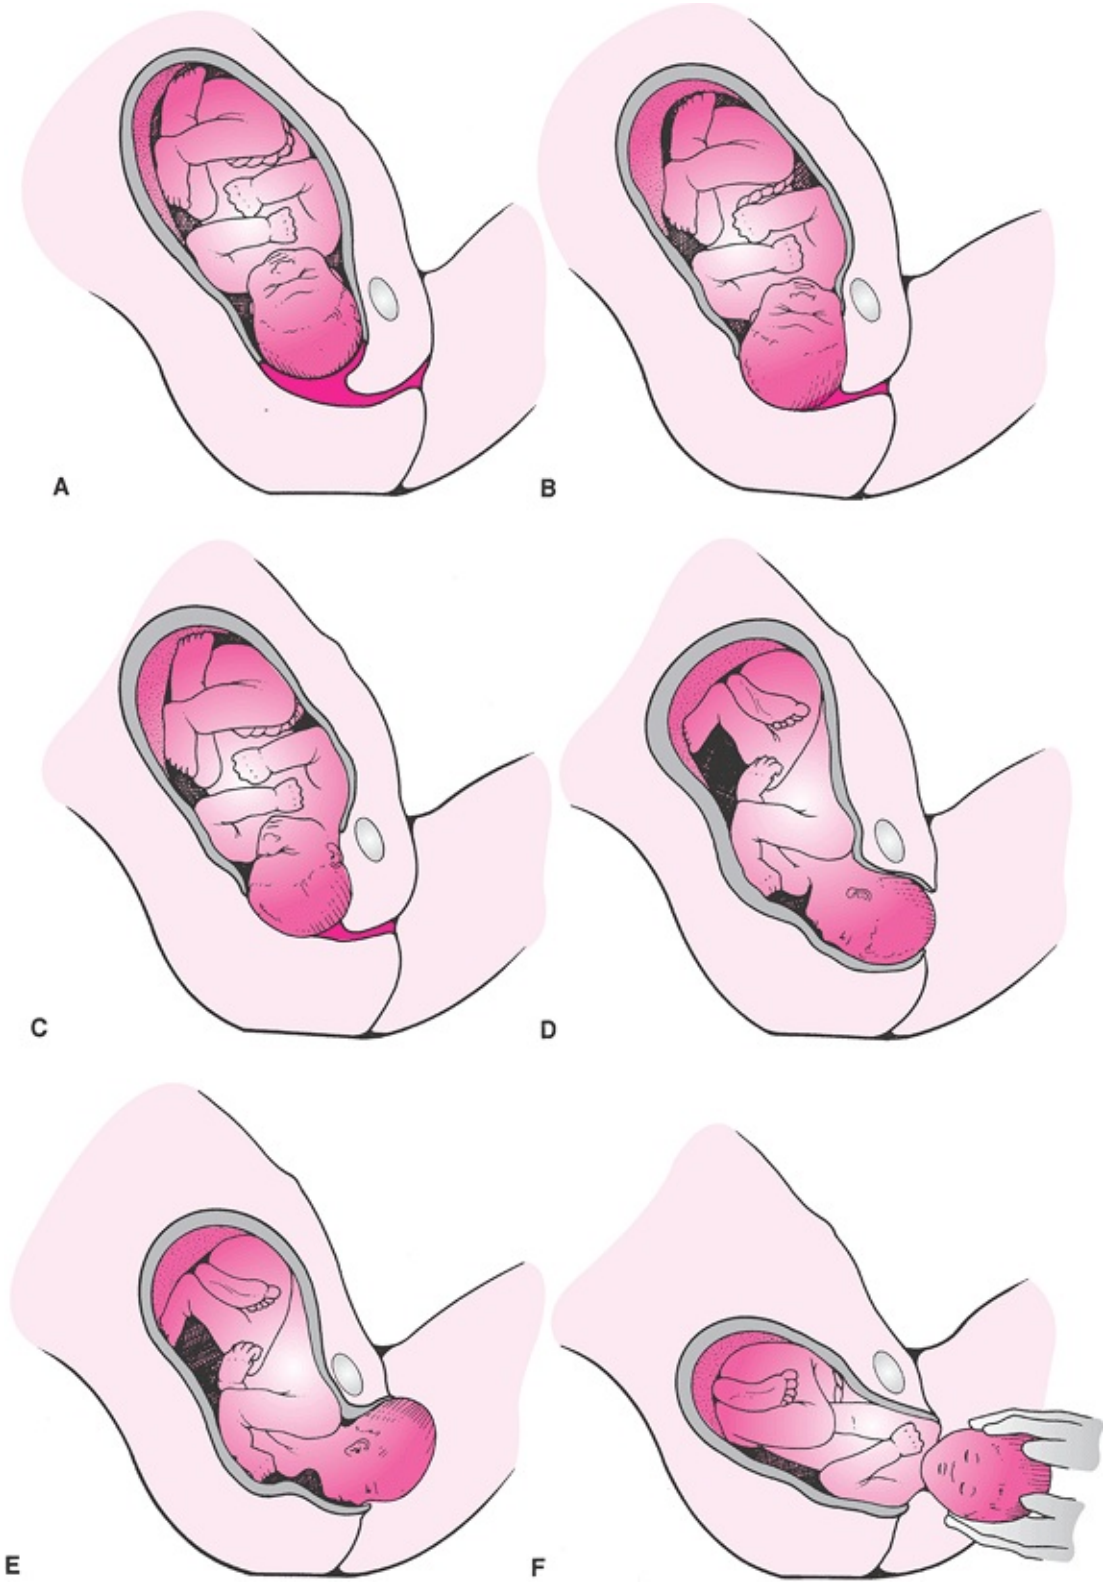

Figure 2.5 Cardinal movements of labor. **A:** Engagement. **B:** Flexion. **C:** Descent and internal rotation. **D, E:** Extension. **F:** External rotation.

- *Flexion* of the neck allows the occiput to lead, thus presenting the smallest diameter of the fetal head to the pelvic inlet.
- *Descent* is progressive as the cervix thins and the lower uterine segment lengthens.
- *Internal rotation* occurs during descent. The occiput rotates from transverse to either a

posterior or anterior position to pass the ischial spines.

- *Extension* occurs as the fetal head distends the perineum and the occiput passes beneath the symphysis.
- *External rotation* of the head after delivery to a transverse position allows the shoulders to rotate internally to an AP position.

Initial Patient Evaluation and Hospital Admission

Women should be advised at each antepartum visit of the circumstances under which they should seek evaluation for labor. These include:

- *Possible rupture of membranes*. In 10% of pregnancies, rupture of the membranes precedes the onset of labor. This presents as fluid leaking through the cervix and out of the vagina. The differential diagnosis includes urine leakage, vaginal infections, and passage of cervical mucus. Because prolonged rupture of the membranes is associated with higher rates of maternal and neonatal infection, optimal treatment of ruptured membranes at term is prompt induction of labor.
- *Regular, painful uterine contractions*. Although regular uterine contractions often signal the onset of labor, it can be difficult to distinguish true latent labor from false labor, or Braxton-Hicks contractions. The contractions of false labor tend to be more irregular both in intensity and in interval and the associated discomfort limited to the lower abdomen and groin. They usually abate with time, analgesia, or sedation. The contractions of true labor are progressive in intensity and are often associated with pelvic pressure as well as abdominal and back pain. In many cases, the only way to confirm the diagnosis of true labor is observation over several hours and serial examinations of the cervix.
- *Significant vaginal bleeding*. A small amount of blood mixed with mucus is a normal sign of early cervical dilation. This is called a *bloody show*. However, heavy vaginal bleeding may indicate placental abruption or an undiagnosed placenta previa.
- *Pain greater than anticipated in the back, abdomen, or pelvis*. Again, this may signal an untoward event such as placental abruption or, in the case of a patient with previous uterine surgery, uterine scar dehiscence.

A careful history will elucidate whether there may be an indication for hospital admission. Physical examination may confirm the diagnosis, although as noted, the diagnosis of labor may take observation over time. If the woman is having contractions, their time of onset and frequency should be recorded. Questions should focus on spontaneous rupture of the membranes, presence or absence of bleeding, and fetal activity. The patient's prenatal record should be reviewed in detail with particular attention to the reliability of the EDC; the details of any previous pregnancies; and past medical, surgical, and social history. Prenatal laboratory data should include blood type (with documentation of appropriate Rh(D) immune globulin administration); hemoglobin/hematocrit; screening for gestational diabetes, if indicated; cervical cytology; rubella antibody status; and infection screening to

include syphilis, hepatitis B, gonorrhea, *Chlamydia*, and HIV status as well as group B streptococcal (GBS) status.

The admission physical examination should include vital signs, auscultation of heart and lungs, and a brief neurologic examination with particular attention to deep tendon reflexes. Fetal orientation should be determined, and the uterus should be palpated or monitored to determine the presence, frequency, and intensity of contractions. A clinical assessment of fetal weight should be performed, and fetal heart tones should be assessed either by auscultation or via electronic monitoring, with specific attention to the response of the fetal heart rate to the uterine contractions.

The external genitalia should be examined for herpetic lesions. If membrane rupture is suspected, this can be confirmed or ruled out by speculum examination. Pooling of amniotic fluid in the vagina or direct visualization of fluid leakage through the cervix is highly suggestive of ruptured membranes. A sample of the pooled fluid is collected and subjected to microscopy and pH testing. Amniotic fluid is relatively basic (compared with normal vaginal secretions that have a pH <4.5) and will turn nitrazine paper blue (although blood will as well). An air-dried sample of amniotic fluid on a slide will show, under the microscope, a characteristic “fern” pattern (Fig 2.6). Because cervical mucus and maternal serum can also demonstrate a fern pattern, care must be taken when collecting the sample.

An internal digital examination may be performed to assess the state of the cervix as well as fetal station and position. It may be appropriate to defer this examination in the case of ruptured membranes if the patient is not clinically deemed to be in active labor, due to the possibility of increasing risk for chorioamnionitis. Digital examinations

---

are contraindicated in undiagnosed vaginal bleeding, as such an examination in the case of a placenta previa can lead to life-threatening hemorrhage. The internal examination includes attention to the following: dilation of the internal cervical os; assessment of consistency (soft or firm); degree of effacement (Fig. 2.7); orientation of the cervical os with respect to the vaginal axis (posterior, midplane, or anterior); and identification, station, position, and attitude, if applicable, of the presenting fetal part. *Station* is defined as the relationship between the lowest presenting bony part and the maternal ischial spines (Fig. 2.8). *Position* is determined by noting the orientation of a chosen fetal part—occiput, sacrum, or mentum—relative to the maternal pelvis (Fig. 2.9). *Fetal attitude* refers to the position of the fetal head relative to the fetal chest and the presence or absence of lateral flexion of the head (Figs. 2.10,2.11,2.12). Clinical pelvimetry should be performed as described previously.

Management of Labor

Management of the First Stage of Labor

The primary management goals in the first stage of labor are to monitor fetal well-being; support the woman through what can be a lengthy, uncomfortable period; and offer intervention as it becomes appropriate. One of the most important steps a clinician can take in the management of labor is to accurately diagnose whether a patient is, or is not, in active labor. Randomized trials have shown that patients in early latent labor who are encouraged to labor at home or to walk have less need for oxytocic agents and anesthesia than those who are admitted directly to the hospital. If a patient has an indication, whether fetal or maternal, for admission to the hospital in early labor, she should be encouraged to maintain as much freedom of movement as possible. Because all forms of monitoring, be it intermittent auscultation, external fetal monitoring, or internal monitoring, can be accomplished in a lying, sitting, or upright position, the only time a healthy woman's movement must be limited is after she has received analgesia or anesthesia and would not be steady on her feet. Patients should be free to position themselves as they like except for the supine position. In the supine position, the gravid uterus may compress the vena cava, leading to decreased venus return, decreased cardiac output, and compromised blood flow to the uterus and other organs. This has been called the *supine-hypotension syndrome of pregnancy*.

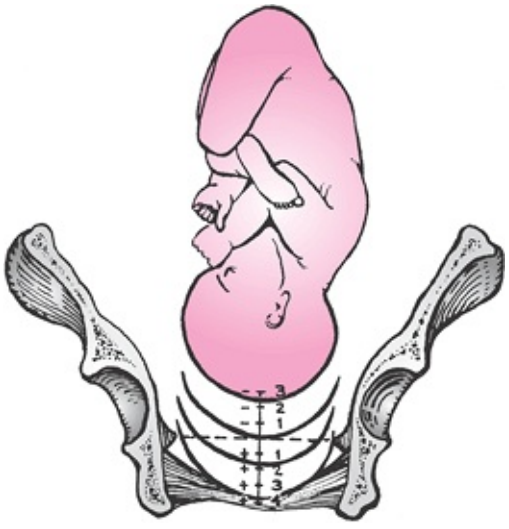

Figure 2.8 Stations of the fetal head. At the 0 station, the fetal head is at the bony ischial spines and fills the maternal sacrum. Positions above the ischial spines are referred to as –1 through –5, referring to the number of centimeters that the head is positioned above the spines. As the head descends past the ischial spines, the stations are referred to as +1 through +5 (head visible at the introitus).

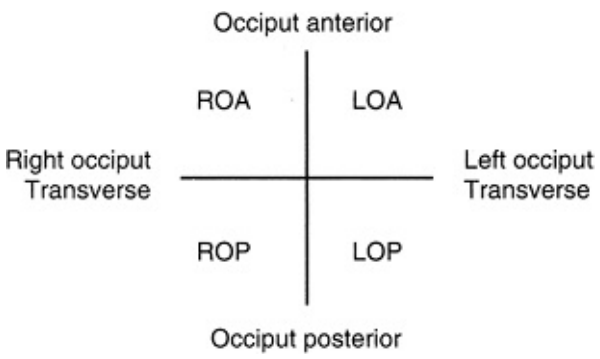

Figure 2.9 Fetal position. The orientation of the presenting vertex within the maternal pelvis.

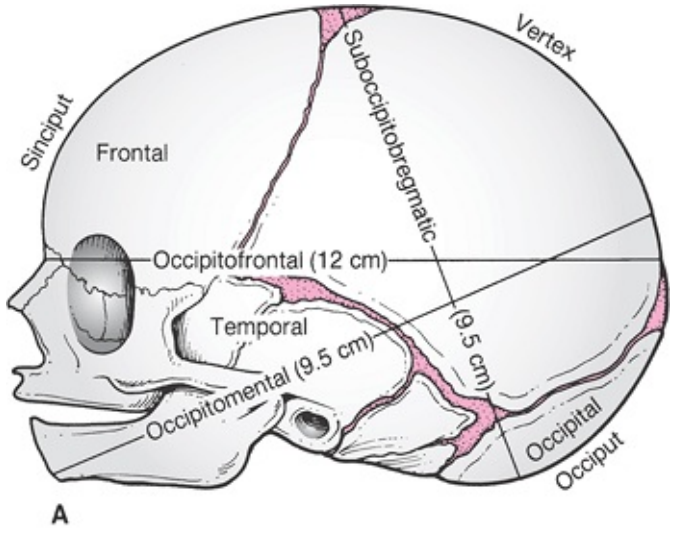

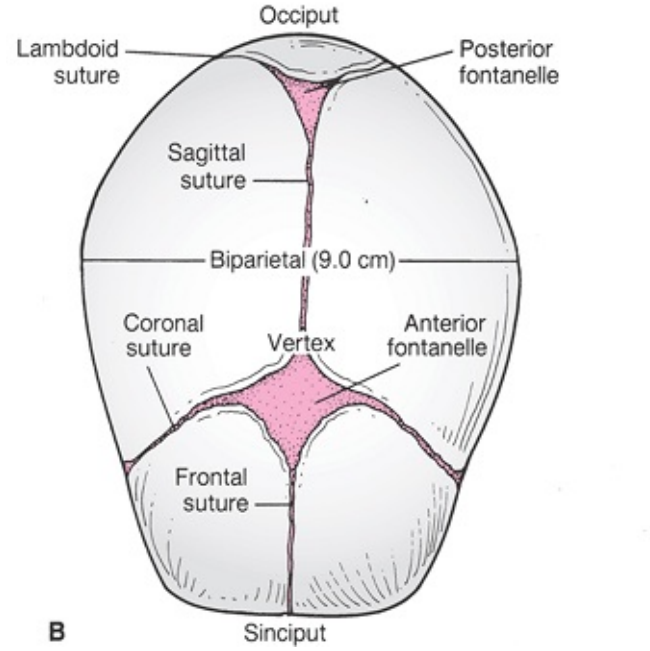

Figure 2.10 A, B: The bones, sutures, fontanelles, and clinically important diameters of the fetal head.

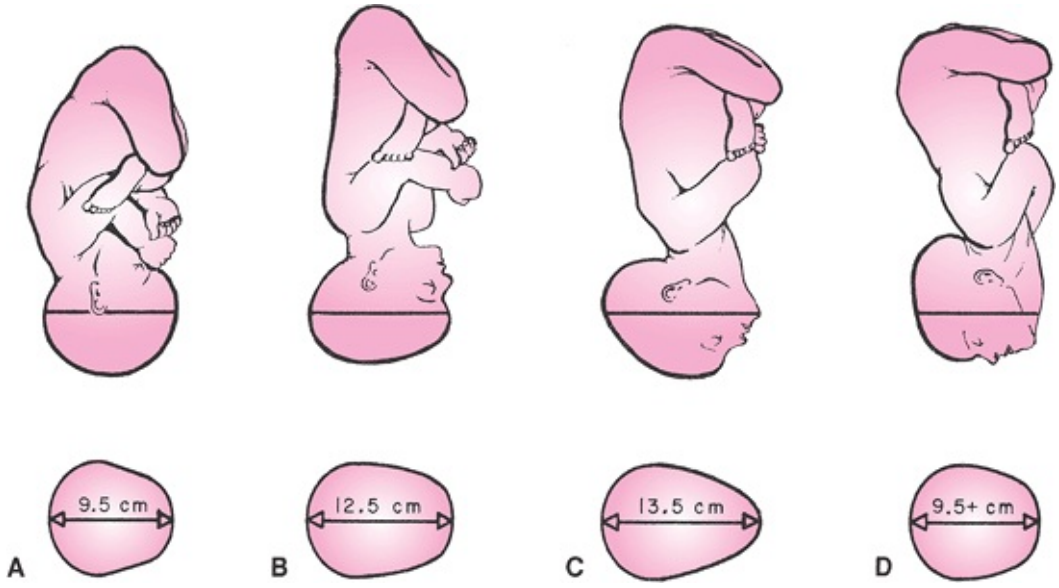

Figure 2.11 Fetal attitude and dimensions of a term-size fetus. **A:** Full flexion presents the smallest circumference of the fetal head to the narrower planes of the pelvis. **B:** Military attitude usually changes to full flexion with descent into the pelvis. **C:** Brow presentation usually converts to full flexion or a face presentation, as the occipitomental diameter is too large for all except the largest pelves to accommodate. **D:** Face presentation shows dimensions that allow descent through the pelvis, unless the chin is posterior. Persistent mentum posterior must be delivered by cesarean section.

Vital signs should be monitored at least every 4 hours or more frequently as clinically indicated. Placement of an intravenous line is not necessary for all women in labor. However, women who are dehydrated or for whom nausea, a common symptom in labor, prevents adequate ongoing oral hydration may benefit from intravenous hydration. It is prudent to establish intravenous access for administration of fluids and medication, should they be necessary, in women at increased risk of postpartum hemorrhage (such as those patients with prior postpartum hemorrhage, prolonged labor, or overdistended uterus).

In most women, laboratory evaluation on presentation in labor can be minimized and tailored to risk factors pertinent to the patient or to the patient population. Although in many units it is customary to perform routine admission blood type and antibody screen, hemoglobin and hematocrit, and syphilis serology, the necessity and cost-effectiveness of repeating these tests in healthy women who have received adequate prenatal care is debatable. If a woman exhibits signs or symptoms of preeclampsia such as hypertension, visual disturbances, or hyperreflexia, appropriate laboratory workup should be pursued. Patients without prenatal care, or for whom such records will not be obtainable during their hospital stay, should have laboratory evaluation for blood type and Rh status; hemoglobin/hematocrit; rubella antibody titer; and hepatitis B, syphilis, and HIV screening.

Patients with positive screening cultures for GBS or who have had a previously affected infant should be given prophylactic intravenous antibiotics during labor in order to decrease the risk of transmission to the fetus and resulting neonatal GBS sepsis. If screening cultures are not available, a risk-based treatment strategy is recommended by the Centers for Disease Control (CDC). Prophylaxis is given for any of the following: labor prior to 37 weeks, rupture of membranes greater than 18 hours, or clinical evidence of maternal intrauterine infection. The consensus treatment in patients without allergies is penicillin G, 5 million units initially followed by 2.5 million units every 4 hours until delivery. Acceptable alternatives include ampicillin; cefazolin (for patients with a nonanaphylactoid response to penicillin); or in cases of grave penicillin allergy, clindamycin, erythromycin, or vancomycin (depending on demonstrated antibiotic susceptibilities). (Further description of GBS infection is presented in Chapter 19, Obstetric and Perinatal Infections.)

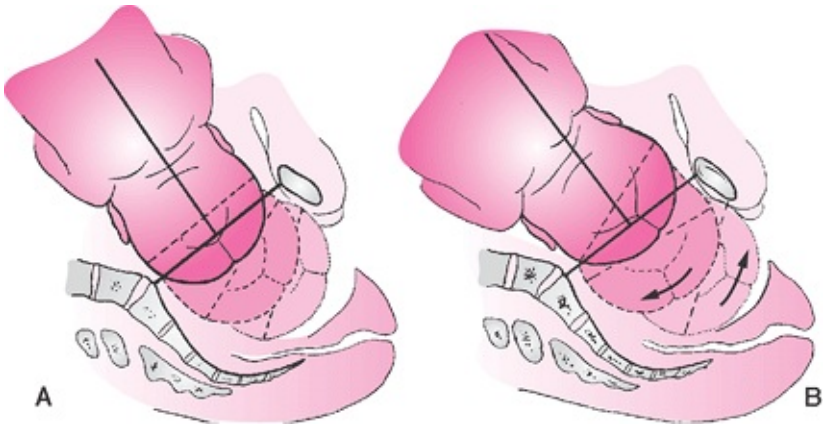

Figure 2.12 Fetal attitude and lateral flexion of the fetal head. **A:** Synclitism—the plane of the biparietal diameter is parallel to the plane of the inlet. **B:** Asynclitism—lateral flexion of the fetal head leads to anterior parietal or posterior parietal presentation.

All women should have access to continuous caregiver support throughout labor. This care may be provided by nurses, midwives, doulas, or other laypeople. Such support has been associated with reduced pain medication requirements, lowered rates of operative vaginal and cesarean delivery, and a decrease in the frequency of 5-minute Apgar scores below 7.

Fetal heart rate monitoring should be tailored to the clinical labor situation. The fetal heart rate may be monitored with intermittent auscultation, with an external monitor used either intermittently or continuously, or with an internal fetal monitor (“scalp electrode”). Continuous electronic fetal monitoring has not been shown to decrease overall perinatal mortality and has been associated with increased rates of cesarean and operative vaginal delivery. By the same token, intermittent monitoring or auscultation may not be safe in complicated pregnancies, as there are no good studies in which such patients were included in an intermittent-monitoring protocol. There are no evidence-based protocols for

frequency of fetal monitoring during labor, although most recommend more frequent monitoring in the second stage than in the first.

There are also no evidence-based criteria to direct how often the cervix should be examined during the first stage of labor. In general, frequent examinations in the latent phase of labor serve little purpose and may arouse unrealistic expectations for cervical change, both on the part of the patient as well as the provider. In the active phase of labor, monitoring progress with cervical examinations every 1 to 2 hours allows identification of those women who are not making normal progress and who should therefore be evaluated for adequacy of labor and possible augmentation.

Early amniotomy in the course of normal labor may shorten the first stage of labor by 1 to 2 hours and reduce the need for oxytocic agents; however, it may also increase intrauterine infections and cesarean delivery rates. Clear indications for amniotomy are the need for internal fetal or uterine monitoring or for abnormal labor progress. Amniotomy is best performed when the presenting part is well applied to the cervix and preferably during a contraction (or with fundal pressure) to avoid umbilical cord prolapse, and the fetal heart rate should be monitored immediately before, during, and after the procedure.

Meconium staining of amniotic fluid occurs in up to one fifth of deliveries. There is no evidence that amnioinfusion or routine oropharyngeal suctioning of the newborn reduces the incidence of meconium aspiration syndrome, although amnioinfusion is associated with a reduction in fetal heart rate abnormalities, particularly significant variable decelerations.

Management of the Second Stage of Labor

The second stage of labor, as noted previously, is characterized by complete cervical dilation; descent of the fetal vertex; and in patients without anesthesia, a sensation of pelvic pressure and the urge to bear down. Internal examination should confirm complete dilation, as well as the fetal position and station, prior to the commencement of maternal pushing efforts. Women should be encouraged to continue to labor in the position that is most comfortable for them and that results in the most effective pushing efforts. However, lying supine is contraindicated, as described previously. The average length of the second stage of labor varies with parity, ethnicity, fetal size, and presence or absence of conduction anesthesia. Yet, the second stage is considered prolonged if it is longer than 1 hour for parous and 2 hours for nulliparous women without epidural, or

---

2 hours for parous and 3 hours for nulliparous women with epidural.

The widespread use of regional anesthesia in labor has affected some aspects of the course of the second stage. There is no doubt that regional anesthesia can improve patients' satisfaction with their labor experience, and evidence to suggest adverse outcomes based on anesthesia use are controversial at best. However, patients with epidural anesthesia may not have the sense of pelvic pressure that accompanies the onset of the second stage in unanesthetized women. If the epidural is dense, the patient may not be able to feel her contractions in order to coordinate her pushing efforts. These factors can combine to increase the length of the second stage by an average of 20 to 30 minutes. Patients with

epidural anesthesia may require more focused coaching than those without. *Passive descent*, or allowing a woman with epidural anesthesia to delay pushing for 1 hour or until she feels an urge to push, has been shown to result in fewer midpelvic operative deliveries, with a trend toward fewer operative vaginal deliveries overall when compared with patients who are instructed to push immediately on entering the second stage.

Delivery of the fetus when labor has been uncomplicated may be effected from a variety of positions depending on the patient's preference. If the patient has risk factors for shoulder dystocia including previous history of shoulder dystocia, large fetus, or poor progress in labor, it is prudent to position the patient in a way that will facilitate corrective maneuvers in the event a shoulder dystocia occurs.

Obstetric lacerations are minimized by keeping the baby's head well flexed until the occiput passes beyond the subpubic arch. Occiput posterior presentations are associated with greater perineal trauma due to the inability to flex the presenting part. As the head appears beneath the symphysis, the perineum is supported by direct pressure over the coccygeal region. As the head delivers, it often will rotate to a transverse position, at which time gentle downward traction combined with maternal pushing effort will achieve delivery of the anterior shoulder. Assessment for the presence of a nuchal cord, with reduction if possible or clamping and cutting of the cord if not, is followed by upward traction and delivery of the posterior shoulder after which the rest of the baby is delivered. The baby can be placed immediately on the maternal abdomen or handed directly to the neonatal care providers depending on the clinical situation or according to maternal preference. While delayed clamping of the cord is associated with higher newborn hematocrit levels, this may not be feasible in situations where immediate newborn care is necessary.

Management of the Third Stage of Labor

Delivery of the Placenta

Immediately following delivery of the baby, the uterus begins the process of involution. Uterine contractions cause shearing of the placenta away from the uterine wall, and the placenta generally delivers shortly after the baby. Signs of spontaneous placental separation include an apparent lengthening of the umbilical cord, a gush of vaginal bleeding, and a change in shape of the uterus from discoid to globular. “Active management” of the third stage of labor has been shown to be of benefit in reducing postpartum blood loss and may include draining the placenta of blood, controlled cord traction, or administration of oxytocic agents. If cord traction is employed, suprapubic pressure with the abdominal hand (Fig. 2.13) will lessen the potential for uterine inversion and catastrophic hemorrhage and shock. If the placenta has not delivered within 30 minutes of childbirth, or in the case of severe hemorrhage, the placenta should be manually removed. Prophylactic antibiotics, such as a first-generation cephalosporin, may be given in association with manual placental removal. The anesthesia provider should be notified in such cases, both because manual removal may require additional anesthetic and because the potential for hemorrhage and possible uterine curettage is increased. Manual

removal is accomplished by developing a cleavage plane with the intrauterine hand between the maternal surface of the placenta and the uterine wall while simultaneously fixing the uterus with the abdominal hand and progressively peeling the placenta free. To ensure complete placental removal, a 4 × 4-inch gauze may be wrapped around the hand and used to abrade the uterine wall.

The placenta should always be carefully inspected for abnormalities of cord insertion, confirmation of a three-vessel cord, and completeness of removal of the placenta and membranes. If any portion of the placenta or the membranes is missing, the uterine cavity should be manually explored. The uterus should be frequently palpated following delivery of the placenta to ensure that it remains well contracted. Oxytocin, administered as a dilute intravenous solution or given 10 to 20 U intramuscularly, decreases the incidence of postpartum hemorrhage due to uterine atony. The birth canal, including the cervix, vagina, and perineum, should be inspected for lacerations requiring repair. Under most circumstances, the baby can remain with the mother or immediate family and attempts at breast-feeding within the first 10 to 20 minutes should be encouraged. This first suckling stimulates endogenous oxytocin release and begins the process of milk production and successful breast-feeding.

Episiotomy and Repair of Obstetric Lacerations

Episiotomy is an incision in the perineum made to facilitate vaginal delivery. There is no role for routine episiotomy in modern obstetric practice, although there are some clinical indications for its use. In general, episiotomy is used to shorten the second stage of labor for fetal indications (terminal bradycardia or shoulder dystocia) or to control perineal damage when the risk of significant

spontaneous laceration is high (operative vaginal delivery, previous large laceration, small perineal body, or large infant). Episiotomy should be performed with adequate local or regional anesthesia and with the verbal consent of the patient, when possible. There are two types of episiotomy techniques in common use: median and mediolateral. The techniques are as follows: after confirmation of adequate anesthesia, the index and middle fingers of the nondominant hand are inserted between the perineum and the fetal head, and scissors are used to incise the perineum to the degree deemed necessary by the clinician. Median episiotomy involves a midline incision directly toward the anus and rectal sphincter; mediolateral episiotomy employs an incision that begins in the midline of the perineum and is carried out through a >45-degree angle on either side.

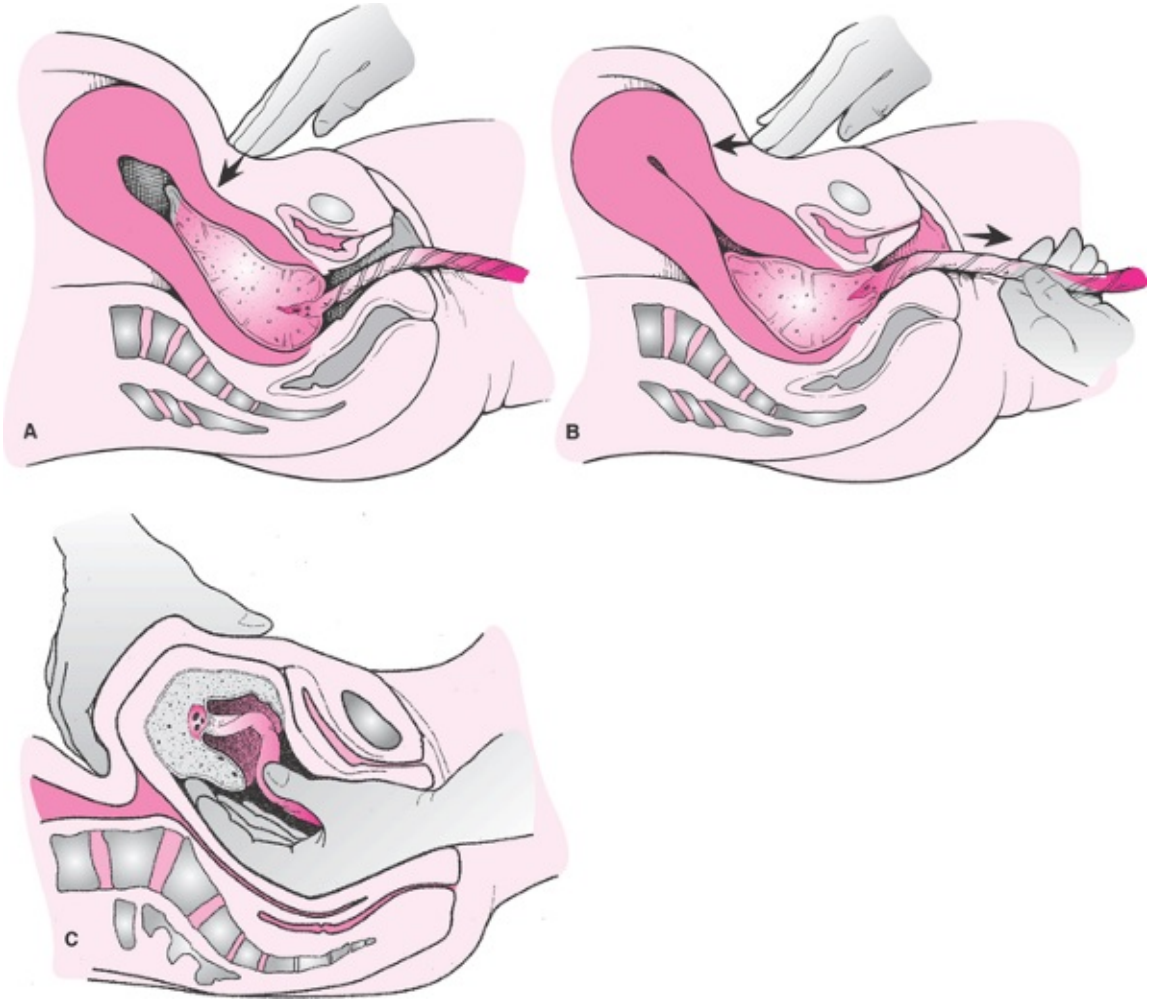

Figure 2.13 Stage three of labor: delivery of the placenta. **A:** Spontaneous separation of the placenta is confirmed. **B:** With gentle traction on the umbilical cord and suprapubic palpation of the fundus, the placenta and membranes are delivered. **C:** If spontaneous separation of the placenta does not occur or bleeding ensues, the placenta is manually separated from the wall of the uterus and removed.

Median episiotomy has been associated with a higher risk for extension into the rectal sphincter and mucosa. It is generally thought to be simpler to repair. Mediolateral episiotomy is associated with greater blood loss and greater postpartum discomfort but reduces the risk of anal sphincter injury. For descriptive and repair purposes, episiotomy incisions and spontaneous perineal lacerations are classified as follows:

- *First degree*—through the vaginal mucosa only
- *Second degree*—through the mucosa and subcutaneous tissues, including the muscles of the perineal body
- *Third degree*—into or through the external anal sphincter
- *Fourth degree*—through the rectal mucosa.

Repair of Obstetric Lacerations

The technique of repair for both types of episiotomy as well as for spontaneous lacerations is similar and entails reapproximation of the vaginal mucosa, subcutaneous tissue, and pelvic floor muscles (Fig. 2.14). For most obstetric lacerations, use of braided

absorbable suture in varying sizes is appropriate. If the laceration extends into the rectal mucosa, this is first repaired with a small (4-0) suture in a running fashion. Injury to the internal and external anal sphincter is best repaired with relatively large (0 or 2-0) interrupted sutures. Although the internal anal sphincter can be difficult to identify, it is a critical component of the fecal continence mechanism. It runs longitudinally between the rectal mucosa and the subcutaneous tissue underlying the vagina. An Allis clamp may be necessary to locate the edges of the external anal sphincter, which tends to retract into the surrounding tissue. Once the underlying musculature is repaired, the vaginal mucosa is reapproximated with a running suture. The remaining defect in the perineal body (the transverse perineal and bulbocavernosus muscles) is repaired with interrupted sutures. With appropriate anatomic repair of the underlying structures, it may not be necessary to close the perineal skin in the absence of active bleeding. Although skin closure yields a more cosmetic result, healing is not affected and postpartum pain may be increased. If skin closure is chosen, a running subcuticular, rather than interrupted technique, is more comfortable for the patient.

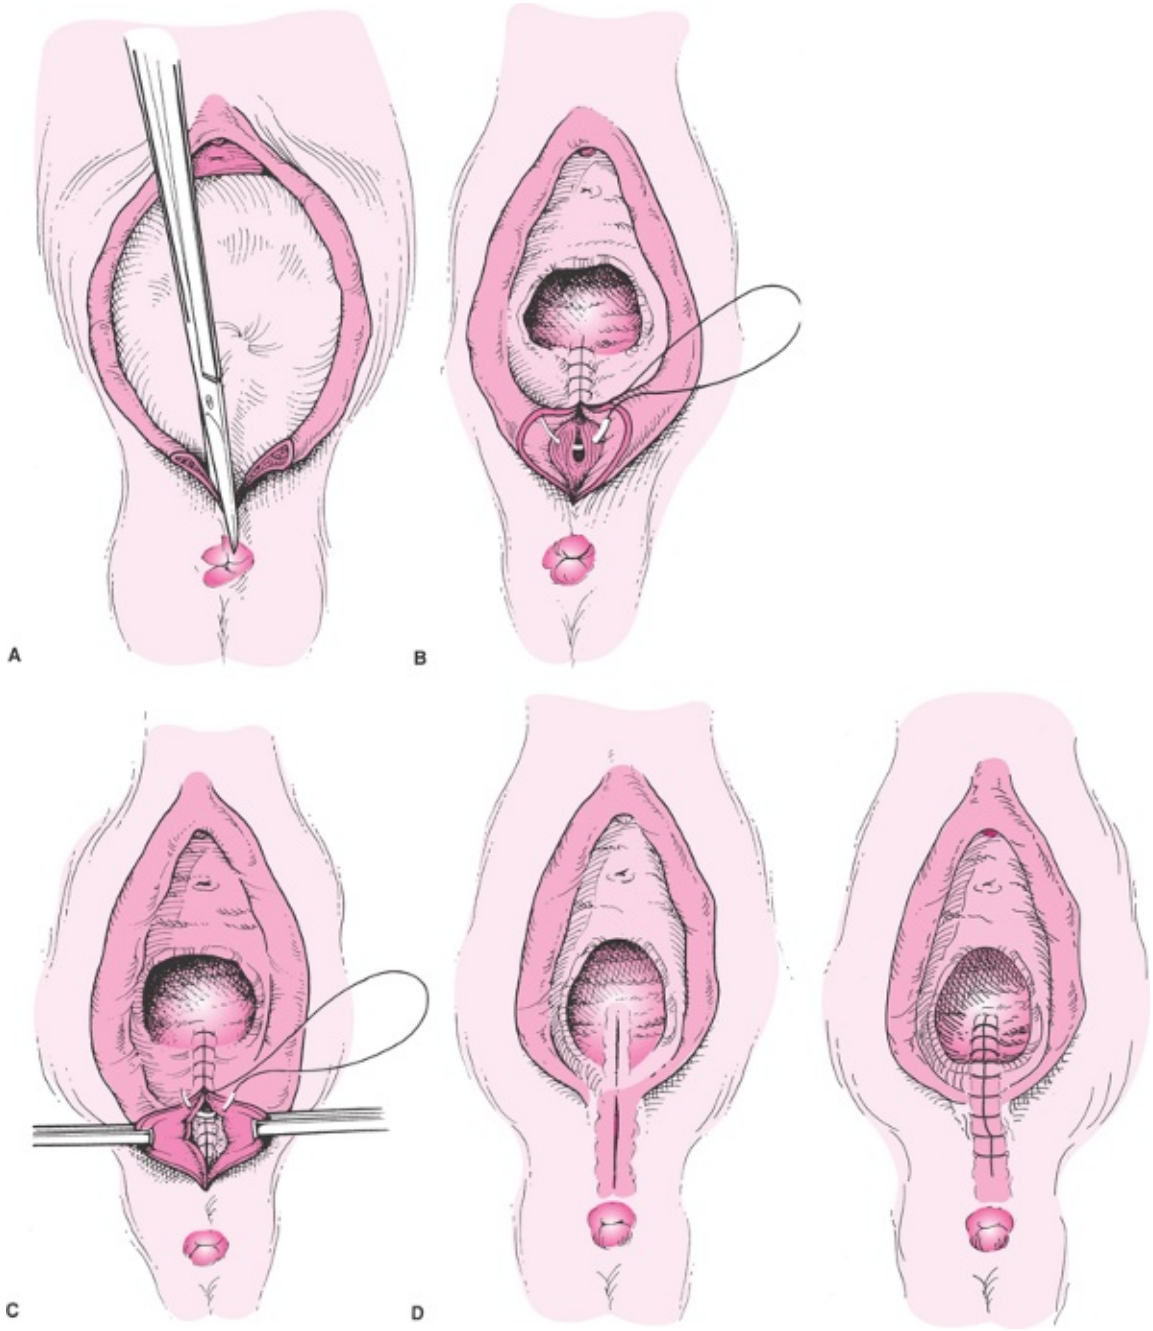

Figure 2.14 Midline episiotomy. **A:** As the fetal head distends, with the perineum under adequate anesthesia, the episiotomy is cut through the perineal body and the tissues of the vagina and the rectovaginal septum. **B:** The episiotomy is repaired by reapproximating the vaginal mucosa in a running fashion with a delayed absorbable suture. **C:** The submucosal tissue of the vagina and the subcutaneous tissue and fascia of the perineal body are then closed. **D:** The skin is then reapproximated with a running subcuticular suture.

Postpartum Care

Many complications of birth occur or become evident during the first hour after delivery. The new mother should be seen at least every 15 minutes by a trained provider to assess vital signs and look for evidence of uterine atony or postpartum hemorrhage. The perineum

should be inspected for any signs of hematoma formation, which may be signaled by inordinate vulvar or rectal pain. If the mother seems clinically stable, it is appropriate to offer a regular diet as soon as she requests food. It is prudent to delay feeding in patients at risk for postpartum hemorrhage who may require additional anesthesia. Full ambulation is encouraged as soon as possible. Showers and baths may be taken immediately in addition to frequent sitz baths or perineal cleansing with a water bottle. Women are at risk for urinary retention due to regional anesthesia, perineal swelling, or pudendal nerve injury and should be encouraged to void within 2 to 3 hours of delivery. Intermittent catheterization may be needed for a short time until these factors resolve. Pain from uterine contractions or perineal injury may be relieved with ibuprofen or acetaminophen, with or without codeine.

Breast-feeding mothers should be encouraged to spend as much time as possible with their infants; many institutions have adopted “rooming-in” models in which the infant is removed from the mother only for necessary examinations. Nursing should be attempted every 2 to 3 hours, and adequate lactation support, especially for first-time mothers, should be available.

It is not necessary to check a blood count postpartum if the estimated blood loss at the time of delivery was not excessive. Rh-negative women whose infants are Rh positive should receive an additional dose of Rh(D) immunoglobulin prior to discharge to prevent sensitization and future pregnancy complications. Rubella seronegative women should be immunized before discharge.

The length of inpatient hospitalization following childbirth has changed remarkably over the past 2 decades, reflecting the decreasing rate of postpartum complications as well as changing medical and societal attitudes toward birth. Many women are now discharged from the hospital 24 to 48 hours after giving birth. The advantages to early discharge include a faster return to a familiar, comfortable, and flexible environment; less exposure to hospital-borne infections; and less emphasis on childbirth as a disease process. Potential risks include lack of breast-feeding or general infant care support for first-time mothers and a resulting risk of readmission for the infant. The quality of available studies on the issue of early postpartum discharge is poor. Current recommendations are for adequate support, either from family or home care services, for patients who are discharged early from the hospital. Breast-fed infants should be evaluated for weight gain and adequacy of lactation within 48 hours of hospital discharge.

Puerperium

The puerperium is the 6 to 8 weeks following delivery of the placenta in which the uterus returns to its normal state. Following delivery of the placenta, the uterus rapidly contracts to half of its predelivery size. The involution that then occurs over the next several weeks is most rapid in nursing women. The contractions of the involuting uterus may be painful, although this is usually relieved with acetaminophen or ibuprofen. Postpartum vaginal discharge, or lochia, changes as the uterus involutes. Initially, the discharge is grossly bloody, persisting for 3 to 4 days. It then decreases in volume and changes to pale brown and becomes thinner, persisting for 10 to 12 days. Finally, the discharge becomes yellowish

white, occasionally tinged with blood, and may persist for several weeks. The total volume of lochia is about 250 mL, and women are usually encouraged to use external pads rather than tampons for absorption. This may minimize the risk of ascending infection. Because of rapid diuresis and autotransfusion from the involuting uterus, a woman's hematocrit may actually rise following delivery. After 1 week, the uterus is firm and nontender and extends to about midway between the symphysis and the umbilicus. By 2 weeks postpartum, the uterus is no longer palpable abdominally.

Puerperal complications including postpartum hemorrhage, postpartum infection, and depression are covered in separate chapters.

Prior to discharge, women should receive instructions regarding what they can expect during the puerperium and

---

recommendations for activity. In general, women should be encouraged to rest as they feel necessary and gradually increase their activity following delivery. Ambulation is unrestricted; women may drive as long as abdominal or perineal pain will not distract them or delay their response to an emergency. Women may resume a regular diet and, if nursing, must remain well hydrated for optimal milk production. Bladder function may be somewhat compromised due to pudendal nerve trauma but should normalize in the months following delivery. Regular pelvic floor exercises may facilitate the return of optimal bladder control. Patients should be educated as to the signs and symptoms of postpartum infections including mastitis, endometritis, and perineal infection or hematoma. Fever greater than 38°C or 100.4°F warrants evaluation, as does pain beyond what might be expected in any of these areas. Signs and symptoms of delayed postpartum hemorrhage and deep vein thrombosis should be reviewed as well. Patients should receive information regarding lochia and its expected volume, changes, and duration; activity level; care of the breasts, perineum, and bladder; and dietary and fluid requirements.

Couples can safely resume coitus when desired and comfortable, although abstaining at least 2 weeks or until bleeding is resolved is recommended to decrease the risk of uterine infection. If immediate pregnancy is not desired, adequate contraception must be in place prior to the resumption of coitus. The low estrogen state associated with nursing, alone or in combination with perineal lacerations, may complicate efforts at sexual activity. Women should also be advised that the fatigue associated with caring for a newborn may decrease libido and that physical readiness for sexual activity is sometimes not sufficient to proceed.

There are many contraceptive options for postpartum women. Because a hypercoagulable state persists for weeks after delivery, initiation of combination oral contraceptives should be deferred until at least 4 weeks postpartum. Progestin-only contraceptives, including oral pills, depot medroxyprogesterone acetate, or the intrauterine levonorgestrel-containing system, do not affect coagulation. The evidence for the use of combination oral contraceptives in breast-feeding women is poor but does suggest a potential adverse effect on milk supply. However, combination oral contraceptives may be used in healthy women with established, adequate milk supply. Placement of an intrauterine device should be delayed until full involution of the uterus occurs at 6 weeks postpartum.

It is traditional to schedule a follow-up outpatient visit at 6 weeks postpartum. This visit

presents an opportunity to screen for complications, confirm normal involution, and review ongoing health care maintenance and family planning issues. The pertinent history should include inquiries into and discussion of nursing success (if breast-feeding); infant development; sleep patterns; maternal mood; activity level; presence of support in the home; plans for return to work; timing of the next desired pregnancy (if applicable); resumption of sexual intercourse; bladder function; and vaginal bleeding, discharge, or pain. A focused breast, abdominal, and pelvic examination is performed, and cervical cytology is obtained if indicated.

Newborn Care

Immediate Assessment and Resuscitation

The transition from fetus to newborn infant is the most dramatic physiologic change that occurs in the human life span. The fetus that received all of its oxygen and nutritional needs via the placenta must now use two entirely different, essentially dormant organ systems to meet these needs. The circulation is rerouted, and the pulmonary bypass paths (ductus arteriosus, foramen ovale, and umbilical circulation) are no longer used. The lungs and left side of the heart that once handled about 15% of the circulation must now deal with 100% of the circulation in series with the right heart and remainder of the body. The fluid-filled, unexpanded lungs must be inflated and cleared of fluid to allow gas exchange, as they are now the sole source of oxygen for the infant.

Resuscitation in the delivery room is geared toward helping the infant accomplish this transition. The American Academy of Pediatrics (AAP) Neonatal Resuscitation Program (NRP) is a training course that all those specializing in pediatrics complete and is strongly encouraged for all individuals who deliver infants or attend deliveries; in fact, many institutions now require current certification for delivery room personnel. The resuscitation algorithm from the current NRP is shown in Figure 2.15.

While every delivery should be attended by personnel trained in newborn resuscitation, the presence of personnel experienced in resuscitation is most desirable for deliveries where the need for resuscitation is more likely. Examples of these situations are summarized in Table 2.1.

Meconium

Meconium passage prior to birth occurs in up to 20% of term deliveries and is a common reason for neonatal resuscitation. In the 1970s, it was recognized that early suctioning by the obstetrician or pediatrician decreased the incidence of meconium aspiration syndrome (MAS). In the 1980s, routine suctioning of the oropharynx at the perineum or endotracheal suctioning were standard practice; however, it became clear that not all cases of MAS could be prevented and that aspiration in utero could occur. In the 1990s, many neonatologists were concerned that vigorous babies with thin meconium had a very low risk of MAS and might actually do better if not intubated for

---

tracheal suctioning. Unfortunately, the majority of studies pertinent to this issue have not

been prospective, randomized, or controlled. The most recent Cochrane Library review concluded that until further evidence is available, endotracheal suctioning for meconium should be reserved for those infants who are depressed or have respiratory difficulties.

TABLE 2.1 Apgar Mnemonic

Mnemonic	Component	Score of 0	Score of 1	Score of 2
Appearance	Color	Blue or pale	Pink body, blue	Complete pink

			extremities	
Pulse	Heart rate	Absent	<100	=100
Grimace	Reflex irritability	No response to suctioning	Grimace	Gag, cough, or sneeze
Activity	Muscle tone	Limp	Some flexion	Active movemen
Respiration	Respiration	Absent	Slow, irregular	Good, crying

The Apgar Score

In 1952, Dr. Virginia Apgar devised a 0 to 10 scale scoring system intended to focus attention on the newborn and allow the systematic assessment of its condition and immediate needs (Table 2.1). Since that time, Apgar scores have become a mainstay in immediate newborn assessment.

The Apgar score is a useful tool to guide those charged with assessment and care of the newborn. It provides an overall picture of infant status and has been used in clinical research to correlate later outcomes with initial appearance. It cannot be used to predict neurologic outcome without other tests or examinations nor is it a validated tool for determining asphyxia. Moreover, it was never intended for use in premature infants. Scores are assigned at 1 minute of age and every 5 minutes thereafter until the score is over 7, or until 20 minutes of age. Clearly, if necessary, resuscitation should begin prior to the 1-minute score.

Breast-feeding

Human breast milk is widely recognized to provide significant nutritional and health advantages to infants through the first year of life; and breast-feeding is increasingly recognized to provide maternal health benefits as well as fostering psychological well-being in both mothers and babies (Suggested Readings Refs. 1,2,3). Breast-feeding rates have increased steadily since 1998 but have failed to meet the Healthy People 2010 goals set by the U.S. Public Health Service (Table 2.2), and significant socioeconomic and regional disparities exist among women who breast-feed (Suggested Readings Ref. 5).

Breast-Feeding Benefits

Breast milk is a complex fluid that has evolved to meet the specific nutritional, immunologic, and developmental needs of the human neonate, making it superior to all other forms of infant nutrition. With few exceptions, human milk is now recommended as the exclusive source of nutrition for full-term infants through 6 months and should be continued with solid food supplementation for at least 12 months (Suggested Readings Ref. 1). In this context, *exclusive breast-feeding* is defined as the consumption of human milk without supplementation of any type except for vitamins, minerals, or medications. The major health benefits of breast-feeding for the infant are summarized in Table 2.3. The benefits for the breast-feeding mother include reduced postpartum blood loss, increased rates of uterine involution, more rapid return to prepregnancy weight, and longer interpregnancy intervals due to lactational amenorrhea. In addition, pregnancy and lactation have been linked to reduced risk of breast and ovarian cancers, and the elevated levels of oxytocin and prolactin found in lactating women promote emotional well-being and feelings of attachment.

TABLE 2.2 U.S. Public Health Breast-feeding Targets[a]

Mothers Who Breast-Feed	1998 Baseline (2005 CDC values[b])	2010 Target
	Percentage of mothers	
Early postpartum period	64	75
At 6 months	29	50
At 1 year	16	25
Exclusively through 3 months	39[b]	60
Exclusively through 6 months	14[b]	25

Contraindications

Relatively few conditions exist in which breast-feeding is strictly contraindicated. Infants with galactosemia cannot metabolize lactose due to deficiency in galactose-1-phosphate uridyltransferase deficiency and should not ingest lactose-containing milk. Milk intake may also need to be restricted for infants with other inborn errors of metabolism depending on desired protein intake and other factors. Conditions in which breast-feeding is contraindicated are indicated in Table 2.4. Numerous other conditions, however, are compatible with breasting-feeding, including mothers positive for hepatitis B surface antigen or hepatitis C, mothers exposed to low-level environmental chemicals, and mothers who smoke (although smoking should be avoided within the home). Excessive alcohol consumption is contraindicated for breast-feeding mothers due to concentration of alcohol in milk and inhibitory effects of alcohol and milk production, but an occasional small alcoholic drink is acceptable if the mother refrains from breast-feeding for at least 2 hours after consumption. The AAP Committee on Drugs has recognized seven classes of drugs and chemicals with known or

possible effects on the infant or lactation (Suggested Readings Ref. 6) and should be consulted when counseling nursing mothers about risks of medications, environmental chemicals, and drugs of abuse on lactation and infant health. In many cases, drug exposure to infants can be minimized by taking medication after breast-feeding or when the infant is expected to have prolonged periods of sleep. In addition, breast milk can be expressed and stored for infant consumption before undergoing medically indicated treatments.

TABLE 2.4 Breast-feeding Contraindications

- Galactosemia; certain inborn errors of metabolism
- Active, untreated tuberculosis
- Human T-cell lymphotropic virus type I and II infection
- HIV infection (for women in the United States, globally the risk of HIV infection should be balanced with risks of other types of infection and proper infant nutrition)
- Women with active herpes or varicella infections of the breast (if only one breast has lesions, the breast without lesions may be used for breast-feeding)
- Treatment with radioactive isotopes and cytotoxic drugs, as long as these substances are in milk
- Mothers using drugs of abuse or with uncontrolled alcohol intake

Functional Anatomy of the Human Breast

The human female breast is composed of glandular and adipose tissue that is held together by a framework of fibrous strands called *Cooper's ligaments*. The glandular component is organized into multiple radially arranged lobes connected to the nipple by a single milk duct. Although the human breast is described in most textbooks as typically containing 15 to 20 lobes, more recent ultrasound measurements put this number at approximately 9, with as few as 4 and as many as 14 detected in some individuals. Each lobe consists of several lobules, which in turn are composed of clusters of alveoli containing secretory epithelial cells that synthesize breast milk. Alveoli are connected to very small ducts that join to form larger ducts draining the lobules. These larger ducts finally merge into a single milk duct that terminates at its orifice on the surface of the nipple. The sites of termination are visualized as numerous small punctate openings on the superior aspect of the nipple. There is extensive branching of ducts under the areola, and the large milk ducts at the base of the

nipple are superficially located and easily compressed, which may be a contributing factor to milk stasis and blockage of ducts during lactation. The pigmented skin of the areola contains numerous elevated nodules overlying sebaceous glands of Montgomery, which produce oily substances that protect the surface of the nipple from cracking and contribute to the infant's breast-feeding performance. Painful nipples can be a significant detriment to successful breast-feeding; proper drying of the nipple area after feeding and the use of breast shields or purified lanolin cream may provide relief.

The adipose tissue of the breast is typically situated between lobes rather than within lobules. In the nonlactating state, approximately 80% of the breast is adipose with the remainder being glandular and connective tissue. During pregnancy and lactation, the glandular component increases to approximately 60% and the amount of adipose tissue decreases to approximately 40%. The codistribution of adipose and glandular tissue within the breast and the lower than expected numbers of ducts feeding into the nipple are possible contributors to impaired milk supply in women who have undergone augmentation or reduction mammoplasty.

The nipple is innervated by the fourth intercostal nerve. During lactation, afferent sensory stimuli from suckling are transmitted to the spinal cord and the brain, resulting in release of prolactin and oxytocin from the pituitary. Prolactin, secreted from the anterior pituitary, acts directly on secretory epithelial cells to foster synthesis and secretion of milk components. Oxytocin, secreted from the posterior pituitary, stimulates contraction of the myoepithelial cells that surround the alveoli and ducts. This process, called the *letdown reflex*, forces the milk from the alveoli through ductules into ducts draining several clusters of alveoli. Milk is removed from the nipple not so much by suction as by the stripping motion of the tongue against the hard palate. This motion carries milk through the teat and into the baby's mouth. Anxiety, psychologic stress, and pain interfere with oxytocin release and the letdown response. These conditions can significantly delay or prevent initiation of successful breast-feeding and need to be monitored carefully by the physician and/or lactation consultant.

Blocked Ducts and Mastitis

Blocked ducts can result from compression of the large superficial ducts under the areola. Typically, this is due to improper latching of the infant to the breast and can usually be resolved without treatment by repositioning the baby and using gentle breast compression while the baby is feeding. Mastitis occurs in 1% to 2% of breast-feeding women. Both blocked ducts and mastitis are associated with painful breast lumps due to incomplete drainage of the breast. Mastitis, however, typically is associated with malaise, chills, and fever and often requires antibiotic treatment to be resolved.

Breast Development

Breast development occurs through both linear and cyclic processes. Linear processes are initiated in utero and regulate nipple formation and growth of rudimentary glandular elements in both sexes prior to puberty. In utero and prepubertal developmental processes are identical for males and females and are controlled by local growth factors,

developmental regulator genes, and systemic hormones that regulate general growth of the body. Beginning with puberty, further increases in breast size and glandular complexity occur in the female breast, but normally no further breast development occurs in males. The onset of menses also begins cyclic changes in breast development. With each ovulatory cycle, there is transient growth and regression of small ductule structures containing alveolar buds, but fully mature glandular structures do not develop in the absence of pregnancy. The greatest change in breast development occurs with pregnancy and lactation. During these periods, alveoli proliferate and differentiate into glandular structures capable of synthesizing and secreting milk for sustained periods. These structures return to their rudimentary structures once lactation ceases. Failure of glandular development occurs rarely but may be a cause of lactation insufficiency.

Lactation

The fall in progesterone around parturition coupled with a rise in serum prolactin levels are the stimuli for milk secretion. In humans, it is known that removal of the placenta, the source of progesterone, is necessary for the initiation of milk secretion. Delayed lactation is a problem for the initiation of breast-feeding for significant numbers of parturient women. Several clinical conditions, including retention of placental fragments, diabetes, obesity, and stress during parturition, are associated with significant delays in early milk production. However, once lactation is established, women with these conditions are able to breast-feed normally. Lactation failure due to impaired prolactin production can result from extensive secondary pituitary necrosis (Sheehan's syndrome) following significant peripartum hemorrhage or other defects in pituitary function. However, these conditions are uncommon.

The volume of milk secreted by women exclusively breast-feeding a single infant at 6 months postpartum is remarkably constant at about 800 mL per day in populations throughout the world. Mothers of twins, and occasionally even triplets, are able to produce volumes of milk sufficient for complete nutrition of their multiple infants, and studies of wet nurses indicate that at least some women are capable of producing up to 3.5 L of milk per day. On the other hand, if infants are supplemented with foods other

---

than breast milk, milk secretion is proportionately reduced. These observations illustrate the important principle that the volume of milk secretion in lactating women is regulated by infant demand. If milk cannot be removed from the breast, local mechanisms bring about an inhibition of milk secretion and down regulation of milk synthetic machinery. With partial removal of milk on a consistent basis, these local factors adjust milk secretion to a new steady state level. If milk removal ceases for extended periods, involution sets in and the gland loses its competency to secrete milk.

Milk Composition

Human milk is composed of sugars such as the disaccharide lactose; proteins including casein, α-lactalbumin, lactoferrin, and secretory immunoglobulin (sIgA); minerals such as sodium, chloride, calcium, and magnesium; and minor nutrients including enzymes,

vitamins, trace elements, and growth factors. These substances are transferred into milk by distinct sets of secretory and transport processes that occur both within and between epithelial cells of the mammary gland to produce milk of relatively constant consistency for a given stage of lactation. As shown in Figure 2.16, proteins, oligosaccharides, and nutrients such as lactose, citrate, phosphate, and calcium are secreted through an exocytotic pathway (I). Lipids and lipid-associated proteins are secreted by an apocinelike process unique to mammary epithelial cells (II). Transcytosis pathways (III) transport a wide range of macromolecular substances derived from serum or stromal cells into milk, including serum proteins such as immunoglobulins, albumin, and transferrin; endocrine hormones such as insulin, prolactin, and IGF-1; and stromal derived agents such as IgA, cytokines, and lipoprotein lipase. Various membrane transport pathways (IV) exist for the transfer of ions and small molecules, such as glucose, amino acids, and water across basal and apical plasma membranes. Paracellular transport (V) provides a direct route for entry of serum and interstitial substances into milk. Transport through these pathways is affected by the functional state of the mammary gland and regulated by direct and indirect actions of hormones and growth factors.

Postpartum Changes in Milk Secretion

Milk volume and composition change dramatically during the first few days postpartum. The volume of milk produced by the breast increases from an initial value of about 100 mL per day on day 1 postpartum to an average of 500 mL per day on day 4 postpartum. Colostrum, the initial fluid secreted from the breast after the birth of the infant, contains higher amounts of minerals and protein and less sugar and fat than mature milk. Maternally derived globulins (particularly immunoglobulin A) and other host resistance factors, including complement, macrophages, lymphocytes, lactoferrin, lactoperoxidase, and lysozymes, are also elevated in colostrum and provide protection for the newborn against enteric pathogens. Oligosaccharides with substantial protective effects against a variety of infections are also elevated in early lactation, comprising as much as 20 g/kg of milk on day 4 postpartum. Increased lactose secretion and closure of the paracellular pathway occur between 48 and 72 hours postpartum. These change increase the water content of milk and reduce transport of serum substances into milk. The substantial volume increase occurring between 36 and 96 hours postpartum is perceived as the coming in of the milk and reflects a massive increase in the rates of synthesis and/or secretion of almost all the components of mature milk, including lactose, milk proteins, lipid, calcium, sodium, magnesium, and potassium.

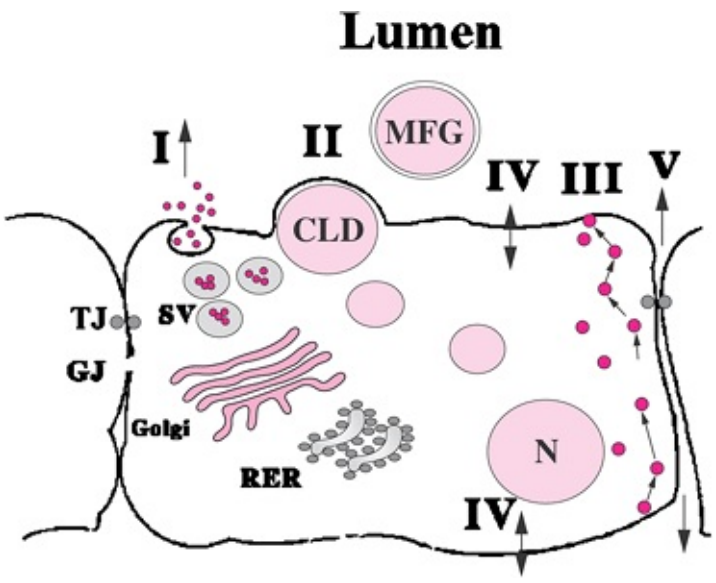

Figure 2.16 Milk secretion pathways. Milk components are secreted by discrete cellular pathways. Proteins, complex sugars, and some micronutrients such as lactose, citrate, phosphate, and calcium are secreted through an exocytotic pathway (I). Lipids and lipid-associated proteins are secreted by an apocinelike process unique to mammary epithelial cells (II). Macromolecular substances including immunoglobulins and certain other serum proteins such as albumin and transferrin as well as endocrine hormones such as insulin, prolactin, and IGF-1 and stromal derived agents such as IgA, cytokines, and lipoprotein lipase are secreted by a transcytotic pathway (II). Membrane transport pathways (IV) exist for the transfer of ions and small molecules, such as glucose, amino acids, and water across basal and apical plasma membranes. A paracellular pathway (V) that is open only during the colostrul phase of lactation provides a direct route for entry of serum and interstitial substances into milk. (MFG, milk fat globule; CLD, cytoplasmic lipid droplet; SV, secretory vesicle; TJ, junction; GJ, gap junction; N, nucleus; RER, rough endoplasmic reticulum.)

Milk Supply

Effective nursing is important for the increase in milk volume and for formation of mature milk; conditions associated with impaired early breast-feeding, such emotional stress, preterm infants, or infants who fail to latch on

correctly, are associated with poor milk supply. For healthy full-term infants, changes in the environment or assistance by a lactation specialist can overcome most difficulties. Breast pumps also can be used to stimulate milk production until proper breast-feeding is established. In particularly refractive cases, oxytocin nasal spray may be helpful.

Breast-Feeding Preterm Infants

Mothers of preterm infants face additional problems to successful breast-feeding, including immature glandular development, additional stress, lack of infant contact, and prolonged

breast pumping. With proper guidance by physicians, nursing staff, and lactation specialists, however, it is possible for the preterm mother to successfully initiate lactation and provide milk for her infant. The immature nature of glandular structure of the preterm breast results in milk that differs from term breast milk and provides significant advantages to preterm infants in host protection and developmental outcomes over formula. Human milk can be stored in glass or plastic containers in the refrigerator or on ice for up to 2 days and can be frozen if longer storage is required.

Breast-Feeding Education

Breast-feeding has economic as well as health benefits. In particular, breast-fed children have fewer illnesses and fewer visits to the doctor and hospital, resulting in lower medical expenses. For women in the workplace, this translates into less absenteeism and increased worker productivity. Despite manifold health and economic benefits of breast-feeding, continued education is required as recent demographic data indicate that significant numbers of women in the United States choose not to breast-feed or fail to breast-feed their infants for the recommended periods (Table 2.2) (Suggested Readings Ref. 5). Education about the practical aspects and health benefits of breast-feeding should be included in preconception and prenatal care and continue through the postpartum period. Educational resources and practical tips about breast-feeding are available for health care workers and patients (Table 2.5).

Summary Points

- *Labor* is defined as regular uterine contractions that lead to effacement and dilation of the cervix.
- Evidence-based guidelines are lacking for many aspects of the management of normal labor and delivery. Care should focus on maximizing patient autonomy and comfort while ensuring maternal and fetal well-being and intervening only as appropriate.
- Restricted use of episiotomy is preferable to routine use, but clinicians should be competent both in the performance of episiotomy and in the repair of both surgical and spontaneous obstetric lacerations.
- Normal labor and delivery can be complicated by infection or hemorrhage, and caregivers must be vigilant for these complications and competent in their management.
- Every delivery should be attended by personnel trained in newborn resuscitation.
- Human milk is nutritionally tailored to the needs of human infants. It is superior to all other forms of infant nutrition, and with few exceptions, all full-term infants should be fed exclusively with human milk during their first 6 months.
- Breast-feeding has numerous health and psychological benefits for infants and mothers—chiefly, protection against bacterial infections for infants, reduced postpartum blood loss, earlier uterine involution, and longer interpregnancy intervals for mothers.
- Breast-feeding is contraindicated for infants with galactosemia or for mothers who are HIV positive, have untreated tuberculosis, or are using drugs of abuse or have uncontrolled alcohol intake.
- Improper infant positioning can cause compression of superficially located milk ducts, which can result in their blockage and possibly lead to painful breast lumps and in some cases mastitis. Repositioning of the baby and gentle breast compression are the best ways to prevent these problems.
- Milk supply is dependent on effective nursing and is not related to breast size. Emotional stress, premature infants, or impaired latching of infants to the breast all can contribute to reduced milk supply. Lactation consultants can help to overcome many problems associated with poor milk supply and other breast-feeding difficulties, especially for new mothers.

Obstetric Analgesia and Anesthesia

Joy L. Hawkins

The purpose of this chapter is to acquaint the obstetrician with the various techniques of obstetric *analgesia* (pain relief) and *anesthesia* (for surgical procedures) and to describe their indications, advantages, disadvantages, and complications. The technical aspects, including the methods of administration, will not be described in detail. Readers seeking specific information on how to perform the various obstetric anesthetic techniques are referred to one of the basic obstetric anesthesia textbooks.

Obstetric analgesia or anesthesia refers to the multiple techniques useful for the alleviation of pain associated with labor, delivery, or surgery. The choice of an appropriate analgesic technique must be made by the patient, the obstetrician, and the anesthesiologist and should take into consideration the patient's anatomy and physiology, the status of her fetus, the obstetric plan for delivery, and the pharmacology of the drugs to be employed. Both the American College of Obstetricians and Gynecologists (ACOG) and the American Society of Anesthesiologists (ASA) have guidelines for the practice of obstetric anesthesia.

Pain of Parturition

Increasing dilation of the cervix; contraction and distention of the uterus; and distention or tearing of the vagina, vulva, and perineum causes the pain that occurs during labor and delivery. Pain may also be generated through stretching or application of pressure to adjacent pelvic organs.

The pain that occurs in the first stage of labor increases in severity as the cervix becomes more dilated. The onset of pain lags approximately 15 to 30 seconds behind the onset of the uterine contraction and is first perceived when the intra-amniotic pressure reaches 15 mm Hg above that of resting tonus. The pain of uterine contractions is conducted through small sensory nerve fibers of the paracervical and inferior hypogastric plexuses to join the sympathetic nerve chain at L2–3. The ascending fibers enter the spinal cord through the nerve roots of T-10 to T-12, with a variable contribution from L-1 (Fig. 3.1). Because the cutaneous branches of the lower thoracic and upper lumbar nerves migrate caudally for a considerable distance before they innervate the skin, the pain of uterine contractions is often referred to the area over the upper sacrum and the lower lumbar spine.

Pain from the uterus and cervix is transmitted through the small-diameter myelinated A-delta fibers and unmyelinated C fibers. Because there are relatively fewer nociceptive afferent nerves from visceral structures than from somatic structures, visceral pain is perceived as being diffuse and difficult to localize. These visceral afferents also synapse on and excite the same dorsal horn neurons as afferents from somatic structures. This arrangement is responsible for the phenomenon of referred pain.

In the second stage of labor, sharp pain occurs as the tissues of the vagina and perineum are stretched. Stretching stimulates the second, third, and fourth sacral nerve roots, which carry nociceptive information to the spinal cord through the sensory fibers of the pudendal nerve. Adnexal pressure and traction on the bladder, urethra, rectum, and peritoneum also contribute to the pain of parturition. Compression of the lumbosacral plexus by the fetal head, particularly in the occiput posterior position, may cause pain even before the onset of labor.

The gate theory of Melzack and Wall holds that stimulation of the large cutaneous A-beta nerve fibers closes a “gate” in the substantia gelatinosa of the spinal cord, preventing pain impulses from being carried rostrally by

---

the A-delta and C nerve fibers. This theory forms the basis for the use of acupuncture, transcutaneous electrical nerve stimulation (TENS), and intracutaneous nerve stimulation with sterile water injections for the relief of pain associated with parturition.

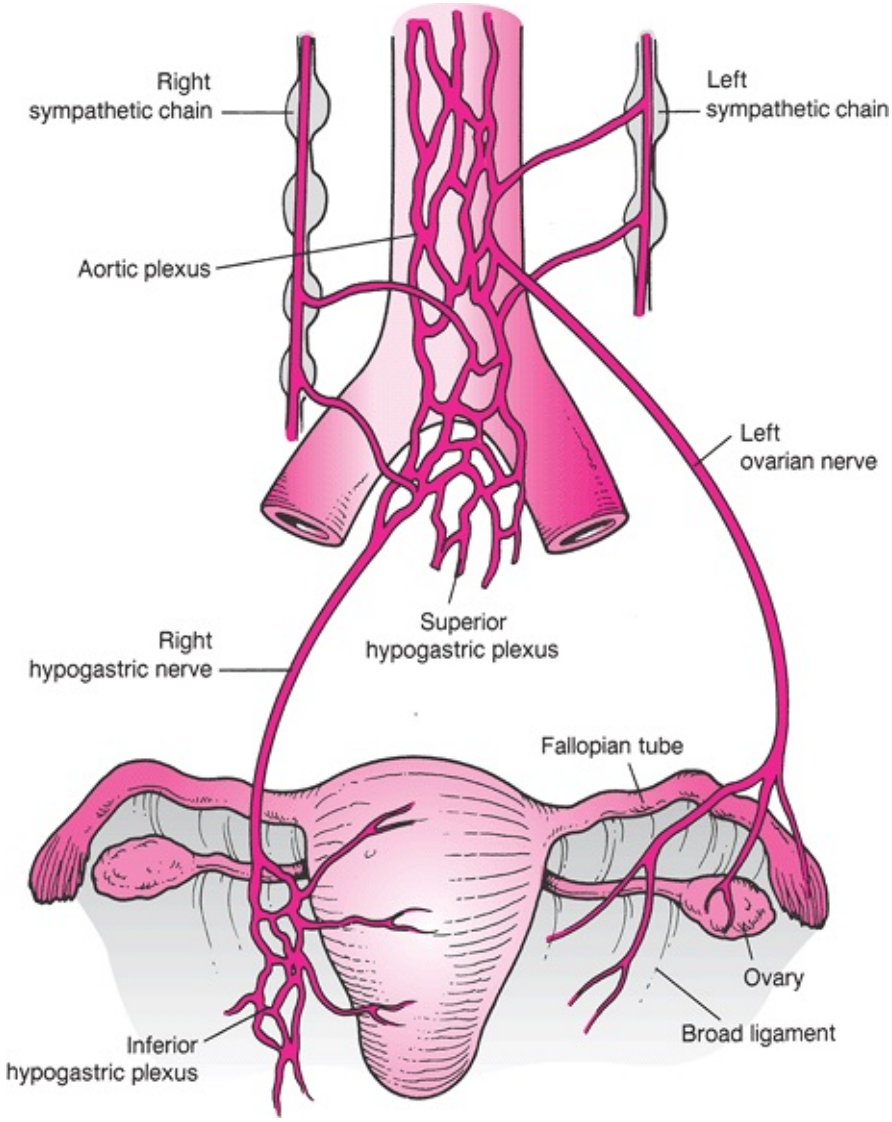

Figure 3.1 Sympathetic nerve supply of the uterus from the pelvic and abdominal distribution. The uterine nerves arise from the upper part of the uterus (i.e., upper uterine segment), the contraction of which contributes to pain; from the lower part of the uterus (i.e., lower uterine segment), the distention of which contributes to pain; and from the cervix, the dilation of which contributes to pain. The ovarian nerve supplies the ovary, fallopian tube, broad ligament, round ligament, and the side of the uterus, and it communicates with the uterine plexus. The sympathetic efferent and afferent fibers are shown together. (Adapted from Abouleish E. *Pain control in obstetrics*. Philadelphia: JB Lippincott Co, 1977.)

Pregnancy appears to reduce anesthetic requirements. It has been postulated that high progesterone levels lead to increased quantities of endogenous endorphins, which may increase the maternal threshold to pain. One study correlated pain intensity during labor and plasma levels of ß-endorphin. The lowest endorphin levels were found after abolition of labor pain by epidural analgesia. The highest concentrations were observed in the first few minutes after delivery, immediately after cessation of the severe pain of expulsive labor.

The nature of the pain of labor varies in intensity with the stages of labor. The intensity of

pain is related to physical factors such as the strength and duration of uterine contractions; the rapidity of cervical dilation; the degree of distention of the vaginal and perineal tissues; the requirement for operative delivery; and the size, presentation, and position of the infant. Augmentation of labor with oxytocin increases the strength and pain of uterine contractions. The primiparous woman may perceive greater pain than the multipara who enters labor with more advanced cervical dilation and who may also be more psychologically prepared (Fig. 3.2). Exhaustion, lack of social supports, other psychologic factors, and protracted nausea and vomiting may also increase the parturient's perception of labor pain.

Pain management is an important part of modern obstetric care. A joint statement by the ACOG and the ASA notes that “Labor results in severe pain for many women. There is no other circumstance in which it is considered acceptable for a person to experience untreated severe pain, amenable to safe intervention, while under a physician's care. In the absence of a medical contraindication, maternal request is a sufficient medical indication for pain relief during labor.” Most women now request some form of analgesia during childbirth (Table 3.1). The obstetrician should appreciate the importance of providing pain relief during labor through the use of nonpharmacologic techniques, systemic analgesics, or regional block analgesia. During the second stage of labor, additional analgesia

may also be needed through perineal extension of a segmental epidural, spinal analgesia, or through the use of pudendal or local infiltration.

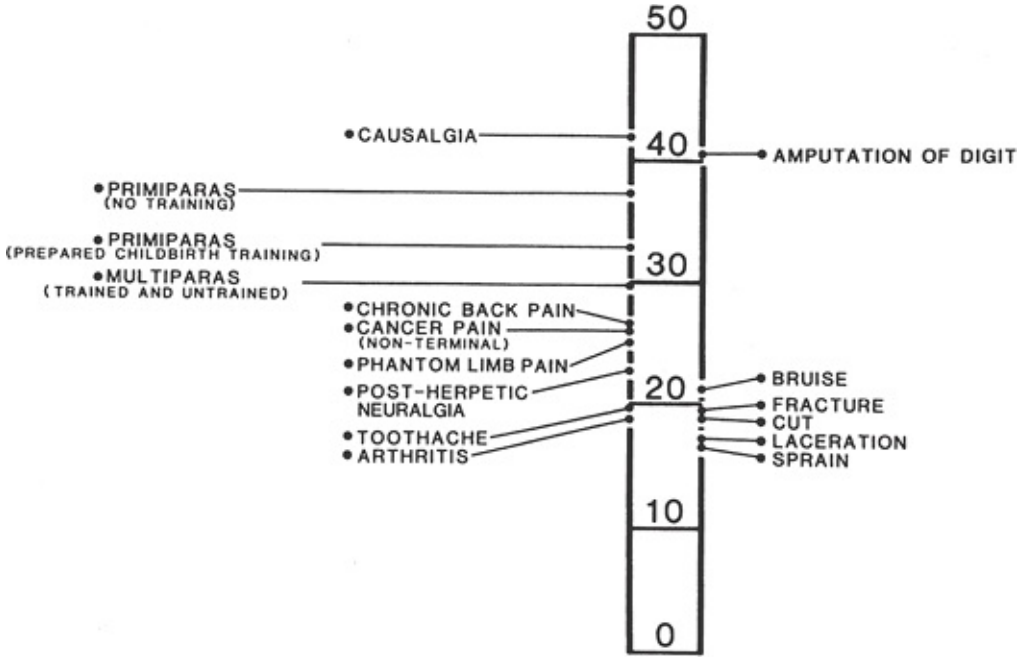

Figure 3.2 Comparison of pain scores obtained from women during labor and from patients in a general hospital pain clinic or emergency department using the McGill pain questionnaire. (From Melzack R. The myth of painless childbirth. *Pain* 1984;19:321–337.)

Systemic Analgesia and Sedation

In the management of labor pain, systemic narcotics are usually considered to be the first step beyond the less invasive or "natural" methods such as massage, water baths, and birth attendants (doulas). They may also be necessary for patients who are not candidates for regional analgesia. Research indicates that the analgesic effects of parenteral agents used in labor is limited, and the primary mechanism of action is heavy sedation. Although narcotics may be effective for some patients in relieving the pain of labor, their side effects prohibit the use of large doses. The physician must balance maternal sedation, nausea, and respiratory depression and neonatal respiratory depression with effective relief of pain. The pain of labor occurs intermittently with contractions. Maternal hyperventilation during a contraction lowers pCO_2 and leads to hypoventilation for 2 to 3 minutes between contractions, especially when narcotics have shifted the carbon dioxide response curve. There are advantages and disadvantages of all available narcotics, and a drug should be chosen with knowledge of its side effects and pharmacokinetics (Table 3.2).

Use of Systemic Medications

The use of systemic narcotics and tranquilizers does not require special training or the availability of anesthesia personnel, and they are used extensively in the United States to provide labor analgesia, either alone or before provision of neuraxial analgesia (Table 3.1). These compounds do not induce fetal heart rate (FHR) abnormalities other than reductions in variability and rarely sinusoidal heart rate patterns, nor do they cause fetal acidosis. The drug-related adverse maternal effects of narcotics can include decreased gastric motility, nausea, vomiting, pruritus, sedation, loss of protective airway reflexes, and hypoxia due to respiratory depression. The adverse neonatal effects of these agents include central nervous system (CNS) depression, respiratory depression, impaired early breast-feeding, altered neuroadaptive behavior, and decreased ability to regulate body temperature. To minimize these side effects, the lowest effective dosage should be employed, and the timing with respect to delivery must be carefully considered. Resuscitation equipment should be kept at hand, and naloxone (Narcan), used to antagonize opioids, should be readily available. Benzodiazepine effects may be reversed with flumazenil (Romazicon).

TABLE 3.2 Parenteral Medications for Labor Analgesia

Drug/Dose (IV)	Pros	Cons
Meperidine, 25 to 50 mg	Rapid onset (5 min) Can be used as PCA	Neonatal depression (max at 2 h) Active metabolite (3-d excretion) Tachycardia Nausea
Morphine, 5 to 10 mg	Anxiolytic, sedative	Long onset (20 min) Long duration (4 to 6 h) Neonatal respiratory depression Hypotension (histamine

		release) Nausea
Fentanyl, 1 μg/kg or 50 to 100 μg	Rapid onset No metabolites Minimal fetal effect Minimal sedation Minimal nausea Can be used as PCA	Short duration (45 min) Potent respiratory depressant Accumulates with repeated doses Minimal sedation
Butorphanol, 1 to 2 mg	Rapid onset (5 min) Sedative Minimal fetal effect Minimal nausea “Ceiling” for respiratory depression	Dysphoric reactions “Ceiling” for analgesia Withdrawal in susceptible patients Blocks intrathecal narcotics
Nalbuphine, 5 to 10 mg	Rapid onset (5 min) Sedative Minimal nausea Can be used as PCA “Ceiling” for respiratory depression Minimal fetal effects	Dysphoric reactions “Ceiling” for analgesia May precipitate withdrawal Blocks intrathecal narcotics

IV, intravenous; PCA, patient-controlled analgesia.

Systemic Narcotics

Meperidine

Meperidine (Demerol) has achieved wide popularity for systemic analgesia during labor. It is preferred over morphine because it produces less emesis and may not depress newborn carbon dioxide response curves as much as morphine. It can be administered intravenously or intramuscularly during labor. Current usage consists of small, incremental intravenous doses of 25 to 50 mg. Small doses (12.5 mg) can also be used to treat shivering. Placental

transfer of meperidine occurs rapidly. Maximal depression of the infant occurs when delivery takes place 2 to 4 hours after maternal intravenous or intramuscular administration. Delivery of the infant within 1 hour of administration produces little evidence of newborn depression. A study using meperidine for labor analgesia by a patient-controlled infusion device found 5% of infants required naloxone at delivery.

Meperidine has as its principal metabolite the compound normeperidine, which is equipotent with meperidine in its ability to produce respiratory depression and can also cause seizures. Repeated intravenous administration of small doses of meperidine leads to increasing maternal and fetal levels of normeperidine. Meperidine has an elimination half-life in neonatal blood of 22.7 hours, and that of normeperidine is measured in days, reflected in abnormal neurobehavioral scores for up to 3 days.

Morphine

Morphine is pharmacologically more potent than meperidine by a factor of approximately 10. Morphine may depress the newborn carbon dioxide response curve more

---

than meperidine, perhaps due to greater permeability of the infant brain to morphine. Because of this reputation, morphine is rarely used by the obstetrician for the management of pain during labor.

Fentanyl

Fentanyl (Sublimaze) is a potent synthetic narcotic with analgesic activity approximately 100 times that of morphine. Its onset of action is rapid, and its duration of activity is short (i.e., 20 to 30 minutes) because of its rapid distribution from plasma. The terminal drug elimination half-life after a single small dose is 1 to 2 hours. Fentanyl is highly bound to protein, which may limit its placental transfer. It has no active metabolites. Fetal–maternal blood concentration ratios average 0.31 over the first 10 minutes after intravenous administration. Fentanyl produces moderate analgesia and mild sedation. There may be a brief period of decreased FHR variability, but no other disturbing FHR patterns have been reported. Comparative studies with meperidine indicate that the need for newborn naloxone administration is less after use of fentanyl.

Nalbuphine

Nalbuphine (Nubain) is a potent narcotic agonist–antagonist agent which, at equianalgesic doses, produces respiratory depression equivalent to that of morphine. The advantage and disadvantage of nalbuphine is that as the dosage is increased, a ceiling effect is seen for respiratory depression and unfortunately also for analgesia. Maximal respiratory depression occurs with a dose of 30 mg in a 70-kg adult. Sedation and dysphoric reactions may also occur. Reversal of other opioid effects may precipitate withdrawal in opioid-tolerant patients.

Butorphanol

Butorphanol (Stadol) is another synthetic narcotic with agonist–antagonist properties. It is five times more potent than morphine. It has achieved moderate popularity in the United States in the management of the pain of the first stage of labor. It is usually administered intravenously in doses of 1 to 2 mg. Butorphanol exhibits the same ceiling effect for analgesia and respiratory depression as nalbuphine. Maternal side effects may include sedation, dysphoric reactions, and reversal of other opioid effects.

Patient-controlled Intravenous Analgesia

Intravenous patient-controlled analgesia (PCA) is widely available and provides pain relief through self-administration of small doses of intravenous opioids. Fentanyl, remifentanil, and meperidine are the analgesics most commonly employed with this technique. The infusion pump is programmed so that the patient receives an incremental dose when she pushes a button, followed by a lockout interval when additional requests by the patient will not be administered. An hourly maximum may also be programmed. A basal infusion is rarely used in labor because of the risk of respiratory depression between contractions. The actual settings are dictated by the pharmacokinetics of the narcotic chosen. The main advantage of PCA is improved patient satisfaction due to a feeling of control and not having to wait for a nurse to bring pain medication. Use of PCA may also decrease nursing staffing requirements.

In a study by Rosenblatt and colleagues, metoclopramide (Reglan) was used as an antiemetic and analgesic adjunct to PCA for patients undergoing prostaglandin induction of labor for second-trimester termination of pregnancy. Patients were given intravenous metoclopramide, 10 mg, or saline placebo followed by PCA-administered morphine. Those receiving metoclopramide used 54% less morphine and had lower pain scores.

Narcotic Antagonists

Naloxone

Because all narcotics cross the placenta and can produce respiratory depression in the neonate, availability of an effective antagonist is essential. Naloxone also reverses analgesia, thus its prophylactic use is not advised. Naloxone may be administered to the parturient as an intravenous bolus of 0.1 to 0.4 mg to treat severe maternal respiratory depression, using the lowest possible dose. Care must be taken to titrate naloxone to the desired effect, since large doses have been implicated in the causation of myocardial infarction, pulmonary edema, and severe hypertension. Naloxone, 0.01 mg per kg, may also be administered intravenously, intramuscularly, or through the endotracheal tube to the newborn to reverse the respiratory depressant effects of placentally transferred narcotics. The effect is usually apparent within a few minutes and persists for as long as 2 hours. The neonate must be carefully observed for evidence of renarcotization, because the half-life of naloxone is less than that of most narcotics.

Sedative Drugs

Benzodiazepines

The principal benzodiazepine drugs are diazepam (Valium) and midazolam (Versed). Diazepam has been used extensively in other parts of the world for seizure prophylaxis in patients with severe preeclampsia. However, because of its side effects on the newborn, it has found little favor in the United States. Newborns exposed to diazepam characteristically exhibit hypotonicity, hypoactivity, and impaired temperature regulation and metabolic response to cold stress.

Midazolam is a newer benzodiazepine anxiolytic, a sedative drug with significant amnestic properties. It is five times more potent than diazepam and is soluble in water, a property that reduces pain associated with intravenous administration. Midazolam crosses the sheep placenta,

---

achieving a fetal–maternal concentration ratio of 0.15. Its metabolites are inactive, and the drug is excreted more rapidly than diazepam. Midazolam has been used in large doses as an induction agent for cesarean delivery, but because of its ability to cross the placenta, it has produced neonatal respiratory depression and decreased body tone and temperature. Midazolam has not been recommended for use as a tranquilizer-sedative in labor, because its amnestic properties are unacceptable to most parturients.

Barbiturates

Barbiturates may be used in the latent phase of labor. Although they cause maternal sedation and decreased anxiety, barbiturates lack analgesic properties and may increase the perception of pain when given without concomitant administration of a narcotic. Most barbiturates have long elimination half-lives and readily cross the placenta. Prolonged neonatal effects have led to the virtual elimination of these drugs from use during labor.

Other Sedatives

Phenothiazine derivatives, such as promethazine (Phenergan), have been used in obstetrics to provide sedation and decrease nausea. Maternal sedation is achieved without significant maternal or newborn side effects. It is important to remember that none of these drugs provides analgesia, and some parturients may object to the heavy sedation they cause. In addition, promethazine is a very painful intramuscular injection. It should have little place in the management of labor pain.

Ketamine (Ketalar), when administered intermittently at low doses (10 to 20 mg), can produce analgesia in parturients without causing maternal loss of consciousness or neonatal respiratory depression. For patients who are opioid tolerant, or for whom parenteral narcotics have proven inadequate for pain control, 20 mg ketamine intravenously followed by a low-dose ketamine infusion of 20 mg per hour may be helpful. However, the profound amnesia and potential for dysphoria or other psychomimetic effects when using ketamine limit its general use for labor analgesia. It is most often used for short painful procedures such as urgent forceps delivery or manual removal of the placenta.

Inhalational Agents

Nitrous oxide can be inhaled periodically during contractions in a 50% mixture with oxygen. During a painful contraction, the mother breathes from a mask connected to the regulator valve of a breathing circuit. A scavenging system is required by the Occupational Safety and Health Administration (OSHA) to eliminate exhaled waste anesthetic gases. When nitrous oxide is used in conjunction with narcotics, maternal oxygen saturation may decrease. Use of a pulse oximeter to ensure adequate maternal oxygenation is recommended. In practical terms, since almost all deliveries in the United States now take place outside the operating room, an anesthesia machine will probably not be available to safely administer inhalational agents.

Regional Analgesia

Local Anesthetic Agents

Most local anesthetic agents share a common structure consisting of a hydrophilic amino group connected by an intermediate chain to a lipophilic aromatic residue. Their mechanism of action is to block exchange of sodium and potassium ions across the cell membrane, probably through mechanical interruption of ion flow through cell wall channels. Local anesthetic drugs are manufactured as chloride salts. The nonionized base is able to diffuse across tissues, while the ionized form is actually the active component. The amounts of nonionized (mobile) and ionized (active) drug depend on the pKa of the local anesthetic and tissue pH. After injection of lidocaine (Xylocaine), the sensory nerve action potential decreases more sharply in pregnant women than in nonpregnant women. This implies that pregnant women have an increased susceptibility to the effects of local anesthetic agents.

Local anesthetics belong principally to two groups, those of ester and amide configurations. Ester drugs are generally characterized by their rapid onset of action, short duration, and low toxicity. Chloroprocaine (Nesacaine) is a representative of this group. It is rapidly metabolized by serum pseudocholinesterase, forming para-aminobenzoic acid. Lidocaine, bupivacaine, and ropivacaine are representatives of the amide group. These drugs are more highly bound to protein and have a slower onset and a longer duration of action. They are metabolized in the liver. Toxicity is usually greater for amides than for drugs of the ester group (Table 3.3).

Adverse Effects of Local Anesthetic Drugs

Systemic Toxicity

Systemic complications of local anesthetics include toxic blood levels of the drug and allergic reactions as well as reactions due to epinephrine that is often added to local anesthetic solutions to retard systemic absorption and prolong duration of action.

Maximal safe doses for healthy young adults are approximately 7 mg/kg (500 mg) of lidocaine with epinephrine, 2 to 3 mg/kg (200 mg) of bupivacaine, and 20 mg/kg (1500 mg)

of chloroprocaine (Table 3.3).

The most common reason for high blood levels of local anesthetic drugs is accidental intravascular injection. This usually occurs during a pudendal block or when an epidural catheter has been placed or migrated into a vein. To minimize accidental intravenous injection, gentle aspiration

should be undertaken before each injection. Injection should be done slowly and incrementally with no more than 5 mL of local anesthetic drug to reduce the chance of a sudden increase in plasma levels. A marker such as epinephrine may be added to the local anesthetic solution so that intravascular injection will manifest as tachycardia.

TABLE 3.3 Characteristics of Local Anesthetics Commonly Us Obstetric Anesthesia

	Chloroprocaine (Nesacaine)	Lidocaine (Xylocaine)	Bupivacaine (Marcaine)	Ropi (Nar
Class	Ester	Amide	Amide	Ami
Onset	Fast	Intermediate	Slow	Slow
pKa	9.1	7.9	8.1	8.1
Duration	Short	Intermediate	Long	Lon
Protein binding	—	65%	95%	—
Usual concentrations:				
Infiltration	1%	1%	0.25%	0.2%
Epidural analgesia	1%–2%	1.0%–1.5%	0.125%–0.250%	0.1%
Epidural anesthesia	3%	2%	0.5%	0.5C 0.75

Spinal anesthesia	—	5%	0.75%	—
Maximum dose (mg/kg)	20	5–7	2–3	4–5

The infiltration of a local anesthetic agent into an area rich in vessels, such as the region of the uterine artery (e.g., paracervical block [PCB]), pudendal vessels, or the epidural space, may be associated with absorption of the drug through blood vessel walls. The serum levels tend to rise slowly, and toxic manifestations usually occur only after multiple injections or prolonged infusion. Repeated injections of slowly metabolized local anesthetic drugs, such as the amides, may lead to accumulation in the serum such that toxic levels are achieved. This phenomenon does not occur readily with esters such as chloroprocaine, which are rapidly metabolized (maternal serum half-life of 21 seconds and fetal serum half-life of 43 seconds for chloroprocaine). To minimize the likelihood of producing high serum levels, care should be taken to record the amount and concentration of local anesthetic solution and to limit use to approximately 25% less than the maximal safe dose.

Signs and symptoms of local anesthetic drug toxicity include a relaxed feeling, drowsiness, lightheadedness, tinnitus, circumoral paresthesias, metallic taste, slurred speech, blurred vision, unconsciousness, convulsions, and cardiac dysrhythmias and arrest. In 1983, the U.S. Food and Drug Administration issued an advisory warning that 0.75% bupivacaine should no longer be used in obstetrics because of reports of bupivacaine-induced cardiac arrest. The advisory stated that the resuscitation in these cases had been “difficult or impossible despite apparently adequate preparation and appropriate management.” Inadvertent intravascular injection causes high serum levels, which produce cardiac arrest through blockade of the cardiac sodium channels, inhibiting repolarization of the nerve cell membranes of the conduction system of the heart. Bupivacaine has been found to bind avidly to nonspecific cardiac protein–binding sites, slowing the conduction of impulses arising in pacemaker cells and causing a dose-dependent reduction in the strength of myocardial contractility, leading to cardiac arrest.

Initial treatment includes the use of mask oxygen, a reliable intravenous line, and measures to ensure and protect the airway. These include use of cricoid pressure to occlude the esophagus, the availability of adequate suction, and the capability to perform endotracheal intubation if needed. Adequacy of respirations must be ensured, if necessary, by means of positive pressure ventilation with 100% inspired oxygen. The patient should be hyperventilated to help correct metabolic acidosis caused by seizure activity and decreased cardiac output. CNS hyperreactivity and convulsions are treated with thiopental (Pentothal) in small, incremental doses of 25 to 50 mg intravenously or with 1 to 5 mg of midazolam given intravenously. In the event of cardiovascular depression, elevate the lower extremities and verify left uterine displacement. Vasoactive drugs such as ephedrine, phenylephrine, epinephrine, and calcium may be employed to support the circulation. If

cardiopulmonary resuscitation is indicated, advanced cardiac life support (ACLS) protocols should be followed, and the fetus should be delivered within 5 minutes to relieve maternal central venous compression so that cardiopulmonary resuscitation (CPR) can be more effective.

Use of Regional Anesthetic Blocks

Local Infiltration of the Perineum

Local infiltration of the perineum is commonly performed when an episiotomy is needed and time or fetal head position does not allow a pudendal block to be administered.

An average of 10 to 20 mL of local anesthetic solution is employed. The preferred drugs are lidocaine 1% or chloroprocaine 2%.

Pudendal Block

The pudendal block provides analgesia of the vaginal introitus and perineum. There are several advantages of this analgesic technique. Because the elapsed time between administration and delivery is short, there is relatively little systemic absorption and therefore little opportunity for the drug to directly affect the fetus. The block is easy to accomplish but provides analgesia of the perineum only. Pain of contractions is unaffected. The disadvantages include the need for large drug doses and the potential for local anesthetic toxicity, hematoma, and infection leading to retropsoas or subgluteal abscess.

With the transvaginal approach, the ischial spine must first be identified. Through a guide, a needle is inserted into the vagina and directed laterally and posteriorly to the ischial spine. A submucosal wheal is made, and the needle is advanced into the sacrospinous ligament, where resistance is felt. As the needle passes the ligament, a loss of resistance is felt. The needle has now entered the pudendal canal, which contains the pudendal nerve and associated vessels (Fig. 3.3). After aspirating the needle for blood, 3 to 5 mL of local anesthetic solution (usually lidocaine 1%) is injected, and the needle is advanced another 0.5 to 1.0 cm. If aspiration is again negative, 5 to 7 mL of solution is injected. A total of 10 mL is injected on each side. Approximately 10 minutes are required for anesthesia to occur. Chloroprocaine 1% to 2% may also be used for this block. Analgesia with chloroprocaine lasts less than 1 hour, while lidocaine analgesia is more prolonged.

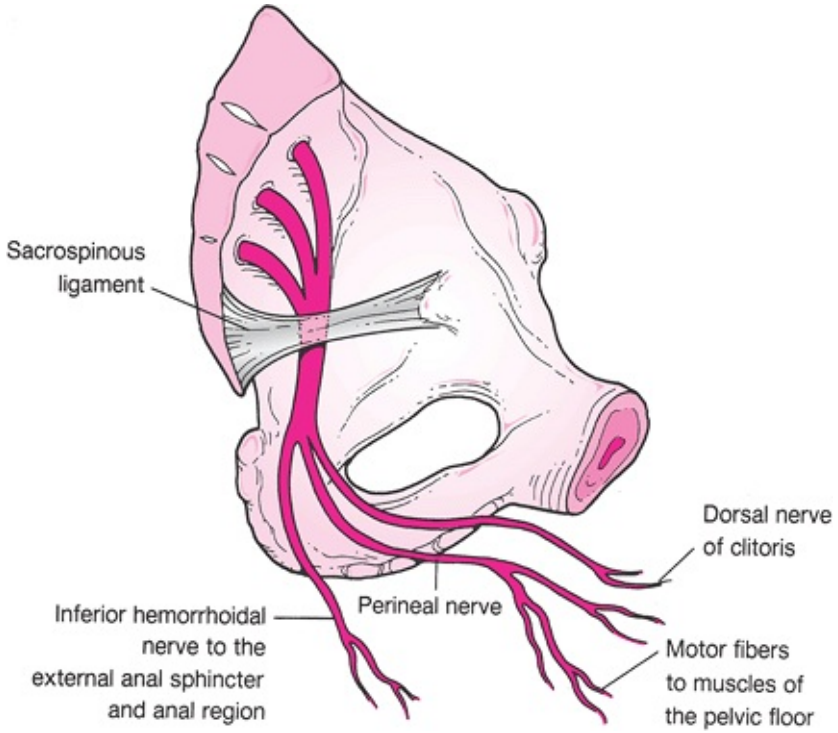

Figure 3.3 The pudendal nerve and its branches. The inferior hemorrhoidal nerve can arise higher up from the pudendal nerve or separately from the sacral plexus. (Adapted from Abouleish E. *Pain control in obstetrics*. Philadelphia: JB Lippincott Co, 1977.)

Paracervical Block

PCB anesthesia may be used when the active phase of labor begins, and it can be employed until approximately 8 cm of dilation has been achieved. Although formerly popular, this block has fallen into relative disuse since the description of bradycardia after PCB and its proven association with fetal acidosis. The PCB is useful when anesthesia personnel are unavailable and parenteral narcotics are inadequate.

The PCB relieves the pain associated with uterine contractions, but it is not effective for pain associated with distention of the pelvic floor. The local anesthetics of choice are 2% chloroprocaine or 1% lidocaine. Typically, 6 mL of drug is administered superficially, just under the vaginal mucosa, at the 4- and 8-o'clock positions (Fig. 3.4). Bradycardia occurs in 10% to 30% of cases. The landmark study by Baxi and colleagues, using a transcutaneous oxygen electrode attached to the fetal scalp, demonstrated that bradycardia is related to decreasing fetal oxygenation, which becomes maximal approximately 10 minutes after injection. This research has been corroborated by the study of isolated human uterine artery segments and by work in animals, indicating that direct uterine artery vasoconstriction and uterine hypertonus occur in response to the injection of a local anesthetic drug, diminishing uterine blood flow and fetal oxygenation.

Lumbar Epidural Analgesia

Standard Technique

Lumbar epidural analgesia was first performed in 1884 by Corning, who recognized that analgesia could still occur when attempted spinal analgesia failed. In 1921, Pages

applied the technique to surgery. Obstetric applications were made by Graffagnino and Seyler in 1935.

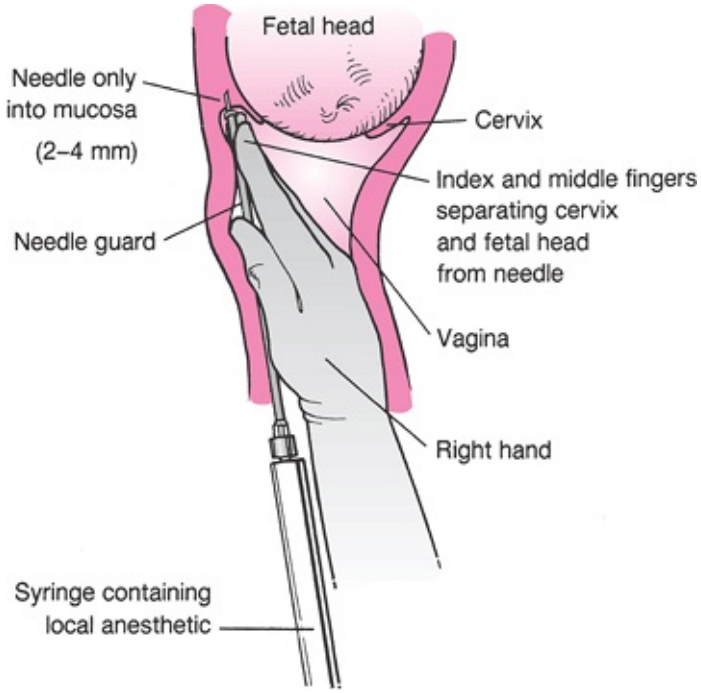

Figure 3.4 Technique of PCB. Notice the position of the hand and fingers in relation to the cervix and fetal head and the shallow depth of the needle insertion. No undue pressure is applied at the vaginal fornix by the fingers or needle guide. (Adapted from Abouleish E. *Pain control in obstetrics*. Philadelphia: JB Lippincott Co, 1977.)

The technique of lumbar epidural analgesia involves the insertion of a 17- or 18-gauge hollow-bore needle through the ligamentum flavum into the epidural space at the L4–5, L3–4, or L2–3 interspace. Most physicians prefer the loss-of-resistance technique with air or saline as the one that affords the least risk of penetration of the dura. A 20-gauge catheter is passed through the epidural needle for a distance of 3 to 5 cm within the epidural space. This catheter is securely taped in place and serves as an avenue for intermittent or continuous infusion of local anesthetic agents or opioids. The most commonly used local anesthetic agents for epidural analgesia for labor are bupivacaine 0.0625% to 0.125% and ropivacaine 0.1% to 0.2%.

Combined Spinal-Epidural Analgesia

The combined spinal–epidural (CSE) technique adds a subarachnoid injection of an opioid with or without a small dose of local anesthetic in a needle-through-needle technique to

provide faster onset of analgesia with a smaller dose of medication than is possible using epidural medications alone. The epidural catheter is still available for additional analgesia. A Cochrane review comparing CSE and conventional epidural analgesia for labor concluded that there was no difference in progress of labor, incidence of instrumental deliveries or cesareans, or postdural puncture headache (PDPH). However, analgesia was faster in onset, and there was higher patient satisfaction in the CSE group than in the epidural analgesia group.

Patient-Controlled Epidural Analgesia

Patient-controlled epidural analgesia (PCEA) is a technique by which the patient self-administers on-demand doses of an analgesic mixture via an epidural catheter, whenever she perceives discomfort. To avoid overdosage, a lockout period follows each self-administration. This technique is associated with decreased use of local anesthetic solution and less demand on staff time compared with continuous epidural infusion (CEI). Most studies have found that patients will self-administer less local anesthetic solution than continuous infusions provide and that anesthesia workforce needs are reduced by about 40%. Quality of analgesia, complications, and amount of motor block are similar between the two techniques.

Epidural Medications in Labor

Epidural injection of opioids alone has been shown to be of limited value for the relief of labor pain. Fentanyl and sufentanil used alone can provide analgesia for early labor but require high doses—100 µg fentanyl or 30 µg sufentanil. In contrast, spinal injection of opioids alone provides excellent, although time-limited, analgesia for labor in small doses—10 to 25 µg fentanyl or 2.5 to 5.0 µg sufentanil.

Fortunately, the addition of opioids to dilute concentrations of epidural local anesthetics has been proven to be quite effective in the relief of labor pain. The combination is a rational one because local anesthetic solutions relieve somatic pain preferentially, whereas opioids are more effective in relieving visceral pain. By combining a lipid-soluble opioid such as fentanyl or sufentanil to bupivacaine or ropivacaine, the concentration of local anesthetic can be dramatically decreased and motor block can be minimized. The addition of fentanyl or sufentanil approximately doubles the analgesic efficacy of any concentration of bupivacaine or ropivacaine while shortening the time to complete analgesia. Many women experience shivering during normal labor and delivery, and the rate increases with epidural analgesia. Shivering can be diminished or abolished through epidural injection of opioids (e.g., fentanyl 100 µg) or small intravenous doses of meperidine (e.g., 12.5 mg).

The beneficial effects of epidural opioids in labor include:

- Ability to use lower concentrations of local anesthetic agents
- Reduction in motor block, allowing improved mobility of the patient
- Decreased incidence of hypotension
- Reduction in shivering

- Greater maternal satisfaction with the analgesia they provide.

Effects of Epidural Analgesia on Uterine Blood Flow

Studies investigating changes in intervillous blood flow and mean arterial pressure with lumbar epidural analgesia have demonstrated a negligible reduction in these parameters with the onset of effective analgesia. Well-hydrated patients with preeclampsia experience improvement in intervillous blood flow along with a slight decrease in blood pressure.

Advantages and Disadvantages of Lumbar Epidural Analgesia

There are principal advantages of lumbar epidural analgesia, as shown in Table 3.4.

Indications and Contraindications for Lumbar Epidural Analgesia

Indications for lumbar epidural analgesia include pain in labor, management of the patient with preeclampsia who does not have a coagulation abnormality, management of labor in patients with certain medical co-morbidities, and management of twin delivery. A joint statement by the ACOG and ASA notes that "Of the various pharmacologic methods of pain relief used in labor and delivery, regional analgesia techniques—spinal, epidural, and CSE are the most flexible, effective, and least depressing to the CNS, allowing for an alert, participating mother and an alert neonate."

There are absolute and relative contraindications to the induction of lumbar epidural analgesia, as shown in Table 3.5. Absolute contraindications include the following: patient refusal, hemodynamic instability, infection at the anticipated site of puncture, and absence of resuscitation equipment. Relative contraindications may include fever, preexisting CNS disease, hypovolemia, lack of experience by the anesthetist, and blood coagulation defects.

TABLE 3.4 Principle advantages and Disadvantages of Lumbar Epidural Analgesia in Labor

Advantages:

- The parturient remains unsedated and cooperative.
- The incidence of complications is very low when the technique is used correctly.
- Once an epidural catheter is in place, it can be used to provide analgesia or anesthesia of any duration for a vaginal or cesarean delivery.

Disadvantages:

- There is a possibility of poor sacral or perineal analgesia.
- There may be a presence of "hot spots," where analgesia is insufficient.
- There may be delayed onset of action.
- There may be technical difficulty; technical failure occurs in approximately 4% of cases.
- There may be intravascular injection and local anesthetic toxicity.
- There may be accidental dural puncture leading to headache.
- There may be hypotension.

TABLE 3.5 Absolute and Relative Contraindications to the Induction of Spinal or Epidural Anesthesia

Absolute	Relative
• Patient refusal • Hemodynamic instability • Infection at the anticipated site of puncture • Absence of resuscitation equipment	• Fever • Preexisting CNS disease • Hypovolemia • Lack of experience by the anesthetist • Blood coagulation defects

CNS, central nervous system.

Although an arbitrary platelet count of 100,000 per mm^3 has been advocated as the lower limit for safe lumbar epidural analgesia, successful blocks without epidural bleeding complications have been obtained with much lower platelet counts. The underlying cause of the thrombocytopenia is important and must be considered along with any absolute number. For example, the patient with idiopathic thrombocytopenic purpura or gestational thrombocytopenia is much less likely to bleed at a low platelet count than the patient with HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome. The best indicator of potential bleeding is a clinical history of bruises, petechiae, or bleeding from the gums.

Subarachnoid Analgesia

Subarachnoid (also called *spinal* or *intrathecal*) analgesia for labor has become increasingly popular. The major advantages of spinal analgesia include use of a very low dose of local anesthetic or narcotic analgesic drug and the excellent analgesia provided. Onset of action is rapid, and uterine activity is not affected. The disadvantages include the possibility of PDPH, which is increasingly rare with the use of pencil-point needles and the time-limited nature of a single-shot technique. For this reason, spinal analgesia is commonly combined with an epidural catheter as a CSE technique. Indications and contraindications are similar to epidural analgesia.

Opioids alone can provide analgesia during labor when administered intrathecally in small doses. Labor analgesia usually lasts for 1 to 3 hours and is not accompanied by motor block. The major disadvantages include pruritus and nausea. Pruritus can be antagonized with small doses of intravenous nalbuphine or naloxone. PDPH can be minimized through the use of 22- to 27-gauge Whitacre, Sprotte, or other pencil-point needles.

Complications of Regional Block Analgesia

Hypotension

Hypotension is common, occurring in 10% to 20% of patients undergoing epidural analgesia for labor and 50% to 80% for cesarean delivery. It often occurs despite left uterine displacement and administration of an intravenous preload. Treatment should consist of the following steps:

1. Ensure or verify uterine displacement.
2. Increase intravenous fluid infusion to the maximal available rate.
3. Administer phenylephrine 100 µg or ephedrine 5 to 10 mg intravenously until hypotension resolves.

Phenylephrine, an α-agonist, has been avoided in the past because of concerns about compromising uterine blood flow. Recent work has shown higher fetal umbilical pH values after maternal administration to treat hypotension than using ephedrine as well as less maternal nausea.

Postdural Puncture Headache

When a large-bore epidural needle (e.g., 18-gauge Tuohy) penetrates the dura, the incidence of PDPH is greater than 50%. Other factors governing the incidence of PDPH include the number of times the dura has been punctured, the direction of the bevel, and the type of needle used. When spinal anesthesia is planned, pencil-point spinal needles should be used instead of cutting-bevel spinal needles to reduce the incidence of headache.

PDPH occurs because a decrease in cerebrospinal fluid (CSF) volume causes compensatory

cerebral vasodilation and traction on the pain-sensitive blood vessels and meninges. Assumption of the erect position increases traction on these structures and aggravates the pain. Therefore, the main diagnostic criterion of PDPH is that it is postural. Ocular and auditory symptoms, such as vertigo, ataxia, and diplopia may be associated with PDPH.

Many different treatment regimens have been employed for this condition, including administration of saline through an epidural catheter, the use of abdominal binders, the administration of intravenous or oral caffeine (as a cerebral vasoconstrictor), bed rest, analgesics, and epidural blood patches. The most effective of these is the epidural blood patch.

Back Pain

Low-back pain is a common complaint in the peripartum period. A controversy exists as to the role that epidural analgesia for labor and delivery might play in the subsequent development of low-back pain. Prospective studies have shown no increased risk of new-onset low-back pain after epidural use. A study by Loughnan and colleagues examined the risk of low-back pain 6 months after delivery in patients who received epidural analgesia, as compared with those who received intravenous meperidine. This prospective follow-up study showed no difference in the prevalence of low-back pain at 6 months after delivery, although the overall incidence was very high in both groups.

Neurologic Complications

Neurologic complications of epidural and spinal analgesia are rare. A meta-analysis involving 1.37 million women who received an epidural for labor analgesia found an incidence of persistent neurologic injury of 1 in 240,000 and of transient neurologic injury of 1 in 6,700. Many postpartum neurologic sequelae are related to intraoperative positioning problems. An example is foot drop associated with pressure on the lateral peroneal nerve, caused by an improperly placed stirrup. In the lithotomy position, pressure applied on the femoral cutaneous nerve by the inguinal ligament may cause pain and numbness in the lateral thigh. Pain and numbness in the distribution of the sciatic nerve may result from forceps delivery or passage of the baby's head through the pelvis.

Spinal nerve root neuropathy may be caused by traumatic insertion of a spinal needle or an epidural needle or catheter. In this case, pain and paresthesias along the distribution of the nerve are perceived immediately, but they tend to disappear when the needle or catheter is removed. Rarely, symptoms may appear as long as 2 days after the procedure. Recovery usually occurs in 1 to 2 weeks, but injury can be permanent.

Accidental injection of an irritant solution (e.g., thiopental) or a prep solution into the CSF may produce adhesive arachnoiditis, which can cause permanent loss of spinal cord function. Epidural abscess (risk of 1 in 145,000) is caused by aerosolized mouth commensals or hematogenous spread rather than by instrumentation during epidural placement.

Epidural hematoma is a serious complication that, although rare (1 in 168,000), may occur in conjunction with coagulopathy. A hematoma should be suspected if recovery from the block is slow or absent or if neurologic function worsens after a period of initial recovery.

The primary symptoms are pain and weakness, which may progress rapidly to paralysis. Early surgical drainage provides the only chance for recovery of neurologic function.

Effects of Epidural Analgesia on Progress of Labor

The association of regional analgesic techniques with an increased rate of cesarean delivery has been ongoing and controversial, but the concern was mainly based on results from small retrospective studies. There is definitely an association between use of epidural analgesia for labor and cesarean delivery, but the confounding factor is that nulliparous women with longer and more painful labors are also the patients who choose epidural analgesia. They are at higher risk to have a cesarean delivery regardless of their choice of labor analgesia. The presence of severe pain during early labor signals an increased risk for prolonged labor and operative delivery, regardless of their choice of analgesia. A secondary analysis of women randomized to receive

---

patient-controlled intravenous (not epidural) meperidine analgesia for labor found that those who required higher doses of narcotic had higher pain scores initially, longer labors (9 vs. 5 hours), and more cesarean deliveries for dystocia (14.0% vs. 1.4%). Also, regional analgesia is often recommended to women in whom operative or instrumental delivery is thought to be likely. Designing a study to remove that bias or association has proven difficult, both for the ethical reason that you cannot refuse a treatment available to a patient if requested (i.e., if a patient is randomized to receive “no epidural” but she later requests it because of inadequate pain relief, she must be allowed to cross over) and because there is no other form of pain relief to offer that provides equivalent analgesia (i.e., a “control group”). For this reason, many studies done prior to the last decade were methodologically flawed.

More recent studies have attempted to control for the fact that women already at increased risk for an operative delivery are more likely to choose epidural analgesia. They have not found regional analgesia to be associated with cesarean delivery. There are different methodologic ways to accomplish this. Several retrospective, population-based studies have found that the introduction of an epidural analgesia service or the increased use of epidural analgesia did not increase the cesarean delivery rate. In a “natural” experiment, a military hospital went from a 1% to 84% epidural analgesia rate in 1 year while other conditions remained unchanged. A review of singleton, nulliparous, term patients in spontaneous labor before and after the change found no differences in rates of cesarean delivery overall or for dystocia, no change in instrumental delivery rates, and no change in duration of first and active stages of labor but an increase in the second stage of labor of about 25 minutes.

Other studies have used generous doses of narcotics in the control group to prevent crossover to the epidural analgesia group. A meta-analysis of 2,703 nulliparous patients randomized to epidural analgesia or intravenous meperidine using standardized labor management at a single institution found no difference in the rate of cesarean delivery in an intent-to-treat analysis.

Obstetric management must also influence the cesarean delivery rate. Even randomized

trials cannot blind the obstetrician to the type of analgesia being used, and the obstetrician makes the decision regarding the need for cesarean delivery. If epidural analgesia has an influence on the risk of cesarean delivery, then those obstetricians whose patients have a higher use of epidural analgesia should have a higher cesarean delivery rate. In contrast, a review of 110 obstetricians in a single hospital practice found no relationship between frequency of epidural analgesia use and rate of cesarean section for dystocia across practitioners ($R^2 = 0.019$). The study concluded that after accounting for a number of known patient risk factors, obstetric practice style appears to be a major determinant of rates of cesarean delivery.

Two recent randomized controlled trials have investigated the role of timing of epidural analgesia on the incidence of cesarean delivery. Wong and associates randomized 750 nulliparous women in spontaneous labor to receive a CSE or parenteral narcotic if they requested pain medication when less than 4 cm dilated. Pain scores were lower after CSE, and rates of cesarean delivery were no different. Newborn outcomes (Apgar score less than 7) were worse in the parenteral narcotic group. Interestingly, time to complete dilation and to vaginal delivery were significantly shorter in the CSE group. In another trial, 449 term nulliparous women less than 3 cm dilated were randomized to immediate epidural analgesia or delay of epidural until the cervix was at least 4 cm dilated. The rates of cesarean delivery were not significantly different, and again, the duration from randomization to full dilation was significantly shorter in the early epidural group. An accompanying editorial notes that “No longer should a patient be made to feel guilty about her wish for pain relief early in labor, powerless in her choices or conflicted about the consequences of such a choice…. What a concept—pain relief of real pain when requested. We all should now feel comfortable supporting this position for the patient in labor.”

Thus, it would appear that there are many variables with the potential to affect the risk of cesarean delivery besides choice of analgesia during labor. These would include patient-related factors such as parity, induction, level of pain, labor pattern, and oxytocin use as well as obstetrician-related factors such as active or passive management. Maternal-fetal factors and obstetric management, not neuraxial analgesia, are the most important determinants of cesarean delivery rate. Use of epidural analgesia during labor may decrease the use of general anesthesia with its attendant risks if emergency cesarean delivery is required. If epidural analgesia is avoided, maternal administration of high doses of narcotics may result in substantial neonatal effects such as respiratory depression.

Other Methods of Pain Relief

Prepared Childbirth

Prepared childbirth techniques are based on the belief that pain can be eliminated or reduced by conditioned reflexes of controlled relaxation and that education about the birth process can diminish the pain resulting from fear of the unknown. Parturients and their significant others are offered a series of five to ten weekly lectures and are educated about pregnancy, labor, and the delivery process. The parturient is taught how to relax and engages in exercises to strengthen her back and abdominal muscles. She also learns specific

breathing patterns to be used while she experiences the pain of uterine contractions. All parturients should have access to emotional support, whether by her husband, a family member, a birth attendant (doula), or

professional hospital staff. Insurance companies are beginning to pay for doulas, as the literature supports the beneficial effect on decreasing interventions. Effective courses also teach pregnant women that additional methods of pain relief are available and that these do not cause harm to the fetus. The pregnant woman should be advised that to ask for these other methods does not imply that she is a failure.

Hypnosis

Hypnosis is a state of altered consciousness that requires deep concentration. The patient is not asleep, but she initiates a trance as labor begins and continues it until delivery is completed. The patient must undergo a time-consuming series of training sessions with a hypnotist, and this technique is not always successful.

Acupuncture

Acupuncture has been used to help control labor pain in China and the Far East for many years. Since the early 1970s, mixed reports of its efficacy have been published in the West. Some studies indicate that acupuncture can significantly lower pain scores and may decrease the duration of the first stage of labor. A systematic review of three randomized controlled trials found that evidence for acupuncture as an adjunct to conventional pain control during labor is promising but not convincing because of the limited amount of trial data.

Biofeedback

Biofeedback is provided by a portable electromyographic device through an audible sound and visual monitor. Electrodes placed over the maternal abdomen monitor tension of the abdominal musculature. This technique may be helpful during the first stage of labor.

Transcutaneous Electrical Nerve Stimulation

TENS analgesia is based on the observation that application of a mild electric current to the skin can result in reduction of pain. Activation based on the gate theory and release of enkephalins are possible modes of action. Studies evaluating the effectiveness of TENS suggest that although the method does no harm, it probably does little good and should not be advocated for widespread use for labor analgesia.

Intracutaneous Sterile Water Blocks

Trolle and colleagues evaluated the analgesic effect of intradermal sterile water blocks in women complaining of severe low-back pain during labor. Saline solution was used as a control. Sterile water or saline (0.1 mL) was injected at four different spots in the low-back area, approximately corresponding to the borders of the sacrum. Eighty-nine percent of

women in the sterile water group reported an analgesic effect compared with 45% in the saline group. However, meperidine use in the two groups was similar, as were the rates for oxytocin use and dystocia. The cesarean section rate in the saline water group was significantly higher due to more cephalopelvic disproportion and malposition of the occiput. This technique is free of adverse effects and enjoys a high degree of patient acceptance although the mechanism is unclear.

Anesthesia for Cesarean Delivery

There are three anesthetic choices for cesarean delivery. Selection of one over the others depends on the patient's desires, medical status, and the urgency of the operation. Regional anesthesia is strongly preferred in the United States (Table 3.6).

Epidural Anesthesia

Epidural anesthesia accounts for approximately 25% of anesthetics used for cesarean section. It offers the advantages of unlimited duration, minimal risks of airway management, and a route for postoperative pain management.

To carry out a cesarean delivery, a sensory dermatome level of at least T-4 is required. Anesthesia to this level may eliminate proprioception from the respiratory muscles of the chest wall, and the parturient may experience a subjective sensation of dyspnea. Reassurance will usually allay this fear. The patient should be placed on the operating table with the uterus displaced laterally through elevation of the right hip or by tilting of the operating table, to prevent aortocaval compression.

An intravenous preload of 1,000 to 2,000 mL of a non–glucose-containing crystalloid solution should be administered before dosing with the local anesthetic solution. A surgical concentration of a local anesthetic (often 2% lidocaine) with added opioid is administered through the catheter in 3- to 5-mL increments. The patient may be given oxygen by nasal cannula or by mask. Several studies have failed to find any differences in the clinical condition of neonates, as assessed by Apgar scores and blood gas analyses, whether oxygen is administered by mask or cannula.

Epidural opioids have been useful for relieving pain of visceral origin, which affects as many as one third of the women who have cesarean deliveries under epidural anesthesia. Visceral pain occurs primarily during bladder retraction, exteriorization of the uterus, and suturing of the peritoneum. The addition of fentanyl or sufentanil to the local anesthetic reduces the time of onset of analgesia, decreases the incidence of nausea, and increases the quality

of analgesia without depressing the neurobehavioral status of the newborn.

TABLE 3.6 Types of Cesarean Anesthesia Provided by Size of Hospital in Three Time Periods

CSE, combined spinal–epidural.
Adapted from Hawkins JL, Gibbs CP, Orleans M, et al. Obstetric anesthesia work force survey, 1981 versus 1992. *Anesthesiology* 1997;87:135, and Bucklin BA, Hawkins JL, Anderson JR, et al. Obstetric anesthesia workforce survey, twenty-year update. *Anesthesiology* 2005;103:645.

Studies of fentanyl concentrations in neonates demonstrate that fentanyl crosses the placenta after maternal epidural administration. Even high maternal doses (e.g., 100 µg) of fentanyl yield safe levels in the newborn. Morphine 2 to 4 mg is often administered through the epidural catheter after delivery to provide 12 to 24 hours of postoperative analgesia, although the incidence of associated pruritus and nausea can be high.

There are advantages and disadvantages to using epidural anesthesia for cesarean delivery, as shown in Table 3.7. The advantages include:

- If an epidural catheter is already in place, it can be used expeditiously for a cesarean.

TABLE 3.7 Advantages and Disadvantages of Using Epidural Anesthesia for Cesarean Delivery

Advantages:

- If an epidural catheter is already in place, it can be used expeditiously for a cesarean.
- Maternal hypotension may be less pronounced and slower in onset with epidural than with spinal anesthesia.

- Headache is usually avoided, unless the patient sustains an accidental dural puncture.
- The length of anesthesia is controllable if surgery is prolonged.
- The technique is adaptable for postoperative pain relief.

Disadvantages:

- There is a slower onset of anesthesia as compared with spinal.
- There is a requirement for a larger dose of local anesthetic solution than spinal anesthesia, with an attendant increased risk of systemic toxicity.
- There is a lower success rate than that experienced with spinal anesthesia. To improve onset time and success rate while providing unlimited duration, CSE may be used.

CSE, combined spinal–epidural.

- There is a requirement for a larger dose of local anesthetic solution than spinal anesthesia, with an attendant increased risk of systemic toxicity.
- There is a lower success rate than that experienced with spinal anesthesia. To improve onset time and success rate while providing unlimited duration, CSE may be used.

An unexpectedly high level of anesthetic block may be achieved with epidural or spinal anesthesia, and this should be monitored. The likelihood of inadvertent spinal anesthesia while attempting epidural block can be minimized through gentle aspiration of the catheter combined with a test dose of sufficiently small volume that it is unlikely to produce a high block. A total spinal block generally occurs within several minutes of injection, but it may be delayed for as long as 20 minutes. Dyspnea, hypotension, unconsciousness, and apnea are signs and symptoms of total spinal block. Treatment includes ventilation through an endotracheal tube and circulatory support as needed.

Subarachnoid or Spinal Anesthesia

A subarachnoid block provides excellent anesthesia for cesarean section delivery. Over 70% of cesarean deliveries are performed by using this technique (Table 3.6).

Prehydration is administered with 1,000 to 2,000 mL of a non–glucose-containing crystalloid solution. A 22- to 27-gauge pencil-point spinal needle is inserted into the subarachnoid space, which is identified by the characteristic feel of the needle penetrating the dura and observing CSF in the needle. Bupivacaine 0.75%, 11 mg, with dextrose, is most commonly used.

Opioids may also be administered intrathecally to improve quality of analgesia, decrease nausea, and improve cardiovascular stability by allowing a lower dose of local anesthetic. Spinal (as well as epidural) narcotics are associated with a high incidence of pruritus as well as the rare but real potential for delayed respiratory depression. Fentanyl 10 to 25 µg may be administered to improve intraoperative analgesia, while the addition of morphine 0.10 to 0.25 mg can provide postoperative analgesia that may last for 18 to 24 hours.

Contraindications to spinal anesthesia are the same as for epidural anesthesia and include patient refusal, septicemia, infection of the puncture site, acute or chronic hypovolemia, and abnormal clotting parameters. Spinal anesthesia is sometimes avoided in pregnant women with active CNS disease.

The most common complication of spinal anesthesia is hypotension. This should be treated promptly with fluid administration and intravenous phenylephrine 100 µg or ephedrine 5 to 10 mg depending on maternal heart rate. Oxygen should be given, and the parturient's oxygen saturation should be monitored with a pulse oximeter. In the event of a high spinal block that compromises ventilation or airway control, cricoid pressure should be applied and endotracheal intubation performed to prevent aspiration of gastric contents.

With the increasing use of spinal and epidural narcotics, pruritus is becoming a commonplace side effect. Its incidence approaches 90% when spinal or epidural morphine is employed. The cause is related to stimulation of opioid receptors rather than release of histamine. Nalbuphine may be used to antagonize the opioids receptors and is unlikely to antagonize analgesia. Naloxone can also be used to control pruritus, but the dose must be titrated carefully to avoid antagonism of analgesia.

General Anesthesia

General anesthesia is used for cesarean delivery when the patient refuses regional analgesia; has a contraindication to regional analgesia; or a need exists for rapid delivery because of fetal distress, cord prolapse, uterine rupture, or maternal hemorrhage.

The ACOG in *Guidelines for Perinatal Care*, 5th edition, cites risk factors for failed intubation and urges obstetricians to be alert to the presence of factors that place parturients at increased risk for complications from emergency general anesthesia (Table 3.8). Among these are marked obesity, severe facial and neck edema, extremely short stature, short neck, difficulty opening the mouth, a small mandible, protuberant teeth,

arthritis of the neck, anatomic abnormalities of the face or mouth, a large thyroid gland, poorly controlled asthma, serious medical or obstetric complications, and a history of problems with anesthetics. If any of these factors are identified, a member of the anesthesia team should be consulted to prepare for the potential need to induce general anesthesia. If the anesthesiologist has concerns about his or her ability to intubate the patient, early placement of a regional anesthetic should be planned or arrangements for an awake intubation should be made.

TABLE 3.8 Factors Placing Parturients at Increased Risk for Complications from Emergency General Anesthesia

- Marked obesity
- Severe facial and neck edema
- Extremely short stature
- Difficulty opening the mouth
- Small mandible
- Protuberant teeth
- Arthritis of the neck
- Anatomic abnormalities of the face or mouth
- Large thyroid gland
- Poorly controlled asthma
- Serious medical or obstetric complications
- History of problems with anesthetics

Pneumonitis resulting from aspiration of gastric contents has long been feared as a complication of general anesthesia in parturients but is extremely rare. One review compared the incidence of aspiration in obstetric and gynecologic patients. The incidence of clinically significant aspiration was 0.11% in women undergoing cesarean delivery compared with 0.01% in gynecology inpatients. No patient died, but morbidity was significant. It seems prudent to administer a nonparticulate oral antacid such as sodium citrate to increase the gastric pH. If time allows, an H_2-blocker (e.g., famotidine 20 mg intravenously) should be administered. Intravenous metoclopramide 10 mg hastens gastric emptying, increases gastroesophageal sphincter tone, and may decrease nausea.

Before induction of anesthesia, the patient should be preoxygenated with 100% oxygen by mask for at least 3 minutes. Induction is commonly carried out using thiopental 3 to 4 mg/kg or propofol (Diprivan) 1.5 to 2.0 mg/kg. Propofol is associated with a blunted hypertensive response to endotracheal intubation and has yielded similar and satisfactory Apgar scores, neurologic and adaptive capacity scores, and umbilical cord blood gas analyses. If propofol infusion is used for maintenance of anesthesia for a prolonged time before delivery, neonatal blood levels are high and neurologic and adaptive capacity scores may be impaired. If the patient is hemodynamically unstable, ketamine 1 mg/kg or etomidate 0.3 mg/kg may be used for induction of anesthesia.

Intubation is facilitated by use of succinylcholine for muscle relaxation. Cricoid pressure is maintained during induction of anesthesia until the endotracheal tube is in place, the cuff has been inflated, and end-tidal carbon dioxide is present on the capnograph. After successful intubation, a mixture of equal parts of nitrous oxide and oxygen may be administered, and a low dose of an inhalational agent, such as desflurane 3.00%, sevoflurane 1.00%, or isoflurane 0.75%, is administered to optimize maternal anesthesia. These low concentrations help ensure maternal amnesia but have minimal effects on uterine contractility and are not associated with postpartum hemorrhage. After delivery of the infant, the nitrous oxide concentration may be increased to 70%, and narcotics may be given intravenously to supplement the anesthesia. Midazolam may be used to decrease the risk of maternal recall.

The advantages of general anesthesia, as shown in Table 3.9, include:

- Reliability of the technique
- Rapidity of induction of anesthesia
- Avoidance of sympathetic blockade and hypotension.

The disadvantages include:

- Maternal aspiration of gastric contents
- Failed intubation in approximately 1:250 cases
- Maternal awareness of intraoperative events
- Hypertension during manipulation of the larynx
- Delay in maternal bonding with her neonate
- Less effective maternal postoperative pain control.

If the cords are poorly visualized during laryngoscopy, no more than three attempts at endotracheal intubation should be made before beginning a failed intubation drill. The initial maneuver in the failed intubation drill depends on the obstetric indication for cesarean delivery. If the operation is not emergent, the patient should be awakened and a regional anesthetic or awake intubation performed. In an obstetric emergency where surgery must proceed, the patient must be ventilated with bag and mask or laryngeal mask airway, and anesthesia may be maintained with inhalational or intravenous agents throughout the remainder of the cesarean delivery. Use of an esophageal gastric tube airway (Combitube) or laryngeal mask may also enable adequate ventilation in that situation. The continuation of cricoid pressure is important to reduce the maternal risk of aspiration. If it should prove impossible to ventilate the patient, an emergency surgical airway must be obtained.

TABLE 3.9 Advantages and Disadvantages of General

Anesthesia

Advantages:

- Reliability of the technique
- Rapidity of induction of anesthesia
- Avoidance of sympathetic blockade and hypotension

Disadvantages:

- Maternal aspiration of gastric contents
- Failed intubation in approximately 1:250 cases
- Maternal awareness of intraoperative events
- Hypertension during manipulation of the larynx
- Delay in maternal bonding with her neonate
- Less effective maternal postoperative pain control

Inability to intubate has been estimated to occur seven times more commonly in the obstetric patient than in the general operating room and continues to contribute significantly to anesthetic causes of maternal mortality. Anticipation of a difficult intubation allows the anesthesia team to be prepared to avoid general anesthesia or plan an awake intubation.

Analgesia after Cesarean Section

Considerable advances have been made in the management of pain after cesarean delivery. The availability of spinal and epidural narcotics has enabled the anesthesia team to provide the postsurgical patient with effective, long-term analgesia. Morphine is the most commonly used neuraxial opioid because of its long duration and lack of motor block compared with local anesthetic infusions. The most feared complication is respiratory depression, but the risk of analgesia-related respiratory depression is rare. Patients receiving postoperative neuraxial opioid analgesia may be safely nursed on the general ward if the nurses are appropriately educated in monitoring the degree of somnolence and the respiratory rates of their patients. Patients who did not receive regional anesthesia may receive intravenous PCA. Combining narcotics and nonsteroidal anti-inflammatory medications such as ketorolac (Toradol) or ibuprofen improves the quality of analgesia and allows reduced doses of narcotics.

Summary Points

- The ACOG and the ASA have stated that "In the absence of a medical contraindication, maternal request is a sufficient medical indication for pain relief in labor."

- Pain management is an important part of modern obstetric care. Most women will request some form of analgesia during childbirth.
- Parenteral narcotics for labor analgesia may be administered by intermittent injection or patient-controlled intravenous infusion. There are advantages and disadvantages to the use of all opioids, and practitioners should be aware of their side effects.
- High systemic blood levels of local anesthetic caused by intravascular injection or excessive absorption may lead to convulsions and cardiac arrest. High regional block may impair respiration and sympathetic tone. Resuscitation equipment must be immediately available whenever regional blocks are used.
- Modern techniques of regional analgesia for labor (dilute concentrations of epidural local anesthetics, CSE analgesia with opioids, and patient-controlled epidural infusions) emphasize pain relief with minimal motor block. Studies indicate that these techniques do not impact progress of labor or rates of cesarean delivery.
- Although modern anesthetic care for cesarean delivery is extremely safe (anesthesia-related maternal mortality = 1.1 per million live births), general anesthesia complications are more common than regional anesthetic complications because of difficulties with airway management.

Early Pregnancy Loss

T. Flint Porter
D. Ware Branch
James R. Scott

Miscarriage, also termed *spontaneous abortion*, is most commonly used to describe first-trimester loss, although it has also been used to describe loss before 20 weeks. These arbitrary time limits have become less useful with advances in developmental biology and diagnostic sonography. Early pregnancy loss is more precisely defined as preembryonic (conception through the first 5 weeks of pregnancy from the first day of the last menstrual period), embryonic (6 to 9 weeks gestation), or fetal (10 weeks until delivery).

Epidemiology

Miscarriage is the most common complication of pregnancy, occurring in at least 15% of clinically recognized pregnancies. Histologically defective ova found in hysterectomy specimens (Fig. 4.1) and data on early pregnancies detected with sensitive ß-human chorionic gonadotropin (ß-hCG) assays indicate that the rate is two to three times higher in early, unrecognized pregnancies. Miscarriage rates also vary with maternal age, ranging from 12% in women younger than 20 years of age to over 50% in women older than 45 years of age (Fig. 4.2). The likelihood of miscarriage is heavily dependent on past obstetric history, being higher among women with prior miscarriages and lower among women whose past pregnancy or pregnancies ended in live births.

Embryology

Successful pregnancy is dependent on integration of several complex processes involving genetic, hormonal, immunologic, and cellular events, all working together in perfect order to achieve fertilization, implantation, and embryonic development. It is not surprising that early pregnancy loss can occur because of a number of embryonic and parental factors.

Embryonic Factors

Most single, sporadic miscarriages are caused by nonrepetitive intrinsic defects in the developing conceptus, such as abnormal germ cells, chromosomal abnormalities in the

conceptus, defective implantation, defects in the developing placenta or embryo, accidental injuries to the fetus, and probably other causes as yet unrecognized. Fifty percent of women presenting with spotting or cramping already have a nonviable conceptus by sonogram, and many of these embryos are morphologically abnormal. About one third of abortus specimens from losses occurring before 9 weeks gestation are anembryonic. Some cases of empty gestational sacs or “blighted ova” actually represent pregnancy failures with subsequent embryonic resorption. The high proportion of abnormal aborted concepti is apparently the result of a selective process that eliminates about 95% of morphologic and cytogenetic errors.

The frequency of chromosomally abnormal spontaneously aborted products of conception in the first trimester is approximately 60%, decreasing to 7% by the end of the 24th week (Fig. 4.3). The rate of genetic abnormalities is higher in anembryonic miscarriages. Autosomal trisomies are the most common (51.9%), arising de novo as a result of meiotic nondisjunction during gametogenesis in parents with normal karyotypes. The relative frequency of each type of trisomy differs considerably. Trisomy 16, which accounts for about one third of all trisomic abortions, has not been reported in live-born infants and is therefore uniformly lethal. Trisomy 22 and 21 follow in frequency. The next most common chromosomal abnormalities, in decreasing order, are monosomy 45,X (the single most common karyotypic abnormality), triploidy, tetraploidy, translocations, and mosaicism.

Media publicity tends to give the impression that a variety of agents such as infections, video display terminals, cigarette smoking, coffee, ethanol, chemical agents, and drugs markedly increase the risk of miscarriage. In reality, there is little credible supportive evidence.

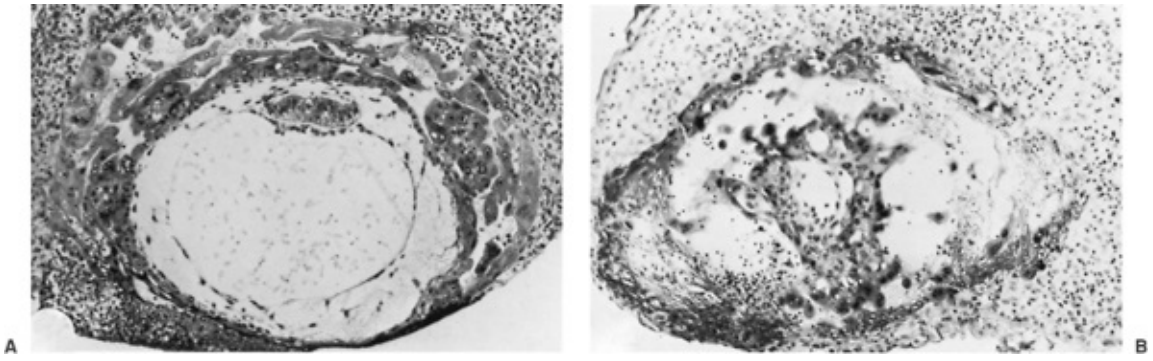

Figure 4.1 Histologic comparison of **(A)** a morphologically normally implanted human ovum estimated to be about 11 to 12 days of age with **(B)** an abnormal conceptus, showing a defective trophoblast with pathologically large lacunae and an empty chorionic sac that is destined to abort. Pathology

Most miscarriages occur within a few weeks after the death of the embryo or rudimentary analog. Initially, there is hemorrhage into the decidua basalis, with necrosis and inflammation in the region of implantation. The gestational sac is partially or entirely detached. Subsequent uterine contractions and dilation of the cervix eventually result in expulsion of most or all of the products of conception. When the sac is opened, fluid is often found surrounding a small macerated embryo, although no visible embryo may be present. Histologically, hydropic degeneration of the placental villi caused by retention of tissue fluid is common.

Clinical Features and Treatment

An unrecognized pregnancy should always be considered in any woman of reproductive age with abnormal bleeding or pain. Likewise, a patient with known pregnancy should notify her physician promptly about vaginal bleeding or uterine cramps. Since management depends on several clinical factors, it is useful to consider miscarriage under the following subgroups.

Threatened Miscarriage

Any bloody vaginal discharge or uterine bleeding that occurs during the first half of pregnancy has traditionally been assumed to be a threatened miscarriage. Spotting or bleeding during the early months of gestation occurs quite commonly, in as many as 25% of pregnant women. Bleeding is typically scanty, varying from a brownish discharge to bright red bleeding. It may occur repeatedly over the course of many days and usually precedes uterine cramping or low backache. On pelvic examination, the cervix is closed and uneffaced, and no tissue has passed. The differential diagnosis includes ectopic pregnancy, molar pregnancy, vaginal ulcerations, cervicitis with bleeding, cervical erosions, polyps, and carcinoma.

Women presenting with threatened miscarriage should receive an ultrasound examination to determine location, viability, and gestational age. Accurate knowledge of gestational age is necessary for proper interpretation, as a sonographically empty uterus may imply an abnormal intrauterine or ectopic pregnancy when it actually represents a normal early gestation. Serial testing of ß-hCG measurements is a useful adjunct if the diagnosis remains uncertain, along with a follow-up sonogram a few days later.

A viable conceptus can be detected with modern ultrasound as early as 5.5 weeks

gestation. It is possible to visualize the yolk sac and gestational sac starting at 5 to 6 weeks by using transvaginal ultrasound, with cardiac activity seen thereafter. Ultrasound findings suggesting impending pregnancy loss include an abnormally sized or shaped gestational sac and yolk sac, an embryo small for dates, and slow embryonic heart rate. In the absence of signs of miscarriage, more than 95% of pregnancies continue if a live embryo is demonstrated sonographically at 8 weeks gestation. Even in the setting of uterine bleeding, more than two thirds survive as long as ultrasound demonstrates an appropriately sized embryo with a normal cardiac rate. The subsequent pregnancy loss rate is only 1% if a live fetus is seen at 14 to 16 weeks gestation.

Although there is no convincing evidence that any treatment favorably influences the course of threatened miscarriage, a sympathetic attitude by the physician along with continuing support and follow-up are important to patients. This includes a tactful explanation about the pathologic process and favorable prognosis when the pregnancy is viable. An optimistic but cautious approach is prudent, since a few of these women will have a later embryonic or fetal death. It is reasonable to advise patients to remain available to medical care until it can be determined whether the symptoms will persist or cease. Continued observation is indicated as long as bleeding and cramping are mild, the cervix remains closed, quantitative ß-hCG levels are increasing normally, and a normal embryo or fetus is evident on follow-up sonogram. If the bleeding and cramping progressively increase, the prognosis becomes worse. An unfavorable outcome is also associated with negative or falling ß-hCG values, sonographic evidence of an embryo or fetus decreasing in size (Fig. 4.4), a slow heart rate, and a uterus that is not increasing in size on pelvic examination.

Inevitable and Incomplete Miscarriage

Miscarriage is considered inevitable when bleeding and cramping is accompanied by gross rupture of the membranes or cervical dilation. The miscarriage is incomplete when the products of conception have partially passed from the uterine cavity, are protruding from the external os, or are in the vagina with persistent bleeding and cramping. There is no viable conceptus in most instances of inevitable or incomplete miscarriages. Rarely, a single twin may survive and continue to term after miscarriage of the other conceptus.

Women with incomplete or inevitable miscarriage typically present with bleeding that can be profuse occasionally and produce hemodynamic instability. A careful pelvic examination is usually sufficient to establish the diagnosis, although ultrasound examination is often performed. Evacuation of the uterus is advisable to prevent further maternal hemorrhage or infection. Clinically stable patients can be treated as outpatients by either medical or surgical means. However, patients with uncontrolled bleeding should be transferred to the operating room for an examination under anesthesia and immediate surgical evacuation of the uterus. They should be observed postoperatively for several hours and discharged when considered stable.

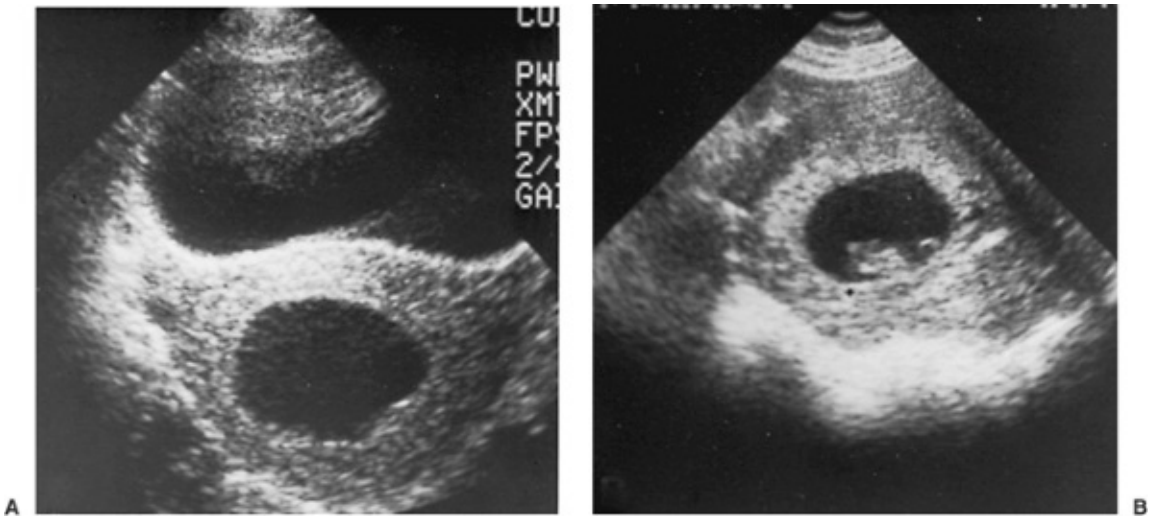

Figure 4.4 Ultrasonic comparison of **(A)** an anembryonic pregnancy with no fetal tissue that is destined to abort with **(B)** a normal gestational sac with a transonic area, echogenic rim, and fetal pole.

Suction curettage can be performed promptly and safely in an inpatient or outpatient setting by using analgesia, a paracervical block, and an intravenous infusion of normal saline containing 10 to 20 U of oxytocin. The cervix is sometimes dilated, and ring forceps can be used to remove products of conception from the cervical canal and lower uterine segment, thereby facilitating uterine contractions and hemostasis. Suction curettage with a plastic curette and vacuum pressure is used to remove the remaining tissue. The curette is rotated 360 degrees clockwise as it is withdrawn, and the procedure is repeated in a counterclockwise direction. When a grating sensation is noted and no more tissue is obtained, the endometrial cavity has been emptied. The tissue obtained should be examined to confirm the presence of products of conception and rule out the possibility of ectopic pregnancy.

Problems that can occur include allergic reactions to medication, uterine atony, uterine perforation, seizure, or cardiac arrest. A complete blood count level should be obtained, and blood replacement may be necessary if hemorrhage occurs. Rh-negative women should receive 50 g (in the first trimester) or the standard 300-g (in the second trimester) dose of Rh immune globulin to prevent Rh immunization.

Medical management of incomplete miscarriage has been studied in well-designed trials and may be used instead of surgical evacuation in clinically stable patients, although uterine curettage may eventually be required. In one randomized, controlled trial, an 80% complete abortion rate was achieved by using 800 mg of misoprostol (four 200-mg tablets) per vagina every 4 hours. Most patients responded to the first dose. Curettage was necessary in 28% of patients. When successful, misoprostol treatment of incomplete miscarriage is associated with lower rates of short- and long-term complications compared with surgical evacuation. Combinations of misoprostol with methotrexate or RU-486 appear promising but are not available for clinical use.

Complete Miscarriage

Patients followed for a threatened miscarriage should be instructed to save all tissue passed for later inspection. When the entire products of conception have passed, pain and bleeding soon cease. If the diagnosis is certain, no further therapy is necessary. In questionable cases, ultrasound is useful to confirm an empty uterus. In some cases, curettage may be necessary to be sure that the uterus is completely evacuated. Removal of remaining necrotic decidua decreases the incidence of bleeding and shortens the recovery time.

Missed Miscarriage

The reason that expulsion of a dead conceptus does not occur despite a prolonged period is uncertain. The patient's symptoms of pregnancy typically regress, quantitative ß-hCG levels fall, and no fetal heart motion is detected by ultrasound. While most patients eventually abort spontaneously, and coagulation defects due to retention of the conceptus are rare, expectant management is emotionally trying, and many women prefer to have the uterus evacuated. Either medical or surgical evacuation of uterine contents is acceptable.

In the second trimester, the uterus can be emptied by dilation and evacuation (D&E) or induction of labor with intravaginal prostaglandin E_2 (PGE_2) or misoprostol. D&E is an extension of the traditional dilation and curettage (D&C) and vacuum curettage. It is especially appropriate at 13 to 16 weeks gestation, although many proponents use

---

this procedure through 20 weeks. The cervix is usually first prepared by using misoprostol or passively dilated with laminaria to avoid trauma, and the fetus and placenta are mechanically removed with suction and instruments.

If induction of labor is chosen, vaginal PGE_2 may be used; one 20-mg suppository is placed high in the posterior vaginal vault every 4 hours until the fetus and placenta are expelled. Between 2.5 and 5.0 mg of diphenoxylate given orally and 10 mg of prochlorperazine given intramuscularly can control diarrhea and nausea, and narcotics or epidural anesthesia can be used to control pain. In this situation, a retained placenta is relatively common and may require manual removal and uterine curettage.

Misoprostol has become more commonly used in recent years because of its equal efficacy and markedly lower incidence of unpleasant side effects; 200-mg tablets are placed high in the vagina every 4 hours until delivery of the fetus and placenta. Medical treatment of nausea, vomiting, diarrhea, and fever are rarely necessary, although retained placenta is not uncommon.

Septic Miscarriage

Septic abortion, once a leading cause of maternal mortality, has become less frequent, primarily because of changes in abortion laws making pregnancy terminations more easily available to women with unwanted pregnancies. However, any type of spontaneous miscarriage can also be complicated by endometritis, which can progress to parametritis

and peritonitis. The clinical presentation typically includes fever, abdominal tenderness, and uterine pain.

Septicemia and shock may occur if the local infection is left untreated. The polymicrobial infection mirrors the endogenous vaginal flora and includes *Escherichia coli* and other aerobic, enteric, gram-negative rods, group B-hemolytic streptococci, anaerobic streptococci, *Bacteroides* species, staphylococci, and microaerophilic bacteria.

The initial evaluation and management of septic abortion should include:

- Physical and pelvic examination
- Complete blood cell count and determination of electrolyte, blood urea nitrogen, and creatinine levels
- Type and screen or cross match of blood
- Smears from cervix for Gram stain
- Aerobic and anaerobic cultures of endocervix, blood, and available products of conception
- Placement of indwelling Foley catheter
- Administration of intravenous fluids (e.g., saline, Ringer lactate) through a large-bore angiocatheter
- Administration of 0.5 mL of tetanus toxoid, given subcutaneously for immunized patients, or 250 U of tetanus immune globulin, administered deep within the muscle
- Abdominal x-rays to detect free air or foreign bodies.

Optimal therapy consists of evacuation of the uterus and aggressive use of parenteral antibiotics before, during, and after removal of necrotic tissue by curettage (Table 4.1). Prompt removal of the infected tissue is important and should be performed within a few hours after beginning intravenous antibiotics. Numerous antibiotic regimens have been recommended, but high-dose, broad-spectrum coverage as outlined in Table 4.1 is essential. Although most patients with septic abortions respond favorably to treatment, septic shock syndrome is a serious complication that requires aggressive management in an intensive care setting.

TABLE 4.1 Antibiotic Regimens for Septic Abortion

Gram-positive anaerobe and aerobic organism coverage:

1. Aqueous penicillin G, 4–5 million U i.v. q4–6h (20–30 million U each 24 h); or
2. Ampicillin, 2 g i.v. q4–6h; or
3. Clindamycin (Cleocin), 600 mg i.v. q6h or 900 mg i.v. q8h; or

4. Cefoxitin (Mefoxin) (or other cephalosporin), 1–2 g i.v. 6h (for penicillin-allergic patients, there is a 10% cross allergy); or
5. Imipenem-cilastatin (Primax), 250–500 mg q6h (must decrease dose for patients weighing <70 kg or with renal compromise)

Resistant gram-negative aerobic organism coverage:

1. Gentamicin, 1–1.5 mg/kg i.v. q8h (adjust dose according to peak and through levels, monitor for nephrotoxicity and ototoxicity, decrease dose in patients with renal compromise); or
2. Aztreonam (Azactam), 1–2 g i.v. q8–12h or q6h in cases of serious infection (alternate antibiotic for patients who develop gentamicin toxicity; decrease dose in patients with renal compromise); or
3. Imipenem-cilastatin (see dose schedule with #5 above)

Gram-negative anaerobic organism coverage:

1. Clindamycin, 600 mg i.v. q6h or 900 mg q8h; or
2. Metronidazole, 1 g i.v. loading dose, followed by 500 mg q6h; or
3. Imipenem-cilastatin (see dose schedule with #5 above)

The usual approach is to start one drug from each group. Recommended regimens are based on clinical effectiveness and may change as new antibiotics become available.

Recurrent Miscarriage

Recurrent miscarriage (RM), traditionally defined as three or more consecutive first-trimester spontaneous losses, affects up to 1% of couples. Primary RM is diagnosed in women without any prior successful pregnancy, while secondary RM refers to those whose repetitive losses follow a live birth. There is no specific classification for women who have multiple miscarriages interspersed with normal pregnancies. It is generally agreed that a workup for possible causes of RM is indicated in most patients after two or three consecutive miscarriages.

The evaluation and subsequent management of couples with RM is controversial, receiving considerable attention

in the lay and medical literature in recent years. General etiologic categories of RM

include genetic, uterine pathologic, endocrine, immunologic, thrombophilic, and environmental. Unfortunately, a cause for recurrent pregnancy loss is identified in only about 50% of affected couples. There is little evidence supporting poor nutrition, infections, unrecognized diabetes, toxic agents, or psychologic trauma as significant etiologic factors.

A typical evaluation of patients with RM includes investigation of anatomic, immunologic, endocrine, genetic, and infectious factors. These may be criticized because the derivation of their diagnostic use and treatments advocated are empirical, and many come under scrutiny because they were never submitted to a properly designed study. Importantly, evidence has mounted that the average woman with RM has a fairly good prognosis for a successful next pregnancy without any specific treatment.

Some alleged causes of RM have received considerable attention, and new diagnostic tests for RM are continually being proposed to replace those that have been previously disproved and discarded. Among these are antithyroid antibodies, elevated follicular-phase luteinizing hormone levels, circulating maternal embryotoxic factor, and abnormal lymphocyte subset ratios (elevated CD56+ levels). Most concerning is that despite a lack of scientific supportive evidence, empiric and alternative treatment regimens based on these tests are prescribed to women who are desperate to seek a solution to their repeated losses. Moreover, it is beyond the scope of this chapter to critically analyze each new "treatment" or assay, but the mechanism of pregnancy loss and potential relationship to each of these remains largely theoretical. Until effective treatments are identified and proven by properly designed studies, these screening tests have little use in the routine evaluation of patients with RM.

Known and Suspected Causes of Recurrent Miscarriage

Structural Uterine Defects

The mechanism of pregnancy loss in women with uterine anomalies is uncertain, although a diminished blood supply interfering with normal implantation and placentation and the reduced size of the uterine cavity are often cited as possible culprits. Between 7% and 8% of women have a uterine abnormality (müllerian anomaly), with the prevalence among women with RM estimated to be 10% to 15%. The prognosis for successful pregnancy is related to the type of malformation, with asymmetric fusion defects carrying the worst prognosis and septate, bicornuate, and didelphic uteri carrying increasingly better prognoses. While an arcuate uterus is the most commonly identified müllerian anomaly, its association with adverse reproductive outcome, including RM, is uncertain. Other uterine abnormalities such as leiomyoma, diethylstilbestrol (DES) exposure, and intrauterine synechiae (Asherman syndrome) may interfere with implantation and also result in pregnancy loss.

Hysterosalpingography, magnetic resonance imaging (MRI), hysteroscopy, sonohysteroscopy, and laparoscopy can be used to diagnose uterine structural defects. Abdominal metroplasty has been replaced in most cases by the hysteroscopic removal of uterine septa. Hysteroscopy can be accomplished in an outpatient setting and eliminates the need for

cesarean delivery in patients who achieve pregnancy. Uncontrolled, retrospective studies suggest that the subsequent live-birth rate is greater than 80%. Removal of synechiae and submucous myomas can also be performed hysteroscopically.

Endocrine Dysfunction

The luteal phase defect (LPD) has long been suspected of causing sporadic miscarriage. Evidence linking LPD to RM is less certain and subject to criticism. Women with LPD are thought to have short menstrual cycles, postovulatory intervals less than 14 days, and secondary infertility. Initially, LPD was theorized to result from a failure of the corpus luteum to make enough progesterone to establish a mature endometrial lining suitable for placentation. This theory has evolved to implicate poor follicular-phase oocyte development, which also results in disordered estrogen secretion, inadequate ovarian steroidogenesis, and subsequent maldevelopment of endometrial receptors. In turn, these effects could result from excess luteinizing hormone or hyperandrogenic states.

Some investigators claim that LPD accounts for over one fourth of cases of RM, but none of their studies has included concurrently tested controls, and they cannot agree on appropriate diagnostic criteria. Originally, LPD was diagnosed in the presence of so-called “out-of-phase” endometrial biopsies, which lagged 2 days behind the actual ovulation date, estimated by counting backward from the next menstrual period. However, the diagnostic accuracy of endometrial tissue phasing fell out of favor because of considerable interobserver and intraobserver variation in pathologic interpretation, not to mention the fact that many women without miscarriage exhibit the same out-of-phase endometrial biopsies. Progesterone levels have also been proposed as diagnostic criteria for LPD. However, in patients with RM, low serum progesterone in the luteal phase is only 71% predictive of LPD based on an abnormal endometrial biopsy.

Despite this, endometrial biopsy or luteal-phase serum progesterone levels are widely used to make the diagnosis of LPD. In turn, many clinicians treat women with supposed LPD and RM with progesterone in a subsequent pregnancy. One commonly advocated treatment is a 25-mg progesterone suppository, administered vaginally twice daily (morning and night) with treatment beginning after ovulation and continuing until either menses begin or through the first 8 to 10 weeks of pregnancy. Comparable doses of oral micronized progesterone have also been

---

used. Early studies of progesterone supplementation reported improved pregnancy outcomes in treated women. However, the reliability of these findings has been questioned because no appropriate control groups were treated for comparison. The most recent meta-analysis of progesterone for women with RM found no benefit in the prevention of miscarriage.

Clomiphene and other ovulatory agents, as well as human chorionic gonadotropin (hCG), have also been tried in an attempt to improve follicular development and stimulate corpus luteum function in women with LPD, with varying results. One placebo-controlled, multicentered trial using hCG found no significant difference in the successful pregnancy rates (83% vs. 79%).

Polycystic Ovarian Syndrome

A possible link between polycystic ovarian syndrome (PCOS) and RM has been hypothesized based on the finding that 36% to 56% of women with RM have PCOS based on ultrasound examination of the ovaries. Interestingly, sonographic evidence of PCOS in women with RM does not predict miscarriage when compared with women with RM without PCOS. It has been postulated that pregnancy loss in women with PCOS may be related to elevated serum utilizing hormone levels, high testosterone and androstenedione concentrations, and/or insulin resistance. Indeed, insulin resistance is more common in women with RM compared with fertile controls regardless of whether or not they have PCOS. Treatment of insulin resistance with metformin has been reported to reduce miscarriage in small studies. However, none has included appropriate control groups, and study subjects have not necessarily had RM. Metformin has been shown to cross the placenta, although several studies have failed to find evidence of teratogenesis when used during pregnancy.

Genetic Abnormalities

Approximately 2% to 4% of couples experience RPL because one partner is a carrier of a balanced structural chromosomal rearrangement, usually a balanced translocation. The incidence of balanced translocations is twofold higher among females compared with males. While carriers of balanced translocations are phenotypically normal, meiotic segregation results in chromosomal duplications or deficiencies in offspring leading to spontaneous abortion or an abnormal live born. About 60% of balanced translocations are reciprocal, while 40% are robertsonian. The risk of recurrent aneuploidy is dependent on which parent is heterozygous for the translocation as well as the chromosomes involved. In general, the risk is higher if the translocation is maternal in origin; translocations involving homologous chromosomes preclude the possibility of any normal live-born infants.

Chromosomal *inversions* have also been linked to RPL. The risk of abnormal offspring depends on the size and location of the inversion and whether or not the carrier is male or female. Inversions of small portions of the total chromosomal length lead to large duplications and deficiencies and are generally lethal. Paradoxically, larger inversions are more likely to be compatible with survival. The risk of abnormal offspring is slightly higher if the heterozygous carrier of a *pericentric* inversion is female (7% vs. 5%). *Paracentric* recombinants are universally lethal.

The evaluation of couples with RM should include cytogenetic evaluation of both partners. Genetic counseling should be given to those with parental chromosomal abnormalities in an effort to predict recurrence, and genetic amniocentesis or chorionic villus sampling should be offered in subsequent pregnancies. Chromosomal analysis of the products of conception is also clinically useful, particularly in the evaluation of the reason for failure of a treatment regimen. Parental chromosomal abnormalities do not usually preclude further attempts at pregnancy, because most couples eventually have normal offspring. For the rare homologous robertsonian translocation that prevents successful pregnancy, therapeutic possibilities include artificial donor insemination, in vitro fertilization with donor oocytes, and adoption.

Molecular mutations that may be shown in the future to cause recurrent miscarriages include lethal, single-point mutations, possibly linked to *MHC* genes; mutations in genes that code for products critical for normal development; mutations in homeobox genes that control transcriptional regulation; mutations that lead to severe metabolic errors and embryonic death; and disorders of protooncogenes and oncogenes. One group has shown that certain polymorphisms of the *HLA-G* gene are associated with significantly higher rates of miscarriage among couples presenting with RM. Marked skewing of the normal 50:50 distribution of X chromosome inactivation in the mother, a condition termed *highly skewed X-chromosome inactivation*, has been theorized to cause otherwise unexplained RM. However, recent studies have found no association between RM and skewed X chromosome inactivation.

Antiphospholipid Syndrome and Other Autoimmune Disorders

Antiphospholipid syndrome (APS) has been recognized as a proven cause of pregnancy loss in approximately 5% to 15% of women with RM. The diagnosis is based on the presence of either the lupus anticoagulant (LA), moderate to high levels of IgG anticardiolipin (aCL) antibodies, or both. These acquired antiphospholipid autoantibodies are induced by as yet unknown stimuli in the setting of aberrant immunoregulation. Low levels of immune globulin G or IgM aCL are of questionable significance.

Although women with APS may present with RM in the first trimester, fetal death in the second or early third trimesters may be more specific for the condition. Patients with high levels of IgG aCL or a history of prior fetal death

---

are at greatest risk of another fetal loss. The cause of fetal death appears to be a decidual vasculopathy that results in decidual infarction and insufficient blood flow to the placenta. Intervillous thrombosis has also been described. However, these lesions are nonspecific, and the degree of pathology is not always sufficient to explain the fetal death. The mechanisms by which aCL may cause decidual vasculopathy and fetal death are unknown. A number of pathophysiologic mechanisms have been proposed, including an imbalance of local prostacyclin and thromboxane production, enhanced platelet aggregation, decreased activation of protein C, increased tissue factor, and decreased trophoblast annexin V production or availability. Most recently, the complement system has been invoked as having a major role in APS-related pregnancy loss.

Maternally administered unfractionated heparin (UF) and low-molecular-weight heparin (LMWH) are considered the treatment of choice for APS pregnancies, both to improve embryo-fetal outcome and to protect the mother from thrombotic events (Table 4.2). Treatment regimens are usually initiated in the early first trimester after ultrasonographic demonstration of an intrauterine pregnancy. The optimal dosing regimen is debated. Some experts advocate thromboprophylactic, unadjusted, low doses of UF (e.g., 5,000 to 7,500 U b.i.d.) or once daily LMWH (1 mg/kg) when treating women with APS and a history of RM and other APS-related complications in the absence of prior thrombosis. However, full-dose anticoagulation regimens with UF or LMWH (1 mg/kg b.i.d.) are generally recommended for pregnant APS patients with prior thrombosis. In most case series and trials, daily low-dose

aspirin is also included in the treatment regimen. One important caveat deserves mention—a small, placebo-controlled trial found that otherwise healthy women with RM and low titers of antiphospholipid antibodies do not require treatment.

TABLE 4.2 Anticoagulation Regimens Used in the Treatment of Antiphospholipid Syndrome during Pregnancy

Prophylactic Regimens (unadjusted)	Full Anticoagulation Regimens (adjusted)
1. Women with recurrent embryonic or preembryonic loss, *without* prior thrombosis *Unfractionated heparin*: 5,000–7,500 U q12h in the first trimester; 5,000–1,0000 U q12h in the 2nd and 3rd trimesters *Low-molecular-weight heparin*: 1. Enoxaparin 40 mg once daily or dalteparin 5,000 U once daily, or 2. Enoxaparin 30 mg or dalteparin 5,000 U q12h 2. Women with prior fetal death or early delivery because of severe preeclampsia or severe placental insufficiency; without prior thrombosis *Unfractionated heparin*: 7,500–10,000 U q12h in the 1st trimester; 10,000 U q12h in the 2nd and 3rd trimesters *Low-molecular-weight heparin*: 1. Enoxaparin 40 mg once daily or dalteparin 5,000	Women *with* prior thrombosis *Unfractionated heparin*: 7,500 U q8–12h adjusted to maintain the midinterval heparin levels[a] in the therapeutic range *Low-molecular-weight heparin*: 1. Weight-adjusted (e.g., enoxaparin 1 mg/kg q12h or dalteparin 200 U/kg q12h), or 2. Intermediate dose (e.g., enoxaparin 40 mg once daily or dalteparin 5000 U once daily until 16 wk gestation and q12h from 16 wk gestation onward)

U once daily, or
2. Enoxaparin 30 mg or dalteparin 5,000 U q12h

[a]Heparin levels = anti-Factor Xa levels. Women without a lupus anticoagulant in whom the activated partial thromboplastin time is normal can be followed by using the activated partial thromboplastin time.

Intravenous immune globulin (IVIG) has also been used during pregnancy, usually in conjunction with heparin and low-dose aspirin, especially in women with APS and particularly poor past histories or RM during heparin treatment. However, a randomized, controlled, pilot study of IVIG treatment during pregnancy in unselected APS cases proved negative.

Anticoagulant coverage of the postpartum period in women with APS, regardless of prior thrombosis history, is critical. Heparin regimens may be continued, or patients can be transitioned to warfarin thromboprophylaxis after delivery. In most cases, an international normalized ratio of 3.0 is desirable, and postpartum coverage should extend for 6 to 8 weeks after delivery. Both heparin and warfarin are

safe for nursing mothers. The need for postpartum anticoagulation in women with primary APS diagnosed solely on the basis of recurrent preembryonic and embryonic losses is unclear.

Autoantibodies to thyroid antigens are associated with a modest increased rate of pregnancy loss if identified in early pregnancy or immediately before pregnancy. Some investigators have found a significant proportion of women with RM to have antithyroid antibodies; others have not. Even so, no treatment options for women with RM and antithyroid antibodies have proven beneficial.

Approximately 15% of women with RM have detectable antinuclear antibodies (ANA). However, subsequent pregnancy outcomes among women with a positive ANA test result are no different from those among women with a negative ANA test result. A randomized treatment trial of women with RM and a positive ANA found no benefit to treatment with prednisone and low-dose aspirin compared with treatment with placebo. Currently available data do not support testing women with RM for ANA.

Thrombophilic Disorders

Inherited thrombophilic disorders are identified in 50% of women with pregnancy-related venous thrombosis as well as in women with several obstetric complications including RPL,

preeclampsia, and uteroplacental insufficiency. Thrombophilic defects, including factor V Leiden and prothrombin G20210A mutations and deficiencies in protein C, protein S, and antithrombin III, have been reported significantly more often in women with pregnancy complications compared with women with normal pregnancies. The factor V Leiden and prothrombin G20210A mutations are by far the most common of the inherited thrombophilias, present in 8% and 3%, respectively, of the general white population in the United States. Some, but not all, studies have found an association between inherited thrombophilic disorders and RM. The association appears to be strongest with fetal loss in the second and third trimesters. However, in a recent observational trial of women with RM, the presence of an inherited thrombophilia was actually *protective* against miscarriage in a subsequent pregnancy.

The high prevalence of inherited thrombophilias in women with obstetric complications has led to the use of prophylactic anticoagulation during pregnancy. However, there is limited supportive evidence for this practice in women without a history of venous thrombosis. A variety of treatment regimens have been used, and no study has included an appropriate control group for comparison. Until randomized controlled trials have been performed, prophylactic anticoagulation should be reserved for selected women with thrombophilia and RM after an informed discussion of the risks and limited data suggesting benefit.

Idiopathic Recurrent Miscarriage

An etiology cannot be identified in at least 50% of couples with RM, despite a thorough evaluation. This has led to speculation about other potential causes of RM with particular attention to the role of alloimmune factors in pregnancy maintenance. A relationship between alloimmunity and RM has yet to be proven, largely because little is known about the mechanisms that prevent immunologic rejection of the conceptus in successful pregnancies. Early reports proposed that HLA compatibility between couples, the absence of maternal leukocytotoxic antibodies, or the absence of maternal blocking antibodies were related to RM. The importance of these factors has not been substantiated, and tests for detection are expensive and not clinically useful. Research has also focused on local decidual or trophoblast immunosuppressive factors such as cytokines, growth factors, hormones, enzymes, and endometrial proteins. Some of these immunoactive factors appear to be necessary for implantation and growth and development of the early placenta and embryo, and others may cause abortion, when expressed. There are, however, no practical clinical tests available for these factors and no proven treatment if they were found abnormal.

Although no alloimmune mechanism has been unequivocally shown to cause RM in humans, several types of immunotherapy have been advocated. Originally, the attempt to improve maternal immunotolerance in recurrent aborters was based on evidence that pretransplant blood transfusions decreased rejection of organ allografts and that the rate of resorption or abortion in animal models was reduced by prior immunization with spleen cells from a paternally related strain. The most popular regimen involves injections of the father's leukocytes. Although proponents persist, this treatment is questionable at best and harmful at worst. Most randomized trials have proven negative, and the largest and only

multicenter randomized trial found that treated pregnancy outcomes were worse in the women who received leukocyte immunization. Based largely on this trial, the U.S. Food and Drug Administration has stated that the administration of this therapy for RM may only be done as part of a clinical investigation, and then only if there is an investigational new drug application in effect. Participating women should be counseled that immunization using viable leukocytes carries the risks of any blood transfusion, such as hepatitis, HIV, and cytomegalovirus infections. Reactions have been uncommon but include soreness and redness at the injection site, cutaneous graft-versus-hostlike reaction, fever, maternal platelet and leukocyte alloimmunization, and blood group sensitization.

Intravenous immune globulin has been proposed as an alternative therapy in patients with idiopathic RM. A number of randomized trials have been reported, and the results are conflicting. Nevertheless, this treatment seems to be no more successful than paternal cell immunization, and IVIG is not recommended outside of a research protocol by either the ACOG or the American Society of Reproductive Medicine.

It is imperative for physicians to recognize that the prognosis for idiopathic RM is by no means dismal. Numerous studies and several meta-analyses indicate that the average next pregnancy live-birth rate for placebo-treated women with idiopathic RM is 60% to 70%. Many couples see this modestly favorable prognosis in a somewhat positive light, and it compares favorably with the prognosis for conditions such as APS or parental karyotype abnormalities. Understanding this prognosis may allow the couple to choose against an expensive unproven treatment. One caveat—as expected, increasing maternal age and increasing number of miscarriages are negative variables.

Recommendations for Recurrent Miscarriage

The scheme for a reasonable and cost-effective evaluation of women with RM shown in Table 4.3 is based on current guidelines published by the ACOG and the Royal College of Obstetricians and Gynaecologists. A sympathetic attitude by the physician is crucial—establishment of trust and rapport and a sincere appreciation of the distress and grief experienced by these couples permit tactful and thorough discussions with patient and partner. It is reasonable to institute an evaluation after two consecutive miscarriages in anxious women or if the patient has few reproductive years remaining or has had an infertility problem. Couples interested in an investigational protocol are perhaps best referred to legitimate research centers.

TABLE 4.3 Suggested Evaluation of Patients with Recurrent Miscarriage

History
Determine pattern and trimester of pregnancy losses and

whether a live fetus was present; clues suggestive of autoimmune disease; unusual exposure to environmental toxins, drugs, infections; previous gynecologic disorders or surgery, including dilation and curettage; and previous diagnostic tests and treatments

Physical
Abnormalities on pelvic examination, including findings suggesting abnormal cervix, DES exposure, or uterine anomalies

Tests
Lupus anticoagulant and anticardiolipin antibodies
Parental chromosome analyses (father and mother)
Uterine cavity and shape evaluation by hysterosalpingogram, hysteroscopy, MRI, or other studies
Chromosome analysis of products of conception
Other laboratory tests if suggested by history and physical examination

DES, diethylstilbestrol, MRI, magnetic resonance imaging.

Summary Points

- Miscarriage occurs in at least 15% of clinically recognized pregnancies; the rate is two to three times higher in early, unrecognized pregnancies.
- More than 95% of pregnancies continue if a live embryo is demonstrated sonographically at 8 weeks gestation.
- Women with three or more consecutive miscarriages should undergo evaluation; workup may be appropriately sooner in older couples or in those with infertility.
- Miscarriage is the most common complication of pregnancy, and the most frequent etiology is a chromosomal abnormality of the conceptus.
- Ultrasound is helpful in determining whether or not the embryo is viable, and appropriate modern management may be observation or medical or surgical evacuation of the uterus.
- Misoprostol and curettage are equally safe and effective methods of uterine evacuation in patients with incomplete miscarriage.
- Recurrent early pregnancy loss is sometimes associated with

underlying maternal abnormalities that can be detected with a standard evaluation.
- Unproven tests and controversial treatments for recurrent miscarriage should not be used routinely until supportive evidence is available.

Ectopic Pregnancy

Beata E. Seeber
Kurt T. Barnhart

Ectopic pregnancy, the implantation of a fertilized ovum outside of the endometrial cavity, is a condition that is unique to primates. Although ectopic pregnancy remains a leading cause of life-threatening first-trimester morbidity, informed clinical suspicion and modern diagnostic procedures now routinely lead to diagnosis and treatment at the early signs of symptoms. Management of ectopic pregnancy has changed dramatically over the years. Medical therapy with systemic methotrexate, an intervention targeted specifically toward proliferating trophoblasts, is now often preferred to surgery as standard first-line treatment. However, surgery remains the first choice when rupture causes intraperitoneal hemorrhage, medical failures, neglected cases, and cases where medical therapy is contraindicated. In the wake of these changes, the United States has seen a considerable drop in maternal morbidity and mortality from this disease.

Early diagnosis and selection of optimal therapy are key to prevention of complications, preservation of fertility, control of costs, and elimination of mortality. The optimal dosing protocol for methotrexate therapy remains controversial. Similarly, the timing and technique for surgical intervention during medical failures are for the most part empirical. Using an evidence-based approach to the diagnosis of and treatment for ectopic pregnancy, this chapter provides a comprehensive examination of the standard of care for this serious gynecologic disease.

Incidence

The incidence of ectopic pregnancy in the United States is not known precisely. Recent attempts by the Centers for Disease Control and Prevention (CDC) to estimate the incidence of this disease have been thwarted, because there are no clear reporting standards and many cases are treated medically in outpatient facilities and are thus not recorded in hospital registries. The latest reported numbers date back to the mid 1990s. Where hospital records were used, a relentless increase in ectopic pregnancies from 4.5 per 1,000 in 1970 to 16.8 per 1,000 in 1989 to 19.7 per 1,000 (108,000 cases) in 1992 was reported. Several recent epidemiologic trends make it likely that the current incidence of ectopic pregnancy is even higher. First, there is a continued increase in the risk factors associated with ectopic pregnancy (Table 5.1). Second, there is increased ascertainment of

ectopics from use of more sensitive and specific diagnostic methods that detect many cases that in the past may have resolved spontaneously without diagnosis or treatment (increase in prevalence due to lead-time bias). Third, with the increasing use of assisted reproductive technology (ART) for treatment of infertility, there is increased risk of ectopics, which comprise up to 5% of pregnancies achieved by using ART. Not surprisingly, heterotopics also are being reported with increasing frequency in ART pregnancies. Between 1979 and 1986, 13% of maternal deaths were secondary to ectopic pregnancy; by 1992, this dropped to 9%. However, ectopic pregnancies continue to be the leading cause of maternal death in the first trimester, accounting for 5% to 6% of all maternal deaths in the United States. Ninety percent of these deaths were due to hemorrhagic complications.

Pathogenesis

Any event that impairs the ability of the tube to transport gametes or embryos will predispose to ectopic implantation. The most common site of ectopic pregnancy is the fallopian tube, which accounts for 98.3% of all ectopic gestations. Of tubal implantation sites, the ampulla is observed in 79.6%, 12.3% are in the isthmus, 6.2% are in the fimbrial end, and the remaining 1.9% occur in the interstitial (cornual) region. Ectopic nidation outside the fallopian tubes is rare; only 1.4% of ectopic pregnancies are abdominal pregnancies, 0.15% ovarian, and 0.15% cervical (Fig. 5.1).

TABLE 5.1 Risk Factors Associated with Ectopic Pregnancy

Patients at increased risk need aggressive monitoring of their pregnancies immediately after first missed menses.

Risk Factor	Odds Ratio[a]
High risk	
Tubal surgery	21.0
Tubal ligation	9.3
Previous ectopic pregnancy	8.3
In utero exposure to DES	5.6
Use of IUD	4.2–45.0

Tubal pathology	3.8–21.0
Assisted reproduction	4.0
Moderate risk	
Infertility	2.5–21.0
Previous genital infections	2.5–3.7
Multiple sexual partners	2.1
Salpingitis isthmica nodosa	1.5
Low risk	
Previous pelvic infection	0.9–3.8
Cigarette smoking	2.3–2.5
Vaginal douching	1.1–3.1
First intercourse <18 y	1.6

DES, diethylstilbestrol; IUD, intrauterine device.
[a]Single values, common odds ratio from homogenous studies; point estimates, range of values from heterogenous studies.

In most tubal implantations, the proliferating trophoblast invades the tubal wall. Ectopic pregnancies in the ampullary portion of the tube are often within the tubal lumen and have not caused tubal rupture, while those in the isthmic portion are more likely to be found outside the lumen, having caused tubal rupture. The degree of trophoblastic invasion of maternal tissues, the age and viability of the pregnancy, and the site of implantation determine the sequence of clinical events. As the trophoblasts proliferate, the growth may extend from the luminal mucosa, into the muscularis and lamina propria, through to the serosa and, ultimately, full thickness even into large blood vessels in the broad ligament. With vascular disruption, bleeding takes place that distorts the tube, stretches the serosa, and causes pain. The embryo is abnormal and degenerates in about 80% of cases. If left

untreated, spontaneous tubal abortion occurs in about 50% of tubal ectopic pregnancies and may often be clinically silent. Likewise, spontaneous tubal abortion with hemorrhage can occur with bleeding that is self-limited. However, the remaining cases of ectopic pregnancy will eventually cause tubal rupture and are associated with significant and possibly life-threatening hemorrhage. As noted previously, this complication is most likely to occur in the isthmic part of the tube, which has limited distensibility. Chronic tubal rupture with extension into the broad ligament can produce a pelvic hematoma that can last for several weeks. Unruptured ectopic pregnancies can produce a chronic course, with persistently elevated ß-human chorionic gonadotropin (ß-hCG) levels that may last for weeks.

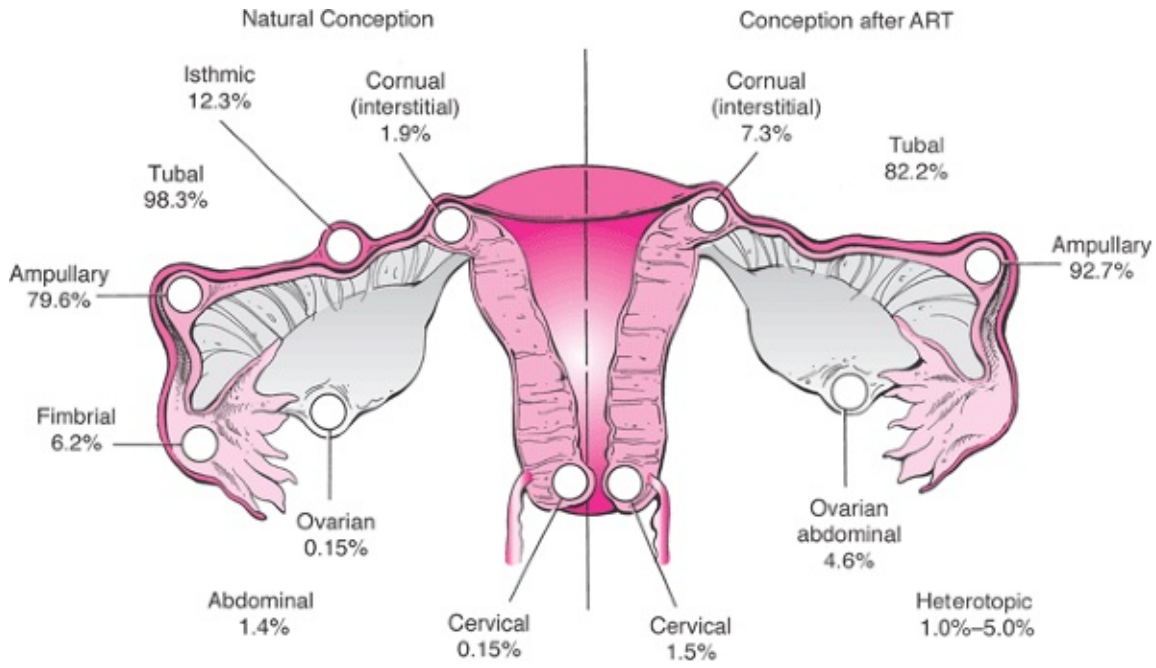

Figure 5.1 Implantation sites for ectopic pregnancy following natural cycles and ART.

Besides tubal disease, factors inherent to the embryo itself may theoretically lead to premature implantation in the tube, prior to its entry into the uterine cavity. However, studies have not supported the theory that genetic or other morphologic abnormalities of the embryo cause implantation at an ectopic site, as the rate of chromosomal abnormalities in surgically excised tubal pregnancies is comparable to that expected for gestational and age-related factors.

Other molecular-level factors that may be responsible for the molecular dialog between embryo and implantation site, or cell-cell and cell-extracellular matrix interactions, are being studied for their possible role in aberrant implantations.

Risk Factors

Ectopic pregnancy most often is associated with risk factors leading to tubal epithelial damage, which alters gamete and embryo transport. Meta-analyses identify the risk factors

listed in Table 5.1 as the most influential.

Tubal Damage and Infection

Documented tubal pathology carries a 3.5-fold common adjusted odds ratio for ectopic pregnancy. Patients with a previous ectopic pregnancy are six to eight times more likely to experience another ectopic pregnancy, and 8% to 14% of patients experience more than one ectopic pregnancy. The approximate recurrent ectopic pregnancy rate is 13% after a history of one ectopic and 28% after two previous ectopics. Patients with a history of tubal surgery have a 21-fold common adjusted odds ratio of ectopic pregnancy, but it is not clear if it is the tubal disease itself or the surgery required for the disease.

Tubal pathology frequently results from pelvic infections. Patients with a history of pelvic infections, including gonorrhea, serologically confirmed chlamydia, and nonspecific pelvic inflammatory disease, have a twofold to fourfold higher risk of developing an ectopic pregnancy. The ectopic pregnancy rate is 4% in women with laparoscopically documented salpingitis, compared with 0.7% in women with normal-appearing tubes. In evaluating histologic specimens of ectopic pregnancy, microscopic evidence of salpingitis is present in 38% of cases. Recurrent episodes of pelvic infections increase the likelihood of tubal occlusions: 12.8% after one infection, 35.5% after two infections, and 75% in women with three or more infections.

Salpingitis Isthmica Nodosa

Salpingitis isthmica nodosa is a disease defined by an anatomic thickening of the proximal portion of the fallopian tubes at the junction with the uterus and is histologically characterized by multiple luminal diverticula. The etiology of this disease is not known; however, this pattern of tubal pathology increases the incidence of ectopic pregnancy by 52% in age- and race-matched controls.

Diethylstilbestrol

Prenatal exposure to diethylstilbestrol (DES) alters fallopian tubal development, resulting in absent or minimal fimbrial tissue, a small tubal os, and decreased length and caliber of the tube. This abnormal tubal anatomy is associated with a fivefold increase in the risk for ectopic pregnancy.

Cigarette Smoking

Patients who smoke cigarettes are at a slightly increased risk for ectopic pregnancy. It is difficult to conceptualize the link between ectopic pregnancy and cigarettes. Theories include impaired immunity in smokers predisposing them to pelvic infections, alterations in tubal motility, or a representation of a lifestyle associated with an increased risk of tubal infection.

Contraception

Intrauterine devices (IUDs) have been associated with ectopic pregnancy. A multicenter case-controlled study conducted by the World Health Organization in ten countries found an odds ratio of 6.4 for ectopic pregnancy in current IUD users compared with pregnant controls, whereas the odds ratio was only 0.5 when the comparison was made with nonpregnant controls. Similarly, in the Oxford Study of 17,032 contraceptive users, the proportion of unplanned pregnancies that were ectopic was higher in women using IUDs compared with women taking oral contraceptives. Thus, IUDs effectively prevent pregnancy, but if pregnancy does occur in a woman using an IUD, there is increased likelihood that the pregnancy will be ectopic.

Tubal ligation carries a similar risk for ectopic pregnancy to what is observed with current IUD use. A meta-analysis using case-controlled studies found the odds ratio for tubal sterilization to be 9.3 when compared with pregnant controls and 0.52 when compared with nonpregnant controls, a finding confirmed by two additional multicenter case-controlled trials. As with the IUD, tubal ligations effectively prevent pregnancy, but if pregnancy does occur, the suspicion for an ectopic pregnancy should be high.

Tubal sterilization by using electrocoagulation procedures are associated with higher ectopic pregnancy risk than other methods of tubal sterilization, possibly resulting from tubal recanalization or uteroperitoneal fistula formation. Uteroperitoneal fistulas have been found in up to 75% of hysterectomy specimens from women with previous tubal ligations in which the tubes were cauterized flush with the uterus.

Oral contraceptives are associated with a reduced risk of ectopic pregnancy when compared with nonpregnant controls but with elevated risk when compared with pregnant controls. This protection is presumably due to the suppression of ovulation by oral contraceptives. It is therefore not surprising that patients who take emergency contraception, such as oral contraceptives after fertilization, are at

---

substantial risk for an ectopic pregnancy. This has been attributed to altered tubal motility, but this etiology remains controversial.

Barrier contraception (condoms, spermicides, and diaphragms) also reduces the odds ratio of ectopic pregnancy. An additional advantage may be attributed to the decreased risk of sexually transmitted diseases in women using barrier methods.

Evidence-Based Recommendation

Women with a previous ectopic pregnancy, tubal surgery, tubal pathology, or with prenatal DES exposure are at high risk for ectopic pregnancy. Women who have experienced genital infections, infertility, or more than one sexual partner have a moderate risk of ectopic pregnancy. Previous pelvic or abdominal surgery, smoking, vaginal douching, or an early age of first sexual intercourse have only a slightly increased risk of ectopic pregnancy.

Contraception, if used properly, is an effective way of reducing pregnancy, both intrauterine and ectopic. If pregnancy occurs in women with an IUD, after tubal ligation, or following emergency contraception, suspicion for ectopic pregnancy should be high. (Strength of recommendation: A.)

Signs and Symptoms

The classic symptoms of an ectopic pregnancy are abdominal or pelvic pain and vaginal bleeding or spotting in the context of a positive pregnancy test. However, these symptoms may be variable, range from mild to severe, and are neither sensitive nor specific for the diagnosis of ectopic pregnancy. Today, many ectopic pregnancies never produce symptoms; rather, they are diagnosed and treated in a timely fashion because the patient is identified as high risk. Table 5.1 summarizes and weighs risk factors that should be examined in every woman who has just been identified as being pregnant. However, the medical and economic benefits of screening asymptomatic women, including those who are considered at high risk, are outweighed by the still overall low incidence of ectopic pregnancy and the high false-positive rate of doing so. Thus, universal screening of all women, including some considered at higher risk, is not recommended. Since at least 40% to 50% of patients with proven ectopic pregnancies have no risk factors, absence of these factors is not wholly reassuring and does not exclude an ectopic pregnancy. Unfortunately, early diagnosis is not always achievable, and fallopian tube rupture secondary to ectopic pregnancy remains a relatively frequent clinical occurrence.

The most common signs are detected on abdominal examination. Abdominal tenderness is present in 90% of patients and rebound tenderness in 70%. The pelvic examination is usually nonspecific; cervical motion tenderness is present in up to two thirds of patients, while a tender adnexal mass is present in 10% to 50%. Pain radiating to the shoulder, syncope, and shock, as a result of hemoperitoneum, occur in up to 20% of patients and are indications for immediate surgical intervention.

Diagnosis

Ectopic pregnancy can be diagnosed as early as 4.5 weeks gestation. Unfortunately, visualizing an ectopic pregnancy this early frequently is not possible. More importantly, traditional laparoscopic visualization (Figs. 5.2, 5.3, 5.5) is now rarely necessary. Routine diagnostic tests are serial measurements of ß-hCG, ultrasonography, uterine sampling via manual vacuum extraction or curettage, and, in some instances, serum progesterone levels.

Outpatient diagnosis of ectopic pregnancy by using various algorithms has been shown to be safe and effective without need for hospitalization even when the diagnosis is equivocal. The clinical algorithm in Figure 5.4 is highly efficacious in diagnosing ectopic pregnancy.

The diagnosis of ectopic pregnancy begins by excluding a normal intrauterine pregnancy. Transvaginal ultrasound examination should identify an intrauterine pregnancy with nearly 100% accuracy for gestations greater that 5½ weeks by identifying structures such as a gestational sac, a yolk sac, and fetal pole with later cardiac motion (usually seen around 6 weeks). Because of the inaccuracies inherent in pregnancy dating, ß-hCG is often used as a surrogate marker for pregnancy dating. As will be further discussed below, an intrauterine pregnancy should be visualized at the “discriminatory cutoff” of ß-hCG, a level corresponding to 1,500 to 2,500 IU/L (depending on

operator and equipment used) with near 100% sensitivity. These ß-hCG thresholds are not universal, and each institution must identify its own values to avoid terminating normal intrauterine pregnancies. The absence of such implies an abnormal gestation. If the pregnancy is earlier than the aforementioned 5½ weeks and/or the ß-hCG is below the "discriminatory cutoff," then serial ß-hCG measurements aid in the diagnosis and determine the need for intervention.

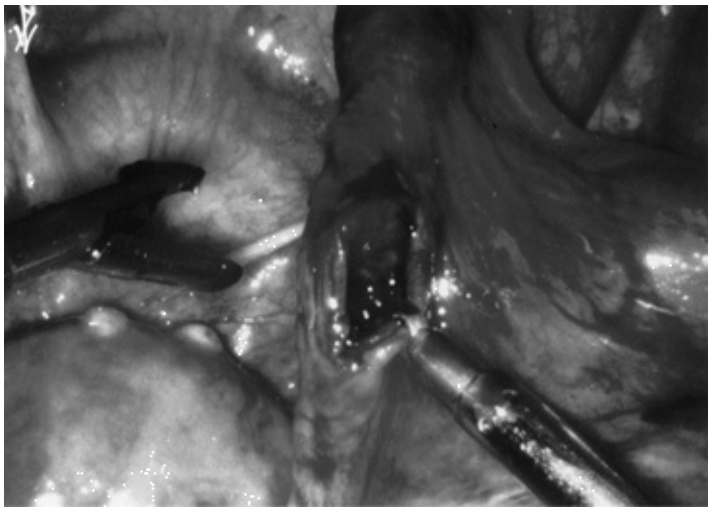

Figure 5.2 Laparoscopic visualization of an isthmic ectopic pregnancy.

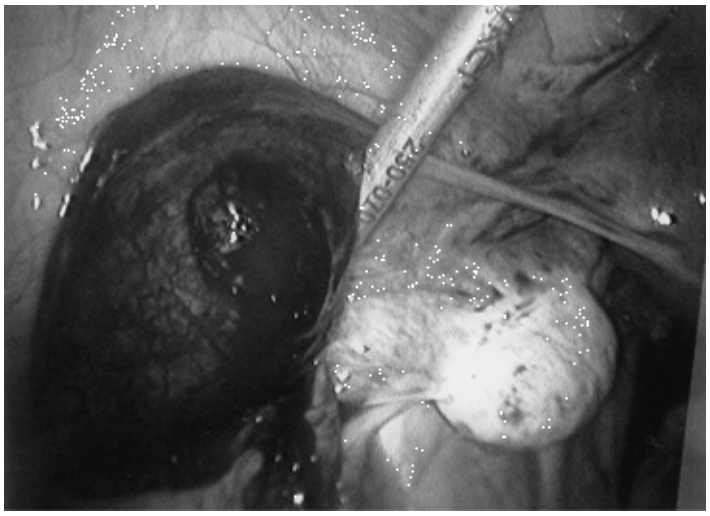

Figure 5.3 Laparoscopic visualization of an ampullary ectopic pregnancy.

Serial ß-Human Chorionic Gonadotropin Determinations

The advent of radioimmunoassay (RIA) and specific antiserum to the ß-subunit of hCG has allowed for the accurate quantification of ß-hCG and the ability to closely follow trends in the rise and fall of this hormone, detecting low ß-hCG concentrations in urine and serum,

20 mIU/mL down to 1 mIU/mL, respectively. Currently, ß-hCG is almost exclusively assayed using the third International Reference Preparation (IRP), a standard very similar to the original first IRP.

The ß-hCG, produced by trophoblastic cells in normal pregnancy, has long been accepted to rise at least 66% and up to twofold every 2 days. Recent data has shown that the minimum rise for a potentially viable pregnancy that presents with pain and/or vaginal bleeding may be as low as 53% in 2 days, based on the 99th percentile confidence interval (CI) around the mean of the curve of normal

ß-hCG rise. Thus, intervention for a ß-hCG rise of less than 66% over 2 days, a practice supported by previous data, may potentially interrupt a normally developing intrauterine pregnancy. This generally applies to ß-hCG values below 10,000 mIU/mL.

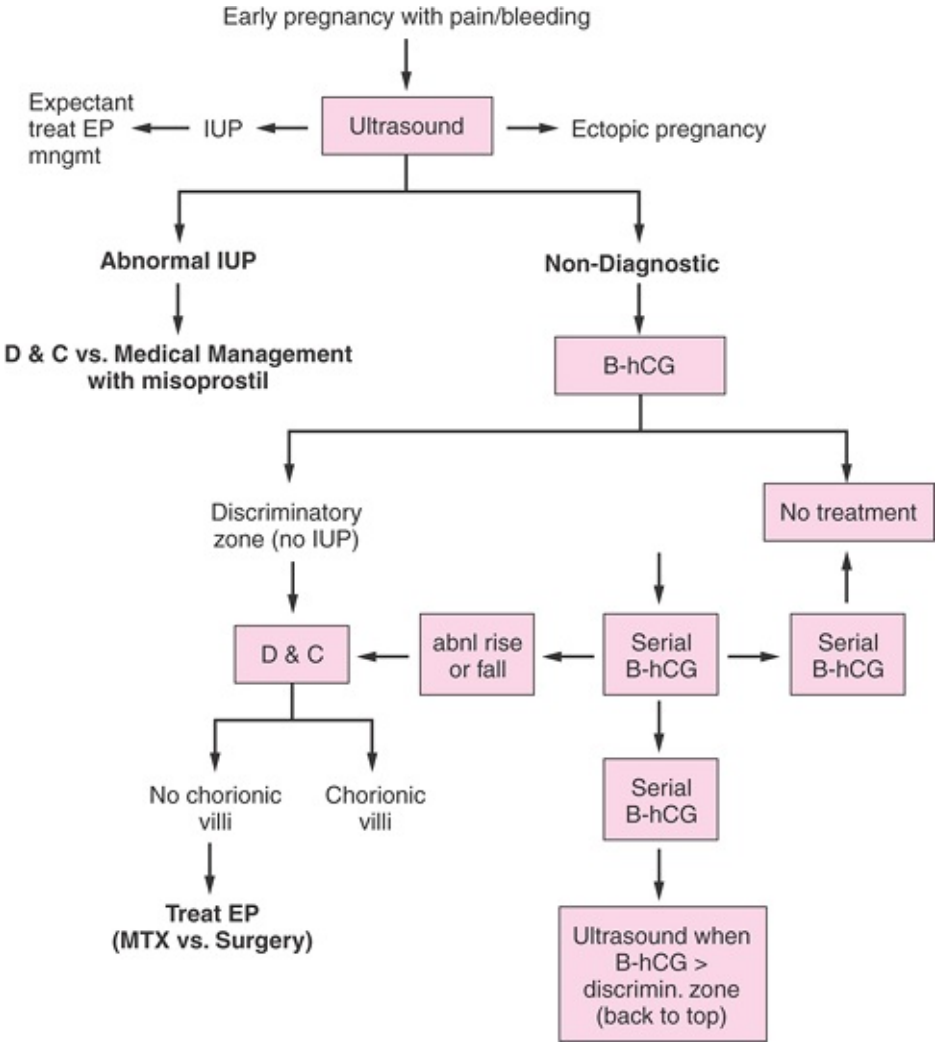

Figure 5.4 Diagnostic algorithm for ectopic pregnancy. (From Seeber BE, Barnhart KT. Suspected ectopic pregnancy. *Obstet Gynecol* 2006;107:402.)

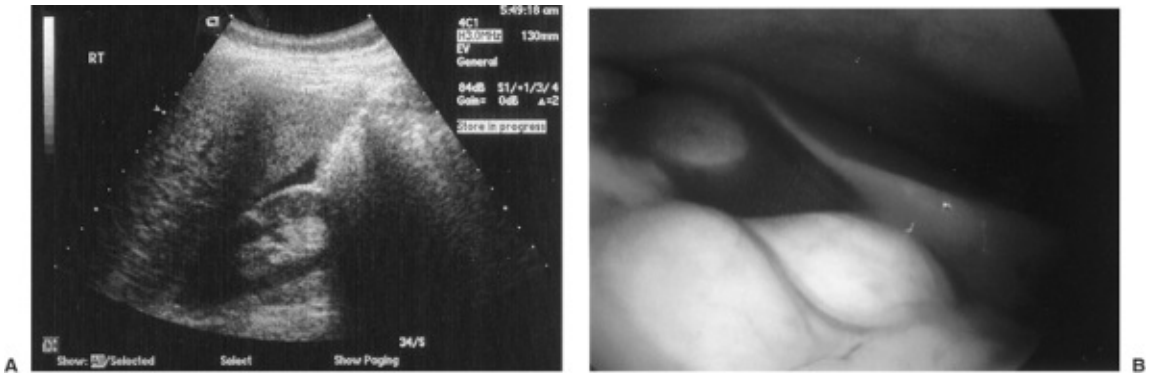

Figure 5.5 Ultrasonogram of free fluid noted under the liver edge above the right kidney. Confirmed to be blood from a ruptured ectopic pregnancy at the time of surgery. (Courtesy of R. Mangal, M.D., Obstetrics/Gynecologic Associates, Houston, TX.)

Eight-five percent of abnormal pregnancies, whether intrauterine or ectopic, have impaired ß-hCG production with an abnormal rate of ß-hCG rise. ß-hCG levels that plateau or fail to rise normally along with a low serum progesterone value should be considered nonviable. Rapidly declining ß-hCG values (at least 21% to 35% in 2 days) are likely consistent with a miscarriage that may resolve spontaneously but could still represent a spontaneously resolving ectopic gestation. In such situations, ß-hCG levels should be followed serially until no longer detectable, indicating complete resolution of the pregnancy, regardless of the implantation site.

If a viable intrauterine gestation is not visible by transvaginal ultrasonography when the ß-hCG is above the “discriminatory cutoff,” and no fetal heartbeat can be visualized in the adnexa, uterine curettage or manual vacuum extraction can be performed. This intervention is necessary to accurately differentiate between an abnormal intrauterine gestation (spontaneous abortion) and an ectopic pregnancy. Either treatment of a nonviable intrauterine pregnancy is performed or ectopic pregnancy is diagnosed when the uterine contents fail to demonstrate presence of chorionic villi on histologic examination or the ß-hCG levels do not fall appropriately postuterine evacuation.

If histologic examination is not readily available, ß-hCG determinations are further employed for diagnosis after uterine curettage. If the ß-hCG fails to decline by 15% after 12 to 24 hours from a level drawn immediately before surgery, the pregnancy is presumed ectopic and treatment should be initiated. To definitively confirm resolution of the pregnancy in the absence of a tissue diagnosis, ß-hCG levels should be followed weekly until undetectable.

Progesterone

The diagnostic algorithm presented here does not include the measurement of serum progesterone levels, a test whose results are not immediately available to aid in diagnosis in many clinical settings. Although progesterone levels are higher in intrauterine pregnancies than in ectopic pregnancies, there is no established cutoff to use to discriminate between these two entities. A meta-analysis has shown that although low

progesterone levels can identify patients at risk for ectopic pregnancy, this test alone is insufficient to diagnose ectopic pregnancy with certainty. In addition, a low progesterone level of less than 5 ng/mL can rule out a normal pregnancy with almost 100% accuracy but does not differentiate whether that pregnancy is an abnormal one in the uterus or at an ectopic site.

Ultrasonography

Although the uterus and adnexa may be evaluated by an abdominal or pelvic examination, transvaginal ultrasonography reliably detects intrauterine gestations when the ß-hCG levels are between 1,500 and 2,500 mIU/mL (third IRP), or as early as 1 week after missed menses. An intrauterine gestation should almost always be visualized when the ß-hCG level is greater than 2,000 mIU/mL.

Diagnosis of an ectopic pregnancy can be made with 100% sensitivity but with low specificity (15% to 20%) if an extrauterine gestational sac containing a yolk sac or embryo is identified. A complex adnexal mass without an intrauterine pregnancy improves specificity to 21% to 84% at the expense of lower sensitivity (93.0% to 99.5%). In reviewing the literature, the presence of any noncystic, extraovarian adnexal mass in the absence of an intrauterine gestation was diagnostic of an ectopic pregnancy with 98.9% sensitivity, 96.3% positive predictive value, 84.4% specificity, and a 94.8% negative predictive value (Fig. 5.6). Despite the high resolution of transvaginal ultrasonography, an

adnexal mass will not be found in 15% to 35% of patients with an ectopic pregnancy, particularly in early stages. Some sonographic images, such as the pseudogestational sac, may mislead even an experienced examiner to falsely diagnose a gestational sac. This is a collection of fluid within the endometrial cavity, usually in a central as opposed to eccentric location that occurs due to bleeding from the decidualized endometrium when an extrauterine gestation is present.

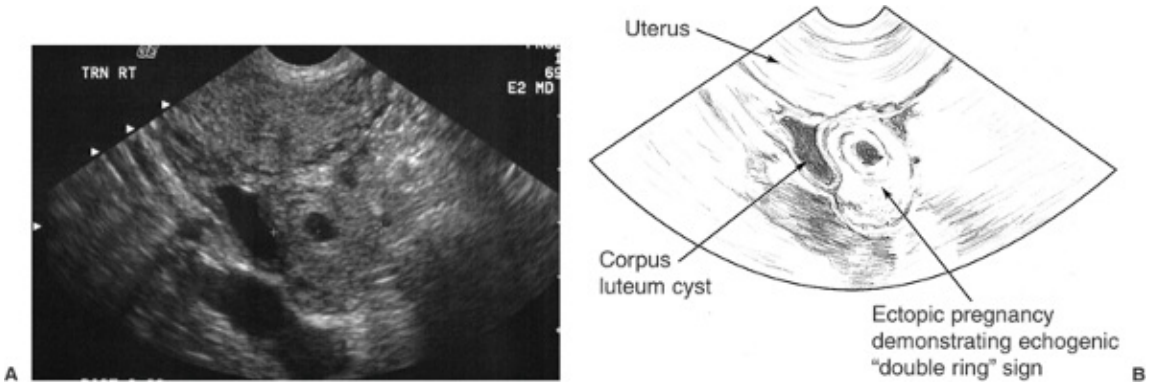

Figure 5.6 Transvaginal ultrasonographic illustration of tubal ectopic gestation.

Serial ß-hCG concentrations and transvaginal ultrasonography predict ectopic pregnancy with a positive predictive value of 95%. Ultrasonography should be used to document the

presence or absence of an intrauterine pregnancy when the ß-hCG levels have risen above the designated discriminatory cutoff zone.

However, in those patients with an “indeterminate” ultrasound, 25% have an ectopic pregnancy. Therefore, serial ß-hCG and ultrasonography alone cannot diagnose all ectopic pregnancies. In order to make the definitive diagnosis and differentiate an abnormal intrauterine from an ectopic pregnancy, uterine evacuation for tissue diagnosis is necessary. In order to minimize the inadvertent interruption of a desired intrauterine pregnancy, a high (not low) discriminatory zone should be used before uterine evacuation is considered.

Uterine Evacuation

Uterine curettage or manual vacuum extraction is necessary when a transvaginal ultrasonogram and a rising or plateauing ß-hCG level below the cutoff value are not sufficient for diagnosis. With this procedure, tissue can be obtained to look for intrauterine products of conception. If present, the patient had an abnormal intrauterine pregnancy and now a completed abortion; if negative, the patient has an ectopic pregnancy needing further management. If histologic examination is not available, then a guideline of a decrease in the ß-hCG level of 15% or more 12 hours after curettage is diagnostic of a complete abortion. If the ß-hCG titer plateaus or rises and the trophoblast was not removed by curettage, an ectopic pregnancy is likely.

Evidence-Based Recommendation

Serial ß-hCG determinations, transvaginal ultrasonography, and uterine sampling allow for definitive diagnosis of ectopic pregnancy. A confirmatory laparoscopy is rarely necessary. (Strength of recommendation: A.)

Treatment for Ectopic Pregnancy

Medical Management

Methotrexate therapy of ectopic pregnancy has been used successfully over the last 2 decades. The folic acid antagonist, methotrexate, inhibits de novo synthesis of purines and pyrimidines, interfering with DNA synthesis and cell multiplication. Rapidly proliferating trophoblasts are very dependent on folic acid and thus differentially vulnerable to the cytotoxic effect of methotrexate, and this differential sensitivity forms the basis of the therapy. When methotrexate is administered to pregnant women undergoing planned termination, a single dose of 50 mg/m^2 significantly blunts the ß-hCG increment over the following 7 days and has been associated with a drop in circulating progesterone and 17α-hydroxyprogesterone concentrations prior to abortion. It appears that methotrexate directly impairs trophoblastic production of hCG with a secondary decrement of corpus luteum progestin secretion. Hemodynamically stable patients with unruptured ectopic pregnancy measuring less than or equal to 4 cm by ultrasonography are eligible for methotrexate therapy. Patients with larger masses or evidence of acute intra-abdominal

bleeding should undergo immediate surgical treatment. Methotrexate treatment regimens are shown in Table 5.2 and include the multiple dose, single dose, and the newly introduced two-dose protocol.

TABLE 5.2 Comparison of Methotrexate Regimens

	Single-Dose Regimen	Multiple-Dose Regimen	Two-Dose Regimen
Methotrexate dose	50 mg/m^2	1 mg/kg	50 mg/m^2
Leucovorin dose	NONE	0.1 mg/kg	NONE
Dose frequency	Day 0 Potential dose on day 7	Alternating-day dosing of methotrexate and leucovorin, maximum of four doses of each	Day 0 and day 4 Potential doses on day 7 and day 11
ß-hCG monitoring	Day 0, day 4, day 7 Day 11 and day 14 if additional doses given	Day 0, and then odd-numbered days until success	Day 0, day 4, day 7 Day 11 and day 14 if additional doses given
Success	15% drop in ß-hCG day 4 to day 7 15% drop	15% drop in ß-	15% drop in ß-hCG day 4 to day 7 15% drop in

determined by	in β-hCG day 11 to day 14 if second dose given	hCG between any two blood draws	hCG day 7 to day 11 or day 11 to day 14 if third and fourth dose given

Multiple-Dose Methotrexate

Multiple-dose methotrexate therapy is tailored to the patient's weight and ectopic pregnancy responsiveness. Outcomes of 12 studies comparing multiple-dose systemic methotrexate with laparoscopic salpingostomy are presented in Table 5.3. Between 1982 and 1997, this tabulation shows 338 cases of ectopic pregnancy treated with variable-dose methotrexate (number of medication administrations varies according to response). Of these cases, 93% were treated successfully with multiple-dose systemic methotrexate (no subsequent therapy was required), and 75% of the women tested had patent fallopian tubes; in addition, of the women desiring pregnancy, 58% had a subsequent intrauterine pregnancy and 7% developed a repeat ectopic pregnancy. These rates all compare favorably with conservative surgical management.

There is one randomized clinical trial comparing laparoscopic salpingostomy with systemic multiple dose methotrexate. In it, 100 patients with laparoscopy-confirmed ectopic pregnancy were randomly treated with systemic methotrexate or laparoscopic salpingostomy. In the 51 patients treated with methotrexate, seven (14%) required surgical intervention for active bleeding or tubal rupture. An additional course of methotrexate was required in two patients (4%) for persistent trophoblast, based on continued β-hCG secretion. Of the 49 patients in the salpingostomy group, four patients (8%) failed and required salpingectomies, and ten patients (20%) required treatment with methotrexate for persistent trophoblast. Homolateral tubal patency was present in 23/42 (55%) of the patients assessed in the methotrexate group and in 23/39 (59%) of those assessed in the salpingostomy group. This randomized study and previous meta-analysis have demonstrated the effectiveness of systemic methotrexate therapy as equal to laparoscopic salpingostomy.

TABLE 5.3 Outcome of Different Treatments for Ectopi

		Subsequent Fertility Rate			
Method	Number of	Number of	Number with Successful	Tubal Patency	Intra Preg

	Studies[a]	Patients	Resolution	Rate	
Conservative laparoscopic surgery	32	1,626	1,516 (93%)	170/223 (76%)	366 (5
Variable-dose methotrexate	12	338	314 (93%)	136/182 (75%)	55/9
Single-dose methotrexate	7	393	340 (87%)	61/75 (81%)	39/6
Direct-injection methotrexate	21	660	502 (76%)	130/162 (80%)	87 (5
Expectant management	14	628	425 (68%)	60/79 (76%)	12/1

Single-Dose Methotrexate

Single-dose methotrexate, although more convenient, is not as efficacious as multiple-dose methotrexate. The high success rates in the initial studies using single-dose

methotrexate were most likely due to the inclusion of spontaneously aborting intrauterine pregnancies. Subsequent studies of single-dose methotrexate therapy involving 393 patients are presented in Table 5.3. Although overall success of treatment, measured as no surgical intervention, is 87%, 8% of patients required more than one dose of methotrexate. Of the patients considered successfully treated (with one or more doses), tubal patency was found in 81% of the women evaluated. The subsequent intrauterine pregnancy rate was 61%, and for ectopic pregnancies 8%, in the patients desiring future fertility in the same group (those treated with either one or more doses of methotrexate). Based on the clinical evidence presently available, the routine use of methotrexate as a single-dose intramuscular regimen is probably not as effective as multiple doses. However, single-dose therapy remains a standard according to publications of the American College of Obstetricians and

Gynecologists.

With this background, a recent meta-analysis of 26 studies evaluating methotrexate dosing for ectopic pregnancy by Barnhart and colleagues showed an odds ratio of 1.96 higher likelihood of rupture with use of single-dose methotrexate over multidose therapy. Controlling for initial ß-hCG value and the presence of cardiac activity, the failure rate with single-dose therapy was almost five times greater (odds ratio 4.75). What makes direct comparisons of these protocols even harder is that based on the data from this meta-analysis, 15% of patients under a single-dose protocol actually receive more than one dose, while 10%, 23%, and 14% of those under a multidose protocol actually need only 1, 2, or 3 doses of methotrexate, respectively.

Two-Dose Methotrexate Protocol

In recognition that the single-dose protocol has fewer visits and fewer injections but may have a higher failure rate, a two-dose protocol was introduced. This protocol uses the dosing and monitoring parameters of the single-dose protocol but gives a second dose of 50 mg/m^2 on day 4, when only a serum ß-hCG would have been drawn according to the single-dose protocol. No leucovorin rescue is used in this protocol. The same logic is used to determine if more methotrexate is needed based on the difference between the serum ß-hCG on day 4 and day 7. In the single-dose protocol, a second dose would be given on day 7 if the ß-hCG did not decline by at least 15% between day 4 and day 7 (Table 5.2). In the two-dose protocol, a second dose is given on day 4, and a third dose can be given on day 7 if the ß-hCG did not decline by a least 15% between days 4 and 7. Thus, the two-dose protocol gives two doses in the first week and has provisions to give up to two more. In this way, the number of visits and surveillance laboratories are the same as the single dose, but more methotrexate is given sooner in hopes of maximizing success rate (without increasing complexity or the number of visits). This regimen was demonstrated to be safe in a three-center trial; the overall success rate will be determined as it is used more widely.

TABLE 5.4 Treatment with Multiple-dose Methotrexate

Indications for systemic methotrexate for uncomplicated ectopic pregnancy:

- No rupture (hemodynamic stability)
- UTZ size ≤4 cm
- ß-hCG ≤10,000 mIU/mL
- Positive fetal heartbeat: proceed with caution
- Willingness of patient to comply with subsequent treatment monitoring

UTZ, ultrasound; hCG, human chorionic gonadotropin.

Safeguards and Counseling

Prior to instituting methotrexate therapy, physicians should evaluate baseline laboratory values. The patient should be screened with a complete blood count, liver function tests, and serum creatinine. A chest x-ray should be considered in women reporting a history of prior pulmonary disease due to their risk of developing methotrexate-related interstitial pneumonitis.

During methotrexate therapy, a woman should be examined by a single examiner only once, to diminish the risk of causing mechanical trauma and tubal rupture. The physician and the patient must recognize that transient pain ("separating" or "tearing pain") is common. Transient pelvic pain from tubal bleeding or hematoma formation at the ectopic site frequently occurs 3 to 7 days after the start of therapy, lasts 4 to 12 hours, and is presumably due to tubal abortion. Perhaps the most difficult aspect of methotrexate therapy is learning to distinguish the transient abdominal pain of successful therapy from that of a rupturing ectopic pregnancy. Physicians must therefore carefully observe for clinical indications that an operation is necessary (Tables 5.4, 5.5). Thus, surgical intervention is required when pain is worsening and persistent beyond 12 hours. Orthostatic hypotension or a falling hematocrit should lead to immediate surgery. Sometimes, it is necessary to hospitalize the

patient with pain for observation (usually about 24 hours) to insure a correct diagnosis. In addition, colicky abdominal pain is common during the first 2 or 3 days of methotrexate therapy, and the woman should avoid gas-producing foods such as leeks and cabbage. Women receiving methotrexate should discontinue prenatal vitamins, as they contain folic acid, and should especially avoid any additional folic acid supplementation. Finally, the patient should avoid exposure to the sun because photosensitivity can be a complication of methotrexate.

TABLE 5.5 Dealing with Methotrexate Failure

Operate when high suspicion of rupture:

- Pain is severe and persistent, regardless of β-hCG levels
- Falling hematocrit
- Orthostatic hypotension

Consider operating when signs of treatment failure:

- Levels of β-hCG do not decline by at least 15% between days 4 and 7 of treatment
- Levels of β-hCG increase or plateau after first week of

Methotrexate by Direct Injection

In 1987, Feichtinger and Kemeter instilled 10 mg (1 mL) of methotrexate into an ectopic gestational sac under transvaginal ultrasonography, and resolution occurred within 2 weeks. Direct injection delivers concentrations of methotrexate to the site of implantation at higher concentrations than those achieved with systemic administration. Less systemic distribution of the drug should decrease the overall toxicity. However, this approach has the substantial disadvantage of requiring laparoscopic or ultrasound needle guidance.

Outcomes in 21 studies involving direct injection of methotrexate with either laparoscopic or transvaginal ultrasound guidance are presented in Table 5.3. Between 1989 and 1997, 75.1% of 668 cases of ectopic pregnancy were treated successfully with methotrexate by direct injection, and some patients required more than one injection. Tubal patency and subsequent pregnancy rates were comparable to conservative laparoscopic surgery and systemic methotrexate: 80.2% of the women tested had patent oviducts, and of the women desiring pregnancy, 57.2% had a subsequent intrauterine pregnancy and 5.9% developed a recurrent ectopic pregnancy.

Randomized, controlled trials have demonstrated successful treatment with methotrexate by direct injection in 86.2% of the patients. Again, successful therapy included some patients who received more than one injection. Tubal patency was present in 85.1% of the women evaluated, and intrauterine pregnancy occurred in 73.1% of the women desiring subsequent fertility. One of the earlier randomized, controlled trials was discontinued because three of seven patients assigned to laparoscopic injection of methotrexate required additional laparoscopic surgery. Even with the higher success rate in the randomized trials, this technique is more cumbersome than systemic methotrexate. Given the overall tolerability and high success rate of systemic methotrexate, it continues to be the most accepted nonsurgical treatment modality.

Side Effects

High doses of methotrexate can cause bone marrow suppression, hepatotoxicity, stomatitis, pulmonary fibrosis, alopecia, and photosensitivity. These side effects are infrequent in the short treatment schedules used in ectopic pregnancy and can be attenuated by the administration of leucovorin (citrovorum factor). The side effects of methotrexate resolve within 3 to 4 days after the therapy is discontinued. Impaired liver function is the most common side effect. Other side effects include stomatitis, gastritis and enteritis, and bone marrow suppression. Local therapy by direct injection of methotrexate into the ectopic gestation resulted in fewer side effects, likely because of less systemic absorption. Even with local injection, impaired liver function tests, gastritis and enteritis, and bone marrow suppression can occur. Additional case reports exist in the literature. Cases of life-threatening neutropenia and febrile morbidity can occur after single or multidose intramuscular methotrexate, requiring hospitalization. Cases of transient interstitial

pneumonitis from methotrexate therapy for ectopic pregnancy have been observed. Reversible alopecia (a loss of 33% to 50% of the scalp hair) on two separate occasions following single-dose therapy for an ectopic pregnancy has also been reported. Rarely, hematosalpinx and pelvic hematoceles have been noted as late sequelae of methotrexate following the normalization of β-hCG levels. These patients have pelvic pain, abnormal bleeding, and a pelvic mass, requiring surgical intervention, 3 to 5 months after therapy.

Fortunately, the side effects reported with methotrexate used to treat ectopic pregnancy have mostly been minor. Out of 100 patients treated in one study, only two patients developed stomatitis and three had transient elevation of transaminases, all resolving spontaneously. Another study that used the single-dose regimen had only one patient reporting nausea and vomiting following methotrexate treatment. Thus, with its overall good tolerability, methotrexate remains the first choice before surgical therapy.

Direct Injection of Cytotoxic Agents

Prostaglandins, hyperosmolar glucose, potassium chloride, and saline by direct injection have been tried as therapeutic alternatives to methotrexate. The limited experience with these agents, poor success rates, and the need for laparoscopic or transvaginal aspiration makes these unattractive treatment alternatives.

Evidence-Based Recommendation

Multiple-dose systemic methotrexate is the first-line medical treatment for ectopic pregnancy. Nearly half of patients under a multidose protocol will require fewer doses for ectopic pregnancy resolution. (Strength of recommendation: A.)

Surgical Treatment

Since the first successful salpingectomy (resection of involved fallopian tube segment with implanted trophoblastic tissue) performed by Tait in 1884, ectopic pregnancies

traditionally have been treated by salpingectomy, usually by laparotomy. Historically, ectopic pregnancies were diagnosed at the time of emergency surgery, when concern for the patient's life superseded any concerns for her future fertility. It was not until 1953, when Stromme performed the first conservative procedure (salpingostomy, or removal of only the ectopic pregnancy with conservation of the tube) for ectopic pregnancy, that subsequent successful pregnancy outcomes were reported, confirming the potential for fertility preservation after salpingostomy. These surgical techniques have been modified for endoscopy. The laparoscopic approach is associated with less blood loss, less analgesia requirement, and a shorter duration of hospital stay. In addition, cost analysis has demonstrated significant savings in randomized trials. When evaluating subsequent fertility, intrauterine pregnancy rates are comparable for laparoscopy and laparotomy, as are rates of recurrent ectopic pregnancy.

Ruptured Ectopic Pregnancy

Early diagnosis and treatment of ectopic pregnancy avoids rupture in most cases. In the 1970s, 13.5% to 17.8% of patients with ectopic pregnancies arrived for treatment in hypovolemic shock, whereas in the early 1980s, only 4.4% of patients arrived in this condition. Today, either laparotomy or laparoscopy with salpingectomy is the first choice for rupture.

Once contraindicated over concern of decreased venous return from intraperitoneal insufflation, laparoscopic salpingectomy can be successful in patients in hypovolemic shock. Still, in critical instances when expeditious entry into the peritoneal cavity and tamponade of bleeding is necessary, rapid laparotomy to stem the bleeding is the preferred method. Nearly all patients in hypovolemic shock require blood transfusions; those with large red blood cell requirements also need fresh frozen plasma. In the hands of a highly skilled laparoscopist, with adequate cardiac monitoring and anesthesia, laparoscopic salpingectomy is an acceptable alternative to laparotomy even when there has been extensive intraperitoneal bleeding. At present, it is the surgeon's choice of laparoscopy or laparotomy for ruptured ectopic pregnancy.

Stable Ectopic Pregnancy

If methotrexate is contraindicated, laparoscopic salpingostomy is the first surgical choice. Alternatively, salpingectomy can be performed either during laparotomy or laparoscopy by using cautery or sutures (laparoscopic or endoloops). A review of data from nine studies showed that subsequent to salpingostomy, 53% of patients have intrauterine pregnancies compared with 49.3% after salpingectomy. Recurrent ectopic pregnancy rates were slightly higher after conservative surgery, 14.8% compared with 9.9%. Other studies have suggested a higher intrauterine pregnancy rate in women after salpingostomy, but at the cost of a possible higher risk of recurrent ectopic after 3 years of follow-up. Laparoscopic salpingectomy is preferred over salpingostomy in cases of uncontrollable bleeding not resolving with conservative measures when extensive tubal damage is present, if the ectopic pregnancy has recurred in the same tube, if it is a large pregnancy (>5 cm), and if sterilization is desired.

The recommended conservative surgical procedure for an ampullary ectopic pregnancy is linear salpingostomy, because the ectopic nidation typically is located between the endosalpinx and serosa rather than in the tubal lumen. A linear salpingostomy is created through a longitudinal incision by electrocautery, scissors, or laser over the bulging antimesenteric border of the fallopian tube. The products of conception are removed with forceps or gentle flushing or suction. After maintaining hemostasis, the incision is left to heal by secondary intention or closed primarily. There appears to be no additional benefit to suturing the tubal defect closed, as studies have shown no difference in subsequent tubal patency rates, postoperative adhesion rates, or cumulative pregnancy rates.

Historically, isthmic segment pregnancies were routinely treated with segmental excision followed by intraoperative or delayed microsurgical anastomosis. The tubal lumen is narrower and the muscularis is thicker in the isthmus than in the ampulla, predisposing the isthmus to greater damage after salpingostomy and greater rates of proximal tubal obstruction. With today's high success rates of in vitro fertilization (IVF), tubal anastomosis

is rarely performed and the resected tubal segment is bypassed altogether by use of ART. Manual fimbrial expression, also known as milking, should not be used unless the trophoblastic tissue is already aborting spontaneously through the fimbriae.

Laparoscopic salpingostomy and fimbrial expression have been evaluated in 32 studies and are presented in Table 5.3. Of the 1,626 patients treated between 1980 and 1997, treatment was successful in 93.4% (defined as requiring no additional therapy). Of the patients evaluated for tubal patency by using either hysterosalpingography or laparoscopy, 76% had patent tubes. Of the women desiring subsequent fertility, 56.6% had an intrauterine pregnancy and 13.4% developed another ectopic pregnancy.

Persistent Ectopic Pregnancy Following Salpingostomy

Persistent ectopic pregnancy is diagnosed by a plateauing or rising ß-hCG concentration following conservative surgical therapy. The ß-hCG level should be checked on postoperative day 1, keeping in mind that a drop of <50% from the preoperative level has been associated with a relative risk of 3.51 for persistent products of conception. Risk factors for persistent ectopic include a very early gestation, a small ectopic of <2 cm, or high starting concentrations of

---

ß-hCG preoperatively. Although the number of reported cases is small, women with persistent ectopic pregnancies are treated successfully by using single-dose systemic methotrexate.

The increased rate of persistent ectopic pregnancies has been a criticism of conservative laparoscopic therapy when compared with laparotomy. A decision analysis that compared prophylactic methotrexate with linear salpingostomy against no methotrexate in a group of 1,000 women concluded that prophylactic methotrexate at the time of surgery was preferable if certain clinical conditions are met as follows: (a) the incidence of persistent ectopic pregnancy is greater than 9% with observation alone after salpingostomy, (b) the incidence of persistence is less than 5% when prophylactic methotrexate is given, (c) the probability of ectopic pregnancy rupture is greater than 7.3% with a persistent ectopic pregnancy, and (d) the complication rate associated with prophylactic methotrexate is less than 18%. Because the great majority of clinical circumstances meet these recommendations, prophylactic methotrexate administration is recommended.

Evidence-Based Recommendation

Due to lower morbidity and equal efficacy, laparoscopic surgery is preferable to laparotomy in the treatment of bleeding or complicated ectopic pregnancy. Salpingectomy by laparotomy is reserved for ectopic ruptures with a hemodynamically unstable patient. (Strength of recommendation: A.)

Ectopic Pregnancy and Assisted Reproductive Technology

Incidence

The risk of ectopic pregnancy is increased in patients undergoing an ART procedure. This increased risk has been attributed to the cause of infertility for which most patients seek treatment, that is, tubal factor infertility. Information on ectopic pregnancies resulting from ART comes from data obtained from institutions in the United States and Canada reporting to the Society for Assisted Reproductive Technology. The rate of pregnancies that resulted in ectopic pregnancies after IVF in 1999 was 3%, with newer figures from 2004 reporting the ectopic rate to be about 2%. The latter included outcome of ART cycles using fresh, nondonor eggs or embryos in approximately 76,000 embryo transfers. This lower percentage likely reflected the trend toward performing salpingectomies when hydrosalpinges are present to improve the success of ART.

Location

As in naturally occurring ectopic pregnancies, the fallopian tube is the most common site for ectopic pregnancies following IVF. Data obtained from three case-control studies reveal that 82.2% of ectopic pregnancies were tubal. When tubal location was specified, 92.7% were ampullary and 7.3% interstitial. Extratubal ectopic nidations were as follows: 4.6% ovarian or abdominal, 1.5% cervical, and 11.7% heterotopic pregnancies (Fig. 5.1).

Tubal Pathology

Tubal pathology is the most important predisposing factor for ectopic pregnancy in patients undergoing IVF. Ectopic pregnancies are four times higher in patients with tubal factor infertility compared with patients with normal tubes. Hydrosalpinges are associated more commonly with ectopic pregnancy than other types of tubal pathology. Prior tubal reconstructive surgery (salpingostomy) increases the risk of ectopic pregnancy by 10% above that in patients with tubal factor infertility without prior surgery.

Thus, it is not surprising that patients with previous pelvic inflammatory disease have a sixfold increase in ectopic pregnancy after IVF. However, a history of prior ectopic pregnancy does not seem as important a risk factor in IVF cycles as in natural cycles.

Salpingectomy, particularly with hydrosalpinx, has been shown to decrease risks of ectopic pregnancy while increasing pregnancy rates after IVF. Meta-analysis has demonstrated that the presence of hydrosalpinges decreases the chance for viable pregnancy by approximately 50% when compared with patients with tubal disease but without hydrosalpinges. The implantation rate was also noted to be 50% lower with a higher chance of miscarriage and ectopic gestation. The ultimate conclusion is that when a hydrosalpinx is present, there is a decreased pregnancy rate with resultant decreased delivery rate following IVF. In addition, patients who undergo salpingectomy or proximal tubal occlusion prior to oocyte retrieval and transfer are at decreased risk for pelvic infection as well as future ectopic pregnancy.

Ovulation Induction

Hormone alterations during ovulation induction theoretically alter tubal function. In animal models, estrogen administration results in functional tubal blockage and embryo

arrest in the fallopian tube. In humans, steroid hormones alter tubal function and contractility, thus affecting tubal peristalsis. There remains controversy as to whether ovulation-inducing agents, including clomiphene citrate, increase ectopic pregnancy rates, but it will be difficult to separate out the impact of the therapeutic agent from occult tubal disease.

Embryo Transfer

Knutzen and associates injected 40 µL of radiopaque fluid in mock embryo transfers and found that the material entered the tubes either partially or totally in 44% of subjects, suggesting that misplacement of embryos into the fallopian tubes leads to ectopic pregnancy. Embryo catheter placement also was implicated in the increased risk of ectopic pregnancies, which occurred more frequently in patients who underwent deep fundal transfer versus midcavity placement. Although transfer techniques may increase the chances of embryos reaching the fallopian tubes, it is the tubal pathology preventing the embryos from moving back into the uterus and resulting in an ectopic pregnancy.

Heterotopic Pregnancy

Heterotopic pregnancies occur in 1% to 3% of pregnancies following ART procedures and are usually diagnosed incidentally on routine follow-up ultrasonographic studies. This increased prevalence of heterotopic pregnancies following ART may be related to ovarian hyperstimulation and multiple ovum development. Of 111 reported heterotopic pregnancies following ART, 88.3% were tubal, 6.3% cornual, 2.7% abdominal, 1.8% cervical, and 0.9% ovarian.

Evidence-Based Recommendation

Heterotopic and extratubal ectopic pregnancies are more frequent following ART than with natural cycles. Salpingectomy or proximal tubal occlusion of a preexisting hydrosalpinx prior to IVF helps to prevent tubal ectopic pregnancies while increasing pregnancy rates following ART. (Strength of recommendation: B.)

Expectant Management

Ectopic pregnancies may resolve spontaneously. In a cavalier experiment in 1955, Lund hospitalized 119 women with ectopic pregnancy for observation. All were at least 6 weeks gestation. Some required multiple blood transfusions, and many were hemodynamically unstable. However, 68 resolved without surgery being required. Twelve additional studies reported in the literature since Lund's study found similar results (Table 5.3). Of the ectopic pregnancies, 67.2% resolved without surgery. Thus, both conservative medical and surgical therapy overtreats at least 50% of women with ectopic pregnancy. Falling ß-hCG levels under 1,000 mIU/mL have been followed with conservative expectant management. Although patients with an equivocal diagnosis of ectopic pregnancy may be treated in this fashion, there are no data to support expectant management in clinical practice. In

addition, despite close follow-up and even in the context of declining ß-hCG levels, tubal rupture may still occur.

Evidence-Based Recommendation

Expectant management of ectopic pregnancy may be considered an appropriate conservative therapy for some patients with low initial (1,000 mIU/mL) and falling ß-hCG levels. Both clinicians and patients need to be aware of the potential risks of choosing expectant management over proven therapies.

Cost Analysis

The last estimated U.S. costs for ectopic pregnancy are over 15 years old. In 1990, total costs for ectopic pregnancies were estimated to be $1.1 billion. Direct costs, expenditures for health care, accounted for 77% of the total costs, and the remainder were incurred as a result of lost wages or household responsibilities not performed due to illness (indirect costs). Direct costs from hospital charges were estimated at $6,079 per case, with hospital accommodations (mean length of stay, 3.47 days) and operating room charges accounting for the majority of the hospital expense, 36% and 40%, respectively. An additional $3,254 for professional fees increased inpatient charges to $9,333, and $149 for postoperative follow-up visits increased the total direct cost to $9,482 per case. Indirect costs for a 28-day disability were estimated at $250.5 million, 67% as a result of lost wages and the remainder from lost household duties. These costs are likely substantially higher today.

European studies by Mol and colleagues have attempted to evaluate costs, but it is important to remember that they figured in longer hospital stays and more sick days than are customary in the United States and that the costs they estimated are within a socialized medical system. A study undertaken to compare the costs of systemic methotrexate with surgery concluded that there would be a reduction in overall costs if patients were treated without confirmatory laparoscopy when ß-hCG levels were below 3,000 mIU/mL; otherwise, there was not a substantial cost saving over surgery. Because a confirmatory laparoscopy is no longer required for diagnosis, the lower cost for medical therapy is more realistic. Compared with the cost of a laparoscopic salpingostomy, methotrexate results in an estimated 20% decrease in the cost of treatment.

A decision analysis by Morlock and associates created a model to estimate the costs incurred by treating ectopic pregnancy by methotrexate or by laparoscopic salpingostomy. They felt that such an analysis was important because although previous studies found cost advantages with

---

methotrexate, they had not adequately considered failure of ectopic resolution after only one dose of methotrexate or the potential side effects and complications of methotrexate use. They also felt that several European studies had calculated the costs of inpatient laparoscopy, not currently standard care in the United States where treatment is routinely done in the outpatient setting. Incorporating all of the assumptions about failed methotrexate treatment and costs of surgery and hospitalization for medical failures, the authors found a $3,011 cost saving with methotrexate treatment compared with

laparoscopy. Even when they altered the model by assuming the lowest resolution rate for methotrexate-treated ectopic pregnancy of 57% and highest complication rates, the model still supported the use of methotrexate with a saving of $760.

Finally, it should be noted that Ailawadi and colleagues performed a decision analysis comparing the complicating rate and cost of diagnosis ectopic pregnancy with evaluation of the uterus prior to medical management versus presumptively treating women with a presumed ectopic pregnancy with methotrexate without confirming the diagnosis with a dilation and curettage (D&C). Surprisingly, the outcomes were quite similar. Thus, there is no advantage to taking the "shortcut" of treating women presumed to but not confirmed to have an ectopic pregnancy in terms of cost and/or complications. Data supporting the definitive diagnosis was that there were fewer visits required by patients after performance of an evacuation of the cavity, as fewer women needed medical management and evaluation of serial ß-hCG concentration. Moreover, a more accurate prognosis can be given to a woman regarding recurrence of miscarriage, ectopic pregnancy, or overall fecundity if a miscarriage is accurately distinguished from an ectopic pregnancy.

Evidence-Based Recommendation

Systemic methotrexate for unruptured ectopic pregnancy is less expensive than surgery, and direct costs are decreased substantially with methotrexate therapy. In addition to its cost effectiveness, systemic methotrexate does not subject patients to the risks of surgery. This cost benefit, however, diminishes with higher ß-hCG titers and even disappears with levels greater than 3,000 mIU/mL because of single-dose methotrexate treatment failures and increased complications. (Strength of recommendation: B.)

Rare Types of Ectopic Pregnancy

Abdominal Pregnancy

The incidence of abdominal pregnancy is estimated at 1 in 8,000 births and represents 1.4% of all ectopic pregnancies. The prognosis is poor, with an estimated maternal mortality rate of 5.1 per 1,000 cases. The risk of dying from an abdominal pregnancy is 7.7 times higher than from other forms of ectopic pregnancy. The high rate of morbidity and mortality from abdominal pregnancy often results from a delay in diagnosis.

Abdominal pregnancies can be categorized as primary or secondary. These ectopic pregnancies may become apparent anywhere throughout gestation, from the first trimester to fetal viability. Symptoms may vary from those considered normal for pregnancy to severe abdominal pain, intra-abdominal hemorrhage, and hemodynamic instability. Primary abdominal pregnancies are rare and are thought to occur as a result of primary peritoneal implantation. They usually abort early in the first trimester due to hemorrhagic disruption of the implantation site and hemoperitoneum. Secondary abdominal pregnancies occur with reimplantation after a partial tubal abortion or intraligamentary extension following tubal rupture. Historical criteria to distinguish between primary and secondary abdominal pregnancies are moot, because treatment is guided by the clinical picture.

Ultrasonography is the diagnostic tool of choice and usually can identify the empty uterus along with the extrauterine products of conception. If the fetus is near viability, hospitalization is recommended. If time permits, bowel preparation, administration of prophylactic antibiotics, and adequate blood replacement should be made available prior to an operative delivery. Unless the placenta is implanted on major vessels or vital structures, it should be removed. Although complications may occur, including sepsis, abscess formation, secondary hemorrhage, intestinal obstruction, wound dehiscence, amniotic fluid cyst formation, hypofibrinogenemia, and preeclampsia, the placenta can be left in place to prevent further hemorrhage at the time of surgery. In contrast to the typical tubal ectopic pregnancy, methotrexate is unlikely to accelerate retained placental absorption because the trophoblastic cells are no longer actively dividing.

Ovarian Pregnancy

Ovarian pregnancy, the most common form of abdominal pregnancy, is rare, accounting for less than 3% of all ectopic gestations. Clinical findings are similar to those of tubal ectopic gestations: abdominal pain, amenorrhea, and abnormal vaginal bleeding. In addition, hemodynamic instability as a result of rupture occurs in 30% of patients. Women with ovarian pregnancies are usually young and multiparous, but the factors leading to ovarian pregnancies are not clear.

The diagnosis usually is made by the pathologist because many ovarian pregnancies are mistaken for a ruptured corpus luteum or other ovarian tumors. Only 28% of cases were diagnosed correctly at time of laparotomy. The recommended treatment is cystectomy, wedge resection, or

---

oophorectomy during laparotomy, although laparoscopic removal has been successful.

Cornual Pregnancy

Cornual or interstitial pregnancy accounts for 4.7% of ectopic gestations and carries a 2.2% maternal mortality. Clinically, a pregnancy implanted at this site where the fallopian tube is traversing the muscular wall of the uterus is seen as a swelling lateral to the round ligament. Almost all cases are diagnosed after the patient is symptomatic. The most frequent symptoms are menstrual aberration, abdominal pain, abnormal vaginal bleeding, and shock, resulting from the brisk hemorrhage associated with uterine rupture. Due to myometrial distensibility, rupture is usually delayed, occurring at 9 to 12 weeks gestation.

A unique risk factor for interstitial pregnancy is previous salpingectomy, present in about 25% of patients. Only a high index of suspicion and repeated ultrasonographic examination with Doppler flow studies allows early diagnosis. With a timely early diagnosis, alternatives to the traditional cornual resection during laparotomy have been performed successfully. These include laparoscopic cornual resection, systemic methotrexate administration, local injection of methotrexate, potassium chloride injection, and removal by hysteroscopy. Regardless of the initial treatment attempted, if uncontrolled hemorrhage occurs, immediate laparotomy with uterine repair or hysterectomy is warranted to stop the blood loss.

Cervical Pregnancy

The incidence of cervical pregnancy ranges from 1 in 2,500 to 1 in 12,422 pregnancies. The most common predisposing factor is a prior D&C, present in 68.6% of patients. Interestingly, 31% of these were performed for termination of pregnancy. Other predisposing factors implicated in cervical pregnancies are previous cesarean delivery and IVF.

The most common initial symptom of cervical pregnancy is painless vaginal bleeding. These extrauterine pregnancies are usually diagnosed incidentally during routine ultrasonography or at the time of surgery for a suspected abortion in progress. In reported cases, 91% of patients sought treatment for vaginal bleeding, and 29.2% had massive bleeding. Not surprisingly, abdominal pain occurred with vaginal bleeding in only 25.8% of cases. The cervix is usually enlarged, globular, or distended. On occasion, it appears cyanotic, hyperemic, and soft in consistency. Sonography and magnetic resonance imaging have improved diagnosis of cervical pregnancy. Up to 81.8% of patients have been diagnosed correctly with ultrasonographic identification of the gestational sac in the cervix below a closed internal cervical os, with trophoblastic invasion into the endocervical tissue.

When the patient is hemodynamically stable, conservative therapy commonly is employed. There are no large studies—only several case series for clinical guidance. These have shown that use of methotrexate, local prostaglanding or hyperosmolar glucose injection, curettage, or a combination of these methods have been successful. Prior to curettage, uterine artery embolization minimizes the substantial risk of postevacuation hemorrhage. Systemic and local treatment with various agents carries an overall success rate of 81.3%. Unfortunately, massive hemorrhage may occur despite conservative measures, and hysterectomy may be the only lifesaving option.

Heterotopic Pregnancy

Heterotopic pregnancy is the coexistence of an intrauterine and ectopic gestation. In 1948, the spontaneous heterotopic pregnancy rate was calculated as 1 in 30,000 pregnancies, based on an ectopic pregnancy incidence of 0.37% and dizygous twinning rate of 0.8%. In the 1980s, the calculation rose to 1 in 10,000 due to an increased ectopic pregnancy rate. Today, heterotopic pregnancies occur in 1 in 3,889 to 1 in 6,778 pregnancies in the general population. Out of almost 133,000 pregnancies reported in the U.S. ART Registry between 1999 and 2002, 207 heterotopic pregnancies were reported, an incidence of about 1:640. In a review of 66 heterotopic pregnancies by Reece and associates, 93.9% were tubal and 6.1% ovarian.

Simultaneous existence of intra- and extrauterine pregnancies poses several diagnostic pitfalls. Heterotopic pregnancies are diagnosed in most cases after clinical signs and symptoms develop, and 50% of patients are admitted for emergency surgery following rupture. The delay in diagnosis is secondary to the finding of an intrauterine pregnancy, which provides false reassurance of absence of pathology, with the assumption that any symptoms will be self-limited.

Similar to tubal ectopic pregnancies, the most common complaint is lower abdominal pain.

Routine ultrasonography detects only about 50% of tubal heterotopic pregnancies, and the remainder are diagnosed during laparoscopy or laparotomy when patients become symptomatic. Serial levels of the ß-hCG are not helpful due to the effect of the intrauterine pregnancy.

If patients are hemodynamically unstable, exploratory laparotomy is warranted. If the diagnosis is suspected or the patient is symptomatic but hemodynamically stable, laparoscopy can be performed. Expectant management is not recommended, because ß-hCG levels cannot be monitored adequately and the course of the ectopic cannot be followed. Systemic methotrexate is contraindicated if a viable intrauterine pregnancy is present and desired. Local injection of methotrexate with potassium chloride has been noted as successful in a small case series.

Summary Points

- In most circumstances, ectopic pregnancy can be diagnosed before symptoms develop and treated definitively with few complications.
- Quantitative β-hCG testing, ultrasonography, and curettage allow early diagnosis of ectopic pregnancy and use of medical therapy as the initial therapy option.
- Conservative surgical therapy and medical therapy for ectopic pregnancy are comparable in terms of success rates and subsequent fertility. Medical therapy is the preferred choice because of the freedom from surgical complications and lower cost.
- Surgery is the treatment of choice for hemorrhage, medical failures, neglected cases, and when medical therapy is contraindicated.
- Multiple-dose methotrexate is preferable to single-dose methotrexate, direct injection, or tubal cannulation and is the first choice for unruptured, uncomplicated ectopic pregnancy.
- Laparoscopic salpingostomy or salpingectomy is favored for cases of intra-abdominal hemorrhage, medical failure, neglected cases, and complex cases when medical therapy is contraindicated.
- Prophylactic postoperative systemic methotrexate (a single dose) can prevent virtually all cases of persistent ectopic pregnancy following salpingostomy.
- Salpingectomy prior to IVF decreases ectopic pregnancy incidence while increasing pregnancy rates in select patients with preexisting tubal disease.

6

Genetics in Obstetrics and Gynecology

Kenneth Ward

Stating that “the rapid growth and clinical adaptation of genetically based information and technology are fundamentally changing the practice of medicine in general, and obstetrics and gynecology in particular,” the Council on Resident Education in Obstetrics and Gynecology added a seventh unit to the residency curriculum—a unit on genomics. The two fundamental paradigms in biology are that all health and disease have a molecular basis based on the deoxyribonucleic acid (DNA) “blueprint” and that phenotypes evolve through changes in the genome. Thus, *genomics*—the study of genes and their functions—has arguably become the central science of medicine.

Genetic variables affect most diseases. Mutations may cause or serve as a cofactor for disease; polymorphisms may protect against disease or affect responses to treatment. Genetic screening has become an increasingly important component of prenatal care. Recent discoveries have expanded the indications for cytogenetic or molecular genetic tests performed on chorionic villi, amniocytes, and fetal blood. First-trimester DNA-based prenatal diagnosis is now possible for hundreds of conditions. New technologies enable testing of a single cell for chromosomal or mendelian problems, allowing preimplantation testing of embryos, and minimally invasive screening using the small population of fetal cells, which are present in the maternal circulation. Gene therapy is being applied, even prenatally, to treat inborn errors and genetic diseases. The expansion of preventative and therapeutic options will provide additional impetus for genetic evaluation.

More than 25 million Americans have a diagnosed genetic disease. One percent of all newborns have a recognizable mendelian disorder; 0.5 percent have a chromosomal syndrome; and many more have a polygenic, multifactorial disorder. Most pregnancy losses and most congenital anomalies have genetic causes. Genes also play an important role in common gynecologic disorders such as leiomyomata, endometriosis, gynecologic cancers, and infertility. There are inherited tendencies to have multiple gestations, preeclampsia, gestational diabetes, and other pregnancy complications. Susceptibilities to infectious or teratogenic agents are usually genetically determined.

Recognizing that a condition is genetic enables us to find the gene responsible for the trait or illness, which can lead to improved means of, classification, diagnosis, prevention, and treatment. Correlation of the phenotype with the genotype often provides specific predictive insights. Because any DNA test can be performed prenatally, discovery of the

gene that causes a particular disease can give at-risk couples the necessary information to prepare for having an affected child, to consider prenatal therapy if available, or to choose to terminate the pregnancy.

Patients often have genetic illnesses that will affect pregnancy or their gynecologic care, illnesses that may remain undiagnosed unless physicians are thorough in their evaluation of unusual signs or symptoms. For example, a new obstetric patient presents with a wasted facial appearance, generalized weakness, and difficulty releasing her grip when shaking the physician's hand. Hopefully, this patient has already been evaluated and correctly diagnosed. If not, it is the obstetrician's responsibility to refer a patient with unusual signs and symptoms for evaluation. In this case, the patient has the classic signs of myotonic dystrophy, an autosomal dominant disorder. Formerly, myotonic dystrophy was a difficult diagnosis to establish in some patients, but the diagnosis can be made easily by using DNA analysis. The physician and this woman need to know that she is at significant risk for developing polyhydramnios, which could result in preterm labor; her fetus may have positional

---

deformities and is at risk for a severe, often fatal, neonatal form of myotonia; her labor is likely to be prolonged, and she may be unable to push in the second stage. If she requires a cesarean section, she may have undiagnosed cardiac problems, which place her at higher risk for anesthesia. If failure to recognize these risks results in a bad outcome, a lawsuit claiming negligence might be brought.

Patterns of Inheritance

Single Gene (Mendelian) Disorders

The observations that “like begets like” has been stated throughout recorded history, but current theories describing how genetic traits and illnesses are inherited are just over 100 years old. In the late 1800s, Mendel described how individual genetic traits were passed on from generation to generation. Single gene disorders (i.e., mendelian disorders) are conditions caused by a mutation at a single site in the DNA and inherited in the proportions predicted by Mendel's laws. These disorders can be dominant conditions in which the phenotype is expressed even when only one chromosome of a pair has a defect or recessive conditions that are only expressed if the defect exists on both chromosomes. Classically, these different modes of inheritance are revealed by pedigree analysis (Figs. 6.1, 6.2).

As more information about the tremendous variation that occurs at every locus becomes available, the distinctions between dominant and recessive conditions have become blurred. Dominance and recessiveness are attributes of the phenotype, not attributes of the gene or allele. They are empiric terms, and they depend on the sensitivity of the method used to describe the phenotype. The researchers must specify particular phenotypic features when describing inheritance. For instance, sickle cell anemia is a recessive disease only if the full-blown disease is considered, but it is a codominant condition if the hemoglobin is being analyzed by electrophoresis. The ABO blood group is an example of a trait in which both codominant and recessive inheritance is seen. The

retinoblastoma gene is a recessive tumor suppressor gene at the cellular level, but abnormalities in the gene are responsible for the autosomal dominant tendency to develop retinoblastomas and osteosarcomas.

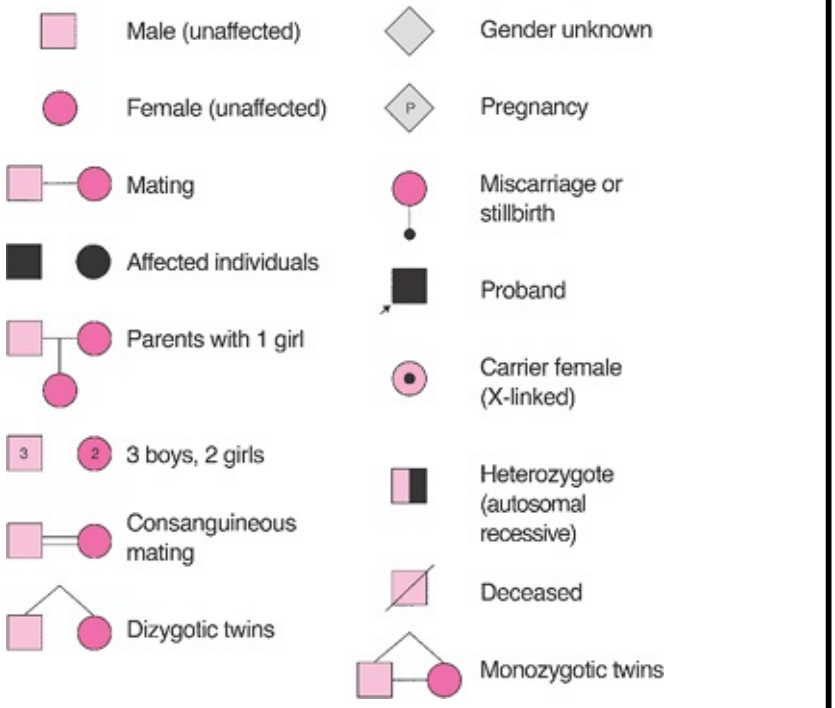

Figure 6.1 Symbols used to draw a pedigree.

In autosomal dominant conditions, the disease is expressed in persons who are heterozygous for the disease-causing mutation. McKusick's catalog of mendelian disorders describes more than 3,000 dominant conditions. Marfan syndrome, myotonic dystrophy, neurofibromatosis, achondroplasia, and Huntington disease are examples of autosomal dominant disorders. The probability of an affected person transmitting the abnormal gene to his or her children is 50% with each pregnancy. Typically, autosomal dominant conditions have less than 100% penetrance, and fewer than 50% of the offspring show signs of the disorder. Male and female offspring are usually affected with equal frequency and severity. The trait passes through one parental line only, and father to son transmission can occur. For highly penetrant, autosomal dominant conditions, the gene is expressed in each generation (i.e., vertical transmission). New mutations are relatively common, and on average, paternal age is advanced when isolated, sporadic, or new mutation cases appear. Autosomal dominant phenotypes often involve isolated or multiple *structural* defects. They can be extremely variable, and the onset of clinical features is often age dependent. Dominant disorders tend to be less severe than recessive diseases, but they are usually lethal in the rare persons who are homozygous for a dominant disease.

Autosomal recessive conditions are only expressed in persons in whom both versions (i.e., alleles) of the involved gene are abnormal. More than 1,500 autosomal recessive conditions have been described. Cystic fibrosis, sickle cell anemia, Tay-Sachs disease, and phenylketonuria are examples of autosomal recessive disorders. Male and female offspring

are affected with equal frequency and severity. Each parent is a heterozygous carrier, and abnormal genes are inherited from both parents. Each offspring of two carrier parents has a 25% chance of being affected, a 50% chance of being a carrier, and a 25% chance of being neither a carrier nor affected. If the recessive phenotype is extremely rare, consanguinity is usually found in the pedigree. Affected persons rarely have affected children; autosomal recessive inheritance shows a “horizontal” pattern in a pedigree, with typically only a single generation of siblings affected. Affected persons who mate with unaffected persons who are not carriers have only unaffected, carrier

offspring. Most autosomal recessive phenotypes are biochemical or enzymatic in nature, and they tend to be less variable and more severe than dominant conditions.

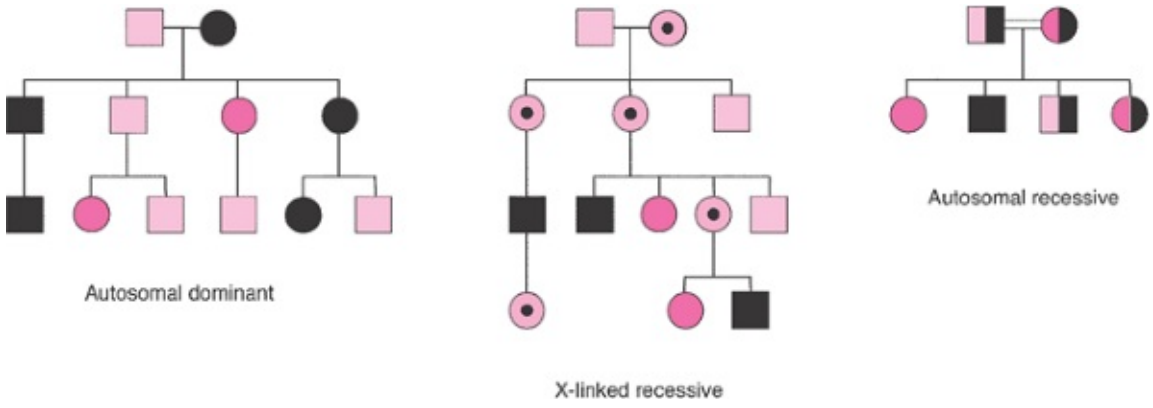

Figure 6.2 Patterns of inheritance revealed in pedigree analysis.

X-linked inheritance occurs when a trait is carried on the X chromosome. Boys are hemizygous for X chromosome genes, but girls can be homozygous or heterozygous. Of the 300 X-linked recessive diseases that are recognized, the hemophilias and Duchenne muscular dystrophy are the best known. Characteristics of X-linked recessive inheritance include a higher incidence of the disorder in male than female offspring. The mutant gene or disease is never transmitted directly from father to son, and all the daughters of an affected man are carriers. The trait is transmitted through carrier females, and affected males in the same kindred are related to one another through the females. X-linked dominant diseases are much rarer; examples include Alport syndrome, vitamin D resistant rickets, and incontinentia pigmenti. They appear twice as often in female as in male offspring. All daughters of an affected man have the disorder, but no sons are affected. Heterozygous affected women transmit the mutant allele at a rate of 50% to progeny of both sexes. If the affected woman is homozygous, all of her children will be affected.

Y-linked or holandric inheritance occurs when a trait is carried on the Y chromosome. Only male offspring are affected, and there is only male-to-male transmission. There are no known disease genes that are inherited in this fashion, but genes for gender determination, tooth size, and height occur on the Y chromosome.

Mitochondrial inheritance is also relatively uncommon; these traits and disorders are

inherited through mutations on the mitochondrial chromosome (Fig. 6.3). Since mitochondria are inherited exclusively with the cytoplasm of the egg, a woman who carries a disease will pass the disease to 100% of her offspring. Male carriers will pass the disorder to none of their offspring. Mitochondrial diseases often affect tissues dependent on the chemical energy produced by mitochondria; Leber optic atrophy and certain rare myopathies are examples.

Polygenic, Multifactorial Disorders

Multifactorial or polygenic inheritance is the most common form of inheritance. Even in the classic mendelian disorders described previously, there can be tremendous quantitative and qualitative differences in the phenotype between persons who have the same allele or the same genetic mutation. This variability can be evident as nonpenetrance of certain features (or the entire phenotype) and as differences in the severity of features, the frequency of cyclic or episodic events, or the age of onset of the first clinical sign of the disorder. The underlying genetic background of the affected person, including gender influences and limitations, can cause genetic variability. The phenotype may be further influenced by maternal factors such as cytoplasmic inheritance, the intrauterine environment, or imprinting. X-linked disorders can be altered by variations in X inactivation or lyonization. Each genotype undergoes subtle changes through somatic mutation, gene amplification, or transpositions and positional effects over time. Exogenous factors such as the environment, teratogens, medical intervention, and chance also influence variability.

Most congenital anomalies show multifactorial inheritance (Table 6.1). A common error made by some obstetricians is to counsel a patient that rare conditions will not occur repetitively in her family. If the birth defect in question has a strong genetic component or if there is an identifiable environmental or teratogenic component, which would recur, in subsequent pregnancy, the risks may remain high for that patient (Table 6.2). The rates may be even higher if a mendelian or chromosomal condition has gone unrecognized in the affected child. Before counseling patients about the recurrence risk of any birth defect, it is pertinent to review which syndromes are associated with that birth defect and ask whether any member of the family has those syndromes. When this requires skill or knowledge beyond the usual expertise of an obstetrician-gynecologist, referral to a medical geneticist is appropriate.

Multifactorial inheritance usually works according to a threshold model (Fig. 6.4). Several factors must

---

collaborate to cause a bodily function to go awry, and only after these factors reach some critical point is the phenotypic effect seen. Many different factors can affect the observed recurrence risk. The intrinsic heritability “or geneticness” of the condition is frequently the most important factor. This is usually determined by examining whether monozygotic twins are concordant for a particular condition relative to dizygotic twins. For instance, neonatal seizures show a very high heritability rate, with 85% to 90% concordance in

monozygotic twins versus 10% to 15% concordance in dizygotic twins. The population incidence of the condition is another important variable. The recurrence risk is higher for common disorders or within populations with a high incidence of the disorder. In disorders with a relatively high heritability, the recurrence risk of the disorder approximates the square root of the population incidence. There can be marked variation in the population frequency of different disorders and different ethnic groups. For instance, cleft lip occurs commonly in Native Americans, but African Americans have a ninefold lower incidence of cleft lip than the general population.

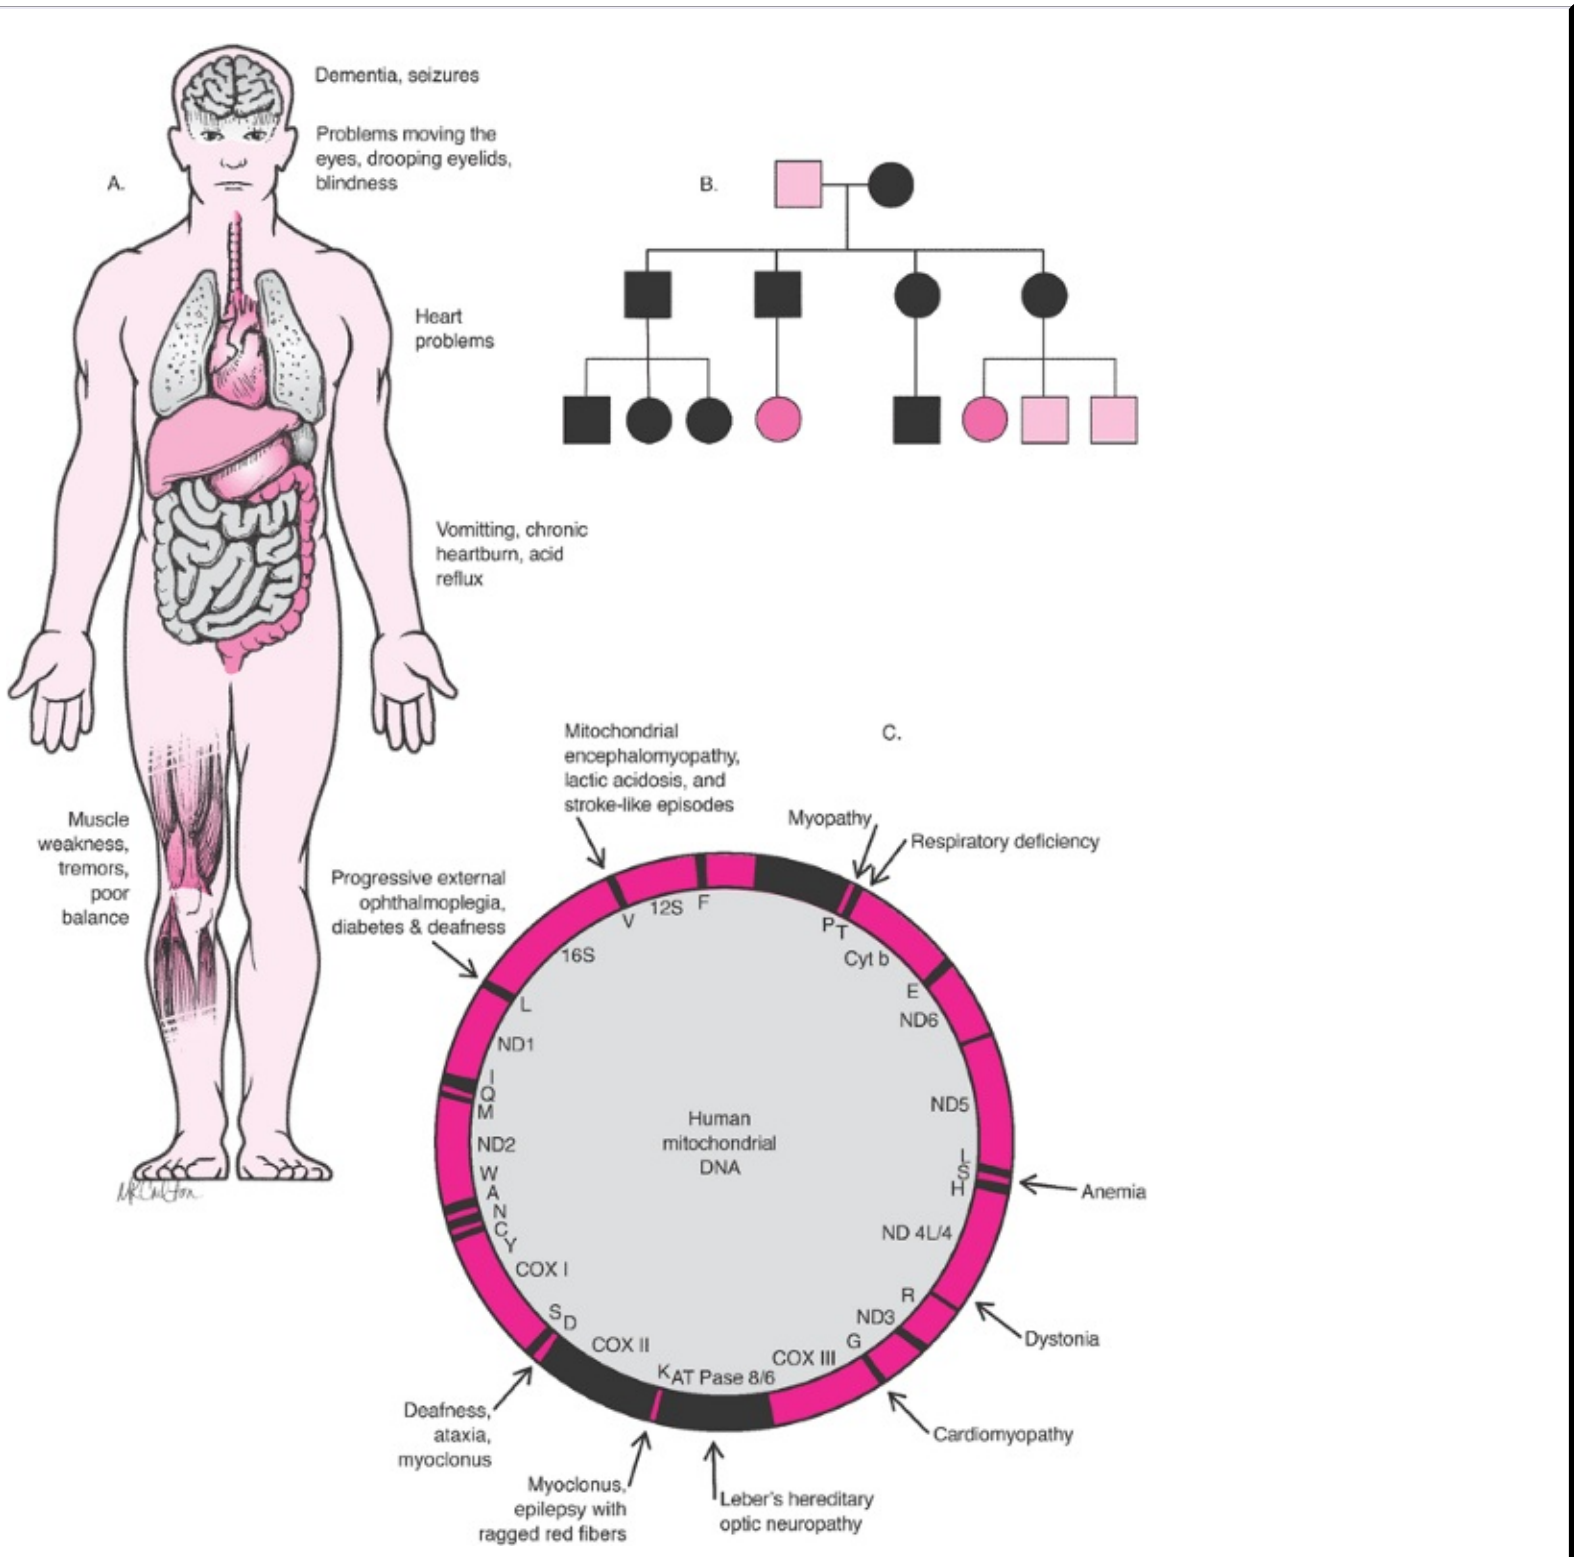

Figure 6.3 Mitochondrial diseases. **A:** Features of mitochondrial diseases. **B:**

Mitochondrial (cytoplasmic) pedigree analysis showing pattern of inheritance. **C:** Disease map of mitochondrial DNA.

TABLE 6.1 Types of Birth Defects

Anomaly is a structural feature that departs from the normal.
Association is a grouping of anomalies that frequently occur together but are not actual syndromes.
Deformation is an abnormal form, shape, or position caused by mechanical forces.
Disruption is morphologic defect resulting from extrinsic breakdown or interference with normal development.
Malformation is a morphologic defect resulting from abnormal development.
Sequence is a pattern of defects that results from single event early in pregnancy.
Syndrome is a recognizable pattern of structural defects often with a predictable natural history that can be identified on several patients, thus allowing diagnosis and classification.

TABLE 6.2 Empiric Recurrence Risks for Common Congen

	Normal Parents, One Affected Child, Risk for Subsequent Children	One Affected Parent, Risk for First Child	Identical Twin	Male:F Ratio
Cleft lip and palate	4.0% unilateral lip 2.5, bilateral lip +	3.2%	31%	2:1

	palate 5.6

P.S.	3%	—		
A.S.	2%	—		
Coarctation	2%	—		
Transposition	2%–3%			
AV canal		—		
Neural tube defect	3%(U.S.A.)	3%	23%	Varie defec

(Spinal bifida/Anencephaly)	5% (G.B.)			
whites				
Jews				
blacks				
Puerto Ricans				
Congenital dislocation hip	3.5%	3%–5%	35%	1:7
Pyloric stenosis	3.2% (if brother affected)	25.4% (if mother affected)		4:1
	6.5% (if sister affected)	4.2% (if father affected)		

VSD, ventricular septal defect; PDA, patent ductus arteriosus; AT
defect; P.S., pulmonary stenosis; A.S., aortic stenosis; AV, atriove

If the incidence of a congenital anomaly shows a sex bias, the recurrence risk is higher in the offspring (and other relatives) if the parent is the less frequently affected sex. For example, pyloric stenosis affects five times as many male as female offspring, and empiric data show that there is a 25% chance of producing an affected child if the mother

had pyloric stenosis at birth and only a 4% risk if the father is the affected parent. Similarly, the recurrence risk is higher when the gender of the affected child is the less frequently affected sex. Again, the risk of having another child with pyloric stenosis is 3.2% if the first affected sibling is a boy and 6.5% if the affected sibling is a girl. Hirschsprung disease, clubfoot, and cleft lip are examples of anomalies that are more common in male infants: cleft palate, anencephaly, hip dysplasia, and scoliosis are more common in female infants.

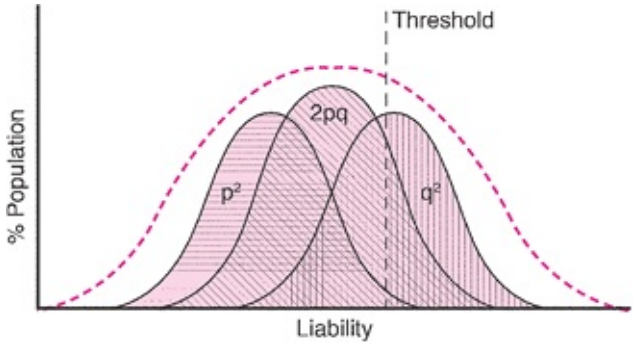

Figure 6.4 Polygenic multifactorial inheritance. Individuals homozygous for the p allele are at decreased risk; while individuals homozygous for the q allele are at increased risk for developing the disease. Heterozygous individuals have an intermediate risk.

The number of affected individuals in a kindred can affect the recurrence risk. The greater the number of family members who have already been affected with a multifactorial condition, the more likely it is that the genetic background is favorable for expression of this condition. After a couple has one affected child with cleft lip and palate, there is a 4% empiric recurrence risk. After two affected children, the risk rises to 10%. Consanguinity also increases the risk of recurrence because of the greater likelihood of deleterious genes being shared, but a more distant relationship from an affected person decreases the risk of recurrence.

The severity of the disorder often predicts the recurrence risk. An illustration of this is found in Hirschsprung disease; the recurrence risk is proportional to the length of the aganglionic segment of the colon. Neural tube defects are the most notable exception to this rule, because the recurrence risk for any neural tube defect appears to be the same whether the first affected child had anencephaly or a small spina bifida lesion.

Cytogenetic Disorders

Cytogenetic disorders are changes in the genome visible under light microscope. These gross lesions involve the loss or duplication of a large number of genes; multiple malformations and dysfunctions are usually observed clinically. Diagnostic clues for a cytogenetic disorder can range from subtle dysmorphic features to major structural malformations, particularly craniofacial, skeletal, cardiac, and genitourinary malformations. No individual anomaly is pathognomonic for a particular chromosomal syndrome; rather, it is the pattern that can be distinctive. There is tremendous overlap between patterns, and because nonchromosomal syndromes can mimic chromosomal abnormalities, obtaining a karyotype is always necessary to confirm the diagnosis. Cytogenetic disorders are usually associated with some degree of mental retardation and growth deficiency. Most have an increased rate of perinatal loss and premature mortality of live-born neonates. The rate of chromosome abnormalities is at least 40% to 60% in first-trimester abortuses, and the rates of abnormalities are also elevated in fetal deaths and preterm and post-term deliveries (Tables 6.3, 6.4). About 1 in 160 babies is born with a

genetic defect detectable by ordinary cytogenetic means (Table 6.5).

TABLE 6.3 Incidence of Chromosomal Aberrations in Pregnancy Losses at Various Gestational Ages

Gestational Age (in weeks)	With Chromosome Abnormalities (%)
<8	72.1
8–11	53.5
12–15	47.9
16–19	23.8
20–23	11.9
24–27	13.2
Stillbirths	6.0
Neonatal deaths	5.5

Data from Angell RR, Sandison A, Bain AD. Chromosome variation in perinatal mortality: a survey of 500 cases. *J Med Genet* 1984;21:39–44, with permission.

Cytogenetic studies have been used clinically for approximately 40 years. In the late 1950s, it was determined that humans have 46 chromosomes and that many of the recognized birth defect syndromes, such as Down

syndrome, Turner syndrome, and Klinefelter syndrome, have abnormalities of chromosome number or structure. Normally, the nucleus of most human cells contains two sets of chromosomes, with one set contributed by each parent. Each set has 22 autosomes and either an X or a Y sex chromosome (Fig. 6.5). Cells duplicate their chromosomes through *mitosis*; germ cells divide by a related process called *meiosis* (Fig. 6.6). Errors in meiosis or

mitosis can cause the resulting cells to have an incorrect number of chromosomes, called *aneuploidy* (Fig. 6.7).

TABLE 6.4 Types of Chromosomal Abnormalities in Spontaneous Abortuses

Type	Frequency (%)
Trisomy 14	3.7
Trisomy 15	4.2
Trisomy 16	16.4
Trisomy 18	3.0
Trisomy 21	4.7
Trisomy 22	5.7
Other trisomies	14.3

Hook EB, Hamerton, JL. The frequency of chromosome abnormalities detected in consecutive newborn studies—differences between studies—results by sex and by severity of phenotypic involvement. In Hook EB and Porter H, eds. *Population Cytogenetics: Studies in Humans*. Academic Press: New York, 1977;80–92.

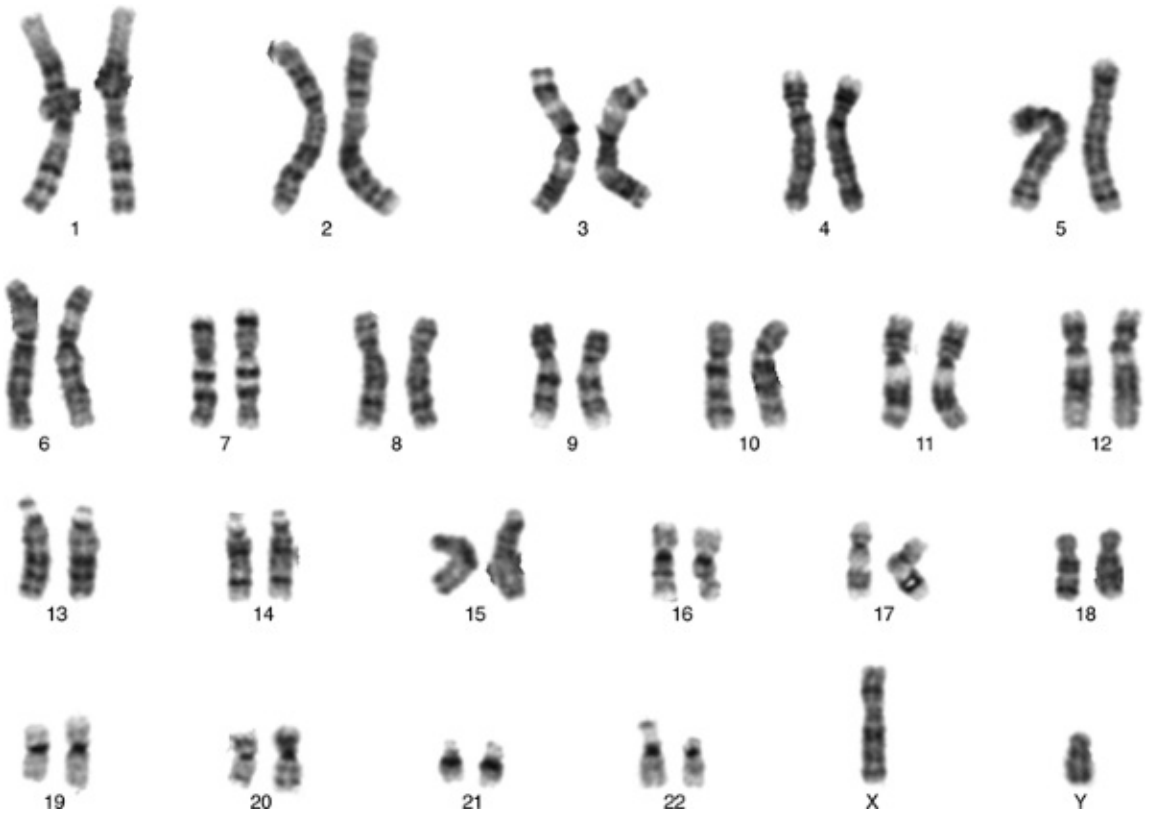

Figure 6.5 Normal human karyotype (46XY).

Metaphase chromosome preparations can be prepared from any cell undergoing mitosis. Typically, in order to obtain adequate numbers of cells, mitosis is induced artificially by using a mitogenic chemical such as phytohemagglutinin. The cells are then incubated in a dilute solution of an agent that poisons the mitotic spindle. The chromosomes are swollen by using a hypotonic salt solution, fixed on slide, and dried for staining. The stained chromosomes can be observed by light microscopy.

The dyes used to stain chromosome preparations reveal patterns of light and dark bands that reflect regional variations in the molecular composition of each chromosome. Giemsa is the most commonly used dye. Q-banding is a fluorescence technique that gives results

similar to the G-banding (i.e., Giemsa banding), while R-banding (i.e., reverse banding) gives a pattern opposite to that with G- or

Q-banding. T-banding specifically stains the telemetric regions of chromosomes, which can help to screen for missing regions at the ends of the chromosomes, and C-banding primarily stains the centromeric region of the chromosomes.

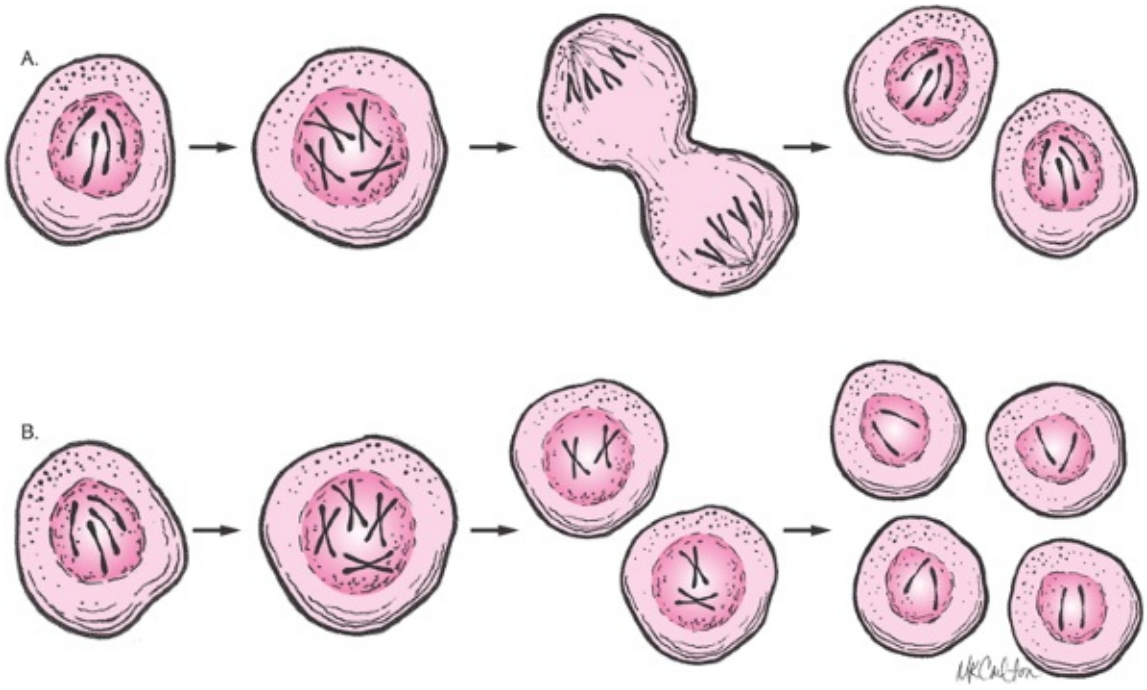

Figure 6.6 Mitosis and meiosis. The processes of mitosis **(A)** and meiosis **(B)** are complex and highly regulated. During mitosis, the chromosomes condense and attach to fibers that pull the sister chromatids to opposite sides of the cell. The cell then divides in cytokinesis, to produce two identical daughter cells. In meiosis, a second reduction division results in a haploid gamete—a gamete with only one member of each chromosomal pair.

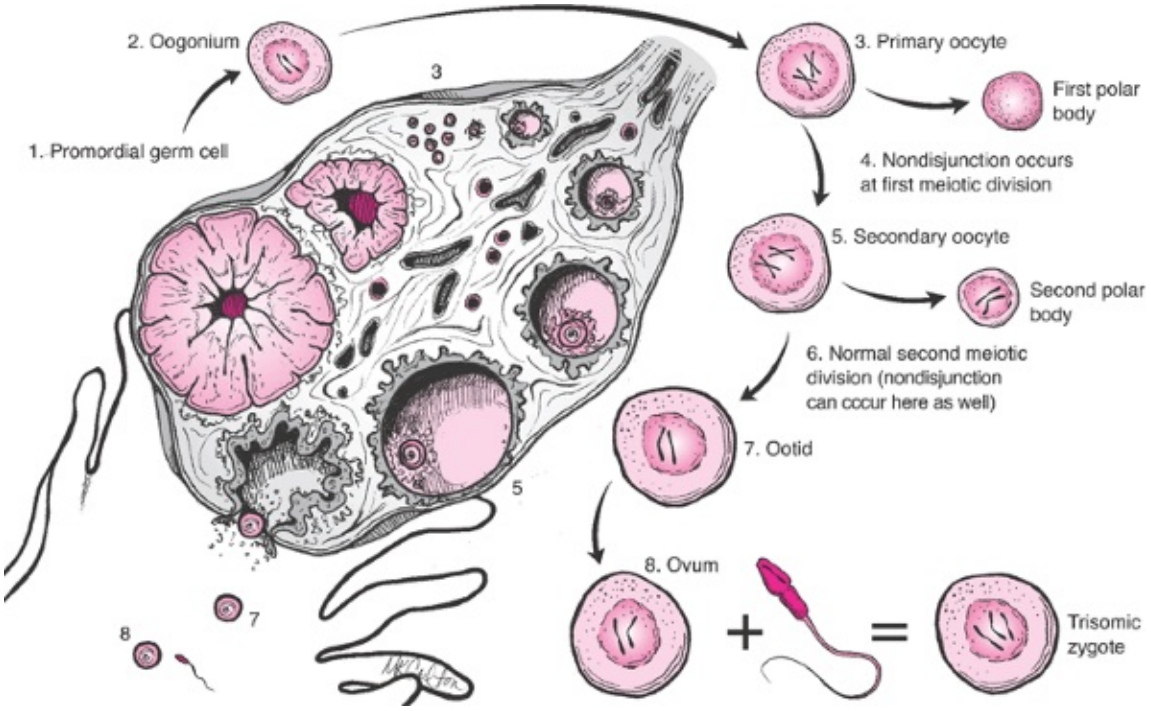

Figure 6.7 Nondisjunction. Two sister chromatids are abnormally "stuck together" and travel into the same daughter cell.

Differences in the size of the chromosomes, the banding pattern, and the centromere position allow the 24 chromosomes to be differentiated from each other in an analysis called a *karyotype*. The most common features looked for on a karyotype include the presence of aneuploidy (i.e., abnormal number of chromosomes) or structural chromosome abnormalities such as deletions, inversions, insertions, or translocations (Table 6.6; Fig. 6.8).

Because the technology to study cytogenetic disorders is well established, there is greater clinical experience with this than with other types of genetic testing. There are several well-defined indications for obtaining a fetal karyotype (Table 6.7). Pregnant women who are 35 years old or older are routinely offered a fetal karyotype because trisomy tends to occur more commonly with advancing maternal age (Table 6.8). Other indications for obtaining a fetal karyotype include having a previous child with an abnormal karyotype, parental chromosomal rearrangements, unexplained intrauterine growth retardation (IUGR), and an abnormal biochemical or an abnormal sonographic (nuchal translucency) screen. Many fetal anomalies associated with karyotypic abnormalities can now be visualized by using high-resolution ultrasound (Table 6.9). A fetal structural abnormality detected by ultrasound is another frequent indication for obtaining a fetal karyotype. In 2007, the American College of Obstetrics and Gynecology (ACOG) stated that all women, regardless of age or risk factors, should have the option of invasive testing.

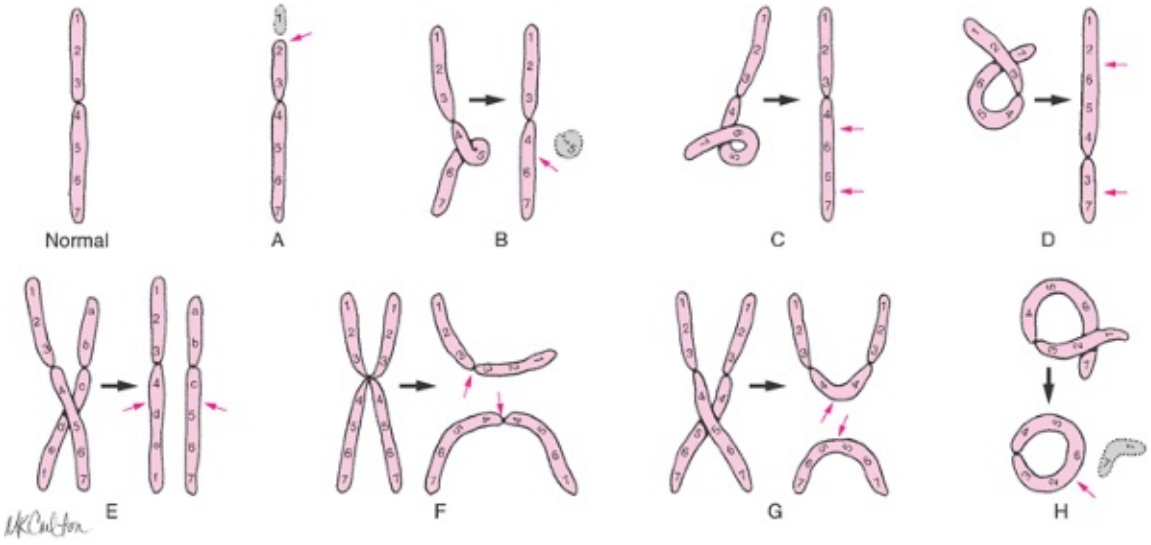

Figure 6.8 Types of chromosomal abnormalities. **A:** Terminal deletion. **B:** Interstitial deletion. **C:** Paracentric inversion. **D:** Pericentric inversion. **E:** Translocation. **F:** Isochrome. **G:** Dicentric chromosome. **H:** Ring chromosome. *Small arrows* indicate the sites of chromosomal breaks where rearrangement occurs.

TABLE 6.6 Chromosomal Nomenclature

p	Short (“petite”) arm of a chromosome
q	Long arm of a chromosome
del	Deletion of a chromosomal segment
der	Derivative chromosome resulting from a structural rearrangement
dup	Duplication of a chromosome segment
i	Isochromosome
ins	Insertion of a chromosomal segment into another chromosome
inv	Inversion of a chromosomal segment

r	Ring chromosome
rob	Robertsonian translocation
t	Translocation
ter	Terminal segment of chromosome (pter, terminal short arm; qter, terminal long arm)
/	Diagonal hash-line indicates mosaicism (46XX/45X indicates a mosaic patient with cell lines containing 46 chromosomes and 45 chromosomes, respectively, i.e. mosaic Turner syndrome)
+ or –	When the symbol appears before a chromosome, it indicates the addition or loss of that whole chromosome (i.e., +21 indicated trisomy 21, Down syndrome). When the symbol appears after a chromosome, it indicates the addition or loss of a part of a chromosome (i.e., 8q– indicates the loss of part of the long arm of chromosome 8).

A variety of genetic defects, including the common trisomies and many chromosomal translocations, can be detected by routine karyotype analysis (Fig. 6.9). Recent modifications, including chromosome painting that allows a particular chromosome to be identified directly or fluorescent in situ hybridization (FISH) that allows specific

sites along the chromosome to be identified, have greatly extended the capabilities of the cytogenetics laboratory. However, there are molecular and single gene rearrangements that cannot be observed by light microscopy and require molecular genetic technology for evaluation (see chromosomal microarrays discussion below).

Abnormal biochemical or nuchal translucency screen

IUGR, intrauterine growth retardation.

Sometimes, different cells within an individual have a different chromosomal makeup, even though all of their cells are derived from a single fertilized egg. The phenomenon is called *mosaicism*, and it most frequently involves a normal cell line and a trisomic line. Mosaicism can arise in a number of ways; for instance, the conceptus may have started as a trisomic zygote, but the extra chromosome may be lost during an early mitotic division, leaving the embryo with the original trisomy cell and "rescued" cells with a normal karyotype. Trisomy mosaicism confined to the placenta may occur in 2% to 5% of all pregnancies (Fig. 6.10).

TABLE 6.8 The Risk of Karyotypic Abnormalities Related to Maternal Age At Delivery

Age	Trisomy 21		Any Abnormality	
	Live Birth	Amnio	Live Birth	Amnio
20	1/734	1/1231	1/526	—

Data from Hook EB, Cross PK, Schreinemachers DM. Chromosomal abnormality rates at amniocentesis and in live-born infants. JAMA 1983;249:2034–2038, with permission.

TABLE 6.9 The Risk of a Chromosomal Abnormality with Selected Sonographic Findings

Finding	Abnormal Karyotype[a] (%)
Holoprosencephaly	40–60
Dandy-Walker malformation, cerebellar hypoplasia	—
Isolated hydrocephalus	5–10
Spina bifida	1–5
Agenesis of the corpus callosum	—
Choroid plexus cysts—large or associated with other abnormalities	1–2
Facial abnormalities	—
Cystic hygroma	>60
Nuchal thickening	—
Cardiac malformations	20–35
Duodenal atresia	30
Omphalocele	10
Hydrothorax	—
Diaphragmatic hernia	—
Genitourinary anomalies	4–10
Obstructive uropathy	—

Renal cystic dysplasia with other abnormalities	—
Clubfoot with other abnormalities	—
Severe IUGR	—
Polyhydramnios or oligohydramnios and other abnormalities	—
Single umbilical artery with other anomalies	—
Multiple placental cysts	—
Nonimmune hydrops	10–20

IUGR, intrauterine growth retardation.
[a]Numbers are provided only when there is a large enough experience and general consensus in the literature.

FISH is a cytogenetic technique in which a specific DNA probe with a fluorescent label is bound to homologous DNA in a clinical sample. FISH can be performed either on a metaphase chromosome spread to detect microdeletions and microduplications or during interphase to detect a larger chromosomal region in a nondividing cell. Interphase FISH can be performed on cultured cells, tissue sections, and cytologic smears. FISH has been used to detect common aneuploidies, such as trisomy 21, trisomy 18, trisomy 13, and the sex chromosome aneuploidies in prenatal diagnosis.

Because uncultured amniocytes can be used, the FISH technique can offer more rapid detection of chromosome aneuploidies. In one of the first large studies, FISH was performed as an adjunct to conventional cytogenetics in 4,500 patients. Region-specific DNA probes to chromosomes 13,

18, 21, X, and Y were used to determine ploidy by analysis of signal number in hybridized nuclei. A sample was considered to be euploid when all autosomal probes generated two hybridization signals and when a normal sex chromosome pattern was observed in greater than or equal to 80% of hybridized nuclei. A sample was considered to be aneuploid when greater than or equal to 70% of hybridized nuclei displayed the same abnormal hybridization pattern for a specific probe. The accuracy of all *informative* FISH results,

euploid and aneuploid, was 99.8%, and the specificity was 99.9%.

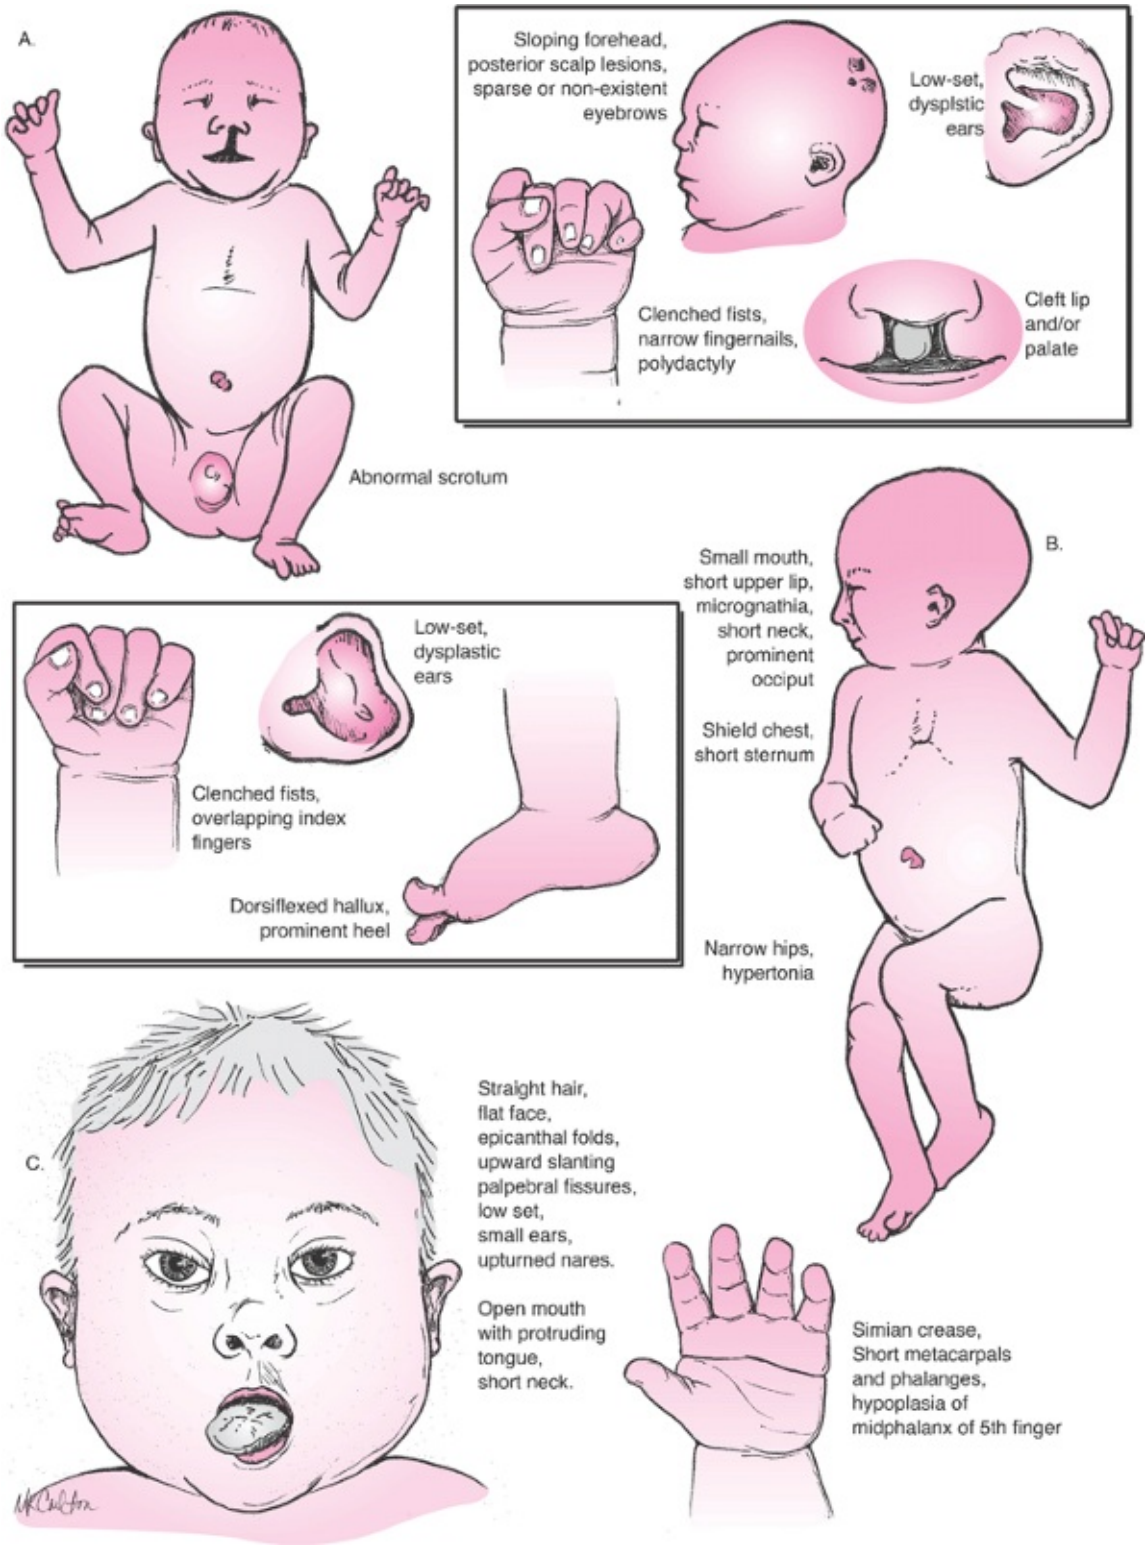

Figure 6.9 Characteristic features of the three most common autosomal trisomies: trisomy 13, trisomy 18, and trisomy 21.

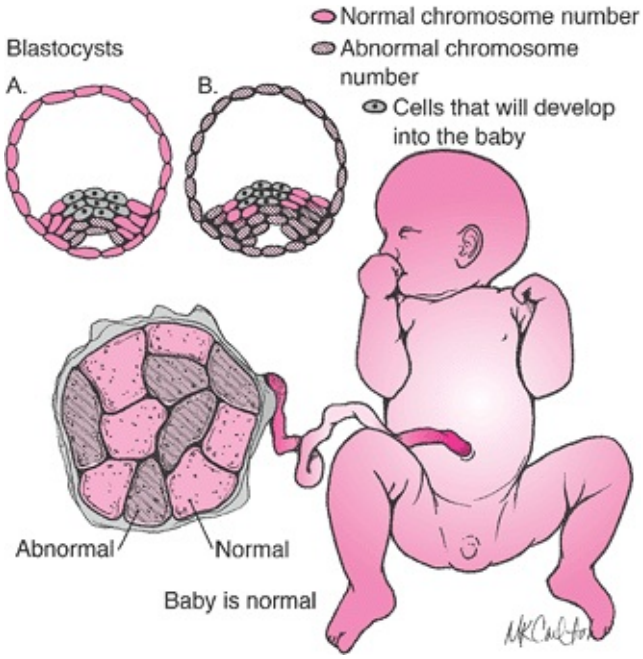

Figure 6.10 Confined placental mosaicism (CPM) represents a discrepancy between the karyotype of the placenta and the baby. CPM is diagnosed when trisomic cells are detected on CVS and only normal cells are found on a subsequent prenatal test, such as amniocentesis or fetal blood sampling. CPM for trisomy 2, 3, 7, 15, 16, 20, and 21 are most common. Several obstetric phenotypes have been associated with CPM, including normal term pregnancy, IUGR, preeclampsia/HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome, preterm labor, placental abruption, fetal death, and spontaneous abortion. CPM are categorized (after Kalousek): Type I—confined to trophoblast, Type II—confined to the chorionic stroma, and Type III—involves both cell lineages. Obstetric outcomes seems to depend on the type and extent of the CPM, the placental location, the chromosome involved, whether there is uniparental disomy (both chromosomes of a pair came from the same parent), whether there is heterodisomy or isodisomy, and of course the genetic and environmental background.

Current prenatal FISH protocols are not designed to detect all chromosome abnormalities and should only be utilized as an adjunctive test to cytogenetics. FISH can provide rapid and accurate clinical information in pregnancies where fetal abnormalities had been observed by ultrasound. FISH protocols are under development that would allow the simultaneous and unequivocal discernment of all human chromosomes. A “spectral karyotype” can be generated that allows visualization of a unique, defined emission spectra for each human chromosome. Computerized analysis may allow automatic and rapid analysis with resolution exceeding that of high-resolution G-banding.

Parent of Origin Effects

Genomic imprinting refers to the differential expression of genes based on the parental origin of the gene. Imprinting is usually mediated by differential methylation of the alleles involved. Most experimental evidence regarding imprinting comes from animal studies, but

some naturally occurring human analogs exist. The paternal genetic contribution appears to be essential for the development and function of the placenta and extraembryonic tissues, but the maternal contribution is required for embryonic development. Ovarian teratomas, the most common benign pelvic tumor in women of reproductive age, are characterized by a diploid karyotype, in which both haploid sets of chromosomes are maternal in origin. Complete hydatidiform moles, which show failure of normal embryonic and fetal development, are usually diploid with two paternal haploid chromosome sets and no maternally derived chromosomes.

The differential function of parental chromosomal contributions in development is also evident when studying human triploidy (Fig. 6.11). In an android conception

(i.e., two paternal, one maternal chromosome set), the fetus is severely growth retarded with a disproportionately large head and syndactyly of digits of the hand. The placenta is usually very large and hydropic. Survival into the second trimester or occasionally into the third trimester is possible but usually requires the presence of mosaicism with a diploid cell line. When the chromosomal constitution is gynoid (i.e., two maternal, one paternal set), the conceptus is underdeveloped and the placenta is small and cystic; such pregnancies rarely continue beyond the first trimester.

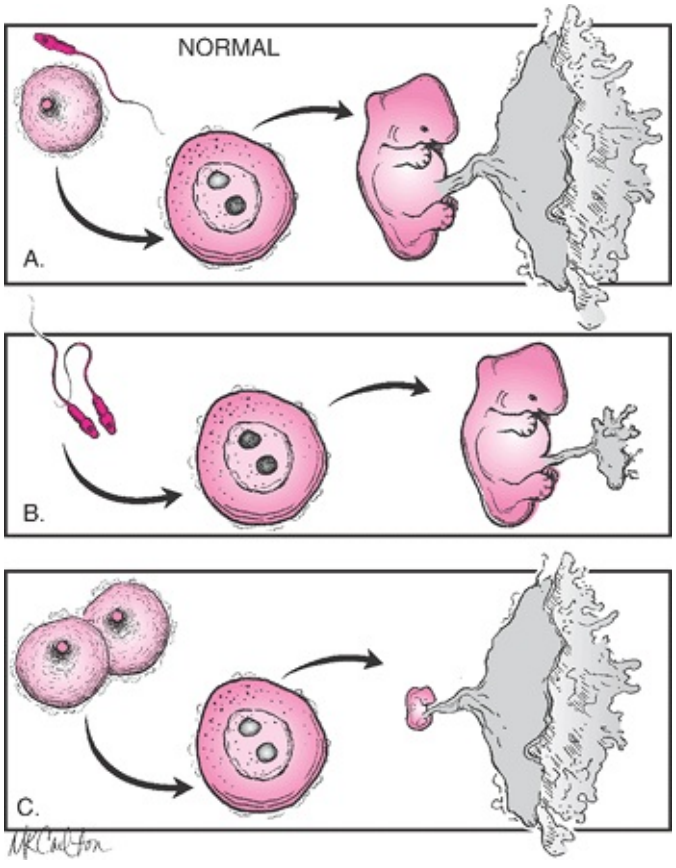

Figure 6.11 Imprinting. **A:** Both maternal and paternal contribution: normal fetus, normal placenta, and normal pregnancy. **B:** Androgenote: no inner cell mass, hydropic placenta, fails during embryo development, and a molar pregnancy. **C:** Gynogenote: there is fetal development, underdeveloped placenta, and a dermoid pregnancy.

In some persons with an apparently normal karyotype, both versions of a pair of homologous chromosomes were inherited from one parent, a phenomena called *uniparental disomy*. This can give rise to abnormalities if genomic imprinting causes regions of both chromosomes to be inactivated or overexpressed.

The Molecular Genetics Revolution

In the mid 1950s, there were only two "facts" known about the human genome. It was thought that humans had 48 chromosomes and that X-chromosome inactivation in humans occurred by the same mechanism that had been observed in fruit flies. Both of these observations have been proven to be in error. In the past few decades, there has been an explosion of knowledge about the human genome, largely attributed to advances in molecular biology.

Deoxyribonucleic Acid

Genes are the instructions required for building structural proteins and enzymes and peptide hormones, and the complete set of genetic instructions for any organism is called its *genome* (Table 6.10). The human genome has 46 chromosomes, including 22 pairs of autosomes and two sex chromosomes. The genome is made up of three billion base pairs and somewhere between 32,000 and 36,000 genes. The functions of approximately 10,000 human genes have been characterized, and in 2005, the first draft of the human genome sequence was completed.

In 1944, Avery and colleagues demonstrated that DNA is the chemical that carries genetic instructions. Roughly equal parts of DNA and its supporting proteins make up the 46 chromosomes. If the strands of DNA in the nucleus of a single cell could be unwound and spliced together, the resulting DNA molecule would stretch more than 1.5 miles long but would be only 20 trillionths of a centimeter wide. If a person read the human genome sequence at a rate of one nucleotide per second, 24 hours a day, it would take them a full century to complete. If all the DNA in your body were tied together end to end, it would stretch 315 billion miles—the distance to the sun and back over 600 times.

TABLE 6.10 The Human Genome

46 chromosomes, including
22 pairs of autosomes
2 sex chromosomes
>32,000 genes
3,200,000,000 base pairs

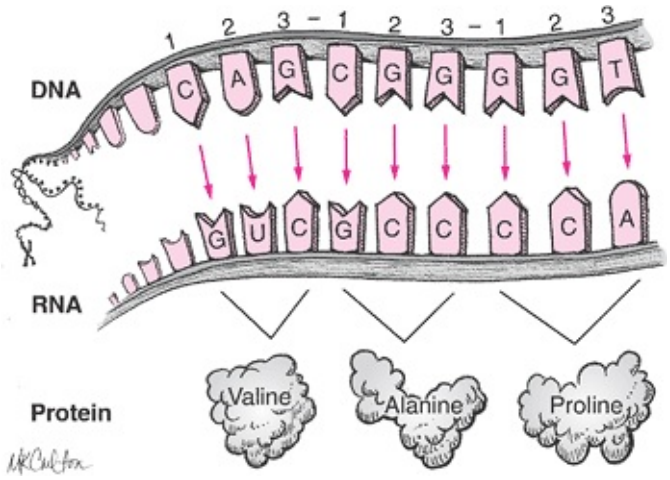

Figure 6.12 The DNA code consists of four characters and is read three characters at a time. It is transcribed into a ribonucleic acid (RNA) message, which instructs cells how to assemble proteins from amino acids.

The genetic code is spelled out with the four nitrogenous bases: adenine, thiamine, cytosine, and guanine (Fig. 6.12). The purine and pyrimidine bases are arranged in a ladderlike, double helix arrangement that is very stable (i.e., theoretical dissociation constant = 10^{-23}). During cell division, DNA is duplicated with extremely high fidelity by synthesis of a new strand of one side of the molecular ladder (Fig. 6.13).

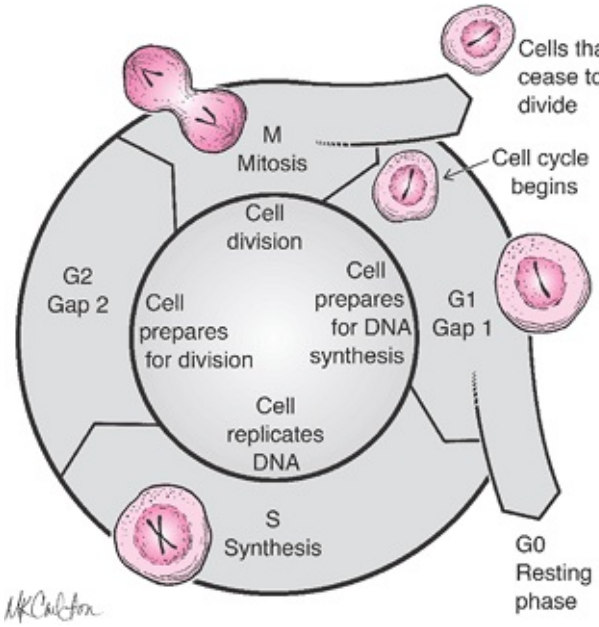

Figure 6.13 Normal cell cycle.

Although the human genome consists of at least 32,000 genes, genes comprise only one tenth of the encoded information. Most of the genome is of unknown function, but it probably codes for the proper spacing, alignment, and punctuation of the genetic instructions. About 99.8% of the DNA sequence is identical from one person to the next. Stated another way, there are many minor differences between any two persons; on average, there is a variation of one nucleotide for every 200 to 500 base pairs. When these sequence differences occur within genes, they can lead to genetic diseases or genetic variation. Most of the minor differences have no observable effect since they occur in the noncoding regions of the genome, regions of DNA that do not contain genes. These otherwise unimportant differences have been the basis of the current explosion of genetic knowledge, because much of our ability to study genes or diagnose genetic illness exploits differences (i.e., DNA sequence polymorphisms) in these regions to track or find neighboring genes.

Cellular enzymes read the DNA sequence three bases at a time, and each triplet directs the positioning of a particular amino acid within the structure of a protein (Fig. 6.12). The protein coding instructions are transmitted to the cellular machinery through messenger RNA, a transient, intermediary molecule that is similar to a single strand of DNA (Fig. 6.14). The RNA strand is transcribed from the DNA template in the nucleus and has an opposite or complementary genetic sequence. Messenger RNA moves from the nucleus into the cytoplasm, where the protein manufacturing organelles build a protein. Analysis of messenger RNA molecules is extremely useful in the laboratory for detecting genes.

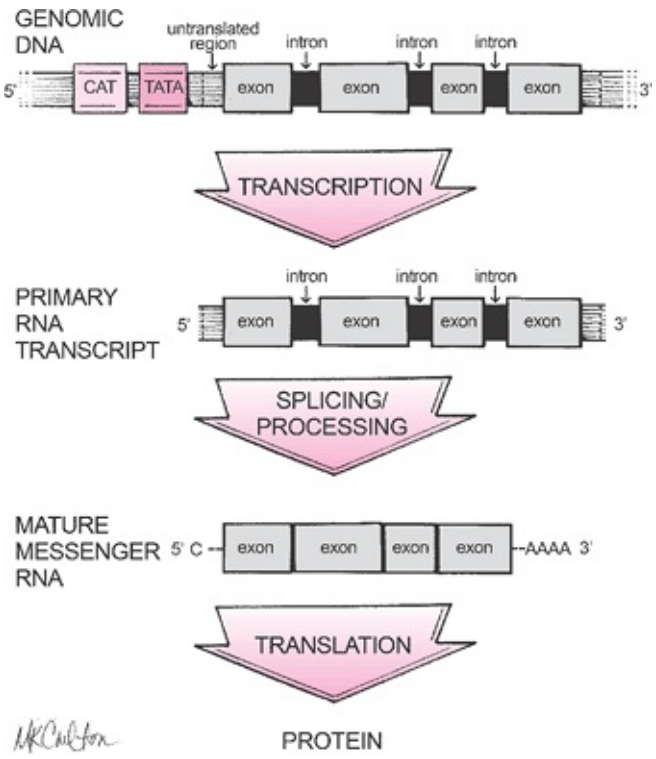

Figure 6.14 Anatomy of a gene. Regulatory regions are present in the 5′ region. Introns are spliced out of the final messenger RNA.

Some heritable variations in gene regulation and the resulting phenotypes occur without any change in the DNA sequence. In fact several “epigenetic” mechanisms have been uncovered that affect transcriptional control and regulate gene expression. These include RNA-associated silencing, DNA methylation, and histone modification. DNA methylation is the best understood; it is involved in transcriptional silencing of genes, regulation of expression of imprinted genes, controlling tumor suppressor, and silencing (lyonization) of genes located on the inactive X chromosome.

Several advances in molecular biology have enabled the molecular genetics revolution to take place. The first was the discovery of restriction enzymes, which are bacterial proteins that can cut DNA molecules at specific sites by recognizing the DNA sequence at those sites. Over 400 restriction enzymes have been discovered, many are commercially available, and about 25 are used commonly. Restriction fragment length polymorphisms (RFLPs) occur because of minor sequence changes (usually single base substitutions) that abolish or create a recognition site, altering the length of a digestion fragment. Restriction sites occur frequently, and several restriction sites can occur in the vicinity of any given gene. When these RFLPs are polymorphic, they become useful markers for linkage studies, diagnostic testing, and paternity testing (Fig. 6.7). RFLPs and other DNA polymorphisms provide the landmarks for genetic maps.

The polymerase chain reaction (PCR) is used to exponentially amplify DNA, via enzymatic replication, without using a living organism. The basic reaction is the workhorse behind a wide array of genetic manipulations. PCR is commonly used for mutation detection, DNA sequencing, the identification of genetic fingerprints, the diagnosis of infectious diseases, paternity testing, and disease gene discovery. PCR is designed to amplify only a specific small region of a DNA strand (usually between 50 and 10,000 base pairs). One or more primers (small fragments of DNA synthesized to be complementary to the DNA regions at the 5′ and 3′ ends of the DNA region that is to be amplified) provide the specificity as to which genetic region will be amplified.

DNA sequencing is the process of determining the order of the nucleotide bases of a DNA sample. Most clinical sequencing depends on the PCR reaction. Fluorescently labeled chemically modified nucleotides are included as part of the PCR reaction. Each of the four nucleotides is labeled with a separate fluorescent dye, which fluoresces at a different wavelength. The labeled nucleotides are designed to stop the PCR reaction each time they are incorporated into the complementary strand, thus when the products are separated by size (usually by capillary electrophoresis through a polymer), a multicolored “ladder” is obtained that reflects the DNA sequence of the sample being tested (Fig. 6.15). Automated DNA sequencers can test thousands of samples

each day, but current methods can directly sequence only short lengths of DNA at a time (usually <800 base pairs). Soon automated “genomic sequencing” will allow determination of the entire diploid sequence of a patient in less than 24 hours at a medically reasonable cost.

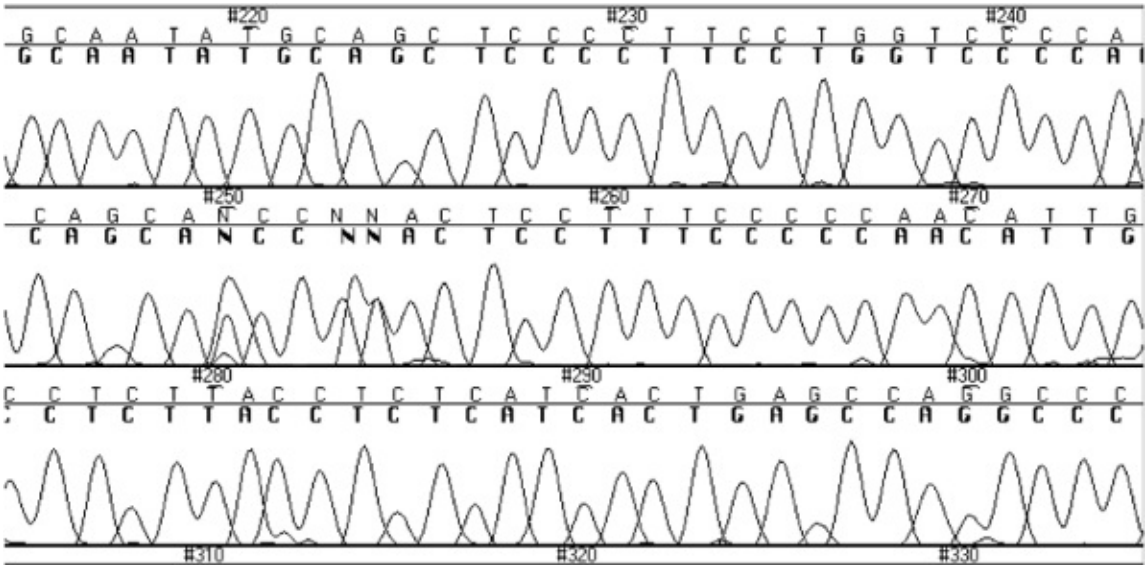

Figure 6.15 Example of a DNA sequence produced by an automated sequencer.

Scientists have gained a greater understanding of how to manipulate the physical conditions such as pH, salt concentration, and temperature of in vitro DNA reactions. These skills—combined with the use of restrictions enzymes—allowed the development of recombinant DNA or new combinations of DNA engineered in the laboratory. Recombinant DNA technology has made possible the development of gene probes (pieces of DNA usually radioactively labeled) that recognize and bind specifically to homologous sequence in another sample of DNA. These technologies also underlie cloning—the copying of DNA segments in lower animals and the manufacturing of human proteins using bacteria or cell cultures.

Various blotting technologies are commonly used to study DNA. With blotting, biologically relevant molecules undergo electrophoresis and are transferred to a stable membrane for repeated experiments. Blots are called Southern blots if DNA is being analyzed, Northern blots if RNA is analyzed, and Western blots if proteins are being analyzed.

The Genome Project

The Human Genome Project promises to be the single most important project in biology. An understanding of the relationship between genetic variation and disease risk will alter the future prevention and treatment of common illnesses. The full human sequence was completed in 2005. Disease gene identifications that formerly required years of chromosome walking and jumping, cloning, physical mapping, sequencing, and sequence assembly can now be completed in weeks. Industrialized sequencing technologies using capillary electrophoresis, microarrays, and the like developed for the genome project are now widely used for medical genotyping and sequencing.

A tremendous catalog of individual sequence variation in humans is now available, and tens of thousands of micro satellite markers are now available for linkage analysis and hundreds of thousands of single nucleotide polymorphisms (SNPs) for genetic association studies. The tools are now well developed for doing these functional studies to find which

variations and mutations cause individuals to be at risk for numerous medically important, genetically complex human diseases. The genome project has delivered improved cDNA resources, better predictive software, and additional knowledge about the nonprotein-coding regions of the genome. Remarkable technologies are commercially available for comprehensive analysis of gene expression in single cells, tissues, or whole organisms.

Advances in gene knockout technology, antisense technology, gene transfer, and gene transfection allow greater in vitro insights using appropriate model systems, including both cell culture and whole organisms. The complete genomic sequence for dozens of model organisms provide important evolutionary clues to gene function and extend the range of experiments possible. At the same time, there has been parallel improvements in the technology for global protein analysis. Gene expression is played out at the protein level—elegant techniques are now available to examine spatial and temporal patterns of protein expression, protein-ligand interactions, and protein modifications.

The genome project occurred at the same time as the information technology revolution. Tremendous bioinformatics and computational software are now available for gene discovery, expression profiling, understanding gene-environment interactions, and the like. Suffice it to say, better tools are now available for making advances in woman's health care than ever before in human history.

At least 3% of the annual budget of the U.S. genome effort went to the Ethical, Legal, and Social Issues section of the enterprise. This amount of early attention to societal impact is unprecedented for a science and technology project. Grant-funded programs have examined privacy issues, genetic discrimination in insurance and employment, and the role of coercion. Genetic discoveries are challenging long-held beliefs about equality, predetermination, and free will as we learn about genes that have a major role in personality, creativity, intelligence, and mental illness. The safety, efficacy, and utility of new gene tests absolutely require careful consideration of the societal issues, especially whenever effective treatment is not widely available.

Deoxyribonucleic Acid Diagnostics

DNA testing is clinically applicable to many disorders and can be performed in one of several ways (Table 6.11). When the molecular basis of a disease is known, direct mutation testing can provide a yes or no answer on any DNA sample. For instance, in cystic fibrosis, hundreds of mutations have been discovered. A battery of mutations can be tested for using various methods such as yes-no dot blots that are as simple to interpret, such as modern urine pregnancy tests.

Similarly, fragile X syndrome is usually the result of an expansion of a triplet sequence within the gene. Normal persons usually have only 5 to 50 copies of this triplet repeat, but affected patients have hundreds or thousands of copies of the triplet repeat. Similar triplet expansions cause myotonic dystrophy, Huntington disease, and Kennedy disease. The region containing the triplet can be amplified by using PCR. PCR produces millions of copies of the small region of DNA from the X chromosome that contains the fragile X repeat. Specificity is achieved by directing the reaction using two complementary primers on either side of

the region of interest. Once amplified, the size of the product can be measured to evaluate the number of triplets, determining whether the mutation exists (Fig. 6.16).

TABLE 6.11 Common Conditions for Which Deoxyribonucleic Acid Testing Is Available

Disease	Inheritance	Methodology Used
Adult polycystic kidney disease	AD	Linkage analysis, sequencing
Retinoblastoma	AD	Linkage analysis, sequencing
Myotonic dystrophy	AD	Mutation test (triplet expansion)
Huntington chorea	AD	Mutation test (triplet expansion)
Cystic fibrosis	AR	Mutation screen, sequencing
Sickle cell anemia	AR	PCR and ASO mutation detection
β-thalassemia	AR	PCR and ASO mutation detection
α1-antitrypsin deficiency	AR	PCR, then ASO mutation detection
Lesch-Nyhan syndrome	XLR	Multiplex PCR, then sequence
Ornithine transcarbamylase deficiency	XLR	PCR, then chemical cleavage

Fragile X syndrome	XLR	Mutation test (triplet expansion)
Hemophilia	XLR	Linkage analysis, mutation scanning, inversion test
Steroid sulfatase deficiency	XLR	Multiplex PCR for deletion detection
Duchenne muscular dystrophy	XLR	Multiplex PCR for deletion detection, linkage analysis

AD, autosomal dominant; AR, autosomal recessive; PCR, polymerase chain reaction; ASO, allele-specific oligonucleotide; ALR, X-linked recessive.

For families with unusual mutations or with diseases for which the molecular basis is unknown, linkage testing can be performed. Linkage tests compare DNA polymorphisms close to the disease-causing gene in family members known to have or carry the disease with those of unaffected and at-risk family members. Indirect assessments can be made about whether at-risk persons have the disease allele. The accuracy of these predictions depends on correct diagnosis and relationships of the family members and the genetic distance between the polymorphism tested and the disease allele. But for some families, linkage testing can be uninformative (Fig. 6.17).

Molecular Cytogenetics

Chromosomal microarray (CMA) chips are likely to revolutionize cytogenetic testing in the next few years. These microarrays have hundreds to millions of molecules (oligonucleotides, cloned DNA, etc.) arrayed on a suitable surface (Fig. 6.18). The attached molecules are used to probe a variety of chromosomal regions simultaneously. Manufacturers can place picogram amounts of a probe at defined locations, and each probe can be just a few

micrometers apart. The molecular probes may be attached to plastic, glass, nylon, or even silicon wafers. Each individual probe is placed at a precisely defined location on the array support, which is usually a flat, two-dimensional surface. The identity of the molecule

fixed to each spot for any particular array design never changes. The microscopic scale of the array keeps assay costs lower and allows high-throughput "parallel" testing of clinical samples.

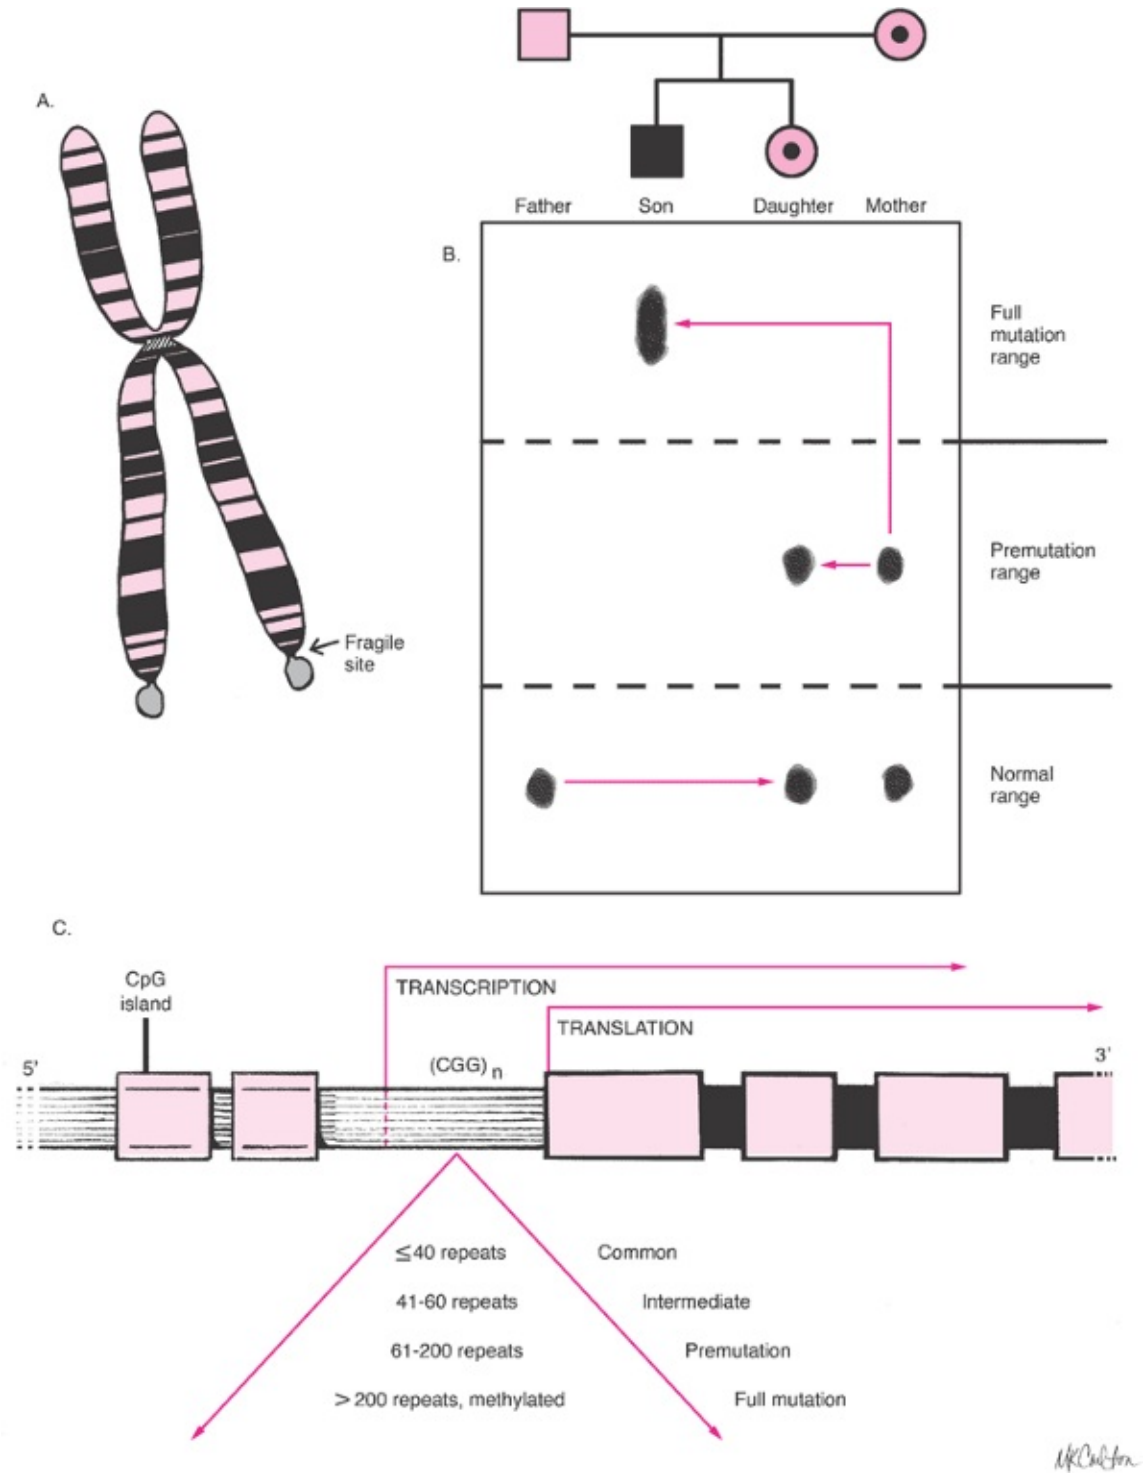

Figure 6.16 Fragile X syndrome is the most common inherited cause of mental retardation. Fragile X occurs in 1 in 2,000 males and in 1 in 4,000 females of all races and ethnic groups, and about 1 in 300 women carry fragile X. **A:** The fragile X chromosome. The cytogenetic marker is Xq27.3. The "fragile" site occurs when chromatin fails to decondense properly when placed in folate-deprived medium. **B:** Expansion diagram. During female meiosis, there is a 20% to 100% risk of permutation expansion to full mutation. **C:** Molecular defect. There is a triplet repeat (CGG) in 5′

untranslated region that causes abnormal methylation (inactivation) of CpG island in promoter region, which in turn causes absent or reduced FMR-1 protein. There is also neighboring molecular instability on the X chromosome.

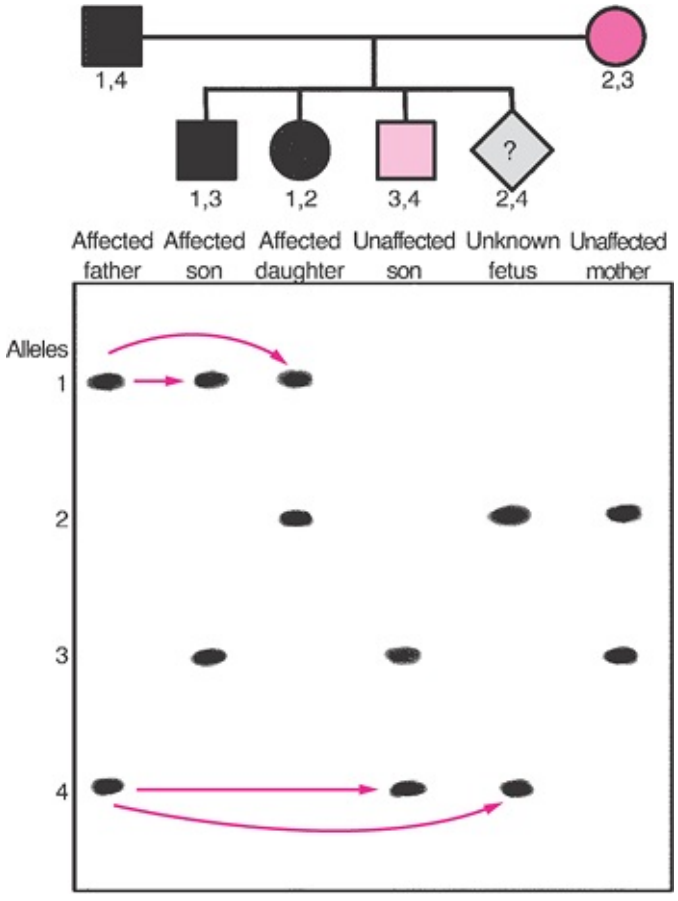

Figure 6.17 Linkage.

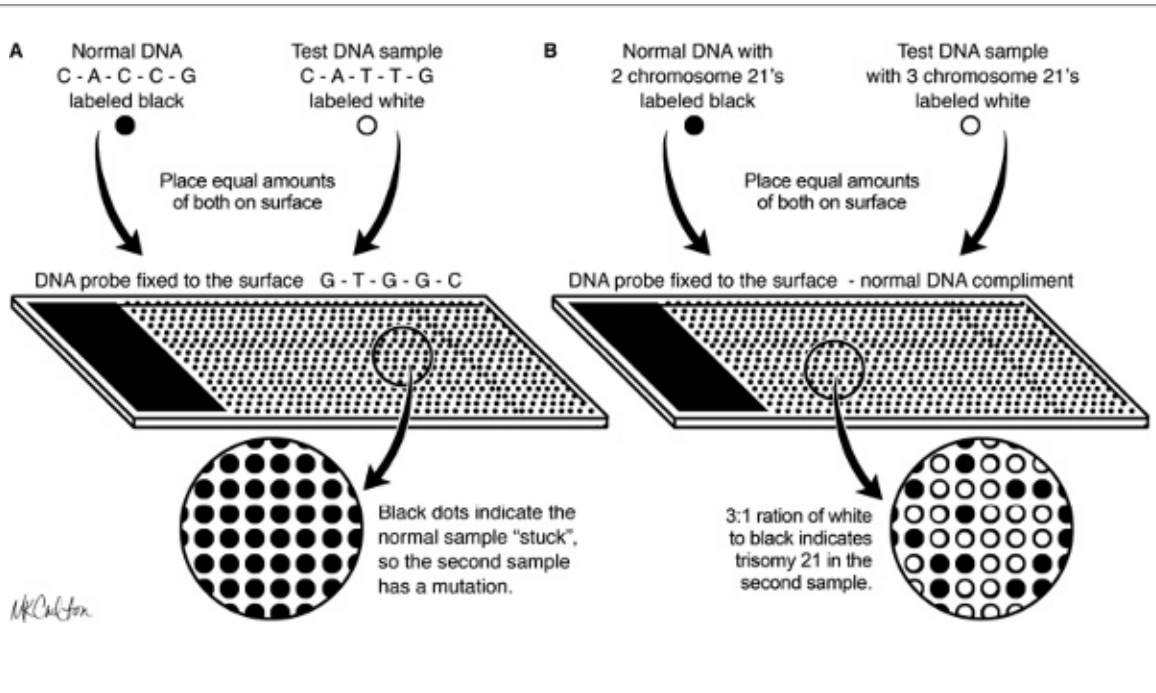

Figure 6.18 Microarrays for detecting karyotypic abnormalities.

Regardless of the array design, hybridization—the ability of two complementary nucleic acid molecules to lock together—is the critical feature. Single-stranded DNA probes will hybridize or "stick" to the strands of DNA sample to be tested following the usual rules of base pairing (A to T, C to G). Complementary DNA sequences have incredibly high affinity for each other and thus the target DNA in a solution literally "find" and attach itself to the immobilized probe DNA. Probes as short as 20 nucleotides in length can be highly specific, while even a single mismatched base will greatly reduce the strength and likelihood of hybridization. Thus, highly specific DNA capture molecules can be designed and prepared either by chemical synthesis or by using PCR.

The probes, which are fixed onto the array surface, capture the nucleic acid in the clinical sample to be tested, which is in a solution applied to the array. Most microarrays use fluorescent tags as the means of identifying whether hybridization has occurred (whether the target molecule is stuck to the probe molecule on the array). Array scanners can rapidly detect very low levels of fluorescence and map the signal to its source on the array with great certainty. Usually, the fluorescent tags are excited by a laser and the signal captured by a high-resolution "digital" camera. Most protocols improve sensitivity of detection by chemically attaching more than one copy of fluorescent tag per target molecule detected.

With CMAs, it is possible to perform a "molecular karyotype." The resolution of a CMA is better than the resolution of conventional cytogenetics, and no culture time is required. Furthermore, probes can be included for all of the microdeletion regions commonly tested by ancillary FISH tests (i.e., Di George syndrome caused by a chromosome 22 microdeletion). Moreover, all of these common microdeletion regions can be tested in parallel rather than one at a time. The patterns obtained on arrays are easier to read by computer compared with G-banded metaphase spreads. Although CMAs cannot detect low-level mosaicism or balanced rearrangements, they can detect many important abnormalities missed by conventional cytogenetics. CMA is such a sensitive test for small duplications and microdeletions that genetic variants of unknown clinical significance will be detected. Blood from both parents will usually be requested to help determine the significance of these findings. Prenatal CMA can detect the disorders that are usually identified by karyotypic analysis, including Down syndrome, trisomy 13, trisomy 18, and sex chromosomal abnormalities. CMA testing can be performed on chorionic villus sampling (CVS), amniocentesis, or fetal blood. It is likely that CMA will become the preferred method for the prenatal diagnosis of chromosomal abnormalities.

Genetic Evaluation

Genetic History and Physical Examination

Important details are being learned about many rare disorders that practitioners may see only once in their career. In the past, many practitioners have had a "laissez-faire"

attitude about genetic disorders, since “you can't do anything about your genes.” However, it is important to detect genetic conditions so that the patient can have adequate counseling about the condition and the risk to offspring. For severe conditions, patients are often interested in prenatal diagnosis, so they can consider pregnancy termination or prepare for the birth of an affected child. Our new predictive powers have led to an expanded medicolegal duty to warn patients of risks of which they may not have been aware. Failure to provide accurate and timely reproductive counseling has resulted in a host of lawsuits. Genetic diagnosis becomes even more critical as more treatment options become available for the child with a severe genetic disease.

In light of these expanding obligations to screen, what is expected of the general obstetrician-gynecologist? As with any medical diagnosis, the history is the most important part of the genetic evaluation. Important aspects of a genetic history, such as the patient's age, menstrual history, and obstetric history, are routinely queried as part of any routine obstetric or gynecologic history. In addition, it is important to ask about the patient and her partner's ethnicity (Table 6.12). The family history should extend to third-degree relatives (i.e., cousins). A minimal familial history can usually be elicited by using the following questions:

- Do you have a family history of diabetes, hypertension, cancer, or twins?
- Are there any diseases that seem to run in your family?
- Is there a history of genetic disease like cystic fibrosis, hemophilia, or muscular dystrophy?
- Is there anyone with mental retardation or any kind of birth defect?
- Have any of your sisters, cousins, or other relatives had problems with their pregnancies?
- Are your parents alive? Are they healthy?
- As far as you know, are you and your husband or partner related by blood?
- Do you know your ethnic background? (Do you know where your relatives are originally from?)
- Is there any reason why you are especially concerned that you might have trouble with your pregnancy or that your baby may be born with a birth defect or other medical problem?

TABLE 6.12 Single Gene Disorders with an Ethnic Predilection

Ethnic Group	Disorder
	Hemoglobinopathies, especially Hb S, Hb

Africans	C, α- and ß-thalassemia, persistent Hb F
	G6PD deficiency, African type
	Adult lactace deficiency
	Abetalipoproteinemia
	Bloom syndrome
	Dystonia musculorum deformans (recessive form)
	Familial dysautonomia
	Factor XI (PTA) deficiency
Ashkenazi Jews	Gaucher disease (adult form)
	Iminoglycinuria
	Niemann-Pick disease
	Pentosuria
	Spongy degeneration of brain
	Tay–Sachs disease
	α-thalassemia
Chinese	G6PD deficiency, Chinese type
	Adult lactase deficiency
Eskimos	E1S (pseudocholinesterase deficiency)

Finns	Congenital nephrosis
	Aspartylglucosaminuria
	Acatalasia
Japanese	Oguchi disease
Mediterranean peoples	Thalassemia (mainly ß)
(Italians, Greeks, Sephardic Jews)	G6PD deficiency, Mediterranean type
	Familial Mediterranean fever

Modified from McKusick VA. *Mendelian inheritance in man*, 9th ed. Baltimore: Johns Hopkins Press, 1990, with permission.

These questions take only a few minutes to ask a new patient. The final, open-ended question is often the most revealing. Alternatively, many practitioners find it helpful to ask similar questions by using a patient-completed questionnaire. Many standard prenatal forms, including those suggested by the ACOG, include a family history form designed so that only “yes” responses need to be dealt with further. Including a form such as this one in the patient's chart clearly documents that a genetic history was obtained for medicolegal purposes. More than one fifth of healthy obstetric patients affirmatively answer at least one important question on the form.

The physician should suspect genetic factors if a patient presents with an unusual problem and other people in her family have the same disorder. Similarly, if a patient reports a positive family history, it is important to decide whether the patient unknowingly has the same disease. When a patient reports an unfamiliar genetic condition or a rare illness, the physician should seek out information about the genetics of this condition. Is she at risk of passing the condition to her offspring? Is prenatal diagnosis available? Is prenatal treatment available? For instance, consider a patient whose first child died of methylmalonic aciduria. In a subsequent pregnancy, her obstetrician noted this history on his prenatal record but did not inform the patient that there was a one in four risk that her current fetus could be affected. The obstetrician was unaware that prenatal diagnosis is available and more importantly that a simple treatment (i.e., giving the mother supplemental vitamin B_{12}) could prevent much of the morbidity of this particular form of methylmalonic aciduria. The child was born severely damaged and died at 2 years of age. The patient was

very angry that she was not informed about prenatal therapy, and a lawsuit was initiated. Obstetricians cannot be expected to be expert in every rare enzymopathy, but this case illustrates how important it is to seek out additional information about rare conditions through a literature search or by consultation with a genetics center. Fortunately, helpful computerized databases are available on the Internet such as OMIM (Online Mendelian Inheritance in Man) and GeneTests (a directory of DNA diagnostic laboratories).

The general physical examination may reveal dysmorphic features or a distinctive physical finding that is frequently associated with genetic problems. For instance, a dislocated lens found on fundoscopic examination of the eye is a distinctive feature consistent with Marfan syndrome or homocystinuria. If the patient has no history of severe ocular trauma, she probably has one of these conditions. Obstetricians cannot be as good at detecting

such clues as an expert medical geneticist, because “the eye cannot see what the mind does not know.”

Genetic Counseling

Genetic counseling is a communication process that deals with the occurrence or risk of occurrence of a genetic disorder in a family. As our abilities to learn about the fetus have increased, more couples have an indication for prenatal diagnosis or a need to discuss reproductive options. Although every obstetrician has a role in providing genetic counseling, many practitioners find that genetic counselors—persons with advanced degrees and who are specially trained in the educational, psychologic, and administrative aspects of medical genetics—are helpful consultants. Genetic counselors are experienced in obtaining and interpreting a thorough family history; often, counselors are involved in the establishment or confirmation of a diagnosis. When presented with a prenatal diagnosis, they can obtain and interpret the history of a current pregnancy, explaining fetal risks and discussing the options available. Genetic counselors can provide the detailed counseling that is necessary regarding fetal chromosomal abnormalities of consanguinity, recurrence risks of multifactorial disorders, fetal abnormalities identified by ultrasound, or infertility and habitual abortion. They are extensively trained about genetic screening for diseases that are common in various ethnic groups. Genetic counselors play a central role in the discussions regarding the option of aborting a genetically abnormal fetus. This type of counseling is traditionally informational and nondirective.

Pregnancy Termination

Pregnancy termination for genetic reasons can be particularly heart wrenching for a couple because the pregnancy usually is a desired pregnancy. Patients should be encouraged to involve their doctor, genetic counselor, clergy, other support persons, and family in these difficult decisions.

It is the physician's responsibility to explain the fetal diagnosis and prognosis. If a woman decides to have a pregnancy termination, the physician should explain the termination procedure, options if there are any, and the relative risks of the different procedures. The cost of the procedure is discussed and whether the procedure is covered by public funding

or insurance. The physician should explain the benefits of diagnostic examination of the fetus by DNA, metabolic, or chromosomal analysis or by dysmorphologic examination. The disposition of the fetal remains should be discussed. The possibility that a fetus may live for a short period after induced labor termination should be discussed. With late second-trimester or third-trimester inductions, it is often appropriate to encourage patients to see or hold the baby and to name their baby. Patients are advised that lactation may occur after the delivery, and they should be told about the options available to reduce lactation. With late terminations, the option of having a memorial service or in some way commemorating the baby's existence should be discussed. Physicians and counselors help couples to decide what information to tell other children and family members, friends, and acquaintances.

It is important to reinforce the fact that the genetic defect is not caused by the patient. The woman who is carrying the pregnancy and undergoes the termination may grieve in different ways than the father of the baby. Referral to local support groups and counselors is often appreciated. In 6 to 8 weeks after the procedure, a follow-up visit should be scheduled to summarize the diagnostic findings, review recurrence risks, and discuss prenatal diagnosis or therapy options for future pregnancies.

Laboratory Screening

Laboratory studies play an important role in the diagnosis of genetic disorders. A genetic illness is sometimes first discovered as an incidental finding on blood studies or an ultrasound examination. For instance, a low mean corpuscular volume on an automated complete blood count suggests thalassemia. In some instances, a positive family history prompts laboratory studies that clarify a patient's risk. Some programs have evolved to screen entire populations for genetic conditions by using laboratory assays. Just as we currently perform a history and physical exam or a cholesterol screen to identify disease risk, soon there will be a DNA screen to detect mutations in dozens of important genes involved in cancer, cardiovascular, and metabolic disease.

Population screening is appropriate when a defined subset of the population is at risk and an accurate and inexpensive heterozygote test is available (Table 6.13). It is optimal if prenatal diagnosis is available as well (e.g., sickle cell anemia, Tay–Sachs disease, thalassemia). The goals of screening programs are early diagnosis to allow better treatment of affected persons or identification of at-risk matings between persons who are heterozygotes or carriers of recessive disease. Neonatal screening programs for phenylketonuria, galactosemia, and hypothyroidism are carried out in most states. Successful carrier screening for Tay–Sachs disease has been achieved in several Jewish populations. The cost-effectiveness of the screening program is often a primary concern in deciding whether to proceed with population screening. Equally important issues include the ability to manage minor variants that do not require action, stigmatization of carriers, and responsibility for decisions not to screen.

Genetics in Gynecologic Disorders

Genes play an important role in the pathogenesis of many common gynecologic disorders.

pseudohermaphroditism have defined many aspects of human sexual differentiation. Because the Y chromosome is the smallest chromosome, it became the first human chromosome to be completely mapped.

TABLE 6.13 Population Screening Frequency Incidence Esti Autosomal Recessive Disorders in Defined Ethnic

Disease	Ethnic Group	Carrier Frequency	Disease Incidence Newborns	"At-Risl Couple Frequen
Sickle cell anemia	Blacks	.080	1/600	1/500
Tay–Sachs disease	Ashkenazi Jews	.032	1/3.600	1/900
ß-thalassemia	Greeks, Italians	.032	1/3,600	1/900
α-thalassemia	Southeast Asians and Chinese	.040	1/2,500	1/625

Cystic fibrosis	Northern Europeans	.040	1/2,500	1/625
Phenylketonuria	Europeans	.016	1/16,000	1/4000

[a]Likelihood that both members of a couple are carriers assuming that both are of the “at-risk” ethnic group.

Genetic testing for susceptibility to ovarian cancer is rapidly becoming part of routine practice. Most cancers are clonal in origin, meaning that they arise from a single aberrant cell. Cytogenetic or molecular alterations are uniformly observed in malignant cells. Although some of these changes appear to be random events occurring in rapidly dividing cells, other specific genetic changes play an etiologic role in development of certain cancers. Particular mutations may be either germinal (i.e., inherited) or somatic (i.e., acquired). Either can be seen in familial cancer clusters: germinal because of segregation within the family of a cancer-causing mutation and somatic because of shared environmental exposures to carcinogens. Mendelian transmission of cancer predisposition usually is observed as multifocal and early-onset disease. Typically, cancer-predisposing mutations are found to overexpress proto-oncogenes that normally drive important cell functions or to inactivate tumor suppressor genes that normally exert a protective effect.

Genetic testing for BRCA1 and BRCA2 mutations is now recommended to most women with invasive ovarian cancer. These cancer genes normally play critical roles in the maintenance of genome stability. BRCA1 is an E3 ubiquitin ligase that has an impact on DNA repair, transcriptional regulation, cell-cycle progression, and meiotic sex chromosome inactivation. BRCA2 is a component of the cell's homologous recombination machinery. Approximately 10% of ovarian cancer patients will have mutations detected in these genes, including 4% of women without a family history of ovarian cancer. Women with a BRCA mutation have better ovarian cancer survival rates for than women without a mutation, possibly due to enhanced susceptibility to chemotherapy. A variety of strategies for prevention of ovarian cancer in relatives at risk, including chemoprevention and prophylactic oophorectomy, has shown some efficacy.

Common gynecologic diseases such as endometriosis and polycystic ovary syndrome are familial, and genes involved in these conditions are likely to be discovered over the next few years. Age at menopause, susceptibility to hot flushes and osteoporosis, susceptibility to pelvic relaxation, and susceptibility to chronic vaginitis are likely to have genetic components as well. Disease gene discoveries related to these conditions may suggest novel diagnostic and therapeutic approaches.

Trends

The genome project promises to provide us with the most important information in human biology. Technologies developed for the genome project and the genomic sequence itself will provide the basis for much of biomedical research in the next century. The possibilities for understanding normal development, disease predisposition, and cancer are staggering. The ability to obtain an accurate prenatal diagnosis will expand exponentially over the next few decades. Gene therapy is becoming a reality faster than anyone thought possible. The challenge is for the obstetrician-gynecologist to stay abreast of all these developments and to educate patients about developments that can influence their care.

Summary Points

- Most obstetric and gynecologic diseases show a polygenic, multifactorial pattern of inheritance. One in 20 newborns have a diagnosable genetic disorder.
- Taking a thorough family history is currently the most important part of a genetic evaluation, but laboratory screening of the general population is becoming available for an increasing number of genetic conditions
- Accurate prenatal diagnosis is now possible for hundreds of genetic conditions through ultrasound and genetic testing.
- The Human Genome Project is providing new information each month, making it difficult for care providers to keep abreast of all the new developments, especially for rarer diseases. Reference to current, on-line data and liberal referral to genetic counselors and geneticists are necessary when encountering rare conditions.
- Over the next decade, genetic testing will continue to become less invasive, and there will be greater opportunities to prevent the morbidity of genetic disease through prenatal and presymptomatic treatments.

Prenatal Diagnosis

Lorraine Dugoff

The ongoing advances in molecular genetics and discoveries in cytogenetics are increasing the potential indications for prenatal diagnosis. It is now possible to identify hundreds of genetic syndromes prenatally by using technology including florescence in situ hybridization (FISH), mutation analysis, and biochemical markers. There have been recent advances in prenatal screening for Down syndrome. The use of nuchal translucency and first-trimester maternal serum marker screening has made it possible to detect 85% of cases of Down syndrome as early as 10½ weeks gestation. This chapter will review prenatal screening for aneuploidy and neural tube defects and the invasive techniques currently available in prenatal diagnosis, including chorionic villus sampling (CVS), amniocentesis, and percutaneous umbilical blood sampling.

Screening for Chromosomal Abnormalities

Down syndrome occurs in approximately 1 of 800 live births. In 95% of cases, it is a result of meiotic nondisjunction of the chromosome 21 pair, usually in the mother's gamete, resulting in a 47, +21 karyotype. The risk of a fetus with Down syndrome, as well as trisomy 13 and 18, increases with maternal age. The incidence of karyotypic abnormalities at birth including Down syndrome in relation to maternal age is shown in Table 6.8 in this book. Four percent of cases of Down syndrome result from a translocation, and approximately 1% result from mosaicism. These cases are not related to advanced maternal age.

A number of maternal serum markers have proven useful in screening for Down syndrome. Historically, a maternal age at delivery of 35 years was used as a cutoff to identify women at the highest risk for having a baby with Down syndrome. Various combinations of serum biochemical markers have been used to screen for Down syndrome since 1984, when it was found that low second-trimester maternal serum α-fetoprotein (MSAFP) levels were associated with Down syndrome. In the 1990s, it was reported that elevated human chorionic gonadotropin (hCG) levels and decreased unconjugated estriol (uE_3) levels were associated with Down syndrome. The combination of these three markers in combination with maternal age, the triple screen, or triple test yields a 69% detection rate for Down syndrome at a 5% positive screen rate. A fourth marker, inhibin A, which may be increased in the serum of women carrying a fetus with Down syndrome, further increases the detection rate for Down syndrome in the second trimester. When inhibin A is included in the

second-trimester screening test, known as the quadruple or quad screen, the estimated detection rate increases to 81% with a 5% false positive rate. The triple and quadruple screens should ideally be offered between 15 and 18 weeks gestation, although they can be performed between 15 and 22 weeks. It is critical to know the precise gestational age, because the median values for the biochemical markers and the risk ratios are based on gestational age.

First-trimester screening for Down syndrome using fetal nuchal translucency, a measurement obtained by ultrasound, and maternal serum markers, pregnancy-associated plasma protein A (PAPP-A) and the free beta subunit of human chorionic gonadotropin (fß-hCG) in conjunction with maternal age (combined screening), yields a detection rate of approximately 85% at a 5% false-positive rate. The optimal gestational age for first-trimester screening appears to be 11 weeks, as the detection rate may be the highest (87%) at this time. First-trimester screening may be performed between 10 weeks/3 days and 13 weeks/6 days. The first-trimester combined screen may also be used to screen for trisomy 18. Nuchal translucency alone is associated with detection rates of 75% rate for trisomy 18, 72% for trisomy 13, 87% for Turner syndrome, 59% for triploidy, and 55% for other significant chromosomal abnormalities.

Down syndrome screening strategies that involve a combination of first- and second-trimester markers yield the

---

highest detection rates. There are a variety of possible approaches to combined first- and second-trimester screening. The various Down screening tests and their detection rates are listed in Table 7.1. The integrated screen determines a Down syndrome risk assessment based on a combination of maternal age, first-trimester nuchal translucency, and PAPP-A and the second-trimester quad screen markers. The patient is provided with a single risk for Down syndrome after the quad screen has been interpreted. The integrated screen yields a 94% to 96% detection rate at a 5% positive screen rate. A potential disadvantage of the integrated screen is that the patient does not receive any information regarding Down syndrome risk until the second trimester. The serum integrated screen is similar to the integrated screen except that the patient does not have a nuchal translucency measurement in the first trimester. The serum integrated screen is an effective screening option for patients who do not have access to a center that can perform nuchal translucency measurement This yields a detection rate of 88% at a 5% positive screen rate. The stepwise sequential screen consists of the measurement of nuchal translucency, PAPP-A, and fß-hCG in the first trimester and the quad screen in the second trimester. The results are provided to the patient after each test. An advantage of the stepwise sequential screen is that Down syndrome risk assessment is provided after the first-trimester screen, which gives the patient the option of having CVS if her initial risk is high. The stepwise sequential screen has a 95% detection rate at a 5% positive screen rate. The contingent sequential screen determines an initial Down syndrome risk based on first-trimester nuchal translucency, PAPP-A, and fß-hCG measurements. Women with the highest risk from first-trimester screening are offered invasive testing by CVS, and women with the lowest risks are told that second-trimester testing is not necessary. Women with intermediate risks after the first-trimester screen have their risks reassessed by integrating

their first-trimester results with second-trimester quad screen results.

TABLE 7.1 Down Syndrome Screening Tests and Detection Rates (at a 5% positive screen rate)

Screening Test	Detection Rate (%)
First trimester	
NT measurement	64–70
NT, PAPP-A, free or total ß-hCG (combined screen)	82–87
Second trimester	
MSAFP, hCG, unconjugated estriol (triple screen)	69
MSAFP, hCG, unconjugated estriol, inhibin A (quad screen)	81
First and second trimester	
Integrated (NT, PAPP-A, quad screen)	94–96
Serum integrated (PAPP-A, quad screen)	85–88
Stepwise sequential	95
First-trimester test result: Positive: CVS offered Negative: quad screen offered Final: risk assessment incorporates first and second results	

Contingent sequential	88 to 94

First-trimester test result:
Positive: CVS offered
Negative: no further testing
Intermediate: quad screen offered
Final: risk assessment incorporates first and second results

NT, nuchal translucency; PAPP-A, pregnancy-associated plasma protein A; ß-hCG, beta human chorionic gonadotropin; MSAFP, maternal serum alpha feto protein; CVS, chorionic villus sampling.
American College of Obstetricians and Gynecologists. *Clinical management guidelines for obstetrician-gynecologists. Screening for chromosomal abnormalities.* ACOG Practice Bulletin No. 77, January 2007, with permission.

In cases of first-trimester screening where the fetal nuchal translucency is 3.5 mm or greater, patients should be offered a targeted ultrasound examination and fetal echocardiogram. In addition to the increased risk for aneuploidies, these fetuses are at increased risk for having structural abnormalities, including heart defects as well as genetic syndromes.

Women with an increased nuchal translucency measurement or abnormal first-trimester serum markers may be at increased risk for adverse obstetric outcomes, including preeclampsia, preterm birth, low birth weight, spontaneous fetal loss before 24 weeks gestation, and fetal demise later in gestation. Currently, there are no data to indicate whether or not fetal surveillance in the later pregnancy will be helpful in the care of these patients.

In addition to nuchal translucency, other ultrasonographic markers for Down syndrome have proven to be useful adjunctive noninvasive screening tools. Absence of the fetal nasal bone in the first trimester has been observed in fetuses with Down syndrome. The assessment of absence of the fetal nasal bone, increased resistance to flow in the ductus venosus, or the presence of tricuspid regurgitation may be used to further modify first-trimester Down syndrome risk assessment.

The American College of Obstetrics and Gynecology published an updated technical bulletin on Screening for Fetal Chromosomal Abnormalities in January, 2007. The previous bulletin had recommended that screening for aneuploidy should be offered to all women younger than 35 at their estimated date of delivery and that invasive prenatal diagnostic testing should be offered to all women who will be 35 years or older at the estimated date of their delivery and to women with risk factors for having a fetus with aneuploidy including a significant family history, a positive screening test or an abnormality noted on prenatal

present for prenatal care before 20 weeks of gestation regardless of maternal age.

It is likely that new markers may be implemented in the future to improve the sensitivity and specificity of maternal serum screening. ADAM 12, a metalloprotease that binds insulin growth factor binding protein-3 (IGFBP-3), appears to be an effective early Down syndrome marker. Decreased levels of ADAM 12 may be detected in cases of trisomy 21 as early as 8 to 10 weeks gestation. Maternal serum ADAM 12 and PAPP-A levels at 8 to 9 weeks gestation in combination with maternal age yielded a 91% detection rate for Down syndrome at a 5% false-positive rate. When nuchal translucency data from approximately 12 weeks gestation was added, this increased the detection rate to 97%.

Cellfree fetal DNA was first detected in the maternal circulation over a decade ago. Fetal epigenetic markers such as DNA methylation or a placental epigenetic marker called *maspin* can be utilized to discriminate fetal DNA from maternal DNA. The detection of fetal DNA in the maternal circulation holds great promise for prenatal diagnosis of fetal disorders and pregnancy complications. To date, cellfree DNA has been used for fetal rhesus D blood typing and fetal gender determination for carriers of X-linked recessive disease and fetuses at risk for congenital adrenal hyperplasia.

Screening for Neural Tube Defects

Neural tube defects are an etiologically heterogeneous group of conditions characterized by failure of closure of the embryonic neural tube. These abnormalities of the brain and vertebral column can occur as an isolated defect or as part of a genetic syndrome. Isolated neural tube defects occur in approximately 1.4 to 2 per 1,000 pregnancies and are the second most common major congenital anomaly. They are thought to result from a combination of genetic predisposition and environmental influences. Approximately 90% to 95% of all infants with neural tube defects are born to women with no history of a child with a neural tube defect. Factors known to be associated with neural tube defects include low folic acid intake, geographic region, ethnicity, maternal valproic acid and carbamazepine exposure, high maternal core temperature, and maternal diabetes.

MSAFP screening for neural tube defects was introduced in the 1980s. MSAFP evaluation is an effective screening test for neural tube defects and should be offered to all pregnant women. This type of screening is most accurate from weeks 16 to 18, as there is the widest margin between abnormal and normal distributions at this period in gestation. Although screening for neural tube defects should optimally be performed between 16 and 18 weeks gestation, it can be done between 15 and 22 weeks.

In the United States, a screen-positive cutoff of 2.5 multiples of the median (MoM) is commonly used, yielding a screen-positive rate of approximately 5%. This results in the detection of more than 95% of anencephalic fetuses and 80% of fetuses with open spina bifida. It is important to adjust MSAFP values for diabetes, race, maternal weight, and multiple gestation. In insulin-dependent diabetics, the MSAFP level is approximately 60% of

nondiabetic controls, and it is inversely correlated with the hemoglobin A_{1C} levels. Blacks have approximately 1.1 times the MSAFP level of whites, and Asians have an intermediate level between blacks and whites. The median twin MSAFP level from 16 to 20 weeks is approximately 2.5 multiples of the median for a singleton pregnancy. The detection rate for twins is approximately 80%.

An inaccurate gestational age determination is the most common reason for an abnormally elevated MSAFP. The false-positive rate can be lowered by performing an ultrasound examination before MSAFP screening to verify the gestational age and diagnose multiple gestations and cases of intrauterine fetal demise, which may also be associated with elevated MSAFP levels. Table 7.2 lists conditions that may be associated with an elevated MSAFP level.

Women with MSAFP levels higher than the predetermined cutoff (usually 2.0 to 2.5 MOM) and women with risk factors for carrying a fetus with a neural tube defect including a positive family history or previous affected

pregnancy, diabetes, or first-trimester valproic acid or carbamzepine use should be referred for genetic counseling and consideration of a diagnostic test. All women with a positive MSAFP screen should have a specialized ultrasound to further assess the risk of neural tube defects and rule out other fetal anomalies. According to the ACOG bulletin, genetic amniocentesis is the traditional diagnostic test offered to women with an elevated MSAFP. An elevated amniotic fluid AFP in association with the presence of acetylcholinesterase in the amniotic fluid is considered diagnostic for a fetal neural tube defect. If an amniocentesis is performed secondary to an elevated MSAFP, a sample of amniotic fluid should also be sent for cytogenetic analysis, as there are several studies that have reported an association between elevated MSAFP levels and fetal aneuploidy.

TABLE 7.2 Conditions Associated with an Elevated Maternal Serum Alpha-fetoprotein Level

- Neural tube defects
- Fetal demise
- Multiple gestation
- Selective fetal reduction
- Ventral wall defects:
  - Gastroschisis
  - Omphalocele
- Esophageal or duodenal atresia
- Urinary tract disease:
  - Renal agenesis
  - Congenital nephrosis

- Polycystic kidney disease
- Obstructive lesion

Integumental defects:

- Congenital ichthyosiform erythroderma
- Epidemolysis bullosa

Hydrops or ascites
Cystic hygroma
Placental abnormalities:

- Placental lakes
- Retroplacental hemorrhage
- Hemangiomas of placenta and cord

Maternal hepatoma

There are many centers in the United States that use ultrasound as a diagnostic tool in women with a high risk for neural tube defects. Studies have shown that in experienced centers, ultrasound can yield a 97% sensitivity and a 100% specificity in the diagnosis of neural tube defects. If the fetal anatomy is well visualized and no abnormalities are detected, the risks and benefits of both amniocentesis and specialized ultrasound examination can be discussed with the patient. Many high-risk patients decline to have amniocentesis performed after a reassuring specialized ultrasound examination. Alternatively, amniocentesis should be offered if ultrasound visualization of the fetus is suboptimal and in patients in whom a fetal defect is identified.

Indications for Prenatal Diagnosis

The most common indications for consideration of invasive prenatal diagnostic testing include an abnormal prenatal screen conferring an increased risk for fetal aneuploidy or spina bifida, a thickened nuchal translucency >3 mm, increased risk for a genetic condition based on parental carrier status, and identification of a fetal anomaly on prenatal ultrasound. Table 7.3 lists indications for consideration of invasive prenatal diagnostic testing.

TABLE 7.3 Indications for Invasive Prenatal Diagnostic Testing

Abnormal biochemical screening result
Fetal anomaly diagnosed on ultrasound
Thickened nuchal translucency (>3 mm)
Cystic hygroma
Patient request for invasive testing for fetal karyotype
Parent or previous fetus/child with a chromosomal abnormality

Parents are carriers for a monogenic disorder (i.e., Tay–Sachs disease, Huntington disease, myotonic dystrophy)

Invasive Prenatal Diagnosis Procedures

Amniocentesis

Amniocentesis was introduced in the 1950s for fetal sex determination. The first prenatal diagnosis case of trisomy 21 was reported in 1968. Since that time, the role of amniocentesis has dramatically expanded to include the diagnosis of various cytogenetic and biochemical abnormalities, fetal infections, and a multitude of mendelian disorders. Amniocentesis is the most extensively used fetal sampling technique.

Technique for Amniocentesis

Amniocentesis is typically performed at 15 to 16 weeks gestation. Prior to the amniocentesis, an ultrasound examination is performed to assess fetal viability and number, gestational age, and fetal anatomy. Next, an optimal pocket of amniotic fluid is identified, ideally avoiding the fetus, umbilical cord, and placenta. The abdomen is then prepped with an antiseptic solution. Then, using continuous ultrasound guidance, the physician introduces a 20- to 22-gauge spinal needle into the pocket of fluid (Fig. 7.1). Approximately 20 mL of fluid is aspirated. The first 1 to 2 mL of amniotic fluid is generally aspirated in a separate syringe and is discarded to minimize the chances of maternal cell contamination.

Multiple Gestation

Prior to the procedure, an ultrasound examination should be performed to determine the position of the fetuses, the placenta(s), and the membrane(s) separating the sacs.

Chorionicity should be determined. It is important to describe the location of the fetuses and their placentas at the time the procedure is performed, as it may be necessary to later identify a fetus with abnormal results. Although the fetuses can change their relative positions, their placentas cannot. Thus, it is valuable to trace the umbilical cords to their placentas and to describe any other ultrasound features, including phenotypic gender, that may help to identify the fetuses at a later date.

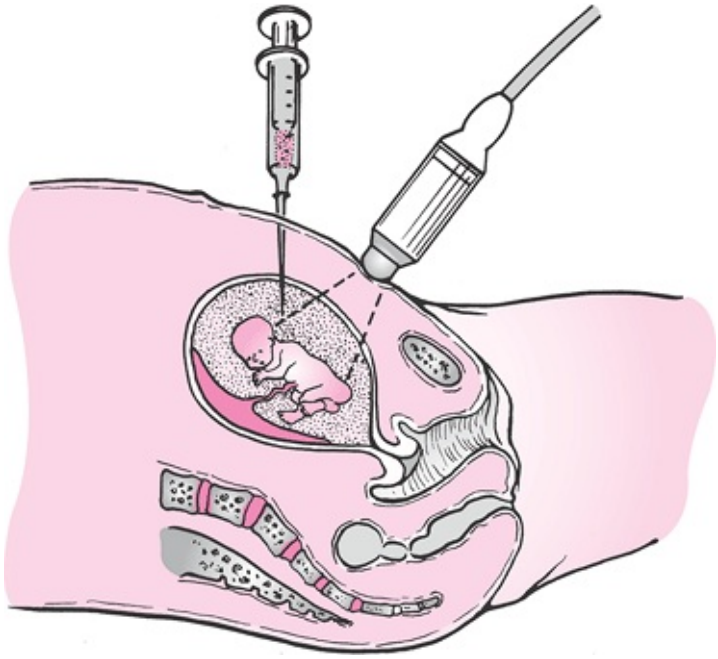

Figure 7.1 Amniocentesis.

A number of techniques involving amniocentesis in twin gestations have been described. The most common technique used to ensure that the same sac is not sampled twice involves the injection of indigo carmine into the first sac after the amniotic fluid sample has been withdrawn. When higher-order multiples are sampled, indigo carmine can be injected into each successive sac. Methylene blue should not be used, as it has been reported to cause methemoglobinemia, hemolytic anemia, and intestinal obstruction.

A single needle puncture technique has been reported for twin gestations. After the first sac has been sampled, the same needle is advanced into the sac of the second twin. The first 1 to 2 mL of amniotic fluid is discarded to avoid contamination from the first twin. Another reported technique involves simultaneous visualization of two needles on each side of the separating membrane by using a curvilinear or linear transducer. Both of these techniques eliminate the need to inject dye into the amniotic cavity.

Potential Complications and Risks

Fetal Loss

Several large prospective trials have been undertaken to establish the safety of midtrimester amniocentesis. A multicenter study sponsored by the National Institute of Child Health and Human Development (NICHD) found no significant difference in fetal loss rates between 1,040 patients who underwent midtrimester amniocentesis (3.5%) and matched controls (3.2%). A Canadian trial also reported similar fetal loss rates in the amniocentesis group and a matched control group. A British study published in 1978 was not as reassuring as the two previous collaborative studies. The group of 2,428 women who underwent amniocentesis had a 1.0% to 1.5% increased fetal loss rate compared with the matched control group. This study has been criticized for ascertainment bias, as many of

the matched controls were not selected until a later gestation than the subjects at the time of the amniocentesis, so some potentially eligible controls may have aborted before they had the opportunity to be selected. In addition, some of the patients in the amniocentesis group had elevated MSAFP levels, which may be associated with adverse pregnancy outcomes including fetal loss. None of these studies was randomized, and all were performed in the 1970s before ultrasound guidance was routinely used.

The only randomized trial addressing the safety of amniocentesis was performed in Denmark and published in 1986. In this trial, 4,606 low-risk women between 14 and 20 weeks gestation were randomized into two groups: amniocentesis under ultrasound guidance or no procedure. The total fetal loss rate was noted to be significantly higher in the amniocentesis group (1.7%) compared with the control group (0.7%) ($P < 0.01$). This yielded a relative risk of 2.3 for the amniocentesis group.

A review of “contemporary” second-trimester amniocentesis publications that each included over 1,000 amniocentesis cases with sufficient detail and follow-up data up to 28 weeks gestation was published in 2004. Twenty-nine reports involving 68,119 amniocentesis procedures were examined. There was a procedure-related rate of excess pregnancy loss of 0.33% (95% confidence interval [CI], 0.09, 0.56) in a comparison of all studies to available control subjects. There were five controlled studies that used concurrent ultrasound needle guidance, including the randomized Danish trial. The procedure-related loss rate was 0.6% (95% CI, 0.31, 0.90) in the subset of the five controlled trials. The background loss rate among the control patients who did not undergo amniocentesis was 1.08%.

A procedure-related loss rate of 0.06% was reported in a study of the 3,096 women who were enrolled in the FASTER (First and Second Trimester Evaluation of Risk for Aneuploidy) trial who chose to have amniocentesis performed. This subgroup of women was compared with the 31,907 women in the FASTER trial who did not undergo amniocentesis. The spontaneous fetal loss rate at less than 24 weeks gestation in the study group was 1.0% and was not statistically different from the background 0.94% rate seen in the control group ($P = 0.74$; 95% CI, 0.026, 0.49). There have been a number of criticisms regarding the study design and statistical methodology of this trial. The authors acknowledged potential limitations of the study, including its nonrandomized study design and the insufficient sample size. More than 400,000 women would be needed in each arm of the study to have 80% power to detect a difference of 0.05% in spontaneous loss rates between the two groups.

Factors that have been reported to be associated with increased rates of fetal loss include a large number of needle insertions, using a needle greater than 18 gauge, perforation of the placenta, and discolored amniotic fluid. The NICHD study reported a 2.9% incidence of fetal loss with one needle insertion, 4.3% for two insertions, and an 8.1% loss rate with three or more insertions. Although brown fluid was related to adverse pregnancy outcome, the NICHD study did not find an association between bloody amniotic fluid and increased fetal loss rates. The Canadian study also reported a correlation between fetal losses and more than two needle insertions per procedure and the use of needles of 19 gauge or greater. The Danish study reported that withdrawal of discolored amniotic fluid, increased levels

of MSAFP, and perforation of the placenta were associated with increased fetal loss rates.

The impact of placental penetration on the risk of pregnancy loss has been addressed in a review of nine reports in the literature involving a total of 5,203 transplacental amniocentesis procedures. In these cases, the loss rate of 1.4% was identical to the overall loss rate noted in the total group of 34,144 women who did not have placental perforation at the time of amniocentesis. Although there is no demonstrable increased risk, it still seems prudent to avoid the placenta where possible. In cases where this is not possible, the cord insertion should be identified and avoided and the thinnest portion of the placenta should be punctured.

Although a contemporary randomized trial would be the optimal approach to assess the fetal loss rate attributable to amniocentesis, it is unlikely that another randomized trial will be performed due to practical and ethical reasons. Although the exact risk associated with amniocentesis is controversial, it is not a completely innocuous procedure. Based on a review of all of the available literature, the risk associated with genetic amniocentesis is likely close to 1 in 300 in experienced hands. Factors associated with increased fetal loss should be avoided when possible.

Other Risks of Midtrimester Amniocentesis

Other potential procedure-related complications include leakage of amniotic fluid, amnionitis, vaginal bleeding, and needle puncture of the fetus. Leakage of amniotic fluid occurs in approximately 1% of women after undergoing amniocentesis. Fortunately, in most cases, this is minimal and resolves within several days. Pregnancies with ruptured membranes after amniocentesis result in better outcomes compared with pregnancies complicated by spontaneous rupture at a similar gestational age. Intra-amniotic infection after amniocentesis occurs in approximately 0.1% of cases. Vaginal bleeding may occur in 2% to 3% of cases and is self-limiting in most cases. With the use of continuous ultrasound guidance, needle puncture of the fetus should be avoidable in the great majority of cases.

Local Anesthesia

Two randomized trials compared local anesthesia using 1% lidocaine with no anesthesia in over 400 women undergoing midtrimester amniocentesis. There were no significant differences in pain perception between the two groups. Based on these data, local anesthesia should not be used for amniocentesis except in select cases.

Early Amniocentesis

Early amniocentesis, performed prior to 14 to 15 weeks gestation, potentially provides fetal karyotype results earlier than midtrimester amniocentesis. Studies have shown that the cytogenetic results from early amniocentesis cell cultures are as accurate as those obtained in the second trimester. In contrast to CVS, potential advantages associated with early amniocentesis include the use of a familiar technique that is widely available, reduction of maternal cell contamination and placental mosaicism, and the ability to

assess amniotic fluid AFP.

The technique for early amniocentesis is similar to the technique used for midtrimester amniocentesis. Early amniocentesis may be more difficult to perform because the amnion and chorion are often still separated by the extraembryonic coelom until 14 weeks gestation. This may result in tenting and stretching of the amniotic membranes and prevent access to the amniotic cavity. This potential problem may be avoided by advancing the needle tip vigorously into a fetusfree pocket of fluid so that the tip “pops through” the membranes. In early gestation, access to an optimal pocket of fluid may require a transplacental approach. There does not appear to be any increased rate of complications specifically associated with transplacental early amniocentesis.

Complications and Risks

Based on the results of several studies, it appears that early amniocentesis at 11/0 and 12/6 weeks gestation is associated with an increased risk of fetal loss and talipes equinovarus. Currently, there are not enough data available to make conclusions regarding the safety of early amniocentesis between 13/0 and 14/6 weeks gestation. The Canadian Early and Mid-trimester Amniocentesis Trial (CEMAT) randomized 4,374 women to early amniocentesis (11/0to 12/6 weeks gestation) or midtrimester amniocentesis (15/0to 16/6 weeks gestation). All procedures were performed with a 22-gauge needle. There was a statistically significant increase in total fetal losses (7.7% vs. 5.9%) and talipes equinovarus (1.3% vs. 0.1%) in the early amniocentesis group. There was also a significantly increased rate of postprocedural amniotic fluid leakage in the early amniocentesis group (3.5% vs. 1.7% in the midtrimester amniocentesis group). Amniotic fluid leakage after early amniocentesis was associated with a 15% incidence of talipes equinovarus compared with a 1.1% incidence after procedures without leakage of fluid. There were no other significant congenital anomalies in either group, and there was no difference in the incidence of neonatal ventilation or prolonged oxygen use between the two study groups; however, a comparison with controls not exposed to amniocentesis was not performed.

Two studies randomized patients to early amniocentesis versus transabdominal CVS. Both studies reported a significantly increased incidence of talipes equinovarus in the early amniocentesis group. A study by Sundberg and colleagues was stopped prematurely secondary to the significant association between early amniocentesis and talipes equinovarus. There were nine cases of talipes equinovarus out of 548 cases in the early amniocentesis group and no affected cases out of 555 CVS procedures. The authors were unable to make a definitive conclusion regarding fetal loss, as although the total fetal losses were

---

similar in both groups, the power of the study was limited since the study was terminated early. A study by Nicolaides and associates found significantly higher rates of talipes equinovarus and spontaneous loss in the early amniocentesis group (1.6% and 5.9%, respectively) compared with the CVS group (0.5% and 1.2%, respectively).

Summary

Amniocentesis performed at 15 weeks or later is safe and effective. The fetal loss rate associated with amniocentesis at this gestational age is likely approximately 1/300 in experienced hands. Amniocentesis should not be performed earlier than 12 weeks and 6 days due to the increased risk of fetal loss and talipes equinovarus. The safety of performing amniocentesis between 13 weeks, 0 days and 14 weeks, 6 days is unknown at this time. Amniocentesis procedures should generally not be performed at this gestational age except for in extenuating circumstances.

Chorionic Villus Sampling

CVS involves sampling of the developing trophoblast in the first trimester. The indications for CVS are similar to amniocentesis. CVS is usually performed between 10 and 12 weeks gestation. The chorion frondosum, which contains the most mitotically active cells in the developing placenta, is sampled by using either a transabdominal or transcervical approach, depending on the placental location and the preference of the patient and/or the physician performing the procedure (Figs. 7.2, 7.3). An ultrasound should be performed prior to the procedure to assess fetal viability, gestational age, and placental position.

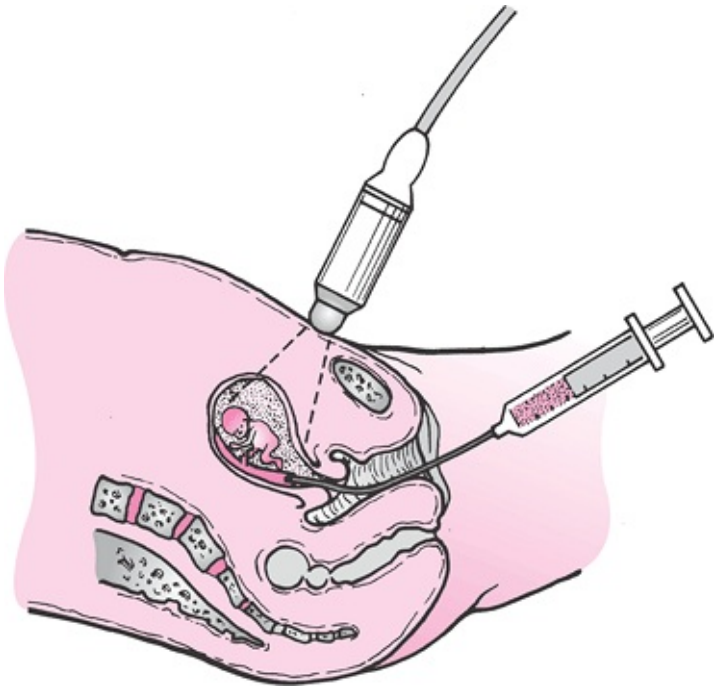

Figure 7.2 Transcervical CVS.

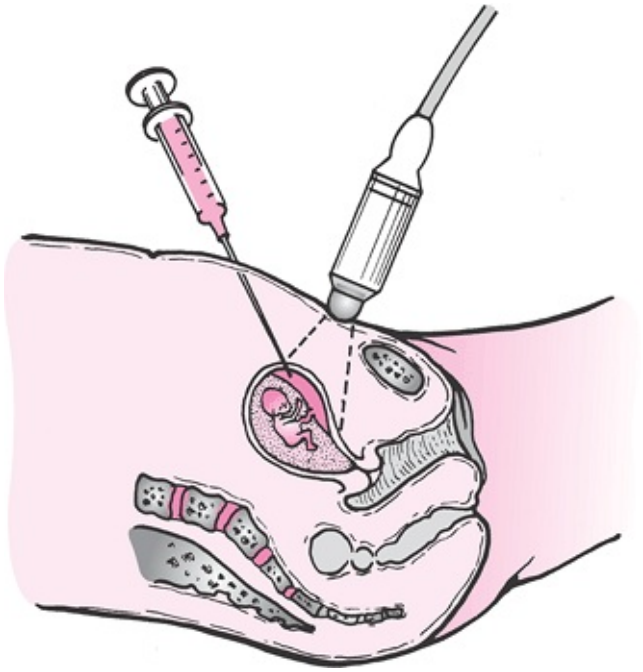

Figure 7.3 Transabdominal CVS.

Transcervical Chorionic Villus Sampling

Fetal tissue sampling was first performed using a transcervical route in the late 1960s. Ultrasound guidance for CVS was first reported in 1979. Brambati and colleagues in Italy were the first to describe the technique that is used for transcervical CVS in most centers today. A polyethelene catheter with a malleable obturator is passed through the cervix into the thickest part of the placenta under ultrasound guidance. Placental trophoblast is then aspirated through the catheter into a 20-mL syringe containing tissue culture medium.

Transabdominal Chorionic Villus Sampling

This technique, which was first described in the medical literature in 1984, can be performed by using a freehand technique or a needle-aspirator transducer. Some operators prefer to use a double-needle technique, in which a smaller needle may be introduced into a larger needle. A 19- or 20-gauge needle is directed into the thickest part of the placenta that is readily accessible under ultrasound guidance. After the stylet is withdrawn from the needle, a syringe containing tissue culture medium is attached to the hub of the needle, and suction is applied as the needle is moved up and down through the placenta until an adequate amount of tissue is obtained.

The sample should be inspected to ensure that an adequate amount of chorionic villi have been obtained. The average sample from a CVS aspiration contains from 15- to 30-mg wet weight of villus material. Transabdominal samples tend to be slightly smaller. A 20-mg sample is ideal for cytogenetic analysis; however, results can be obtained after cell culture with significantly smaller samples. Larger samples of 20 to 40 mg of tissue may be required if direct molecular and biochemical studies are to be performed in addition to cytogenetic analysis.

Transcervical versus Transabdominal Approach?

In most cases, physician or patient preference will dictate which method is used, as in most cases, CVS can be performed by using either a transcervical or a transabdominal approach. However, in approximately 3% to –5% of cases, clinical circumstances will support one approach over the other. Posterior placentas in a retroverted uterus are especially amenable to a transcervical approach, whereas a transabdominal approach would be preferable in cases involving anterior placentas in an anteflexed uterus and fundal placentas. The transcervical and transabdominal approaches have been shown to be equally safe and effective provided that centers have expertise with both approaches.

Absolute contraindications to the transcervical approach include maternal blood group sensitization and active cervical or vaginal infections such as herpes, chlamydia, or gonorrhea. Relative contraindications include vaginal bleeding within 2 weeks prior to the procedure; uterine fibroids that prevent passage of the catheter; cervical polyps; and a markedly retroverted, retroflexed uterus.

Confined Placental Mosaicism

Chromosome mosaicism is defined as the presence of two or more karyotypically different cell lines in the fetoplacental unit arising from a single zygote. Frequently, in cases where a CVS result shows chromosome mosaicism, an amniocentesis will be performed to determine whether the fetus is affected. Confined placental mosaicism refers to cases in which the fetus does not carry the mosaic cell line that was identified in the placenta. It is detected in approximately 1% to 2% of CVS samples. Pregnancies with confined placental mosaicism may be at risk for spontaneous abortion, perinatal loss, or intrauterine growth restriction. A mosaic normal cell line in the placenta of fetuses with chromosomal abnormalities such as trisomy 13 or 18 may allow for prolonged survival of the fetus.

Pregnancies with confined placental mosaicism involving a trisomic cell line may be at risk for uniparental disomy. Uniparental disomy refers to the inheritance of two copies of a chromosome, or part of a chromosome, from the same parent. Isodisomy results when a chromosome or gene is present in two identical copies from the same parent, and heterodisomy results when nonidentical copies from the same parent are present. Trisomic rescue is thought to be the most common cause of uniparental disomy. Trisomic rescue occurs when a zygote is initially trisomic for a particular chromosome but subsequently loses the extra chromosome. In two thirds of the cases, the lost chromosome is of the parental origin that contributed the extra chromosome. In one third of the cases, the lost chromosome will result in uniparental disomy. Isodisomy results when nondisjunction occurs during meiosis I, and heterodisomy results from nondisjunction in meiosis II. Uniparental disomy has been described for chromosomes 6, 7, 11, 14, 15, and 16. Paternal isodisomy for chromosome 15 is associated with Angelman syndrome, and maternal isodisomy for chromosome 15 is associated with Prader Willi syndrome. Maternal isodisomy for chromosome 16 is associated with pregnancy loss and severe intrauterine growth restriction.

Karyotype analysis is usually insufficient to detect uniparental disomy, as specific parentally derived homologues cannot be distinguished at the microscopic level of resolution. Uniparental disomy can be detected with molecular genetic techniques. Thus, in cases of confined placental mosaicism involving trisomy, consideration must be given regarding uniparental disomy. Ideally, the patient should be referred for a prenatal genetics consultation so that she can receive appropriate counseling regarding the potential outcomes and be offered the opportunity to have molecular genetic studies to rule out uniparental disomy.

Safety of Chorionic Villus Sampling

Pregnancy Loss

Four prospective randomized controlled trials that provide data on the safety of CVS have been published to date. The three largest of these studies were performed in the 1980s, soon after the introduction of this procedure, when many providers were still gaining experience with the technique. Patients in these trials were randomized to CVS and midtrimester amniocentesis. An early prospective trial found CVS to have a 0.4% greater rate of loss before 20 weeks gestation and a 0.7% greater rate of loss up to 28 weeks gestation compared with midtrimester amniocentesis. Another early nonrandomized study found a 0.8% increase in fetal loss after CVS as compared with midtrimester amniocentesis. It has been shown that loss rates from CVS are inversely correlated with provider experience. It is unlikely that additional randomized trials will be performed secondary to problems with patient recruitment. A recent retrospective cohort study compared the loss rates before 24 weeks gestation in women who had amniocentesis and CVS with women who did not undergo an invasive procedure between 1983 and 2003. All providers performed a minimum of 50 amniocentesis or 100 CVS procedures under supervision. After adjusting for the background loss rate, the overall amniocentesis loss rate was 0.46%, and the rate from 1998 to 2003 decreased to 0.27%, or 1 in 370. The CVS loss rate was 2.35% overall and decreased to 1.16% in the interval between 1998 and 2003. The difference in pregnancy loss rates between CVS and amniocentesis procedures decreased over the 20-year interval. There was no clinically or statistically significant difference between CVS and amniocentesis loss rates in the most recent interval from 1998 to 2003.

Limb-Reduction Defects

In 1991, Firth and associates reported that 5 of 289 cases of CVS performed at 56 through 66 days gestation had severe limb abnormalities. Four of the infants had oromandibular-limb hypogenesis, and the fifth had an isolated transverse limb-reduction defect. Since this initial report, there have been many other publications both supporting and refuting this association. It appears as though

---

there may be an association of transverse limb defects with CVS procedures performed very early in gestation. Brambati and colleagues observed a 1.6% incidence of severe limb-reduction defects in cases performed at 6 and 7 weeks, a 0.1% incidence at 8 to 9 weeks,

and no increased incidence of limb defects in cases performed after 9 weeks. Eighteen of 19 cases of transverse limb reduction reported by Hsieh and associates, including four cases of oromandibular-limb hypogenesis, had CVS performed before 9 weeks. It also appears that limb-reduction defects may be associated with less-experienced operators. The CVS procedures in the Hsieh report were performed by relatively inexperienced operators in Taiwan.

The World Health Organization (WHO)–sponsored CVS registry in Philadelphia, which was started in 1983, reviewed outcome results from a total of 138,996 cases performed at 63 programs between 9 and 12 weeks gestation. There was no increased incidence of limb-reduction defects in the CVS population (5.2 to 5.7 per 10,000 cases) compared with the general population (4.80 to 5.97 per 10,000). The pattern distribution of limb defects, including transverse limb defects, in the CVS group was similar to the pattern of limb defects in the general population.

Summary

It is important that women are educated regarding the potential benefits and risks associated with CVS, including a potentially slightly higher loss rate compared with second-trimester amniocentesis. This increased risk may become negligible as operator experience increases. It appears as though CVS performed after 10 weeks by an experienced operator is not associated with an increased incidence of limb defects compared with the general population. CVS procedures should generally not be performed prior to 10 weeks gestation.

Percutaneous Umbilical Blood Sampling

First attempts to enter the fetal circulation were based on endoscopic techniques. In 1973, Hobbins and Mahoney published their ability to obtain fetal blood with an endoscopic technique by utilizing a 1.7-mm diameter endoscope combined with a 25-gauge sampling needle. Later, this team reported on the successful diagnosis of hemoglobinopathies by utilizing this technique.

Daffos was the first to utilize an ultrasound guided percutaneous technique to enter the umbilical cord. He initially used this technique to diagnose fetal toxoplasmosis in patients at high risk for this condition. Since that time, percutaneous umbilical blood sampling (PUBS) has been used in the diagnosis of fetal infection, hemoglobinopathies, and chromosomal abnormalities; to explore the etiology of fetal hydrops; to assess fetal acid-base status in growth restriction; and to diagnose and treat erythroblastosis fetalis. Presently, there are noninvasive approaches available that obviate the need to access the fetal circulation for the majority of the initial uses of percutaneous blood sampling. Percutaneous access to the fetal circulation is still used to perform intravascular transfusion to treat fetal anemia. This is most commonly performed in cases of Rh-sensitization, in which there is evidence of underlying significant fetal anemia based on noninvasive studies using ultrasound.

Technique

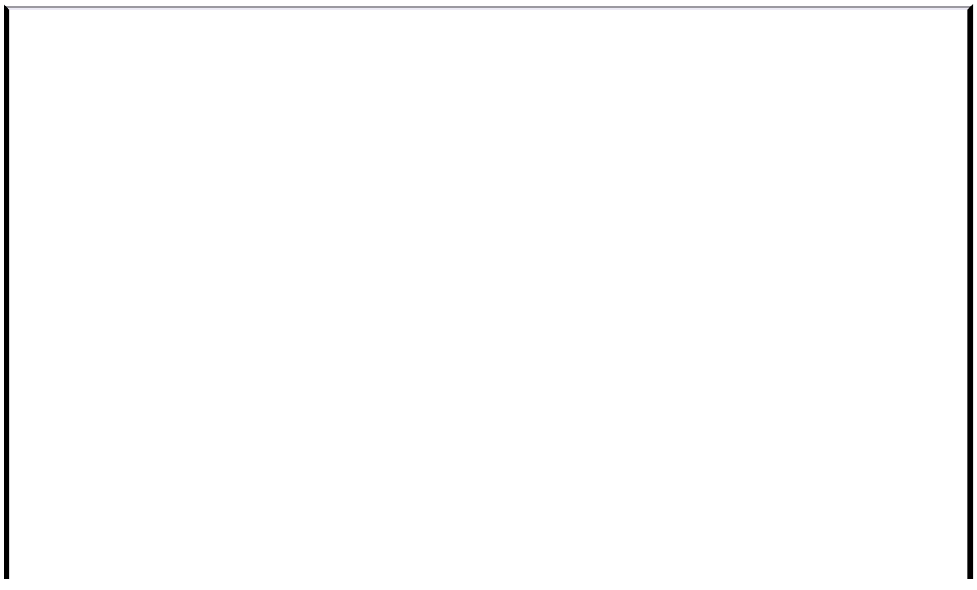
PUBS involves obtaining a sample of fetal blood by placing a needle into the umbilical vein, generally where it inserts into the placenta, as this is where the cord is least mobile. Fetal blood sampling has been obtained from the umbilical artery; however, the umbilical vein is preferred because it is larger and less likely to be associated with fetal bradycardia when punctured. In cases when it is not possible to access the umbilical cord vessels, alternative techniques including sampling from the intrahepatic vein and cardocentesis have been reported, but these techniques are associated with increased risks compared with umbilical cord blood sampling.

A variety of methods have been used for PUBS. The needle may be inserted by using a freehand technique or by using a needle-guiding device that is fixed to the transducer. A 20- or 22-gauge needle may be used. Once the needle has been guided into the umbilical vein, fetal blood is aspirated into a syringe (Fig. 7.4). In order to confirm that the sample is fetal in origin, the mean corpuscular volume (MCV) of the sample should be assessed. Fetal blood cells (140 fl) are larger than maternal cells (80 fl). The MCV of a sample of fetal blood should be above 100.

Risks

The most critical factor related to the safety of the procedure is operator experience. Ghidini and colleagues published a meta-analysis that was designed to assess the true

risk of PUBS. Reports from centers that had performed more than 100 procedures were included. In an attempt to identify procedure-related loss rates, a subset of low-risk cases was analyzed that excluded patients with fetal pathologic conditions including chromosomal abnormalities, structural defects, intrauterine growth restriction, nonimmune hydrops, and fetal infection. The meta-analysis in this low-risk group of patients yielded a loss rate of 1.4% in patients less than 28 weeks gestation and 1.4% in patients greater than 28 weeks. The total fetal loss rates in the low-risk groups ranged from 1.2% to 4.9%. Almost half of the cases analyzed by Ghidini and his group were contributed by a single operator. His loss rate of 2 per 1,021 (0.2%) represented an extremely low loss rate. If one were to exclude these data from the meta-analysis, the resulting loss rates for PUBS in all cases was 7.2% (96/1328) and 3% in the low-risk group (20/660).



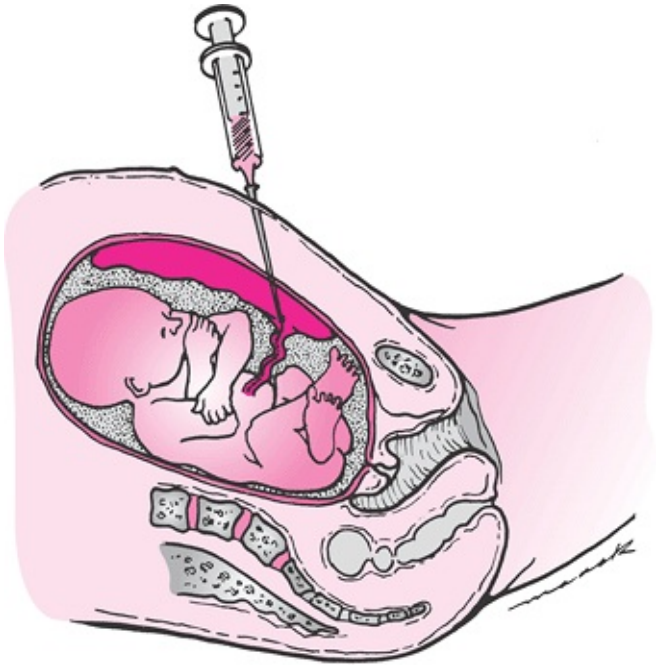


Figure 7.4 Percutaneous umbilical blood sampling.

In addition to fetal loss, other complications associated with PUBS include bleeding from the puncture site in the umbilical cord, cord hematomas, transient fetal bradycardia, infection, and fetomaternal hemorrhage. Bleeding from the cord puncture site is the most common complication and may occur up to 40% of cases. In most cases, it is self-limited. Fetal bradycardia occurs in approximately 9% of procedures and lasts for a short time in most cases. The incidence of a clinically significant fetal bradycardia was noted to be 6.6% in one report. Both umbilical artery puncture and severe, early onset growth restriction were associated with increased rates of bradycardia.

Rh Prophylaxis

It is critical to obtain the blood type on all patients who undergo amniocentesis, CVS, or PUBS, as patients who are Rh-negative and unimmunized should be given a 300 mg intramuscular dose of Rh immune globulin to avoid Rh sensitization.

Future Trends in Prenatal Diagnosis

It is likely that future advances in ultrasound, molecular genetics, cytogenetics, and other technology will continue to increase the alternatives for less invasive and thus less risky prenatal diagnosis options. A trend in this direction has already been observed. Conditions that were first diagnosed using fetoscopy may now be diagnosed using ultrasound, in some cases as early as the first trimester. Identification of additional maternal serum and ultrasound markers may allow for earlier and improved identification of patients at risk for fetal aneuploidy as well as early identification of women at risk for obstetric complications. The discovery of fetal DNA in the maternal circulation holds great promise for noninvasive prenatal diagnosis of fetal disorders and pregnancy complications.

Summary Points

- It is possible to detect approximately 85% of cases of Down syndrome in the first trimester by using a combination of maternal age, nuchal translucency measurement, and maternal serum PAPP-A and free or total β-hCG.
- Down syndrome screening strategies that involve a combination of first- and second-trimester markers yield the highest detection rates and may still provide the option for first-trimester invasive prenatal diagnosis.
- Accurate prenatal diagnosis is now possible for hundreds of genetic conditions through genetic testing.
- Amniocentesis performed at approximately 15 weeks gestation is safe and effective. The fetal loss rate is approximately 1/300 in experienced hands.
- As first-trimester screening continues to increase in popularity, the demand for invasive first-trimester prenatal diagnosis will likely increase. When performed after 10 weeks gestation by an experienced operator, the risk associated with CVS may be comparable to the risk associated with amniocentesis.
- All unimmunized Rh-negative women who undergo invasive prenatal diagnostic testing should be given a 300 mg intramuscular dose of Rh immune globulin to avoid Rh sensitization.

Drugs in Pregnancy

Jerome Yankowitz

Principles of Teratology

Anything a pregnant woman ingests or is exposed to could potentially affect her fetus. This is problematic for health care providers who must treat a variety of conditions during pregnancy. In fact, over 60% of American women receive a prescription for at least one medication during pregnancy. This figure is about 99% for women in France, over 70% for Hungarian women, and over 46% for Finnish women. The most common conditions for which medications are prescribed include gastrointestinal, infectious, dermatologic, psychologic, or psychiatric disorders and to relieve pain.

Generally, whatever medication would be given to a nonpregnant woman is the appropriate choice in pregnancy. In order to be aware of the few exceptions or how to choose between several available options requires knowledge of teratology and alterations in drug metabolism related to pregnancy. *Teratology* is the study of abnormal development or the production of defects in the fetus. Birth defects affect 2% to 3% of all neonates. With longer follow-up, at least 5% of individuals are affected by a birth defect. Exogenous causes of birth defects, including drugs or chemical exposures, account for almost 10% of birth defects. Thus, at least 0.2% to 0.3% of pregnancies are affected by a birth defect due to a teratogen.

The Food and Drug Administration (FDA) introduced a drug classification system in 1979 to discourage nonessential use of medication during pregnancy. Drugs are classified as A, B, C, D, or X, with the latter being the most teratogenic. There has been growing perception that the FDA classification has led to excessive maternal anxiety and unnecessary pregnancy termination. Several years ago, the FDA began evaluating a revised labeling system for drugs and biologics to include a description of the drugs based on clinical management, summary of risk assessment, and discussion of data. This initiative, begun in the late 1990s, has so far yielded little change in the old classification system. The situation is exemplified by data published in 2002 that shows that over 90% of drug treatments approved between 1980 and 2000 still had undetermined teratogenic risk!

Many health care providers continue to use the FDA classification system but, it is probably more useful to use the myriad commercial drug databases that are frequently updated as new information becomes available. Free resources are also available on the Internet.

How much drug the fetus will be exposed to is determined by a complex interaction of many factors, including how the agent is absorbed, the volume of distribution, metabolism, and excretion. Absorption is via the gastrointestinal tract, skin, lungs, or after parenteral administration. Pregnancy alters absorption in a variety of ways, including prolongation of gastric emptying time by the increased progesterone. The volume of distribution is generally increased during pregnancy. Estrogen and progesterone alter hepatic enzyme activity with varying affects on drug metabolism and clearance depending on the precise pathway. Renal excretion is generally increased during pregnancy. Other factors affect precisely how much drug crosses the placenta, which is influenced by several factors. Lipid-soluble substances readily cross the placenta, and water-soluble substances pass less well. Those with greater molecular weight also cross the placenta less easily. The degree to which a drug is bound to plasma protein influences the amount of drug that is free to cross. Virtually all drugs cross the placenta to some degree, with the exception of large organic ions such as heparin and insulin. Active placental transfer must also be considered.

Other concepts related to teratology include specificity, timing, dose, maternal physiology, embryology, and genetics. Specificity indicates that a substance may be teratogenic in some species but not others. For example, thalidomide produces phocomelia in primates but not rodents. Often, animal data of either safety or teratogenic effect is not necessarily applicable to humans. Timing also is critical. When administered between 35 and 37 days, thalidomide

---

produces ear malformations, but between 41 and 44 days, it produces amelia or phocomelia. Dosage also is important. In most cases, administration of a low dose will result in no effect, while malformations occur at intermediate doses and death at higher doses. Death may cause organ-specific teratogenic action to go unnoticed. The route of administration, possibly secondary to absorption, also is important. Small doses over several days may have an effect different from the same total dose given at once. Sequential dosing as opposed to a bolus may induce an enzyme to metabolize the substance that potentially causes less damage. Constant exposure may destroy cells, which would have catabolized the drug if administered in periodic doses. As noted previously for thalidomide, timing of exposure relative to embryologic events is important. Teratogen exposure in the first 2 to 3 weeks after conception is generally thought to have no effect or result in spontaneous loss (all-or-nothing phenomenon). The period of susceptibility to teratogenic agents is during the period of organogenesis, which occurs primarily at 3 to 8 weeks postconception (35 to 70 days after the last menstrual period [LMP]) or to 10 weeks from the LMP. After this period, embryonic development is characterized primarily by increasing organ size (10 to 12 weeks). Thus, the principal effect of exposure will be growth restriction and/or effects on the nervous system and gonadal tissue. These systems continue to develop throughout pregnancy. During organogenesis, each organ system will have different critical periods of sensitivity. A teratogen can act by causing cell death, altering tissue growth (hyperplasia, hypoplasia, or asynchronous growth), or interfering with cellular differentiation or other basic morphogenic processes.

TABLE 8.1 Antibiotics Used for Common Infections in Pregr

Condition	Drug (generic name)	Drug (trade name)	Dose	Co
Asymptomatic bacteriuria or cystitis	Nitrofurantoin	Macrobid, Macrodantin	100 mg p.o. b.i.d.–q.i.d. × 3–10 d	Do if ma G6 de
	Trimethoprim-sulfamethoxazole	Bactrim, Septra	DS, 1 p.o. b.i.d. × 3–10 d	Av fir tri an 2 v de
	Amoxicillin	Amoxil	500 mg t.i.d. × 3–10 d	No lin inc res
	Cephalexin	Keflex	500 mg q.i.d. × 3–10 d	—
	Amoxicillin-clavulanate	Augmentin	p.o. b.i.d. × 7–10 d	—
	Cefazolin	Ancef	1g q6–8h i.v.	Ca ge if ill; afe dis on co 10

Pyelonephritis				co
	Ampicillin	—	2g q6h i.v.	Ca ge
	Gentamicin	—	1.5–2.0 mg/kg load, then 1.5–1.7 mg/kg q8h	—
Group A streptococcal pharyngitis	Penicillin	—	500 mg 2–3 x/d until afebrile 2 days	—
Otitis media	Penicillin	—	250–500 mg q6h until afebrile 2 days	—

G6PD, glucose-6-phosphate dehydrogenase; DS, double strength.

The genetic makeup of the mother and fetus can affect individual susceptibility to a drug. Fetuses with low levels of the enzyme epoxide hydrolase may be more likely to manifest the fetal hydantoin syndrome than those with normal levels of epoxide hydrolase. Combinations of agents may produce different degrees of malformation and/or growth restriction than if given individually. Fetuses whose mothers are on combination antiepileptic agents are at the highest risk for malformations, including neural tube defects and facial dysmorphic features.

Most drug therapy does not require cessation of nursing because the amount excreted into breast milk is small enough to be pharmacologically insignificant.

Antibiotics and Other Anti-infective Agents

Antibiotics are widely used during pregnancy to treat a variety of disorders, including upper respiratory tract infections and urinary tract infections (Table 8.1). Pregnant patients are particularly susceptible to vaginal yeast infections. This is one reason that antibiotics

should be used only when clearly indicated. Therapy with antifungal agents may be necessary after the course of antibiotic therapy.

Antibiotics

Penicillins

Penicillin and its derivatives, including amoxicillin and ampicillin, have a wide margin of safety and lack toxicity for both the woman and her fetus. Penicillin is a ß-lactam that inhibits bacterial cell wall synthesis and can be administered orally, intramuscularly, and intravenously. It is the drug of choice for the treatment of a wide variety of bacterial infections, including group A streptococcal pharyngitis, otitis media, and mild *Streptococcus pneumoniae* pneumonia. Penicillin is the drug of choice to treat syphilis. In fact, pregnant women with allergy to penicillin should be desensitized to receive their full course in the face of a syphilis infection. Ampicillin and amoxicillin are good choices for enterococcal urinary tract infections, but many other pathogens are resistant, so they should be used selectively. Amoxicillin-clavulanate (Augmentin) combines the ß-lactam with a ß-lactamase inhibitor that expands the spectrum of activity. This combination can be used for sinusitis and urinary tract infections.

The extended spectrum penicillins are also safe but much more expensive and generally not used as a first line for most disorders during pregnancy. The cephalosporins are safe and used for urinary tract infections including pyelonephritis and for gonorrhea.

The penicillins can safely be used during breast-feeding.

Clindamycin

Clindamycin is a macrolide and acts on the bacterial ribosome preventing transcription. It can be used to treat bacterial vaginosis, although metronidazole is the first-line medication. It is generally reserved for anaerobic infections that are not sensitive to other agents. Up to 10% of patients will develop pseudomembranous colitis. Clindamycin is safe during breast-feeding.

Metronidazole

Metronidazole inhibits bacterial protein synthesis. It is used to treat trichomonas and bacterial vaginosis. This agent was found to be positive in the Ames test but has not been proven to be carcinogenic in humans nor has it been shown to produce birth defects. Although some authorities suggest deferring use past the first trimester, there is no data supporting this suggestion. This medication is safe in breast-feeding, although the American Academy of Pediatrics recommends interrupting breast-feeding for 12 to 24 hours following a 2 g dose.

Aminoglycosides

Aminoglycosides inhibit bacterial protein synthesis. They can be used to treat pyelonephritis but should be used only when serious gram-negative infection is suspected. Maternal administration is said to be associated with ototoxicity in the fetus leading to hearing loss. This association has not been clearly proven. Breast-feeding is safe, as little drug passes to the neonate via the breast milk.

Trimethoprim-Sulfamethoxazole

Trimethoprim-sulfamethoxazole (Bactrim or Septra) inhibits folic acid metabolism and is very active against many organisms that cause urinary tract infections. In 2,296 Michigan Medicaid recipients, first-trimester trimethoprim exposure was associated with a slightly increased risk of birth defects, particularly cardiovascular, and in a retrospective study, the odds ratio was 2.3. Several other case-control studies have shown an increased odds ratio of neural tube defects (potentially consistent with inhibition in folic acid metabolism) and cardiovascular defects. Given these studies showing increased risks of anomalies and the mechanism of action via the folate pathway, avoidance in the first trimester is prudent. Trimethoprim-sulfamethoxazole also displaces bilirubin from its protein binding sites in the neonate, potentially contributing to an increased risk of hyperbilirubinemia or kernicterus in newborns. Therefore, it should not be used close to delivery. This theoretic effect has not been substantiated in clinical trials. Trimethoprim-sulfamethoxazole has been used to treat otitis, sinusitis, *Shigella* colitis, and *Pneumocystits carinii* infections in addition to both asymptomatic bacteriuria and acute cystitis. Use of this medication is safe during breast-feeding.

Nitrofurantoin

Nitrofurantoin inhibits bacterial protein and cell wall synthesis. It is eliminated by excretion, and this bactericidal activity makes it highly active in treating uncomplicated lower urinary tract infections. It can induce hemolytic anemia in glucose-6-phosphate dehydrogenase–deficient patients, and because the newborn's red blood cells are deficient in reduced glutathione, the label carries a warning against use of the drug at term. Hemolytic anemia in the newborn after exposure in utero has been reported. This medication is compatible with breast-feeding.

Erythromycin

Erythromycin and azithromycin inhibit bacterial protein synthesis. They are often used as an alternative to the penicillins and are first-line treatment for mycoplasma and chlamydia. These medications are also useful in treating community acquired pneumonia or severe bronchitis. Use of both erythromycin and azithromycin are compatible with breast-feeding.

Tetracyclines

The tetracyclines, including doxycycline, have not been definitively associated with a teratogenic effect; however, it is known that they may cause staining of the teeth and,

potentially, skeletal abnormalities. The staining has not been associated with increased risk of tooth anomalies or later caries. Attempts are generally made to avoid this class of medications, but depending on perceived

risk–benefit assessment and organism sensitivities, they may be suggested. Anthrax exposure is one potential area in which benefits of doxycycline use may outweigh the risk.

Quinolones

The quinolones class of medications includes ciprofloxacin. Although studies have not shown detrimental affects in humans, fluoroquinolones are toxic to developing cartilage in experimental animal studies. Thus, this class of drugs should be avoided during pregnancy except in severe cases.

Antiviral Agents

The emergence of HIV and AIDS has resulted in development of many antiviral agents. Previously, herpes was one of the few viral infections for which pregnant women might be exposed to treatment (Table 8.2).

Acyclovir and Valacyclovir

Acyclovir (Zovirax), a synthetic purine nucleoside, has resulted in no fetal abnormalities in the hundreds to thousands of exposures reported. The Centers for Disease Control and Prevention recommends that pregnant women with disseminated infection, such as herpes, hepatitis, or varicella pneumonia, be treated with acyclovir. Acyclovir is the active metabolite of valacyclovir, and this latter agent has been used safely as well. Both drugs are also used to suppress recurrence of genital herpes virus infection. No human studies during pregnancy have been carried out with famciclovir, although a registry is in place to collect reports on maternal–fetal outcomes of women exposed to famciclovir during pregnancy. The registry can be reached at 888-669-6682.

TABLE 8.2 Antivirals in Pregnancy

Condition	Drug	Dose	Comments
	Acyclovir	400 mg b.i.d.	—
Suppression of herpes simplex	Famciclovir	250 mg b.i.d.	—

	Valacyclovir	500 mg q/d	—
Antiretroviral drugs (used to treat HIV)			
Nucleoside reverse-transcriptase inhibitors	Zidovudine	100 mg 6 × d	Rare mitochondrial toxic effects but generally very safe and should be part of standard regime
	Lamivudine	150 or 300 mg b.i.d.	First-line agent with zidovudine
	Didanosine	≥60 kg: 200 mg b.i.d.	Can be part of HAART therapy in pregnancy
	Stavudine	≥60 kg: 40 mg b.i.d.	Should not be used with zidovudine
	Zalcitabine	0.75 mg t.i.d.	Rarely indicated in pregnancy
Non-nucleoside reverse-transcriptase inhibitors	Nevirapine	200 mg q/d × 2 wk, then 200 mg b.i.d.	Part of HAART therapy
	Delavirdine	400 mg t.i.d.	No human studies; not recommended
	Indinavir	800 mg q8h	Can be part of HAART

	Ritonavir	600 mg b.i.d.	Use in low dose to enhance a second PI
PIs	Saquinavir	600–1200 mg t.i.d.	Can be part of HAART
	Nelfinavir	750 mg t.i.d.	Can be part of HAART
	Amprenavir or Lopinavir		No studies in humans

HAART, highly active antiretroviral therapy; PI, protease inhibitor.

Human Immunodeficiency Virus Treatment

A variety of agents may be used to treat patients with HIV infection. The medications generally fall into three categories—the nucleoside reverse transcriptase inhibitors (nRTI), the nonnucleoside analog reverse transcriptase inhibitors (NNRTI), and the protease inhibitors (PI). Zidovudine is the most widely studied nRTI, and there is unlikely to be a major teratogenic risk. This medication has been associated with a low (about 0.5%) risk of mitochondrial dysfunction in neonates after maternal treatment. In the same class of medications, didanosine, stavudine, and lamivudine also seem to not have significant teratogenic risk. A related drug, tenofovir, is an nRTI. There is little human data about this agent. All medications in this class can cause mitochondrial dysfunction. There were several reports of adverse maternal outcomes when combining didanosine and stavudine, leading the manufacturer to advise caution with use of this combination.

The NNRTI class includes nevirapine and delavirdine. Neither has had reported adverse teratogenic effects.

The PI class, which now includes amprenavir, atazanavir, darunavir, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir and tipranavir, has not been extensively studied. The Antiretroviral Pregnancy Registry has been established to enter all antiretroviral exposures in pregnancy (*http://www.apregistry.com*). Obviously, maternal infection with HIV necessitates collaborative care with an infectious disease expert in addition to obstetric input. In addition, because HIV can be excreted in breast milk, breast-feeding in developed countries is not advised.

Upper Respiratory Tract Complaints

The common cold is the most frequent acute illness, and most colds are self-diagnosed and treated. Medicines used to treat symptoms associated with the common cold are among the most common used drugs in pregnancy. Most patients complain of fatigue, malaise, rhinorrhea, nasal congestion, cough, and sore throat. The cold can be caused by a variety of viruses, rhinoviruses, coronaviruses, respiratory syncytial virus, adenovirus, parainfluenza and influenza virus, and others. Therefore, in the absence of a complicating superinfection with bacteria, antibiotic treatment is not appropriate.

The most common treatments are used to address the listed symptoms and include antihistamines, decongestants, and cough suppressants.

Antihistamines

Most antihistamines are safe during pregnancy. Brompheniramine (Bromfed) was associated with an increased relative risk of malformations in the Collaborative Perinatal Project that could be explained by methodological flaws. This was not confirmed the Boston Collaborative Drug Surveillance Program. Other safe antihistamines include chlorpheniramine, clemastine, diphenhydramine, and doxylamine.

There are newer antihistamines with only a little data supporting safety in pregnancy that are best used as second-line therapy. These include astemizole (Hismanal), cetirizine (Zyrtec), and loratadine (Claritin). This is even less information concerning fexofenadine (Allegra).

Decongestants

The most common oral decongestants are all sympathomimetic agents and include pseudoephedrine, phenylephrine, and phenylpropanolamine. There have been some reports of an association between gastroschisis and first-trimester maternal exposure to pseudoephedrine. In the first trimester, an alternative would be to try use of topical preparations including the nasal decongestants oxymetazoline (Afrin) or phenylephrine (Neo-Synephrine).

Cough Suppressants

Codeine and dextromethorphan are the most common cough suppressants. Neither has been associated with a teratogenic effect.

Most cold treatments, including the antihistamines, decongestants, and cough suppressants, are safe during breast-feeding.

Asthma Treatment

While the cold is the most common acute illness during pregnancy, asthma is the most common chronic respiratory condition. About 5% of pregnancies are complicated by asthma, which may cause increases in preterm birth, low birth weight, and other

complications. Whether aggressive and active management reduces these risks to the background level is a controversial issue. Asthma is characterized by airway inflammation and hyperreactivity.

Treatment of the asthmatic should start with reduction of environmental factors that worsen disease. All patients should receive the influenza vaccination yearly. Allergens should be avoided, as should both active and passive exposures to cigarette smoke. For patients who do not respond optimally to these environmental alterations, a variety of pharmacologic treatments are available (Table 8.3).

β-Sympathomimetic Agents

The short-acting β-sympathomimetic agents are the first-line treatment for acute asthma exacerbations. Albuterol inhalers (Proventil, Ventolin) are commonly used. Terbutaline and metaproterenol inhalers are acceptable alternatives. No teratogenic risks have been ascribed to these medications, and all are compatible with breast-feeding. For longer-term treatment, salmeterol, a long-acting β-sympathomimetic is available and safe.

All of the β-sympathomimetic agents can cause tachycardia and other cardiovascular effects. These are usually mild and self-limited.

Corticosteroids

Inhaled corticosteroids are also first-line therapy. They act by reducing inflammation. Agents include beclomethasone, fluticasone, and others. No teratogenicity for inhaled steroids has been seen, and they are compatible with breast-feeding.

Systemic corticosteroids also can be used for acute exacerbations but may increase the risk for cleft lip and palate up to fivefold.

Theophylline

Theophylline was at one time a first-line agent for treatment of asthma, but with the emergence of the β-agonists and inhaled corticosteroids, its role has been markedly

reduced. This agent can be administered intravenously for acute asthma or orally for chronic suppression. The narrow therapeutic window has contributed to this medication falling out of favor. Used for many years, theophylline has shown no evidence of teratogenicity, and it can be used during breast-feeding.

TABLE 8.3 Medications to Treat Asthma

Medication	Dose	Comments
Inhaled corticosteroids		

Beclomethasone	4–8 puffs b.i.d.	MDI 42 μg/puff
Vanceril DS	2–4 puffs b.i.d.	MDI 84 μg/puff
Triamcinolone	2 puffs t.i.d.–q.i.d. or 4 puffs b.i.d.	MDI 100 μg/puff
Fluticasone	2–4 puffs b.i.d.	MDI 44, 110, and 220 μg/puff
Flovent Rotadisk	1 inhalation b.i.d.	Dry powder inhaler 50, 100, and 250 μg/inhalation
Flunisolide	2–4 puffs b.i.d.	MDI 250 μg/puff
Budesonide	1–2 inhalations b.i.d.	Dry powder inhaler 200 or 400 μg/inhalation
Systemic corticosteroids		
Methylprednisolone	1 mg/kg i.v. or 40–60 mg p.o. with rapid taper	—
β-sympathomimetics		
Albuterol	2 puffs q4–6h p.r.n.	Short acting
Pirbuterol	2 puffs q4–6h p.r.n.	Short acting

Terbutaline	2 puffs q4–6h p.r.n.	Short acting
Metaproterenol	2–3 puffs q3–4h p.r.n. or 20 mg p.o. q6–8h	Short acting
Bitolterol mesylate	2 puffs q4–6h p.r.n.	Intermediate-acting ß-mimetic
Salmeterol	2 puffs q12h	Long-acting ß-mimetic
Theophylline	400–1600 mg q/d	Therapeutic serum level 8–12 µg/ml
Cromolyn sodium	200 mg p.o. q.i.d. or inhaler 2–4 puffs q.i.d.	—
Leukotriene receptor antagonists		
Zafirlukast	20 mg p.o. b.i.d.	Little information available on use during pregnancy
Montelukast	10 mg p.o. q.h.s.	Little information available on use during pregnancy
Zileuton	600 mg p.o. q.i.d.	A 5-lipoxygenase inhibitor; little information available on use during pregnancy

MDI, metered-dose inhaler; DS, double strength.
Reprinted from Hansen WF, Yankowitz J. Pharmacologic therapy for medical disorders during pregnancy. *Clin Obstet*

Gynecol 2002;45:136–152, with permission.

Cromolyn Sodium

Cromolyn sodium is used for long-term therapy in patients with atopy functioning as a mast cell stabilizer. Administered by inhaler, there are no known teratogenic or breast-feeding concerns.

Leukotriene Receptor Antagonists and Lipoxygenase Inhibitors

The leukotriene receptor antagonists (Zafirlukast, Montelukast) and the 5-lipoxygenase inhibitors affect the inflammatory pathways. These agents are new, and human data are sparse. If these agents can be avoided during pregnancy and lactation, other drugs should be used.

Gastrointestinal Disorders

Gastrointestinal problems are extremely common in pregnancy and include nausea, vomiting, hyperemesis gravidarum, gastroesophageal reflux, intrahepatic cholestasis of pregnancy, and inflammatory bowel disease. The presentation of several serious disorders may be altered or overlooked during pregnancy and include appendicitis, cholecystitis, pancreatitis, hepatitis, and carcinoma of the gastrointestinal tract.

Nausea and vomiting, or “morning sickness,” occurs in as many as 90% of pregnancies. Nonpharmacologic treatment can include acupressure at the Neiguan point (2 inches proximal to the wrist crease between the tendons of the flexor carpi radialis and palmaris longus muscles),

which may be of benefit. Ingestion of ginger appears to reduce nausea and vomiting in pregnancy. Pyridoxine, or vitamin B_6, also appears to reduce symptoms. Pharmacologic treatment can include use of antihistamines, antidopaminergics, and other agents (Table 8.4).

Antihistamines

Doxylamine (Unisom) is an antihistamine that was a component of bendectin. Bendectin was an effective treatment for the nausea and vomiting of pregnancy that was withdrawn from the American market in 1983 because of unproved allegations that it increased the risk of malformations. Doxylamine can be combined with pyridoxine, reconstituting the two active ingredients of bendectin. Other commonly used antihistamines include dimenhydrinate (Dramamine); diphenhydramine (Benadril); and hydroxyzine (Vistaril, Atarax), which has both antianxiety and antihistamine properties. Promethazine (Phenergan) has a central cholinergic blocking activity.

TABLE 8.4 Drugs Commonly Used for Management of Nause Vomiting, and Hyperemesis Gravidarum

Generic Drug Name	Trade Name	Pharmacologic Class of Drug	Dosage
Dicyclomine	Bentyl	Anticholinergic	20 mg p. i.m. q.i.
	Bendectin	Antihistaminic	—
Doxylamine	Unisom	Antihistaminic	25 mg p. min prio bed
Dimenhydrinate	Dramamine	Antihistaminic	50–100 m p.o. q4° 50 mg i.m i.v. q3–4
Diphenhydramine	Benadryl	Antihistaminic	50 mg p. q6–8° 20–50 mg or i.v. q2
Meclizine	Antivert	Antihistaminic	20–50 mg q/d
Hydroxyzine	Vistaril, Atarax	Antihistaminic	25–100 m p.o. q6–8 25–100 m i.m. q4–6
Promethazine	Phenergan	Antihistaminic	12.5 mg p.r., or i q4–6°
			10–25 mg q4–6° 25 mg p.

Chlorpromazine	Thorazine	Antidopaminergic	q12° 25–50 mg q3–4°
Perphenazine	Trilafon	Antidopaminergic	2–4 mg p q4–6° 5 mg i.m once
Prochlorperazine	Compazine	Antidopaminergic	5–10 mg or i.m. q 10 mg p. 6°

Haloperidol	Haldol	Antidopaminergic	1–5mg p. b.i.d. 1–5 mg i. q12°
Metoclopramide	Reglan	Antidopaminergic	5–10 mg q.i.d. 5–20 mg or i.v. q.
Trimethobenzamide hydrochloride	Tigan	Miscellaneous	250 mg p or p.r. q6
Ondansetron	Zofran	Miscellaneous	8 mg p.o i.v. q8°
Pyridoxine	Vitamin B_6	Vitamin	10–25 mg t.i.d.

Reprinted from Hansen WF, Yankowitz J. Pharmacologic therapy fo medical disorders during pregnancy. *Clin Obstet Gynecol* 2002;45: 152, with permission.

Antidopaminergic Agents

Several antidopaminergic agents have been used in pregnancy and are probably safe. The list includes prochlorperazine (Compazine), metoclopramide (Reglan), chlorpromazine (Thorazine), perphenazine (Trilafon), droperidol (Inapsine), and haloperidol (Haldol). There tend to be more maternal side effects with these medications compared with the antihistaminic agents. There are also some conflicting data about possible minimal increased risks of birth defects with the latter members of the group. I tend to suggest use of the prochlorperazine or metoclopramide as first-choice agents in this class. These agents are probably safe in breast-feeding, but some require observing the neonate for sedation.

Other Agents

Trimethobenzamide (Tigan), which provides nausea inhibition at the chemoreceptor level, and ondansetron

(Zofran) have been used, but there is less experience with these agents and certainly the latter is much more expensive with no greater efficacy than standard antihistamines.

Reflux or heartburn is a common complaint during pregnancy, particularly in later gestation. Up to 80% of women may have some symptoms of reflux or heartburn. As with hyperemesis, starting with the least invasive environmental or lifestyle changes is prudent. Advise includes elevation of the head of the bed while sleeping, wearing loose clothing, eating frequent small meals that are low in fat, and smoking cessation. Antacids would then be the first-line therapy (Table 8.5) and are not known to be associated with any fetal risk. The next class of agents is the histamine receptor antagonists, which can have a reduced bioavailability following antacid use. Therefore, the antacids and the histamine receptor antagonists should be given at least 1 hour apart. The histamine antagonists include cimetidine (Tagamet), famotidine (Pepcid), ranitidine (Zantac), and nizatidine (Axid). There is limited data concerning nizatidine, so the first three would be initial choices. All are compatible with breast-feeding. Promotility drugs can be used and include metoclopramide (described previously) and cisapride (Propulsid), about which there is little data. Sucralfate (Carafate) inhibits pepsin activity and may improve symptoms. The proton pump inhibitors are relatively new agents, and therefore I would not recommend them. Misoprostol, a prostaglandin E_1 analog, is contraindicated in pregnancy.

TABLE 8.5 Drugs Commonly Used for Gastroesophageal Reflux in Pregnancy

Generic Drug Name	Trade Name	Class of Drug	Dosage
Antacids			
Cimetidine	Tagamet	H_2-Receptor antagonist	300 mg p.o. a.c. & h.s. 200 mg p.o. a.c. & 400 mg h.s. 400 mg p.o. b.i.d. 500 p.o. h.s.
Famotidine	Pepcid	H_2-Receptor antagonist	40 mg p.o. q.h.s. 20 mg p.o. b.i.d.
Ranitidine	Zantac	H_2-Receptor antagonist	150 mg p.o. b.i.d. 300 mg p.o. q.h.s.
Nizatidine	Axid	H_2-Receptor antagonist	300 mg p.o. q.d. 150 mg p.o. b.i.d.
Metoclopramide	Reglan	Promotility	10–15 mg p.o. q.i.d. to be taken 30 min a.c. & h.s.
Cisapride	Propulsid	Promotility	10 mg p.o. a.c. & h.s.
Sucralfate	Carafate	Antisecretory	1 g p.o. q.i.d.
Omeprazole	Prilosec	Proton pump	

		inhibitor	20 mg p.o. q.d.
Lansoprazole	Prevacid	Proton pump inhibitor	15 mg p.o. q.d.

Reprinted from Hansen WF, Yankowitz J. Pharmacologic therapy for medical disorders during pregnancy. *Clin Obstet Gynecol* 2002;45:136–152, with permission.

Intrahepatic cholestasis of pregnancy causes itching of the extremities, trunk, palms, and soles. The pruritus can worsen at night and become severe. In the past, cholestyramine (Questran) was the treatment of choice. Cholestyramine is a nonabsorbable anion-exchange resin that binds bile acids, which are elevated in cholestasis. There is now some evidence that ursodeoxycholic acid (UDCA) (ursodiol), a minor, naturally occurring hydrophilic bile salt, both reduces maternal pruritus and improves biochemical abnormalities without obvious adverse effects on the newborn. Evidence is accumulating from controlled clinical trials that UDCA is safe. When intrahepatic cholestasis is diagnosed, UDCA coupled with close maternal fetal surveillance is indicated due to potential increases in spontaneous preterm delivery, fetal distress with meconium staining of amniotic fluid, and fetal death.

Inflammatory bowel disease in the form of ulcerative colitis and Crohn disease occur commonly during the reproductive years. Sulfasalazine (Azulfidine) is used for the treatment of both ulcerative colitis and Crohn disease. It is composed of 5-aminosalicylic acid and sulfapyridine. It is poorly absorbed from the gastrointestinal tract and is therefore safe in pregnancy. There is a potential for side effects if used during breast-feeding, so the American Academy of Pediatrics cautions women about use of sulfasalazine during lactation. Mesalamine (Asacol) can also be used during pregnancy and may have less maternal side effects than sulfasalazine. Azathioprine is an immunosuppressant and appears safe to use during pregnancy.

Analgesic Use

Analgesics, both by prescription and over-the-counter purchase, are among the most commonly used medicines in pregnancy. This class of drugs basically falls into two categories—the nonsteroidal anti-inflammatory agents and the opioid family.

Nonsteroidal Anti-Inflammatory Drugs

Aspirin is one of the nonsteroidal anti-inflammatory drugs (NSAIDs) and acts by irreversible inhibition of enzymes in the prostaglandin synthesis pathway. Caution should certainly be advised in use of aspirin beyond the lowest daily doses, as this drug readily crosses the

placenta. First-trimester use has been associated with an increased risk of gastroschisis. While doses at or below 100 mg per day have been studied to determine whether there is a reduction in preeclampsia or intrauterine growth restriction without complications, higher doses have been associated with increased risk of placental abruption. The World Health Organization (WHO) Working Group on Human Lactation and the American Academy of Pediatrics Committee on Drugs both raise concern about maternal use of aspirin while breast-feeding.

Indomethacin and ibuprofen are commonly used NSAIDs that cause competitive and reversible inhibition of prostaglandin synthesis. These NSAIDs can cause constriction of the fetal ductus arteriosus as gestational age progresses, and therefore their use is not suggested after about 32 weeks. They have not been shown to cause malformations, but use beyond the first trimester can cause oligo- or anhydramnios secondary to direct renal effects. Both indomethacin and ibuprofen are considered compatible with breast-feeding.

Acetaminophen is widely used in pregnancy. It crosses the placenta but is considered safe in the usual doses. It can be routinely used in all trimesters to relieve pain and lower fevers. It is usually the analgesic of choice for a wide variety of aches, pains, and headaches. It is compatible with breast-feeding.

Opioid Analgesics

Many narcotic preparations are available and are used during pregnancy. They all cross the placenta but have not been associated with malformations when used in usual doses. Use close to delivery can result in neonatal depression. The common narcotics—codeine, meperidine, and oxycodone—are all compatible with breast-feeding.

Psychiatric Disorders

Major depression and schizophrenia are very common during the reproductive years. with incidences of 15% and 8% to 10%, respectively. As with any medication, there are concerns about teratogenesis, neonatal withdrawal, or long-term neurobehavioral effects, but these issues must be balanced by the risks to the mother and fetus/infant of withdrawing the necessary medication (Table 8.6).

The tricyclics have been widely used to treat depression and also anxiety, obsessive-compulsive disorders, migraines, and other problems. None of the tricyclics has been associated with causing malformations. If needed, it would be prudent to use the agents with the most accumulated experience, including nortriptyline, desipramine, amitriptyline, and imipramine. There is no evidence to date of clear adverse neonatal effects during breast-feeding, but the American Academy of Pediatrics classifies amitriptyline and imipramine as drugs whose effects on the nursing infant are unknown but may be of concern.

The selective serotonin reuptake inhibitors (SSRIs) include fluoxetine as well as newer agents—fluvoxamine, paroxetine, and sertraline. Extensive experience with fluoxetine shows no clear increased risk of malformations. Fluoxetine and the other SSRIs have been associated with abnormalities of neonatal adaptation, including respiratory difficulty,

cyanosis on feeding, and jitteriness. There is recent data that supports an increased risk of cardiac defects with paroxetine as well as an increased risk of persistent pulmonary hypertension in the newborn with third-trimester maternal treatment. In 2006, the American College of Obstetrics and Gynecology (ACOG) suggested that use of paroxetine be avoided, when possible, by pregnant women or women planning to become pregnant due to these risks. The issues with neonatal adaptation and the reports of a teratogenic risk for some members of the SSRI family have caused some controversy among health care providers as to appropriate care of depression during

pregnancy. Clearly, discussion between psychiatric and obstetric providers on a patient-by-patient basis is warranted.

TABLE 8.6 Starting Dosages for Psychotropic Medications in Pregnancy

Medication	Dosage
Amitriptyline	25–50 mg q.h.s.
Chlorpromazine	100 mg once or twice daily
Desipramine	25–50 mg q.h.s.
Fluoxetine	10–20 mg q.h.s.
Haloperidol	5–10 mg/d
Imiprimine	25–50 mg q.h.s.
Lithium	0.6–2.1 g/d in 3 divided doses
Nortriptyline	10–25 mg q.h.s.

Reprinted from Hansen WF, Yankowitz J. Pharmacologic therapy for medical disorders during pregnancy. *Clin Obstet Gynecol* 2002;45:136–152, with permission.

Fluoxetine is among the group of drugs whose effects on the infant are unknown but may be of concern in relation to breast-feeding. The patient should weigh the strength of her desire to breast-feed and the benefits of breast-feeding against the potential effects of continued SSRI use.

Other agents are prescribed for depression. Monoamine oxidase inhibitors have not been studied sufficiently to draw a conclusion about their safety. The psychostimulants may cause problems following in utero exposure and also are best avoided. St John's wort, an extract of the plant *Hypericum perforatum* has been touted for antidepressant properties, but recent studies have not proven efficacy, so this medication also should be avoided.

The mood stabilizers, specifically lithium, valproic acid, and carbamazepine have all been identified as teratogens. The data on lithium causing malformations has weakened with additional studies. Initial reports found a 5% to 10% risk of malformations with a markedly increased risk of Ebstein anomaly. More recent reports show little if any increased risk of malformation and have failed to confirm the specific association with this anomaly. For the patient with a first-trimester exposure to lithium, a targeted ultrasound in the second trimester is warranted. Lithium has also been associated with hydramnios, possibly secondary to fetal diabetes insipidus. Although there is little data, the American Academy of Pediatrics considers lithium to be contraindicated during lactation.

Valproic acid and carbamazepine are both associated with an increased risk of neural tube defects and second-trimester serum screening for alpha-fetoprotein, and targeted ultrasound is warranted. Yet, many of the neural tube defects are closed and difficult to detect.

The antianxiety agents generally fall into the benzodiazepine family. There have been reports of an increased risk of cleft lip after exposure not substantiated in other reports. While the odds ratio may have been increased, the absolute rate of clefting would still be low given a rate of only 0.06% in the normal population. The American Academy of Pediatrics states that the effects on the neonate during lactation are unknown but may be of concern.

The antipsychotic agents include the butyrophenones (including haloperidol) and phenothiazines. No clear teratogenic effect has been seen with either. Haloperidol is classified as having an unknown but possibly concerning effect if used during breast-feeding.

Vitamin and Mineral Use

Many health care providers for pregnant women commonly advocate prenatal use of multivitamins, often with additional iron. There is clear evidence that the folate component reduces the first occurrence and recurrence rate of neural tube defects. Other studies point to possible reduction in cardiac and urinary tract abnormalities. For the woman who eats a balanced diet, most of the recommended daily allowances should be attained except for folate and iron. However, there are multiple at-risk populations who may not attain the goals, including those patients with eating disorders, vegetarians, the poor, substance abusers, women carrying multiple gestations, and so on.

The only clear teratogenic vitamin is vitamin A, which when used at over 10,000 IU per day can cause cranial neural crest anomalies. It would be prudent to not exceed 5,000 IU per day in supplementation.

For minerals, supplementation of iron can improve hematocrit at the time of delivery and 6 weeks postpartum. Some studies have shown a benefit of calcium in reducing the risk of gestational hypertension and preeclampsia, although other studies fail to confirm this finding. Zinc may increase birth weight and head circumference in populations with zinc deficiency but probably not in the United States.

Recreational Drug Use

Recreational drug use is a major problem in the United States. Anonymous testing studies have found rates of positivity of opiates, cocaine, or cannabinoids to be between 7.5% to over 13% in a variety of populations.

As concerning as the illicit drugs are, the effects of tobacco are also well described and of great impact. Some studies suggest that one sixth of low birth weight incidence could be prevented if women did not smoke during pregnancy. Nicotine reduces uteroplacental blood flow, increases the risk of preterm birth, increases the risk of low birth weight, and increases the risk of sudden infant death syndrome postpartum.

Maternal alcohol use can cause fetal alcohol syndrome, characterized by craniofacial changes and impaired cognitive development. Although the full-blown picture can be seen with excessive consumption, no safe level of alcohol use has been established.

The effects of recreational opioid use appear to be confined to an increased risk of growth restriction, intrauterine fetal death, and neonatal withdrawal. No clear long-term effects have been proven.

Marijuana use during pregnancy has not been linked with any clear teratogenic effect or long-term developmental consequences.

Cocaine use has been associated with an increased risk of placental abruption, preterm premature rupture of membranes, and low birth weight. A variety of congenital abnormalities have been described with maternal cocaine use, but no definite connection has been established. A variety of neurobehavioral effects have also been described, but long-term problems are not clear.

Amphetamines, described as stimulants for depressed patients, are becoming a commonly abused drug. Although

---

no clear pattern of malformations has been seen, increases in cleft lip and palate have been seen in some but not all studies. Concern has been raised about long-term physical growth and intellectual and behavorial development.

Anticonvulsants

Epilepsy is the most common neurologic disorder in pregnancy. Five percent of the population report having had a seizure at some point in their lives. All antiepileptic drugs

(AEDs) cross the placenta and therefore have potential for teratogenicity (Table 8.7). Given the incidence of epilepsy, one in 250 fetuses are exposed to an AED. Recent studies are making it clear that AEDs are responsible for the congenital malformations found in the offspring of pregnant women with epilepsy and not the epilepsy itself, as has been conjectured in the past.

Phenytoin (Dilantin) is a hydantoin AED. Fetal hydantoin syndrome includes a constellation of anomalies including craniofacial, limb, and neonatal growth and performance delays. The risk of teratogenicity is about two times the background risk. Phenytoin is compatible with breast-feeding.

Carbamazepine (Tegretol) causes a group of defects similar to fetal hydantoin syndrome in addition to the increased risk of spina bifida. The risk of spina bifida is about 0.5% to 1.0%. It is compatible with breast-feeding.

Phenobarbital is in the barbiturate class. In addition to findings similar to hydantoin syndrome, it has been associated with congenital heart defects and orofacial clefting. Breast-feeding is acceptable unless the infant develops sedation, in which case breast-feeding should be discontinued.

TABLE 8.7 Anticonvulsants

Drug	Dose and Comments
Phenytoin (Dilantin)	300–600 mg/d in divided doses Therapeutic level: 10–20 μg/mL
Carbamazepine (Tegretol)	200–1,200 mg/d Therapeutic level: 4–12 μg/mL
Phenobarbital	60–240 mg/d Therapeutic level: 10–40 μg/mL
Valproic acid (Depakote)	10–15 mg/kg/d Therapeutic level: 50–100 μg/mL
Ethosuximide (Zarontin)	500–2000 mg/d in divided doses Therapeutic level: 40–100 μg/mL
Clonazepam (Klonopin)	1.5–20.0 mg/d

Gabapentin (Neurontin)	New agent
Lamotrigine (Lamictal)	New agent

Reprinted from Hansen WF, Yankowitz J. Pharmacologic therapy for medical disorders during pregnancy. *Clin Obstet Gynecol* 2002;45:136–152, with permission.

Valproic acid (Depakote) has a 1% to 2% risk of causing spina bifida. These neural tube defects tend to occur in the lumbosacral area. Valproic acid use also has been associated with cardiac defects, orofacial clefting, and genitourinary anomalies. There is a fetal valproate syndrome, which includes facial, central nervous system, and limb anomalies. Breast-feeding is permissible with use of this medication.

Several newer AEDs have been developed and include felbamate, gabapentin, lamotrigine, and others. Many patients who have completed the first trimester present to prenatal clinics on these medications. Patients should be counseled that, at present, there is no evidence of teratogenicity, but little information is available.

Headaches

Headache is a very common problem in pregnancy. Evaluation of a complaint of headaches requires categorizing the headache as primary or secondary. Secondary is due to another condition such as flu, while in primary, the headache itself is the disorder. Primary headaches include migraine, tension-type headache, and cluster headache. Criteria have been developed for differentiating these categories and include frequency, degree of pain, and location of pain.

Sumatriptan is a selective serotonin receptor agonist. There is no evidence that it is a human teratogen based on limited numbers of patients reported to the Sumatriptan Pregnancy Registry maintained by Glaxo Wellcome and patients who contacted a teratogen hotline. There is even less data about three newer drugs in this class—naratriptan, zolmitriptan, and rizatriptan.

ß-Adrenergic blockers such as propranolol have been used as preventive therapy. ß-Blockers, calcium channel blockers, and many of the antidepressants discussed previously have been used as preventive therapy and appear safe in pregnancy and breast-feeding.

Antineoplastic Agents

Cancer is relatively common during pregnancy. One in 1,000 to 1 in 1,500 pregnancies is complicated by cancer. The most common malignancies include carcinoma of the cervix and breast, lymphoma, melanoma, leukemia, and carcinoma of the ovary and colon. Chemotherapeutic agents act on rapidly dividing cells and therefore are potentially harmful to the fetal tissue. The trimester of exposure is, of course, critically important to

what potential effect the drug may have. Teratogenesis is a concern in the first trimester, but impact on the continued development of the brain in the second and third trimester is of importance. Delivery planning also is important, as both maternal and neonatal blood counts may be adversely affected by the chemotherapy. For the most part, chemotherapeutic drugs

are secreted into the breast milk, making breast-feeding contraindicated for the woman receiving this therapy.

There are many classes of drugs that can be used as chemotherapy. The alkylating agents cross-link DNA. These drugs, including busulfan, chlorambucil, cyclophosphamide, and nitrogen mustard, are all considered teratogens in the first trimester. The antimetabolites are also teratogenic, possibly due to their effect on folic acid metabolism. This class includes aminopterin and methotrexate. Other antimetabolites that do not affect folic acid metabolism, such as the pyrimidine antagonist 5-fluorouracil, 6-mercaptopurine, and cytarabine, have much less frequently been associated with birth defects.

The taxanes, including paclitaxel, have not been used in pregnancy enough to comment on safety. Cisplatin has been used in pregnancy, but most experience is in the second and third trimesters. Growth restriction is common.

The therapy of pregnant women with cancer must be individualized and based on collaboration between the primary care provider, perinatologist, oncologist, and neonatologist.

Anticoagulation

Thromboembolism is a leading cause of morbidity and mortality in pregnancy and postpartum. It is the second most common cause of pregnancy-related maternal mortality in the United States. Anticoagulation is used for thromboembolism, valvular heart disease, inherited thrombophilias, and acquired thrombophilias such as antiphospholipid antibody syndrome. The agents available (Table 8.8) are the coumarin derivative, unfractionated heparin, and low-molecular-weight heparin (LMWH). The Cochrane Databases indicate that use of LMWH to treat recurrent pregnancy loss secondary to antiphospholipid antibody syndrome may not be as efficacious as the use of unfractionated heparin.

Thromboembolism occurs in 0.5 to 3.0 of every 1,000 pregnancies. Treatment of acute deep vein thrombosis includes bed rest, elevation of the extremity to promote venous return, and heparin. Heparin is used with a target activated partial thromboplastin time (aPTT) of 1.5 to 2.5 times control. For pregnant patients, a switch to subcutaneous heparin takes place at 3 to 5 days as opposed to the initiation of warfarin sodium (Coumadin) in the nonpregnant state.

Anticoagulation in the face of artificial heart valves can be a difficult dilemma. For patients with particularly thrombogenic valves, it may be necessary to consider use of oral anticoagulation. For both inherited and acquired thrombophilias, use of unfractionated or LMWH are probably acceptable.

Use of the oral anticoagulant warfarin sodium is problematic, as there is a known

teratogenic effect. This agent easily crosses the placenta. Warfarin depresses the vitamin K–dependent clotting factors (II, VII, IX, and X). Its effectiveness is measured by use of the prothrombin time (PT) expressed as an international normalized ratio (INR). The first case of teratogenicity of warfarin was reported in 1966, and the infant in this case had nasal hypoplasia, bilateral optic atrophy, blindness, and mental retardation. In a review of all published cases up to 1980, one sixth had abnormalities and another one sixth ended in stillbirth or spontaneous abortion. Two thirds of exposed pregnancies had a normal outcome. Some reports cite a teratogenic effect in up to two thirds of fetuses exposed between 6 and 12 weeks. Other reports state that the embryopathy effects as few as 5% to 10% of fetuses exposed in the first trimester. The problem is in differing doses and the nature of neonatal evaluation.

It appears that neither unfractionated heparin or LMWH cross the placenta to any appreciable degree and are therefore not teratogenic. Patients can develop heparin-induced thrombocytopenia at about 2 weeks after initiation of therapy. Osteopenia is also a problem with prolonged use. Both of the latter complications are more common with unfractionated heparin.

All three classes of anticoagulants are compatible with breast-feeding.

Radiologic Examinations

Many women require diagnostic imaging studies during pregnancy. The two main concerns are exposure to ionizing radiation and effects of contrast agents. The vast majority of data derives from relatively few pregnant women exposed to high doses of radiation from the atomic bombs dropped over Hiroshima and Nagasaki. From these few individuals, it has been extrapolated that there is a threshold dose of at least 5 rads required to cause concerning effect on the developing fetus. The particular effect depends on gestational age at exposure and radiation dose (Table 8.9). Lethality may be possible during preimplantation with doses as low as 5 rads, but by 9 days postconception, at least 25 to 50 rads is needed. Malformations only occur between about 9 and 60 days postconception, and the threshold is at least 10 rads. Mental retardation is possible between 61 and 104 days postconception with a threshold of 12 rads.

Due to increasing concern about the escalating number of rads of exposure inherent in newer computed tomographic (CT) technology, the University of Iowa Department of Radiology has developed a protocol to avoid unnecessary exposures and adequately counsel the pregnant patient. Counseling includes a discussion of a 1.5 to 2-fold increased risk in childhood leukemias for a 1- to 2-rad exposure in the midtrimester and into the third trimester. It is important to be aware of typical radiation exposures of commonly used examinations (Table 8.10) but also to enlist the expertise of a radiation physicist to assist in calculation of doses in specific cases.

TABLE 8.8 Anticoagulation in Pregnancy

Feature	Care in Pregnancy
APS with recurrent pregnancy loss or prior fetal death	Heparin prophylactically 15,000–20,000 U/d administered s.q. in divided doses and low-dose aspirin
APS with prior thrombotic event	Heparin full anticoagulation or prophylactically 15,000–20,000 U/d
APS without pregnancy loss or thrombosis	Uncertain, options include no treatment or low-dose aspirin or prophylactic heparin at 5,000–20,000 U q12h and low-dose aspirin with all of the above
Antiphospholipid antibodies without APS	Uncertain; no treatment reasonable or low-dose aspirin or prophylactic heparin and low-dose aspirin
Other antibodies	Uncertain, no treatment or low-dose aspirin
Previous DVT or PE prior to current pregnancy	Surveillance with warfarin postpartum for 4–6 wk or heparin 5,000 U q12 with p.p. warfarin or LMWH or 5,000 U q12h in first and second trimester and increase in the third trimester to prolong aPTT to 1.5× or

	10,000 U q12h throughout pregnancy or prophylaxis intrapartum and 6 wk postpartum or 7,500–10,0000 U q12h throughout pregnancy with postpartum prophylaxis
DVT or PE during this pregnancy	Heparin i.v., then q12h heparin to elevate PTT into therapeutic range
Mechanical heart valves	Heparin to prolong aPTT into therapeutic range or heparin in first trimester and end of third trimester with warfarin (INR 2.5–3.5) other times

APS, antiphospholipid syndrome; DVT, deep vein thrombosis; PE, pulmonary embolism; LMWH, low-molecular-weight heparin; aPTT, activated partial thromboblastin time; PTT, partial thromboblastin time; INR, international normalized ration.
Reprinted from Hansen WF, Yankowitz J. Pharmacologic therapy for medical disorders during pregnancy. *Clin Obstet Gynecol* 2002;45:136–152, with permission.

Nuclear medicine studies involve exposure to ionizing radiation from a variety of isotopes. In most cases, the fetal dose will be less than 1 rad except for sodium iodide, Ga67, iodinated red blood cells, or thallous chloride Ti201. Iodine-131 can cause fetal thyroid damage, goiter, and local effects when concentrated by the fetal thyroid after 70 days post-LMP. Use of iodine-131 to treat hyperthyroidism and/or ablate the thyroid can result in substantial fetal doses.

The most widely used radioisotope in pregnancy is technetium-99. It can cross the placenta, but the amount of radiation from any routine study is small.

Magnetic resonance imaging (MRI) involves exposure to magnetic fields rather than ionizing radiation. There

are few studies evaluating the effects of MRI on fetuses. There are also virtually no data on gadolinium, a nonionic contrast agent typically used for MRI evaluations. For this reason, MRI is reserved for situations when it is clearly clinically warranted.

TABLE 8.9 Risks of Irradiation per Gestational Age

Defect and Gestational Age	Occurrence	Threshold	Risk per Rad
Lethality			
0–8 d (PC)	+++	5–10 rads	1.00% max
9–60 d	+	25–50 rads	ND
61–104 d	+	50 rads	ND
105–175 d	—	—	—
>175 d	—	—	—
Malformation			
0–8 d	—	—	—
9–60 d	+++	10–20 rads	0.50%
61–104 d	—	—	—
105–175 d	—	—	—
>175 d	—	—	—
Mental retardation			
0–8 d	—	—	—

9–60 d	—	—	—
61–104 d	+++	12 rads	0.40%
105–175 d	+	65 rads	0.10%
> 175 days	—	—	—
Microcephaly			
0–8 d	—	—	—
9–60 d	++	10–20 rads	1.00%
61–104 d	++	10–20 rads	1.00%
105–175 d	—	—	—
> 175 d	—	—	—
Growth retardation			
0–8 d	—	—	—
9–60 d	+++	5–25 rads	ND
61–104 d	++	5–25 rads	ND
105–175 d	—	—	—
> 175 d	—	—	—

PC, postconception; ND, no data; —, no observed effect; +, demonstrated effect; ++, readily apparent effect; +++, occurs in high incidence.

during pregnancy. In: Yankowitz J, Niebyl JR, eds. *Drug therapy in pregnancy*, 3rd ed. New York: Lippincott Williams & Wilkins, 2001, with permission.

Complementary and Alternative Therapy

Complementary and alternative therapy includes use of acupuncture, acupressure, massage, aromatherapy, and use of herbal preparations (phytomedicine). A wide variety of herbs are used, but there is limited scientific evaluation. Thus, safety and efficacy cannot be clearly addressed. Certain ingredients should be avoided altogether and include anthraquinone and berberine, which may stimulate uterine contractions. Many other herbs are thought to have similar properties and should be avoided. Patients should be queried about use of complementary medicines. An effort should be made to determine the constituents of the preparation and then to evaluate the safety of each component.

TABLE 8.10 Typical Radiation Exposure to the Fetus for Selected Diagnostic Studies (1 rad = 1,000 mrad)

Chest x-ray	2–8 mrad
Dental x-ray	<1 mrad
Mammography	7–10 mrad
Abdominal x-ray	200–700 mrad
Lumbar spine x-ray	300–600 mrad
Hip x-ray	200–500 mrad
Upper GI series	100–550 mrad
Barium enema	800–1,300 mrad
Intravenous pyelogram	600–1,000 mrad

Cholecystography	100 mrad
CT head	50 mrad
CT chest	1,000 mrad
CT abdomen	3,000–4,000 mrad
CT pelvimetry	250 mrad
Cardiac catheterization	<500 mrad

GI, gastrointestinal; CT, computed tomography.

Summary Points

- Most diseases should be treated similarly in the pregnancy patient as for other patients.
- Rather than using the FDA Drug Classification System, specific references and information in databases should be sought out for particular medications in specific clinical situations.
- Most drugs are safe to use during pregnancy, including most antibiotics and medications to treat common conditions such as upper respiratory tract and gastrointestinal complaints.
- There are a few medications that are known teratogens, and the list includes coumadin, lithium, the anticonvulsive medications, several antineoplastic drugs, and vitamin A and its derivates.
- Most drugs are safe during breast-feeding, as subtherapeutic amounts of approximately 1% to 2% of the maternal dose appear in breast milk. One notable exception is lithium.

Ultrasound has evolved dramatically over the last 35 years and has gone from a tool used to answer a limited number of clinical questions to an essential tool in the care and management of virtually every modern pregnancy. The technology has evolved from the generation of limited, static two-dimensional (2D) images to real-time moving three-dimensional (3D) images. In addition, the practitioner now has the ability to “fly” through any acquired volume to better appreciate fetal anatomy—a technological breakthrough that has never been possible before. Indeed, so extensive and penetrating has the ultrasound revolution been that this chapter, in its finite scope, can only serve as a brief summary of much of modern obstetrical practice.

Early Pregnancy

Early pregnancy can be divided into the preembryonic period (conception to 5 menstrual weeks); the embryonic period, during which time organogenesis is the major activity (4 to 9 menstrual weeks); and the early developmental or fetal period, during which time the fetus continues to grow.

The first ultrasound sign of pregnancy is a gestational sac that appears as a double ring that is comprised of the decidua capsularis and the decidua parietalis. The sac should be seen when the β human chorionic gonadotropin (hCG) is between 1,000 and 2,000 mIU/mL. Once identified, the sac diameter should grow by an average of 1 mm per day.

The yolk sac can be seen when the mean sac diameter (MSD) is 5 mm, and it definitely should be seen by the time the MSD is 8 mm. The yolk sac provides nourishment and produces the stem cells that develop into red blood cells, white blood cells, and platelets. Thus, until approximately 7 menstrual weeks, the yolk sac provides the immunologic potential for the fetus, after which time those functions are taken over by the fetal liver.

By 5 menstrual weeks, one can see an embryo. One can determine gestational age by adding 42 days to the crown-rump length (CRL) measurement in millimeters (Fig. 9.1). The embryo should increase its CRL by 1 mm per day. Failure to visualize an embryo when the MSD has reached 6 mm is indicative of a pregnancy loss.

Cardiac activity should be visualized when the embryonic length is 4 mm or greater, and the absence of a heartbeat at this embryonic size is an ominous sign. Additionally, it has been noted that with a heart rate (HR) less than 90 beats per minute (BPM) in pregnancies that are less than 8 weeks, there is an 80% chance of fetal death. If the HR is below 70, virtually 100% will ultimately experience an intrauterine demise.

Human Chorionic Gonadotropin

hCG is a product of the human placenta that rises linearly throughout the first trimester and decreases through the second trimester. The assays commonly used today for monitoring early pregnancy measure intact hCG.

Initially, Kadar and colleagues described a “discriminatory level,” above which one should see an embryo sonographically. These initial values were based on transabdominal ultrasound (TAU) and an assay that has been replaced by the second international standard. The hCG level above which one should identify an embryo by transvaginal ultrasonography (TVU) is now 1,000 to 2,000 mIU/mL, as determined by the second international standard. When there is clinical concern for a potential pregnancy loss or an ectopic pregnancy, serial measurements of hCG can be useful. In a normal intrauterine pregnancy, the hCG level

---

generally doubles every 48 hours and at minimum should increase by more than 66% in that time period.

Figure 9.1 Crown-rump length.

The Natural Progression of Early Pregnancy Loss

A great number of pregnancies are lost within days of conception. Thereafter, the loss rate diminishes steeply until the 12th week of gestation. A patient can be counseled with regard to the chances of a losing a pregnancy based on the following sonographic findings.

When Present	Chance of Loss before 12 Weeks (%)
Gestational sac only	11.5
Yolk sac only	8.5
Embryo <6 mm	7.2
Embryo between 5 and 10 mm	3.3
Embryo >10 mm	0.5

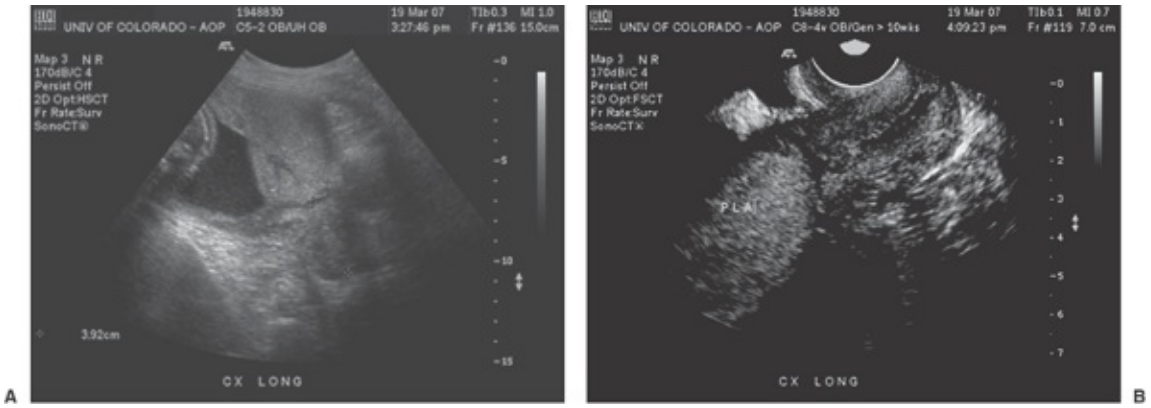

Figure 9.2 A: Placenta previa. Transabdominal scan. Note that the inferior portion of the placenta appears to extend over the internal cervical os. **B:** Placenta previa. Transvaginal scan, same patient as in Figure 9.2A. The placenta is confirmed to be overlying the internal cervical os.

Loss rates increase in the setting of first-trimester bleeding. It has been estimated that about 25% of all patients will have some bleeding or spotting in the first trimester, and in half of these pregnancies, a viable fetus will not result. The most common reason for early loss is aneuploidy. Ohno found that 69.4% of products of conception from 144 spontaneous abortions had abnormal chromosomes, with the majority representing trisomies. Also, the overwhelming majority of pregnancies are nonviable many days before the onset of vaginal bleeding, and the embryonic size can provide information as to when demise might have occurred.

Examination of the Placenta

The placenta is a fetal organ, and many fetal problems are linked in some way to the placenta. Indeed, even early maternal complications, such as preeclampsia, can be directly traced to the placenta.

Placental Position

Determining placental location is a requirement of every set of guidelines for a basic ultrasound examination. The main clinical concerns regarding placental location are whether the placenta obstructs the cervix or if it is located anteriorly in the lower uterine segment over a prior cesarean section scar.

The incidence of placenta previa (Fig. 9.2) in full-term pregnancies is about 2.8/1000. However, this incidence rises with increasing parity, approaching 5% in patients with five or more previous pregnancies. The rate of placenta previa is higher in women of advanced maternal age (AMA), in those with multiple gestations, and in those

---

having had previous cesarean sections. With the current U.S. cesarean section rate of 29%, there is an increase in the prevalence of placenta previa, and with it, an increase in associated complications such as preterm birth (PTB) and placenta accreta is expected.

A placenta that is within 2 cm of the internal os of the cervix is unlikely to remain low lying. About 5% of patients will have a placenta previa diagnosed between 10 and 20 weeks, but only 10% of these will remain over or close to the endocervix at term. However, if the diagnosis is made at 28 to 31 weeks, 62% will persist, and if found between 32 and 35 weeks, about 75% will remain at delivery.

In placenta previa, the extent to which the placenta overlaps the cervix appears to be extremely important. Studies show that if the placenta extends past the cervix by 1.5 cm in the second trimester, the likelihood of placenta previa at term is about 20%. If the overlap is more than 2.4 cm, then 40% of these will remain.

This apparent migration of the placenta is due to passive movement away from the cervix as the lower uterine segment expands with advancing gestational age.

The transvaginal examination with the bladder empty is the best way to diagnose placenta previa, although the combination of TAU and TVU may be needed to identify an accessory lobe or interconnecting vessels to an accessory lobe (i.e., a vasa previa).

Placenta Accreta

Placenta accreta occurs in about 1 in 10 patients with placenta previa, compared with 4 per 10,000 in the general pregnant population. The risk for this condition is elevated in patients of AMA with previa who have also had a previous cesarean section. In this circumstance, there is a 40% chance of placenta accreta. Additional clinical clues as to the presence of an accreta is an elevated maternal serum α-fetoprotein (MSAFP) that is significantly greater than 2.5 multiples of the median (MoM); such an abnormality in the

MSAFP has been noted in half of patients with placenta accreta.

The strongest ultrasound markers for placenta accreta are the findings of placental lakes, often beneath a previous cesarean section scar, that possess a characteristic, slow lacunar flow. It is difficult to outline an uninterrupted myometrial margin as evidenced by a sonolucent clear space even when there is no accreta, and thus this is not necessarily a reliable marker. The diagnosis is easier to make when there is invasion through the myometrium (increta) or through the serosa and potentially into adjacent organs, such as the bladder (percreta). It is important to not mistake dilated basal veins for the tornado-shaped lacunar areas synonymous with accreta. The former will have a clear rim of myometrium under them.

Magnetic resonance imaging (MRI) may be useful adjunctively when the evidence for placenta accreta is equivocal by sonographic exam, especially when the placenta is implanted posteriorly.

Placental Abruption

Placental separations most frequently occur in the placental periphery. The blood then travels extramembranously to the cervix and then through the cervical canal. The diagnosis can be confirmed if the blood stops along the way as a clot, but this occurs in only 50% of cases. In these cases, the diagnosis is made by excluding a placenta previa and documenting clinically that the bleeding is emanating from the cervical os and not from the cervix itself.

Rarely can the diagnosis can be made by identifying with ultrasound a separation between the placenta and the uterine wall. Additionally, in such cases, the patient or the fetus is usually showing signs of clinical instability.

The overwhelming majority of patients with one vaginal bleed will not have a recurrence. However, they do have a higher rate of PTB and premature rupture of the membranes (PROM). In the latter case, Lockwood has postulated that the presence of the components of the clot itself will have a direct effect on the integrity of the membranes. Also, with abruption, the membranes are separated from their source of nutrition for some time, making them more susceptible to rupture.

Placental Grading

In 1979, Grannum published a placental grading classification that was originally designed to replace amniocentesis for fetal pulmonary maturity. Although the most mature-grade placenta was a very reasonable predictor of pulmonic maturity, it was only found in about 15% of term pregnancies. In current clinical practice, the grading system has largely fallen out of use.

Abnormalities of the Cord

Single Umbilical Artery

A single umbilical artery (SUA) is found in 0.2% to 1.0% of pregnancies. Since it has been associated with a higher rate of fetal anomalies, it is important to be certain of the diagnosis. The best way to confirm cord vessel number is the identification of an umbilical artery on either side of the fetal bladder. A variant of the SUA theme is a segmental fusion occurring anywhere along the length of the umbilical cord, and this may be the reason for an erroneous diagnosis of a SUA being made with cross-sectional views alone.

Many studies have documented the association between SUA and congenital anomalies, and these rates vary between 33% and 74%. The major anomalies most commonly associated with SUA involve the fetal heart, central nervous

system (CNS), and kidneys, and thus these organ systems should be thoroughly evaluated. Chromosomal abnormalities linked with SUA are trisomies 13 and 18. If any fetal anomaly is found, then the risk of aneuploidy also increases appreciably and warrants an amniocentesis.

Umbilical Cord Insertion

The umbilical cord is usually inserted into the main body of the placenta, but variations can occur. The most extreme is velamentous insertion, where the cord inserts into the membranes close to the margin of the placenta. Velamentous or marginal insertions have been associated with a higher rate of intrauterine growth restriction (IUGR), especially in twin and multifetal gestations. In general, velamentous cord insertions that occur more inferiorly in the uterine cavity, and hence closer to the cervical internal os, tend to involve longer exposed vessel lengths than velamentous insertions occurring higher up in the uterus. Predictably, the incidence of variable decelerations and “nonreassuring fetal status” are significantly greater when a velamentous insertion occurs in the lower uterine segment versus higher locations. As a result, the cesarean section rate is also greater with lower-segment velamentous insertions as compared with higher insertions.

Vasa Previa

Vasa previa, a potentially lethal problem, complicates approximately 1 in 2,500 pregnancies overall and occurs in as many as 1 in 293 pregnancies conceived by assisted reproductive technology (ART). Vasa previa can occur either when the connecting vessels from the main body of the placenta course directly over the cervix to an accessory lobe or when a velamentous insertion of the cord resides in the membranes lying directly over the cervix. Presumably, since the vascular environment of the lower uterine segment is poorly suited to support placental development, the placenta preferentially grows superiorly while atrophying inferiorly, leaving the umbilical cord in the same place—over the cervix—but with no cushion of intervening placental tissue. As a result, although standard performance guidelines of a basic ultrasound examination do not include a search for the cord insertion, this should certainly be evaluated among all patients with either a low-lying placenta or a placenta previa.

The diagnosis of vasa previa can be made with color Doppler ultrasound demonstration of blood vessels traversing immediately over the endocervix. This is best done with TVU, and

with pulse Doppler, the artery in question can be seen to be beating at a fetal rate.

Nuchal Cord

The inadvertent finding of an umbilical cord around the neck creates angst that in virtually every case is unnecessary. Indeed, about 1 in 5 fetuses have at least one loop of cord around the neck at delivery. In one observational study involving 11,200 deliveries, 19.0% of infants were born with one loop of cord around the neck, 5.3% had two loops, and 1.2% had three. From an ultrasound perspective, in a recent study, follow-up information was obtained from 118 consecutive fetuses diagnosed with ultrasound to have nuchal cords between 17 and 36 weeks. These data were compared with 233 matched controls. There was no difference in time of birth, cesarean section rate, abnormal fetal HR pattern, meconium-stained amniotic fluid, low Apgar scores, or admissions to the newborn special care unit.

Assessment of Amniotic Fluid

An excess of fluid, i.e., polyhydramnios, does not directly affect the fetus but can lead to preterm labor. In contrast, insufficiency of fluid (oligohydramnios) can have a negative impact on fetal lung and limb development, both of which need adequate amniotic fluid to develop.

The amniotic fluid volume rises linearly until about 33 to 34 weeks, when the average is about 1,000 cc, after which time it drops slowly to about 800 cc at 40 weeks gestation and to 600 cc at 42 weeks.

There are three sonographic methods commonly used to assess the adequacy of amniotic fluid—the vertical pocket technique, the amniotic fluid index (AFI), and subjective assessment.

The largest vertical pocket concept came into being when it was first described by Manning and Platt in 1981 as part of the biophysical profile (BPP). Two centimeters is considered the lower limit of normal for a single deepest vertical pocket. Most investigators use a pocket exceeding 8 cm to connote polyhydramnios.

The AFI was devised by Phelan in 1987. The uterus is divided into four quadrants, and the largest vertical fluid pockets in each quadrant are measured and totaled. An AFI equal to or greater than 20 cm constitutes polyhydramnios.

The single vertical pocket technique has been compared with the AFI, using a dye dilution technique by amniocentesis as a gold standard. Three studies showed that AFI had a poor correlation with amniotic fluid volume (R^2 of 0.55, 0.30, and 0.24), and two of these three studies demonstrated a slightly better performance with a cutoff of either a single vertical diameter of 2 cm or two pockets of 2 cm. Also, in general, it is reasonable to find a vertical pocket that does not contain cord on standard 2D for measurement purposes.

Finally, the subjective assessment of amniotic fluid volume by an experienced operator is at least as good as any of the above attempts at over-quantification, since the aim of the exercise simply is to determine if there is too much, too little, or a reasonable amount of

amniotic fluid present.

Abnormalities of Amniotic Fluid Volume

Oligohydramnios

Fetal renal abnormality, IUGR, and ruptured membranes are three of the most serious possibilities for oligohydramnios, and these should be ruled out before considering this finding to be a normal variant.

For any degree of oligohydramnios due to renal abnormalities, both kidneys would have to be affected. It is important to assess the size and texture of the kidneys as well as the configuration of the kidneys, ureters, and bladder.

In the setting of growth restriction, an affected fetus will shunt blood to the cerebral cortex at the expense of peripheral perfusion, including renal perfusion. With decreased renal blood flow, less urine is produced and oligohydramnios occurs.

Once urogenital anomalies and growth restriction have been ruled out, the remaining important diagnosis of consideration is rupture of membranes. This may be deduced from a patient's description of a sudden onset of leakage of fluid from the vagina that does not seem to be related to urination. A pelvic examination is of course helpful to confirm the diagnosis, but on occasion, the clinical history and examination may be equivocal. Ultrasound may reveal diminished amniotic fluid volume transabdominally. A TVU examination also can be extremely helpful by identifying membranes coursing over the cervix if they are intact. In contrast, the integrity of the membranes cannot be demonstrated when oligohydramnios is secondary to ruptured membranes. This method is a better excluder of ruptured membranes than confirming rupture, because in the setting of oligohydramnios, the ability to visualize the membranes may be hampered.

In severe oligohydramnios or anhydramnios, irrespective of the cause, the major threat to the fetus is pulmonary hypoplasia, especially if the fetus is deprived of amniotic fluid during the second trimester (especially prior to 24 weeks gestation), when bronchiolar branching is in progress.

When oligohydramnios is truly isolated, it is reasonable to expectantly manage such a patient.

Polyhydramnios

An AFI of greater than 20 cm or a single pocket of greater than 8 cm defines polyhydramnios (Fig. 9.3), which theoretically means an amniotic fluid volume exceeding 2,000 cc. This happens in 0.25% to 3% of pregnancies. When present, the etiologies can include a gastrointestinal (GI) obstruction above the ileum, a tracheoesophageal fistula, a CNS abnormality, or a syndrome that would interfere with fetal swallowing (including the presence of a mass causing shifting or compression of the mediastinum that can obstruct the esophagus). In addition, the incidence of aneuploidy can be as high as 20% in

polyhydramnios. Carlson and Platt noted the increase in fetal anomalies to be mostly in those with AFIs of greater than 24 cm. Thus, a careful evaluation of the fetal heart, GI tract, CNS, and limbs is necessary. If an abnormality is found, karyotyping should be undertaken.

Figure 9.3 Polyhydramnios. Note that the maximum vertical pocket is greater than 8 cm.

Poorly controlled maternal diabetes can be associated with polyhydramnios. The mechanism appears to be fetal polyuria secondary to fetal hyperglycemia. Indeed, fetal macrosomia, with or without diabetes, can result in excess amniotic fluid volume due to a substantial but proportional production of urine. A patient presenting with polyhydramnios, a large fetus with body-to-head disproportion, and a large fetal bladder should be investigated for diabetes.

In severe polyhydramnios, therapeutic amniocentesis may be required for patient comfort or to discourage the development of preterm labor. Certainly, karyotyping would be worthwhile once the fluid has been obtained.

Fetal Measurements

The fetal measurements generally accomplished during a standard ultrasound examination of the fetus are the biparietal diameter (BPD) (Fig. 9.4), the head circumference (HC) (Fig. 9.4), the abdominal circumference (AC) (Fig. 9.5), and the femur length (FL) (Fig. 9.6). Although each measurement tells us something different about the fetus, the relationship between these measurements will give an observer an idea regarding the fetal configuration and will often represent familial tendencies toward small or large stature. Also, the trancerebellar diameter (TCD) (Fig. 9.7) is an excellent indicator of gestational age, especially where alterations of growth and development exist.

Estimated Fetal Weight

There are more than 40 formulas in the literature for estimated fetal weight (EFW). The Hadlock formula, which

is incorporated into most North American ultrasound machine software packages, utilizes four variables: the BPD, HC, AC, and FL.

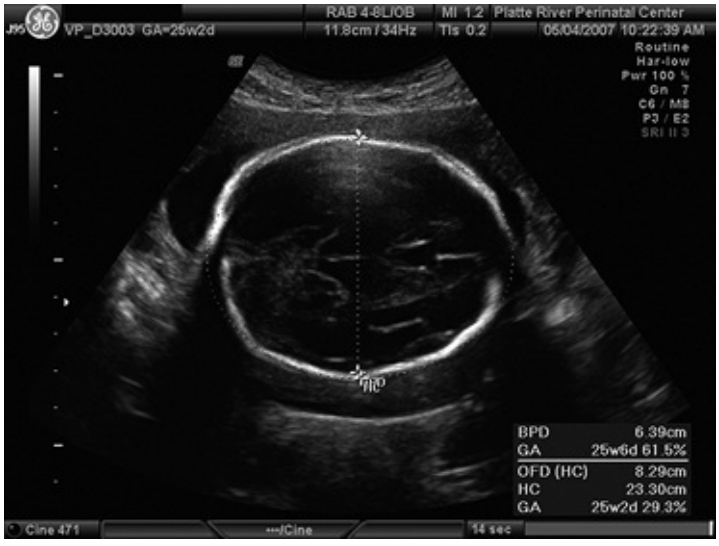

Figure 9.4 Biparietal diameter and head circumference.

The greatest problem with EFW is not the accuracy of the formula used but the growth curves into which the EFWs are plotted. Most North American machines have Hadlock's growth curve, which was constructed from a mixed population at sea level in Houston, Texas. Other growth curves available are from the East and West coasts of the United States as well as from countries in Europe and Asia. In Denver, Colorado, at 5,000 feet above sea level, EFWs are about 5% lower than the EFWs from Houston, translating into Denver's 15th percentile being analogous to Houston's 10th percentile. To compound the confusion, growth curves in the literature are not only from different populations but also are based on a variety of EFW formulas.

Part of the difficulty is that EFW is based on diameters and circumferences that are simply reflecting the volume of the fetus, but there is no reflection of fetal density in such calculations.

Figure 9.5 Abdominal circumference.

Figure 9.6 Femur length.

Despite all of these limitations to EFW, it does allow the clinician to quantify a deficit and to evaluate for the presence or absence of adequate growth over a given time interval. In addition, it enables some level of patient counseling by neonatologists regarding the prognosis for a premature fetus.

Estimating Gestational Age

Gestational age is commonly determined by taking the average of the biometric parameters (BPD, HC, AC, FL). This is usually displayed on the ultrasound report page as an average ultrasound age (AUA). This can then be compared with the patient's menstrual dates. The dating precision varies according to the gestational age of the patient. A first-trimester CRL is the most accurate way to date a pregnancy, but

Chervenak has found that the BPD in the second trimester also has very reasonable accuracy. However, most clinicians will use the AUA to establish dates. The TCD is a very good indicator of gestational age in the second trimester, and it is the best dater of pregnancy in the third trimester because it rarely is affected by aberrations in fetal growth.

Figure 9.7 Transcerebellar diameter.

With regard to establishing pregnancy dating, priority should be given to the earliest scan and should not be changed thereafter.

Fetal Anomalies

Although earlier studies, such as the Routine Antenatal Diagnostic Imaging with Ultrasound (RADIUS) trial, have shown a poor performance of ultrasound in identifying fetal anomalies, more recent studies, such as the Eurofetus trial, have indicated that the majority of major anomalies can be identified in the second trimester. Now, some studies are emerging that suggest a reasonable ability to identify fetal abnormalities prior to 14 weeks gestation. Anomalies of the cranium, renal system, GI tract, and spine are more amenable to diagnosis than the fetal heart, which notoriously presents a more difficult challenge for the diagnostician.

Fetal Cranium

Most major anomalies of the fetal cranium can be suspected by the careful examination of the anatomy in the plane of the BPD, cerebral ventricles, and the posterior fossa. If any of the views produces concern about the anatomy, other techniques can be added to accomplish further investigation, which would include 3D.

Fetal Face

Cleft lip and palate complicates about 1 in 500 pregnancies. About 25% of the time, it involves the lip alone; 50% of the time both lip and palate are involved; and in 25% of cases, the palate is the only structure affected. This means that since about 75% to 80% of fetuses with cleft lip will have an affected palate, one should thoroughly scrutinize this area before deciding that the defect involves the lip alone.

The new version of the American Institute of Ultrasound in Medicine/American College of Radiology (AIUM/ACR) guidelines for the standard ultrasound examination suggests that an attempt should be made to evaluate the fetal face. The integrity of the fetal lip can be determined by a coronal slice that isolates the nose, nostrils, philtrum, and mouth. If a cleft is suspected by noting an apparent communication between the nostril and the mouth or by an inability to completely image the philtrum, an in-depth evaluation of the fetal lip and palate should take place.

Clefts are most commonly isolated but can occasionally be associated with other anomalies, and if it is a midline defect, it is always accompanied by other anomalies or an abnormal karyotype.

If the cleft lip and palate are isolated, the prognosis for infants is excellent, although generally, the more tissue that is missing, the more extensive the corrective surgery needs to be, and hence the longer the recovery period. 3D surface-rendered pictures can be very useful in preparing and counseling patients as well as in communicating with pediatric surgeons.

Fetal Heart

The Four-Chamber View

Essential information comes from the four-chamber view (Fig. 9.8), including cardiac orientation, overall heart size as well as chamber size, the presence or absence of pericardial effusions, and the integrity of the interventricular septum. The standard approach is to use a cross section of the chest above the diaphragm, although it can be done on occasion by an angled approach from under the diaphragm. Additional information can be gained by visualizing the outflow tracts.

Congenital Abnormalities of the Heart

About 8 per 1,000 fetuses will have a structural cardiac abnormality, and in many cases, a prenatal diagnosis of a cardiac defect provides key information for the pediatricians to prepare for the delivery of such an affected infant.

A family history of cardiac abnormalities and preexisting, poorly controlled diabetes mellitus are two of the biggest risk factors for congenital heart disease. Generally, the recurrence rate for most cardiac anomalies is about 3% to 4% if a parent or sibling has a defect. However, there are some anomalies involving the left side of the

heart, especially the aorta, that have recurrence rates of up to 15%. With the exception of the left heart abnormalities, when a defect does recur, it may not surface as the same anomaly. Among preexisting diabetics, using glycosylated hemoglobin (HbA1C) as an indicator of long-term glucose control, those patients with values below 6 mg percent have the same risk of a fetal cardiac abnormality as the overall population. On the other hand, those with levels above 12 mg percent have a 25% chance of fetal cardiac abnormalities.

Figure 9.8 Four chamber view of heart. Note the relatively equal-sized right and left atria as well as the right and left ventricles. The atrioventricular valves (i.e., the tricuspid and mitral valves) are open.

Among other possible predisposing factors to fetal cardiac anomalies is exposure to medications known to be teratogenic to the heart. Lithium has been associated with Ebstein anomaly. Additionally, Down syndrome fetuses have a 30% chance of having a major cardiac anomaly and therefore warrant a comprehensive evaluation.

Fetal Spine

Open Spina Bifida

The neural tube normally closes between 20 and 28 days postconception, and interruption of this closure results in spina bifida. This defect can be closed or open. A closed defect, otherwise known as spina bifida occulta, is not uncommon and indeed may go unnoticed because the full thickness of skin over the bony defect prevents the complications seen in open defects.

Open spina bifida comes in two forms: meningocoele, in which a meningeal sac herniates through the open defect, or a myelomeningocoele, which also contains neural tissue. In general, the level of the defect predicts the postnatal consequences for the infant, which would include at least bowel and bladder dysfunction with lower defects and difficulties in

ambulation and paralysis with larger and higher defects.

The prevalence of open spina bifida has decreased somewhat from 10 years ago, when it occurred in approximately 1 in 1,000 births. One reason for this downward trend is the use of folic acid, which will prevent some fetuses from developing neural tube defects. For example, the recurrence rate of neural tube defects is about 4%, but if a patient is on folic acid from before conception until 28 days postconception, the recurrence rate is reduced to 1.5%. Another reason that the incidence of this condition at birth has dropped is that screening with MSAFP and improved ultrasound diagnosis of spina bifida have been effective in identifying most fetuses with this condition in the second trimester.

Virtually every fetus with an open defect will have disruption of the posterior fossa, despite the level of the defect. This can cause obstructive hydrocephalus, either in utero or postnatally following surgical correction, which requires ventriculoperitoneal shunting. It is theorized that tethering of the spinal cord occurs at the level of the defect, where the cord becomes stuck to a placode, preventing the cord from moving freely upward through the spinal canal as the fetus lengthens out. As a result, the cerebellar vermis gets pulled downward into the foramen magnum, leading to an Arnold-Chiari malformation. An alternative theory is that large amounts of spinal fluid are lost through the defect, thereby creating a negative pressure that carries the posterior fossa structures downward into the foramen magnum.

Due to the almost universal effects on the posterior fossa, the sonographic evaluation should start there. Findings include (a) a “banana sign,” in which the downward displacement of the cerebellar vermis produces a bananalike shape to the cerebellar hemispheres; (b) complete obliteration of the cisterna magna in essentially every instance; and/or (c) a lemon-shaped calvarium, in which there are temporal indentations of the fetal skull. This occurs in approximately 75% of cases in the second trimester but not in the third trimester.

Fetal Abdomen

The existing guidelines indicate that the stomach, bladder, and kidneys need to be evaluated as well as the ventral wall of the fetus. This should allow for the diagnosis of tracheoesophageal fistulas, GI tract obstruction, the identification of echogenic bowel, ventral wall defects (e.g., omphalocele, gastroschisis, and bladder exstrophy), and limb-body wall complex.

Fetal Kidneys

Obstructive and dysplastic renal abnormalities can be relatively easily identified and if found would necessitate consultation and referral to pediatric urologists.

Fetal Limbs

Many syndromes involve the fetal long bones, hands, and feet, including clubfoot, short limb dysplasias, heterozygous achondroplasia, thanatophoric dysplasia, achondrogenesis, hypophosphatasia, osteogenesis imperfecta, radial aplasia, lobster claw deformity, and and

a variety of miscellaneous dysplasias. The hands should be one of the first areas to scrutinize when any type of fetal abnormality is found, as they are involved in so many syndromes and aneuploidies.

The Biophysical Profile

In 1980, Manning and Platt reported on a method of fetal surveillance that involved fetal HR monitoring combined with five biophysical parameters as documented on ultrasound—hence, the BPP.

Each of the five parameters represents a separate evaluation of fetal behavior and function and is scored as either 0 or 2 points, reflecting absence or presence, respectively, of the given parameter.

Fetal Heart Rate Monitoring

The nonstress test (NST) involves monitoring the fetal HR over a 20-minute period. As described elsewhere, a reactive tracing is defined by the presence of two accelerations of 15 BPM above baseline that last for at least 15 seconds in total duration in a 20-minute tracing.

Fetal Breathing

After 30 weeks gestation, the fetus will spend about 30% of its time making breathing motions. Prolonged hypoxia and/or acidemia will blunt this activity. Fetuses having at least one episode of 30 seconds of fetal breathing during an observation period of up to 20 minutes will get 2 points for this parameter.

Fetal Movement

Normally, fetuses should demonstrate at least three gross body movements during a 20-minute observation period. Profound hypoxia and acidemia can limit or completely abolish such movement due to effects on the fetal cerebral cortex.

Fetal Tone

Fetal tone, which is dependent on an intact cortex and subcortex, is the last to go in a sequence of events ending in severe fetal compromise. At least one episode of extension with a return to flexion during the examination period is considered normal. Usually, by the time tone is lost, all of the other categories will have had scores of 0 (except in the circumstance of a primary neuromuscular disorder).

Amniotic Fluid Assessment

One 2-cm vertical pocket is sufficient for earning 2 points. The amniotic fluid category relates only indirectly to the fetal brain, which under the influence of hypoxia will be “spared,” resulting in blood being shunted away from the kidneys. This results in less urine

production and, ultimately, oligohydramnios. The oligohydramnios seen in post-term pregnancy (PTP) may represent an exception to the brain-sparing concept. Here, there is evidence to suggest that there may be a direct effect on the kidneys rather than a steal mechanism employed by the brain.

How the Biophysical Profile Relates to Fetal Behavior

The fetal brain develops in a very predictable order with the brain stem, medullary, and subcortical areas developing first and the cortical areas and hypothalamus being refined last. Under the influence of progressive hypoxia, the characteristic behavior patterns linked to these portions of the brain are lost in reverse order from their appearance in the developmental time line. For example, the NST becomes nonreactive, and the respirations are lost at roughly the same level of partial pressure of oxygen (PO_2) in the fetal blood. However, fetal movement slows and stops at a lower PO_2. The last to be affected is fetal tone.

The BPP is affected by the two major fetal sleep states—1F (a period of quiet sleep) and 2F (a period of rapid eye movement sleep associated with active fetal motion). For example, NSTs are often nonreactive during quiet sleep (1F), and respirations and movement are normally depressed during this time. Quiet sleep usually does not last more than 20 minutes, and thus the recommended testing length of a typical BPP is 20 minutes.

Factors other than hypoxia can affect the variables in the BPP. For example, various drugs such as narcotics, tranquilizers, alcohol, and cigarettes will depress fetal HR variability, respirations, and movement, while maternal hyperglycemia will increase fetal movement and respirations.

Vintzileos and colleagues correlated BPP findings with umbilical cord pH at birth. Breathing was lost at a pH of <7.20, while all movement and tone were gone at a pH of <7.10.

Finally, the “modified BPP” came into being as a substitute for the full BPP. It consists of an NST and an evaluation of amniotic fluid. The NST assesses the fetus for acute hypoxia, and the amniotic fluid assesses for the chronicity of a problem. With regard to perinatal death, Miller and associates found a false-positive rate of 60% with the modified BPP but only a 0.08% false-negative rate.

Intrauterine Growth Restriction

There has been a great deal of confusion with the terms *small for gestational age* (SGA) and *intrauterine growth restriction*. In most circumstances, SGA simply represents a small fetus, while IUGR indicates a small fetus that is deprived (usually due to a placental reason). This is how these terms will be used here.

IUGR fetuses are typically defined as being at or below the 10th percentile of mean weight for gestation (SGA is often defined as being less than the 10th percentile as well but is generally a term used in the pediatric literature and may include constitutionally small infants). Alternatively, an AC of greater than 2 standard deviations below the mean for gestation can also be used as a threshold to identify the IUGR fetus. IUGR fetuses have

higher rates of perinatal as well as long-term mortality and morbidity than appropriate-for-gestational-age (AGA) fetuses, depending on the degree of the deficit.

There are four basic reasons why fetuses can be smaller than expected: (a) there is incorrect dating; (b) there is a problem with nutritional and oxygen supply; (c) they are genetically programmed to be small; or (d) there is a condition responsible for the primary growth failure (such as aneuploidy or fetal infection).

Scrutiny of the individual biometric parameters will settle a dating question. The presence or absence of oligohydramnios also will aid somewhat on narrowing down the diagnosis. A detailed fetal survey should rule out a major anomaly syndrome, and a search for markers for aneuploidy can exclude the more common trisomies.

Doppler in the Management of Intrauterine Growth Restriction

Doppler ultrasound has emerged as an essential tool for the surveillance and management of the IUGR fetus (this is further addressed in other chapters of this text). Evaluation of the umbilical arteries provides information on the status of the placenta, with relative decreases in diastolic flow indicative of abnormal placental development and elevated resistance. In extreme circumstances, diastolic flow may be absent or even reversed. Often, the first sign of fetal compromise is a decrease in umbilical artery end diastolic flow. This will often worsen as pregnancy progresses. Absent end diastolic flow at any time signifies trouble, and reverse flow is an ominous sign. The latter is a very late finding, correlating strongly with fetal death or neonatal morbidity.

In IUGR due to uteroplacental insufficiency, the hypoxic fetus will spare its brain, heart, and adrenals, which will result in a drop in resistance in these areas. Under these circumstances, the middle cerebral artery (MCA) end diastolic flow rises, resulting in a waveform that resembles a normal umbilical artery waveform. This increase in diastolic flow is a fetal adaptive mechanism intended to preferentially preserve the brain. This mechanism is linked to the PO_2 of the fetus, and thus its presence is an indicator of deficient placentation.

Umbilical artery waveform abnormalities precede MCA changes, especially when growth curtailment occurs prior to 30 weeks. If there is a late onset of IUGR, then MCA changes may actually precede umbilical artery abnormalities. The oligohydramnios seen in IUGR is due to autoregulation and is virtually always found in association with increased end diastolic flow in the MCA.

Evaluation of the fetal venous circulation, especially at the level of the ductus venosus (DV), provides more detailed information on the status of the fetal heart as well as indirect information on the fetal acid–base status. Indeed, appropriate evaluation of blood flow through the DV can provide an opportunity to deliver an IUGR fetus prior to the onset of acidosis, which has been shown to be most correlative to mortality and long-term morbidity.

Genetic Sonogram

In 1992, Nicolaides reported that an enlarged fetal nuchal translucency (NT) (Fig. 9.9) was frequently noted to be associated with fetal chromosome abnormalities. This measurement was made behind the fetal neck from the inner margin of the membrane to the inner margin of the underlying tissue. When combined with the patient's age and CRL of the fetus, Nicolaides' group reported a detection rate for trisomy 21 of 77% at a screen-positive rate of 5%. This exceeded the sensitivity of other diagnostic tests for fetal aneuploidy.

Figure 9.9 Nuchal translucency.

The second-trimester genetic sonogram has emerged as a noninvasive way to further drop a patient's risk of having a fetus with Down syndrome, which can work adjunctively with serum biochemistry screening as well as first-trimester NT measurement. Fundamentally, it is an ultrasound examination containing three major components: standard biometry with the humerus added, a basic fetal anatomy survey, and a search for markers for Down syndrome. About 20% of fetuses with this condition will have a major congenital abnormality, which, if present, generally involves the fetal cranium, heart, or renal system. Ultrasound markers for Down syndrome include an enlarged nuchal skinfold thickness, assessment of the fetal heart (especially for the presence of an echogenic intracardiac focus or endocardial cushion defect), shortened nasal bone length, shortened frontal lobe length, shortened fetal ear length, absence of the middle bone of the fifth digit, echogenic bowel, excessive iliac angle, and bilateral pyelectasis. Additionally, about 20% of fetuses with Down syndrome will have femur and/or humerus lengths that are 2 weeks less than expected by pregnancy dating. The ultrasound signs of duodenal atresia, which occurs in about 12% of infants with Down syndrome, may not appear until the end of the second trimester.

Similarly, a number of ultrasound findings are associated with trisomy 18 that can include:

- Choroid plexus cysts (40%)
- Cerebellar hypoplasia

- Enlarged cisterna magna
- Strawberry-shaped calvarium

- Micrognathia
- Small ears
- Cardiac defects (~90%)
- Early IUGR
- SUA
- Echogenic bowel
- Clubbed hands and feet
- Overlapping fingers
- Rocker bottom feet.

Multiple Gestations

Over the last 15 years, ART has increased the incidence of twin pregnancies from 1 in 80 to 1 in 40, while the rate of higher-order multiples has increased by 400%. Twins comprise 21% of low-birth-weight babies and are responsible for 13% of infant mortality; in addition, twins generally make up 25% of most newborn special care units' censuses. In general, twins have higher perinatal mortality and morbidity rates than singletons, but those twins from ART have even greater elevations of PTB and cerebral palsy than do twins from spontaneous conceptions. In addition to prematurity, twins are also at risk for an increased incidence of fetal anomalies as well as discordant growth and IUGR.

Membranicity

All of the previously mentioned complications are higher among monochorionic twin pregnancies as compared with dichorionic gestations.

About one third of spontaneously conceived twins are monozygotic and hence from a single egg, while the remaining are dizygotic and thus from two fertilized eggs. The overwhelming majority of twins conceived through ART (ovulation induction or in vitro fertilization [IVF]) are dizygotic due to reinsertion of multiple embryos, but occasionally, one does encounter a monozygotic placentation in these patients.

One indirectly determines the *zygosity*, a diagnosis made after the fact by examination of the placental membranes or through human leukocyte antigen (HLA) typing of the infants, by the number of chorions present in the separating membranes. Monochorionic pregnancies are monozygotic, but dichorionic pregnancies may also be monozygotic. Up to 20% to 30% of monozygotic twins will separate early enough to result in a single placenta, dichorionic/diamniotic (di/di)-type of picture. It is likely that these types of identical twins behave the same as fraternal twins with regard to a diminished risk of adverse pregnancy

outcome when compared with monozygotic/dizygotic (mono/di) identical twins.

The earlier in pregnancy one assesses chorionicity, the more accurate is the answer. For example, at 6 to 7 weeks gestation, dichorionic twin sacs are clearly separated by a substantial band of tissue compared with monochorionic twins, which appear early as a single cavity with a thin membrane separating the two twin units.

Figure 9.10 Twin peak sign. The *arrow* indicates the "peaking" of the membranes that separate two gestations. Note the presence of placental tissue in the peak—a characteristic finding in dichorionic, diamniotic twin pregnancies.

Often, two separate placentas can be outlined, which will tip off the observer to a di/di pregnancy in the second trimester, and zygosity should be obvious. The ultrasound clues include (a) assessment of the thickness of the separating membranes, (b) counting the number of these membranes, and (c) the presence or absence of a "twin peak." Obviously, gender determination also will be of help.

When concentrating on the separating membranes, one keeps in mind that di/di twin sacs are separated by four membranes; if the diameter of the separating membranes exceeds 2 mm, this is usually synonymous with a di/di situation. This becomes less accurate in later gestation due to hydrostatic stretching of the membranes.

In dizygotic twins, the membranes come together at their junction with the middle of the placenta or at the placental edge in such a way as to form a lambda sign. This has been labeled as a "twin peak" (Fig. 9.10) that clearly can be distinguished from the T-shaped configuration seen in mono/di twins.

Twin Anomalies and Aneuploidy

Approximately 2% to 3% of singleton fetuses will have a major congenital anomaly, but in twins, the anomaly rate is over 6%. One reason for the higher rate of anomalies and aneuploidy in twins is due to a higher number of fetuses. Nevertheless, identical twins have

a higher rate of anomalies than fraternal twins. Some of these abnormal fetal conditions are more specific to multiple gestations, such as conjoined twins, twin reversed-arterial perfusion (TRAP) sequence, and twin-to-twin transfusion syndrome

(TTTS), while others are shared by singletons but at a higher prevalence in twins. These include cardiac anomalies, neural tube defects, facial clefting, clubfoot, intestinal atresia, and cystic hygromas.

The higher rate for aneuploidy among twins than singletons is in part due to AMA and hence decreased egg quality. Half of patients with twins conceive them through ART, and a substantial percentage of those are AMA, resulting in a magnified risk for age-related aneuploidy, such as trisomies 18 and 21.

Please refer to other sections of this text for further information on the risk of preterm delivery, TRAP sequence, and TTTS as well as the ideal management of multifetal gestations.

Diabetes

Congenital anomalies occur in 10% to 16% of pregestational diabetic pregnancies compared with about 3% in nondiabetics. This is largely related to maternal glucose control during organogenesis, which in turn is indirectly reflected in the glycosylated hemoglobin (HbA1c) percentage. For HbA1c values greater than 8.5 mg percent, the anomaly rate is over 20%.

Cardiac anomalies complicate approximately 27 in 1,000 diabetic pregnancies as compared with 8 in 1,000 in nondiabetic pregnancies. Also, the rate of neural tube defects in diabetics is about 20 in 1,000 versus 1 in 1,000 in the overall population. Although the numbers are not as dramatic as the incidence of heart and spine anomalies, fetuses of diabetics also are at slightly greater risk for GI and genitourinary abnormalities. Caudal regression syndrome is the best-known anomaly to which diabetes is linked, and it occurs in 1 in 200 diabetic pregnancies; this condition can involve many or only a few spinal segments.

The clinical emphasis should be on prevention of anomalies through strict diabetic control during organogenesis as well as early detection of anomalies through staged ultrasound investigation.

An additional potential problem for fetuses of diabetics is macrosomia; 20% of gestational diabetics and 25% of insulin-requiring diabetics deliver large-for-gestational-age (LGA) infants. These patients also have a threefold higher risk of having shoulder dystocia and, with it, the occasional brachial plexus injury. This is due to the predilection for body-to-head disproportion in this condition. Body-to-head disproportion can be assessed in a variety of ways. The often-used HC:AC ratio represents a very indirect reflection of the relationship of the fetal head to shoulders, and variations of this method have been published. Elliott was the first to describe a relationship between the abdomen and head as a way to predict shoulder dystocia. This was later refined by Cohen and colleagues, who compared the average abdominal diameter (AAD), taken at the standard plane for AC, with the BPD. If the AAD exceeded the BPD by more than 2.5 cm, the risk of shoulder dystocia

was 33%. If this figure was less than 2.5, the risk of shoulder dystocia was 0.

Preeclampsia

It has become clear that poor trophoblastic invasion of the maternal myometrial spiral arteries predisposes the mother to the subsequent development of preeclampsia. In the overwhelming majority of preeclamptics, transformation of spiral artery bed into a low-resistance system fails to occur, and thus there is increased resistance to flow into the intervillous space. Uterine artery pulse Doppler waveform analysis provides indirect information pertinent to the quality of trophoblastic invasion into the decidua and myometrium. When trophoblastic invasion has occurred, the uterine artery end diastolic flow increases. If invasion has not been successful, end diastolic flow never rises and a diastolic notch is often present on the Doppler waveform. In a properly selected high-risk population, the predictive accuracy of uterine artery Doppler waveform analysis for prediction of preeclampsia is 60% to 95%. Also, it is now clear that abnormal spiral artery remodeling is associated with other pregnancy complications such as thrombophilia, chronic hypertension, and placentally mediated IUGR.

Preterm Birth

The cervix prematurely shortens in patients delivering early, and often the shortening is present by 20 to 24 weeks gestation. Although little progress has been made in preventing PTB, much progress has been accomplished in predicting PTB, primarily through ultrasound studies involving the cervix.

Midtrimester Cervical Length as a Predictor of Preterm Birth

Iams and others have constructed normative values for cervical length (CL) in pregnancy. In singletons at 20 to 24 weeks, the median CL is 3.5 cm and the 10th percentile is 2.5 cm. A CL below this threshold is associated with a sixfold increased risk of PTB compared with those above the median. In addition, cervical shortening occurs along a linear continuum. The prevalence of PTB, defined in Iams' original study as occurring at less than 35 weeks, was 4.3% in the overall population and 17.3% in those with CLs below 2.5 cm. Thus, more than four out of five women with short cervices did not deliver preterm.

Heath, using an endpoint of 32 weeks, below which neonatal morbidity appreciably increases, found that 50% of patients delivering in this time frame had CLs at 20 to 24 weeks that were 1.5 cm or less. In twins, the CL at which

50% of patients delivered by 32 weeks was 2.5 cm. In converse, the high negative predictive value of a long cervix (>3.5 cm) at 20 to 24 weeks gestation can be very reassuring, especially in those with a history of midtrimester or early third-trimester losses.

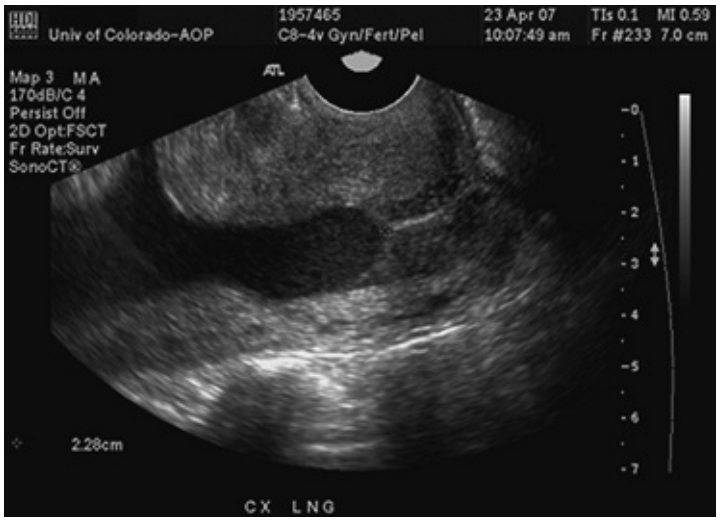

Figure 9.11 Premature cervical change. Note the dilation of the inner portion of the cervix, including the internal os. This appears as a pronounced "U" shape to the internal portion of the cervix.

Zilianti noted that in most cases of PTB, the cervical configuration follows a pattern described by the letters *TYVU* (Fig. 9.11). Thus, the cervix usually thins from the internal os outward by the creation of funneling or wedging, but occasionally the cervix does shorten without the accompaniment of funneling.

In the setting of preterm contractions, a CL threshold of 1.5 cm appears to be the best predictor of early delivery in patients with preterm contractions. Forty-seven percent of patients with CLs less than 1.5 cm delivered within 7 days, and only 1.8% of patients with CLs greater than 1.5 cm delivered within 7 days. Conversely, if the CL exceeds 3 cm, nearly all of these patients deliver after 34 weeks.

Rh Disease (Erythroblastosis Fetalis)

In the past, the diagnostic method of choice in following Rh and Kell sensitized pregnancies was to monitor maternal immunoglobulin G (IgG) titers and to perform serial amniocenteses if the antibody titer exceeded a certain threshold. The fluid then would be evaluated by optical density characteristics for the presence and quantification of unconjugated bilirubin, a product of fetal red blood cell hemolysis. If the optical density difference (delta OD) at 450 μm was elevated on the Liley curve, intrauterine fetal red cell transfusions would be initiated for the preterm fetus.

Today, ultrasound has revolutionized the diagnosis and therapy of this condition by focusing on key organs that are affected by the pathophysiology of this disease. Examination of the fetal spleen, liver, and heart give indirect evidence for fetal hemolysis. The spleen and liver are often enlarged due to their additional function as extramedullary hematopoeitic sites. Additionally, the spleen becomes enlarged due to its role in the clearance of the antibody-tagged red cells and their debris. In part due to reduced blood viscosity, the fetal heart compensates for the resultant reduction in oxygen delivery to peripheral tissues by increasing cardiac output; with ongoing and worsening anemia, this compensatory

mechanism is eventually overcome, leading to high-output cardiac failure and fetal hydrops.

While examination of the fetal spleen, liver, and heart gives an indirect assessment of fetal anemia, the most precise way to evaluate for this is pulse Doppler interrogation of the MCA. Due to the elevated cardiac output, which is largely due to the reduction in blood viscosity, the MCA peak systolic velocity (PSV) is dramatically increased in severe anemia. Mari developed an MCA PSV curve; if the fetus is severely anemic, the peak velocity in the MCA is always above 1.5 MoM. Using 1.5 MoM as a cutoff, the false-positive rate is 12% to 18%. It is extremely unlikely for fetuses to be severely anemic when peak velocities are below 1.5 MoM. Prospective study has shown the MCA PSV to be an excellent excluder of fetal anemia resulting from Rh disease, Kell sensitization, and parvovirus (which can cause severe fetal anemia due to suppression of fetal hematopoiesis). Serial amniocenteses are rarely needed, and unnecessary cordocenteses are avoided.

Three- and Four-dimensional Ultrasound

Three- and four-dimensional (4D) ultrasound is rapidly moving from an area of novelty geared toward patient satisfaction to modalities of great use in confirming or establishing a number of diagnoses. Particular areas of use for 3D technology currently include evaluation of the fetal face for clefting; the brain for evaluating the corpus callosum and cerebellar vermis; the spine for spina bifida, especially with identification of the level of the defect; skeletal dysplasias through the use of surface rendering; the fetal heart for characterizing complex congenital defects; and in assessing fetal organ size, such as the fetal liver, spleen, or lung (e.g., in situations concerning for possible lethal hypoplasia, although such use has yet to be successfully validated for its predictive ability).

Future uses, although difficult to foresee, include an improvement in accuracy of estimating fetal weight by incorporating limb volumes as well as standardizing and improving efficiency of patient scanning.

Summary Points

- Ultrasonography has become an essential tool for the obstetrician-gynecologist in the modern management of pregnancy.
- One of the best uses of ultrasound is in the dating of a pregnancy.
- A thorough obstetrical examination should include evaluation of the cervix, adnexal structures, placenta, and amniotic fluid in addition to the fetus.
- Ultrasound is useful to detect evidence of fetal structural and chromosomal anomalies, growth abnormalities, and well-being as well as evidence of preterm labor, among many other uses.
- While a good deal of information can be gained about a pregnancy from a sonographic examination, ultrasound is simply an adjunctive tool in the care of a patient and her fetus. The care provider should

always seek clinical correlation and exercise appropriate clinical judgment.

Assessment of Fetal Well-Being

Catherine Y. Spong

In the beginning of the 19th century, reports on the presence of fetal heart tones were published, and nearly 150 years later, continuous fetal heart rate (FHR) monitoring became a reality. By 1998, electronic fetal monitoring was used in 84% of all U.S. births, regardless of whether the primary caregiver was a physician or a midwife. With the advent of these technologies, fetal monitoring is implemented in nearly all pregnancies, either in the antepartum or intrapartum period. The challenge of fetal surveillance is to identify those fetuses whose physiologic defense mechanisms are compromised in order to be able to act before decompensation has occurred. The goal is to prevent fetal and neonatal morbidity and especially mortality.

Why Perform Fetal Monitoring?

Since its inception, the primary objective of FHR monitoring has been to identify the fetus in distress so that measures might be taken in time to avert permanent fetal damage or death. However, a clear consensus regarding the definition of *fetal distress* has not been established. It has been described as “a condition in which fetal physiology is so altered as to make death or permanent injury a probability within a relatively short period of time” and is usually considered to denote disruption of normal fetal oxygenation, ranging from mild hypoxia to profound fetal asphyxia. The term *hypoxia* refers to the reduction of tissue oxygen supply below physiologic levels. *Asphyxia*, derived from the Greek word meaning “a stopping of the pulse,” implies a combination of hypoxia and metabolic acidosis. Historically, the clinical diagnosis of birth asphyxia has been based on findings such as meconium-stained amniotic fluid, abnormal FHR patterns, low Apgar scores, abnormal blood gases, and neonatal neurologic abnormalities. When present together, these findings are highly suggestive of a recent asphyxial insult. Isolated abnormalities, however, correlate poorly with birth-related asphyxia and subsequent neurologic impairment. In 2002, the American College of Obstetricians and Gynecologists Task Force on Neonatal Encephalopathy and Cerebral Palsy stated the criteria to define an acute intrapartum event sufficient to cause cerebral palsy (CP).

Essential criteria (must meet all four):

. Evidence of a metabolic acidosis in fetal umbilical cord arterial blood obtained at

delivery (pH <7 and base deficit >12 mmol/L).

3. Early onset of severe or moderate neonatal encephalopathy in infants born at 34 or more weeks gestation.
4. CP of the spastic quadriplegic or dyskinetic type.
5. Exclusion of other identifiable etiologies such as trauma, coagulation disorders, infectious conditions, or genetic disorders.

Criteria that collectively suggest an intrapartum timing (within close proximity to labor and delivery, e.g., 0–48 hours) but are nonspecific to asphyxial insults:

1. A sentinel (signal) hypoxic event occurring immediately before or during labor.
2. A sudden and sustained fetal bradycardia or the absence of FHR variability in the presence of persistent, late, or variable decelerations, usually after a hypoxic sentinel event when the pattern was previously normal.
3. Apgar scores of 0–3 beyond 5 minutes.
4. Onset of multisystem involvement within 72 hours of birth.
5. Early imaging study showing evidence of acute nonfocal cerebral abnormality.

At the cellular level, asphyxia triggers a cascade of events, including membrane depolarization, disruption of energy metabolism, altered neurotransmission, ion shifts, protease activation, free radical production, and phospholipid degradation. Profound and prolonged asphyxia may result in cell death and, eventually, death of the organism. Sublethal asphyxia may lead to multiorgan system dysfunction. Severe asphyxial brain injury may lead to long-term neurodevelopmental impairment.

Cerebral palsy is a major disorder of neurodevelopment, defined as “a chronic disability, characterized by aberrant control of movement and posture, appearing early in life and not the result of recognized progressive disease.” It may be accompanied by mental retardation (41%), seizures (23%), or cortical visual impairment. The insult responsible for the development of CP may occur at any time during the prenatal, perinatal, or postnatal periods. Unlike other major neurodevelopmental disorders, the relationship between CP and abnormal or difficult birth has long been recognized, publicly dating back to a treatise presented by William John Little in 1862. In 1943, Windle demonstrated clinical and histopathologic evidence of neural damage in experimentally asphyxiated fetal guinea pigs. He later reported the effects of prolonged anoxia on fetal rhesus monkeys. Total anoxia for less than 8 minutes did not produce consistent injury, whereas anoxia for more than 10 minutes invariably resulted in neuropathology. There were no survivors beyond 20 to 25 minutes of anoxia. The pattern of injury produced by prolonged anoxia, however, did not correlate with the cerebral injury, mental retardation, and spasticity seen in CP. Later work demonstrated that prolonged partial asphyxia in monkeys produced acidosis, late FHR decelerations, and neuropathologic defects consistent with the findings in the common forms of CP. In addition to lesions in the thalamus and basal ganglia, prolonged partial asphyxia caused generalized cerebral necrosis or focal necrosis in the parasagittal regions and the border zones between the parietal and occipital lobes.

Although early studies created and fostered the assumption that birth-related asphyxia was the primary cause of CP, recent evidence challenges this assumption. In 1986, Nelson and Ellenberg reported a multivariate analysis of risk in 189 cases of CP. After accounting for major congenital malformations, low birth weight, microcephaly, and alternative explanations for the disorder, they were able to attribute only 9% of CP cases to birth asphyxia. Others have reached similar conclusions. Although birth asphyxia nearly tripled the odds of developing CP, only 8.2% of CP cases were potentially attributable to birth asphyxia.

As early as the 19th century, researchers using auscultation recognized that certain FHR patterns were associated with adverse perinatal outcome. The introduction of direct electronic fetal monitoring and fetal scalp blood sampling in the 1960s provided tools for evaluating the fetus. FHR decelerations have been found to be correlated with fetal acidosis. Fetuses with no decelerations, early decelerations, or mild variable decelerations had average scalp pH values greater than or equal to 7.29, whereas those with severe variable or late decelerations had pH values less than or equal to 7.15. In addition, FHR variability was found to be correlated with scalp pH values, as fetuses with normal FHR variability had higher scalp pH values than those with decreased variability. The absence of FHR accelerations was correlated with poor perinatal outcome, and the presence of FHR accelerations has been shown to predict normal scalp pH values. With the development of indirect monitoring techniques, the experience derived from direct intrapartum monitoring became applicable to the antepartum period, leading to the development of antepartum testing.

Antepartum fetal monitoring has the goal of identifying the fetus at risk, allowing sufficient time to intervene before permanent injury or death occur. Intrapartum fetal monitoring should be able to identify three groups of fetuses:

- The fetus that is not affected by labor
- The fetus that is negatively affected by labor but has enough reserve to compensate fully and is in no immediate danger
- The fetus that is negatively affected and lacks the reserve to compensate, thus uses its key resources to survive and is in danger for morbidity/mortality.

It is the third group that would most benefit from intervention.

Who Should Be Monitored?

Antepartum fetal monitoring typically is offered to patients at increased risk of fetal or neonatal morbidity/mortality. These include maternal medical complications, fetal conditions, and pregnancy complications. Overall, the studies supporting the methods of testing, the timing, and initiation are extremely varied; thus, absolute guidelines based on scientific evidence cannot be established. However, recommended gestational ages for initiation of testing, timing, and methods for specific maternal conditions and the supportive evidence can be found in Table 10.1.

Intrapartum fetal monitoring has remained controversial since its inception. The FHR may

be evaluated by auscultation or by electronic monitoring. Auscultation is typically performed with a DeLee stethoscope or Doppler ultrasound. Electronic monitoring can be either performed externally or internally. External monitors use a Doppler device with computerized logic to interpret and count the signals. Internal monitoring uses a fetal electrode that records the fetal electrocardiogram (ECG). Well-controlled studies have shown the equivalence of intermittent auscultation to continuous fetal heart monitoring when

auscultation was performed at specific intervals with a 1:1 nurse-to-patient ratio. The intensity of monitoring is based on risk factors, with more intensive surveillance required for high-risk pregnancies.

What Can We Monitor?

Fetal Heart Rate

The FHR can be monitored and recorded indirectly through the use of an ultrasound transducer or directly via a subcutaneous ECG electrode placed on the fetus (Fig. 10.1). The indirect method can be used throughout pregnancy and has no contraindications. Using the indirect method, ultrasound waves originating from the transducer penetrate the tissues and are reflected by tissue interfaces. Waves reflected from the moving structures of the fetal heart return to the transducer and are translated into electrical signals. In the direct method, the subcutaneously placed ECG electrode detects electrical impulses originating in the fetal heart. Amplified signals are processed by a cardiotachometer, comparing each incoming QRS complex to the one immediately preceding it. The interval between the two complexes is used to calculate a heart rate. The process is repeated, with each cardiac cycle yielding a graphic beat-to-beat display of the FHR. The direct method requires rupture of the fetal membranes for placement of the ECG electrode. In addition, in light of the potential risk of infection, the

electrode for direct assessment only should be used when the benefits outweigh this risk.

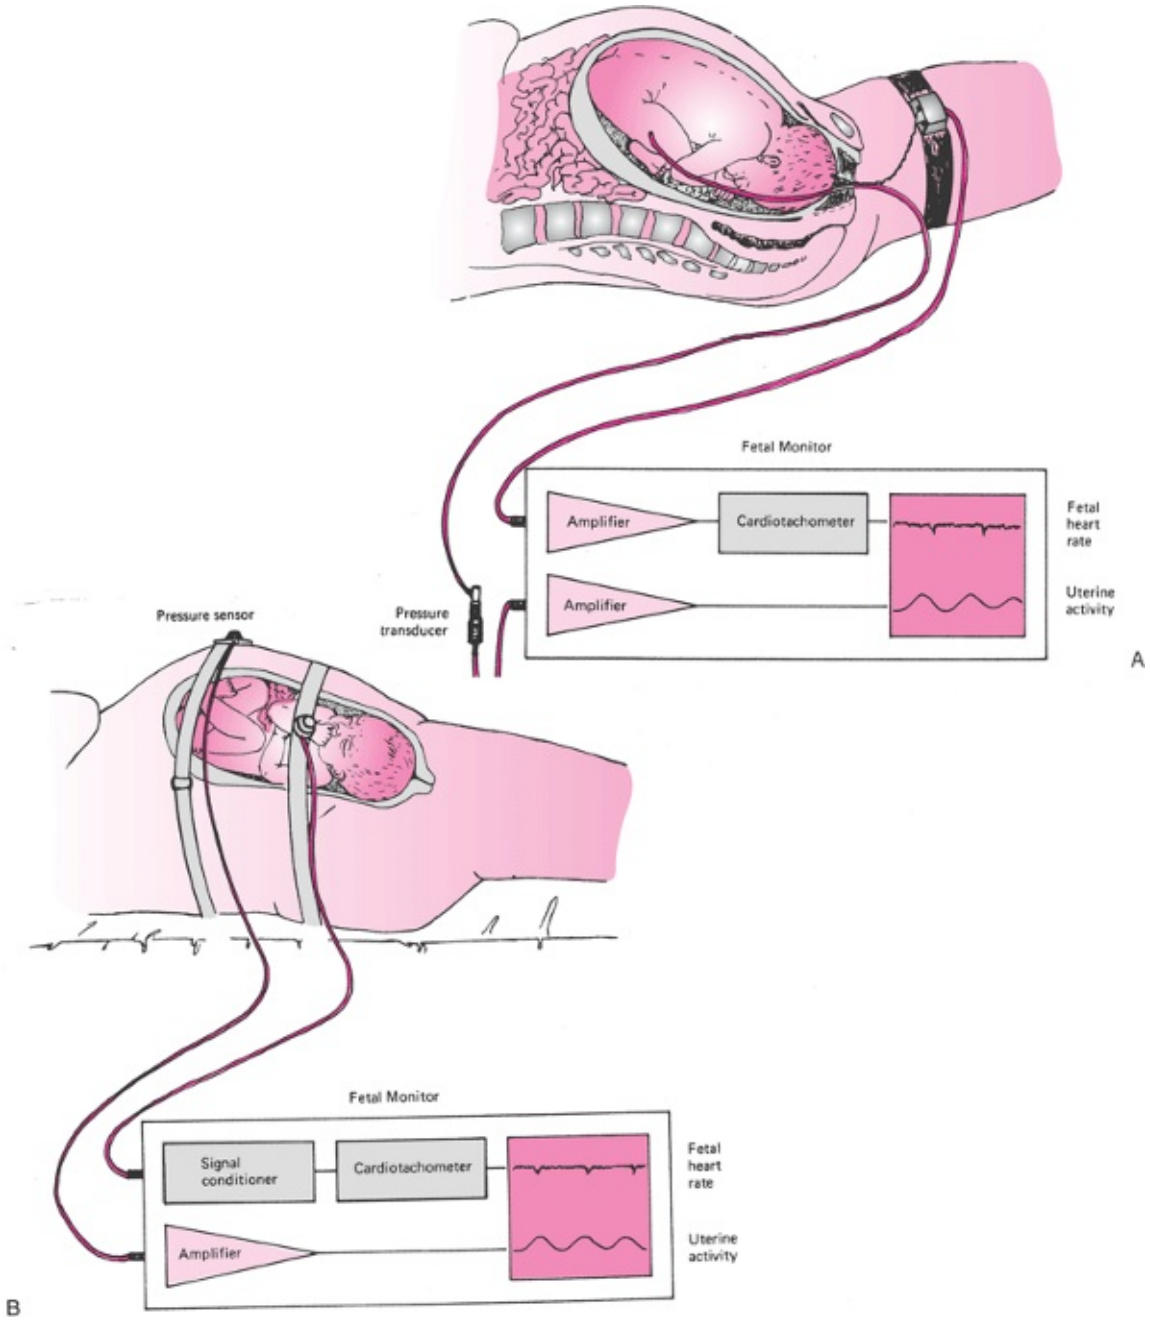

Figure 10.1 Direct and indirect fetal monitoring. **A:** Direct method. Recordings are made from a fetal electrocardiograph electrode applied directly to the fetus. A transcervical intrauterine pressure catheter is used to monitor the strength of uterine contractions. **B:** Indirect method. The FHR is derived from a Doppler ultrasound transducer applied to the maternal abdominal wall. A pressure sensor (tocodynamometer) detects uterine contractions. (Courtesy of Richard H. Paul.)

Uterine Activity

Similar to FHR, the detection and measurement of uterine activity can be performed indirectly or directly (Fig. 10.1). Indirect assessment of uterine activity is performed with a pressure transducer (tocodynamometer) applied snugly to the maternal abdomen over the uterine fundus. Uterine contractions exert pressure on the abdominal wall that is transmitted to the tocodynamometer. Changes in pressure are converted into signals and

plotted on the uterine activity graph. The indirect method is noninvasive and can be performed at any time during pregnancy. The limitations of the indirect method are that the readout can be used only to determine contraction frequency, not strength of the contraction (a tightly fit belt will record larger contractions than a loosely fitting or misplaced belt), and the ability to detect contractions in extremely obese women may be difficult. Direct assessment of uterine activity employs a thin, flexible intrauterine pressure catheter (IUPC) placed transcervically into the amniotic cavity. Intrauterine pressure is transmitted from the amniotic fluid through the fluid-filled IUPC to a pressure transducer. The transducer converts pressure measurements into electrical signals, and continuous pressure readings are displayed on the uterine activity graph. The direct assessment is invasive and requires ruptured membranes. The direct method allows the readout of both the frequency and the strength of the uterine contractions. This can be especially useful in the evaluation and assessment of patients with prolonged labor.

Fetal State (Tone/Breathing/Movements)

Using real-time ultrasound, the state of the fetus can be evaluated. Typically included in this evaluation are assessments of fetal tone, movements, and breathing. Fetal voiding and swallowing also can be evaluated. Specific assessments of fetal tone, breathing, and movements are discussed later in the section Biophysical Profile.

Amniotic Fluid Volume

The volume of amniotic fluid is a measure of fetal well-being. By the second trimester, the predominant source of amniotic fluid is fetal urine. The level of amniotic fluid is thought to represent “long-term” fetal well-being. A compromised fetus will preferentially shunt blood to the major organs, such as the central nervous system [CNS] and adrenals, and away from others, such as the kidney. Decreased fetal renal perfusion results in a decrease in fetal renal function and subsequent oligohydramnios. The amniotic fluid can be assessed ultrasonographically. There are a number of methods to quantitate the volume, including the amniotic fluid index (AFI), single deepest pocket, two-dimensional pocket, and a subjective assessment.

How Do We Monitor?

Equipment

The fetal monitor tracing is a continuous paper strip composed of two cartesian graphs. The FHR tracing is displayed on the upper graph, with time on the x-axis and heart rate on the y-axis (range 30 to 240 beats per minute). Uterine activity is displayed on the lower graph, with time on the x-axis and pressure on the y-axis (range 0 to 100 mm Hg). Heart rate and uterine activity are plotted separately on the heat-sensitive paper by two thermal pens. On both grids, fine vertical lines represent 10-second intervals, and heavy lines denote 1-minute intervals. In the United States, the standard paper speed is 3 cm per minute.

Interpretation of the Fetal Monitor Tracing

Analysis of the fetal monitor strip requires a systematic approach. First, the FHR is analyzed with respect to (a) the baseline, (b) variability, and (c) periodic patterns, including FHR accelerations and decelerations (Table 10.2). Uterine activity is evaluated with attention to the frequency, duration, and strength of contractions as well as the baseline uterine tone between contractions.

Fetal Heart Rate Interpretation

Baseline Fetal Heart Rate

The normal FHR baseline ranges from 120 to 160 beats per minute. Early in pregnancy, it is closer to 160 beats per minute, declining as gestational age advances. Likewise, the FHR may decrease gradually toward 120 beats per minute during the course of labor. An FHR

baseline below 120 beats per minute is termed *bradycardia*, and a rate in excess of 160 beats per minute is termed *tachycardia*. Abnormalities in the FHR baseline may have very different causes and consequences. It is important, therefore, to characterize the underlying etiology as accurately as possible and to institute appropriate therapy at the earliest possible time.

Bradycardia

Bradycardia is defined as an abnormally low baseline FHR (<120 beats per minute) and must be differentiated from the episodic FHR changes characteristic of decelerations. Although FHR decelerations are very common, true fetal bradycardia is not. A bradycardic FHR baseline between 100 and 120 beats per minute observed in association with otherwise reassuring FHR patterns probably represents a normal variant. Rarely, fetal bradycardia may be seen in association with maternal ß-blocker therapy, hypothermia, hypoglycemia, hypothyroidism, or fetal cardiac conduction defects (congenital atrioventricular block). Documentation of fetal heart block should prompt a search for structural fetal cardiac abnormalities, which may be present in 20% of cases. Other causes of heart block include viral infections (e.g., cytomegalovirus) and damage to the cardiac conduction system by transplacental passage of maternal anti-Ro (anti–SS-A) antibodies. Most congenital causes of fetal bradycardia do not present as abrupt changes in the FHR and rarely require emergency intervention. Any abrupt decline in the FHR below 120 beats per minute more likely represents a deceleration than a change in the baseline and should be considered pathologic until proven otherwise.

Tachycardia

Fetal tachycardia has many possible etiologies. Most often, it is the result of decreased vagal or increased sympathetic outflow, associated with fever, infection, fetal anemia, or fetal hypoxia. Other causes include maternal hyperthyroidism, fetal tachyarrhythmias (e.g., paroxysmal supraventricular tachycardia, atrial fibrillation, atrial flutter, and ventricular tachyarrhythmias), and medications including sympathomimetics (e.g., ritodrine, terbutaline) and parasympatholytics (e.g., atropine, phenothiazines).

Sinusoidal Pattern

The sinusoidal FHR pattern is an uncommon FHR baseline abnormality. It has the appearance of a smooth sine wave with an amplitude of 5 to 15 beats per minute and a frequency of 2 to 5 cycles per minute. There is little beat-to-beat variability, and accelerations are absent. Although the pathophysiologic mechanism is unclear, this pattern classically is associated with hypoxia and severe fetal anemia. Additionally, it has been reported in association with fetomaternal hemorrhage, chorioamnionitis, fetal sepsis, and administration of narcotic analgesics. A persistent sinusoidal pattern that is not attributable to medications is a concerning finding that demands immediate evaluation.

Fetal Heart Rate Variability

Variability in the FHR results from constant interplay between the sympathetic and parasympathetic arms of the fetal autonomic nervous system. Modulation of vagal tone occurs in response to changes in blood pressure detected by baroreceptors in the fetal aortic arch. Oxygen and carbon dioxide fluctuations, detected by chemoreceptors in the carotid bodies, similarly influence vagal outflow. In the absence of stress, sympathetic outflow is thought to be relatively tonic. Continual adjustments in vagal tone are manifested in the FHR tracing as "short-term" (beat-to-beat) variability superimposed on broader, cyclical fluctuations of three to five cycles per minute, referred to as "long-term" variability. In clinical use, the term *fetal heart rate variability* refers to the composite of short-term and long-term variability and is quantitated by measuring the difference between the peaks and troughs of the long-term fluctuations (Fig. 10.2). FHR variability is considered normal or average when both short-term and long-term variability are present, and the difference between the peaks and troughs of the long-term fluctuations is 6 to 25 beats per minute. Average variability reflects a nonacidotic vagal connection between the fetal CNS and the cardiac conduction system. Increased variability (more than 25 beats per minute), or saltatory FHR pattern, is uncommon and most often represents an exuberant autonomic response of a normal fetus. On occasion, it may reflect increased catecholamine release in the early stages of fetal hypoxia. Careful evaluation of the

associated FHR findings should help to clarify such cases. Decreased (three to five beats per minute) or absent (zero to two beats per minute) FHR variability reflects diminished fetal CNS activity, usually attributable to fetal sleep cycles or to medications administered to the mother (e.g., analgesics, magnesium sulfate, benzodiazepines, phenothiazines, atropine). Persistently decreased variability, however, may signal fetal acidosis. This is particularly true in the presence of other FHR findings suggestive of hypoxia, including tachycardia, loss of reactivity, or repetitive decelerations.

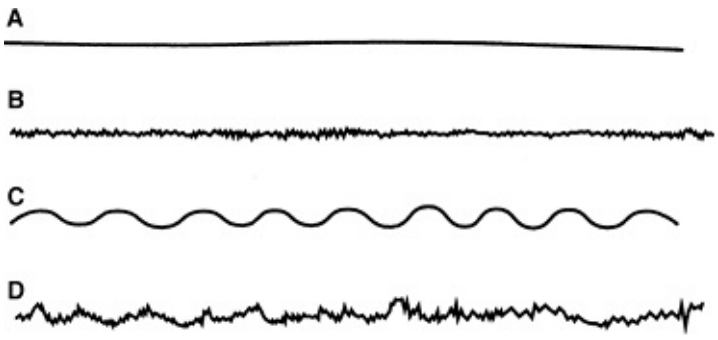

Figure 10.2 FHR variability. **A:** Short-term variability absent, long-term variability absent—abnormal. **B:** Short-term variability present, long-term variability absent—abnormal. **C:** Short-term variability absent, long-term variability present—abnormal. **D:** Short-term variability present, long-term variability present—normal.

Periodic Patterns

The FHR baseline is frequently interrupted by accelerations or decelerations in rate. These periodic patterns have important clinical implications regarding the well-being of the fetus.

Accelerations

Accelerations in the FHR occur with 90% of fetal movements as early as the second trimester, probably as a result of increased catecholamine release and decreased vagal stimulation of the heart (Fig. 10.3). By 32 weeks gestation, nearly all normal fetuses will have 15 to 40 spontaneous accelerations per hour, reflecting normal oxygenation of the CNS–cardiac axis. The frequency and amplitude of accelerations may be diminished by fetal sleep states, medications (narcotics, magnesium sulfate, atropine), prematurity, or fetal acidosis. Often, fetal scalp stimulation or vibroacoustic stimulation will provoke fetal movement and FHR accelerations. If these measures fail to induce FHR accelerations, hypoxia should be suspected, particularly if other FHR characteristics are not reassuring.

Decelerations

Decelerations in the FHR are most commonly encountered during the intrapartum period. They are divided into three categories: early, variable, and late decelerations (Fig. 10.4). Classification is based on the characteristic appearance of the deceleration and its temporal relationship to the onset of a uterine contraction.

Early Decelerations

Early decelerations are typically uniform, shallow dips in the FHR (rarely below 100 beats per minute) that mirror uterine contractions, beginning at the onset of the contraction and ending when the contraction ends. They are thought to result from fetal head compression, transient elevation of intracranial pressure, and reflex augmentation of vagal tone. Early decelerations classically appear during labor when the cervix is dilated 4 to 6 cm. Perinatal outcome is not adversely affected by these decelerations, and they are considered clinically benign.

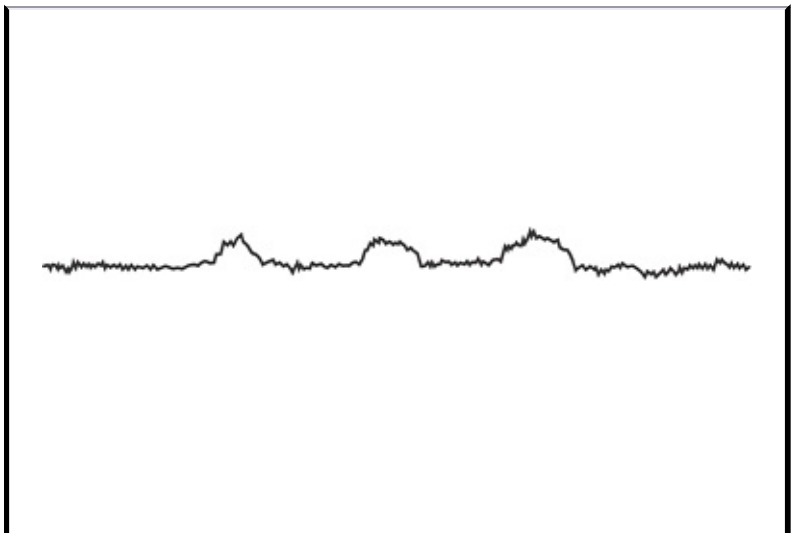

Figure 10.3 FHR accelerations.

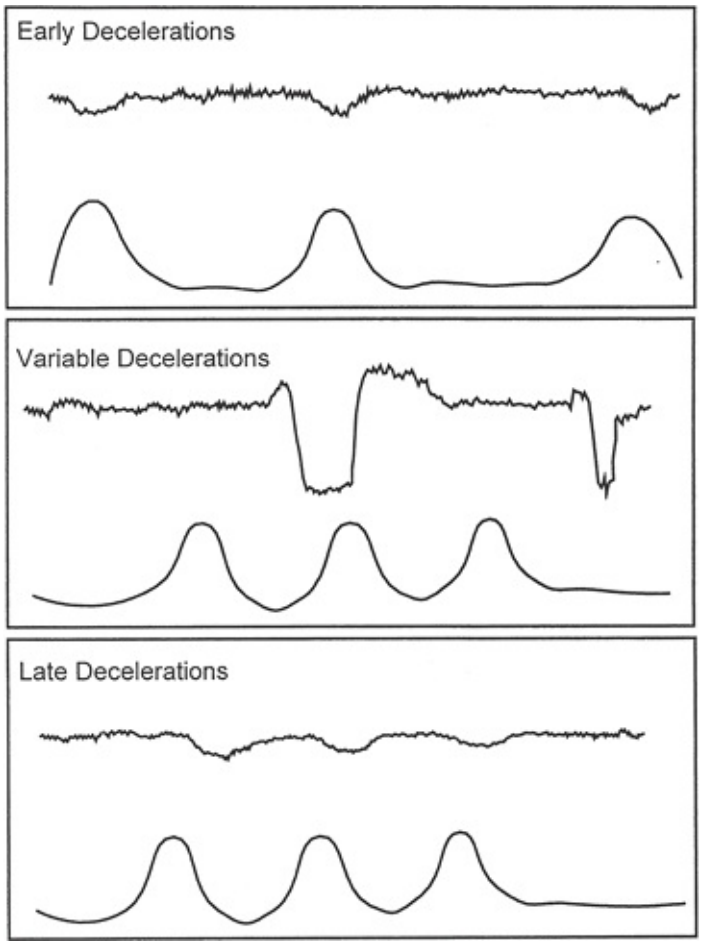

Figure 10.4 FHR decelerations.

Variable Decelerations and Prolonged Decelerations

Variable decelerations result from umbilical cord compression. They are abrupt and angular in appearance and have a variable temporal relationship to uterine contractions. As the umbilical cord is compressed, the thin-walled, compliant umbilical vein is the first vessel occluded, resulting in decreased fetal venous return, relative hypovolemia, and a reflex increase in the FHR. This observation often is called a *shoulder*. Further compression of the umbilical cord leads to occlusion of the umbilical arteries, removing the low-resistance placenta from the circuit and dramatically increasing fetal peripheral resistance. This leads to elevation of the fetal blood pressure and a baroreceptor-mediated slowing of the FHR in an attempt to return the blood pressure to normal. Maximum vagal tone may result in a junctional or idioventricular escape rhythm that appears as a relatively stable rate of 60 to 70 beats per minute at the nadir of the deceleration. As cord compression is relieved, this sequence of events occurs in reverse, at times resulting

in transient tachycardia or “overshoot” at the end of the deceleration. Variable decelerations are classified as:

- Mild—duration less than 30 seconds, depth of deceleration less than 70 beats per minute
- Moderate—duration 30 to 60 seconds, depth less than 70 beats per minute
- Severe—duration greater than 60 seconds, depth less than 70 beats per minute.

Isolated, infrequent variable decelerations have little clinical significance. Repetitive severe variables, however, may not allow sufficient fetal recovery between decelerations, resulting in persistent hypoxemia, hypercapnia, and respiratory acidosis. Prolonged tissue hypoperfusion may lead to metabolic acidosis and, ultimately, fetal death. In animal models, Clapp reported that frequent episodes of hypoxemic stress, produced by intermittent umbilical cord occlusion over a period of hours, produced fetal injury even in the absence of acidosis. When repetitive, severe variable decelerations are present, prolapse of the umbilical cord must be excluded. Other causes include nuchal cord, true knot in the cord, uterine rupture, placental abruption, uterine hypertonus, and tachysystole. Occasionally, variable decelerations fail to return promptly to the baseline and may more accurately be called *prolonged decelerations*.

Late Decelerations

Late decelerations reflect inadequate uteroplacental transfer of oxygen during contractions. Typically, they are smooth, uniform decelerations that begin after the onset of a contraction and end after the contraction stops. During uterine contractions, decreased maternal perfusion of the uteroplacental unit causes a decline in fetal Po_2. Fetal Po_2 levels below a critical threshold of 15 to 18 mm Hg trigger a chemoreceptor- and baroreceptor-mediated reflex. Initially, centralization of blood volume (favoring perfusion of the brain, heart, and adrenals) occurs via vasoconstriction in the vascular beds of the limbs and gut. The resulting increase in peripheral resistance provokes a reflex deceleration in the FHR. Isolated late decelerations within an otherwise normal tracing have little clinical significance. However, repetitive hypoxemia and centralization of blood volume, as evidenced by repetitive late decelerations, may force hypoperfused tissues to convert from aerobic to anaerobic metabolism. Organic acid by-products of anaerobic metabolism (pyruvate, lactate) diffuse slowly across the placenta and may accumulate in the fetus, leading to metabolic acidosis, asphyxia, and possibly death. Late decelerations may be caused by any factor that (a) reduces the normal placental transfer of oxygen or (b) increases the fetal oxygen demand beyond the available supply. Such factors include uterine hypertonus or tachysystole (oxytocin, prostaglandins, uterine rupture, placental abruption), maternal hypertension (chronic hypertension, preeclampsia, collagen vascular disease, renal disease, diabetes), suboptimal maternal cardiac output (cardiac disease, hypovolemia, supine hypotension, sympathetic blockade from regional anesthesia, sepsis), maternal hypoxia (apnea, cardiac disease, pulmonary disease), reduced oxygen-carrying capacity of maternal blood (anemia, hemoglobinopathy), and fever (increased fetal metabolism and increased oxygen consumption).

Uterine Activity

Uterine activity is evaluated with attention to the frequency, duration, and strength of contractions as well as the baseline uterine tone between contractions. The frequency is assessed by counting the number of contractions as recorded over a period of time. The normal frequency of uterine contractions during labor is every 2 to 3 minutes; however, cervical change may result from contractions occurring less frequently. In most cases, five to seven uterine contractions within a 15-minute period reflect adequate uterine activity. Increased contraction frequency is termed *uterine tachysystole* and is defined by six or more uterine contractions within a 10-minute window for two consecutive windows. Tachysystole may be seen in cases of placental abruption or hyperstimulation of the uterus by oxytocin or prostaglandin cervical-ripening agents. The duration is assessed by calculating the length of the contraction on the monitor tracing; the fine vertical lines represent 10-second intervals, and heavy lines denote 1-minute intervals (run at 3 cm per minute). Normal uterine contractions last approximately 40 to 60 seconds. Prolonged contractions may result from “coupling” of contractions, uterine hyperstimulation, or acute complications such as placental abruption or uterine rupture. The strength of the contractions can only be assessed with the direct IUPC. The normal baseline uterine pressure between contractions is approximately 10 mm Hg. Abnormally high baseline pressures in excess of 20 mm Hg may result from hyperstimulation or occasionally from overdistention of the uterus by excessive amnioinfusion, polyhydramnios, or fetal macrosomia. During contractions, normal uterine pressure ranges from 30 to 80 mm Hg, although pressures in excess of 80 mm Hg may be observed during the second stage of labor. A calculation of the strength of the contraction is based on the sum of contraction pressures (peak minus baseline) per 10-minute interval and is expressed in Montevideo units. For example, four contractions in a 10-minute window, each 50 mm Hg above the baseline, would yield 200 Montevideo units. Montevideo units in excess of 180 to 200 usually are considered to reflect adequate uterine activity to effect cervical change in labor.

Antepartum Testing/Fetal Monitoring

The goals of antepartum testing are (a) to identify fetuses in jeopardy so that permanent injury or death might be prevented and (b) to identify healthy fetuses so that unnecessary intervention might be avoided. The key measure of the effectiveness of an antepartum test is the false-negative rate, defined as the incidence of fetal death within 1 week

---

of a normal antepartum test. Reported false-negative rates range from 0.4 to 1.9 per 1,000 with current testing methods. Another important measure is the false-positive rate. A false-positive test may be defined as an abnormal test that prompts delivery but is not associated with evidence of acute fetal compromise (e.g., meconium-stained amniotic fluid, intrapartum fetal distress, low Apgar scores) or chronic fetal compromise (e.g., fetal growth restriction). False-positive rates range from 30% to 90% with current testing methods.

Antepartum testing is used primarily in patients who are considered to be at increased risk for fetal hypoxia or asphyxia secondary to suboptimal uteroplacental transfer of oxygen. It

is expected that the use of antepartum testing in these high-risk patients will reduce their risk of fetal/neonatal morbidity/mortality to the level of the low-risk patient. The optimal gestational age at which to begin antepartum testing is not known and varies according to the underlying condition (Table 10.1). However, for most medical indications, testing is initiated by 32 to 34 weeks. In view of the high false-positive rates of most testing protocols, earlier initiation of testing should be expected to increase the incidence of unnecessary intervention and iatrogenic prematurity, with its attendant complications.

Decisions on timing for initiation of fetal monitoring and which conditions are “high risk” rely on determining when the risk for fetal death is significantly higher than that in low-risk pregnancies and is somewhat subjective. In general, a two- to threefold increase in fetal death relative risk as compared with a low-risk pregnancy is considered a reasonable threshold. In addition to the conditions listed in Table 10.1, the risk of stillbirth in women with advanced maternal age and maternal obesity has recently been shown to exceed this threshold. Pregnant women aged 35 to 39 have a twofold increase in risk of fetal death (95% confidence interval [CI] 1.3, 2.7) versus women <35, and the risk increases at 39 weeks gestation. Women over 40 years have a 2.4-fold increased risk (95% CI 1.3, 4.5) that begins at term (<37 weeks). Maternal obesity is associated with a 2.7-fold increased risk (95% CI 1.85 to 4.68). Although studies on antepartum testing are not available for these conditions, it would be reasonable to perform antepartum surveillance; however, it is important to acknowledge that the use of antepartum testing is associated with iatrogenic prematurity due to intervention for false-positive tests, which is estimated to occur in 1.5% of tests before 37 weeks.

Fetal Movement Counts

Maternal perception of normal fetal movement has long been recognized as a reliable indicator of fetal well-being. Cessation of fetal movement in response to hypoxia has been demonstrated in animal studies; however, controlled data in human fetuses are lacking. Nevertheless, any acute decrement in the number or strength of fetal movements should raise the suspicion of fetal compromise and should prompt further evaluation. Many clinicians recommend routine fetal movement counting, particularly in patients who are considered high risk. A common approach is to recommend daily counting of fetal movements for 1 hour. Ten fetal movements in a 1-hour period are considered reassuring. If fewer than ten movements are appreciated, counting is continued for another hour. Fewer than ten movements in a 2-hour period should alert the patient to contact her physician for further evaluation. Another protocol calls for movement counting two to three times daily for 30 minutes. With this approach, further evaluation is recommended if there are fewer than four strong movements in a 30-minute period.

Although controlled trials in low-risk patients have not demonstrated a significant benefit of formalized movement counting over routine questioning during prenatal visits, evidence from one study using nonconcurrent controls suggests a lower rate of fetal death and a higher incidence of intervention for fetal distress in patients by using a formalized protocol of fetal movement counting. Fetal movement counting is an inexpensive method of involving the patient in her own care and may be a valuable adjunct to routine prenatal

care, regardless of risk category.

Nonstress Test

FHR accelerations occurring in association with fetal movements form the basis of the nonstress test (NST). Although many criteria have been reported, a normal or “reactive” NST usually is defined by two accelerations in a 20-minute period, each lasting at least 15 seconds and peaking at least 15 beats per minute above the baseline. In most institutions, the test is repeated once or twice weekly. In 1986, Boehm and colleagues reported that the latter approach yielded a threefold reduction in the incidence of fetal death, although the difference was not statistically significant. In 1982, Freeman and associates reported a false-negative rate of 1.9 per 1,000 among 1,542 women tested weekly with the NST. In 1983, Manning and coworkers reported an average false-negative rate of 6.4 per 1,000 among nine large clinical trials by using the NST as the primary method of surveillance. Assessment of FHR characteristics other than reactivity (baseline rate, variability, decelerations) may improve the sensitivity of the test. The findings from an NST must be interpreted in the context of the pregnancy. Preterm infants commonly do not meet the 15 beats per 15 seconds criterion for reactivity. Once the fetus is 34 weeks, the tracing should be reactive. However, once a fetus demonstrates FHR reactivity, even if earlier than 34 weeks gestation, it should continue to have reactive tests. Reported false-positive rates of the NST vary widely, with an average rate of approximately 50%. When performed twice weekly and interpreted in the context of associated FHR patterns, the NST alone appears to be an acceptable, although not optimal, method of assessing fetal well-being. Advantages include ease of use and interpretation, low cost, and minimal time requirement. The chief disadvantages include a

---

high false-positive rate and a higher false-negative rate than achieved with other methods. Commonly, the NST is used as a screening test, and if abnormal, a backup test such as the contraction stress test or biophysical profile (BPP) is used.

Contraction Stress Test and Oxytocin Challenge Test

The first antepartum testing technique, the contraction stress test (CST) or oxytocin challenge test (OCT), arose from intrapartum observations linking late FHR decelerations with poor perinatal outcome. The test sought to identify uteroplacental insufficiency by demonstrating late decelerations in fetuses exposed to the stress of spontaneous (CST) or induced (OCT) uterine contractions. Late decelerations occurring during uterine contractions were associated with increased rates of fetal death, growth restriction, and neonatal depression. The CST is performed weekly and is considered negative if there are at least three uterine contractions in a 10-minute period with no late decelerations on the tracing. Failure to produce three contractions within a 10-minute window or inability to trace the FHR results is an unsatisfactory test. Prolonged decelerations, variable decelerations, or late decelerations occurring with fewer than half of the contractions constitute a suspicious or equivocal test. Unsatisfactory, suspicious, or equivocal tests require repeat testing the following day. The CST or OCT is considered positive when at least half of the contractions during a 10-minute window are associated with late

decelerations. In 1982, Freeman and colleagues tested more than 4,600 women with the CST and reported a false-negative rate of 0.4 per 1,000. When the last test before delivery was a reactive, negative CST, the perinatal mortality rate was 2.3 per 1,000 compared with a mortality rate of 176.5 per 1,000 when the last test was a nonreactive, positive CST. Reported false-positive rates for the CST range from 8% to 57%, with an average of approximately 30%. Principal advantages of this form of testing include excellent sensitivity and a weekly testing interval. Limitations include a high rate of equivocal results requiring repeat testing, increased expense and inconvenience (particularly if oxytocin is required), and increased time requirement compared with the NST. Additionally, use of the CST is contraindicated in clinical settings where labor/uterine contractions are undesirable, including preterm labor, placenta previa, vasa previa, cervical incompetence, multiple gestation, and previous classic cesarean section.

Biophysical Profile

The BPP assesses five variables: FHR reactivity, fetal movement, tone, and breathing (reflecting acute CNS function), and amniotic fluid volume (a marker of the longer-term adequacy of placental function). Two points are assigned for each normal variable and 0 for each abnormal variable for a maximum score of 10. A BPP score of 8 to 10, with normal amniotic fluid volume, is considered normal. A score of 6 is considered suspicious, and testing usually is repeated the following day. Scores of less than 6 are associated with increased perinatal morbidity and mortality; they usually warrant hospitalization for further evaluation or delivery. Among 12,620 women tested weekly by using the BPP, Manning and coworkers reported a false-negative rate of 0.6 per 1,000. The false-positive rate of the BPP varies with the score of the last test prior to delivery. Manning and coworkers reported a false-positive rate of 0 among 11 patients in whom the last BPP score before delivery was 0 compared with a false-positive rate greater than 40% among 182 patients with a last BPP score of 6. The BPP is a reliable predictor of fetal well-being. The false-negative rate is superior to that of the NST alone and compares favorably with the false-negative rate of the CST. Advantages of the BPP include excellent sensitivity, a weekly testing interval, and a low false-negative rate. The primary limitation is the requirement for personnel trained in sonography. Additionally, although the duration of ultrasound observation is typically less than 10 minutes, the complete BPP is more time-consuming than other noninvasive tests.

Modified Biophysical Profile

The modified biophysical profile (MBPP) combines the strengths of the NST (ease of use, low cost) and the complete BPP (improved sensitivity, low false-negative rate) while minimizing the requirement for additional training in sonographic visualization of the fetus. The test is performed once to twice weekly and uses the NST as a short-term marker of fetal status and the AFI as a marker of longer-term placental function. Interpretation of the NST incorporates assessment of reactivity, baseline rate, variability, and FHR decelerations. Late, prolonged, or significant variable decelerations, particularly in the setting of borderline amniotic fluid volume (AFI 5 to 10 cm), are considered abnormal. Regardless of reactivity, oligohydramnios (AFI <5 cm) constitutes an abnormal test. In 1994,

Nageotte and associates evaluated 2,774 high-risk pregnancies with twice weekly MBPPs and reported one unexplained fetal death within 1 week of a normal test result, for a false-negative rate of 0.36 per 1,000. In 1996, Miller and colleagues reported 54,617 MBPPs in 15,482 high-risk pregnancies. Antepartum testing in high-risk pregnancies yielded a fetal death rate that was nearly sevenfold lower than that in the untested, low-risk population. The overall false-negative rate of the MBPP was 0.8 per 1,000, and the false-positive rate was 60%. Abnormal test results prompted intervention in 15.5% of the tested population; iatrogenic prematurity occurred in 1.5% of women tested before 37 weeks. The false-negative rate of the MBPP is similar to the CST and the complete BPP. Additionally, it is easier to perform and less time-consuming than the CST or the complete BPP. The sensitivity of the MBPP is superior to that of the NST alone. Limitations include the need for backup testing in

---

10% to 50% of patients, a high false-positive rate, and a twice weekly testing interval.

Doppler Velocimetry

Doppler velocimetry of fetal, umbilical, and uterine vessels has been the focus of intensive study in recent years. This technology uses systolic-to-diastolic flow ratios and resistance indices to estimate blood flow in various arteries. Studies have shown significant improvement in perinatal outcome with the use of Doppler ultrasonography in pregnancies complicated by growth restriction. Although severe restriction of umbilical artery blood flow, as evidenced by absent or reversed flow during diastole, has been correlated with fetal growth restriction, acidosis, and adverse perinatal outcome, the predictive values of less extreme deviations from normal remain undefined. In conditions other than fetal growth restriction, Doppler velocimetry does not appear to be a useful screening test for the detection of fetal compromise and is not recommended for use as a screening test in the general obstetric population. Doppler velocimetry is used in some settings as an adjunct to standard methods of fetal assessment but should not be considered a replacement for traditional fetal monitoring.

Other Methods and Intrapartum Evaluations

Fetal Scalp Blood Sampling

Fetal scalp blood sampling allows for the determination of the fetal acid–base status during labor. The technique requires dilation of the cervix, rupture of the membranes, and access to the fetal presenting part. A lighted plastic endoscopic cone is inserted into the vagina and through the cervical os so that it rests against the fetal presenting part. Care should be taken to ensure that it is not placed over a fontanelle. The area to be sampled is dried with a sponge and coated with a thin layer of silicone to facilitate the formation of a blood droplet. The scalp is then punctured with a microscalpel, and blood is collected by capillary action in a heparinized capillary tube. After the sample is mixed, it is transported on ice to the laboratory for blood gas analysis. During labor, a normal scalp blood pH is 7.25 to 7.35. A fetal scalp pH greater than or equal to 7.25 provides evidence of a nonacidotic

fetus. A scalp pH of 7.20 to 7.25 is considered suspicious, and sampling should be repeated within 30 to 60 minutes. Historically, pH values less than 7.20 have been considered acidotic; however, minor deviations below normal correlate poorly with perinatal outcome. Because abnormal perinatal outcome has not been consistently observed with values greater than 7.0, there is debate regarding the specific pH value that should be considered acidotic. In addition, fetal scalp sampling reflects the status of the peripheral blood, where acidosis is inherent, owing to the accumulation of CO_2. Since respiratory acidemia is generated in the blood and metabolic acidemia is generated in the tissues, a scalp sample may not reflect the state of the fetus. In light of the technical difficulty of the procedure and the uncertainty regarding interpretation of results, many centers have reduced their reliance on fetal scalp blood sampling.

Percutaneous Umbilical Blood Sampling

Electronic FHR monitoring, ultrasound, and fetal scalp blood sampling can provide useful information regarding the acid–base status of the fetus. Occasionally, however, direct access to circulating fetal blood is necessary. A classic example is the fetus with severe anemia secondary to Rh isoimmunization. Doppler studies of the middle cerebral artery are a noninvasive method for the assessment of fetal anemia. In some cases, direct sampling of the fetal blood and intrauterine blood transfusion may be required. Percutaneous umbilical blood sampling (PUBS) is a procedure that affords direct access to fetal venous blood. Using sterile technique and direct ultrasound guidance, a needle is passed transabdominally into the umbilical vein. Medications or blood may be infused through the needle once fetal blood samples have been obtained. Other indications for PUBS include suspected antibody-mediated fetal thrombocytopenia and fetal cardiac arrhythmias requiring assessment of fetal drug levels or direct fetal administration of antiarrhythmic agents.

Fetal blood sampling can be used along with cardiotocography (CTG) to assess fetal acid–base status during labor. However, it requires additional expertise, is time-consuming, has some significant risks, and provides only intermittent information. For these reasons, it is not widely used.

Fetal Scalp Stimulation and Fetal Vibroacoustic Stimulation

FHR accelerations in response to fetal scalp stimulation have been shown to predict a scalp pH greater than or equal to 7.19. Among fetuses without an acceleratory response to scalp stimulation, 39% were acidotic (pH <7.19). A similar relationship has been reported between fetal scalp pH and the FHR response to vibroacoustic stimulation with an artificial larynx applied to the maternal abdomen over the fetal head for 1 to 3 seconds. Among 30 fetuses with FHR accelerations in response to this stimulus, all had scalp pH values greater than or equal to 7.25. Half of the fetuses that did not respond to acoustic stimulation had pH values less than 7.25. FHR accelerations in response to external stimuli are thought to have the same predictive value as spontaneous accelerations. Fetal stimulation is used in antepartum testing to shorten the time of the NST and in the intrapartum period to confirm fetal well-being when spontaneous accelerations are absent. There is no evidence in humans of adverse long-term effects of vibroacoustic stimulation.

Fetal Pulse Oximetry (Fetal Oxygenation)

Fetal pulse oximetry assesses fetal oxygen saturation and can provide a noninvasive continuous measurement of fetal arterial oxyhemoglobin saturation once membranes have been ruptured. A sensor similar to an IUPC is placed transvaginally between the uterine wall and fetal face and measures oxyhemoglobin saturation through the same technology as transcutaneous oxygen monitors. This technology has been evaluated as an adjunct assessment of fetal well-being during labor in conjunction with FHR monitoring.

One multicenter trial of fetal oximetry in women with abnormal FHR patterns (n = 1,010) found a rate of cesarean delivery for fetal distress significantly lower in the fetal oximetry group (4.5%) compared with 10.2% in the conventional fetal monitoring group. Unexpectedly, however, the cesarean rate for dystocia was significantly higher in the oximetry group (18.5% versus 8.6% in the control group), thus the overall cesarean rates were not different (29% oximetry plus FHM vs. 26% FHM). A second multicenter trial of over 5,000 women did not confirm these findings, with no difference in overall cesarean delivery rates (26.3% vs. 27.5% P = 0.3), cesarean for nonreassuring fetal heart patterns (7.1% vs. 7.9% P = 0.3), or cesarean for dystocia (18.6% vs. 19.2%). Knowledge of the fetal oxygen saturation was not associated with a decrease in the rate of cesarean delivery or improvement in neonatal outcome.

Fetal Cardiotocography Plus Pulse Rate Interval Analysis

Normally, there is a negative relationship between the pulse rate (PR) interval and the FHR: as the FHR slows, the PR interval lengthens, and vice versa. In acidemic infants, this relationship is reversed. A retrospective study of 265 women suggested that the addition of time-interval analysis of the fetal ECG would decrease the rate of unnecessary fetal blood sampling or assisted delivery for presumed fetal distress. However, in a prospective randomized trial of the use of fetal ECG time-interval variables in addition to CTG in fetal surveillance during labor, there was no difference in operative intervention or neonatal outcome. The use of fetal CTG plus PR interval analysis is investigational.

ST Waveform Analysis

Another method of fetal assessment involves evaluation of the changes in specific end organs, such as the fetal heart, through ST waveform analysis to aid in the interpretation of ominous FHR patterns.

ST analysis of the ECG during exercise is a method for assessing myocardial function in the adult. As a corollary, ST waveform analysis of the fetus during labor is analogous to a fetal “stress test” and may provide information on the ability of the fetal heart to respond. An ST segment rise indicates a fetus responding to hypoxia. A negative ST indicates a fetus that is unable to respond or has not had time to react.

The fetal ECG is readily obtainable during labor from the same scalp electrode used to obtain the FHR. The evidence from experimental work indicates that ST waveform

elevation reflects compensated myocardial stress and a switch to anaerobic myocardial metabolism. A study of 4,966 women with CTG versus CTG plus ST analysis revealed that intrapartum monitoring with CTG combined with automatic ST waveform analysis increased the ability of the obstetrician to identify fetal hypoxia. Currently, the use of ST segment elevation in clinical interpretation of fetal heart tracings is considered investigational, and studies are ongoing to assess its effectiveness.

Summary Points

- Electronic FHR monitoring is a very sensitive tool for the detection of fetal compromise; truly compromised fetuses rarely fail to exhibit abnormal FHR patterns. The converse, however, is not true. Abnormal FHR patterns frequently are observed in the absence of fetal compromise. The limited positive predictive value is the principal shortcoming of FHR monitoring.
- Accuracy may be improved by combining FHR analysis with assessment of biophysical variables such as amniotic fluid volume, fetal movement, breathing, tone, and blood flow characteristics.
- Other variables under investigation include fetal ECG interpretation and ST waveform analysis.
- To date, the most effective combination of variables has not been defined, and no one approach to fetal surveillance has demonstrated clear superiority over the others. Yet, despite the limitations, antepartum testing in "high-risk" pregnancies has been reported to yield a fetal death rate nearly seven times lower than that in untested, "low-risk" pregnancies. If this observation is substantiated, future investigation will be needed to address the role of antepartum fetal surveillance in uncomplicated, low-risk pregnancies.

Preterm Labor and Post-Term Delivery

J. Chris Carey
Ronald S. Gibbs
The authors wish to acknowledge the contributions of Debra Guinn, Lisa Moore, and James N. Martin Jr, to this chapter in the last edition of this text.

Preterm Labor

Preterm birth is a leading cause of neonatal morbidity and mortality. Over the past several decades, there has been a marked increase in survival of very low-birth-weight infants. This increase in survival has been attributed to increased use of corticosteroids, regionalization of perinatal care, improved methods of mechanical ventilation, availability of exogenous surfactant, and improved nutritional therapy. However, the reduction in mortality has not been accompanied by a reduction in neonatal morbidity or long-term handicaps. It is estimated that 50% of all major neurologic handicaps in children result from premature births.

Despite widespread awareness of the problem and use of therapies believed to be beneficial to prevent preterm births, the rate of preterm delivery has increased in the United States. The majority of spontaneous premature births occur to women who develop preterm labor or preterm premature rupture of the membranes (PPROM). Cervical incompetence may also result in preterm delivery. Historically, researchers and epidemiologists have approached these conditions as being distinct processes that were mutually exclusive of one another. Recent evidence would suggest that many women have overlapping conditions that predispose them to deliver preterm. This concept is depicted in Figure 11.1. For example, a woman who has preterm delivery secondary to PPROM at 27 weeks gestation may have had weeks of “silent” or painless contractions or cervical dilation prior to developing ruptured membranes and delivery. Using this broader conceptual framework, this chapter will review the epidemiology, etiology, prevention, and treatment of women with preterm labor.

Mechanisms of Labor Onset

Labor occurs when the uterus converts from a state of containment to an environment that attempts to expel the fetus. In humans, the average gestational period is 280 days ±14 days. Therefore, *term labor* is defined as labor that occurs between 37 and 42 weeks

gestation. *Preterm labor* is defined as labor that occurs between 20 and 37 weeks gestation. In theory, pathologic activation of the normal parturition process results in preterm labor and delivery.

In both term and preterm labor, following an unknown stimulus, the mechanisms that produce labor override those that maintain the pregnancy. Activation of the parturition process results in membrane activation, cervical ripening, and an increase in myometrial responsiveness to endogenous and exogenous signals. Subsequently, labor progresses along a common pathway that results in uterine contractions that are sufficient to cause progressive cervical dilation to allow for expulsion of the fetus. A number of inciting events have been implicated in premature births. These events include decidual hemorrhage (abruption), mechanical factors (overdistension of the uterus, cervical incompetence), hormonal changes (fetal or maternal stress), or subclinical/clinical infection. Infection is associated with as many as one third of preterm deliveries, particularly those occurring at the earliest gestational ages. The role of infection in preterm labor will be reviewed separately in this chapter.

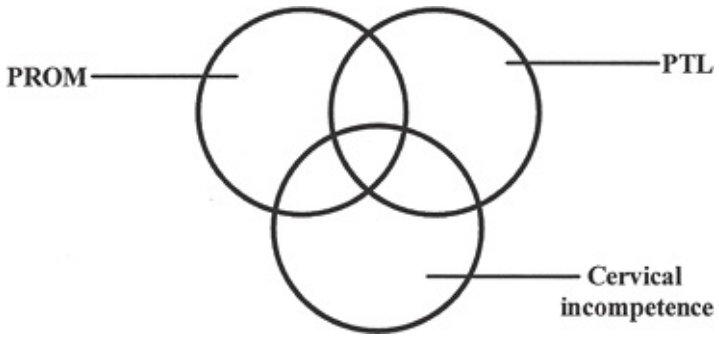

Figure 11.1 Overview of spontaneous preterm birth.

Animal models have helped in understanding labor. Important findings in animal labor models include an increase in oxytocin receptors present in the myometrium, gap junctions developing between myometrial cells, an increased response to agents capable of producing contractions in the uterus, and physical and biochemical changes of the cervix resulting in a softened consistency. Uterine smooth muscle contractility is produced by the actin–myosin interaction, following myosin light chain phosphorylation, which is controlled by myosin light chain kinase. Myosin light chain kinase is activated by calcium as a calmodulin–calcium complex. Cyclic adenosine monophosphate (cAMP) also regulates kinase by inhibiting phosphorylation. Many factors are involved in this control. Some of the proposed theories of labor will be discussed in the following sections.

Hormonal

Alteration in systemic or local levels of steroid hormones is an initiating factor of labor in some animals. The role of hormonal changes in initiating human labor is less clear. The

withdrawal of the uterine inhibitor hormone progesterone has been shown to play a major role in many animals (e.g., sheep, rats, rabbits). In sheep, progesterone withdrawal seems to be caused by an increased responsiveness of fetal adrenal cells to adrenocorticotropic hormone (ACTH), resulting in increased production of cortisol. Through several steps, cortisol redirects placental steroid biosynthesis and decreases progesterone secretion. The decreased circulating progesterone in the sheep leads to increased myometrial gap junction formation, an increase in prostaglandin formation, and increased response of the uterus to agents capable of producing contractions. In this sheep model, fetal ACTH secretion controls the onset of labor.

However, major differences exist, between sheep hormonal status and that of primates, including humans. In humans, there is not a great increase in cortisol from the fetal adrenal gland before labor, nor has a dramatic decrease in progesterone been consistently demonstrated. Yet, progesterone is important in human pregnancy, and numerous studies have examined the role of the progesterone-to-estrogen ratio before the onset of labor. In 1974, investigators demonstrated a significant fall in serum progesterone levels and a rise in estrogen levels in many women before labor. This finding has not been reproduced consistently. Estriol may be a signal from the fetus indicating that it is mature and ready for delivery. Production of estriol increases during the last month of pregnancy. In the large amounts produced, estriol is as active as estradiol in stimulating uterine growth. There are reports of an elevation in the estradiol/progesterone ratio at the end of pregnancy.

The antiprogesterones—RU-486 (mifepristone) and ZK-98299 (onapristone)—in humans and other primates can enhance the responsiveness of the uterus and induce cervical change within 12 to 48 hours, again suggesting a role for progesterone in preventing labor onset.

Administration of progesterone has been demonstrated to prevent preterm birth in humans. The National Institute of Child Health and Human Development Maternal-Fetal Medicine Units (MFMU) Network progesterone trial demonstrated that women at high risk for preterm birth who were treated with progesterone were significantly less likely to deliver preterm than those treated with placebo. In that trial, women with a previous preterm birth were treated with weekly injections of 250 mg of 17-alpha-hydroxyprogesterone caproate or placebo from 17 to 20 weeks until 36 weeks or delivery. They reported that 111/306 (36.3%) of women treated with progesterone delivered at less that 37 weeks compared with 84/153 (54.9%) treated with placebo (relative risk [RR] 0.66; 95% confidence interval [CI] 0.54 to 0.81). Significantly fewer women treated with progesterone also delivered at <35 and <32 weeks. Several subsequent studies have shown that progesterone therapy reduces the risk of preterm birth in women at high risk for preterm birth. A meta-analysis concluded that progestational therapy reduced the risk of preterm birth and low birth-weight (LBW) infants. The authors concluded that with progesterone therapy, there was a reduction in the risk of preterm birth less than 37 weeks (six studies; 988 participants; RR 0.65; 95% CI 0.54 to 0.79) and preterm birth less than 34 weeks (one study; 142 participants; RR 0.15; 95% CI 0.04 to 0.64). Infants born to mothers administered progesterone were less likely to have birth weight less than 2,500 grams (four studies; 763 infants; RR 0.63; 95% CI 0.49 to 0.81) or intraventricular hemorrhage (one study; 458 infants; RR 0.25; 95% CI 0.08 to 0.82).

As of this writing, the optimal route and dose of progesterone have not been established. Published studies have used intramuscular injections of 17-alpha-hydroxyprogesterone caproate, progesterone suppositories, oral progesterone, and intramuscular progesterone tablets. The Food and Drug Administration (FDA) has not approved any progesterone preparation for the prevention of preterm birth, and the injectable formulations must be compounded prior to use. Compounded formulations are

not overseen by the FDA, and accuracy of dosing and sterility are in the hands of the compounding pharmacy.

Oxytocin

It is well known that oxytocin produces uterine activity when administered to pregnant women. The role of endogenous oxytocin as an initiator of term or preterm labor is less well defined. Some reasons to suspect that oxytocin is a universal initiator of labor are its ability to induce labor when given exogenously and the increase in blood levels that accompanies labor in most species. Because of the pulsatile manner of oxytocin release and the difficulty in measuring the hormone, its precise role in humans has been difficult to ascertain. Compared with nonlaboring patients, oxytocin levels appear to be significantly increased during the first stage of labor and increase to a greater amount during the second stage of labor. Oxytocin levels are higher in umbilical artery blood than in umbilical vein or maternal blood. This finding suggests that the fetus is a source of oxytocin production and release during labor. It is clear that the uterus becomes more sensitive to oxytocin in the days preceding labor. The number of myometrial cell membrane oxytocin receptors greatly increases as pregnancy advances, with a further increase during labor itself. In humans as well as in other species, the concentration of oxytocin receptors is a major reason for increased contractility of the uterus. The increase in oxytocin receptors is the result of increased estrogen levels.

Prostaglandins

Another important part of the parturition model is the synthesis and release of prostaglandins E_2 and F_2. This is supported by an increase in prostaglandins or metabolites in the amniotic fluid, endometrium, decidua, myometrium, and blood at the time of labor; the administration of prostaglandins inducing labor; and inhibitors to prostaglandin synthesis delaying labor. It is likely that the prostaglandins have a role in parturition originating from the decidua and myometrium. Oxytocin has the ability to stimulate prostaglandin release through the decidual receptors. In addition, infection of the membranes can release prostaglandins and may be an initiating factor in many cases of preterm labor.

Bacterial by-products may be directly responsible for the stimulation of prostaglandin release in the following ways. Bacterial phospholipase releases the precursor arachidonic acid from the amnion, leading to increased prostaglandin synthesis. Gram-negative organisms also may be able to produce prostaglandins through endotoxin stimulation of the decidua or membranes. Gram-positive organisms also may have prostaglandin-stimulating

abilities through peptidoglycans. Phospholipase A_2 is contained within the lysosome of the fetal membranes. As phospholipase A_2 is released from the lysosome, prostaglandin may be synthesized, resulting in uterine contractions.

Cytokines

Cytokines are proteins secreted by the immune system in response to infection. There is recent interest in the role of cytokines and growth factors (e.g., epidermal growth factor, insulinlike growth factors 1 and 2) as potential initiators of labor. The cytokines interleukin 1 (IL-1), IL-6, and tumor necrosis factor (TNF) stimulate the amnion and decidua to produce prostaglandins and increase at time of labor, while transforming growth factor-ß (TGF-ß) inhibits prostaglandin production by other cytokines and may have antiprogestin properties. Finally, several different cytokines have been found in the amniotic fluid of patients with preterm labor.

Other Factors

Endothelins are potent vasoconstrictors in the sarafotoxinlike family. Some isoforms of endothelins are potent uterotonics. Although endothelin does not appear to increase at time of labor, uterine sensitivity and endothelin-receptor numbers do increase in the pregnant uterus. There is some decrease of endothelin-1 in the amniotic fluid of patients in labor, but this may be a consequence rather than an initiator of labor. Nitric oxide, produced from l-arginine by the enzyme nitric oxide synthase (NOS), mediates relaxation of vascular smooth muscle. It has been shown in various animal tissues, including human, that the NOS enzyme is decreased in myometrial tissue at term. Thus, nitric oxide may have a role in maintaining a quiescent uterus.

It can be hypothesized that parturition is a development of an estrogen environment. This estrogen environment promotes changes in the maternal pituitary with increased oxytocin synthesis and release. Estrogen may also be acting directly on the placenta and cervix. As the antiestrogen progesterone level decreases, estrogen can act to increase oxytocin receptors, prostaglandin production, and gap junction number and size. As the cervix ripens, the underlying membranes and decidua become exposed to the vaginal bacteria, triggering an inflammatory response with release of cytokines and prostaglandins. At this point, the paracrine events take dominance over the endocrine effects. Some conditions, such as infection, can overwhelm the endocrine phase of parturition.

Infection as a Cause of Preterm Birth

Preterm birth has been linked with symptomatic nongenital infections such as acute pyelonephritis and pneumonia. A large body of evidence suggests that subclinical infection may be an important cause of premature labor, especially labors resulting in very early delivery.

The hypothesis linking subclinical infection and premature birth may be summarized as follows. Microbes or their products such as endotoxin enter the uterine cavity during

pregnancy, most commonly ascending from the lower genital tract. Blood-borne infection from a nongenital focus occurs less commonly. Microbes or their products then interact, most likely with the decidua or possibly with the membranes, producing prostaglandins or directly leading to uterine muscle contraction. This interaction is most likely mediated through a cytokine cascade. As a result, there is cervical dilation, entry of more microbes into the uterus, and continuation of “the vicious cycle” resulting in premature birth.

The first piece of evidence linking subclinical infection to preterm birth is that the prevalence of histologic chorioamnionitis is increased among preterm births. In membranes from preterm deliveries, there is a consistent and very strong association between positive membrane cultures and the likelihood of membrane infiltration. For example, when the birth weight is greater than 3,000 g, the percentage of placentae showing histologic chorioamnionitis is less than 20%; when the birth weight is below 1,500 g, the percentage is 60% to 70%. Most cases of histologic chorioamnionitis are caused by infection.

TABLE 11.1 Prenatal Infections as a Cause of Preterm Birth: Association and Treatment Recommendations

Infection	Association with PTB	Treatment
Bacteriuria—untreated	Approximately a 2-fold increase.	It is standard practice to screen for and treat bacteriuria to prevent symptomatic UTI as well as to prevant PTB.
Neisseria gonorrhoeae—untreated	Old studies suggest an increase.	It is a standard practice to screen, at least in at-risk population, for and treat this infection to prevant neonatal infection and to control STD spred. Treatmet may decrease PTB.
Chlamydia trachomatis—	No consistent association of PTB with infection. Subpopulations	As for *N. gonorrhoeae*.

untreated	such as those with recent infection may be at risk.	
Group B streptococci (GBS)	Heavy lower genital colonization is associated with small, but significant, increase in risk for LBW.	Prenatal treatment does not decrease risk of PTB. Prenatal treatment is not recommended for GBS genital colonization to prevent perinatal infection, but GBS bacteriuria should be treated when diagnosed.
Ureaplasma urealyticum	Best evidence shows no association of lower genital tract colonization with PTB.	Do not screen for or treat lower genital tract infection with *U. urealyticum*.
Bacterial vaginosis (BV)	BV is associated with a 2- to 3-fold increase in PTB.	Treatment trials reveal conflicting results. Routine screening and treatment cannot be recommended. Symptomatic women may be treated in any trimester. In women with a history of preterm birth, screening and treating is an option. In women with previous preterm birth and with BV treatment in second trimester for ≥1 wk with oral metronidazole results in significant reduction in PTB. Shorter courses or topical treatment have not led to a decrease in PTB.

LBW, low birth weight; STD, sexually transmitted disease; UTI, urinary tract infection.

Second, clinically recognized infections are increased in mothers and neonates after preterm birth. Sepsis and meningitis are increased 3- to 10-fold in preterm infants. Less widely recognized is the increase in maternal infection after preterm birth. These observations suggest that subclinical infection underlies preterm birth and that the infection became clinically evident during or shortly after birth.

Third, there are associations of preterm birth with various maternal lower genital infections or microbes (Table 11.1). Although *Ureaplasma urealyticum* in the lower genital tract had been associated with LBW infants in earlier studies, a large National Institutes of Health (NIH) study reported no associations of *U. urealyticum* in the vagina with any adverse pregnancy outcome (preterm birth, PPROM, LBW, or birth weight <1,500 g). Interestingly, then, *U. urealyticum* in the lower genital tract is *not* associated with LBW/preterm pregnancies, even though this organism is one of the most common isolates from the amniotic fluid of women in preterm labor. Lower genital infection with

Chlamydia trachomatis has also not been consistently associated with adverse pregnancy outcome. However, women with active chlamydial infection and with a positive serum antichlamydial immunoglobulin M (IgM) have an increased risk of preterm delivery. Although a consistent association has not been observed between maternal group B streptococci (GBS) colonization and premature birth in several small studies, a large investigation of approximately 13,000 women showed that pregnant women with heavy GBS colonization had a small but significant increase in risk for LBW (odds ratio [OR] 1.2; 95% CI 1.01 to 1.50). There were no significant increases in other adverse outcomes, including preterm birth, among heavily colonized women. Women with light colonization were not at an increased risk for any adverse outcomes. There is increasing evidence of an association between *Trichomonas vaginalis* and premature birth. Although small, earlier studies had conflicting results, the large Vaginal Infections and Prematurity Study found that the presence of *T. vaginalis* in the vagina at midpregnancy was significantly associated with preterm LBW (7.1% of women with *T. vaginalis* vs. 4.5% without *T. vaginalis*; OR 1.6; 95% CI 1.3 to 1.9). The MFMU Network bacterial vaginosis/*T. vaginalis* trial showed an association between carriage of *T. vaginalis* and preterm birth. Considerable data have linked lower genital tract anaerobes with preterm labor. Further, bacterial vaginosis, in which there is a predominance of anaerobes, has been consistently associated with approximately a two- to threefold increase in spontaneous preterm delivery. Among other infections, untreated pyelonephritis has been associated with a risk of preterm delivery of approximately 30%, and asymptomatic bacteriuria is associated with a 60% higher rate of LBW (95% CI 1.4 to 1.9) and a 90% higher rate of preterm delivery (95% CI 1.3 to 2.9).

Fourth, positive cultures of the amniotic fluid/membranes/decidua are found in some patients in premature labor. The range of positive amniotic fluid cultures obtained by amniocentesis from asymptomatic women in premature labor is 3% to 24%. When more sensitive testing for detection of bacteria (polymerase chain reaction) is carried out in

amniotic fluid from women in preterm labor, bacteria are detected in 30% to 50%. The most likely route of upper genital tract infection in preterm labor is an ascending path through the vagina and cervix. Similarities in organisms isolated from the amniotic fluid and the lower genital tract support this pathogenic route. It is also possible that bacteria may enter the uterine cavity hematogenously through spread via the placenta, by contamination at the time of instrumentation such as during amniocentesis or chorionic villus sampling, or even by spread from the abdominal cavity via the fallopian tubes. Other sources of organisms for hematogenous spread include bacteremia from periodontal disease or procedures. Among women in spontaneous preterm labor with intact membranes, genital mycoplasmas, anaerobic organisms, and *Gardnerella vaginalis* (the so-called bacterial vaginosis organisms) are the organisms most commonly found in the amniotic fluid. Sexually transmitted organisms such as *Neisseria gonorrhoeae* and *C. trachomatis* are rarely found in the amniotic fluid, and GBS and *Escherichia coli* are found occasionally. Patients in preterm labor at early gestational ages have the highest likelihood of having a positive culture of the amniotic fluid. It may be speculated that intrauterine infection occurs early in pregnancy (or even has preceded the pregnancy) and may remain without clinical detection for months.

Fifth, biochemical “markers” of infection are often present among women in premature labor. In infection-induced premature labor, the primary site of infection is probably not the amniotic fluid but the decidua or membranes. More sensitive markers of infection potentially include amniotic fluid glucose concentrations, serum white blood cell counts, C-reactive protein, and amniotic or serum cytokines. Unfortunately, relatively few are clinically useful. Among patients in preterm labor, a low amniotic fluid glucose (<14 mg/dL) correlates well with the likelihood of a positive culture. Among the cytokines, an elevated amniotic fluid IL-6 level is probably the most sensitive marker for infection but is not yet widely available for clinical use.

Sixth, bacteria or their products induce preterm birth in animal models. Animal models have provided direct evidence that infection triggers preterm birth in the rabbit, monkey, and mouse.

The evidence linking infection to preterm birth has led to many trials of antibiotic therapy to prevent preterm birth. Antibiotic treatment trials may be classified as one of four designs:

- Those conducted prenatally in patients at high risk for preterm delivery
- Those directed toward a specific organism or condition
- Those conducted in women in preterm labor with intact membranes, as adjuncts to tocolytic therapy
- Those conducted in women with PPROM.

Chapter 12 discusses antibiotics in PPROM. Table 11.2 summarizes current practices for use of antibiotics to prevent preterm birth. The discordant results in antibiotic trials raise the question as to why antibiotics have not consistently prevented preterm birth or neonatal morbidity associated with preterm birth. One explanation is that infection is simply not a

significant cause of preterm labor, but this seems unlikely in view of all the other evidence. Another explanation is that studies have had too low a power. However, large meta-analyses, the MFMU Network trials, and the ORACLE trial appear to exclude this possibility. Further, because preterm labor has multiple causes, a true effect of antibiotics may be diluted by those cases of preterm labor not caused by infection. It may also be that only a subset of pregnant women (e.g., perhaps genetically predisposed women) with high cytokine response are at risk for preterm labor after subclinical infection. Another explanation is that the antibiotics studied in most

of the trials were simply the wrong ones (e.g., not including antibiotics with better anaerobic activity), the antibiotics were given too late, or the antibiotic dose or timing were incorrect. Because infection is more likely to cause very early preterm birth (<32 weeks), trials focusing on women at later gestational ages may not show an effect. For example, the ORACLE I trial enrolled women up to 37 weeks gestation, and only 10% delivered at less than 32 weeks. It has also been speculated that bacterial lysis as a result of antibiotic therapy may lead to increased exposure to lipopolysaccharide and thus enhance preterm labor. Finally, it is possible that changes in the vaginal flora during pregnancy are responsible for preterm labor. Early screening and treatment may not identify women who are at risk. Antibiotic therapy may actually increase the risk of preterm birth by changing the vaginal flora. The MFMU bacterial vaginosis/*T. vaginalis* trial found that women with *T. vaginalis* who were treated with metronidazole were more likely to deliver preterm than those treated with placebo. The PREMET trial also found that women with a positive fetal fibronectin were more likely to deliver preterm if they were treated with metronidazole than placebo. It is possible that metronidazole therapy changes the vaginal flora in women who do not have bacterial vaginosis in such a way as to increase the risk of preterm birth.

TABLE 11.2 Use of Antibiotics to Prevent Preterm Birth in Women with Preterm Labor and Premature Rupture of the Membranes

Use of antibiotics in preterm labor with intact membranes to prevent PTB:

- GBS prophylaxis is indicated.
- Do not give antibiotics routinely to prevent PTB.

Use of antibiotics with PROM to prevent PTB:

- GBS prophylaxis is indicated.
- At 24 to 32 wk, antibiotic regimens are an option. Ampicillin plus erythromycin for 7 d or erythromycin alone for 10 d

decreases preterm birth and delayed delivery and decreases perinatal complications.

PTB, preterm birth; GBS, group B streptococci; PROM, premature rupture of the membranes.

Epidemiology of Preterm Labor

In 2004, 12.5% of women in the United States delivered preterm. The vast majority of preterm deliveries are a result of preterm labor (50%), premature rupture of the membranes (PROM) (33%), or cervical incompetence. The contributions of preterm labor and PROM to preterm deliveries vary depending on a number of factors, including socioeconomic status (Fig. 11.2). In a large study from North Carolina, Meis and colleagues found that PPROM (34%) was the most common reason for delivery of less than 2,500 g infants in women who were receiving public assistance. In contrast, in women who had private insurance, the most common reason for early delivery was preterm labor (52%). Indicated preterm deliveries accounted for 14% and 18% of preterm deliveries, respectively.

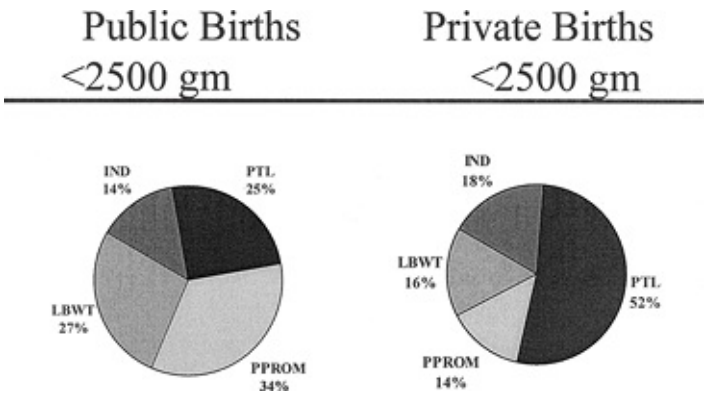

Figure 11.2 Causes of LBW births in public and private patients. (IND, indicated by maternal–fetal condition; PTL, preterm labor; LBWT, low birth weight PPROM, preterm premature rupture of the membranes.) (Meis P, Ernest J, Moore M. Causes of low birth weight births in public and private patients. *Am J Obstet Gynecol* 1987;156:1165–1168, with permission.)

Several major and minor risk factors are associated with development of preterm labor and PROM (Tables 11.3, 11.4). One of the most obvious and important risk factors for prematurity is a prior history of preterm delivery. To better quantify this relationship, Mercer and associates performed a subgroup analysis of data collected during a large population-based observational study evaluating risk factors for preterm delivery. In this study, gravid women with any prior spontaneous preterm birth had a 2.5-fold increased risk of spontaneous preterm delivery in the current pregnancy. This risk increased to 10.6-fold if

the spontaneous preterm birth occurred prior to 28 weeks gestation. Interestingly, women with a history of loss between 13 and 22 weeks gestation had rates of prematurity that were similar to women who did not have this history (10.1% vs. 8.8%; P =.69).

Another major risk factor for preterm labor and birth is multiple gestation. The rate of multiple gestations has increased dramatically over the past 15 years. The increase in twins and higher-order multiples is largely a reflection of

increased use of ovulation induction and assisted reproductive technologies. Fifty percent of twins deliver prematurely, with a mean gestational age at delivery of approximately 35 weeks. As expected, the percent of preterm deliveries increases in proportion to the number of fetuses. Triplets and quadruplets deliver on average at 32 weeks and 30 weeks, respectively. Until researchers develop techniques to perform artificial reproductive technologies that minimize the risk of having high-order multiples, then these women will continue to be at significant risk for delivering prematurely and suffering the consequences of preterm birth.

TABLE 11.3 Major Preterm Labor Risk Factors

	Relative Risk
Prior preterm birth	6–8×
Multiple gestations	6–8×
African American race	3.3×
Low socioeconomic status	1.9–2.6×

TABLE 11.4 Minor Preterm Labor Risk Factors

Modifiable Risks	Nonmodifiable Risks
Poor maternal weight gain	Extremes of age (<17 or >40)

Physically demanding work	Prior multiple abortions
Smoking	History of DES exposure
Anemia	History of uterine abnormality
Bacteriuria	Short stature
Bacterial vaginosis	Low prepregnancy weight
Maternal systemic infections: pyelonephritis	

DES, diethylstilberol.

Blacks are 1.6 to 2.5 times more likely to deliver prematurely than white women of similar age and socioeconomic status. Although blacks have higher rates of prematurity, the rates of neonatal morbidity are lower in black neonates when compared with whites born at similar gestational ages. This suggests that the gestational period may be shorter in black women. Low socioeconomic status is also strongly associated with prematurity. It is not clear whether this is related to environment, genetic predisposition, infection, or access to medical care.

Table 11.4 also lists a number of “minor” risk factors for preterm labor and delivery. Several of these will be discussed in more detail later in this chapter. In general, the minor risk factors can be broken into two categories: those that are potentially modifiable and those that are not. Many of the minor risk factors are common in pregnancy. Individually, their contribution to prematurity is small; however, the risk is compounded by the addition of other risk factors. The impact of work on preterm birth remains controversial. Prolonged, physically demanding work does appear to independently increase the risk of prematurity and is potentially modifiable.

Prediction of Women at Risk for Preterm Labor

Over the past 2 decades, many researchers have focused on identification of women who are at risk for preterm delivery. Theoretically, identification of asymptomatic women at risk for preterm delivery would allow obstetricians to effectively intervene to prevent preterm delivery or to decrease neonatal morbidity and mortality in preterm neonates. In an American College of Obstetricians and Gynecologists (ACOG) Practice Bulletin titled *Assessment of Risk Factors for Preterm Birth*, the authors wrote “the ability to predict

whether a women is at risk of preterm delivery has value only if an intervention is available that is likely to improve the outcome." It is believed that identification of women at risk for preterm birth will be beneficial if it allows women to:

- receive a complete course of antenatal corticosteroids prior to delivery
- if necessary, receive tocolytic agents to maximize the probability that antenatal corticosteroids will be given
- be transported to a level III perinatal center.

Another potential benefit of screening is to identify women at low risk for preterm delivery and thereby avoid administration of potentially dangerous medications or therapies to these women.

Table 11.5 is a review of "ideal" criteria for a screening test. An ideal screening test should have high sensitivity and positive predictive value as well as high specificity and high negative predictive value. Most screening tests do not meet these requirements and trade off sensitivity for specificity. Depending on the clinical scenario where screening tests are used and the consequences of treatment or no treatment, one must decide which test characteristic to stress. For example, one could argue that given the high morbidity associated with preterm birth, the ideal screening test should have a high sensitivity to allow treatment of the majority of women "at risk" and accept a lower specificity rate. On the other hand, one could argue, as the ACOG did, that avoidance of treatment with potentially hazardous drugs is beneficial in women with symptoms who are at "low risk" for delivery, thus stressing the importance of the test's specificity and negative predictive value. The following will review available screening tests.

TABLE 11.5 Criteria for Screening Tests

- Ascertainment of early, asymptomatic disease
- Early treatment alters health outcomes
- Disease is important, prevalent
- Screening acceptable to population
- Diagnosis/treatment readily available
- Screening test: simple, reliable, valid
- Cost proportional to benefit

Risk Scoring Systems

Risk scoring systems were promoted heavily in the 1980s to identify women at risk for preterm delivery. The risk scoring systems weigh major and minor risk factors for preterm

birth as well as current pregnancy complications (Tables 11.3, 11.4). The scoring systems work best in multiparous patients and worst in privately insured nulliparas with singleton gestations. Overall, the sensitivity of the screening tool ranges from 3% to 30% and the positive predictive values from 0% to 20%, depending on the population studied. While easy to use to identify women who may have modifiable risk factors for preterm delivery, the scoring systems do not reliably identify women at risk. They should not be used alone to institute interventions that may or may not be warranted.

Contraction Monitoring

Contraction monitoring has also been advocated to identify women at risk for preterm birth. Main and associates, in an inner-city clinic in Philadelphia, had low-risk women between 28 and 32 weeks' gestation wear tocometers while waiting in the clinic to be seen. Women with six or more uterine contractions per hour were more likely to deliver prematurely than women who did not. Using this cutoff, the sensitivity was 75% and the specificity was 79%. As technology became more advanced, this concept was developed further and home uterine activity monitoring (HUAM) became possible. HUAM, as initially promoted, was a combination of telemetric recording of uterine activity and daily contact with perinatal nurses trained to identify signs and symptoms of early preterm labor. The following assumptions were used to establish a role for HUAM:

- Women with preterm uterine activity are more likely to deliver prematurely than women who deliver at term.
- Women at risk for preterm labor may be unaware of their contractions, thus they present too faralong in established labor for treatment to be effective.
- Effective treatment for preterm labor is available.

At least 13 randomized clinical trials have evaluated the role of HUAM. These trials differ dramatically depending on the inclusion and exclusion criteria, the use of adjunctive tocolytic agents, and the primary end points. Despite being “randomized clinical trials,” many of the reports were so severely flawed that they were not included into several meta-analyses on the subject. After review of all of the evidence, both the ACOG (HUAM: not recommended) and the U.S. Preventive Services (HUAM: devise not effective) discouraged the use of this expensive and unproven therapy. Additional research may be warranted in specific at-risk subgroups.

Screening for Bacterial Vaginosis

Bacterial vaginosis is a common alteration of normal vaginal flora affecting 10% to 25% of normal women. The majority of infections are asymptomatic. The presence of bacterial vaginosis has been clearly associated with preterm births in both prospective cohort studies and case-control studies. As a result, investigators and clinicians have attempted to eradicate bacterial vaginosis in an effort to reduce the incidence of preterm delivery. The largest randomized controlled trial to date was conducted by the MFMU Network. In this double-blinded, randomized clinical trial, women with bacterial vaginosis were randomized to receive metronidazole 2 g orally for two consecutive days or placebo. Women were

rescreened and retreated, if indicated, at 24 to 29 weeks gestation, according to the original treatment assignment. Figure 11.3 summarizes the principal findings of the trial. Overall, there was no reduction in preterm deliveries. This result was confirmed in women who had prior preterm delivery. In one recent meta-analysis that included 15 trials of treatment for bacterial vaginosis, the authors concluded that treatment of bacterial vaginosis with clindamycin or metronidazole did not reduce the risk of preterm birth or PPROM. In a statement by the ACOG, the organization does not endorse routine, universal screening for bacterial vaginosis. However, another analysis in women with prior preterm delivery found that treatment of bacterial vaginosis for 7 days or more with oral metronidazole decreased recurrent preterm birth. This area remains controversial (Table 11.1).

Fetal Fibronectin

Fetal fibronectin has been widely promoted as a tool to identify women at risk for preterm delivery. Fetal

fibronectin, a basement membrane protein, is a normal constituent of the extracellular matrix of the maternal–fetal interface. It is present in normal human pregnancies prior to 20 weeks gestation and near term. Its presence between 20 and 34 weeks gestation strongly has been associated with preterm birth, but more important, its absence has been associated with low risk of preterm delivery.

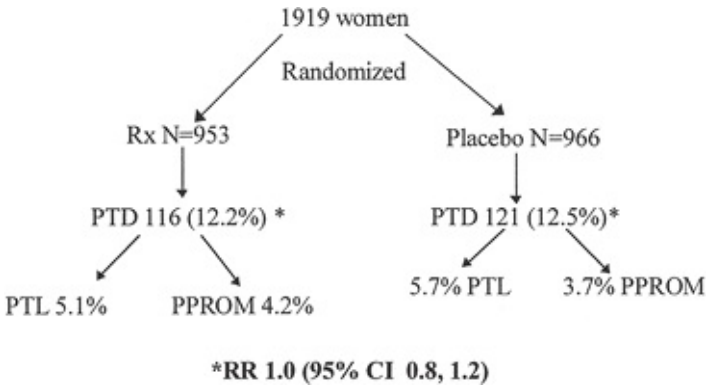

Figure 11.3 Metronidazole to prevent preterm delivery in pregnant women with asymptomatic bacterial vaginosis. (Rx, prescription; PTD, preterm delivery; PTL, preterm labor; PPROM, preterm premature rupture of the membranes; RR, relative risk; CI, confidence interval.) (Carey J, Klebanoff M, Hauth J, et al. Metronidazole to prevent preterm delivery in pregnant women with asymptomatic bacterial vaginosis. National Institute of Child Health and Human Development Network of Maternal-Fetal Medicine Units. *N Engl J Med* 2000;8:534–540, with permission.)

Leitich and coworkers performed a comprehensive meta-analysis on the efficacy of fetal fibronectin in identifying women at risk for preterm delivery. They included 27 articles

using fetal fibronectin in a variety of settings. Similar to other investigators, they noted that the test's usefulness was a result of its high specificity and was limited by the low sensitivity in identifying women who would go on to deliver prior to 34 weeks gestation. The sensitivity of the test decreased further in identifying women who would deliver prior to 37 weeks but increased when it was used serially.

In order to maximize fetal fibronectin, its use should be restricted to women with intact membranes, cervical dilation less than 3 cm, and gestational age between 24 and 34 completed weeks gestation, and results should be available within 24 hours. False-positive fetal fibronectins may be obtained in women with recent intercourse or vaginal examinations or in the presence of bacterial vaginosis and vaginal bleeding.

In general, the sensitivity of fetal fibronectin increases in symptomatic women, women with a cervical length of less than 2.5 mm, women with a history of prior preterm delivery, and women with bacterial vaginosis. The negative predictive value in women with preterm contractions ranges from 69% to 92% before 37 weeks gestation. Importantly, a negative fetal fibronectin has a 95% likelihood that delivery will not occur within 14 days of sampling.

Will fetal fibronectin change management and improve outcomes? Fetal fibronectin results have been shown to alter clinical management in certain settings and may be cost-effective. Physicians may use the test to determine who will receive tocolytic therapy and antenatal corticosteroids as well as who is appropriate for a maternal transport. Clearly, this test has potential, yet further work is required to determine what interventions are appropriate and whether the test improves outcomes. An ACOG summary states that “fetal fibronectin may be useful in determining women at high risk for preterm labor. However, their clinical usefulness may rest primarily with their negative predictive value given the lack of proven treatment options to prevent preterm birth.”

Cervical Evaluation

It long has been noted that premature dilation or effacement of the maternal cervix is associated with preterm birth. There has been a great deal of research interest in precisely measuring the uterine cervix with ultrasound to identify women at risk for preterm birth. Several techniques for measuring the cervix have been advocated. In general, it is believed that vaginal measurements are superior to abdominal measurements. Furthermore, several measurements should be obtained and averaged given the variability in cervical lengths for a given individual at a single monitoring session. In order to improve inter-interpreter variability, individuals who are performing the ultrasound should undergo formal training and participate in continuing quality assurance.

Several large prospective cohort studies have been performed that have been useful in establishing cervical nomograms for low-risk and high-risk women. In general, as the cervix becomes progressively shorter or dilates, the risk of preterm delivery increases. Cervical length is also correlated with gestational age (i.e., as gestation advances, the cervix matures and shortens). Different cutoff values have been tested. The sensitivity and positive predictive value depend on the prevalence of preterm birth in the population and the gestational age at testing and delivery. A cervical length of <30 mm or a dilation of the

internal cervical os will identify 80% to 100% of women or 70% to 100% of women who will subsequently have a preterm delivery.

The proponents of cervical ultrasound evaluation stress the benefit in obtaining more precise measurements with vaginal ultrasound than digital evaluation and the improved ability to detect subtle changes. Furthermore, vaginal ultrasound allows one to avoid vaginal examinations. To date, only two published randomized clinical trials have evaluated the use of cervical cerclage in women with premature shortening of the cervix with no evidence of preterm labor. In the first, the Cervical Incompetence Prevention Randomized Cerclage Trial (CIPRACT), women with the following histories were approached:

- A history consistent with cervical incompetence
- PPROM prior to 32 weeks gestation
- History of cold-knife conization
- Diethylstilbestrol exposure
- Uterine anomaly.

Consenting women who met the inclusion criteria and who had a cervical length less than 2.5 cm prior to 27 weeks were randomized to receive a McDonald cerclage and bed rest or bed rest alone. Placement of a cervical cerclage resulted in a significant decrease in preterm delivery prior to 34 weeks gestation (0 of 19 in the cerclage group vs. 7 of 16 in the expectant management group; P = .002). The decrease in preterm delivery prior to 34 weeks gestation also was associated with a decrease in composite adverse neonatal outcome (1 of 19 vs. 8 of 16; P = .005). In contrast, Rust and colleagues randomized women with a shortened cervix detected on routine ultrasound evaluation between 16 and 24 weeks gestation were randomized to receive a cerclage (n = 31) or expectant management (n = 30). The groups were well balanced at randomization for potential confounders. Overall, there was no difference in gestational

---

age at delivery (33.5 ±6.3 weeks in the cerclage group vs. 34.7 ±4.7 weeks in the expectant management group; P = .4) or the perinatal death rate (12.9% in the cerclage group vs. 10.0% in the expectant management group; P = .9).

At this time, there does not appear to be sufficient evidence to recommend routine ultrasound screening of the uterine cervix, as no treatment has been definitively established that will improve neonatal outcome.

Summary of Screening Tests Used to Identify Women at Risk for Preterm Labor

Several screening tests are available to identify women at risk for preterm delivery. All fail to meet the goals of an “ideal screening test,” since no therapy has been proven to be effective in preventing preterm labor and delivery. As a result, these tests should be considered experimental and used as part of randomized clinical trials with sufficient

power to evaluate treatments for prevention of preterm birth.

Preterm Labor Defined

Preterm labor is defined as labor occurring prior to 37 weeks gestation. Clinically, it is difficult to distinguish women with true preterm labor from women who are experiencing preterm uterine contractions. In order to improve the accuracy of the diagnosis, Creasy has proposed using the following criteria: uterine contractions (>4 contractions per 20 minutes) and cervical dilation (≥2 cm in a nullipara and ≥3 cm in a multipara) and cervical effacement (>80%) or uterine contractions and cervical change. Cervical change is the most well-accepted clinical criteria, yet it is the criteria most vulnerable to bias. For example, what constitutes minimal cervical change and over what time period does cervical change need to occur to be acute and warrant intervention? While this definition is more stringent than that proposed by the ACOG and others, over 50% of women who fulfill Creasy's criteria will deliver at term with or without treatment. An alternate approach is to await cervical change during a prescribed period of observation. Utter and colleagues defined *minimal cervical change* as dilation of the cervix by at least 1 cm and effacement of at least 1 cm in women less than 3 cm dilated on admission. Is it appropriate to wait for cervical change, and will waiting until labor becomes more established affect treatment success? In a retrospective case-control study, Utter and associates compared the outcomes of pregnancies in women treated with ritodrine on admission who had uterine contractions and “minimal” cervical change with women who were observed and treated only when cervical change as defined above was determined. There were no differences in any maternal or neonatal outcomes, including the number of days to delivery and “success” rates with tocolysis. Similarly, Guinn and colleagues randomized women with uterine contractions who were >2 cm to one of three therapies: observation alone, subcutaneous terbutaline, or intravenous hydration. Overall, there were no differences in any outcome measures between groups. Approximately 15% of women assigned to each of the groups went on to make cervical change during observation and were treated with parenteral tocolysis. In all cases, parenteral tocolysis was successful in delaying delivery for a minimum of 48 hours to allow treatment with antenatal corticosteroids. This approach avoided administration of tocolytic agents to 85% of women with no increase in morbidity or preterm delivery rates. An alternative strategy to awaiting cervical change is to use the rapid fetal fibronectin test and treat only women with a positive test. However, this strategy remains under investigation.

Treatment of Preterm Labor

Once the diagnosis of preterm labor is made, what treatments are available and do they work? Several agents have been used as tocolytic agents to suppress uterine activity in hopes that prolongation of pregnancy would improve neonatal outcomes (Table 11.6). The vast majority of placebo-controlled clinical trials were published during the 1970s and 1980s. Most of the placebo-controlled trials were small, and the concurrent use of antenatal corticosteroids was low. Overall, women who received any tocolytic agent had a mean time to delivery of approximately 48 hours. Therefore, it is not surprising that tocolytic therapy has not been associated with improvements in neonatal outcomes.

Despite this finding, tocolytic agents are widely prescribed throughout the world. The justification for the continued use of unproven drugs is the supposition that had the drugs been administered along with antenatal corticosteroids, the 48 hours gained in utero would be beneficial to the neonate and result in improved outcomes. This theory remains untested. However, given the current "standard of care" in the United States, it is unlikely that placebo-controlled trials will be performed to confirm the need to administer tocolytic agents in addition to antenatal corticosteroids. The individual agents that are commonly used throughout the world will be reviewed subsequently. The absolute and relative contraindications to administering tocolytic therapy are listed in Tables 11.7 and 11.8.

TABLE 11.6 Overview of Tocolytic Agents

- Severe bleeding, any cause
- Frank chorioamnionitis
- Fetal death
- Fetal anomaly incompatible with life
- Severe fetal growth restriction
- Mature lung studies
- Maternal cardiac arrhythmias

β-Adrenergic Agonists

ß-Mimetics are the most widely prescribed and best-studied tocolytic agents. The two most commonly used ß-mimetic agents in the United States are ritodrine and terbutaline. There are a number of treatment protocols for both ritodrine and terbutaline. In the acute setting, the medications can be administered intravenously (ritodrine and terbutaline) or subcutaneously (terbutaline). The dose is increased until uterine quiescence is achieved or maternal side effects develop that prevent the provider from increasing the dose further. Development of tachyphylaxis occurs rapidly. As a result, it is common to need to increase the dose of the medication to maintain an acontractile state once steady state levels are achieved.

The maternal side-effect profile with ß-agonists is of particular concern. None of the ß-agonists used for tocolysis are completely ß-2 selective. Therefore, mothers can experience side effects from both ß-2– and ß-1–sensitive tissues. The negative ß–2 effects include maternal hypotension, decreased urinary output, increased glucose secretion, hypokalemia, and pulmonary edema. The negative ß-1 effects include tachycardia, palpitations, constipation, decreased gastric emptying, hypokalemia (decrease 0.6 to 1.5 mEq below pretreatment levels), agitation, and jitteriness. The most severe maternal adverse effects include cardiac arrhythmias, myocardial infarction, pulmonary edema, postpartum cardiomyopathy, and death. These risks can be minimized by judicious use of fluids, close monitoring of intake and output, and avoidance of other tocolytic agents.

TABLE 11.8 Relative Contraindications to Tocolytic Therapy

- Mild chronic hypertension
- Mild abruptio
- Stable previa
- Maternal cardiac disease
- Hyperthyroidism
- Uncontrolled diabetes mellitus
- Fetal distress
- Fetal anomaly
- Mild intrauterine growth restriction
- Cervix greater than 4 cm dilated

ß-Mimetics rapidly cross the placenta. The fetal response is similar to the adult. Cardiovascular effects include tachycardia, increased cardiac output and redistribution of blood flow, increased thickness of the intraventricular septum, neonatal supraventricular tachycardia, myocardial ischemia, myocardial necrosis, hydrops, and hypoglycemia. Long-term follow-up studies demonstrated no overall difference in children exposed to ß-mimetics versus control groups that received placebo. However, evidence suggests that ß-mimetics may increase the incidence of intraventricular hemorrhage in preterm neonates.

This finding has been noted in a couple of case-control studies performed in large neonatal databases. This finding was not previously noted in the randomized placebo-controlled trials of ß-mimetics. Further studies are necessary to evaluate this potential adverse effect of ß-mimetics.

Are ß-mimetics efficacious? The largest placebo-controlled trial of ß-mimetics was performed in Canada and published in 1992. In this trial, 708 women with preterm labor, with or without ruptured membranes, were randomized to receive ritodrine or placebo infusions. Treatment with ritodrine did not reduce perinatal mortality or morbidity, prolong pregnancy, decrease the percent of preterm deliveries, or increase the percentage of women who completed a course of antenatal corticosteroids. The findings of this individual trial are consistent with a previously published meta-analysis of ß-mimetics when used as tocolytic agents. The Canadian study has been widely criticized for including women with PPROM. Tocolytics and antenatal corticosteroids do not appear to be as efficacious in the setting of PPROM, thus potentially diluting any positive effect of ritodrine.

At this time, advocates for the use of ß-mimetics believe that the benefit-to-risk ratio is favorable and that prolonging pregnancy may increase the proportion of women who complete a course of antenatal corticosteroids prior to delivery. As newer agents with less potential for maternal and fetal adverse effects become available, the use of ß-mimetics will continue to decrease in the acute setting.

Magnesium Sulfate

In recent years, magnesium sulfate has become the tocolytic of choice in many labor and delivery units. The use of magnesium sulfate as a tocolytic was adopted despite the absence of data of its effectiveness and safety in well-designed, placebo-controlled trials. Several randomized trials have shown that magnesium sulfate is no more effective than placebo as a tocolytic, and a meta-analysis concluded that “magnesium sulphate is ineffective at delaying birth or preventing preterm birth, and its use is associated with an increased mortality for the infant.”

Magnesium sulfate is the most widely prescribed tocolytic agent used in the United States. For acute tocolysis, magnesium sulfate is administered intravenously. A number of protocols for loading the patient and maintenance dosing exist. In general, the magnesium “bolus” is administered in doses that range from 4 to 8 g over a period of 20 minutes to 1 hour. Next, a maintenance infusion (2 to 4 g per hour) is started and adjusted until uterine contraction frequency decreases to less than four contractions per hour and no further cervical change is occurring. The infusion is stopped after the patient remains acontractile for 12 to 24 hours. In certain clinical situations (advanced dilation at early gestational ages, women who continue to contract despite high doses of magnesium sulfate, etc.), it may be warranted to continue the infusion for 48 hours to allow for administration of a full course of antenatal corticosteroids.

Magnesium sulfate primarily is cleared by the kidneys and rapidly is excreted in the pregnant woman with normal renal function. It generally is accepted that blood levels of 6 to 8 mg/dL of magnesium sulfate are optimal for tocolysis. However, there is a great deal

of variation in the biologic response to this agent, including the level that is required to achieve uterine quiescence and the level associated with toxicity. For example, in one study, investigators used a case-control study design and compared women who did and did not respond to magnesium sulfate tocolysis. Overall, there were no significant differences in serum levels of magnesium sulfate in the women who did and did not respond to tocolysis. This finding is similar to that of a randomized controlled trial comparing a high-dose magnesium protocol (8-g load, then 2 to 4 g per hour) to a low-dose magnesium protocol (4-g load, then 2 to 4 g per hour). The high-dose protocol did achieve tocolysis more rapidly than the low-dose protocol. However, there was a corresponding increase in maternal side effects with the high-dose protocol. Overall, there was no difference between the protocols with respect to prolongation of pregnancy or a reduction in neonatal morbidity. Finally, many physicians believe that it is necessary to wean patients from magnesium sulfate tocolysis. This practice was evaluated in a randomized trial comparing a weaning protocol with immediate withdrawal of magnesium sulfate. Not surprisingly, weaning prolonged labor and delivery stays by approximately 8 hours. Overall, there was no difference in time gained in utero or differences in neonatal outcomes between the two groups. Women who were weaned had significantly higher rates of recurrent labor in the current admission and in the future.

Maternal side effects are common with magnesium sulfate and are presented in Table 11.9. As blood levels of magnesium increase, so does the potential for severe toxicity. Maternal deaths have occurred with magnesium sulfate as a result of respiratory depression and cardiac arrest. In general, these events should be preventable by following the patient's clinical status carefully. This monitoring should include hourly assessments of intake and output, the level of deep tendon reflexes, and oxygen saturation using a pulse oximeter. Careful labeling of all medications as well as strict adherence to concentration should reduce the likelihood of an inadvertent bolus of large amounts of magnesium sulfate. In cases of extreme magnesium toxicity, administration of calcium gluconate may be useful to try and reverse the effects of magnesium sulfate.

TABLE 11.9 Maternal Side Effects Related to Magnesium Sulfate

Common
Flushing
Sense of warmth
Headache
Nystagmus
Nausea
Dizziness
Lethargy
Serious

Pulmonary edema
Neuromuscular blockage
Osteopenia

Magnesium sulfate also has significant fetal and neonatal effects. Magnesium sulfate crosses the placenta and accumulates in the fetus. As a result, it can affect fetal biophysical parameters (primarily fetal breathing activity) and decrease fetal heart rate variability. Neonates born with cord levels of magnesium sulfate greater than 4 mg per 100 mL may show signs of depression, including decreased muscle tone, drowsiness, poor respiratory effort, and low Apgar scores. A case of neonatal osteoporosis with associated fractures has been reported in a woman undergoing long-term tocolysis with magnesium sulfate.

Controversy exists over the long-term effects of magnesium sulfate. A number of cohort and case-control studies have suggested that magnesium sulfate exposure at birth may reduce rates of cerebral palsy in preterm infants. The MagNet trial was the first trial published that formally evaluated this hypothesis. This trial randomized women with preterm labor and intact membranes to receive magnesium sulfate or other tocolytics if ≤4 cm dilated on admission or magnesium sulfate or placebo if more than 4 cm dilated. The trial was stopped at the first planned interim analysis because there were seven pediatric deaths (n = 46) in the magnesium arm compared with no pediatric deaths (n = 47) in the tocolytic/placebo arm (OR 15.2; 95% CI 4.8 to 25.6). The groups were well balanced at randomization for potential confounders. Thus, there was no obvious explanation for the excess deaths in the magnesium arms of the trial other than magnesium sulfate exposure. In a recent opinion by Grimes and Nanda, the place of magnesium sulfate as an effective tocolytic has been seriously questioned. The University of Colorado recently

has moved away from magnesium sulfate as a first-line tocolytic.

Calcium Channel Blockers

Calcium channel blockers or calcium antagonists are nonspecific smooth muscle relaxants. They prevent the influx of extracellular calcium ions into the myometrial cell. The effects are not specific to the uterus.

Nifedipine has been used as a tocolytic agent. Numerous protocols for nifedipine exist. In general, 10 mg nifedipine is administered orally. If contractions persist, the dose can be repeated every 20 minutes for a total of 30 mg in 1 hour. Maternal hypotension is relatively common. If hypotension develops, additional doses of nifedipine must be held. Once contractions decrease, the patient may receive 10 mg every 6 hours of nifedipine orally or receive 30 to 60 mg of the sustained-release nifedipine per day. Nicardipine, a potent uterine relaxant, may be administered as a 40-mg loading dose followed in 2 hours by a 20-mg dose to a maximum dose of 80 mg if uterine contractions do not abate. This can be followed by sustained-release nicardipine 45 mg every 12 hours.

Calcium channel blockers produce vasodilation and decrease peripheral vascular

resistance. Maternal hypotension defined as either a 25% decrease in mean arterial pressure or symptomatic hypotension is relatively common. Many patients experience transient facial flushing or develop nausea and headache. Maternal side effects appear to be less common than in women treated with the ß-sympathomimetics, but severe complications have been reported. For example, there has been a case of maternal myocardial infarction associated with high-dose nifedipine therapy following ritodrine treatment in women in preterm labor. The authors have had a similar case using a low dose of nifedipine following magnesium sulfate tocolysis. Nifedipine potentiates the toxicity of magnesium sulfate by causing neuromuscular blockade. There have been reports of profound hypotension, neuromuscular blockade, and maternal death resulting from the combination of magnesium sulfate therapy and calcium channel blockers. This complication may not be as frequent as initially believed. However, there are no protocols that establish the safety of using these medications together. Therefore, they should not be used concurrently.

In general, calcium channel blockers appear to be well tolerated by the fetus and neonate. There has been one case of neonatal heart block associated with their use. Concerns remain that calcium channel blockers may have adverse effects on the fetal and placental circulation resulting in growth restriction, acidosis, and stillbirth.

No randomized trial has been published that compares calcium channel blockers with placebo for tocolysis. Several meta-analyses have been conducted comparing nifedipine with other tocolytics. A Cochrane review found that calcium channel blockers (mainly nifedipine) were superior to ß-mimetics (mainly ritodrine) as a tocolytic. A meta-analysis concluded that “Although calcium antagonists have not been evaluated against placebo, comparative trials with beta-agonists have shown more favorable neonatal outcomes and better prolongation of gestation…. There is no clear first-line tocolytic agent.”

Prostaglandin Synthetase Inhibitors

Prostaglandins are integrally involved in cervical ripening and labor. Therefore, it would make sense that inhibiting prostaglandin synthesis should prevent preterm labor and delivery. Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit cyclooxygenase, thus preventing the conversion of arachidonic acid to prostaglandin. The effects are not limited to the uterus. Indomethacin is the most widely studied prostaglandin synthetase inhibitor used for treatment of women in preterm labor.

The authors' protocol for indomethacin tocolysis involves the administration of a 100-mg loading dose given as a suppository per rectum. If regular uterine contractions persist 1 to 2 hours after the initial 100-mg suppository, an additional 50 to 100 mg may be given. Oral therapy is then instituted at 50 mg every 6 hours for 48 hours while betamethasone is dispensed. The absorption of indomethacin is excellent from both the rectal and oral routes. Therefore, if rectal suppositories are not available, the oral formulation can be effectively substituted. Fetal echocardiography is not considered necessary when administering indomethacin as outlined above. Fetal contraindications to the use of indomethacin include growth restriction, renal anomalies, chorioamnionitis, oligohydramnios, ductal dependent cardiac lesions, and twin–twin transfusion syndrome.

Indomethacin is very well tolerated in the gravida in comparison to other tocolytic agents. Serious maternal side effects are rare when the agent is used in a brief course of tocolysis. As with any NSAID, mild gastrointestinal upset may occur. More serious potential complications include gastrointestinal bleeding, alterations in coagulation, thrombocytopenia, and asthma in aspirin-sensitive patients.

Prolonged treatment can lead to renal injury, especially when nephrotoxic drugs such as aminoglycosides are employed. Drugs of this class are antipyretic agents and may obscure a clinically significant fever. Maternal contraindications to indomethacin include renal or hepatic disease, active peptic ulcer disease, poorly controlled hypertension, asthma, and coagulation disorders.

In contrast to the generally favorable maternal side-effect profile, the potential for fetal and neonatal complications of indomethacin tocolysis is worrisome. In actuality, serious complications are rare when limiting treatment to short courses and adhering to established protocols.

The principal side effects of indomethacin tocolysis have been constriction of the ductus arteriosus, oligohydramnios, and neonatal pulmonary hypertension. The ductal

---

constriction occurs because formation of prostacyclin and prostaglandin E_2, which maintain ductal vasodilation, is inhibited by indomethacin. Moise and colleagues reported Doppler evidence of ductal constriction in 7 of 14 fetuses exposed to indomethacin between 27 and 31 weeks gestation. Tricuspid regurgitation occurred in three fetuses. All ductal abnormalities resolved within 24 hours of discontinuation of indomethacin, and none of the neonates had pulmonary hypertension. The Moise group later reported on the effect of advancing gestational age on ductal constriction in association with indomethacin and stated that “a dramatic increase in constriction was noted at 32 weeks gestation when the rate of compromise approached 50%.” However, ductal constriction was noted as early as 24 weeks and occurred in 11 of the 23 fetuses prior to 30 weeks. This was a retrospective analysis of echocardiograms performed on 44 patients with premature labor or hydramnios treated with indomethacin. Although never clearly stated, these patients appeared to be on courses of therapy for greater than 48 hours. Indomethacin was the “third-line agent” in premature labor unresponsive to terbutaline or magnesium sulfate.

Oligohydramnios associated with indomethacin tocolysis is common, dose-related, and reversible. The oligohydramnios is a consequence of reduced fetal urine production due in turn to reduction by indomethacin of the normal prostaglandin inhibition of antidiuretic hormone and by direct effects on the renal blood flow. Indomethacin can be an effective therapy for hydramnios, especially when complicated by preterm labor.

Primary pulmonary hypertension in the neonate is a serious condition that also has been reported with prolonged (more than 48 hours) indomethacin therapy. This complication has not been reported when therapy was restricted to 24 to 48 hours; however, the incidence may be as high as 5% to 10% with long-term therapy.

Necrotizing enterocolitis and intraventricular hemorrhage have been observed in the LBW neonate exposed to indomethacin in utero when it was used outside of standardized

protocols that did not limit the duration of treatment or was the second or third agent added to recalcitrant preterm labor. Since such patients have an increased risk of subclinical intra-amniotic infection, and since intra-amniotic infection is associated with a greater risk of such complications, it is not clear that indomethacin incurs independent risk for these morbidities. Subsequently, two larger studies have not confirmed this finding or demonstrated any association between indomethacin exposure and any adverse neonatal outcome. Follow-up studies of children treated in utero with indomethacin have not found significant long-term effects, although they did not specifically target the LBW neonate.

Indomethacin has been reported to be effective in two small randomized, placebo-controlled trials. The first found that indomethacin was superior to placebo in delaying delivery for 48 hours (80% vs. 33%). The second demonstrated a sustained delay in delivery for patients treated with indomethacin (95% at 48 hours and 83% at 7 days) compared with placebo (23% at 48 hours and 16% at 7 days). Additional prospective, randomized trials have found indomethacin to be comparable to ritodrine and magnesium sulfate and superior to nylidrin for tocolysis. There are additional reports that describe indomethacin tocolysis favorably, but many used other tocolytic agents simultaneously or sequentially.

Indomethacin appears to be an effective tocolytic agent that is well tolerated by the mother and appears to be tolerated by the fetus when used appropriately. Exposure should be limited to 48 consecutive hours to allow for administration of antenatal corticosteroids and should be restricted to gestational ages less than 32 weeks.

Other Tocolytic Agents

Several other tocolytic agents have been proposed for use. These include the oxytocin analogs, nitroglycerin, cyclooxygenase 2 (COX-2) inhibitors, ketorolac, progestins, and nitric-oxide inhibitors. The oxytocin analogs have been the most widely tested. Atosiban is an oxytocin receptor antagonist that has been shown to be more effective than placebo in quieting uterine contractions and comparable to ß-mimetics in prolonging gestation with fewer maternal side effects. A Cochrane review “failed to demonstrate the superiority of atosiban over beta-mimetics or placebo in terms of tocolytic efficacy or infant outcomes” and concluded that “compared with placebo, atosiban did not reduce incidence of preterm birth or improve neonatal outcome.” Atosiban was not approved as a tocolytic by the FDA.

Maintenance Tocolysis Following Arrest of Preterm Labor

If preterm labor is arrested, the patient remains at high risk for a recurrent episode of preterm labor and preterm birth. Maintenance tocolytic therapy may decrease chances for delivery in some cases. Several agents including ß-mimetics (ritodrine and terbutaline), magnesium sulfate, prostaglandin synthetase inhibitors, and the calcium channel blockers have been tested in randomized trials.

Efficacy of Oral Tocolysis with ß-Mimetics

The authors have been able to identify eight randomized placebo-controlled trials of oral ß-mimetic maintenance therapy to prevent recurrent preterm labor and preterm delivery.

A total of 915 patients were randomized in these eight trials. In six of the eight trials, there was no decrease in the preterm delivery rate or a prolongation of pregnancy with maintenance tocolytic therapy when compared with controls receiving no treatment. Seven of the eight trials

reported on the number of women treated for recurrent preterm labor. Overall, for women receiving a ß-mimetic, the rate of recurrent preterm labor was 32.5% (range, 2% to 59%) and for patients receiving placebo or no therapy 28.3% (range, 12.9% to 63%). Despite obvious differences in the trials, Sanchez-Ramos and colleagues combined these data by using meta-analysis (Table 11.10). When they restricted the analysis to trials comparing ß-mimetics to placebo or no therapy, there was no benefit of treatment for prevention of preterm birth (OR 1.08; 95% CI 0.82 to 1.43) or risk of recurrent preterm labor (OR 0.90; 95% CI 0.63 to 1.28). One could argue that it is not appropriate to combine trials when there is no consistency between the trials in inclusion criteria and definitions of preterm labor and recurrent preterm labor. Regardless, whether the trials are evaluated individually, cumulatively as a review, or by using meta-analysis, there does not appear to be any benefit of oral ß-mimetic tocolysis.

TABLE 11.10 Impact of Maintenance Tocolysis on Preterm Delivery

Study Interval	Preterm Birth Tocolysis (%)	Preterm Birth Placebo (%)	Odds Ratio	95% Confidence

[a]Pooled odds ratio.

Several potential explanations can be offered as to why oral ß-mimetic therapy appears to be ineffective. Oral administration of terbutaline results in inconstant drug levels, characterized by peaks and troughs. The need to take the drug every 2 to 4 hours throughout the day, including awakening at regular intervals throughout the night, may decrease compliance. Finally, long-term exposure to ß-mimetic agents results in desensitization of the ß-adrenergic receptors in the myometrium. Development of tolerance is related to both the duration of therapy and the total dose of ß-mimetics. As a result, the drugs may lose effectiveness over time.

Efficacy of Continuous Subcutaneous Administration of Terbutaline

Terbutaline may be administered by a continuous portable subcutaneous pump for maintenance therapy. Its theoretical advantages over oral maintenance therapy are continuous low-maintenance drug levels and the ability to bolus the drug if uterine contractions develop, thus preventing or decreasing the development of tolerance of the ß-receptors to the ß-agonist terbutaline.

A number of descriptive studies of terbutaline pump therapy for prevention of preterm birth have been published in peer-review journals. It was not until 1997 that the first randomized, placebo-controlled trial of the terbutaline pump was published. In this study, women with preterm labor were assigned to receive terbutaline pump therapy (n = 15),

placebo pump therapy (n = 12), or oral terbutaline (n = 15). If women developed recurrent preterm labor, the blind was broken and women receiving placebo were crossed over to terbutaline. Although conclusions were limited by the small number of patients in each group and the crossover design, there were no differences in the mean delay to delivery or in neonatal morbidity.

Despite very limited information regarding terbutaline pump therapy, its use has been widely promoted by several home health care corporations that target the majority of their services to the obstetric patient. Terbutaline pump therapy, whether used alone or in conjunction with HUAM programs, is extremely expensive, averaging over $200 per day, when compared to oral therapy or no therapy. As its use has increased, so have reports of complications related to therapy. As a result, the FDA issued an alert regarding the potential dangers associated with terbutaline pump therapy and the lack of data supporting the efficacy of this treatment.

Risks Associated with Oral or Subcutaneous β-Mimetic Therapy

Frequent unwanted effects of β-mimetic therapy include palpitations, tremor, nausea, vomiting, headache, thirst, nervousness, and restlessness. Complications of oral β-mimetics and the subcutaneous administration of

---

terbutaline include sudden death, pulmonary edema, cardiac arrhythmias, hepatitis, glucose intolerance, and gestational diabetes. There has also been one case of neonatal myocardial necrosis in a woman receiving high doses of subcutaneous terbutaline.

Summary of β-Mimetics for Maintenance Therapy

There is no compelling evidence from the randomized controlled trials to support the use of β-mimetics for maintenance therapy. Given the potential risks associated with β-mimetics, there is no justification for its continued use as a chronically administered therapy.

Other Maintenance Tocolytic Agents

Compared with β-mimetics, there have been relatively few trials exploring options for maintenance therapy. Magnesium sulfate has been administered on a chronic basis intravenously and orally. Long-term magnesium exposure can result in significant osteopenia, especially when used in conjunction with multiple doses of corticosteroids and bed rest. There have been reports of both mothers and neonates developing significant osteopenia following prolonged magnesium exposure. In the randomized trials that compare oral magnesium with placebo, no apparent benefits were noted in time to delivery or neonatal outcomes.

Long-term tocolysis with the prostaglandin synthetase inhibitors is contraindicated. The fetal risk is far in excess of any potential benefits. It is possible that more selective COX-2 inhibitors will be useful for maintenance therapy. Calcium channel blockers appear to be

gaining popularity to reduce recurrent preterm labor. Two trials have compared nifedipine with ß-sympathomimetic agents. These investigations were equivalent or superior to ß-mimetics for prolonging pregnancy, with lessened maternal side effects. Carr and colleagues published the only randomized trial of nifedipine compared with no therapy. They randomized 74 women to receive oral nifedipine (20 mg every 4 to 6 hours) or no treatment. The groups were well balanced at randomization for potential confounders. There were no differences in the time gained from initiation of therapy until delivery in the two groups (37 days nifedipine and 32 days no therapy) or gestational age at delivery (35.4 weeks nifedipine and 35.3 weeks no therapy). Oral nifedipine following successful tocolysis with magnesium sulfate did not improve pregnancy outcome. While this study did not report any significant complications of therapy, there has been a report of a myocardial infarction following treatment with nifedipine for maintenance tocolysis.

Conclusions Regarding Maintenance Tocolysis

At this time, there is no evidence that any of the available maintenance tocolytic agents are effective in prolonging gestation, reducing preterm births, or improving neonatal outcome. Each of the therapies has been associated with significant complications. Therefore, the authors cannot recommend that any of these agents be used outside of properly designed randomized trials.

Ancillary Therapy for Women in Preterm Labor

Several investigators have studied the impact of adjunctive antibiotic therapy in women with preterm labor and intact membranes. These studies have included women across the spectrum of gestational ages and cervical dilations and have used a variety of antibiotic regimens. This subject was reviewed by King and Flenady in the Cochrane Database. Beneficial effects of antibiotics included a significant prolongation of pregnancy (5.4 days), reduction in maternal infectious morbidity, and a trend toward reduction in neonatal sepsis. However, this was coupled with an increase in perinatal mortality (OR 3.36; 95% CI 1.21 to 9.32). The largest study published to date was ORACLE II. This study included women in preterm labor between 20 and 37 weeks gestation. In this trial, 6,295 women were enrolled, and data from 6,241 women was available for analysis. Overall, use of antibiotics was not associated with a reduction in neonatal morbidity or mortality or prolongation of pregnancy. The only exception was decreased use of postpartum antibiotic prescription in women who had received antibiotics. Based on the results of this trial and the Cochrane Database review, at this time, adjunctive antibiotic therapy for women in preterm labor (with intact membranes) is not indicated. GBS prophylaxis should be administered following the 2002 Centers for Disease Control and Prevention (CDC)/ACOG guidelines.

Hydration therapy, either oral or intravenously, is widely used as adjunctive therapy for women with preterm contractions and preterm labor. This practice was popularized during the 1980s when ß-mimetics were being widely prescribed. Prior to administration of ß-mimetics, women were hydrated to prevent hypotension. In many cases, as women were receiving their hydration therapy, their contractions reduced in frequency, thus obviating

the need for parenteral tocolysis. Guinn and associates published a randomized trial comparing two commonly used therapies for preterm contractions to observation only. Women were included who had cervical dilation less than 2 cm, effacement less than 80%, gestational age 24 to 33 completed weeks gestation, and regular uterine contractions. Women were randomly assigned to receive intravenous hydration, one dose of subcutaneous terbutaline (0.25 mg), or observation only. There were no differences between the groups with time gained in utero, the proportion of women who delivered preterm, or the proportion of women who developed cervical change and received parenteral treatment

---

with tocolytic agents. Intravenous hydration was associated with the highest hospital costs and charges and has the highest potential for adverse effects. Intravenous hydration should be reserved only for women who are obviously dehydrated.

Bed rest also has been widely prescribed for women in preterm labor. There is little if any data that suggests that bed rest is efficacious in women with threatened preterm labor or arrested preterm labor. There are significant costs associated with bed rest, including hospital days, lost wages, and lost domestic productivity. It should not be routinely prescribed to women at risk for preterm labor or delivery.

Two therapies are extremely beneficial to women with preterm labor. The first is antenatal corticosteroids. There have been 15 randomized, placebo-controlled trials that tested the efficacy of antenatal corticosteroids in women at risk for preterm birth. Exposure to a complete course of antenatal corticosteroids (betamethasone 12 mg i.m. q24h × 2 doses or dexamethasone 6 mg i.m. q12h × 4 doses) significantly improves neonatal outcomes, including a reduction in respiratory distress syndrome, intraventricular hemorrhage, and death. The data are so compelling that the ACOG and the NIH recommend that all women at risk for preterm birth prior to 34 weeks gestation receive antenatal corticosteroids. Repeat courses of antenatal corticosteroids are not recommended, as they may reduce respiratory morbidity while increasing the potential for intraventricular hemorrhage and chorioamnionitis. Long-term follow-up studies are under way that will help to define the long-term risks and benefits of repeat courses of antenatal corticosteroids.

The other therapy that appears to be highly efficacious in improving neonatal outcomes is the administration of GBS prophylaxis to women at risk for preterm birth. The attack rates for preterm neonates colonized with GBS are significantly higher than in term infants. As a result, prophylaxis has been demonstrated to be highly beneficial in preventing invasive GBS and its sequelae in preterm neonates.

Conclusions

Prevention of preterm birth remains an elusive goal. However, recent data support the use of progestational agents to prevent recurrent preterm birth. Despite widespread recognition and interest in the problem, the rate of preterm delivery is increasing in the United States. Clearly, continued research efforts are necessary to better elucidate the biology of parturition and abnormal parturition to allow us to develop more effective therapies. In the mean time, it is premature to incorporate screening tests to identify

women at risk for preterm labor outside of randomized treatment trials, as no treatment has been proven to prevent preterm delivery. In women with an acute episode of preterm labor, tocolysis can be administered with antenatal corticosteroids. All of the tocolytic agents are potentially dangerous and should be used with caution in a supervised setting. Currently, there is no data to support the use of maintenance tocolysis in women whose preterm labor is successfully arrested. All women in spontaneous preterm labor should receive a single course of antenatal corticosteroids and GBS prophylaxis following the 2002 CDC/ACOG guidelines.

Prolonged Pregnancy

A prolonged pregnancy, also commonly called *post-term pregnancy*, is one that has lasted longer than 42 weeks, or 294 days beyond the first day of the last menstrual period. Postdatism implies pregnancy lasting beyond the estimated due date at 40 weeks. The term *postmature* is reserved for the pathologic syndrome in which the fetus experiences placental insufficiency and resultant intrauterine growth restriction.

Postdatism occurs in 3% to 12% of all pregnancies. The definition of prolonged pregnancy is, however, somewhat arbitrary and was formulated before ultrasound dating of gestation became routine. Browne described perinatal mortality after 41 weeks as 10.5 per 1,000 pregnancies, doubling that at 43 weeks, and tripling that amount at 44 weeks.

Prolonged pregnancies are at risk for macrosomia resulting in shoulder dystocia and fetal injury, oligohydramnios, meconium aspiration, intrapartum fetal distress, and stillbirth. Maternal risks include trauma, hemorrhage, and labor abnormalities (Table 11.11). Interventions for preventing or improving outcomes in low-risk, prolonged pregnancies have proven to be of minimal benefit.

Etiology

The most common cause of an apparently prolonged pregnancy is inaccurate dating. Early ultrasound dating of pregnancies has been shown to reduce the number of women who are induced for apparently prolonged

pregnancies. One condition associated with prolonged pregnancy is placental sulfatase deficiency, an X-linked disorder that affects male fetuses. The sulfatase-deficient placenta is unable to use DHEA-S and other fetal adrenal precursors to synthesize estrogens. These pregnancies are associated with poor response to cervical ripening and induction as well as postdatism. Other postulated maternal risk factors for prolonged pregnancy include primiparity, previous prolonged pregnancy, and young maternal age.

TABLE 11.11 Complications of Prolonged Pregnancy

Fetal/Neonatal	Maternal

Shoulder dystocia	Trauma
Fetal injury	Hemorrhage
Oligohydramnios	Labor abnormalities
Meconium aspiration	—
Intrapartum fetal heart rate abnormalities	—
Stillbirth	—

Amniotic Fluid

Reduced amniotic fluid (i.e., oligohydramnios) is a frequent finding in prolonged pregnancies. It presents a problem because it can be a marker for fetal compromise and because it puts the fetus at risk for cord accidents. Commonly used ultrasound techniques to estimate the amount of amniotic fluid include the four-quadrant amniotic fluid index (AFI) and the largest vertical pocket.

Antenatal Testing

Any pregnancy at risk for uteroplacental insufficiency is a candidate for antenatal fetal monitoring. It is most likely that the morbidity and mortality associated with prolonged gestation is due to placental insufficiency. The goal of antenatal testing is to identify those fetuses that should be delivered. It is useful to remember that no form of antenatal testing will predict random unfortunate events such as sudden significant umbilical cord compression.

If a pregnancy is managed expectantly beyond 41 weeks, some form of antenatal testing should be initiated in otherwise healthy pregnancies. The frequency and type of antenatal testing is based mostly on physician preference and experience.

The contraction stress test (CST) was the first test used for antepartum fetal monitoring, whereas the nonstress test (NST) is the first-line screening test at many medical centers. It is quickly and easily performed in an outpatient setting. The NST is based on the knowledge that fetal hypoxia interrupts the pathway between the fetal heart and an intact central nervous system (CNS). The fetus with an intact CNS will have heart rate accelerations with movement or stimulation. The CST has a high false-positive rate, and the NST has a false-negative rate of 2.7 per 1,000 in a high-risk population. The biphasic profile (BPP) score

predicts the presence or absence of asphyxia. The loss of the components of the BPP reflects sequential adaptive deletions to reduce fetal oxygen requirements. A normal BPP has a false-negative rate of 0.7 to 0.8 per 1,000.

The CST, NST, and BPP were compared in 583 women who had completed 42 weeks gestation. There were three protocols:

1. Weekly NST with CST for nonreactive NST.
2. Twice weekly NST with BPP for nonreactive NST with induction for a 4/10 BPP.
3. Twice weekly NST with BPP for nonreactive NST and a weekly determination of the amniotic fluid volume.

Patients were induced for low fluid or decelerations on the NST. In protocol 1, patients were reevaluated in 24 hours for a suspicious CST and induced for a positive CST. Protocol 3 had the highest intervention rate and the least perinatal morbidity. Protocol 1 had no interventions and the highest perinatal morbidity rate. Cesarean delivery was more common in protocols 2 and 3. Of note, the best outcomes were achieved with a low threshold for intervention.

The Fetus

In 1954, Clifford described the fetal postmaturity syndrome, in which the postmature infant was characterized by peeling, parchmentlike skin; wasted appearance; and meconium staining of skin, membranes, and the cord. The syndrome progressed in three stages from placental insufficiency with minimal associated morbidity and mortality to chronic insufficiency with an associated anoxic event.

The postmaturity syndrome described by Clifford is seen in only a small percentage of prolonged pregnancies. By far, the most common complication is macrosomia, resulting in dystocia with associated brachial plexus injuries and fractures.

Seven thousand infants were studied to determine the rate of growth after 39 weeks. Mean birth weight increased from 39 to 42 completed weeks. A similar increase was seen in head circumference and crown-to-heel length. In a study of 519 pregnancies beyond 41 weeks, 23% weighed more than 4,000 g and 4% were larger than 4,500 g.

To assess the risk to the fetus in a prolonged uncomplicated gestation, 1,408 infants delivered at 41 weeks and 340 delivered at 42 weeks were compared with 5,915 delivered at 39 or 40 weeks. Fetal distress and meconium release were twice as common at or after 42 weeks than at term. There was an eightfold increase in meconium aspiration, which occurred 1 per 455 at term, 1 per 175 at 41 weeks, and 1 per 57 at 42 weeks. There was no increase in the incidence of birth asphyxia measured by the need for mechanical ventilation at birth.

Management

An adverse event in a pregnancy that has carried beyond 40 weeks seems especially difficult because it might have been avoided by simply delivering the patient. Although

rare, the risk of stillbirth increases as gestational age increases. Nonetheless, available data indicate that induction

and expectant management have similar outcomes, and either is suitable for managing the uncomplicated prolonged gestation.

The NIH sponsored a clinical trial to compare induction at 41 weeks (n = 265) with expectant management (n = 175) consisting of twice weekly NST and AFI. There were no differences in outcome between the two groups. The trial concluded that either approach was acceptable.

The Parkland Group studied 56,317 pregnancies at 40, 41, and 42 weeks. Labor was induced at 42 weeks. Neonatal outcomes were similar in all groups. Sepsis and neonatal intensive care unit admission were more common in the 42-week group. Labor complications increased between 40 and 42 weeks, including length of labor and operative delivery. Their data suggest that routine induction at 41 weeks would increase labor complications with little or no neonatal benefit.

In the Canadian Multicenter Post-term Pregnancy Trial, singleton pregnancies at 41 weeks or more were assigned to induction or monitoring. In the monitored group, women were asked to perform kick counts each day. In addition, the fetuses received NSTs three times a week and AFI determinations two or three times weekly. Patients in the monitored group were delivered either at 44 weeks or for maternal-fetal indication(s). Perinatal morbidity and mortality were the same for both groups.

Prevention

Separation of the membranes from the lower uterine segment (membrane sweeping) is a safe and inexpensive method of inducing labor. In one study, the treatment group had a significant reduction in prolonged gestation—3.3% compared with 15.6% in the control group. In summary, membrane sweeping prior to 40 weeks appears to be an effective method for reducing postdate inductions, but its safety in women who are positive for GBS has not been established.

Induction of Labor

In the presence of a favorable cervix, induction after 41 weeks is the most favored course. Even though induction with an unfavorable cervix may be unsuccessful and lead to cesarean delivery, most practitioners now recommend cervical ripening and induction at 41 weeks with an unfavorable cervix. A recent Cochrane Review noted the following clinical implications: (a) induction of labor at 41 or 42 weeks does not increase the risk of cesarean delivery; (b) induction of labor port term reduces the risk of perinatal death, but the absolute risk is very low; and (c) fetal monitoring should be part of expectant management.

Summary Points

- The rate of preterm birth is increasing in the United States.

- Subclinical infection is an important cause of preterm labor and delivery.
- Risk factor screening misses the majority of women who deliver preterm.
- Fibronectin and vaginal ultrasound of the cervix are promising technologies to identify women at low and high risk for preterm delivery. Their main clinical utility lies in their high negative predictive values. Accordingly, for women with signs and symptoms of preterm labor but with a negative fetal fibronectin test or a long cervical length (e.g., greater than 2.5 to 3.0 cm), there is a very low risk of preterm birth, and expensive and cumbersome interventions may be avoided.
- Universal screening for bacterial vaginosis or *T. vaginalis* is not warranted.
- Management of women with asymptomatic shortening of the uterine cervix is controversial.
- The diagnosis of preterm labor should be made by using objective and reproducible criteria to avoid over- and undertreatment of women at risk for delivery.
- Tocolytic therapy has not been associated with improvements in neonatal outcome.
- All tocolytic agents have the potential to adversely affect the mother and the neonate and should only be administered in a supervised setting.
- Currently, there is no data to support the use of maintenance tocolytic therapy.
- Tocolytic therapy should not be administered without concurrent administration of antenatal corticosteroids.
- Weekly courses of antenatal corticosteroids should not be routinely prescribed.
- Antenatal progesterone therapy may reduce the risk of preterm birth and low birth weight in women with previous preterm birth.
- Accurate dating of the pregnancy is important, and an early dating ultrasound can prevent unnecessary interventions.
- Perinatal morbidity and mortality increase significantly beyond 41 weeks gestation.
- Membrane sweeping can help to reduce the number of pregnancies that continue beyond 40 weeks.
- Antenatal testing is initiated to identify the fetus in need of delivery. No testing modality has been shown to improve outcomes in prolonged gestations.

- The uncomplicated post-term pregnancy with an unfavorable cervix can be watched expectantly with twice weekly fetal assessments, or labor induction can be undertaken. Induction at 41 weeks reduces the risk of stillbirth.

Premature Rupture of the Membranes

Ronald S. Gibbs

Premature rupture of the fetal membranes is one of the most common problems in obstetrics, complicating approximately 5% to 10% of term pregnancies and up to 30% of preterm deliveries. Although the etiology of premature rupture of the fetal membranes often is not clinically evident, a degree of consensus has arisen regarding management options. Gestational age and patient demographics are considerations in selecting management in a particular patient. The clinician is confronted by a complex set of diagnostic and management options, including use of amniocentesis, ultrasound, and biophysical testing as well as corticosteroids, tocolytics, and antibiotics. Of major importance in deciding on the management is the marked improvement in survival of low-birth-weight infants.

Definitions

Premature rupture of the membranes (PROM) is usually defined as rupture at any time before the onset of contractions. Because the word *premature* also carries the connotation of preterm pregnancy, the author uses the word *preterm* to refer to gestational age of less than 37 weeks to avoid confusion. Thus, *preterm premature rupture of the membranes* (PPROM) refers to PROM prior to 37 weeks gestation. The latent period is defined as the time from membrane rupture to onset of contractions. It is to be distinguished from latent phase, which designates the early phase of labor before the active phase. Various terms have been used to describe presumed maternal or perinatal infections related to PROM. During labor, designations have included “fever in labor,” “intrapartum fever,” “chorioamnionitis,” “amnionitis,” “intraamniotic infection,” and “intrauterine infection.” The degree of temperature used to define *fever* has varied. After delivery, maternal infection is referred to as “endometritis” or “postpartum infection.” These diagnoses are usually based on fever, uterine tenderness, and exclusion of other sources of fever. In neonates, the most common term used to report infection is *neonatal* sepsis, but this may mean strictly a positive blood culture or simply clinical signs or symptoms of sepsis.

Incidence

The incidence of PROM ranges from about 5% to 10% of all deliveries, and PPROM occurs in approximately 1% of all pregnancies. Approximately 70% of cases of PROM occur in

pregnancies at term, but in referral centers, more than 50% of cases may occur in preterm pregnancies. PROM is the clinically recognized precipitating cause of about one third of all preterm births. Despite some progress in prolonging the latent period after PPROM and possible prevention of recurrence (such as by the use of progesterone or by treating bacterial vaginosis), PPROM remains a leading contributor to the overall problem of premature birth.

Etiology

In the vast majority of cases, the etiology is not clinically evident. With term PROM, the cause may be physiologic weakening of the membranes. Clinical conditions such as cervical incompetence and polyhydramnios have been identified as risk factors evident in some cases of PROM.

A scholarly review of the etiology of PPROM identified numerous potential causes in any given case. These included a generalized decrease in tensile strength of

---

membranes, local defects in the membranes, decreased amniotic fluid collagen and a change in collagen structure, uterine irritability, apoptosis, collagen degradation, and membrane stretch. The Maternal-Fetal Medicine Units (MFMU) Network found that risk factors for PPROM were previous PPROM, positive fetal fibronectin at 23 weeks, and short cervix (<25 mm) at 23 weeks.

Substantial evidence is available to show that subclinical infection may be a cause of PROM, not merely its result. Support for a role of infection is provided by studies showing an association between clinically diagnosed bacterial vaginosis and preterm birth/PPROM. Some genital bacteria elaborate enzymes such as proteases, phospholipases, and collagenases may act to weaken the membranes. When amniotic fluid is obtained by amniocentesis in cases of PPROM, positive cultures are found in approximately 30% if the specimen is properly handled for aerobes, anaerobes, and genital mycoplasmas.

In a large case-control study, three factors were associated with PPROM in a multifactorial analysis. These were previous preterm delivery (odds ratio [OR] 2.5; 95% confidence interval [CI] 1.4 to 2.5), cigarette smoking (stopped during pregnancy, OR 1.6, 95% CI 0.8 to 3.3; continued during pregnancy, OR 2.1, 95% CI 1.4 to 3.1), and bleeding (first trimester, OR 2.4, 95% CI 1.5 to 3.9; third trimester, OR 6.5, 95% CI 1.9 to 23.0; more than one trimester, OR 7.4, 95% CI 2.2 to 26.0). This study enrolled controls at the same gestational age as cases (thus correcting for the decreasing frequency of coitus closer to term) and found no association between coitus and PROM. Recent coitus is probably not a cause of PROM.

Investigations into the placental histology have provided correlates with clinical outcomes in cases of PPROM. Overall, acute inflammation was seen in 43%, vascular lesions were seen in 20%, inflammation plus vascular lesions in 20%, normal findings in 14%, and “other” findings in 3% (Fig. 12.1). When acute inflammation was seen in the placenta (either by itself or mixed with vascular lesions), birth at less than 26 weeks was more common, and delivery for suspected or proved clinical infection also was more common.

Complications and Consequences of Premature Rupture of the Membranes

Onset of Labor

At term, the onset of labor occurs within 24 hours after membrane rupture in 80% to 90% of patients. Among patients with PROM prior to term, latent periods occur longer. Latent periods of more than 24 hours occur in 57% to 83%, of more than 72 hours in 15% to 26%, and of 7 days or more in 19% to 41%. There is an inverse relationship between gestational age and the proportion of patients with latent periods longer than 3 days. For pregnancies between 25 and 32 weeks, 33% had latent periods longer than 3 days, whereas for pregnancies of 33 to 34 and 35 to 36 weeks, the corresponding values were 16.0% and 4.5%, respectively.

Effect of Tocolytic Drugs

The value of tocolytics in PPROM remains controversial. None of eight prospective trials showed a decrease in neonatal morbidity, whether tocolysis was used prophylactically (for all patients in admission regardless of uterine activity) or therapeutically (for patients who developed uterine contractions). Only three of the eight showed a prolongation of the latency period; an additional study showed a prolongation for gestation less than 28 weeks. Steroids were used in three of these studies; antibiotics were used in another three studies.

A comparison of short-term versus long-term tocolysis in PPROM at 26 to 35 weeks showed an adverse effect of “long-term tocolysis.” Patients with PPROM at 26 to 35 weeks were randomized to receive either an intravenous

---

ß-mimetic drug for less than 48 hours versus until delivery. All patients received corticosteroids, and group B streptococci (GBS) and gonococci were treated. There was no significant difference in the latent period or in neonatal infection, but there was a significant increase in both chorioamnionitis and endometritis with long-term tocolysis. Accordingly, use of tocolytics in patients with PPROM remains controversial, but the bulk of the evidence shows no benefit. However, if tocolytics are used, such as during transfer to a tertiary care center or obtaining benefits of corticosteroids, the course of tocolytics should be limited to less than 48 hours.

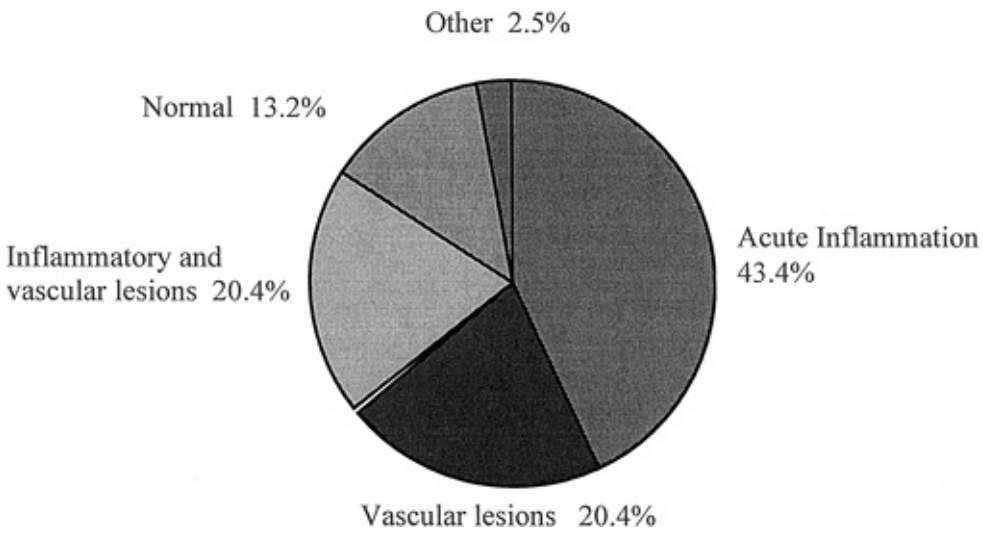

Figure 12.1 Placental histology in 235 cases of premature PROM. (From Sweet RL, Gibbs RS. *Infectious diseases of the female genital tract*, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2002, with permission.)

Respiratory Distress Syndrome, Infections, and Other Complications

The risks of PROM generally have been viewed as those of infection versus those of prematurity. The most common clinically evident complication among pregnancies with PROM before 37 weeks is respiratory distress syndrome (RDS), which, in general, is found in 10% to 40% of neonates. Bona fide neonatal sepsis is documented in less than 10%, and amnionitis (based always on clinical criteria) occurs in approximately 3% to 31%. Subclinical infection based on positive amniotic fluid culture or histologic inflammation of the cord or membranes is seen much more often, in up to 80% at very early gestational ages with PPROM. Endometritis develops in up to 29%. Abruption after PROM is reported in 4.0% to 6.3% of cases, several-fold higher than the rate of 0.5% to 1.0% in the general population. Pulmonary hypoplasia is a serious fetal complication occurring in PPROM. Pulmonary hypoplasia is more common when there is very early PPROM, especially when this occurs in the presence of prolonged PROM and with severe oligohydramnios. There is nearly a 100% probability of lethal pulmonary hypoplasia when PROM occurs before 23 weeks and when there is severe oligohydramnios. With later gestational age at the onset of PPROM, the likelihood of pulmonary hypoplasia decreases. Notably, with PPROM more than 24 to 26 weeks, pulmonary hypoplasia is rare even with oligohydramnios. When PPROM occurs less than 25 weeks with severe oligohydramnios lasting more than 14 days, the likelihood of lethal pulmonary hypoplasia is estimated to be 80%. At the other extreme, when PPROM occurs at more than 25 weeks and when there is either no severe oligohydramnios or severe oligohydramnios for less than 5 days, then the predicted probability of lethal pulmonary hypoplasia is only 2%. These data provide important information for counseling patients with midtrimester PROM.

Recurrence

The reported recurrence rate for PPROM is up to 32% for patients who had PPROM in an index pregnancy. Based on these data, the risk of recurrence is considerable, prompting patient education and close follow-up in subsequent pregnancies. Progesterone therapy appears effective in reducing the risk of recurrent preterm birth due to PROM or preterm labor. Some studies have shown a decrease in recurrent preterm births due to PROM by treating bacterial vaginosis.

Evaluation

Diagnosis

The initial evaluation is likely to reveal amniotic fluid egressing from the vagina. The differential diagnosis of rupture of the membranes includes loss of the mucus plug, vaginal discharge associated with infection, and urinary loss. If the patient is not going to be delivered immediately, then a digital examination should be deferred as examination may introduce bacteria into the uterus and shorten the latent phase. A sterile speculum exam may demonstrate pooling of fluid in the posterior vaginal vault. Direct observation of fluid leaking from the cervical os confirms ruptured membranes. The normal pH of the vagina is between 4.0 and 4.7 in pregnancy, whereas the pH of the amniotic fluid is 7.1 to 7.3. Nitrazine paper changes to a dark blue from yellow with a pH above 6.5. Nitrazine paper to diagnose amniotic fluid in the vagina has an overall accuracy of approximately 93%, but false-positive results can result from blood, semen, alkaline urine, bacterial vaginosis, and trichomoniasis.

The diagnosis of PROM also may be confirmed by observing arborization or “ferning” of dried amniotic fluid on a slide. This method has an overall accuracy of diagnosis of PROM of approximately 96%. False positives occur with contamination by semen or cervical mucus. False negatives can result from a dry swab, contamination with blood at a 1:1 dilution, or not allowing sufficient time for the fluid to dry on the slide. Amniotic fluid arborization is unaffected by meconium at any concentration and is unaffected by pH alteration.

Ultrasound examination has been used widely, since oligohydramnios suggests PROM, but there have been no evaluations of its sensitivity and specificity. A multicenter clinical trial compared fetal fibronectin detection with standard tests for detection of rupture of the membranes at term. Fetal fibronectin showed an excellent sensitivity (98.2%) but a low specificity, leading to speculation that fetal fibronectin in cervicovaginal secretions may be a marker for impending labor, even without frank rupture of the membranes.

When the diagnosis of ruptured membranes is unclear by these tests, a transabdominal dye injection is sometimes performed. Indigo carmine blue (1 mL diluted in 9 mL of sterile normal saline solution) is injected into the amniotic fluid, and a sponge is placed into the vagina and inspected

---

30 minutes later for the dye. Methylene blue should not be used because of reported methemoglobinemia in the fetus. This test is invasive, and the accuracy of diagnosis is not

established.

Fetal Maturity

Determination of the fetal age and maturity status is useful in developing a treatment plan. The patient's history and early milestones of the pregnancy should be used. Ultrasound examination of the fetus can be limited because of the decreased fluid surrounding the fetus, and some measurements, especially of the abdomen and head, may be altered with oligohydramnios after PROM. As part of the overall decision process as to delivery, assessment of fetal lung status may be incorporated (e.g., if gestational age is 32 to 34 weeks or if there is uncertainty regarding gestational age because of possible growth restriction). Amniotic fluid may be collected by amniocentesis or by collection from the vaginal pool. Vaginal pool collection is less accurate for lecithin:sphingomyelin (L:S) ratio determination. Whereas phosphatidylglycerol (PG) production by vaginal bacteria has been described, there has been an excellent correlation between PG detection in amniotic fluid obtained vaginally and transabdominally.

Cervical Status

In addition to documentation of ruptured membranes, the sterile speculum exam can evaluate the degree of cervical dilation and can exclude the possibility of a fetal extremity or umbilical cord prolapsing through the cervix. Endovaginal ultrasound may be used safely in patients with PPROM, as it does not increase the risk of infection.

TABLE 12.1 Markers of Intra-amniotic Infection in 110 Patients with Preterm Premature Rupture of the Membranes

	Sensitivity	Specificity	Positive Predictive Value	Negative Predictive Value
Gram stain	10/42 (23.8%)	67/68 (98.5%)	10/11 (90.9%)	67/99 (67.8%)
IL-6 >7.9 (ng/mL)	34/42 (80.9%)	51/68 (75.0%)	34/51 (66.7%)	51/59 (86.4%)
WBC ≥30 (cells/mm^3)	24/42 (57.1%)	53/68 (77.9%)	24/39 (61.5%)	53/71 (74.6%)
WBC ≥50	22/42	57/68	22/33	57/77

(cells/mm^3)	(52.4%)	(83.8%)	(66.7%)	(74.0%)
Glucose ≤10 (mg/dL)	24/42 (57.1%)	50/68 (73.5%)	24/42 (57.1%)	50/68 (73.5%)

Infection

When the diagnosis of PROM is made, a rectovaginal culture should be taken for GBS, and appropriate antibiotics (usually intravenous penicillin G) for prevention of GBS infection should be given pending culture results.

All patients with PPROM should be evaluated for possible evidence of chorioamnionitis. Physical exam includes maternal or fetal tachycardia; uterine tenderness; and detection of a purulent, foul-smelling discharge. Temperature elevation is often a late sign of chorioamnionitis, especially in PPROM. In Table 12.1, the positive and negative predictive values of several tests for intrauterine infection in PPROM are shown. Most of these tests have modest performance characteristics, thus limiting their clinical utility. Amniocentesis may be performed to evaluate for an intrauterine infection, if there are equivocal clinical signs of infection. Because of the high likelihood of subclinical infection and the association of intrauterine infection with cerebral palsy, there is a growing enthusiasm for early detection of subclinical infection. Accordingly, amniocentesis may become more widely used. Analyses of amniotic fluid for possible infection include Gram stain, glucose concentration, and culture. Gram stain does not identify colonization with genital mycoplasmas. A low amniotic fluid glucose predicts a positive amniotic fluid culture. When the glucose is greater than 20 mg/dL, the likelihood of a positive culture is less than 5%; when glucose is less than 5 mg/dL, the likelihood of a positive culture approaches 90%. Although not widely available, an elevated interleukin 6 (IL-6) in amniotic fluid may be the most sensitive predictor of intrauterine infection. A biophysical profile of 6 points or less has been shown in several studies to correlate with intrauterine infection. Most newborns who are delivered

after clinical chorioamnionitis do not show clinical infection, possibly because of common

use of empiric antibiotic therapy.

Treatment Considerations

The overall approach to management of PROM takes into consideration neonatal survival at the gestational age when rupture occurs. Management may be divided into four different phases of pregnancy. During the second trimester, neonatal survival is nil, leading numerous investigators to adopt a policy of expectant management or induction. Early in the third trimester, neonatal survival rises markedly, but there is still considerable morbidity associated with delivery at this gestational age. In the mid third trimester, neonatal survival is high, but there is still considerable morbidity, whereas in the late third trimester (at or near term), neonatal mortality and morbidity are low. Neonatal outcome is one of the driving features in determining clinical management. Leakage of amniotic fluid into the lower genital tract occurs commonly after amniocentesis, but in the vast majority of cases, membranes reseal and the outcome is good.

Diagnosis of Infection after Premature Rupture of the Membranes

Both invasive and noninvasive tests have been assessed. As shown in Table 12.1, none of these tests is ideal, particularly because of their modest positive predictive values.

Use of Steroids

The 1994 National Institutes of Health (NIH) Consensus Conference concluded that the risk of maternal and infant infection may be increased with corticosteroid use after PROM but that the magnitude of this risk was small. The NIH recommendations are summarized in Table 12.2 and include a single course of antenatal cortecosteroids for women with PROM less than 32 weeks gestation provided there is no clinical chorioamnionitis.

The 2006 Cochrane Update on antenatal corticosteroid recommends a single course of corticosteroids for women between 24 and 34 weeks in whom there is reason to anticipate early delivery, including women with ruptured membranes. Weighing the hypothetical risk of increased infection when corticosteroids are used in PPROM, the author uses 32 weeks as the upper gestational age limit for use.

Weekly courses of antenatal steroids in women with PROM have not improved neonatal measures compared with the results of a single course. Because multiple (i.e., weekly) courses were associated with an increase in the rate of chorioamnionitis, antenatal steroid therapy in PPROM should be limited to a single course.

TABLE 12.2 Corticosteroid use in preterm premature rupture of the membranes

- Antenatal steroids in PPROM reduce the risk of RDS in randomized clinical trials, but the effect was less than with intact membranes.
- Strong evidence suggests reduced neonatal mortality and IVH with use in PPROM.
- Corticosteroid use is appropriate in the absence of chorioamnionitis in fetuses <30 to 32 week.

PPROM, preterm premature rupture of the membranes; RDS, respiratory distress syndrome; IVH, intraventricular hemorrhage.
Data from the National Health Institutes Consensus Conference, 1994.

Effect of Latent Period and Vaginal Examination upon Incidence of Amnionitis

In earlier studies, the incidence of amnionitis rose with increasing length of the latent period, but other investigators have found no increase in the incidence of amnionitis among preterm pregnancies with increasing latent periods. In a comparison of outcomes, women with digital examination after PROM had a significantly shorter latent period (2.1 ± 4.0 vs. 11.3 ± 13.4 days; $P < .001$), more maternal infection (44% vs. 33%; $P = .09$), and more positive amniotic fluid cultures (11/25 [44%] vs. 10/63 [16%]; $P < .05$). Thus, routine vaginal examination should be avoided until labor develops in patients with PPROM.

Use of Prophylactic Antibiotics

In patients with PROM prior to term, there are two indications for prophylactic antibiotics. The first, prevention of perinatal GBS infection, has become a national standard since 1996 and is discussed in Chapter 19.

A second indication for antibiotic prophylaxis has been based on the hypothesis that infection is either the triggering cause of PPROM or that infection ensuing after PPROM triggers the labor. Accordingly, the rationale for prophylactic antibiotics has been to delay delivery after PPROM rather than to prevent clinically evident infection. There is now good evidence to favor use of broad-spectrum antibiotics in selected cases of PPROM. This support was provided in a meta-analysis and in prospective randomized trials. In a systematic review, there were 19 randomized controlled trials containing 6,559 women. There were differences among the trials regarding use of steroids, tocolytics, and prophylaxis for GBS. Nevertheless, benefits were demonstrated in favor of women receiving antibiotics. These benefits included a significant delay in delivery within 48 hours and 7 days, a reduction in maternal infection and chorioamnionitis, and a reduction in neonatal infection (Fig. 12.2). Additional neonatal benefits included: a reduction in positive blood cultures, use of surfactant, need

for oxygen therapy, and abnormal cerebral ultrasound scan before discharge. Perinatal mortality was not decreased.

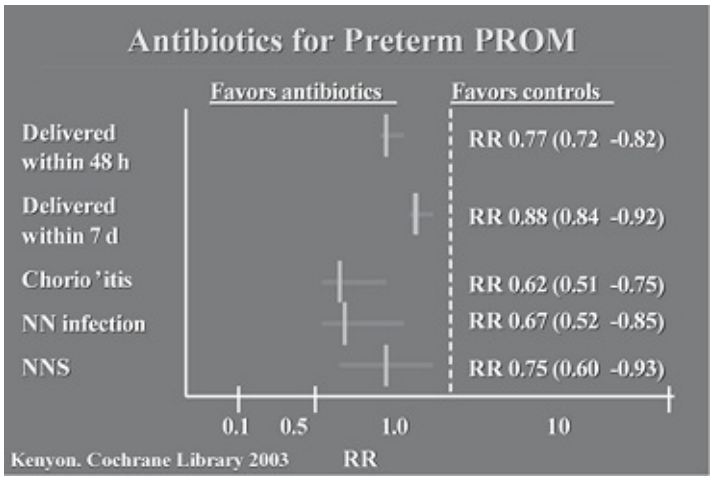

Figure 12.2 Relative risks of antibiotic use in PPROM. Relative risk for each outcome is shown as the *vertical "hatch mark,"* and 95% CI as the *horizontal line*.

In the large MFMU trial, patients were enrolled if they had PPROM for less than 72 hours at 24 to 32 weeks gestation. Patients were excluded if there was chorioamnionitis, labor, or fetal distress. Patients were then randomized to a course of ampicillin plus erythromycin (each for 2 days intravenously followed by up to 7 days orally) versus placebo. Patients with GBS were given treatment during the latent period, but no tocolytics nor steroids were used. The primary end point was a prospectively defined composite of neonatal death, neonatal RDS, grade III or IV intraventricular hemorrhage, grade II or III necrotizing enterocolitis, or neonatal sepsis. Patients randomized to antibiotic therapy had a significantly greater likelihood of remaining undelivered when assessed at 2 days, 7 days, 14 days, and 21 days (Fig. 12.3). In addition, the primary composite outcome was significantly reduced in the total population and in the GBS-negative cohort. Individual adverse outcomes significantly reduced in the antibiotic group included RDS, chorioamnionitis, neonatal sepsis, and neonatal pneumonia. Table 12.3 summarizes the benefits of antibiotics in patients with PPROM and stratifies the results by total population versus the GBS-negative cohort.

TABLE 12.3 Maternal-Fetal Medicine Units Network Trial of Antibiotics after Preterm Premature Rupture of the Membranes: Summary of Benefits

	Total	Cohort Group B Streptococci-

	Population	Negative
Primary outcome	↓ (P = .04)	↓ (P = .03)
RDS	↓ (P = .04)	↓ (P = .03)
NEC	↓ (P = .03)	—
Amnionitis	↓ (P = .01)	↓ (P = .01)
Neonatal sepsis	—	↓ (P = .01)
Neonatal pneumonia	—	↓ (P = .04)

RDS, respiratory distress syndrome; NEC, necrotizing enterocolitis.
Mercer BM Goldenberg RL, Meis PJ, et al. The Preterm Prediction Study: prediction of preterm premature rupture of membranes through clinical findings and ancillary testing. *Am J Obstet Gynecol* 2000;183:738–745.

In a very large (nearly 5,000 patients) international trial (ORACLE I), patients with PPROM were randomized to one of four courses: oral erythromycin, oral amoxicillin–clavulanic acid, both antibiotics, or oral placebo. Each regimen was taken four times a day for 10 days or until delivery. The primary outcome measure used was a composite

of neonatal death, chronic lung disease, or major cerebral abnormality on ultrasound. Erythromycin was associated with several benefits to the neonate (fewer cases with the composite outcome, prolongation of pregnancy, and fewer positive blood cultures). Amoxicillin–clavulanic acid—with or without erythromycin—was associated with prolongation of pregnancy, but it was also associated with a significant increase in neonatal necrotizing enterocolitis. The applicability of this study to contemporary U.S. practice is limited, however, because the authors made no provision for GBS prophylaxis. Other features of the study are that antibiotics were used orally, enrollment was permitted up to 37 weeks (only 50% of cases were less than 32 weeks), and there was no standard approach for use of steroids or tocolytics. Steroids were used in 75% of cases and tocolytics in <15%.

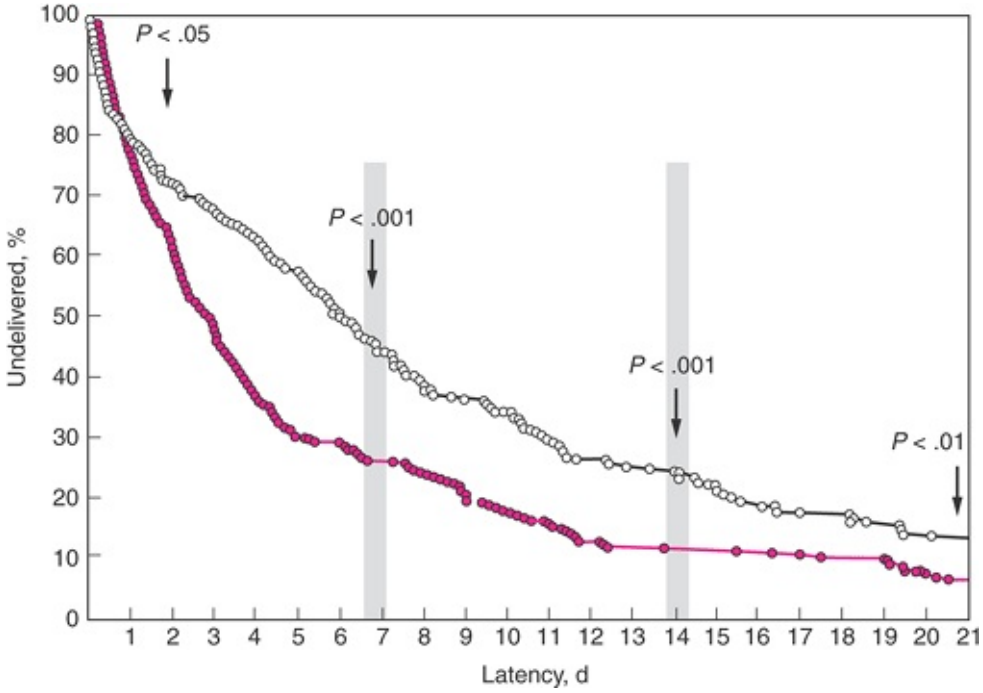

Figure 12.3 Prolongation of pregnancy in a GBS-negative cohort. Antibiotic groups are shown in *open circles* and placebo in *solid circles*. (From Sweet RL, Gibbs RS. *Infectious diseases of the female genital tract*, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2002, with permission.)

Widespread use of antibiotics in PPROM raises concern about selection pressure toward resistant organisms, but in the MFMU trial, there was no significant increase in maternal yeast infection or neonatal *Candida* sepsis, nor were there any cases of pseudomembranous colitis, maternal sepsis, or maternal death. Another hypothetical concern about use of antibiotics in PPROM is suppressing the clinical manifestations of maternal–fetal infection but without clearing the infection. Accordingly, the author uses antibiotics in PPROM where the benefits are most likely to exceed the risk and limit use for prolongation of pregnancy to 24 0/7 to 32 0/7 weeks.

Determination of Fetal Lung Maturity

Because RDS is the single greatest threat to infants born after PPROM, some investigators have determined the status of fetal pulmonary maturity and proceeded with delivery when there was lung maturity. One study used amniocentesis and obtained fluid in about half of the cases. Others have attempted to collect amniotic fluid from the vagina and have had success rates of 80% to 94%. Presence of either PG or an L:S ratio of more than two in amniotic fluid collected vaginally has been reported to be a good predictor of pulmonary maturity.

In a larger series of patients with PROM before 36 weeks, investigators determined whether PG was present in the vaginal pool and delivered patients when there was presence of PG, spontaneous labor, or evidence of sepsis. PG in amniotic fluid from the vagina reliably predicted fetal lung maturity. However, absence of PG did not necessarily mean that RDS

would develop. Of the 131 patients who did not show PG in the vaginal pool in any sample, 82 (62%) were delivered of infants who had no RDS. Thus, even with PROM, delivery of a premature infant simply because its lungs showed biochemical maturity may be questioned in view of other potential hazards of prematurity and the difficulty of the induction. Of note, some genital tract bacteria have been found to yield a false-positive test for PG.

Management

Premature Rupture of the Membranes at or Near Term

Although expectant management with inpatient observation had been employed in the past, this approach has become less popular because of the inconvenience and expense of the hospitalizations. Induction of labor shortly after admission has become more widely used (Table 12.4). Several studies have reported the safety and benefits of prostaglandins and have supported the increased popularity of induction with these preparations. In comparison to patients managed expectantly, those given intravaginal prostaglandin E_2 (PGE_2) shortly after admission had significantly less likelihood of a need for oxytocin and a significantly shorter time to delivery. There was no significant difference in cesarean section rate or in maternal or neonatal infection rates. In the largest trial of management of PROM at term, patients were studied in a four-arm trial with approximately 1,250 patients in each arm. These arms were as follows: expectant management plus oxytocin for induction as needed; induction with intravenous oxytocin shortly after admission; induction with PGE_2 gel in a dose of only 1 to 2 mg shortly after admission; and expectant management followed by PGE_2 induction as needed. One methodological concern regarding this study is the low dose of PGE_2 gel used vaginally. With most patients receiving less than 2 mg, the dose was smaller than used in most U.S. trials. As shown in Figure 12.4, patients randomized to expectant management initially had significantly longer times to delivery than patients randomized to either of the induction arms ($P < .001$). In addition, the rate of clinically diagnosed chorioamnionitis was less in the patients randomized to induction initially (with significance achieved at $P < .01$ comparing arms 1 vs. 2). The distribution of postpartum infection was similar to that of chorioamnionitis. In addition, there was no significant difference in rates of neonatal infection or cesarean section. Of note, patient satisfaction was significantly higher in the induction arms.

TABLE 12.4 Summary of Management: Premature Rupture of the Membranes at or near Term (≥35 wk)

- Induction usually preferred, with oxytocin or prostaglandin preparations (especially with unripe cervix), either on admission or after a finite period of observation (up to 12 or even 24 hours).

- Prophylaxis for GBS with a positive screening culture at 35–37 weeks or with rupture of the membranes >18 hours in patients with unknown culture status.

GBS, group B streptococci.

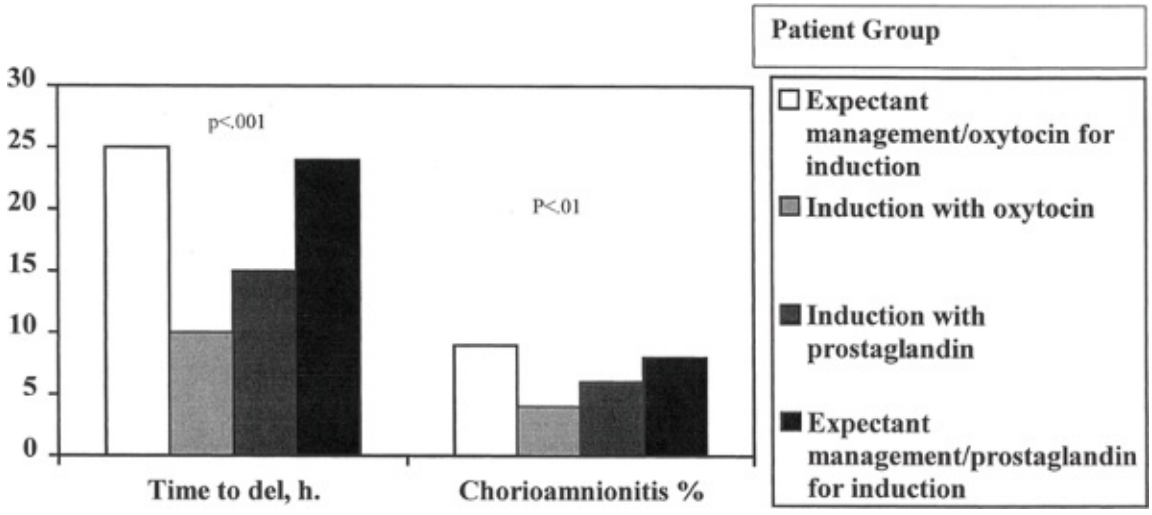

Figure 12.4 Selected outcomes in an international term PROM trial. (From Sweet RL, Gibbs RS. *Infectious diseases of the female genital tract*, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2002, with permission.)

A large meta-analysis involving 23 studies and including nearly 7,500 patients concluded that conservative management may result in more maternal infections than immediate induction with either oxytocin or prostaglandins. This meta-analysis also showed that the rate of chorioamnionitis was higher in patients induced with prostaglandin versus those induced with oxytocin. However, this meta-analysis was heavily influenced by the large international trial, and as noted previously, this trial used a very low dose of prostaglandin.

Within the last few years, intravaginal misoprostol (a PGE_1 analog) has assumed marked popularity for induction because of its efficacy and low cost. Intravaginal misoprostol (50 mg every 4 hours for a maximum of 12 tablets) was compared with oxytocin in women with single pregnancies and an unfavorable cervix (<2 cm dilated and <80% effaced). The results of this trial are presented in Table 12.5. Overall, patients randomized to misoprostol had a shorter induction time, by approximately 2 hours, but they had significantly more uterine tachysystole. Of note, over 85% of patients required only one dose of misoprostol. Compared with other trials evaluating misoprostol in patients at term with intact membranes, the dose used in this trial is relatively high.

TABLE 12.5 Misoprostol versus Oxytocin in Premature Rupture of the Membranes

	Misoprostol (n = 70)	P	Oxytocin (n = 71)
Induction time (min)	416.0	0.04	539.0
One dose (%)	85.7	—	—
Uterine tachysystole[a] (%)	28.6	<0.04	14.0

[a]≥6 contractions/10 minutes × 20 minutes. No difference in mode of delivery or any other complications.
Sanchez-Ramos L, Chen AH, Kaunitz AM, et al. Labor induction with intravaginal misoprostol in term premature rupture of membranes: a randomized study. *Obstet Gynecol* 1997;89:909–912.

A 2007 American College of Obstetricians and Gynecologists (ACOG) Practice Bulletin recommended that with PROM at term, labor should be induced at the time of presentation to reduce the risk of maternal and neonatal complications. In sum, while a range of practices is available and supported in the literature, the decision regarding delivery after PROM at term must take into account fetal presentation, fetal status, cervical ripeness, presence of infection, and patient desires. For patients with a breech (or other malpresentation) infant or an infant with evidence of intolerance of labor, prompt cesarean delivery is most appropriate. If there is clinically evident infection and no contradiction to vaginal delivery, then immediate induction and antibiotic therapy are indicated. If the cervix is ripe, then induction with oxytocin resolves the situation. When the cervix is unripe, induction with either prostaglandins or oxytocin shortens the time to delivery, decreases risk of infection, and does not appear to increase cesarean section rate. The epidemiologic data linking chorioamnionitis with cerebral palsy provide additional impetus to move toward delivery after PROM at term.

Premature Rupture of the Membranes at 32 to 33 Completed Weeks

When there is evidence of fetal lung maturity, two trials have reported benefits to

expectancy. In one trial, induction had several benefits, including a shorter time to delivery (14 vs. 36 hours; P <.001), shorter maternal hospital stay (2.3 vs. 3.5 days; P <.001), and less chorioamnionitis (11 vs. 28%; P = .06). Neonatal hospital stay was also shorter (6.3 vs. 7.3 days), but this difference was not significant. Although the authors found less clinically diagnosed neonatal sepsis in the induction group (28 vs. 60%; P <.003), there was no difference in confirmed sepsis (seven cases in induction group vs. four in expectant). There were no significant differences in the rates for cesarean delivery, postpartum infection, or neonatal survival. The other trial also found advantages to induction versus expectancy. Thus, at 32 to 33 completed weeks induction of labor in pregnancies with PROM may be considered if there is evidence of lung maturity. The evolving concern of intrauterine infection causing cerebral palsy adds strength to arguments for induction in the presence of lung maturity.

For pregnancies with PROM at 32 to 33 weeks when pulmonary maturity studies are not available, expectant management is generally employed (Table 12.6). The author performs amniocentesis selectively, such as when infection or growth restriction is suspected. Then, fetal status is assessed during expectant management with usual testing, mainly daily nonstress tests with biophysical profiles as needed for backup. Delivery is warranted when there are maternal or fetal indications, including evidence of infection. For pregnancies with PROM at 32 to 33 weeks, prophylaxis for GBS is given per the Centers for Disease Control and Prevention (CDC)/ACOG guidelines. An appropriate rectovaginal culture for GBS is obtained at the time of admission, unless delivery is imminent. Then, empirical intravenous prophylaxis is begun and continues until the culture result is available and negative. If the culture is positive, intravenous penicillin is continued for 48 hours, then stopped and recultured. Since the efficacy of corticosteroids in PROM at this gestational age is not clear, the author does not use them in this gestational age bracket with PROM.

TABLE 12.6 Summary of Management: Premature Rupture of the Membranes at 32 to 33 Weeks

- Expectancy versus induction, especially if there is evidence of fetal lung maturity based on analysis of amniotic fluid collected by amniocentesis or from vaginal pool.
- Prophylaxis for GBS.
- Although broad-spectrum antibiotics have been used in some studies to prolong pregnancy in the gestational age bracket, there are concerns about selection pressure for resistant organisms and about masking fetal infection. Therefore, the author limits such broad-spectrum antibiotic use to earlier gestational ages.

- Do not use tocolytics.
- Because efficacy of corticosteroids is not established, the author does not use them in this gestational age bracket.

GBS, group B streptococci.

TABLE 12.7 Summary of Management: Premature Rupture of the Membranes at 25 to 32 Weeks

Expectancy

- Prophylaxis for GBS
- Antibiotics for 7 days; no standard regimen has been established (ampicillin + erythromycin or erythromycin) or alternative regimens
- Corticosteroids
- Use of tocolytics remains controversial; if used, they should be limited to 48 hours

GBS, group B streptococci.

Premature Rupture of the Membranes at 25 to 31 Weeks

Management in the gestational age category remains especially controversial. For management of PROM after viability but before 32 weeks, our practice is to generally follow expectant management and proceed with delivery where there is spontaneous onset of labor or clinical evidence of infection (Table 12.7). The author follows national guidelines for intrapartum prophylaxis for prevention of GBS neonatal sepsis. For patients in whom delivery is not imminent, an appropriate culture for GBS is obtained from the rectovaginal area. Corticosteroids are not administered in a standard regimen. Broad-spectrum antibiotic therapy is applied, usually following the ampicillin/amoxicillin plus erythromycin regimen of the MFMU trial. This regimen is limited to 7 days. When the patient goes into labor, GBS prophylaxis is begun unless the GBS culture was negative on admission, as recommended by the CDC. Use of tocolytics during this gestational age in patients with PPROM remains controversial.

Premature Rupture of the Membranes at Less Than 25 Weeks

For PROM before viability (approximately 24 weeks), several descriptive reports have

demonstrated a highly variable latent period; high maternal infection rates (but with little serious morbidity); and an appreciable survival rate, especially when delivery occurs after week 24 (Tables 12.8, 12.9). Outcome data with expectant management of PROM in the second trimester showed perinatal survival and "intact" neurologic survival stratified by the gestational age at the time of PROM (Fig. 12.5). In sum, when gestational age occurred from weeks 14 to 19, overall survival was only 40%, whereas when PROM occurred at 20 to 25 weeks, overall survival was nearly 90%. The alternative to expectant management is induction. In the patient with PROM

this early in pregnancy, the author individualizes the decision, involving the family fully. In the proper setting, expectant management is offered.

TABLE 12.8 Summary of Management: Premature Rupture of the Membranes <25 Weeks

- Induction vs. expectancy should be weighed, depending on gestational age and patient desires.
- There is no data on steroids, tocolytics, or antibiotics (prophylaxis for GBS or prolonging pregnancy).
- It is unlikely that tocolytics achieve any significant prolongation of pregnancy and may mask early evidence of infection. Therefore, they are not recommended.
- It is unlikely that corticosteroids provide any fetal benefit at this gestational age, and corticosteroids also may increase the risk of intrauterine infection. Therefore, corticosteroids should be reserved for gestational ages where benefit is more likely.
- A course of antibiotics for 7 days may prolong pregnancy and decrease complications, as in pregnancies with PPROM at 25 to 32 weeks.
- After a period of inpatient hospitalization, home management may be used for uncomplicated, selected patients.

GBS, group B streptococci.

Chorioamnionitis Complicating Premature Rupture of the Membranes at Any Gestational Age

When clinically evident chorioamnionitis is diagnosed at any gestational age, broad-spectrum antibiotics, appropriate for the array of suspected aerobes and anaerobes, should be initiated intravenously (Table 12.10). There is no place for expectancy when intrauterine infection becomes clinically overt and preparation should be made for delivery.

TABLE 12.9 Summary of Management: Premature Rupture of the Membranes at 24 Weeks

Outcome Measure	Result
Gestational age at rupture of the membranes (median [range])	23.5 wk (17–26)
Latent period (median [range])	7.6 d (1–161)
Amnionitis (mean [range])	39% (22–63)
Survival (mean [range])	38% (25–46)
Normal development at 1 y (mean [range])	59% (20–68)

Sweet RL, Gibbs RS. *Infectious diseases of the female genital tract*, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2002.

Special Circumstances

Home Management of Premature Rupture of the Membranes

For patients who have PPROM with a previable pregnancy, management at home may be considered if there is no evidence of infection, abruption, or other maternal complications and if the mother is able to return to the hospital promptly in the event of complications.

For patients who have PPROM with a viable pregnancy, the safety of management at home has not been evaluated thoroughly. One study found that few women were eligible. Because complications such as infection, abruption, and

prolapse or delivery may develop rapidly, the author does not recommend home management once fetal viability has been achieved.

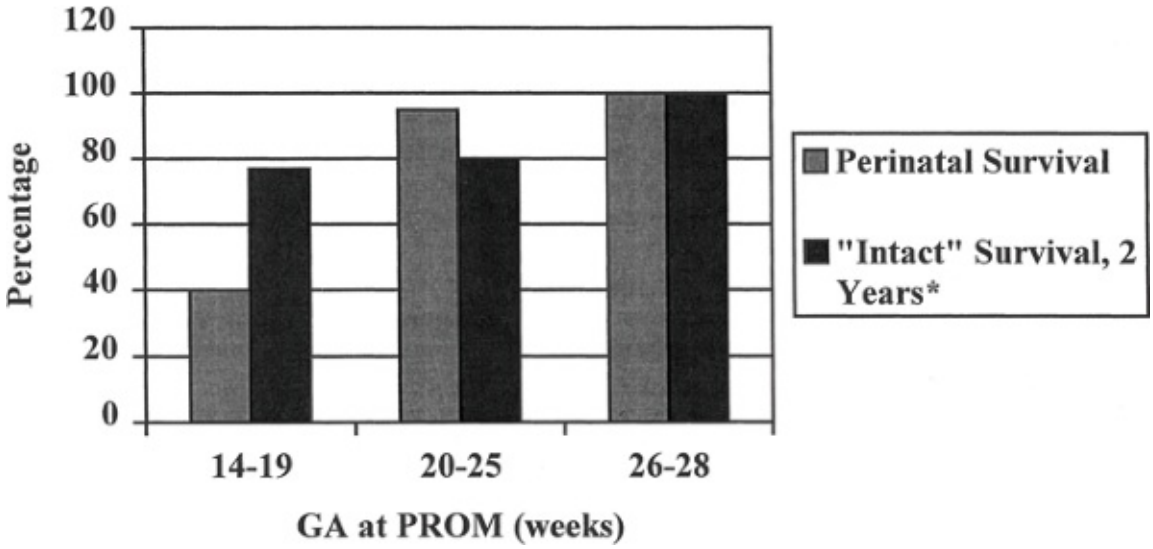

Figure 12.5 Outcome with expected management of second trimester PROM. (From Sweet RL, Gibbs RS. *Infectious diseases of the female genital tract*, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2002, with permission.)

TABLE 12.10 Management of Clinically Evident Chorioamnionitis

- Begin intravenous, broad-spectrum antibiotics, based on the array of aerobic and anaerobic organisms isolated in amniotic fluid of cases of clinical chorioamnionitis.
- There is no place for expectant management in clinically overt chorioamnionitis.
- The route of delivery should be determined by standard obstetric considerations. Immediate cesarean delivery increases maternal morbidity and does not improve neonatal outcome. However, the cesarean delivery rate is high in pregnancies complicated by clinical chorioamnionitis because of poor progress in labor, nonreassuring fetal heart rate patterns, and malpresentation.

Preterm Premature Rupture of the Membranes after Cerclage

No prospective studies have yet been published to resolve this clinical dilemma. There are hypothetical reasons to remove the cerclage (such as it serving as a nidus of infection) or to leave it in place (such as removal may result in prompt delivery).

Descriptive studies have not clarified the best course of management. With PPROM after cerclage, the author individualizes the risks and benefit of removal. In cases where infection is clinically evident, the cerclage must be removed and delivery achieved. Without clinical evidence of infection, the author favors cerclage removal when there is fetal viability and a gestational age of approximately 25 weeks or greater. On the other hand, when there is no evidence of infection and a previable pregnancy, then keeping the cerclage in place is advised.

Preterm Premature Rupture of the Membranes and Clinical Herpes Simplex Virus Infection

There are no controlled trials to guide management of PPROM when associated with herpes simplex virus (HSV) infection, and descriptive series have been small. The risks of expectant management (ascending HSV infection and fetal-neonatal herpes) should be weighed against the risks of preterm delivery. Accordingly, where the risks of prematurity are great (such as less than 30 to 32 weeks), expectant management—usually with prophylactic use of acyclovir or another antiviral—may be used. In the few reported cases of this management, the clinical episode of HSV, which usually lasts for 3 to 5 days, has resolved before the onset of labor, and there have been no cases of neonatal HSV infection. When the risks of neonatal infection appear greater than the risks of prematurity (e.g., at greater than 32 weeks), then cesarean delivery should be carried out in the face of clinically evident maternal genital herpes infection.

Summary Points
Management of Premature Rupture of the Membranes

- At or near term (≥34 weeks) induction usually is preferred; GBS prophylaxis is given with a positive screening culture at 35 to 37 weeks or with rupture of the membranes greater than 18 hours plus an unknown culture status.
- At 32 to 33 weeks, manage by either expectancy or by induction (especially with evidence of lung maturity). Give GBS prophylaxis. Do not use tocolytics; efficacy of corticosteroids is not clear at this gestational age.
- At 25 to 32 weeks, manage by expectancy. Give GBS prophylaxis and corticosteroids. The author gives antibiotics for 7 days to prolong pregnancy. No standard regimen is established. Ampicillin plus erythromycin is used most often. Use of tocolytics is controversial.
- At less than 25 weeks, manage by induction or expectancy, depending on gestational age and patient desires. The author does

not use tocolytics or corticosteroids in this situation. A course of antibiotics for 7 days may prolong pregnancy, as it does at 25 to 32 weeks.

Intrauterine Growth Restriction

Bronwen F. Kahn
John C. Hobbins
Henry L. Galan

Approximately 10% of the almost 4 million infants born each year in the United States are classified as low birth weight (LBW). Terminology used to describe the small fetus/newborn can be confusing. The term *low birth weight* is used clinically by pediatricians postnatally and is defined strictly as a birth weight of <2,500gm. Antenatally, the terms small for gestational age (SGA) and intrauterine growth restriction (IUGR) frequently are used interchangeably. However, the term *small for gestational age* encompasses a group of fetuses that are small for a variety of reasons that confer varying prognoses. These etiologies include infection, congenital malformations, aneuploidy, multiple gestation, maternal disease, malnutrition, and toxins and the normal or constitutionally small fetus. The term *intrauterine growth restriction* is a subgroup of SGA and more specifically identifies the fetus that is pathologically small. Placental insufficiency accounts for the majority of IUGR fetuses. It is important to recognize that not all fetuses or newborns classified as SGA are small due to pathologic reasons (i.e., constitutionally small) but simply represent the smaller fetuses/newborns at the lower end of the bell-shaped distribution of the normal population and are small for familial reasons. Conversely, some fetuses or neonates who are average for gestational age (AGA) may suffer from relative growth restriction if they are not achieving their individual, genetic growth potential. These babies may have normal weight percentiles for their gestational age but suffer from differential growth delay and show abnormal body proportions or ponderal indices. The prognosis for a given SGA fetus is dependent on the etiology.

The scope of the problem of IUGR is broad, not just because it increases morbidity and mortality of the fetus but also because it does so for the newborn and adult who the fetus is destined to become. IUGR places the fetus at risk for hypoxemia, acidemia, antepartum death, and intrapartum distress. Perinatal mortality rates in growth-restricted neonates are six to ten times greater than in normally grown age-matched controls. In one large series, 52% of unexplained stillbirths were growth restricted. In that series, suboptimal growth carried an odds ratio (OR) of 7.0 for sudden intrauterine unexplained death (95% confidence interval [CI] 3.3 to 15.1). IUGR places the neonate at risk for a number of metabolic disturbances, including polycythemia, pulmonary transition difficulties,

intraventricular hemorrhage (IVH), impaired cognitive function, and cerebral palsy. The threshold of viability is both later in gestational age and larger in birth weight among neonates with severe IUGR compared with normally grown infants who are delivered at extremely preterm ages. Several epidemiologic and animal studies in the early 1990s began to report on long-term sequelae of IUGR, including adult hypertension, heart disease, stroke, and diabetes. The theory of fetal programming as the origin of adult disease is commonly referred to as the "Barker hypothesis." The challenge in management of the IUGR fetus is to identify the condition and manage it so that adverse sequelae are minimized and balanced against the risks of premature delivery. The use of real-time ultrasound and Doppler velocimetry play pivotal roles in the diagnosis and management of IUGR. This chapter reviews normal placental–fetal growth, etiology of the SGA fetus, screening for growth restriction, and practical uses of ultrasound and Doppler velocimetry in the diagnosis and management of the IUGR fetus.

Determinants of Normal and Aberrant Placental Growth

Normal Placental Development

Normal growth of the fetus is dependent on normal placentation and growth of the placenta. The placenta is a dynamic and multifaceted organ that serves as

an interface between mother and fetus with the critical role of meeting the metabolic and circulatory demands of the growing fetus. The roles of the placenta include:

Nutritional: Provides oxygen, glucose, amino acid, and volume (fluid) transfer.

Immunologic: Protects the fetus from pathogens and the maternal immune system.

Endocrinologic: Produces numerous hormones, growth factors, cytokines, and other vasoactive mediators.

Metabolic: Serves as the respiratory organ and the kidney for the fetus and is responsible for elimination of carbon dioxide, metabolic acids, and other waste products from the fetus to maintain acid–base balance.

Research has begun to provide an understanding of the complexity of the implantation and placentation processes, which require the production and coordination of numerous angiogenic growth factors (fibroblast growth factor, hepatocyte growth factor, placental growth factor, vascular endothelial growth factor), cell-adhesion molecules, cytokines, nitric oxide, extracellular matrix metalloproteinases, hormones, and transcription factors (hypoxia-inducible factor). This process of coordination begins very early in pregnancy and can dictate whether the pregnancy grows in a normal or abnormal direction. By day 13, the cytotrophoblast layer has differentiated into invasive and noninvasive components. The invasive cytotrophoblast forms cell columns that anchor the trophoblastic tissue to the uterine epithelium and establish blood flow to the placenta and fetus. During this process, the invasive cytotrophoblast cells (extravillous trophoblast):

- *Migrate* through the syncytiotrophoblast and into the decidualized endometrium and

myometrium

- *Invade* the vessel walls of the maternal spiral arteries in these areas
- *Induce* the remodeling of the spiral arteries from high-resistance to low-resistance vessels.

As the invasive cell columns of the cytotrophoblast penetrate the syncytiotrophoblast, spaces called *lacunae* are created, which subsequently fuse to form the intervillous space with intervening syncytiotrophoblast columns called *trabeculae*. The process of intervillous space formation and spiral artery transformation directs an increasing maternal cardiac output into the intervillous space. Loss of spiral artery vessel media is the mechanism by which the spiral arteries decrease their resistance to blood flow (Fig. 13.1).

Angiogenesis represents the formation of new blood vessels from endothelial cells and is classified into branching and nonbranching stages. Branching angiogenesis occurs primarily in the first and early second trimesters and leads to the formation of the immature villous tree. Branching angiogenesis continues until the mid second trimester, when there is a transition to nonbranching angiogenesis. During this process, there is a dramatic elongation of the existing placental vascular tree. A dramatic decrease in vascular resistance and an increase in blood flow through the placenta are coincident with this process and occur via progressive loss of the musculoelastic media in the walls of the maternal spiral arterioles. The decrease in resistance is aided on the fetal side by further villous vascular branching, allowing both fetal and maternal circulations to convert to low-resistance, high-capacitance vascular beds. The progressive decline in vascular resistance is reflected in increasing end-diastolic velocities in Doppler flow velocity waveforms (FVW) of both the uterine and the umbilical arteries (Fig. 13.2). In fact, the resistance in the uterine artery has been shown to be lower on the placental side if the placenta is not in the midline, adding further support to the idea of placental-mediated remodeling of the maternal circulation.

Abnormal Placental Development

In pregnancies complicated by preeclampsia and IUGR, trophoblast invasion is limited to the decidualized endometrium, which results in failure of the spiral arteries to become low-resistance vessels. This failure can be detected by Doppler velocimetry of the uterine artery, which supplies blood to the spiral arteries. The blood FVWs in the uterine artery obtained with pulsed-wave Doppler velocimetry are reflective of the waveforms downstream at the spiral arteries. These abnormalities are identified on a Doppler FVW profile by a high-resistance pattern (low velocity of flow at end-diastole relative to that at systole) and by a protodiastolic (early diastolic) notch (Fig. 13.3). Failure of this process to occur on the maternal side of the circulation may lead to adverse effects on both the mother and the fetus. Maternal vascular endothelial dysfunction may lead to production of a variety of vasoactive mediators, which could subsequently lead to the development of preeclampsia. Sibai and colleagues have recently published a hypothesis addressing the observation that preeclampsia and IUGR share similar placental pathology and that women who have had a pregnancy complicated by either are at higher risk of cardiovascular

disease later in life. They propose that endothelial dysfunction underlies both conditions by predisposing to shallow placentation but that women with metabolic syndrome are prone to preeclampsia. This may be mediated by the action of elevated circulating cytokines. Women with no predisposition to metabolic syndrome, however, may develop IUGR but not preeclampsia. A variety of villous and vascular abnormalities have been described in the placenta of the IUGR fetus. Placentas from IUGR pregnancies have fewer gas-exchanging villi. The villi also are slender, elongated, poorly branched, and poorly capillarized. Vascular abnormalities include reduced branching of stem arteries and disorganized vascular patterns, including less coiling as depicted by placental vascular cast studies. The reduced branching seen in the villous vasculature creates abnormal blood flow and an increase in vascular resistance to flow that can be likened to that of an electric circuit—the fewer downstream tributaries that exist from the main supply line, the higher the resistance.

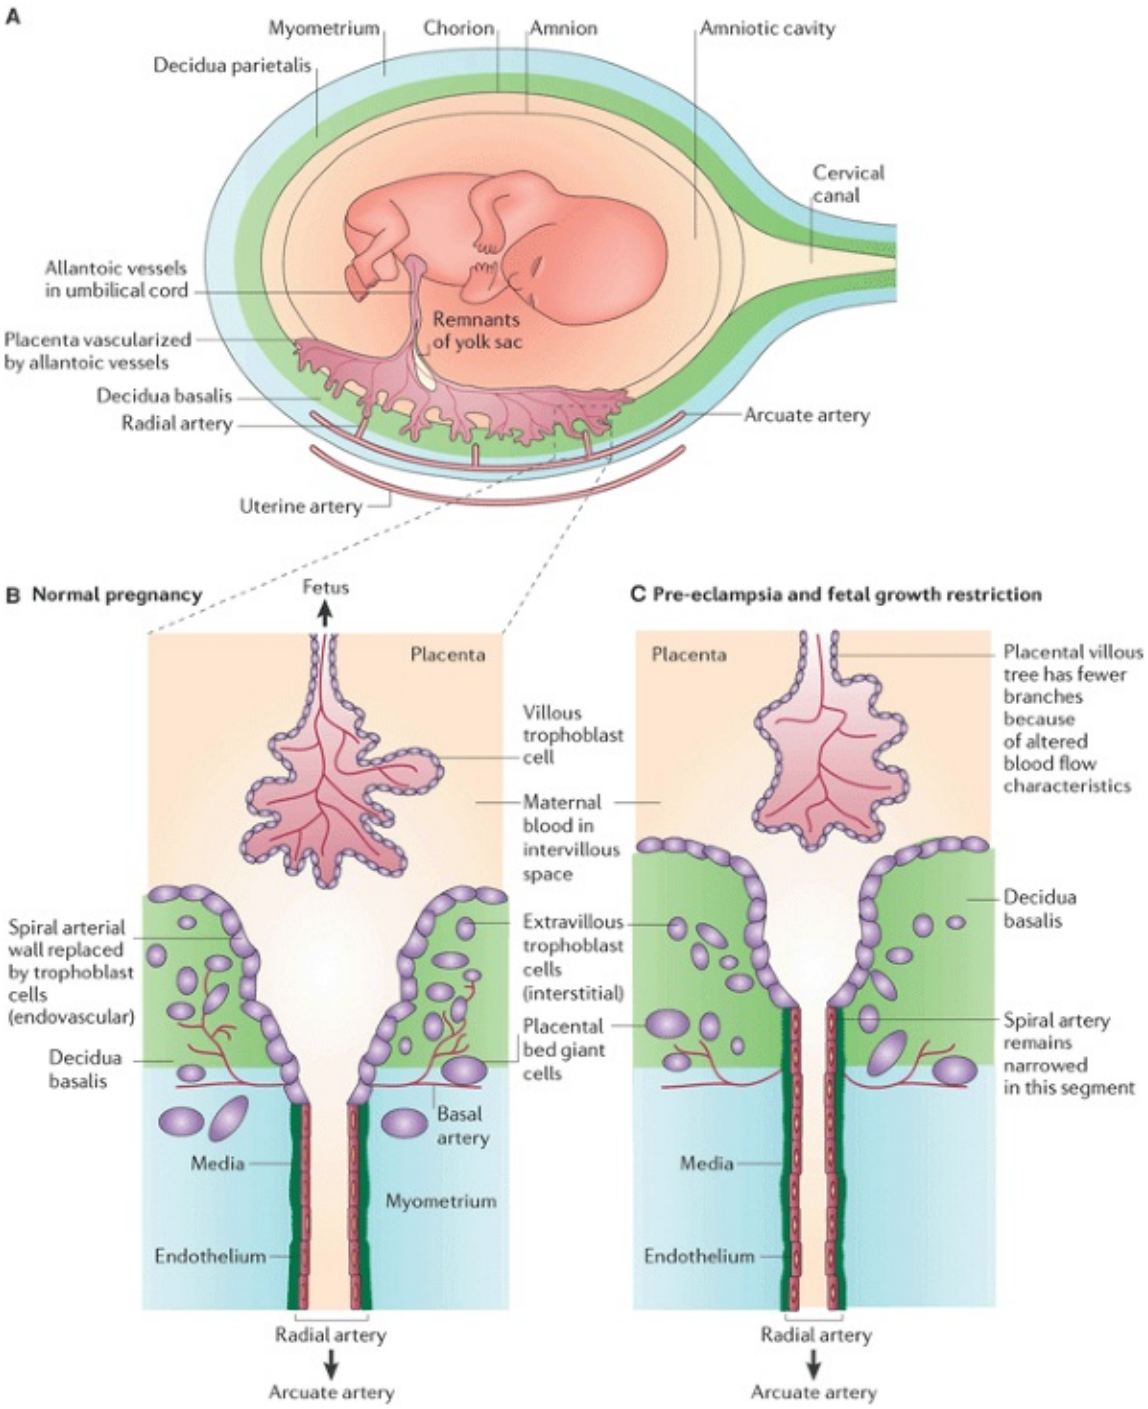

Figure 13.1 (A) Gross anatomy of uterus with placental implantation and blood supply. Remodeling of the spiral arteries in normal pregnancy **(B)**, demonstrating the normal dilation of the artery by means of loss of elastic vascular media and preeclampsia or fetal growth restriction **(C)** with abnormal invasion and remodeling that impedes the development of low-resistance flow. Determinants of Normal and Aberrant Fetal Growth

Normal Fetal Growth

In order for a fetus to grow normally, the placental developmental activities described earlier must proceed

undisturbed. Fetal growth velocity increases across gestation until it peaks at 30 to 35 g per day or 230 to 285 g per week between 32 and 34 weeks. After that, the rate of weight gain decreases, reaching a plateau at 40 weeks and even a decline, or weight loss, at 41 to 42 weeks. At 37 weeks gestation, the placenta has reached maximal villous nutrient exchange via a surface area of 11 m^2 and weighs approximately 500 g. Coincident with this is maximal amniotic fluid volume and maximal human placental lactogen levels, suggesting peak placental function. Interestingly, although the fetus grows less quickly at term, calorie acquisition by the fetus continues to be quite high. At this time in pregnancy, the fetus is rapidly accumulating fat that provides thermal stability for the immediate postnatal period. Fat has a high caloric content (9 calories/g) compared with carbohydrates and proteins (4 calories/g). The high metabolic demands of the fetus result in a fetal temperature that is 0.5°C above that of the mother. This difference in temperature is seen in the maternal immediate postpartum shivering, which reflects a compensatory response to the loss of fetal-derived heat.

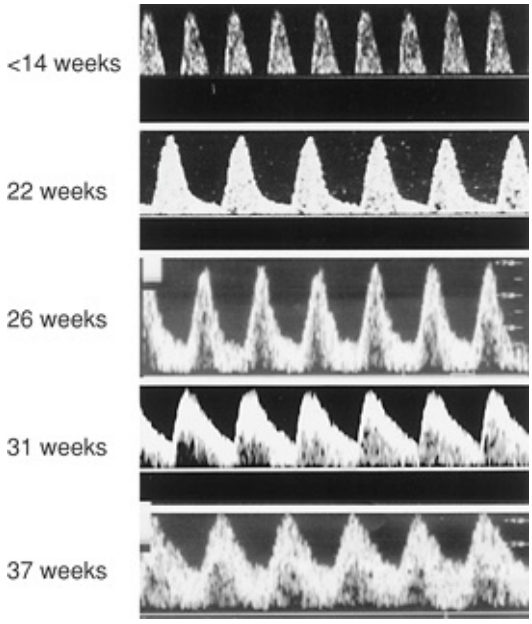

Figure 13.2 Doppler FVW profiles in the umbilical artery across normal gestation. Note the progressive increase in end-diastolic flow.

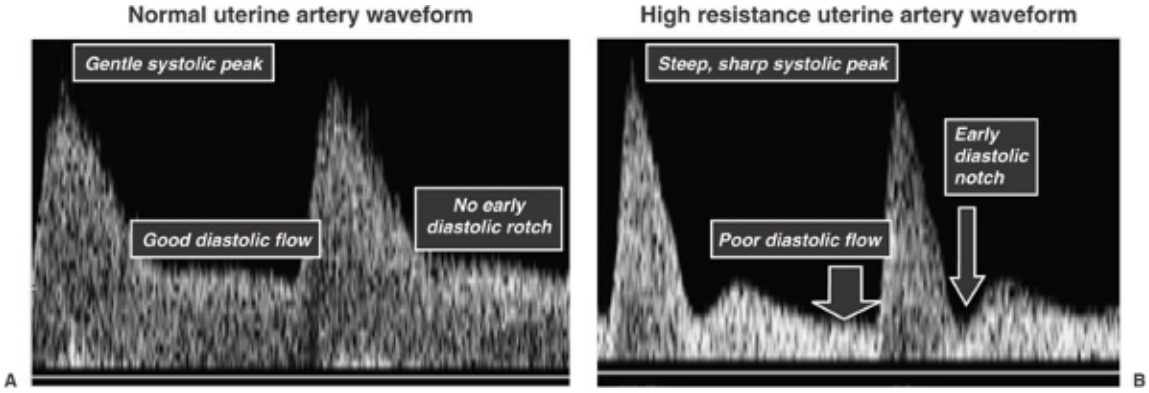

Figure 13.3 Uterine artery FVWs demonstrating normal end-diastolic flow and absence of notching **(A)** and notching and poor diastolic flow **(B)**. The worst prognosis is associated with bilateral notching and poor flow that does not resolve with the later wave of trophoblastic invasion by 24 to 28 weeks. (Images courtesy of Lorraine Dugoff, M.D.)

For the fetus to achieve maximal growth potential, the uterine-placental-fetal circulation must be normal in order for the fetus to receive a variety of necessary substrates. A key feature of the uterine vascular bed in pregnancy is the lack of responsiveness to changes in blood gas tensions (PO_2, PCO_2). Thus, oxygen therapy for either maternal disease or for fetal benefit will not cause vasoconstriction. In contrast, the lack of responsiveness and lack of autoregulation in the uterine vascular bed renders these vessels incapable of compensating for maternal hypotension. Animal studies have shown that the volume blood flows (mL per minute) in the uterine and umbilical circulations are unaffected by maternal hyperoxygenation. This is important clinically since the improvement in fetal PO_2 by maternal oxygen therapy does not appear to have an adverse affect on fetal blood flow.

Glucose, oxygen, and amino acids are the major substrates needed for normal fetal growth. Glucose freely crosses the placenta by facilitated diffusion into the fetus. The maternal-fetal glucose concentration gradient that exists widens with advancing gestational age in order to accommodate the increasing metabolic demands of the fetus. Under normal circumstances, glucose is metabolized by the fetus to produce energy in the form of adenosine triphosphate (ATP) in the presence of oxygen. Oxygen passes across the placenta to the fetus by simple diffusion and is regulated by concentration gradients and uterine blood flow, as described by the Fick principle. Transplacental transport of all essential and nonessential amino acids

occurs by active transport. Animal and human studies have confirmed that amino acid carrier systems are present on both the maternal and fetal sides of the placenta. The placenta is quite active in amino acid metabolism, contributing significantly to net umbilical-fetus uptake of certain amino acids.

Abnormal Fetal Growth

Failure of the placenta to deliver any of these primary substrates to the fetus will result in

diminished protein production by the fetus, reduced glucose metabolism, and reduced glycogen deposition in the liver. If oxygen supply is markedly reduced either from an acute or chronic insult, the fetus will convert from an aerobic to an anaerobic metabolic state in order to meet energy (ATP) requirements. Anaerobic metabolism is far less efficient at producing ATP from a given unit of glucose compared with aerobic metabolism. Furthermore, anaerobic activity will produce “fixed” acids (lactate, urate, etc.), which diffuse slowly across the placenta thus accumulating in the fetal system. If the anaerobic process is not reversed, the accumulation of acids will consume available buffers, and the fetal blood pH will fall, leading to an acidemic and acidotic fetus.

The IUGR fetus attempts to compensate for reduced substrate delivery by several mechanisms. From a metabolic standpoint, the fetus changes the maternal–fetal glucose gradient. The normally wide glucose gradient that exists between the mother and fetus, which is needed for movement of glucose to the fetus, widens further. This compensatory mechanism enhances glucose movement across the placenta to the fetus. The smaller AC noted in the IUGR fetus is a result of less hepatic glycogen formation in order to maximize glucose availability. In a similar fashion to the liver, fat stores, which are normally an important depot site for fat-soluble vitamins and fatty acids, are reduced. This change in body composition is reflected in the ponderal index, which neonatologists use as an index of “scrawniness.” The fetus also adjusts to reduced nutrient delivery by redistributing systemic blood flow to vital organs. The fetus will reduce flow to nonvital organs by reducing vascular resistance and increasing blood flow to the brain, which normally has a relatively high vascular resistance pattern compared with other organ systems. This can be demonstrated with pulsed-wave Doppler velocimetry of the middle cerebral artery (MCA), in which the flow velocity profile shows an increase in end-diastolic velocity. Other organs being “spared” through vascular redistribution include the heart and adrenal glands.

Intrauterine Growth Restriction Defined

A number of definitions of IUGR have been proposed based on percentile, standard deviation (SD), or growth rate. The most commonly used clinical definition of *intrauterine growth restriction* is an estimated fetal weight (EFW) less than the tenth percentile as determined by ultrasound. This mirrors the definition of *small for gestational age*, which originally was described by Battaglia and Lubchenco in 1967 as a birth weight less than the tenth percentile for gestational age. They noted that SGA infants were at increased risk for neonatal death. The problem with the tenth percentile as a cutoff for the diagnosis of IUGR is that a number of fetuses with an EFW below that value will be normally small, otherwise referred to as “constitutionally” small and not at risk. Studies have demonstrated that if determinants of birth weight such as maternal ethnicity, parity, maternal weight, and height are considered, up to 50% of fetuses at less than the tenth percentile will be constitutionally small. This has been the basis for using other definitions, including less than the third or fifth percentile or less than two SDs from the mean. Some authors have suggested using an abdominal circumference (AC) of less than two SDs for gestational age. The AC measurement represents a single objective ultrasound measurement rather than a combination of several fetal biometric ultrasound parameters into a formula where each parameter is weighted differently. This is the measure most closely related to pathologic

growth restriction, as it reflects loss of hepatic glycogen stores and subcutaneous fat, which is correlated with fetal nutritional status.

While it seems that an EFW less than the tenth percentile is not a sufficiently strict definition of IUGR, there is also a significant problem associated with the use of more strict criteria. If a definition of less than the third percentile is used, there is a reasonable chance that one could miss some fetuses that do not meet their growth potential and could be at risk for adverse events. No receiver operator curves have been established to assess sensitivity and specificity in order to establish a "cutoff" for the diagnosis of IUGR. This has been quite difficult to do, in part because of a wide biologic variation between patients and because of a wide variation of parameters used to diagnose IUGR (EFW, AC <2 SD, etc.). Customized growth curves, such as those envisioned and created by Gardosi, which include variables that impact fetal size, may be the answer to establishing a better cutoff value for IUGR. These growth curves are calculated based on maternal ethnicity, parity, height and weight, and fetal gender. When these curves were used in a large retrospective cohort study and compared with the standard population-based growth curve that is based on gestational age alone, a further 4.1% of infants were identified who were SGA. These babies had perinatal outcomes comparable to infants who were SGA by population-based standards, with three- to eightfold increases in perinatal morbidity and mortality above AGA neonates. This study also identified a population of babies who were SGA by population-based standards but not by customized curves and whose perinatal outcomes were similar to AGA babies, with no increased risks based on their size. Software

is available (Gestation-related Optimal Weight (GROW) at *http://www.gestation.net*) in which one may enter specific maternal and fetal variables to generate such a customized growth curve.

Etiology of Intrauterine Growth Restriction

The type and timing of insult during fetal development will dictate the subsequent development and morphology of the fetus. Fetal growth in the first trimester is characterized primarily by hyperplasia (growth in the number of cells), in the second trimester by a combination of hyperplasia and hypertrophy (growth in the size of existing cells), and in the third trimester primarily by hypertrophy. If an insult occurs in the first half of pregnancy where hyperplasia predominates, all fetal cell numbers can be reduced and lead to a small fetus that is symmetrically proportioned. That is, somatic and cerebral growth will both be similarly reduced. The underlying etiology of symmetric IUGR varies widely and includes karyotypic abnormalities, congenital anomalies, or congenital infections. Maternal medical illness, obstetric conditions, or primary placental pathology place the fetus at risk for uteroplacental insufficiency that may lead to a small fetus that is asymmetrically proportioned. Because there is significant overlap between these two types, body proportion alone cannot be used to determine the etiology. If an insult that typically causes uteroplacental insufficiency occurs sufficiently early in pregnancy, there can be an impact on hyperplasia of cells and a symmetric growth pattern. More commonly, there is an impact on hypertrophy that occurs late in pregnancy and primarily affects fat and hepatic glycogen deposition. The reduction in hepatic glycogen stores reduces liver

size and results in an increase in the head circumference to abdominal circumference, which defines asymmetric growth. Asymmetric growth is also characterized by a redistribution of fetal cardiac output to vital organs including the brain, heart, and adrenal glands. The redistribution of blood flow to the head allows the fetal head and brain to be preserved and to maintain a normal growth velocity compared with parameters of somatic growth (abdomen and extremities). This is the basis for the common phrase, “brain sparing.” Thus, the relative proportions of fetal dimensions can provide some insight to the etiology of IUGR based on the symmetric or asymmetric nature of the ultrasound parameters.

Diagnosis of Intrauterine Growth Restriction

Dating the Pregnancy

Accurate dating of pregnancy begins with the establishment of the estimated date of confinement (EDC) based on information gathered on the last menstrual period (LMP). Normal human gestation lasts 280 days from the LMP. The 280-day gestation is, in turn, based on a normal menstrual cycle length of 28 days. However, many patients do not know the date of their LMP, and others will have menstrual cycle lengths that vary from 21 to 35 days, which will shorten or lengthen the gestational dating, respectively. Therefore, the EDC should be adjusted accordingly. Other important questions regarding the LMP include regularity, certainty (calendar recorded, etc.), date of conception, and oral contraceptive use at the time of the LMP. It has been reported previously that the LMP is unreliable up to one third of the time, and it is particularly in these circumstances that ultrasound becomes a valuable resource. Early ultrasound has been shown to be more accurate than most menstrual dating. Because it is more common to ovulate late in a cycle than early, gestational age established by ultrasound is usually younger than menstrual age. Therefore, the new EDC is most often later, meaning that if the first ultrasound is done late in the second trimester, SGA may be overdiagnosed. Well-established dating reduces the incidence of post-term pregnancy as well as false-positive diagnoses of SGA.

After establishment of gestational age by LMP and ultrasound, clinical acumen can lead to a presumptive diagnosis of IUGR. The most commonly used clinical tool for assessing growth of the pregnancy is serial measurement of uterine fundal height during regular clinic visits. Measurement of uterine fundal height (in centimeters) from the symphysis pubis across the uterus to the top of the fundus provides an index of growth for which a nomogram has been reported. In general, the uterine fundus will be within 2 cm of the gestational age in weeks. This simple screening technique has been reported to be up to 75% accurate in diagnosing IUGR. However, the measurement may be erroneous because of several variables that impact uterine size, including interobserver variation, obesity, uterine fibroids, multiple gestation, and polyhydramnios.

Ultrasound

Ultrasound remains the cornerstone for the diagnosis and management of the SGA fetus. The diagnosis of SGA is made by combining ultrasound biometric measurements of the fetus

into a formula that calculates the EFW. The most commonly measured fetal biometric parameters include the biparietal diameter (BPD), the head circumference (HC), the AC, and the femur length (FL). As described earlier, SGA is diagnosed when the EFW falls below the tenth percentile for gestational age. If available, it is important to use local standards for the diagnosis, as it has been shown previously that the tenth percentile for EFW can vary depending on the population studied. For example, a fetal weight nomogram constructed by ultrasound in Colorado suggests that consistently, across gestational ages, fetuses in Denver are lighter than fetuses at sea level. The Shepard and Hadlock formulas are the most commonly used

formulas for calculating EFW. Table 13.1 shows the EFW using Hadlock's formula plotted across gestation, with separate EFWs for the tenth percentile depending on fetal gender. In general, the more parameters included, the more accurate the EFW (Hadlock: 4 parameters; Shepard: 3 parameters). However, as the number of parameters in the formula increases, EFW begins to lose accuracy because of the standard error of the method associated with the measuring of each parameter. Using the Shepard formula, a practitioner will obtain an EFW that will fall within 5% of the true weight 50% of the time and within 10% of the weight 80% of the time.

A commonly encountered clinical scenario is the patient who is sent for evaluation of suspected IUGR in whom clinical dating criteria are poor and gestational age unknown. For example, a fetus measuring 3 to 4 weeks less than expected may be the result of any of the following three possibilities:

. The patient is 3 to 4 weeks off on clinical dating.
. The fetus is truly 3 to 4 weeks less than clinical dating but is genetically predisposed to be small.
. The fetus is small, growth-restricted, and at risk.

Several ultrasound strategies are available to address this problem and to categorize the dating of pregnancy with reasonable accuracy. Ultrasound biometric parameters can be used to calculate ratios and provide some insight into the severity of the IUGR. In the 1970s, Campbell and Thoms first described the HC/AC ratio. In approximately 60% of cases with IUGR, the HC/AC ratio is greater than the 90th percentile for gestational age, which suggests a brain-sparing process. The FL/AC ratio provides information on the amount of muscle and fat mass present on the fetus, providing a picture of “scrawniness” for the fetus. This is analogous to the ponderal index used by neonatologists. Unlike the HC/AC ratio, the FL/AC ratio is gestational-age independent and may be useful when the gestational age is unknown. Other aspects of the fetus that appear to be relatively independent of the IUGR process and that remain consistent throughout gestation include the transcerebellar diameter (TCD), foot length, and epiphyseal centers. These are other strategic tools to help approximate the gestational age when dating criteria are poor.

The TCD measured in millimeters mirrors the gestational age until about 22 weeks and then accelerates. Cerebellar measurements are shown in Table 13.2. If the

gestational age by TCD is greater than that suggested by other biometric parameters and is consistent with the unsure LMP dating criteria, it may be that the fetus is indeed further along and possibly growth restricted. In a similar fashion, Hadlock and colleagues showed that the foot length is gestational-age independent and may be useful in IUGR. Although not useful for estimating gestational age in the second and early third trimester, the appearance of epiphyseal centers of the long bones on ultrasound provides reassurance that the fetus is in the second half of the third trimester of gestation. In general, the distal femoral epiphysis appears at 32 to 34 weeks gestation, the proximal epiphysis at 36 weeks, and the proximal humeral epiphysis at 38 weeks. In a nondiabetic population, the presence of a distal femoral epiphysis of greater than 3 mm and the presence of any proximal tibial epiphysis indicate a mature lung profile in almost all cases. The presence of the tibial and humeral epiphyseal centers are useful markers of pulmonic maturity, while the absence of these centers may suggest a more immature fetus.

Serial ultrasound measurements of fetal biometry and EFW also are useful in assessing the growth-restricted fetus. The fetus that demonstrates appropriate interval growth, that is, continued growth along nomograms, probably represents a fetus genetically predisposed to being small and one that likely is not at immediate risk. Relying on serial ultrasounds does not, however, determine exact gestational age or how the fetus is doing at the first evaluation. As with all of these biometric tools, it is best to look at the big picture and formulate an opinion based on all information that one can obtain with the ultrasound. Pulsed-wave Doppler velocimetry, which has revolutionized the management of the IUGR fetus, also can be used to help delineate whether a fetus is “normal” and small or “abnormal” and small based on FVW assessment in several fetal vessels.

Screening, Prevention, and Treatment of Intrauterine Growth Restriction

Given that pathologic growth restriction may affect up to 3% to 4% of all live births as well as a large proportion of stillbirths and can have profound and lifelong consequences, efforts at screening and prevention are warranted. IUGR meets several criteria justifying a screening program. It is common, has well-defined and easily identifiable risk factors, has a detectable preclinical state, and early diagnosis may allow enough time to enact interventions that can affect outcome. Although treatment options for a growth-restricted fetus remain limited, nonetheless there are surveillance techniques and interventions that can improve outcome and avoid stillbirth. Preventive strategies in general may be divided into primary, secondary, and tertiary efforts. Primary measures are most cost-effective and are aimed at preventing the onset of the targeted condition. Secondary efforts attempt to identify asymptomatic patients in a preclinical disease state and are the level at which screening tests may be useful. According to the 2005 U.S. Preventive Services Task Force's *Guide to Clinical Preventive Services*, tertiary prevention is defined as the care of established disease, is generally the least effective approach, and comprises most of the available literature for the care of SGA pregnancies.

Primary Prevention

Although many risk factors for bearing a growth-restricted baby are not amenable to change, there are several modifiable risk factors by which the chance of growth restriction in a planned pregnancy can be reduced. Factors that should be assessed at preconceptual counseling include reproductive history, exposure to environmental hazards and toxins, substance abuse, smoking history, medication use, nutritional status, folic acid supplementation, weight, genetic and family history, chronic illness, infectious and

---

vaccination history, social and mental health, and family planning. Maternal risk factors for IUGR include medical illness (i.e., hypertension, diabetes mellitus, cardiac disease, or autoimmune disorders), teratogenic exposures, periodontal disease, thrombophilias, high altitude, living in a developing country or low socioeconomic status, race, or personal or family history. A history of a prior SGA infant gives a 25% chance of recurrent growth restriction. Early sonographic dating provides the most accurate dating of a pregnancy and significantly reduces the number of women diagnosed or suspected to have IUGR simply by clearly establishing gestational age.

Of the mentioned risk factors, interpregnancy interval is potentially one of the more easily controlled variables. The optimal interval between pregnancies is 18 to 24 months. With less than 6 months between delivery and conception, the likelihood of SGA in the second child is 30% higher and the likelihood of LBW is 40% higher (due to higher rates of preterm birth as well as IUGR). Assisting women in making their reproductive life plans is one of the most effective methods of risk reduction available.

Interventions aimed at smoking cessation is beneficial to the rates of growth restriction. Meta-analysis of 48 trials with greater than 20,000 subjects found that intervention leads to

a significant reduction in smoking. Smoking cessation interventions also reduced LBW (relative risk [RR] 0.81; 95% CI 0.70 to 0.94) and preterm birth (RR 0.84; 95% CI 0.72 to 0.98), and there was a 33 g (95% CI 11g to 55g) increase in mean birth weight. The most effective strategies included support, encouragement, and reward. These are simple interventions that should be easily attainable in any preconceptional or prenatal visit.

Although there are no specific studies showing the effect of exercise or weight reduction on rates of IUGR, there are many studies on diet and nutrition. Nutritional supplementation clearly will be most effective in an under- or malnourished population. In general, there are not sufficient data to recommend any nutritional supplementation beyond a well-balanced diet and a prenatal vitamin with folate at this time.

Although periodontal disease has been associated with as much as a fivefold increase in the risk of delivering a preterm LBW infant, treatment has not been reliably shown to improve outcome.

Secondary Prevention

Among women with risk factors for IUGR, the careful control of preexisting disease, especially diabetes, and modification of amenable risk factors are essential. These women are candidates for more aggressive screening for early detection of a preclinical disease state.

Obstetricians have screened women for fetal growth abnormality for decades by using the simple measurement of fundal height from the pubic symphysis. In fact, this has been shown to be a poor screening test, in that it misses half of growth-restricted fetuses and overdiagnoses IUGR among normally grown fetuses. The most careful fundal height measurements have a sensitivity of only 26% to 76% in predicting IUGR. Maternal obesity, fetal lie, bladder volume, uterine fibroids, and parity may affect the accuracy of this measurement, which is most sensitive when performed by the same clinician longitudinally and plotted for an individual's growth rather than against standardized values. The Cochrane Database review included only one trial and found that there is insufficient evidence to evaluate the efficacy of this test in prenatal care. Nonetheless, fundal height lag of 4cm or more behind gestational week is considered concerning and should prompt a sonographic look at fetal growth. Normal fundal height in a woman with risk factors for IUGR does not provide sufficient reassurance. These women still should be followed with screening sonograms for fetal growth.

The maternal side of the uteroplacental circulation also has been investigated by Doppler ultrasound and FVW analysis in hopes of identifying those pregnancies at increased risk for developing preeclampsia, abruption, and IUGR. Since the original reports on uterine artery Doppler waveform analyses, several important methodological issues have been established that include proper technology (color Doppler-guided, pulsed-wave Doppler sampling, and site of sampling) and normal reference values (SD ratio >2.6 or resistance index >0.58). The pathophysiologic basis for abnormal uterine artery resistance is that resistance of the smaller spiral artery branches that lie downstream fail to become low-resistance vessels as a result of poor trophoblastic invasion early in pregnancy.

This test has gained a popular role in screening for preeclampsia and IUGR at 20 to 24 weeks gestation. Scoring systems based on FVW abnormalities (increased resistance and notching) have been developed. For the most part, the highest risk for encountering an adverse pregnancy outcome goes up by having both early diastolic notching and high resistance, especially if these occur bilaterally.

A recent, large study has shown the utility of uterine artery Doppler studies at 20 weeks gestation for prediction of complications due to uteroplacental insufficiency. Among 458 women with no risk factors and 170 with high-risk factors, uterine artery notching and resistive indices were evaluated for efficacy in predicting preeclampsia, SGA (birthweight <5th percentile), placental abruption, stillbirth, or early neonatal death. Among the high-risk women, the sensitivity to predict such adverse outcomes was 81.4%, specificity 89.0%, positive predictive value (PPV) 71.4%, and negative predictive value (NPV) 93.4%. These authors conclude that screening is not justified among low-risk women but identifies the majority of high-risk women who will develop such complications. In addition, normal Doppler studies in high-risk women returned their rates of complication to the baseline. There is, however, subjectivity and interobserver variation in the identification of notching, which may require standardization,

---

perhaps by computerized interpretation, in order to refine the sensitivity and reproducibility of this test.

Biochemical Markers

There is increasing evidence regarding the utility of biochemical markers to predict adverse pregnancy outcome in general, including growth restriction.

First-Trimester Biochemical Markers

When measured between 10 and 14 weeks gestation as part of a sequential or integrated screen for Down syndrome, low maternal serum pregnancy-associated plasma protein A (PAPP-A) has been associated in several studies with an increased risk of adverse pregnancy outcome, including nearly a threefold increased likelihood of IUGR. When combined with elevated second-trimester maternal serum α-fetoprotein (MSaFP), the effect is magnified to an eightfold increase in growth restriction. Nonetheless, the PPV of these studies is poor, with only 32% of women with both low PAPP-A and high MSaFP delivering LBW infants. Free ß human chorionic gonadotropin (ß-hCG) at extremely low levels in the first trimester also has been associated with poor obstetric outcome, including IUGR.

Second-Trimester Biochemical Markers

The maternal serum quad screen, which is now routinely offered at 15 to 21 weeks for screening for trisomy and neural tube defects, consists of levels of AFP, ß-hCG, unconjugated oestriol (uE3), and inhibin A. These markers also have been evaluated extensively for their associations with other adverse obstetric outcomes. An abnormal value of one marker may confer a slightly higher risk of growth restriction when defined as birthweight less than the fifth percentile, but two abnormal markers doubles that risk, and

three or four abnormal markers confers a sixfold increase in risk in addition to elevated risks for miscarriage, stillbirth, preterm birth, and preeclampsia. In the presence of the stronger of these markers or combinations of findings, one may consider treatment with low-dose aspirin and uterine artery Dopplers at 20 to 24 weeks and certainly should maintain a higher index of suspicion and close surveillance for IUGR and preeclampsia. However, it should be noted that PPVs for these tests are low, so their use in formulating treatment plans may be questioned. Negative tests, however, are useful for reassurance.

Other Biochemical Markers

Elevated circulating activin-A throughout pregnancy has been associated with pathologic growth restriction but is not yet clinically useful in differentiating between constitutionally small and growth-restricted fetuses. Abnormal maternal and fetal serum leptin levels and hyperhomocysteinemia also may be associated with IUGR, but these markers remain investigational.

Antihypertensive and Prophylactic Aspirin Therapies

Aspirin, at a wide range of dosages, has been used in dozens of trials examining its effect on recurrent preeclampsia and poor placentation and has been found to have benefit of varying degrees. At low doses (75 to 125 mg per day), it has been found to be a safe treatment if started at 10 to 20 weeks. Because there may be an increased risk of gastroschisis (OR 2.37; 95% CI 1.44 to 3.88) among fetuses of women who took it in the first trimester in just three studies included in a large meta-analysis, current recommendations are to begin at 12 to 14 weeks. The overall risk of congenital malformations in offspring of women who were exposed to aspirin was not significantly higher than that in control subjects (OR 1.33; 95% CI 0.94 to 1.89). A Cochrane review of low-dose aspirin therapy in women at risk for developing preeclampsia (25 randomized controlled trials [RCTs] with n = 20,349) showed an overall reduction in SGA by 10% and a decrease in perinatal death by 16%. If therapy was started earlier than 20 weeks, the reduction in SGA improved to 18%, and if the dose was greater than 75 mg daily, growth restriction was decreased by 21%. These differences barely approached statistical significance and are described as “small to moderate” benefits. Another meta-analysis of women with abnormal uterine artery Doppler studies treated with aspirin versus placebo or no treatment found that women on aspirin had babies who were on average 82 g heavier than controls, but this result did not reach statistical significance. Which women are likely to benefit most, what dose to use, and when to begin treatment have yet to be adequately assessed.

There are multiple trials examining the effect of treating mild or moderate chronic hypertension on perinatal outcome and particularly birth weight. In a large meta-analysis, ß-blockade was associated with a 56% increase in SGA over no therapy, and other antihypertensives compared with no therapy showed no effect on SGA. This led to the conclusion that treatment of mild to moderate chronic hypertension, defined as systolic blood pressure (SBP) 140 to 169/diastolic blood pressure (DBP) 90 to 109, is not of benefit. Neither bed rest nor nutritional supplementation have been found to have benefit in the prevention of growth restriction. Heparin therapy has been shown in some studies,

although not in others, to have benefit in women with prior growth restriction and antiphospholipid antibody syndrome (APLS). Currently, it is recommended that women with true APLS should be given low-dose aspirin and subcutaneous heparin starting from the time of documentation of fetal cardiac activity.

Treatment or Tertiary Prevention

Although methods for prediction and surveillance are improving, efforts at treating or preventing the development

---

of IUGR have been disappointing, leading some to question the value of screening programs. With the understanding that the course of growth restriction is most likely established in the first and early second trimester, therapeutic interventions that are instituted after that point can be viewed as too little, too late. However, one can still follow these fetuses with close surveillance and intervene with carefully timed delivery in hopes of improving outcome.

While maternal uterine artery Doppler studies may help to predict IUGR, fetal arterial and venous Doppler studies, as described previously, are useful in the diagnosis and assessment of established growth restriction. Many trials have now shown that umbilical artery Doppler of fetuses with the diagnosis of IUGR, when used to guide timing of delivery, lead to improved perinatal outcomes. A meta-analysis of 11 studies found a 38% decrease in perinatal mortality, lower rates of admission to the hospital, and fewer inductions of labor when umbilical artery Doppler was used as part of antenatal surveillance. There are fewer data regarding the effect of venous Doppler on perinatal outcome.

There is no question that antenatal corticosteroids are of benefit to the larger population of preterm infants and should be administered when delivery appears imminent or likely within the next 7 days. This is one of the most effective treatments that can be offered to improve outcome, although clearly it has no effect on the incidence of growth restriction. The benefits of this treatment in prematurity to reduce the risk of respiratory distress syndrome (RDS), IVH, and neonatal death are widely accepted, but their short-term effects have not been assessed in large numbers specifically in the subgroup of preterm growth-restricted fetuses. It has been demonstrated that corticosteroids have depressant cardiovascular effects on AGA preterm infants, causing decreased variability of the fetal heart rate and decreased biophysical profile (BPP) scores. Based on animal models, the mechanism of these changes is thought to be transient fetal hypertension and increased vascular resistance. A recent small series examining the cardiovascular changes after administration of antenatal corticosteroids found that although half of the 19 fetuses studied showed improvement, and even transient return of previously absent end-diastolic flow, the other half of those studied with absent or reversed end-diastolic flow in the umbilical arteries showed deterioration of Doppler indices. In fetuses that are already compromised, there may not be sufficient cardiovascular reserve to tolerate even a small, transient increase in demand, and these fetuses may show further decompensation under these circumstances. However, we are not yet able to predict how an individual fetus will respond and therefore steroids should continue to be used for fetal lung benefit in all

imminent preterm births.

In the longer term, however, steroids have been shown in a large population-based study to have as much benefit in growth-restricted infants as in AGA neonates. The Vermont Oxford Network database was used for a review of nearly 20,000 deliveries of growth-restricted neonates between 25 and 30 weeks gestation with birth weights between 501 and 1,500 g. Maternal prenatal glucocorticoid administration was associated with significantly lower risks of RDS (OR 0.51; 95% CI 0.44 to 0.58), IVH (OR 0.67; 95% CI 0.61 to 0.73), severe IVH (OR 0.50; 95% CI 0.43 to 0.57), and death (OR 0.54; 95% CI 0.48 to 0.62) but not necrotizing enterocolitis (NEC).

Unfortunately, neither bed rest nor heparin have been shown to reverse the course of IUGR, although as noted previously, heparin may be of benefit in the prevention of IUGR in pregnancies with APLS. Nutritional supplementation or even total parenteral nutrition have been shown to have effect only if the etiology of growth restriction is malnutrition.

Circulation in the Normal and Intrauterine Growthrestricted Fetus

Normal Fetal Circulation

The umbilical vein leaves the placenta and enters the umbilicus with oxygen and nutrient-rich blood and volume, which are necessary for normal development of the fetus. The venous vasculature of the liver is depicted in Figure 13.4 and consists of the umbilical and portal veins, hepatic veins, and the ductus venosus (DV). The umbilical vein turns acutely cephalad as it passes through the umbilicus and in the inferior portion of the falciform ligament. The hepatic portion of the umbilical vein then travels horizontally and posteriorly and bends to the right, where it joins the transverse part of the left portal vein. These then join the right portal vein, which branches anteriorly and posteriorly. As the hepatic portion of the umbilical vein bends to the right, the DV emanates, heading in a posterior and cephalad direction and joins the inferior vena cava (IVC) just below the diaphragm. The three hepatic veins (right, middle, and left) fuse and join at the juncture of the DV and IVC confluence. The ductus can be visualized easily on both axial and midline sagittal views of the fetus with the use of color velocimetry. Its detection can be enhanced by adjusting the velocity scale and looking for aliasing of the color that indicates the area of highest flow velocity. The DV plays a critical role in shunting the most oxygenated and nutrient-rich blood from the hepatic portion of the umbilical vein to the right atrium. More than half of the umbilical vein blood enters the DV. Portal blood primarily travels to the right lobe of the liver, and as a result, 98% of the blood passing through the DV comes from the umbilical vein. Some of the blood supply to the left lobe of the liver comes from branches of the umbilical vein, which increases blood oxygen levels in the left hepatic vein compared with the right. Preferential streaming is a phenomenon that occurs within precordial venous structures and the heart to ensure delivery of the most nutrient-rich

blood to the left side of the heart. Briefly, nutrient-rich blood within the ductus and left hepatic vein course preferentially through the posterior and left portions of the column of

blood in the thoracic IVC. Blood that is deoxygenated and contains waste products from the abdominal IVC and the right hepatic vein streams, preferentially, along the anterior and right portions of the column of blood in the thoracic IVC. Blood from the superior vena cava joins the blood traveling anteriorly and rightward, enters the right atrium across the tricuspid valve, and exits via the pulmonary artery. Only 10% of the blood from the pulmonary artery enters the pulmonary circulation, with the majority crossing the ductus arteriosus into the aorta and the systemic circulation. The posterior and leftward nutrient-rich blood passes across the right atrium through the foramen ovale into the left atrium and out the left ventricle. This ensures that the heart and brain receive the most oxygenated blood.

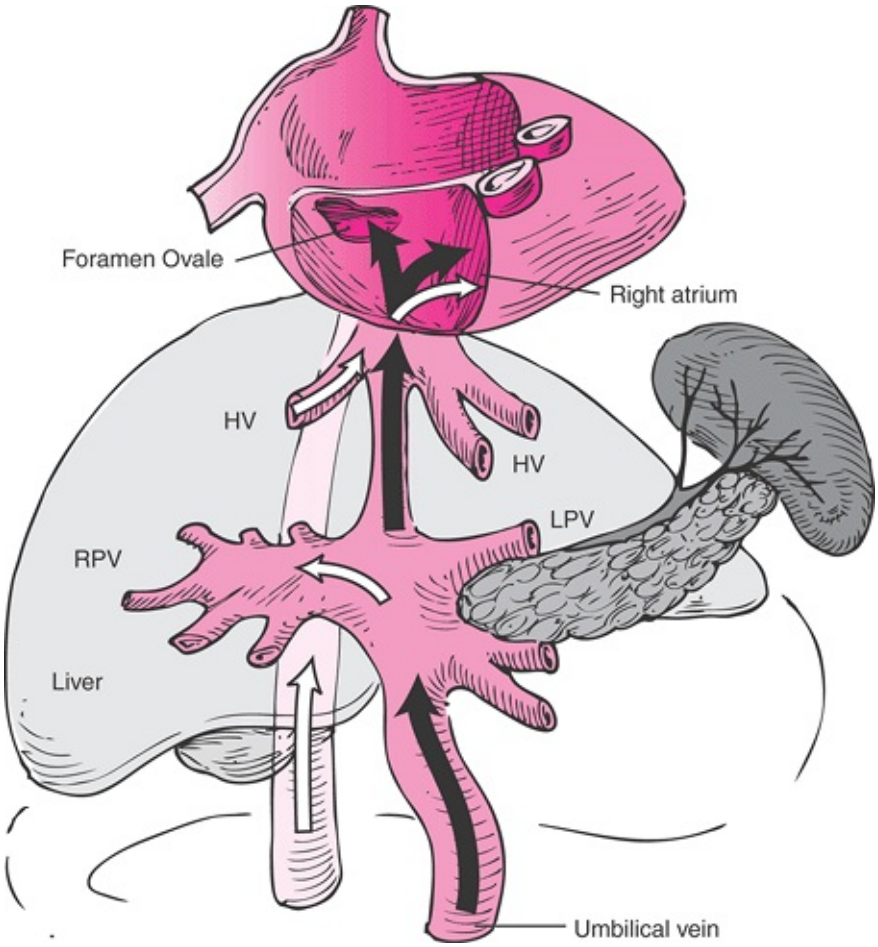

Figure 13.4 Fetal circulation depicting streaming of oxygenated blood flow from the placenta via the umbilical vein through the DV, into the right atrium, and being preferentially shunted through the foramen ovale. (Reprinted from Mavrides E, Moscoso G, Thilaganathan B, et al. The anatomy of the umbilical portal and hepatic venous systems in the human fetus at 14–19 weeks of question. *Ultrasound Obstet Gynecol* 2001;18:598–604, with permission.)

The precordial veins (DV, hepatic veins, IVC, and umbilical and portal veins) have characteristic FVWs, as shown by pulsed-wave Doppler velocimetry. The umbilical and portal veins have FVWs that are steady and without pulsations, while the other precordial

"systemic" veins have FVWs that reflect the central venous pressures. The following information on the precordial venous FVWs is in reference to the hepatic vein, DV, and IVC, which have three characteristic phases during a single cardiac cycle. Ventricular systole induces the greatest pressure gradient between the right atrium and the precordial veins during the cardiac cycle. Thus, the blood traveling within these vessels to the heart will have the highest velocity during systole. This is referred to as the "S" component of the FVW. During early diastolic filling, the second highest velocity of blood through these venous conduits will occur and is referred to as either "D" or "e." The lowest velocity of blood traveling through these vessels is in late diastole, when the atria are contracting; this phase of the FVW is referred to as the "a"-wave. Under normal conditions, the a-wave in the DV remains in a positive direction (i.e., blood continues to move toward the heart even during the phase of lowest pressure gradient during atrial contraction). In contrast, the a-wave in the IVC and hepatic veins is in a negative direction, indicating that blood is moving away from the heart. The difference in the a-waves between these vessels is important clinically because one can easily misdiagnose reversed flow in the DV due to the close proximity of these vessels. However, the use of color Doppler and the identification of aliasing should distinguish the vessels easily.

The vast majority of fetal Doppler studies have adopted qualitative indices to describe FVW indices both for arterial flow and venous flow (i.e., systolic-to-atrial [S/A] ratio

---

of the venous flow of the DV). For some selected areas of investigation, quantitative parameters are calculated (i.e., peak velocity of the outflow tract of the great vessels). The arterial pipelines to almost all organs have been investigated, including the kidneys, adrenal glands, spleen, lower limbs, lungs, and coronary arteries. While these reports provide a piece of the big picture, they do not add to information on fetal status and management gained from cardiac and precordial Doppler studies. As such, they are not discussed but are referenced in the Suggested Readings section.

Circulation of the Intrauterine Growth-restricted Fetus

A convenient way to clinically approach the variety of fetal vessels that lend themselves to Doppler investigation is to conceptualize the progressive nature of the IUGR disease process and categorize it into three compartments related to the fetal heart:

. Postcardiac (arterial) Dopplers

. Cardiac Dopplers

. Precardiac (precordial or venous) Dopplers.

The three general categories and vessels for each category are shown in Table 13.3. This organization follows the physiologic adaptations by the fetal circulation to progressive abnormalities in the placental vascular tree. Changes in the circulatory architecture of the IUGR placenta create a high-resistance vascular bed, which can be detected by Doppler velocimetry of the umbilical artery and the MCA. These represent the earliest Doppler changes in the IUGR fetus. As the IUGR fetus deteriorates, one can detect changes in peak velocities of the cardiac outflow tracts and abnormal valvular flow. Precordial or venous

Dopplers show late changes in the decompensating IUGR fetus, and these vessels include the DV, hepatic veins, IVC, and intrahepatic and intra-amniotic umbilical veins. As a growth-restricted fetus becomes more hypoxemic, umbilical blood flow is preferentially shunted away from the liver and into the DV to increase the supply of well-oxygenated blood from the placenta to the brain and myocardium. This chronic underperfusion of the liver may account for at least part of the lag in growth of the AC.

TABLE 13.3 Categorization of Fetal Vessels for Doppler Study

1. Postcardiac (arterial)
   - Umbilical artery
   - MCA
2. Cardiac
   - Outflow tract peak velocities
   - Mitral and tricuspid valve E/A ratios
   - Tricuspid regurgitation
3. Precardiac (precordial or venous)
   - DV
   - Hepatic veins
   - IVC
   - Hepatic and amniotic cavity umbilical vein

MCA, middle cerebral artery; E/A, early ventricular filling/active atrial filling;DV, ductus venosus; IVC, inferior vena cava.

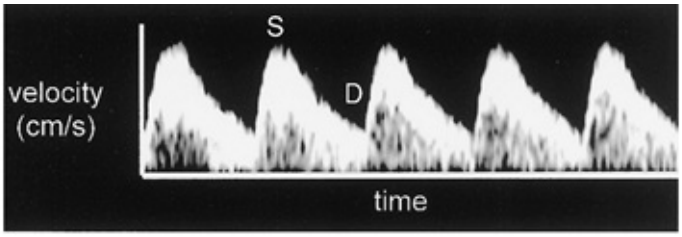
Doppler Volicemetry Changes in the Intrauterine Growth-restricted Fetus

Doppler Ultrasound

The Doppler effect refers to energy that is reflected from a moving boundary and how the frequency of the reflected energy varies in relation to the moving boundary. In ultrasound terms, Doppler depends on the ability of an ultrasound beam to be changed in frequency when encountering a moving object (red blood cells). After cosmetic manipulation, a waveform is generated that has clear systolic and diastolic components, as shown in Figure 13.5. Although resistance to blood flow in a given interrogated vessel in the fetus cannot be directly measured, it is possible from the waveform to obtain an index of resistance. Using the peak systolic and end-diastolic values, it is possible to generate Doppler indices of

resistances. These include the systolic-to-diastolic (S/D) ratio, pulsatility index, and resistance index. Because these three indices are functions of the same variables, they are correlated highly with one another. Their characteristics are also shown in Figure 13.5. The original continuous-wave Doppler

technology has been replaced by pulsed-wave Doppler technology. Doppler velocimetry is useful in cases where the fetus is asymmetrically grown due to a uteroplacental etiology or when the etiology of growth restriction is not known.



systolic/diastolic (S/D) ratio = S/D — *Easiest to calculate Most commonly used*

pulsatility Index (PI) = $\frac{S - D}{\text{mean velocity}}$ — *Requires mean height calculation; more resistant to FHR variation*

resistance index (RI) = $\frac{S - D}{S}$ — *Only normally distributed index; maximum value attainable is one*

Figure 13.5 Umbilical artery Doppler FVW demonstrating peak systolic *(S)* and end-diastolic *(D)* velocities. Doppler indices are defined below the images.

Umbilical Artery Doppler

The first fetal vessel to be assessed by Doppler velocimetry FVW analysis was the umbilical artery in the mid 1970s. During the late 1970s and early 198s, Gill and colleagues and Trudinger and coworkers described the umbilical artery FVW in normal and IUGR pregnancies. In infants with birth weight less than the 10th percentile, Trudinger and colleagues found that the umbilical artery S/D ratio was elevated above the 95th percentile in 85% of cases. This was determined to be related to a decrease in diastolic velocity, which was in turn due to an increase in resistance to blood flow within the placenta. A poorly developed placental vascular bed and progressively abnormal vascularization in the face of increased fetal metabolic demands lead to an increase in placental vascular resistance. This is further supported by research work on hemodynamic bases of waveform changes as affected by increased impedance, changes in the viscosity of the blood, loss of vessel wall compliance, and decreasing inotropic function of the myocardium, all of which contribute to the increased resistance seen in abnormal arterial flow. The umbilical artery was chosen because it was the vessel that extended from the fetus to the placenta as well as because it reflects resistance patterns downstream within

the placenta. This, in turn, could be identified clinically simply by switching a Doppler beam on the umbilical arteries and looking for an increased S/D ratio (low diastolic velocity) of the arterial waveform. During the 1990s, multiple studies on umbilical artery Doppler velocimetry in the IUGR fetus were followed by three major meta-analyses that showed a reduction in perinatal mortality by approximately one third when umbilical artery Doppler velocimetry was used as an adjunct to other means of antenatal biophysical testing. In 1993, a European multicentered, prospective, observational trial reported by Karlsdorp and associates provided strong evidence that growth-restricted fetuses with abnormal umbilical pulsatility index, absent diastolic flow, and reverse diastolic flow had progressively more severe perinatal outcomes.

Middle Cerebral Artery Doppler

Prolonged fetal hypoxia as a result of uteroplacental insufficiency will result in a redistribution of blood flow within the fetus in an attempt to deliver more oxygen by increasing volume blood flow to vital organs. Redistribution of blood flow to the heart, brain, and adrenal glands also has been shown by pulsed-wave Doppler velocimetry to occur in human IUGR fetuses. The fetal brain normally has a high-resistance blood flow pattern, which is depicted by low flow velocity at end-diastole, relative to other organs and large vessels. During hypoxia, cerebral vascular autoregulation adjusts blood flow within the brain by decreasing the resistance to flow. The decrease in resistance can be detected easily by pulsed-wave Doppler, which provides an FVW profile that depicts an increase in end-diastolic flow velocity. This will in turn result in a calculated Doppler index of resistance that is low compared with the normally high resistance seen in the cerebral circulation. The most common cerebral artery used for Doppler assessment of the fetal brain-sparing effect is the MCA. The anatomic site and direction of the MCA is perpendicular to the cerebral midline (Fig. 13.6). This allows for the Doppler beam to be positioned easily along the midportion of the vessel with a minimal angle of insonation, thereby optimizing FVW acquisition.

Both direct and indirect evidence acknowledge that hypoxia is a plausible mechanism for the decrease in MCA pulsatility index (PI) in IUGR. Direct evidence supporting this mechanism was reported by Capponi and colleagues in a group of IUGR fetuses with an abnormal umbilical PI. They showed that the best predictor of hypoxia at cordocentesis was the MCA PI. Baschat and coworkers provided good indirect evidence in support of hypoxia as a mechanism for the decreased MCA PI. In this study of IUGR fetuses with an abnormal umbilical artery PI, those with a decreased MCA PI had significantly higher nucleated red blood cell counts compared with those that had no Doppler evidence of MCA dilation.

Lagging growth of the AC typically precedes Doppler abnormalities in the umbilical artery and the MCA. Doppler studies have shown that the decrease in resistance by the fetal brain and the increase in resistance in the umbilical artery are the earliest arterial changes in Doppler flow velocities in the IUGR fetus. In the authors' experience, they begin more than 3 weeks prior to nonreassuring fetal heart rate recordings. The primary message conveyed by Doppler investigation of the MCA vessel in IUGR fetuses is that the fetus is adapting

appropriately to intrauterine hypoxia by brain sparing. Loss of the brain-sparing adaptation is thought to be due to loss of cerebral autoregulation and is considered to be a very late or terminal sign in the decompensating fetus. Before a loss of the brain sparing is acted on, one must be sure to avoid excessive transducer pressure, because this will artificially lower the end-diastolic velocity. Furthermore, one will not see a loss of brain sparing in the face of otherwise normal Doppler waveforms elsewhere, especially on the venous (precordial) side.

Cardiac Flows

Cardiac Doppler studies in the IUGR fetus primarily include assessment of peak velocities of the outflow tracts, left and right ventricular cardiac output, and flow ratios across

the valves. Variables that influence these measurements include preload, afterload, and intrinsic contractility of the left and right ventricles as well as the valve dimensions. Significant contributions have been published on the changes in the atrioventricular filling waveform and on the flow velocities of the outflow tract of the great vessels. Cross-sectional and longitudinal studies of IUGR fetuses with increased umbilical artery vascular resistance and decreased MCA vascular resistance show a progressive decrease in outflow tract velocity and cardiac output with advancing gestation. Valvular abnormalities tend to occur late in the course of an IUGR fetus that is rapidly decompensating. In one study of 31 IUGR fetuses and 289 normally grown fetuses, tricuspid valve regurgitation (TR) was a frequent but, in most cases, transient finding. Only 2 of the 31 IUGR fetuses showed TR. In one fetus it was only part-systolic, while in the other fetus it was severely compromised with abnormal flows in both the arterial and venous system. That TR is a late sign in the course of IUGR has been confirmed elsewhere.

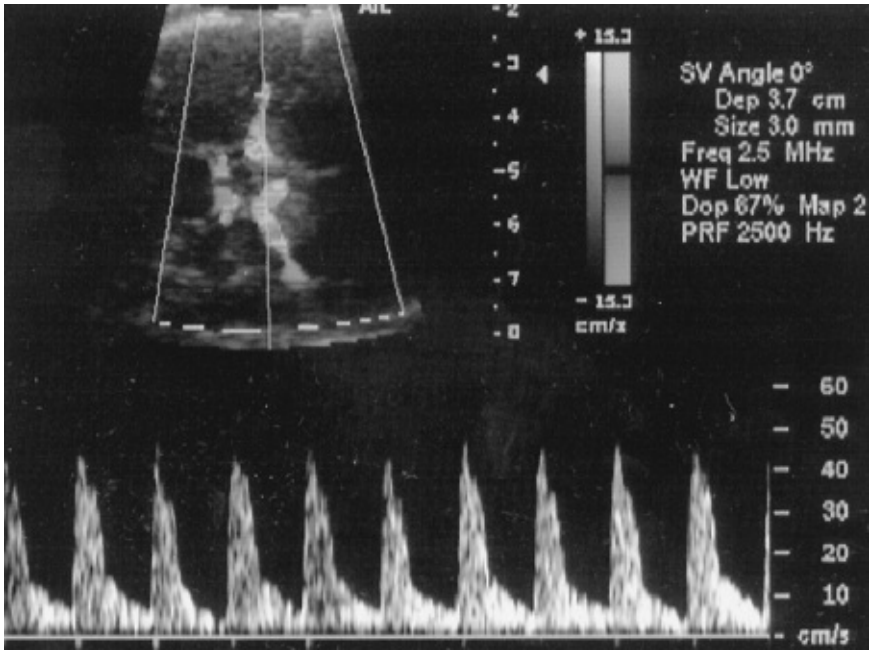


Figure 13.6 The ultrasound color Doppler image shows the circle of Willis and the MCA branches. Also shown is the near 0-degree angle of insonation and a normal MCA FVW.

(See Color Plate)

Precordial or Venous Doppler

As mentioned previously, Doppler velocimetry has been used to assess blood flow through the venous circulation of the IUGR fetus including the umbilical vein, DV, hepatic veins, and IVC. The IVC and the DV essentially represent the preload profile of the cardiovascular system. The DV waveform shows a first peak (S-wave) corresponding with right atrial filling during ventricular systole and a second peak (D-wave) during passive ventricular filling during early diastole. The a-wave is the trough representing atrial contraction ("kick"), the point at which forward flow toward the heart is normally slowest. Abnormalities in the DV are characterized by a decrease in velocity of the a-wave, and if the fetus continues to deteriorate, the DV may show absent or reversed flow velocity of the a-wave. There is significant correlation between abnormal changes in these vessels and acid–base changes of the fetus. Perinatal mortality in the presence of absent or reversed flow in the DV has ranged between 63% and 100%.

Others have correlated these Doppler indices with fetal heart monitoring patterns. The DV waveform in a severely growth-restricted fetus from 20 to 22 weeks gestation of a mother with severe renal disease and hypertension is shown in Figure 13.7. The a-wave at 20 weeks showed

reasonable flow velocity but progressively deteriorated to intermittent absent and reverse flow velocity. This fetus was born at 24 weeks gestation, weighing 320 grams, and died at 24 hours of life.

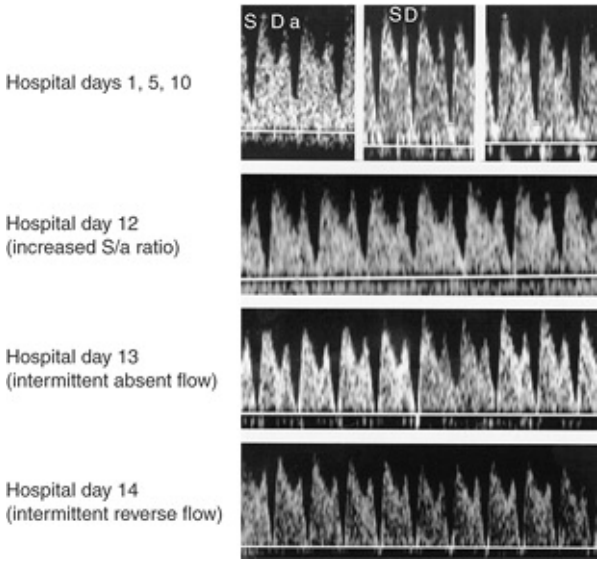

Figure 13.7 DV FVW with abnormal a-waves in a severely growth-restricted fetus admitted at 20 weeks gestation. Note the progressive decrease in velocity of flow in the a-wave. (S, systolic peak; D, diastolic peak; a, trough at atrial contraction; S/A, systolic–atrial.)

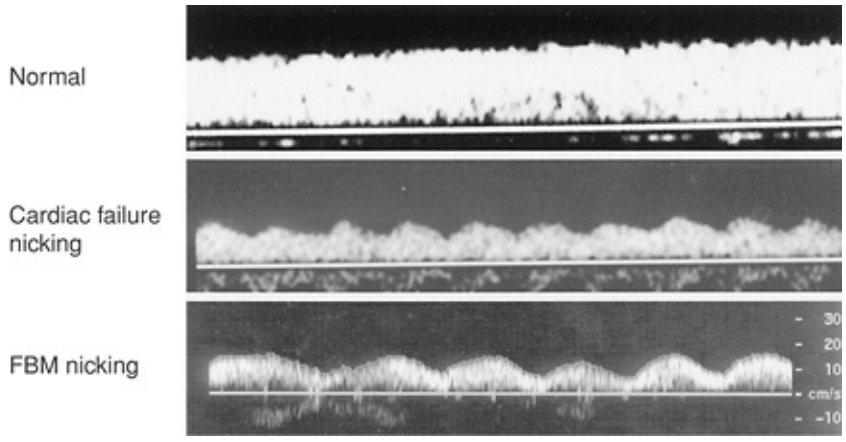

Figure 13.8 Umbilical vein FVW profiles demonstrating pulsations due to cardiac failure and fetal breathing motions compared with normal.

The umbilical vein normally has a steady FVW. The presence of pulsations or nicking at the fetal cardiac rate in the umbilical vein FVW is a very late sign of the decompensating fetus and likely is due to ventricular failure. These pulsations have been shown through animal studies to be initiated from atrial pressure changes and transmitted in a retrograde fashion. In early pregnancy, umbilical venous pulsations can be a normal finding. While assessing the umbilical vein with pulsed-wave Doppler, it is important to be cognizant that fetal breathing can mimic the nicking or pulsations of cardiac origin, and these obviously have largely differing implications. Pulsations due to fetal breathing and cardiac failure can be distinguished easily by looking for fetal breathing motions or by determining the rate of the pulsations seen on the FVW. A normal umbilical waveform, pulsations due to cardiac failure, and pulsations due to fetal breathing movements are shown in Figure 13.8.

In a study that attempted to define which venous Doppler parameter is most predictive of outcome, Baschat and colleagues found that no single index accurately predicted severe metabolic compromise. Rather, a combination of measurements of venous Doppler in three vessels, the IVC, DV, and umbilical vein, improved the sensitivity and specificity of venous Doppler in the prediction of severe metabolic compromise as indicated by fetal acid–base status. After 27 weeks, abnormality of the DV is probably the most important fetal cardiovascular predictor of neonatal complication. Earlier in gestation, DV flows alone do not provide sufficient stratification of risk. The DV shows promise in aiding the timing of delivery for some IUGR fetuses but has not yet been validated with a prospective multicenter randomized trial.

Temporal Sequence of Doppler Changes

While umbilical artery Doppler is useful as an adjunct in antenatal testing, it alone is not capable of distinguishing a decompensating fetus to the extent that morbidity can be reduced. Waiting until there is reverse flow nearly always results in an acidotic fetus with

adverse long-term sequelae. The considerable knowledge gained through Doppler studies on isolated vessels or organs subsequently lead to basic study questions regarding the "big picture":

- Is there a consistent temporally related sequence of Doppler changes within the circulation of the IUGR fetus?
- If so, does it apply to all fetuses, or are there distinct subgroups that may be predicted?
- If there is a progressive sequence of changes, is there a parallel increase in fetal morbidity and mortality?
- What is the last change or set of changes in fetal Dopplers that should prompt delivery in order to maximize time in utero and minimize the risks of prematurity but deliver before irreversible damage has been done?

These questions are just now being addressed.

In 2001 and 2002, three studies introduced the idea that a deteriorating fetus typically follows a sequence of Doppler abnormalities prior to having a markedly abnormal biophysical test (nonstress test [NST], biophysical profile [BPP]) that would normally dictate delivery. It is important to understand that these studies were conducted on very preterm and severely growth-restricted fetuses. Baschat and coworkers reported that sequential deterioration of arterial and venous flows precedes BPP score abnormalities by about 24 hours in 70% of fetuses and that perhaps adding Doppler to the BPP may enhance the performance of the BPP. This group also found that 73% of fetuses showed the above sequence of deterioration. Another group showed venous changes before brain sparing and a third small subset of fetuses showed changes in the DV without ever showing brain sparing, highlighting the idea that all fetuses may not respond to a worsening intrauterine environment with predictable hemodynamic changes. Hecher and associates reported that short-term variability

---

and DV abnormalities are the important indicators for optimal timing of delivery. More recently, Ferrazzi and colleagues reported on fetal–neonatal injury and the sequential changes in Doppler velocimetry. Briefly, increased pulsatility in the umbilical artery, decreased pulsatility in the MCA (i.e., brain sparing), and absent flow in the umbilical artery are considered "early" changes and alone were not associated with fetal injury. The next vessel to become abnormal was the DV, which was subsequently followed by other venous and cardiac Doppler abnormalities. These were considered "late" changes, frequently preceded by NST abnormalities, and were associated with a significant increase in fetal and neonatal morbidity and mortality. These "early" and "late" Doppler changes are shown in Figure 13.9. Thus, these studies suggest that waiting until the NST or the BPP become abnormal before delivery might be too late to prevent serious sequelae to the newborn and the child or adult that the newborn is destined to become. They also suggest that the vessel that best determines the optimal timing for delivery may be the DV.

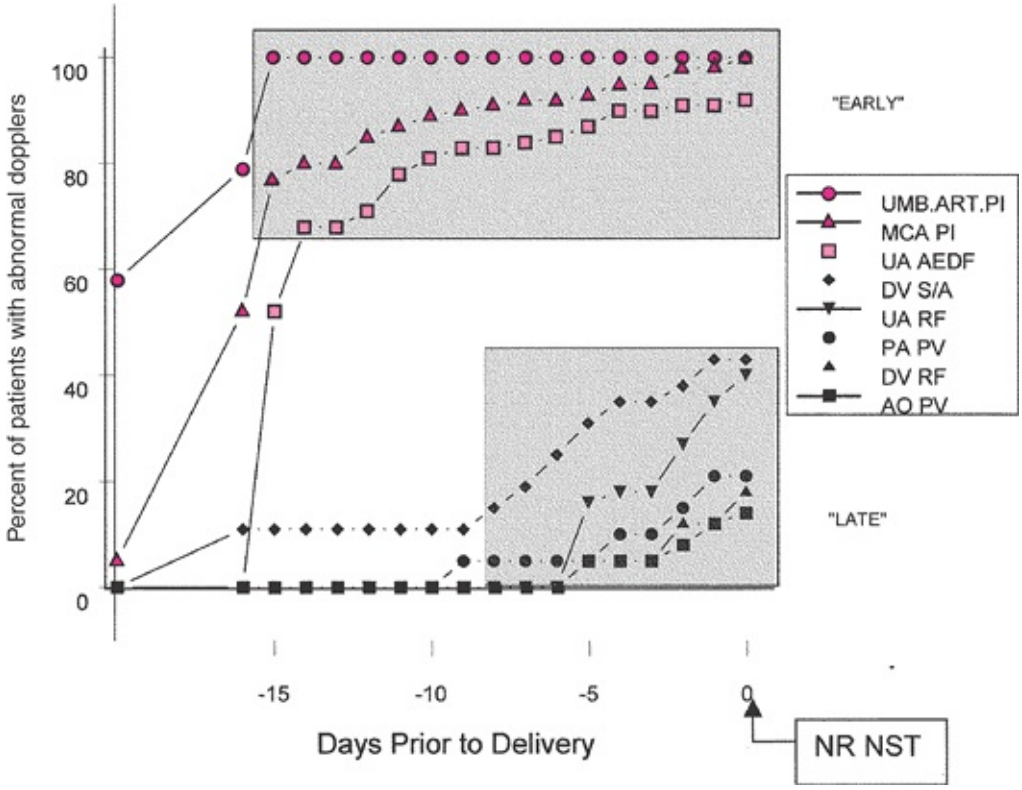

Figure 13.9 Temporal sequence of Doppler velocimetry changes in intrauterine growth-restricted fetuses. UMB.ART.PI, umbilical artery pulsatility index; MCA PI, middle cerebral artery pulsatility index; UA AEDF, umbilical artery absent end-diastolic flow; DV S/A, ductus venosus systolic-to-atrial ratio; UA RF, umbilical artery reversed flow; PA PV, pulmonary artery peak velocity; DV RF, ductus venosus reversed flow; AO PV, aortic peak velocity.) (Modified from Ferrazzi E, Bozzo M, Rigano S, et al. The temporal sequence of changes in fetal velocimetry indices for growth-restricted fetuses. *Ultrasound Obstet Gynecol* 2002;19:140–146, with permission.)

Management of the Intrauterine Growth-restricted Fetus

Historically, the management of the IUGR fetus was based on the fetus reaching fetal lung maturity, flattening of the growth curve, or showing a fetal heart rate change. In the mid 1990s, several meta-analyses demonstrated that perinatal mortality could be reduced by including umbilical artery Doppler velocimetry as part of the fetal biophysical assessment. While this was clearly a major advancement in management of the IUGR fetus, it still fell short of the goal of not only reducing perinatal mortality but also reducing perinatal morbidity. In 1993, investigators in Milan, Italy, reported a useful classification for IUGR severity. In Table 13.4, a classification scheme is shown that is based on fetal heart rate monitoring and umbilical artery Doppler velocimetry and the risk of fetal hypoxemia and academia. The study showed that waiting for the fetal heart rate to become nonreassuring would

result in a hypoxic–acidemic fetus more than 60% of the time. Studies on Doppler changes in the IUGR fetus suggest that the fetus experiencing progressive compromise tends to follow

a sequence of Doppler changes that may allow for better timing of delivery. These Doppler studies will likely be most useful in the management of the very preterm and severely IUGR fetus. Figure 13.10 is an algorithm for management guidelines of the IUGR fetus, which includes workup considerations for symmetric and asymmetric growth, daily routines, fetal monitoring, and gestational age–based timing of delivery. European management relies more heavily on short-term variability of the fetal heart rate and is beginning to use computerized interpretation of cardiotocography. Since amniotic fluid volume is a function of urine output and renal perfusion, the presence of oligohydramnios in an IUGR fetus should serve as a red flag. Oligohydramnios is not included in the algorithm. However, if it is present, hospitalization and delivery should be considered. If the fetus is extremely premature, hospitalization should be considered for intensive fetal monitoring.

TABLE 13.4 Fetal Heart Tracings, Umbilical Artery Doppler, and the Intrauterine Growth-restricted Fetus

Group	Fetal Heart Rate Tracing	Umbilical Artery Doppler	Hypoxemia/Acidemia (%)
I	Normal	Normal	0
II	Normal	Abnormal	5
III	Abnormal	Abnormal	60

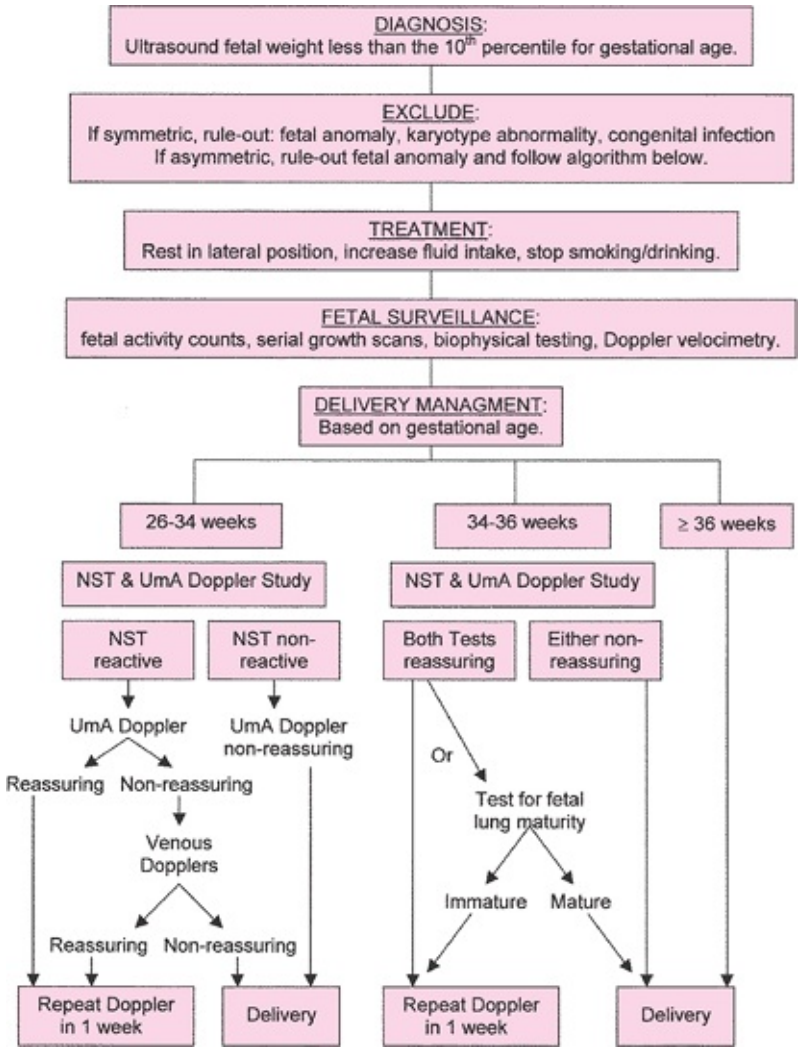

Figure 13.10 Algorithm for management guideline of the intrauterine growth-restricted fetus. Oligohydramnios does not enter this algorithm but if present should be concerning and warrants admission and perhaps consideration for delivery. (NST, nonstress test; UmA, umbilical artery.)

Biophysical Profile: Basic Technique and Use in the Intrauterine Growth-Restricted Fetus

The BPP score was developed by Manning and associates in 1980 and has been used widely in the evaluation of fetal status in many conditions since then. It is based on the theory that fetal asphyxia, regardless of cause, elicits predictable fetal responses that are reflected in easily observed, consistent changes in biophysical variables. It consists of a ten-point score with two points assigned for each of the following aspects: NST, AFI, fetal movement, fetal tone, and fetal breathing. These variables were found to have a predictable sequence of deterioration that correlates closely with worsening acidemia. A recent decision analysis found that BPP was still the best strategy for the timing of delivery of growth-restricted fetuses. However, this model was unable to use venous Doppler parameters, because the literature does not yet provide reliable probability estimates. However, waiting to deliver until the fetal heart rate becomes abnormal or the BPP is ≤4

carries a 60% to 70% risk of fetal acidemia.

Delivery Concerns

Timing of Delivery

There is a great deal of debate in the maternal–fetal medicine community regarding which parameters, and which degree of abnormality, to use as triggers for delivery of an IUGR fetus. In the very preterm fetus with abnormal umbilical artery Doppler FVWs, the question of when the risk of intrauterine hypoxia outweighs the risks of prematurity remains to be answered. There has been a call for a large, multicenter randomized trial to address this question. The Growth Restriction Intervention Trial (GRIT) enrolled 547 pregnancies between 24 and 36 weeks gestation under circumstances in which umbilical artery waveforms were abnormal and the managing obstetricians were uncertain whether to deliver. These pregnancies were randomized to delivery immediately (within 48 hours, to allow administration of corticosteroids) or to delay delivery until the obstetrician was no longer uncertain. The median time to delivery was 0.9 days in the deliver-now group and 4.9 days in the expectant-management group. Total deaths before discharge were 29 (10%) in the deliver-now group and 27 (9%) in the expectant-management group (OR 1.1; 95% CI 0.61 to 1.8). In follow-up of those babies at 2 years, primary outcomes were available on 290 (98%) immediate and 283 (97%) deferred deliveries. The overall rate of death or severe disability at 2 years was 55 (19%) of 290 immediate births and 44 (16%) of 283 delayed births. With adjustment for gestational age and umbilical artery Doppler category, the OR (95% CI) was 1.1 (0.7–1.8). Most of the observed difference was in disability in babies younger than 31 weeks gestation at randomization: 14 (13%) immediate versus five (5%) delayed deliveries. No important differences in the median Griffiths developmental quotient in survivors was seen. These results indicate that there is no significant difference in outcome between immediate versus delayed delivery. From this, it is inferred that obstetricians are delivering at about the right time to minimize hypoxemia (or even a little too late?) but may be forced to deliver so early that the effects of prematurity are unavoidable.

In the search for a definition or assessment of viability (gestational age and/or weight), there has been little consensus. One large population-based study found that survival for infants born at ≤28 weeks gestation and having a birth weight in less than the second percentile is poor. Another recent study described predictors of neonatal outcome that may be used in prospectively managing severely growth-restricted and preterm pregnancies in the periviable period. They found that neonatal survival reached 50% only at 26 weeks gestation, a 2-week delay behind normally grown fetuses. Intact survival only reached 50% at 28 weeks. These authors found that neonatal survival improves by 2% for each day in utero and emphasize the importance of safely prolonging pregnancy until at least 27 weeks and 600 g are reached. The final change in fetal monitoring that should indicate delivery before irreversible fetal decompensation occurs has not yet been demonstrated clearly.

Mode of Delivery

Once the decision to deliver has been made, the mode of delivery also is controversial. Transfer of mothers bearing preterm growth-restricted fetuses to a tertiary care hospital with an advanced neonatal intensive care unit (NICU) is universally recommended. Some would argue to offer elective cesarean delivery to mothers with severely growth-restricted fetuses, some have varying gestational age cutoffs below which they offer or recommend cesarean section, and some advocate a contraction stress test (CST) and, if reassuring, a trial of labor for most patients. Parity, obstetric history, cervical examination, and fetal presentation should be taken into consideration.

Neonatal Intensive Care Unit Course and After

Short-Term Outcomes

Although classic teaching held that the intrauterine stress posed by placental insufficiency caused early maturation of vital organs, especially the lungs, this has not been borne out in the literature. Even full-term infants whose birth weights are at or below the third percentile for gestational age have higher rates of low 5-minute Apgar scores, severe acidemia, intubation in the delivery room, seizures in the first 24 hours of life, sepsis, and neonatal death. Preterm growth-restricted neonates, in fact, have even more difficult courses in the NICU and show no birth weight percentile threshold below which complications increase. Instead, RDS and neonatal death increase along a continuum with decreasing birth weight percentile. Growth-restricted infants also struggle more with metabolic, endocrine, and infectious complications in the NICU, including hypothermia, hypoglycemia, polycythemia, hyperviscosity, and hyperbilirubinemia. Their hospital lengths of stay and charges are higher compared with gestational age–matched controls, especially in the third trimester. A large population-based retrospective study also refuted the older idea that small fetuses show an adaptive reaction to intrauterine stress. Use of the Vermont-Oxford database found a strong association between adverse outcomes and IUGR at very preterm gestational ages. These authors showed that IUGR within the birth weight range of 500 to 1,500 g was associated with higher risks of neonatal death, RDS, and NEC as compared with AGA babies.

Long-Term Outcomes

Fetal programming of adult disease now is called the Barker hypothesis or “fetal origins” theory. This principle argues that the intrauterine nutritional or endocrine environment leads to permanent physiologic or metabolic changes, perhaps mediated by epigenetic factors. These alterations appear to predispose affected individuals to the metabolic syndrome of hypertension, impaired glucose tolerance or insulin resistance, and hyperlipidemia, therefore leading to increased incidence of cardiovascular disease. Nutrient deficiency in prenatal life is said to cause adaptation that is protective in the fetus but leads to a so-called “thrifty metabolism” that is maladaptive under the

circumstance of postnatal nutrient abundance.

Growth restriction has also been associated with small but significant decreases in academic and professional achievement at school age and into adulthood. Although it is difficult to adequately identify confounders, IUGR has been associated with attention-deficit hyperactivity disorder (ADHD) at ages 5 and 6. At age 9, children with IUGR have been shown to have short-term memory difficulties that hinder both serial and simultaneous verbal processing. Much of the literature linking LBW with various psychiatric conditions including both unipolar and bipolar depression, suicide, and schizophrenia has not separated LBW from IUGR, but there are data to suggest that adults who were born at term and weighed less than 5.5 lb (2,500 g, which is less than the tenth percentile at 37 weeks by the Alexander curve) have increased odds of psychologic distress in later life after adjustment for potential confounders. This finding has been validated in other studies that have evaluated depressive symptoms and found them to be related to growth restriction independently of prematurity, maternal depression, and other possible confounders. There also appears to be a relationship with gender, in that girls and women who were growth restricted at birth have a greater susceptibility to mood disorder than their AGA controls or boys or men.

Conclusion

IUGR is a serious obstetric problem with far-reaching consequences for affected mothers and fetuses. Although a greater understanding of the pathophysiologic mechanisms and results of uteroplacental insufficiency is developing, many questions remain. Are uteroplacental insufficiency and IUGR preventable? Are they treatable once they have been diagnosed? Are there ways in which pregnancy could safely be prolonged or other biophysical measures used to further distinguish those fetuses that safely can remain in utero from those that should be delivered? Further efforts to understand this condition are essential for the reduction of both short-term and long-term sequelae.

Summary Points

- Proper establishment of the uterine–placental–fetal circulation early in gestation is critical to appropriate placental and fetal growth.
- Abnormal uterine artery Doppler waveforms reflect abnormal placentation and have been found to predict adverse pregnancy outcome due to placental insufficiency among high-risk women, although its sensitivity is poor among women without risk factors.
- Establishment of accurate dating in pregnancy is necessary for assessment of appropriate growth and management of the pregnancy.
- Ultrasound dating of the pregnancy is most accurate in the first trimester.
- The TCD remains relatively unaffected in asymmetrically growth-restricted fetuses.

- A distal femoral epiphysis of more than 3 mm is consistent with a pregnancy greater than 36 weeks gestation.
- In SGA, it is important to consider the possibility of a constitutionally small baby.
- In IUGR, use of umbilical artery Doppler velocimetry reduces perinatal mortality when used as an adjunct to other tests of fetal well-being.
- Doppler velocimetry studies of the venous circulation may be the best way to optimally assess the timing of delivery in the very preterm and growth-restricted fetus.
- IUGR predisposes affected individuals to both short-term and long-term negative consequences that influence physical and mental health.

Multiple Gestation

Roger B. Newman
Charles Rittenberg

Multiple gestations have become one of the most common high-risk conditions encountered by the practicing obstetrician/gynecologist. In 2003, there were 136,328 multiple gestations delivered in the United States, the highest number ever recorded. Since 1980, the number of twins delivered in the United States has risen over 80%, establishing a new height each year. Twins now represent approximately 3% of all live births. Triplets and higher-order births, formerly statistical improbabilities according to the Hellin-Zeleny hypothesis, have increased 470% over the same time period, and triplets now occur with a frequency approaching 1 in every 500 deliveries.

Although multiples account for only a small percentage of all live births, they are responsible for a disproportionate share of perinatal morbidity and mortality suffered in the United States. Multiples result in 17% of all preterm births less than 37 weeks, 23% of early preterm births less than 32 weeks, 24% of all low-birth-weight (LBW) (<2,500 g), and 26% of all very low-birth-weight (VLBW) (<1,500 g) infants. As a consequence of these high rates of both prematurity and LBW, twins are at an approximate 7-fold greater risk of dying before their first birthday compared with singletons, while triplets are at an almost 17-fold greater risk. Multiples account for 16% of all neonatal deaths in the United States.

Among survivors, there is an increased risk of long-term mental and physical handicaps. Twin pregnancies result in a child with cerebral palsy 12 times more often than do singleton births. One fifth of all triplet pregnancies and one half of all quadruplet pregnancies result in at least one child with a major long-term disability. While many cases of cerebral palsy are related to extreme prematurity, not all are the result of premature birth. Even when matched for gestational age and birth weights >2,500 g, multiples have a nearly threefold greater risk of developing cerebral palsy than do singletons.

Multiples also experience a significantly increased risk of growth restriction, which can compound the problems associated with prematurity. Growth-restricted, premature infants, regardless of plurality, experience greater morbidity and mortality than do appropriately grown infants of the same gestational age. Twins and triplets with intrauterine growth restriction (IUGR) have been shown to experience an excess of neurodevelopmental abnormalities compared with appropriately grown, gestational age-

matched multiples. Multiples are at risk for numerous other complications that contribute to adverse outcomes. These complications include higher rates of congenital anomaly, twin-to-twin transfusion, monoamnionicity, cord prolapse, placental abruption, placenta previa, intrapartum asphyxia, and birth trauma.

Not unexpectedly, multiples also are associated with significantly higher health care costs. Neonatal intensive care unit (NICU) admission is required by one fourth of twins, three fourths of triplets, and virtually all quadruplets, with average NICU stays of 18 days, 30 days, and 58 days, respectively. Women who are pregnant with multiples are almost six times more likely to be hospitalized with antepartum complications—most frequently, preterm labor, preterm premature rupture of the membranes (PPROM), and preeclampsia. In addition to higher rates of antepartum admission, hospital costs for the birth admission average 40% higher than for gestational age–matched singletons due to longer lengths of stay and increased intrapartum complications with multiples.

Epidemiology and Zygosity

Monozygotic (MZ) twins are those gestations where both fetuses arise from single fertilized ova and are genetically identical. MZ twinning is considered to be a random event, independent of modifying influences such as age, race, parity, or heredity. The incidence of MZ twinning is 3 to 4 per 1,000 live births in virtually all populations. One of the few known influences on the rate of MZ twinning is the

---

use of assisted reproductive technology (ART) such as in vitro fertilization. The increased frequency of MZ twinning associated with infertility treatment has been attributed to a defective zona pellucida, which allows premature and partial hatching of the blastomeres.

The incidence of dizygotic (DZ) twinning, on the other hand, is extremely variable and accounts for most of the current increase in multiple births. DZ, or fraternal twins, result from multiple ovulation with fertilization by separate sperm. Multiple factors are known to affect the incidence of DZ twinning, including personal or family history. If a woman has already had one set of DZ twins, her chance of having a second set is increased twofold, and a first-degree relative with twins will increase a woman's risk as well. The father's side of the family contributes little or nothing to the hereditary risk.

It is estimated that approximately one third of the increase in the number of multiple births is due to delayed childbearing and the fact that DZ twinning occurs more frequently among older women, peaking in the mid thirties. The trend toward delayed childbirth has been a significant sociologic phenomenon of the past quarter century. Since 1975, the proportion of first births among women 30 years of age and older has increased from 5.3% to 22.8%, and the proportion of all births to women ≥30 years of age rose from 16.5% to 35.5%. In women younger than 20 years, the multiple birth rate is only 1.5% compared with 4.1% among women between the ages of 30 to 39 years and up to 18% for women 45 years or older. The higher frequency of multiple gestations occurring among older women also complicates prenatal genetic screening and diagnosis.

The majority of the increase in DZ twinning has been the result of ovulation induction therapy and ART. Women contemplating assisted reproduction should receive

preconceptional advisories regarding the risk of multiple birth and the risks associated with those births. The 2002 report of the Society of Assisted Reproductive Technologies (SART) indicated that of all the pregnancies achieved following ART in the United States, 50.9% were singletons, 37.8% were twins, 6.9% were triplets or higher, and 4.4% were unknown. Efforts are being made to reduce the number of oocytes, zygotes, or embryos that are being transferred back in order to minimize the risk of multiple pregnancy. While fewer embryos are being transferred in ART procedures, ovulation induction continues to have a significant impact on the rate of multiple births. A similar proportion of triplets and higher-order gestations results from ART procedures (43%) and ovulation induction (38%), while spontaneous conception accounts for only a minority (19%).

Maternal race also affects the frequency of DZ twinning, which occurs approximately 7 to 10 times per 1,000 live births among whites, 10 to 40 times per 1,000 live births for persons of African descent, and only 3 times per 1,000 live births among Asians. Interestingly, white women are more than twice as likely as black women and three times as likely as Hispanic women to have a triplet or higher-order multiple, which almost certainly reflects a greater use of ART in the white population. Increased maternal parity, higher body mass index (BMI), and recent discontinuation of hormonal birth control agents are also associated with higher rates of DZ twinning.

Placentation

The placentation of DZ twins will always be diamniotic, dichorionic. Two complete placental units are produced, each composed of an amnion and a chorion. As a result, the membrane separating DZ twins will consist of four layers—an amnion and a chorion from each fetus. The placentas themselves may be separate or fused in DZ twins, but the dividing membrane will always consist of four layers. In MZ twins, the placentation depends on the time at which twin division occurs. If division of the zygote occurs in the first 3 days, two complete placental units will be formed and the dividing membrane will contain two amnion and two chorion layers, just as with DZ twins. The syncytiocytotrophoblast cells, which will give rise to the chorion, begin to differentiate about day 3 from the periphery of the blastocyst. If embryonic division occurs between days 3 and 8, the placentation will be a single chorion that has now already differentiated and two amnions that have not yet begun to form. As a result, the dividing membrane will be thin and wispy because it consists of only two opposed amniotic membranes without the intervening chorionic layers. This placentation is referred to as diamniotic, monochorionic. The amnion begins to differentiate by about day 8, and if embryonic division occurs between days 8 and 13, the twins will share a single amnion and chorion—a monoamniotic, monochorionic placentation. This situation, with no dividing membrane separating the fetuses, allows for potentially lethal entanglement of the umbilical cords. Different types of placental development in DZ and MZ twins are illustrated in Figure 14.1. Embryonic division, which occurs after day 13, also results in monochorionic, monoamniotic placentation but with physical attachment of the fetuses producing conjoined twins. Among MZ twins, 18% to 36% are diamniotic, dichorionic; 60% to 70% are diamniotic, monochorionic; and approximately 1% are monoamniotic, monochorionic.

Examination of the placenta(s) and a detailed description of its dividing membrane are critical for determining zygosity of the infants. The microscopic appearance of the dividing membrane consisting of either two or four layers is seen in Figure 14.2. Diamniotic, dichorionic twins are necessarily DZ if the twins are of opposite sex. If the dividing membrane contains only amniotic layers and a monochorionic placenta, the infants are MZ. If the dividing membrane has two amnion and two chorion layers (i.e., diamniotic, dichorionic) and the infants are the same sex, the twins may be either DZ or MZ. Despite these limitations, the

obstetrician can still accurately determine zygosity in the delivery room in over 50% of cases by simply observing the fetal sex and grossly inspecting the placenta. In those cases that remain uncertain, a more specific diagnosis can be made by blood or HLA antigen typing or more sophisticated DNA analyses.

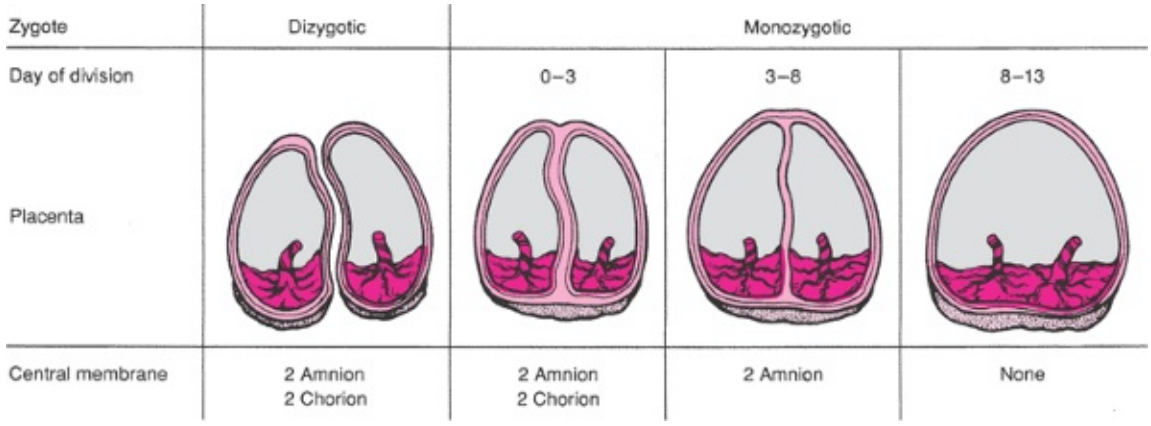

Figure 14.1 Types of placentation in MZ and DZ twinning.

Prenatal Diagnosis

The risk of aneuploidy in multifetal gestations is primarily related to zygosity and, as a secondary factor, the mode of conception. In DZ twins, each fetus has an independent risk for aneuploidy which, like singletons, is related to maternal age. This will be a significant clinical factor, as the risk of DZ twinning increases with maternal age. Alternatively, MZ twins with rare exception will have the same karyotype, and their aneuploidy risk also will be related to maternal age.

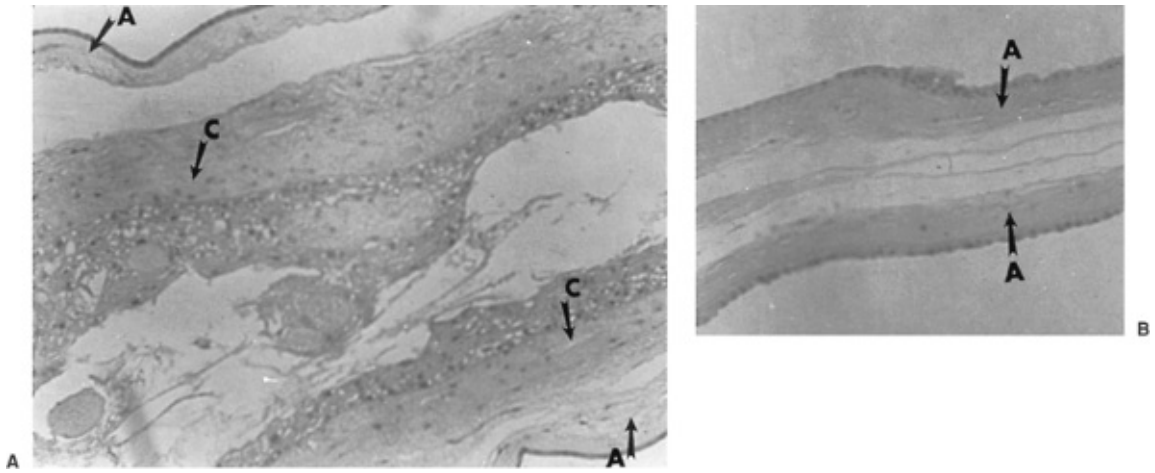

Figure 14.2 In MZ twinning, the dividing membrane can contain either four layers if diamniotic, dichorionic **(A)** or two layers if diamniotic, monochorionic **(B)**. All DZ twins will be diamniotic, dichorionic and four layers as represented in **A**. (A, amnion; C, chorion).

When considering possible zygosity as well as the risk of aneuploidy, the mode of conception needs to be considered. While the percentage of naturally conceived DZ twins will vary somewhat with maternal age and ethnicity, it is generally accepted that in the United States, 33% of naturally occurring twins will be MZ and 67% will be DZ. Of those twins conceived following assisted reproduction, 93% will be DZ and only 7% MZ.

Since DZ twins carry independent risks of aneuploidy, the chance of having at least one affected live-born twin at term is twice the maternal age–associated risk. At a maternal age of 32, the age-associated risk of aneuploidy is 1 in 481 singleton births. The risk for a woman 32 years of age carrying DZ twins is 1 in 240, which is equivalent to a 35-year-old woman carrying a singleton. For a woman carrying MZ twins, her risk of having at least one affected live-born twin at term is the same as her age-associated risk (i.e., 1 in 240 at 35 years of age). Unfortunately, since her twins are MZ, this risk actually is the risk of both fetuses

being affected. Obviously, zygosity can only be determined definitely by genetic analysis of both fetuses, but certainly it can be inferred with a reasonably high degree of accuracy by noninvasive ultrasonic determination of chorionicity and fetal sex. Monochorionic (same sex) twins are always MZ, and approximately 70% of MZ twins are monochorionic. All DZ (same or opposite sex) twins will be dichorionic, while approximately 30% of MZ twins will have a dichorionic placentation.

Second-trimester multiple-marker screening generally has been used in twin pregnancies, although with a decreased sensitivity for aneuploidy and a higher false-positive rate compared with its use in singletons. Production of serum analytes in DZ twins can be affected by one twin differentially from the other. The median second-trimester serum analyte values for normal twins are 1.67 multiples of the median (MoM) for unconjugated estriol, 1.84 MoM for human chorionic gonadotropin (hCG), and 2.13 MoM for maternal

serum alpha-fetoprotein (MSAFP) compared with normal singletons. A pseudorisk for twins can be calculated by dividing measured MoM values for the corresponding medians for unaffected twins. Using this pseudorisk approach and mathematical modeling, the estimated Down syndrome detection rates using a triple screen is 73% for MZ twins, 43% for DZ twins, and 53% for twins overall, with a 5% screen positive rate (SPR). This performance compares poorly with either the triple screen or the quad screen in singleton pregnancies, where there are detection rates of 65% and 75%, respectively, for the same 5% SPR.

A similar situation exists with first-trimester serum screening. Using free ß-hCG and pregnancy-associated plasma protein A (PAPP-A) levels at 10 to 14 weeks, modeling predicted detection rates of 52% in twins discordant for Down syndrome and 55% in twins concordant for Down syndrome, with a 5% SPR compared with an estimated 60% detection rate for singletons.

An attractive alternative for women with multiples is now available with the emergence of first-trimester nuchal translucency (NT) measurement. Between 10 and 14 weeks, the NT mean (in millimeters), median (MoM), and values at the 5th, 50th, and 95th percentiles for normal twins and triplets are almost identical to normal singleton gestations. In 1996, Sebire and colleagues obtained NT measurements in 448 women with viable twins and more than 20,000 singletons between 10 and 14 weeks gestation. Among the twins, 7.3% had an NT of less than the 95th percentile, including 88% of those with Down syndrome; among the singletons, 5.2% had an NT of less than the 95th percentile, which included 79% of those with Down syndrome. In dichorionic pregnancies, the sensitivity and SPR of NT plus maternal age for Down syndrome was similar to singletons. In monochorionic pregnancies, the SPR of NT risk assessment, however, was higher than in singletons. It is possible that this difference in monochorionic pregnancies may be an early manifestation of twin-to-twin transfusion syndrome (TTTS).

In a follow-up study in 1997, Sebire and colleagues compared NT measurements obtained at 10 to 14 weeks from 116 normal monochorionic twin pregnancies and 16 that later developed severe TTTS. An NT of less than the 95th percentile had a positive predictive value of 38% for TTTS and a likelihood ratio of 4.4 (95% confidence interval [CI] 1.8 to 9.7), suggesting that the underlying hemodynamic changes associated with TTTS may manifest as increased fetal NT thickness in monochorionic twins at 10 to 14 weeksgestation.

The appeal of first-trimester NT measurement for multifetal gestations is its ability to individually assess each fetus. The addition of first-trimester serum analytes brings the same concern encountered in the second trimester where abnormalities of one twin may be normalized by the other, reducing sensitivity and increasing the false-positive rate. At present, it appears that first-trimester NT is superior to first-trimester serum screening alone for multifetal gestations. The value of combined first-trimester screening compared with NT measurement alone remains uncertain and requires further investigation.

Maternal Complications

Women who are pregnant with multiples are more likely to be hospitalized antenatally for both an increased frequency and severity of pregnancy-related complications. Some of these increased risks may be associated with maternal characteristics that predate the

pregnancy, such as older maternal age, nulliparity, increased pregravid BMI, and conception by ART. However, the majority of these complications are related directly to higher plurality and the more extreme maternal adaptation required.

Cardiovascular Risks

One of the major physiologic changes occurring with a multiple pregnancy is significant expansion of the plasma volume and cardiac output above that seen in singleton pregnancies. This increased plasma volume has obvious adaptational value as the maternal host tries to meet the demands of a multiple conception. Increased cardiac demand is reasonably well tolerated in the absence of underlying cardiac disease such as undiagnosed mitral valve stenosis. However, the common use of tocolytic therapy, the common iatrogenic fluid overload, and the occasional infection all will generate significant additional cardiovascular demand. Tocolytic therapy (especially ß-adrenergic agonists) has been associated with pulmonary edema, myocardial ischemia, and potentially lethal maternal tachyarrhythmias in multiples, although these complications are infrequent. An increased risk of postpartum cardiomyopathy also has been reported, especially among older gravidas with

---

higher-order multiples. A case-controlled study of pregnant women found that multiple pregnancy was an independent and significant risk factor (odds ratio [OR] 2.3; CI 95% 1.2 to 4.5) for admission to an intensive care unit.

Hematologic Abnormalities

Increased red blood cell volume expansion is unable to keep pace with plasma volume expansion in either singleton or multiple gestations. This results in a physiologic hemodilution. The average hemoglobin concentration for women pregnant with twins is 10 g/dL at 20 weeks gestation. Hemoglobin and hematocrit values decline beginning in the first trimester, reaching a nadir in the second trimester before gradually rising in the third trimester. Hemoglobin levels below 11 g/dL in either the first or third trimester accompanied by a serum ferritin less than 12 mg/dL represents iron-deficiency anemia, which complicates 21% to 36% of multiple gestations. This rate is two- to threefold higher than in singletons. Multiples generate a great demand for elemental iron, of which sufficient quantity might not be available in many diets. This need should be addressed through the consumption of heme-rich animal protein and supplementation with 60 mg per day of elemental iron and 1 mg per day of folic acid when the woman has low or absent stores of these nutrients.

Metabolic Disorders

Women who are pregnant with multiples have lower fasting and postprandial glucose levels, exaggerated insulin responses to eating, and higher levels of ß-hydroxybutyrate than women pregnant with singletons. These differences suggest more rapid depletion of glycogen stores and resultant metabolism of fat between meals and during an overnight fast.

Gestational diabetes represents a disorder of relative insulin deficiency exposed as a consequence of the anti-insulin effects of several placental hormones—most notably, human placental lactogen. Multiple gestations are at increased risk for gestational diabetes due to the elevated levels of these placental hormones associated with increased placental mass. Gestational diabetes appears to be increased two- to threefold among multiples (7% among twins, 9% among triplets, and 11% among quadruplets) compared with a 3% to 4% incidence among singletons. Given the high rate of premature labor among multiples, it should be remembered that both ß-adrenergic agents and corticosteroids can induce both insulin resistance and hyperglycemia.

Pregnancy-Induced Hypertension or Preeclampsia

Pregnancy-induced hypertension or preeclampsia is frequently encountered in multiple gestations. Reported frequencies increase from approximately 7% in singletons to 14% for twins, 21% for triplets, and 40% for quadruplets. A population-based study of singleton and twin births in the state of Washington found twins to have a 4-fold higher risk of preeclampsia and a 14-fold higher risk if the woman is primigravid. Pregnancy-induced hypertension or preeclampsia frequently occurs earlier, is more severe, and more often is atypical in multifetal gestations. Hypertension is not always the presenting sign, nor is proteinuria universally present, especially in higher-order multiples. Only 3 of 16 triplets and quadruplets reported in one study met traditional criteria for preeclampsia. The most common presentation among these higher-order multiples was laboratory abnormalities consistent with HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome.

Placental Abruption

Antepartum maternal hemorrhage also is increased in multiple gestations. Twin pregnancies have an approximately threefold increased risk of abruption, even when controlling for maternal hypertension. Abruption occurs most frequently in the third trimester and also is a significant risk immediately after vaginal delivery of the first infant. Conformational changes in the uterine shape that occur between deliveries can predispose to a sheering off of the attached placenta.

Hydramnios

Hydramnios occurs in 2% to 5% of twin gestations, and twins account for approximately 8% to 10% of all cases of hydramnios. Hydramnios may develop as a consequence of TTTS with the cotwin experiencing both growth restriction and oligohydramnios. The development of idiopathic acute hydramnios with maternal respiratory embarrassment also has been reported in multiples.

Urinary Tract Infection

Women with multiples have a 1.4-fold increased risk of developing urinary tract infection during pregnancy. These infections usually involve only the lower urinary tract because the incidence of pyelonephritis is not significantly increased. This complication is thought to be

a consequence of increased urinary stasis due to the gravid uterus.

Postpartum Hemorrhage

Overdistention of the uterus in a multifetal gestation predisposes to postpartum hemorrhage caused by uterine atony. In addition, women carrying multiples are at increased risk for retention of placental tissue, surgical or mechanical trauma to the genital tract, and pharmacologic effects of medications such as magnesium sulfate, which is frequently used to manage both preeclampsia and preterm

labor. In a British population-based study of postpartum hemorrhage, multiple pregnancy was associated with more than fourfold increased risk (relative risk [RR] 4.46; 99% CI 3.01 to 6.61). In the British study, the risk of postpartum hemorrhage among singletons was 1.2% compared with 6% for twins, 12% for triplets, and 21% for quadruplets.

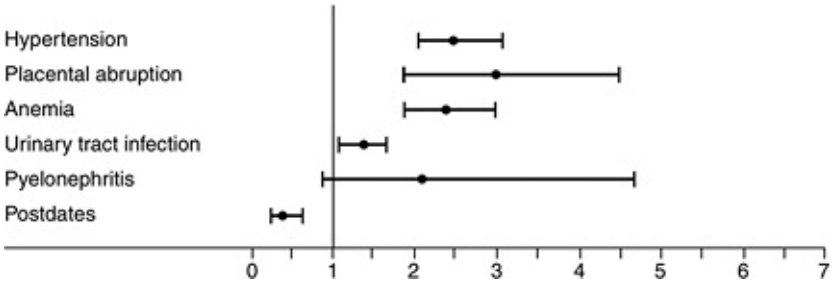

Figure 14.3 OR table for maternal antepartum complications among 1,253 twin and 5,119 singleton pregnancies between 1982 and 1987. (Adapted from Spellacy WN, Handler A, Terre CD. A case-controlled study of 1,253 twin pregnancies from a 1982–1987 perinatal database. *Obstet Gynecol* 1990;75:168–171.)

While the above scenarios represent several of the more significant maternal complications associated with multiples (Fig. 14.3), others also are encountered with increasing frequency. These include cholestatic jaundice, pruritic urticarial plaques and papules of pregnancy (PUPP), hyperemesis, and deep venous thrombosis. Women with multiple gestations also experience an increased number of somatic complaints such as shortness of breath, loss of balance, varicose veins, significant dependent edema, constipation, and hemorrhoids.

Complications Unique to Multiples

Vanishing Twin Syndrome

The loss of one or more fetuses can complicate a multiple gestation at any point during

pregnancy but is most common in the first trimester. Between 20% and 50% of multiple gestations identified by ultrasound in early pregnancy are lost either as a spontaneous abortion of all fetuses or by the spontaneous loss and reabsorption of at least one of the multiples. This latter occurrence is referred to as the “vanishing twin syndrome,” and its exact frequency is difficult to ascertain for obvious reasons.

In the experience of one in vitro fertilization program, spontaneous loss of all fetuses with previously documented cardiac activity occurred in 17 of 165 twin (10.3%), 2 of 26 triplet (7.7%), and 1 of 5 quadruplet (20%) pregnancies. In addition, 33 twins spontaneously reduced to a singleton and 9 triplets spontaneously reduced to twins. Considering both the spontaneous abortion rate and the vanishing twin syndrome, the overall first-trimester pregnancy loss rate was 50 of 165 twins (30.3%), 11 of 26 triplets (42.3%), and 1 of 5 quadruplets (20%). Although these data are limited by the fact that all pregnancies were the result of in vitro fertilization, similar loss rates have been reported in spontaneously conceived multiples.

When vanishing twin syndrome does occur, there usually are no symptoms. However, in some cases, the reabsorption may be associated with a modest amount of vaginal bleeding. Some have estimated that up to 5% of all patients with first-trimester bleeding may be experiencing a vanishing twin. Maternal reassurance should be offered, as the prognosis for the surviving twin is excellent when silent reabsorption occurs in the first trimester. Following delivery, the placenta frequently will show a whitish plaque on the membranes, representing the remnant of the other gestational sac.

While vanishing twin syndrome occurs with a greater frequency than appreciated previously, it is important not to overdiagnose this event. The diagnosis of a vanishing twin should be preceded by identification of specific embryonic parts in each sac as opposed to an anembryonic cavity. Numerous sonographic findings can mimic a second anembryonic cavity, including subchorionic blood clots, chorioamniotic separations, a decidual pseudosac in the contralateral horn of a bicornuate or didelphic uterus, a cystic uterine fibroid, or even excessive transducer pressure on a thin woman. The emotional impact of a vanishing twin should not be underestimated. Parents will perceive the situation as the loss of a child, and perinatal grief counseling may be necessary in some situations.

Fetal Death in Utero (Acute Intertwin Transfusion Syndrome)

After the first trimester, single fetal demise occurs in 2% to 5% of twin gestations and in 10% to 15% of triplet gestations. The risk of a single fetal death in utero is increased three- to fourfold by monochorionicity. When death of one fetus occurs in a dichorionic gestation, the risk to the surviving cotwin is minimal, although higher rates of preterm labor or PPROM have been reported. Virtually all the adverse sequelae for the surviving cotwin occur in monochorionic gestations. Antenatal demise of a monochorionic cotwin is associated with an approximate 25% mortality rate and a similarly high rate of morbidity for the surviving fetus.

Injury to the surviving cotwin was previously thought to be a result of intravascular coagulation and embolism of tissue thromboplastins through ubiquitous placental anastomoses from the fetal demise. The passage of these tissue thromboplastins result in

embolic ischemic organ injury or development of disseminated intravascular coagulopathy in the survivor. The more recent belief is that following fetal demise, there is an acute transfusion into

the dead fetus through the shared placenta. This hemorrhage into the dead fetus may cause severe fetal hypotension, hypoxic end-organ injury, and potentially lethal fetal exsanguination. This is referred to as “acute intertwin transfusion syndrome.” In prospective studies, 5% to 25% of surviving monochorionic twins have ischemic end-organ injury, most frequently neurologic. Neurologic abnormalities reported among surviving twins include necrosis and cavitation of the cerebral white matter, cerebellar necrosis, multicystic encephalomalacia, hydranencephaly, hydrocephalus, porencephaly, microcephaly, and hemorrhagic infarction. In addition to neurologic injuries, other abnormalities seen among surviving cotwins include ischemic bowel lesions, intestinal atresia, renal cortical necrosis, and cystic renal dysplasia.

Most reported cases of demise or neurologic injury occurring in a monochorionic cotwin following death of its sibling have occurred in the third trimester. However, neurologic deficit has been reported in a surviving monochorionic twin following loss of its cotwin as early as 18 weeks gestation.

Following a fetal demise in utero, continuing pregnancy management will depend on gestational age, chorionicity, and maternal and fetal status. If the pregnancy is known to be dichorionic, then no intervention is required unless a term gestation has already been achieved or there is a specific maternal or fetal indication for delivery. A single fetal demise in a monochorionic gestation is an indication for immediate delivery if fetal maturity or near maturity can be inferred based on gestational age or documented by amniocentesis. Decisions regarding delivery at earlier gestations should be based on an assessment of the neonatal complications likely to result from delivery as opposed to the potential risk of remaining in utero. Since it is probable that hypoxic/ischemic end-organ injury occurs almost immediately after demise of the monochorionic cotwin, it is unclear if these injuries can be prevented by prompt delivery. With expectant management, increased fetal surveillance of the surviving twin should be performed, and any evidence of fetal compromise also warrants immediate delivery.

Monoamniotic Twins

Monoamniotic twins are rare, complicating fewer than 1% of MZ gestations. They carry a fetal mortality rate that approaches 40%, primarily as a consequence of cord entanglement and subsequent occlusion. Cord entanglement is present in virtually every case of monoamniotic twins. Monoamniotic twins also are at greater risk for other complications such as congenital anomaly, including conjoining and TTTS.

Some reviews have suggested that spontaneous intrauterine fetal demise due to cord entanglement is unlikely after 32 weeks gestation as intrauterine crowding limits the ability of the fetuses to make major moves in relationship to each other. However, a review of over 200 nonconjoined, monoamniotic twins demonstrated that fetal deaths occur throughout pregnancy, with a high percentage occurring after 32 weeks. In this large

review, monoamniotic twins that were prenatally diagnosed and subjected to intensive antepartum surveillance enjoyed a much higher perinatal survival rate than has been reported historically. Prenatal diagnosis allows for institution of an aggressive management protocol designed to identify fetal compromise, enhance fetal lung maturity, and electively deliver once neonatal survival can be anticipated (Table 14.1).

TABLE 14.1 Management Recommendations for Monoamniotic, Monochorionic Twin Gestations

Confirm monoamnionicity (exclude stuck twin syndrome)
Ultrasonographic evaluation at 18 to 20 weeks to exclude congenital anomalies and conjoining
Parental education regarding unique risks
Serial ultrasonographic assessment of fetal growth (TTTS common)
Daily fetal kick counts beginning at 26 weeks
Nonstress testing three times per week beginning at 26 weeks
Antenatal glucocorticoid administration
Amniocentesis for fetal lung maturity at 32 weeks
Elective delivery at 34 to 35 weeks if fetal lung maturity not previously confirmed
Cesarean delivery usually recommended

TTTS, twin-to-twin transfusion syndrome.

Cesarean delivery is usually recommended due to concerns over intrapartum fetal distress related to tightening of the umbilical cord entanglement. If vaginal delivery is planned, continuous fetal monitoring is essential along with capability for immediate cesarean birth.

Discordant Twin Growth

In addition to concordant IUGR, ultrasound is useful for the detection of significantly discordant fetal growth, which is unique to multiple gestations. In terms of actual birth weight, a large review found that birth weight differed by 500 to 999 g in 18% of twins, and the difference was greater than 1,000 g in 3%. Some 15% to 30% of twins exhibit birth-weight differences of 20%. Discordance between the largest and smallest triplet is 20% in more than 40% of triplet gestations, with 7% exceeding 40% discordance.

Evidence suggests that the smaller infant may be at risk for both increased perinatal morbidity and mortality when birth-weight discordance is excessive (>20% to 25%). Another concern is that significant diversions in twin growth may predispose the smaller twin to

disadvantages in long-term physical and intellectual development.

Much of the discordance in birth weight will be due to constitutional factors such as the genetic dissimilarity of DZ twins. The other major cause of growth discordance in DZ twins is growth restriction affecting a single fetus due to local placental implantation factors (Fig. 14.4). In monochorionic gestations, discordance is more frequent, often more severe, and more likely to be associated with TTTS. Percent discordance is calculated by dividing the actual or estimated weight difference by the actual or estimated weight of the larger twin.

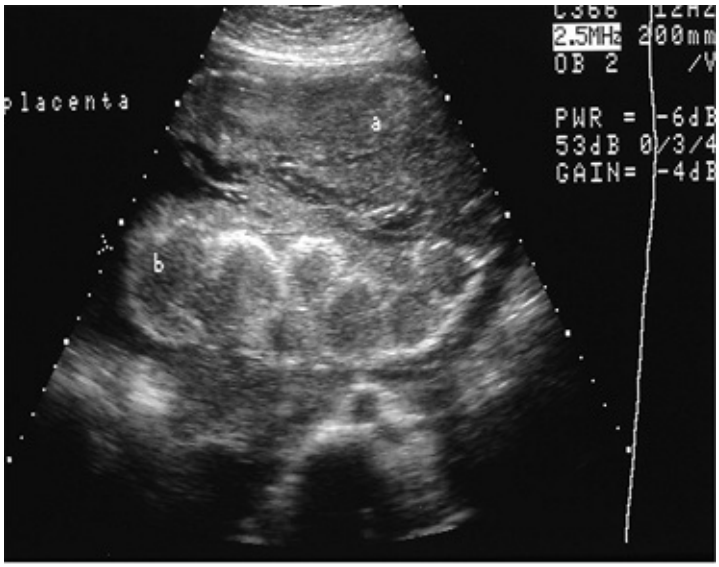

Figure 14.4 DZ twins with significant growth disparity. The etiology of the growth discordance was attributed to a placental implantation abnormality resulting in placental dysmaturity affecting only one of the twins.

It is important to appreciate that birth-weight discordance and IUGR are interrelated. When birth-weight discordance exceeds 20%, one of the fetuses will be growth restricted in more than 50% of the cases. When discordant fetuses are both appropriately grown for gestational age, differences in perinatal outcome have not been identified. Both prematurity and IUGR are much greater threats to the fetus than is the degree of discordancy.

Evaluation of discordant growth should be undertaken simultaneously with consideration of gestational age, individual fetal growth, and fetal well-being. In the absence of IUGR and in the presence of reassuring fetal testing, birth-weight discordance among preterm twins should be managed expectantly in anticipation of achieving a more advanced gestation or enhanced fetal maturity. Some caution is appropriate given that the ultrasound diagnosis of both IUGR and growth discordance is not reliable. The sensitivity of ultrasonography for substantial intertwin discordance is, at best, only 60%. Alternatively, ultrasound evidence suggesting 20% to 25% growth discordance or IUGR of either twin at ≥35 weeks gestation would be appropriate indications for delivery.

Twin-to-Twin Transfusion Syndrome (Chronic Intertwin Transfusion Syndrome)

TTTS is a serious complication affecting multiple pregnancies and is sometimes referred to as “chronic intertwin transfusion syndrome,” a complication of MZ/monochorionic twins in which intraplacental arterial venous shunts are uncompensated and preferential blood flow exists. Vascular communications are present in virtually all monochorionic placentas, and approximately one third will demonstrate at least some clinical evidence of the syndrome. Severely affected pregnancies are much less common, occurring in fewer than 5% of monochorionic gestations. Contrary to what might be expected, severe TTTS is associated with fewer, or even single, arterial venous malformations within the placenta rather than multiple vascular anastomoses. Multiple anastomoses function to restore a balance of bidirectional flow within the monochorionic placenta, while a limited number predispose to preferential flow. Severe chronic intertwin transfusion syndrome identified in the second trimester is associated with loss rates approaching 100% if untreated. Chronic intertwin transfusion syndrome accounts for 15% to 17% of all perinatal mortality in twin gestations.

In chronic intertwin transfusion, the arterial donor twin may be growth retarded, anemic, hypotensive, and oligohydramniotic. If there is little or no amniotic fluid surrounding the smaller fetus, the amniotic membrane may lie in close apposition to the smaller fetus, restricting it to the uterine wall. This is referred to as a “stuck twin.” The stuck twin can sometimes be misidentified as monoamniotic. The arterial donor twin also may experience ischemic organ damage involving the brain, kidneys, or bowel. The venous recipient twin can become hypervolemic, hyperviscous, hypertensive, and polyhydramniotic due to increased renal blood flow. Either twin may become hydropic due to volume overload in the recipient or high output failure in the donor. Polyhydramnios, which is common in the venous recipient, also contributes to a high incidence of premature labor or PPROM.

The diagnosis of chronic intertwin transfusion syndrome has become controversial. Older diagnostic criteria, focused primarily on neonatal measures (i.e., cord blood hemoglobin differences of 5 g/dL or birth-weight differences of 20%). These parameters generally have been discarded, as they did not efficiently identify those gestations thought to be affected by this disorder. Chronic intertwin transfusion syndrome now is diagnosed by using ultrasonographic criteria including:

- Marked size disparity in fetuses of the same sex
- Disparity in size between the two amniotic sacs
- Disparity in size of the umbilical cords
- A single placenta
- Evidence of hydrops in either fetus
- Findings of congestive heart failure in the recipient.

The monochorionic placenta, disparity in umbilical cord sizes, and severely discrepant fetal growth characteristic of TTTS are illustrated in Figure 14.5.

intertwin transfusion syndrome results in normal, nondiscordant systolic/diastolic (S/D) ratios. Abnormal SD ratios are more likely to reflect placental abnormalities associated with fetal growth restriction. The absence of underlying placental vascular lesions in chronic intertwin transfusion syndrome results in concordant uterine artery waveforms, helping to differentiate chronic intertwin transfusion syndrome from fetal growth restriction.

Figure 14.5 Placenta **(A)** and infants **(B)** delivery from a monochorionic, diamniotic twin gestation complicated by TTTS. Note the larger placental area associated with the recipient twin and the palor and impaired growth of the donor twin. (See Color Plate)

Quintero and colleagues have defined TTTS as a deepest vertical pocket ≤2 cm in the donor with a deepest vertical pocket ≥8 cm in the recipient. They also developed a staging system to assess progression and prognosis (Table 14.2).

Management of chronic intertwin transfusion syndrome will be individualized depending on the Quintero stage and the gestational age at which it is encountered. The option of delivery will depend on fetal maturity and the potential morbidity that would be encountered. At earlier gestational ages, serial decompression amniocentesis and tocolytic therapy have been successful in prolonging pregnancy. With the development of fetoscopy, direct laser occlusion of the placental vascular anomaly has become an option. For those patients not delivered, fetal health should be evaluated frequently with biophysical profile scoring or fetal heart rate monitoring. Of all available management options, large volume-reduction amniocentesis is an efficacious and minimally invasive therapy that probably is the treatment of choice after attainment of viability. For the previable patient, the prognosis is extremely poor, and consideration might be given to intrauterine laser ablation of placental surface vascular anastomoses, fetoscopic cord clamping, or termination.

TABLE 14.2 Quintero Staging Criteria for Twin-to-twin Transfusion Syndrome

Stage I: Bladder of donor still visible
Stage II: Bladder of donor no longer visible
Stage III: Critically abnormal Doppler studies (absent/reversal end-diastolic flow in the umbilical artery, reverse flow in the ductus venosus, or pulsatile flow in the umbilical vein) in either twin
Stage IV: Hydrops in one or both twins
Stage V: Demise of one or both twins

Donor, deepest vertical pocket ≤2 cm; recipient, deepest vertical pocket ≥8 cm.

Senat and the Eurofetus Consortium reported on a randomized but nonblinded prospective trial of clinical interventions for chronic intertwin transfusion syndrome prior to 26 weeks gestation. Women were randomized to either serial amnio reduction or fetoscopic laser coagulation of vascular anastamoses followed by amnioreduction to a deepest vertical pocket of 5 to 6 cm in the recipient at the conclusion of surgery. This study was halted following an interim analysis because of better outcomes in the laser group with respect to survival of at least one twin to 28 days of age (76% vs. 56%) There also was a significant reduction in the RR of both fetuses dying (RR 0.63; 95% CI 0.25 to 0.93; p = 0.009) and of both surviving at 6 months of age (p = 0.002). Additionally, surviving infants in the laser group were more likely to be free of neurologic complications at 6 to 12 months of age (52% vs. 31%, p = 0.003). While fetoscopic laser ablation may offer improved outcomes, it is available at only a limited number of centers.

The results of National Institutes of Health (NIH)-sponsored prospective randomized trial of amnioreduction versus selective fetoscopic laser photo coagulation for TTTS

were presented at the 2007 Annual Meeting of the Society for Maternal-Fetal Medicine. Forty-two patients who had failed to respond to an initial amnioreduction were enrolled with a primary outcome of 30-day postnatal survival. There was no significant difference in the primary outcome for either of the recipients (45% vs. 30%) or donors (55% vs. 55%). Additionally, there was no significant difference in 30-day survival of one or both twins between the amnioreduction and selective fetoscopic laser photocoagulation groups (75% vs. 65%) or in overall 30-day survival (60% vs. 43%). Within Quintero stages III and IV, there was a significant reduction in recipient survival for those twins treated by laser coagulation (67% vs. 12.5%; p < 0.03), suggesting that laser photocoagulation may need to be undertaken before TTTS becomes too advanced in order to be beneficial.

Fetal and Newborn Complications

Prematurity

The risk of preterm birth increases with the number of fetuses in utero and is the single greatest threat to the health of the newborns. Premature labor and PPROM are responsible for more than 70% of these premature deliveries. The incidence of preterm birth at less than 37 weeks gestation in the United States is 30% to 55% for twins, 66% to 80% for triplets, and virtually 100% for quadruplets. The mean gestational age at delivery is inversely related to fetal number: 39 weeks for singletons, 35 to 36 weeks for twins, and 32 to 33 weeks for triplets.

The contribution of multiple gestations to national rates of both perinatal morbidity and mortality has been delineated earlier in this chapter. Multiples contribute disproportionately to virtually every measure of perinatal health as well as measures of infant mortality and long-term mental and physical handicap. Infants of multiple gestations account for approximately 20% of all NICU admissions. An admission to a NICU can be expected in approximately 25% of all twins, in 75% of all triplets, and in more than 90% of quadruplets. Respiratory distress syndrome occurs in approximately 14% of twins, more than 40% of triplets, and more than 60% of quadruplets.

While the consequences of prematurity are easily calculable in terms of fetal and neonatal adversity, it must not be forgotten that prematurity also contributes significantly to the long-term health and well-being of these infants. Compared with singletons, the risk of dying before the first birthday is 5 times greater for twins and 14 times greater for triplets. Among survivors, the RR of severe handicap, controlling for both birth weight and gestational age is 1.7 (95% CI 1.6 to 2.0) for twins and 2.9 (95% CI 1.5 to 5.5) for triplets compared with singleton gestations.

Intrauterine Growth Restriction

IUGR certainly is more common in multiple gestations. During the third trimester, the average growth of multiples begins to diverge from that of the average singleton. Healthy twin gestations demonstrate growth velocities similar to that of singletons until approximately 30 to 32 weeks gestation, while triplet and quadruplet growth velocity begins to slow at 27 to 28 and 25 to 26 weeks, respectively. The mean estimated fetal weight for twins falls below the singleton 50th percentile at about 32 weeks but typically remains between the 10th and 50th percentile until approximately 36 weeks. Beyond 36 weeks, twins frequently fall below the 10th percentile compared to singleton norms. Between 36 and 38 weeks gestation, approximately one third of all twins will demonstrate IUGR. In comparison, approximately 12% of triplets will have a weight less than the 10th percentile based on singleton standards by 32 to 34 weeks, increasing to more than 60% by 35 to 36 weeks. Evaluation of the individual parameters of fetal biometry suggests that the reduced growth velocity seen in multiples is most consistent with an asymmetric IUGR. Relative placental insufficiency magnified by the inherent competition for nutrients presented by the multiple fetuses is the most likely cause of this constrained pattern of

growth. Other potential contributors to IUGR identified in multiples include a higher incidence of abnormal placental implantation, umbilical cord abnormalities such as two-vessel cords, velamentous or marginal insertions, chromosomal or structural abnormalities, and chronic intertwin transfusion syndrome.

IUGR in multiples is best predicted by using an estimated fetal weight calculated from multiple biometric parameters, including the abdominal circumference. The detection of IUGR also is aided by early diagnosis and accurate dating of the pregnancy. Beyond 20 weeks gestation, fetal growth in multiple gestations should be evaluated periodically by detailed ultrasonographic studies. In general, these scans can be performed on a monthly basis, although little data exist that define the optimal interval. That interval likely can be extended if results of the previous scan were reassuring, especially in dichorionic gestations. Shorter intervals of every 2 to 3 weeks may be required once IUGR has been identified or is suspected. The diagnosis of IUGR in one or both twins should lead to the institution of antenatal fetal surveillance inclusive of nonstress test, biophysical profile, assessment of amniotic fluid volume, umbilical artery Doppler velocimetry, and consideration given to the safety of early delivery just as it would be in a singleton gestation. If amniocentesis is used to assess fetal lung maturity, results obtained from the amniotic fluid of either twin usually will reflect the lung maturity status of both, making only a single sampling necessary. If IUGR is suspected in only one of the twins, it is likely that the smaller twin will have accelerated lung maturity, and therefore the amniotic fluid of the larger twin should be sampled.

Congenital Anomalies

Congenital malformations occur approximately twice as often in multiples compared with singletons and are more common in MZ than in DZ twins. The majority of malformations occur in MZ twins. However, twins are concordant for fetal anomaly in only a minority of cases. Even higher rates of congenital malformation have been reported in triplet gestations.

Identification of congenital malformations represents an important role for ultrasonography in multiples. Transabdominal evaluation of fetal anatomy is best performed between 18 to 22 weeks. However, transvaginal sonography may allow an opportunity to detect certain malformations even earlier. In a single center series of 245 consecutive twin gestations (490 infants), the use of antepartum ultrasound for the detection of congenital anomalies (4.4% anomaly rate) was excellent, with a sensitivity of 88% (21 of 24 anomalous fetuses detected), a specificity of 100%, a positive predictive value of 100%, and a negative predictive value of 99%. An accurate diagnosis of congenital anomaly is an obvious prerequisite for antepartum or intrapartum interventions. These interventions may include increased fetal surveillance; a change in the timing, location, or mode of delivery; consultation with various neonatal and pediatric subspecialists; and in some cases, interventions such as fetal therapy, selective reduction, or pregnancy termination.

Antepartum Care

Beneficial Interventions

Maternal Nutrition

Alterations in fetal growth described in multiple gestations have been attributed in part to the intensified fetal competition for maternal nutrients. This inherent competition results in a drain on maternal resources and an accelerated depletion of maternal reserves. Placental transfer of an adequate nutrient supply is compromised after a combined fetal weight of 3,000 g is exceeded. Unfortunately, most of the investigations that have evaluated the impact of nutrition on perinatal outcome have involved singleton gestations, overlooking the prenatal care of multiples. This is unfortunate, because there is accumulating evidence that nutrition is an important and modifiable variable that can improve intrauterine growth and potentially lengthen gestation.

The constrained pattern of fetal growth experienced by multiples makes environmental factors, such as nutritional adequacy, a greater influence on ultimate fetal growth than in singleton gestations. This allows a greater opportunity to positively influence birth weight and pregnancy outcome in multiple gestations by modifying maternal nutrition and by monitoring the rate of maternal weight gain.

Maternal weight gains of 24 lb by 24 weeks and overall weight gains of 40 to 45 lb are associated with optimal pregnancy outcomes, defined as an average twin birth weight of greater than 2,500 g. Investigators have emphasized the importance of adequate early weight gain (<24 weeks gestation). A ripple effect of maternal weight gain on fetal growth has been demonstrated with gains before 20 weeks and between 20 to 28 weeks influencing subsequent twin growth from 20 to 28 weeks and 28 weeks to delivery, respectively. Poor weight gain prior to 24 weeks (<0.85 lb per week), regardless of the rate of gain after 24 weeks, has been associated with both reduced intrauterine growth and higher perinatal morbidity. Studies among large cohorts of multiples have demonstrated that maternal weight gain prior to 20 weeks and between 20 to 28 weeks had a greater effect on birth weight in both twin and triplet pregnancies than did weight gain in the third trimester. These effects were most notable among underweight women.

Almost certainly, weight gain recommendations for twins need to be modified based on the maternal BMI, just as they are for singletons. Analyzing patterns of both intrauterine fetal growth and twin birth weights, Luke and colleagues have proposed BMI-specific weight gain guidelines for twin pregnancies. These guidelines were modeled by using multiple regression analysis for the gestational periods of 0 to 20 weeks (early), 20 to 28 weeks (middle), and 28 weeks to delivery (late). As might be expected, excellent twin growth was achieved with lesser maternal weight gains among overweight and obese women compared with underweight or normal weight women (Fig. 14.6).

A recent investigation assessed the validity of these proposed BMI-specific weight gain goals for twin gestations between 2002 and 2006. At the Medical University of South Carolina, Goodnight and coworkers prospectively followed 151 twin gestations by using the

BMI-specific maternal weight gain goals described by Luke and colleagues, which were established for each patient at presentation. Of these twins, 57.8%, 18.6% and 23.5% were under, within, or over their weight gain goals at 20 to 22 weeks, while 55%, 17.9%, and 27.2% were under, within, or over their goals at delivery. Achievement of maternal weight gain goals at 20 to 22 weeks and at delivery was associated with significantly increased birth weight and a nonsignificant increase in gestational age at delivery. After adjustment for gestational age, BMI, maternal age, and chorionicity, maternal weight gain that failed to reach the BMI-specific goals was associated with >½ pound reduction in birth weight (245 g per infant). At the same time, no maternal or fetal benefit was associated with exceeding the preestablished weight gain goals.

In a similar analysis, Luke and colleagues categorized 180 women with twin pregnancies of 24 weeks or greater according to their BMI-specific weight gain at 20 weeks as being below (66%), within (24%), or above (10%) the recommended range. Differences in birth weight and maternal postpartum weight were modeled by using analysis of covariance, adjusting for pregravid weight, length of

---

gestation, and weight gain after 20 weeks. Gaining within the BMI-specific weight gain guidelines at 20 weeks was associated with the best fetal growth, whereas gaining below or above resulted in substantially lower birth weights. In addition, gaining above the recommended range resulted in greater postpartum weight retention.

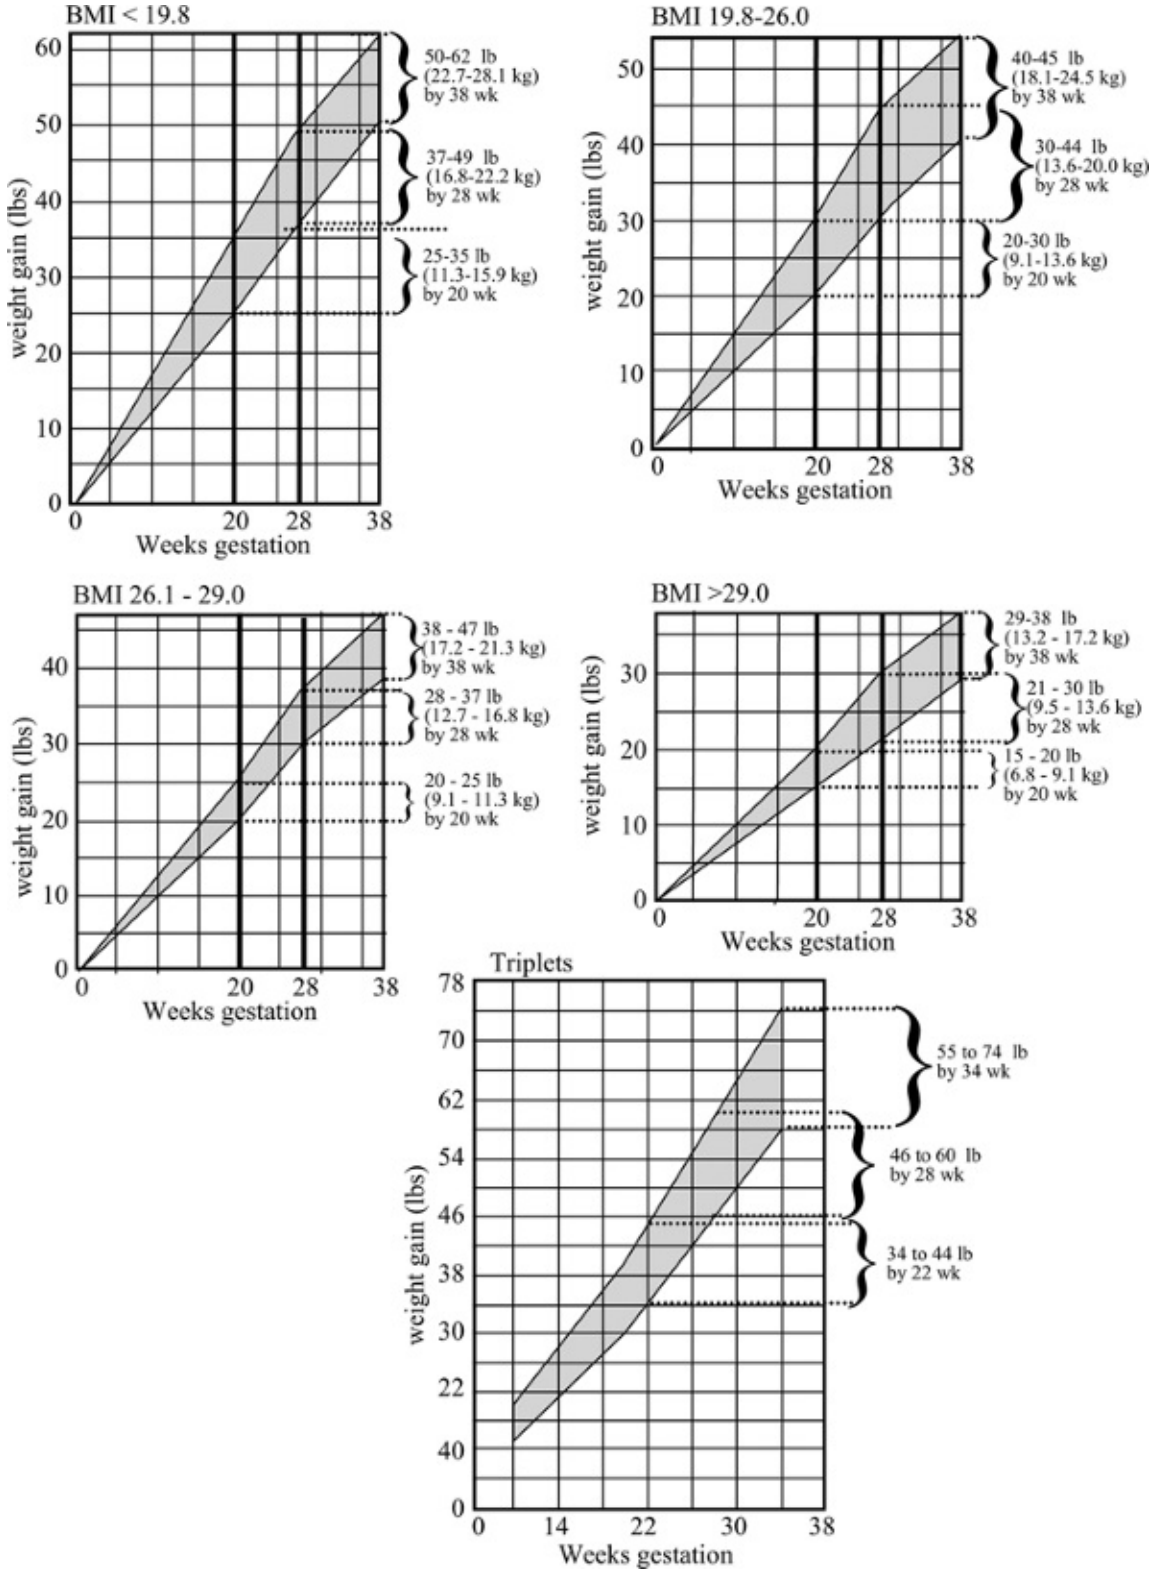

Figure 14.6 BMI-specific weight gain recommendations for twin and triplet gestations. (Modified from Luke B, Hediger ML, Nugent C, et al. Body mass index specific weight gains associated with optimal birth weights in twin pregnancies. *J Reprod Med* 2003;48(4):217–224.)

TABLE 14.3 Recommended Daily Allowances for Nonpregnant Women and Women Pregnant with Singletons, Twins, Triplets, and Higher-order Multiples

	Calories (kilocalories)	Protein (grams)	Carbohydrates (grams)	Fat (grams)
Nonpregnant	2,200	110	220	98
Singletons	2,500	126	248	112
Underweight twins (<19.8 kg/m^2)	4,000	200	400	178
Normal-weight twins (19.8–26.0 kg/m^2)	3,500	175	350	156
Overweight twins (26.1–29.0 kg/m^2)	3,250	163	325	144
Obese twins (>29.0 kg/m^2)	3,000	150	300	133
Triplet and higher-order multiples	4,500	225	450	200

Recommendations for the twin gestations are provided in a BMI-specific format.
Adapted from Institute of Medicine. *Nutrition during pregnancy*. Washington, DC: National Academy Press, 1990, and Luke B, Misiunas R, Anderson E, et al. Specialized prenatal care

and maternal and infant outcomes in twin pregnancy. *Am J Obstet Gynecol* 2003;189:934–938.

In 2003, Luke and colleagues reported on the results of a clinical intervention undertaken to evaluate the effect of intensive prenatal nutrition on the outcomes of twin pregnancies. Recommendations were made to bring the diet to 3,000 to 4,000 kcal per day depending on pregravid BMI, with the distribution of 20% of those calories from protein, 40% of the calories from carbohydrates, and 40% of the calories from fat (Table 14.3). The 190 mothers and their infants enrolled in this nutritional program were compared with 339 women seen during the same period with twin gestations but who were not followed in the enhanced nutritional program.

Compared with the nonprogram participants, the program pregnancies were associated with significantly improved obstetrical and neonatal outcomes (Table 14.4). In addition, at 3 years of age, the program children were less likely to have been rehospitalized (adjusted odds ratio [AOR] 0.31; 95% CI 0.11 to 0.91) or to be developmentally delayed. Finally, the average cost for each twin's birth was $16,115 ±$2,500 for those enrolled in the intervention program and $30,398 ±$2,979 for the nonprogram twins (p = 0.002). Program participation was associated with a savings of over $40,000 per twin pair.

In recognition of the critical role of nutrition, it is advisable that all women with a multiple gestation should receive in-depth education regarding fetal growth, nutrition, diet, avoidance of smoking, drugs and alcohol, and individualized BMI-specific weight gain recommendations. It is believed that this is best achieved through consultation with a dietician or nutritionist who is interested in perinatal outcomes. A survey of 928 twin gestations demonstrated that those women who consulted a registered dietician had higher maternal weight gain and were less likely to have a VLBW infant (2% vs. 12%) compared with women who did not.

Maternal anemia, both from iron and folate deficiency, are common in multiples. Many have recommended supplementation of the standard prenatal vitamin with iron (60 mg per day) and folic acid (1 mg per day) when a multiple pregnancy is diagnosed. The frequency of maternal anemia is related to the overall maternal nutritional status, which again emphasizes the need for adequate nutrition with a focus on heme-rich protein intake and an emphasis on folate-containing green leafy vegetables. Heme-iron rich sources such as red meat, pork, poultry, fish, and eggs are emphasized because of both their better iron absorption and the higher quality and quantity of protein and other nutrients. Other nutrients often lacking in women's diets include calcium, magnesium, and zinc, and their specific supplementation has been recommended to both prevent their further depletion and to reduce pregnancy complications.

There is good evidence that intensive patient education, aggressive nutritional counseling,

nutrient supplementation, and an emphasis on early and appropriate maternal weight gain can contribute to improved intrauterine growth and perinatal outcomes in multiple gestations.

Ultrasound

Ultrasound plays numerous critical roles in the antepartum care of multiples. These include their diagnosis, determination of amnionicity and chorionicity, identification of

fetal or placental anomalies, evaluation of fetal growth and amniotic fluid volume, evaluation of fetal biophysical parameters, and determination of presentation. Accurate determination of chorionicity and amnionicity is important in antepartum management. Monochorionic pregnancies are at substantially higher risk for IUGR, growth discordance, congenital anomalies, and intrauterine fetal death. Although uncommon, monoamniotic placentation represents an extreme risk, with high rates of twin-to-twin transfusion, cord entanglement, and fetal demise. Dichorionic twins are at lower risk, as this placentation does not carry the potential for vascular communication and is associated with a lower risk of congenital anomaly.

TABLE 14.4 Enhanced Nutritional Program for Twins: Obstetri Outcomes

Obstetrical Outcomes	Program	Nonprogram	Adjusted Odds Ratio	9 Conf Int
Length of gestation (d)	251 ±1.3	244 ±1.3	—	
Birth weight (g)	2467 ±37	2217 ±36	—	
PPROM (%)	10	25	0.35	(0.2
Preterm labor (%)	23	42	0.45	(0.3
Preeclampsia (%)	8	17	0.41	(0.2
Delivery <32 wk (%)	7	21	0.27	(0.2

Delivery <30 wk (%)	3	9	0.29	(0.1
LBW (%)	41	64	0.42	(0.3
VLBW (%)	5	16	0.30	(0.2

Neonatal Outcomes	Program	Nonprogram	Adjusted Odds Ratio	9 Conf Int
Length of stay (d)	9.4 ±0.9	15.0 ±1.0	—	
NICU admission (%)	43	62	0.48	(0.4

maternal and infant outcomes in twin pregnancy. *Am J Obstet Gyn*
2003;189:934–938.

If two separate placentas are identified or if the fetuses are of different sex, the placentation is dichorionic. A thin, wispy membrane along with a single placenta and same

sex fetuses suggest monochorionicity. There are several membrane characteristics that can help differentiate a monochorionic placenta from a fused dichorionic placenta. A “thick” dividing membrane composed of four layers suggests dichorionicity. Another helpful characteristic is the “twin peak” or “lambda sign.” The twin peak represents a wedge-shaped projection of placental tissue extending above the fused chorionic surface and separating the diamniotic, dichorionic intertwin membrane. Using these criteria, chorionicity can be predicted accurately in more than 80% to 90% of twin gestations. Determination of chorionicity is most accurate in the first trimester; as pregnancy progresses, the dividing membrane progressively thins and the likelihood of placental fusion increases.

Few studies have specifically addressed the value of serial ultrasound assessment of fetal growth in multiples or the appropriate interval for screening. It can be easily inferred, however, that ultrasound has an important role. IUGR is three times more common among twins compared with singletons, and ultrasound is the only modality capable of assessing individual fetal growth. In twin gestations, asymmetric growth restriction becomes increasingly more common as gestational age advances. The presumption is that ultrasound will allow identification of multiples with growth restriction resulting in either increased antenatal surveillance or early delivery, which may improve perinatal outcome.

Evidence of improved outcomes in multiples through the use of ultrasound is limited. In the routine antenatal diagnostic imaging with ultrasound (RADIUS) trial, twins were diagnosed both more consistently and at earlier gestational ages than in the control group receiving selective ultrasound. More than one third of the twins in the control group were not diagnosed until after 26 weeks gestation, and approximately 10% were not diagnosed until the onset of labor. The RADIUS trial demonstrated a 50% reduction in the incidence of composite adverse perinatal outcomes among the multiple gestations in the routinely screened group. While this reduction was dramatic, it was not statistically significant since the trial was not powered to identify differences in the multiple gestation subgroup. A 10-year study in Europe involving over 22,000 women and 249 multiple gestations also revealed improved perinatal outcomes

---

associated with routine earlier detection of multiples by ultrasound.

A review in 2000 by Kogan and associates evaluated trends in twin births in the United States between 1981 and 1997 that demonstrated an increasing frequency of preterm birth; surprisingly, this was most notable among women receiving the most intensive prenatal care (35.1% in 1981 to 55.8% in 1997). This trend, however, coincided with a reduction in the frequency of twin IUGR at term (30.7% to 20.5%), an increase in preterm growth restriction (11.9% to 14.1%), and a reduction in twin perinatal mortality. Although not defined in the Centers for Disease Control (CDC) database, these trends certainly could reflect the ability of antenatal ultrasonography to detect IUGR resulting in earlier delivery and resultant reductions in stillbirth and neonatal mortality.

Ultrasound is critical to the management of both twin and triplet gestations. In the second half of gestation, fetal growth should be assessed periodically by serial ultrasound examinations. As noted previously, most clinicians repeat these ultrasounds on a monthly

basis, although the appropriate interval between scans is not specifically known.

Multifetal Pregnancy Reduction

Gestational age and birth weight at delivery are the two most important factors determining perinatal morbidity and mortality, and both are inversely related to the number of fetuses present. According to the U.S. Vital Statistics, the average birth weight and gestational age for singletons is 3,358 g at 39.3 weeks compared with 2,500 g at 36.2 weeks for twins and 1,698 g at 32.2 weeks for triplets. Data from smaller series suggest that the average birth weight and gestational age are about 1,455 g at 30.5 weeks for quadruplets and 980 g at 29 weeks for quintuplets. These higher-order multiples are at significant risk of delivery prior to viability and an appreciable risk of serious long-term morbidity among the survivors. Expectantly managed triplets and quadruplets have a 20% to 30% risk of delivery prior to 24 weeks and an 8% to 12% risk of delivery between 24 and 28 weeks. Multifetal pregnancy reduction has emerged as a procedure meant to improve the overall chances of survival and health in higher-order multiple gestations. The preferred technique is the transabdominal, ultrasound-guided fetal intracardiac injection of potassium chloride.

The overall pregnancy loss rate prior to 24 weeks gestation following multifetal pregnancy reduction has dropped from initially reported rates of 15% to 20% to approximately 5% to 8% as experience with the procedure has increased. The risks of pregnancy loss and early preterm birth following multifetal pregnancy reduction also have been described based on the accumulated experience of a consortium of national and international centers. The loss rate prior to 24 weeks is related to both the starting and finishing number of fetuses. A higher starting number is associated with a greater pregnancy loss rate. The loss rate prior to 24 weeks gestation fell from 15.4% to 11.4%, 7.3%, 4.5%, and 6.2% with six or more, five, four, three, and two fetuses present, respectively, at the start of the procedure. The optimal finishing number of fetuses appears to be twins, with loss rates prior to 24 weeks of 10.9% compared with 13.7% and 18.0%, respectively, for singletons and triplets. Reduction to singleton pregnancy also may be considered for patients with cervical insufficiency, history of spontaneous preterm birth in a singleton gestation, or extremes of psychosocial stress. A recent analysis of 2,000 procedures revealed that the rate of reduction to singletons increased from 11.8% among the first 1,000 patients to 31.8% among the second 1,000.

Initially, it was believed that women with quadruplets or more would be ideal candidates for multifetal pregnancy reduction. A meta-analysis of the effect of multifetal pregnancy reduction on pregnancy outcome demonstrated that reduction to twins is associated with longer gestations, higher birth weights, and lower NICU admission rates. The incidence of maternal antenatal hospitalization, preterm labor, and cesarean birth also are reduced, although incidences of preeclampsia, gestational diabetes, and other pregnancy complications are not.

Somewhat more controversial has been the value of multifetal pregnancy reduction in triplets. Smaller series have not identified an improvement in perinatal mortality in reduced versus nonreduced triplets. Several investigators have reported a significant reduction in early preterm births (24 to 32 weeks) among triplets reduced to twins

compared with nonreduced triplets. Because early preterm birth is a known risk factor for disability, reduction of triplets to twins may reduce the rate of serious long-term morbidity and improve the quality of life for those remaining. Two relatively large databases that have specifically addressed the issue of reduction of triplets to twins have identified better outcomes for the reduced triplets, including decreased fetal loss prior to 24 weeks, decreased severe prematurity, increased gestational age at delivery, increased birth weights, decreased perinatal mortality, decreased neonatal respiratory morbidity, and decreased intraventricular hemorrhage.

It also is important to be aware of the psychologic implications for mothers who are undergoing multifetal pregnancy reduction. Follow-up studies of the emotional responses of women undergoing this procedure revealed that 70% mourned for the reduced fetus(es), but most of the depressive symptoms were mild and lasted only 1 month. For a few, however, moderately severe sadness and guilt continued for a longer period. Ultimately, over 90% of the women concluded that they would make the same decision again.

Beyond multifetal pregnancy reduction, selective fetal termination sometimes can be offered following identification of a serious or life-threatening malformation or abnormality of one twin. The most common indications for selective fetal termination include DZ twins discordant for fetal chromosome abnormality, serious fetal structural malformation, or one twin affected by a single gene disorder.

Multifetal pregnancy reduction of triplet and higher-order multiple gestations is associated with longer gestations, higher birth weights, and lower rates of perinatal morbidity. Multifetal pregnancy reduction of quadruplets or quintuplets also would be associated with significant reductions in perinatal mortality. Multifetal pregnancy reduction should be included in the counseling of all women with triplets and higher-order multiples.

Corticosteroid Administration

The efficacy of antenatal corticosteroid administration in multiple gestations has not been specifically examined. However, antenatal corticosteroids significantly reduce respiratory distress syndrome, intraventricular hemorrhage, and other neonatal complications of prematurity in singleton gestations. As a result, the NIH consensus conference statement on corticosteroids recommended that they be administered to women with preterm labor prior to 34 weeks gestation and to women with preterm PROM at <30 to 32 weeks gestation regardless of plurality, provided there are no contraindication to steroid use. It is recommended that they receive only a single course.

Fetal Surveillance

Multiple gestations have an increased risk of stillbirth compared with singletons at any gestational age. Because of this increased stillbirth risk, clinicians frequently initiate antepartum fetal surveillance. Although no prospective trials exist, all retrospective reviews indicate that the nonstress test has equivalent efficacy in multiples to that seen in singletons. Both the nonstress test and the biophysical profile have been shown to be

effective in identifying the growth-retarded multiple, the multiple at risk for hypoxic/asphyxic injury, and the multiple at risk for perinatal mortality. One retrospective cohort study compared 230 twins who received third-trimester nonstress tests with 435 twins who did not. Although the differences did not achieve statistical significance, there was only one intrauterine fetal demise in the nonstress test group compared with nine in the control group. Similar findings have been reported in smaller retrospective studies involving triplet and higher-order gestations.

While the routine use of antepartum fetal surveillance in uncomplicated multiples has been questioned by some, surveillance certainly is indicated in those gestations identified as being at higher risk. These would include those with IUGR, abnormal fluid volumes, growth discordance, decreased fetal movement, pregnancy-induced hypertension, fetal anomalies, monoamnionicity, or with any other pregnancy complications placing one or more of the fetuses at risk for hypoxic/asphyxic injury.

Another recommended method of fetal surveillance is fetal kick counting, although some patients may find it difficult to distinguish the movements of one fetus from those of another. Umbilical cord Doppler velocimetry also may be of help in evaluating growth-restricted fetuses. Ultrasonography obviously contributes to both the risk assessment and surveillance of multiple gestations.

At present, antepartum fetal surveillance in multiples is clearly recommended in all situations for which one would perform similar surveillance in a singleton pregnancy. Further studies are needed to determine if routine antepartum fetal surveillance of twins provides objective benefit. One reason to consider routine surveillance is the failure of ultrasound to reliably diagnose IUGR or significant twin growth discordance.

When instituted, antepartum fetal surveillance is most commonly performed with the nonstress test or the fetal biophysical profile. The contraction stress test is relatively contraindicated due to the risk of inducing a preterm delivery. However, a spontaneous negative contraction stress test also is a reliable assessment of fetal health. Ultimately, the most effective fetal surveillance technique for multiple gestations is unknown, as none of the available data is based on prospective study and none pertains to higher-order multiples beyond triplets. Also uncertain is at what gestational age testing should be initiated or whether testing should be performed once or twice weekly. The authors initiate fetal surveillance at 32 weeks in monochorionic twins and at 34 weeks in dichorionic twins, assuming there is no additional indication to initiate testing earlier. Fetal testing generally is performed on a weekly basis except in the presence of severe IUGR, abnormal umbilical artery Doppler studies, or monoamnionicity, which may require either twice weekly or even more frequent testing.

Controversial Interventions

Preterm Birth Risk Refinement

As described previously, all multiple gestations are at high risk for preterm birth. However, not all twins or triplets will deliver prematurely, and some will certainly be at higher risk

than others. Methods to further refine the preterm birth risk for an individual multiple gestation could be of great value in selecting those twin or triplet gestations that are the best candidates for increased surveillance or for interventions designed to reduce the risk of preterm delivery. Many such interventions attempted previously have been applied routinely to all multifetal gestations. With that approach, it is not surprising that they generally have been unsuccessful. Such risk refinement techniques are available and include digital cervical evaluation for calculation of a cervical score (CS), transvaginal cervical length (TVCL) measurement, and cervical/vaginal fetal fibronectin (FFN). An algorithm suggesting how these techniques may be used to assist with the antepartum care of multiple gestations is provided in Figure 14.7. While identification of the multiple gestation at highest risk for preterm birth is an important prerequisite to preterm birth prevention, it must be emphasized that improvement in outcomes associated with

these risk refinement techniques have not yet been demonstrated. As such, the algorithm presented is best described as a proposed approach to the care of multiple gestations awaiting validation of its individual components. The individual aspects of the authors' risk refinement techniques are discussed in turn.

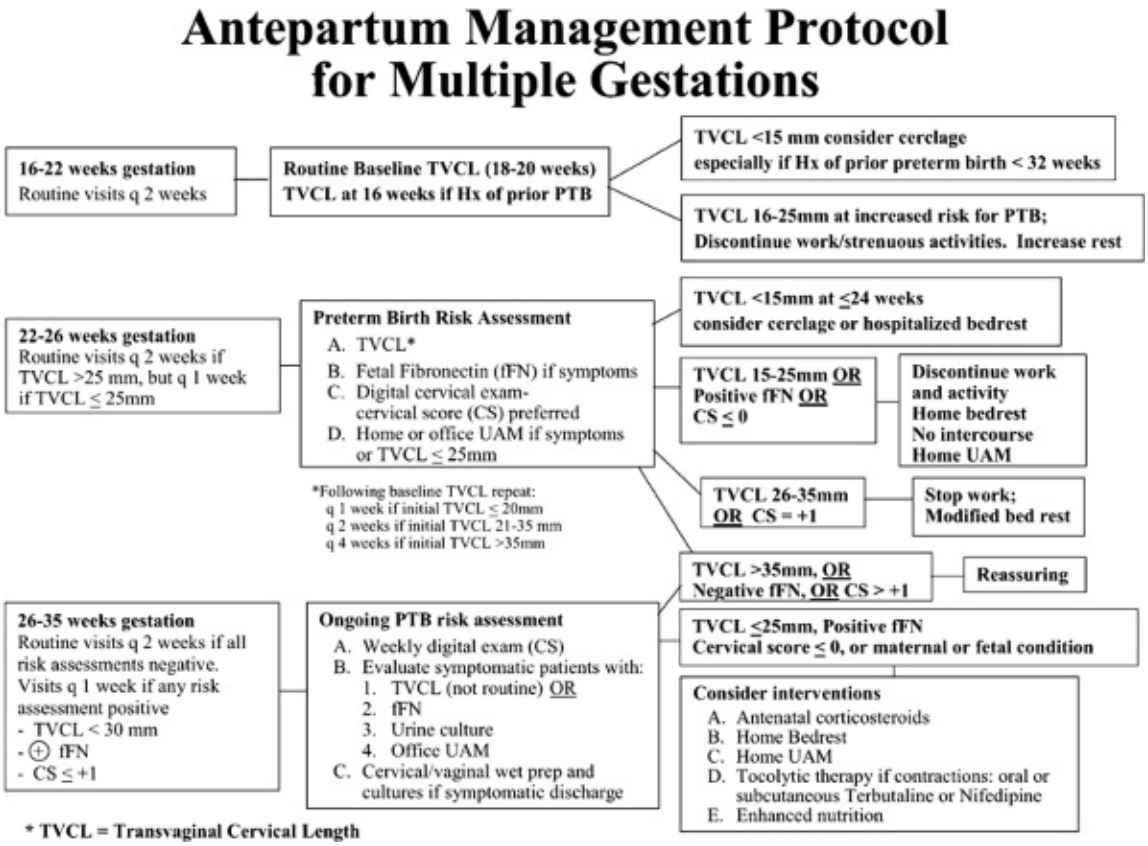

Figure 14.7 Antepartum management protocol for multiple gestations, emphasizing a preterm birth risk refinement strategy.

Serial Digital Cervical Examination

The value of antepartum digital cervical examination lies in its ability to provide ongoing risk assessment, especially in the late second and third trimester. The CS is calculated as follows: cervical length (in centimeters) minus cervical dilation at the internal os (in centimeters). A cervix that is 2 cm long with a closed internal os gives a score at +2. A cervix that is 1 cm long and dilated 1 cm at the internal os gives a score of 0. A cervix that is 1 cm long with an internal os dilated 3 cm gives a score of –2. A CS ≤0 on any single examination predicted preterm labor within 14 days in 69% of one cohort of women with twin gestations. When only multiparous women were considered, the predictive value rose to 80%.

A CS ≤0 is a marker of abnormal cervical status and increased preterm delivery risk. Conversely, women who maintain a CS greater than 0 are good candidates for continued observation without obstetric intervention. Ideally, these examinations should be done by a consistent examiner on an every 1- to 2-week basis between 22 and 35 weeks gestation. There are no prospective studies or cohort series demonstrating that antepartum digital cervical examination is associated with obstetric complications or adverse perinatal outcomes.

Transvaginal Ultrasound Cervical Length Measurements

Endovaginal sonography to measure cervical length has been studied to determine its predictive value for spontaneous preterm delivery in twin gestations. In a large, multicentered study sponsored by the National Institute of Child Health and Human Development (NICHD), predictors of preterm delivery were evaluated in both singleton and twin gestations. A TVCL of ≤25 mm was significantly more common in twin gestations compared with singletons at both

---

24 and 28 weeks. Of all the potential predictors of preterm delivery, a cervical length ≤25 mm at 24 weeks gestation was the best predictor of preterm birth before 32 weeks (27%), 35 weeks (54%), or 37 weeks (73%) gestation in twin pregnancies.

Alternatively, normal midtrimester cervical length measurements are associated with low rates of early preterm delivery. A retrospective cohort study by Imseis and colleagues of 85 twin gestations found that a TVCL of >35 mm between 24 and 26 weeks was associated with only a 3% risk of delivery <34 weeks gestation. Again, there is little evidence that endovaginal sonography has improved outcomes, in multiples. The only successful intervention trial to date based on endovaginal cervical length measurements was published by da Fonseca et al. in 2007. 250 women found to have TVCL ≤15 mm among a universally screened group of 24,620 were randomized to nightly vaginal micronized progesterone or placebo. Spontaneous delivery <34 weeks was significantly less frequent in the treatment arm (19.2% vs. 34.4%, p = 0.02). 24 women with twins were included. While the study was not powered to detect an outcome difference in the twins subgroup, the trend for fewer spontaneous births <34 weeks held. Given Berghella and colleagues' finding that cerclage for short cervix may be harmful in multiples, vaginal micronized progesterone is an alternative treatment that may be used and certainly warrants further investigation in multiples.

Ultrasound Indicated Cerclage

Based on the authors' published experience and a meta-analysis recently reported by Berghella and colleagues, placement of a cerclage for twins with a midtrimester TVCL ≤25 mm has not successfully prolonged gestation or improved neonatal outcomes. The authors' experience has been that women with multiples with a TVCL <15 mm at a previable gestation have remarkably poor outcomes. Cerclage is offered to these women on a case-by-case basis. Overall, however, the evidence is insufficient at present to recommend cerclage placement for a TVCL ≤25 mm or even <15 mm, although this clearly is an area for continued investigation.

Cervical and Vaginal Fetal Fibronectin

In the NICHD Preterm Prediction Study, 147 twins underwent serial assessment for cervical/vaginal FFN in addition to endovaginal ultrasound cervical length measurements. Positive FFN results at 28 and 30 weeks gestation were associated with an increased risk of delivery prior to 32 weeks. However, the association of FFN with preterm delivery was no longer significant after controlling for cervical length by logistic regression analysis.

As women with multiples are often highly symptomatic, one valuable aspect of the FFN test is its high negative predictive value. A negative FFN is associated with <3% risk of delivery in the next 2 weeks despite maternal symptoms assuming the absence of advanced cervical dilation.

FFN in cervical/vaginal secretions in the late second and early third trimester is associated with an increased risk of preterm birth in multiples. Data are conflicting as to whether FFN has predictive value in addition to endovaginal cervical length measurements. Alterations in clinical management based on FFN results have not yet been evaluated, and improved pregnancy outcomes have not yet been demonstrated for multiple gestations.

Reduced Activities and Rest

Activity restriction and increased rest at home commonly is recommended for women with multiples although there are no prospective randomized data evaluating this intervention. Existing data are both dated and limited by study design. Studies evaluating the role of prescribed rest in both twin and triplet gestations compared with similar pluralities with unrestricted activities typically date from periods when the unrestricted multiples were, in reality, undiagnosed until delivery. Maternal rest has been associated with reduced baseline uterine contraction frequency. Restricted activity generally has been accepted as a reasonable approach to the pregnancy prolongation for women with multiples deemed to be at increased risk of preterm birth. Other studies have suggested that the birth weights of twins and triplets may be increased if reduced activity and home bed rest is introduced in the midtrimester. Further research is needed to define the impact of restricted activity and rest on both the duration of pregnancy, fetal growth, and the risk of pregnancy-induced hypertension.

Home Uterine Activity Monitoring

Home uterine activity monitoring (HUAM) has been advocated for multiples due to their increased risk of premature labor combined with observations that multiples may be less accurate in the self-detection of their own prelabor uterine activity compared with women with a singleton. Prospective randomized trials evaluating the efficacy of HUAM in multiples have provided conflicting results.

Dyson and colleagues performed a prospective, randomized, multicentered trial of HUAM involving 2,422 pregnant women, including 844 twins who all received intensive preterm birth prevention education and had 24/7 availability of telephonic contact with a dedicated perinatal nurse. This program was then combined by a random assignment to three subsequent levels of surveillance:

. Weekly contact by a perinatal nurse

. Daily contact by a perinatal nurse

. Daily contact with a perinatal nurse and daily HUAM.

Among the twins, there were no differences in the frequency of preterm birth less than 35 weeks gestation between those women receiving weekly contact (22%), daily contact (24%), or HUAM (24%). At the time that preterm labor was diagnosed, 75% of the weekly contact patients, 76% of the daily contact patients, and 80% of the HUAM patients were <2 cm with no differences in the mean

---

cervical dilation. There was also no difference in the frequency of LBW or VLBW deliveries, mean number of days gained with tocolysis, or number of unscheduled visits.

HUAM in twins has been associated with improved outcomes in two prospective randomized trials that included a standard care control group. No benefit could be ascribed to HUAM when the comparison group received intensive education and was provided with frequent perinatal nursing contact. Similar apparently conflicting findings have been reported in prospective randomized trials of HUAM in high-risk singleton gestations. Both electronic HUAM and human perinatal nursing contact yield improved perinatal outcomes, suggesting that the benefit may arise not from the detection of uterine contractions but rather from the increased surveillance employed in other high-risk case management programs. At present, the benefits of HUAM in twins remain controversial, and its use should be highly individualized. There are no prospective data addressing the use of HUAM in triplets.

Tocolytic Therapy

Tocolytic therapy generally has been found to be of limited benefit in terms of prolonging pregnancy until term. In most investigations of either singletons or multiples, tocolytic therapy can be relied on only to provide a short-term prolongation of pregnancy. Even a short-term prolongation, however, can be beneficial in terms of allowing tertiary care transport; administration of corticosteroids for enhancement of fetal lung maturity; and in some cases, a modest extension of gestation. For gestations <32 weeks, a prolongation of even 1 week will be associated with measurable and significant reductions in neonatal morbidity and mortality.

Tocolytic use in multiples must be accompanied by very careful monitoring of both maternal and fetal condition. Women who are pregnant with multiples are at higher risk for a number of tocolytic-related complications, most notably pulmonary edema. Contributing to this risk is an increased maternal blood volume, a lower colloid oncotic pressure, and anemia in many cases. Concomitant intravenous fluid administration and corticosteroid therapy also contribute to this risk. Tocolytic factors that increase the risk of pulmonary edema include the use of ß-adrenergic agents and prolonging tocolytic therapy for more than 24 hours. Both myocardial ischemia and cardiac arrhythmias also have been reported as a rare consequence of tocolytic therapy. ß-Adrenergic agents are also known to increase maternal glucose levels, aggravating either pregestational or gestational diabetes.

Acute tocolytic therapy was undertaken most often by using intravenous magnesium sulfate. Although not tested in prospective randomized fashion with placebo controls, it does appear to be equivalent in effectiveness to intravenous ß-adrenergic therapy and with much greater tolerability and an improved safety profile. Although frequently associated with lethargy, weakness, nausea, vomiting, and blurred vision, magnesium sulfate has a significantly lower risk of severe hemodynamic, cardiopulmonary, or metabolic disturbances. When necessary, the authors use oral indomethacin in patients <32 weeks gestation as an adjunct to magnesium sulfate or as a second-line agent if magnesium sulfate cannot be tolerated in order to allow for an initial 48 hours for corticosteroid administration.

When increased uterine activity is identified by monitoring and the patient is felt to be at higher risk for preterm birth, attempts are sometimes made to reduce that uterine activity without resorting to intravenous therapy. The authors' choices for this sort of therapy are either oral nifedipine (10 to 20 mg every 6 hours) or oral (2.5 to 5.0 mg every 4 hours) or subcutaneous terbutaline sulfate.

Nonbeneficial Interventions

Prophylactic Cerclage

Two prospective randomized trials have assessed the value of prophylactic cervical cerclage in twin pregnancies, and neither revealed any improvement in preterm birth rate or perinatal mortality. Unfortunately, both studies lack substantial power due to small sample sizes. The studies also suggest that cerclage imparts some risk, specifically an increased risk of maternal infection and PPROM. These prospective findings also are supported by several retrospective studies, none of which reveals any improvement in mean gestational age at delivery or the proportion of preterm deliveries. In triplet pregnancies, the literature consists only of small retrospective studies. One study reported a benefit, whereas two others found none.

Berghella and colleagues recently published a meta-analysis using the patient level data of the four randomized controlled trials of cerclage versus bed rest in asymptomatic patients who had cervical shortening (TVCL ≤25 mm) in the second trimester. While they found a statistically significant decrease in preterm birth among singletons, the opposite was true

for patients with twins. Those patients treated with cerclage had a twofold greater risk of delivery before 35 weeks when compared with those treated with bed rest alone (RR 2.15; 95% CI 1.15 to 4.01).

Sufficient evidence is lacking to support the elective placement of cervical cerclage in either twin or triplet pregnancies. Cerclage should be reserved for patients with a significant clinical history suggesting cervical incompetence. While a shortened TVCL measurement correlates with preterm delivery risk in twins, there is insufficient evidence at present to conclude that cerclage placement for an abnormally short cervix will improve outcome.

Prophylactic Tocolysis

Prescribing prophylactic oral ß-mimetics in twins to reduce the risk of preterm birth has been evaluated in seven prospective randomized trials. Evaluation of these trials is difficult due to their heterogeneity. While all studies used oral ß-mimetic agents, a variety of different drugs were used as well as various dosages and gestational ages at which

the medications were started. Despite this heterogeneity, a meta-analysis of these trials failed to show any consistent effect on the risk of preterm birth, birth weight, or neonatal mortality. Other tocolytic agents such as prostaglandin synthetase inhibitors, calcium channel blockers, and oral magnesium sulfate have not been studied in multiples.

TABLE 14.5 Randomized Controlled Trial of 17-Hydroxyprogesterone Caproate for the Prevention of Preterm Birth in Twins

Outcomes	17-Hydroxyprogesterone Caproate (N = 325)	Placebo (N = 330)	Relative Risk (95% Confidence Interval)
Delivery <35 wk	135 (42%)	123 (37%)	1.1 (0.9, 1.3)
By indication			
Spontaneous	101 (31%)	86 (26%)	1.2 (0.9, 1.5)
		37	0.9 (0.6,

Indicated	33 (10%)	(11%)	1.4)
By chorionicity			
Mono	29/56 (52%)	26/53 (49%)	1.1 (0.7, 1.5)
Di	104/267 (39%)	95/273 (35%)	1.1 (0.9, 1.4)
By mode of conception			
ART	48/122 (39%)	38/108 (35%)	1.1 (0.8, 1.6)
Spontaneous	87/203 (43%)	85/222 (38%)	1.1 (0.9, 1.4)
Delivery <32 wk	54 (17%)	46 (14%)	1.2 (0.8, 1.7)

ART, assisted reproductive technology.

Intramuscular 17-hydroxyprogesterone caproate (17-OHPC) has been shown to reduce the rate of recurrent preterm birth in singleton gestations. An NICHD MaternalFetal Medicine Units Network–sponsored randomized controlled trial of 17-OHPC in twin gestations was reported recently. In a double-blind trial, 661 twin gestations between 16 and 20 weeks were randomized to weekly 250 mg intramuscular injections of 17-OHPC oridentical-appearing placebo, and treatment was continued until 35 weeks gestation. There was no significant difference in the primary outcome variable of delivery <35 weeks between the 135 women who received 17-OHPC (42%) and the 123 women who received placebo (37%). Nor were there any differences in other selected secondary outcomes (Table 14.5). Prophylactic treatment with 17-OHPC did not reduce the rate of preterm birth in women with twins. A similar study involving 17-OHPC in triplet gestations is ongoing with unknown results.

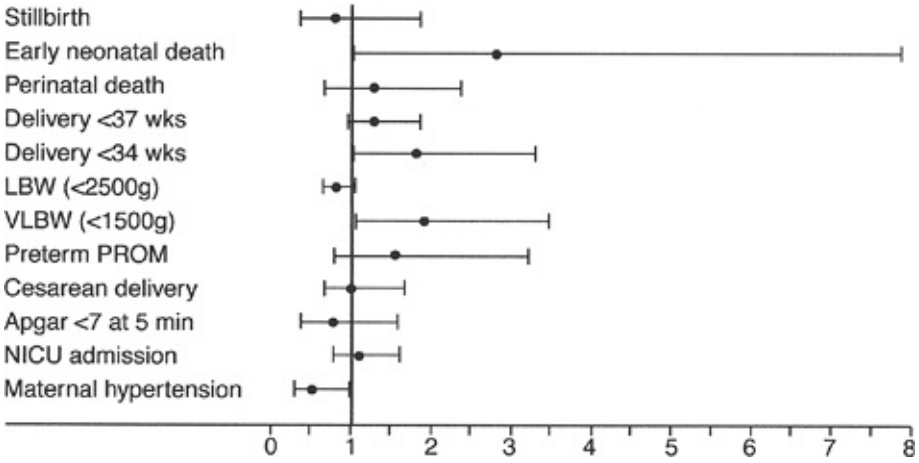

Figure 14.8 OR table of the effect of routine hospitalization for bed rest on obstetrical outcomes among women with uncomplicated twin pregnancies. (LBW, low birth weight; VLBW, very low birth weight; PPROM, preterm premature rupture of the membranes; NICU, neonatal intensive care unit.) (Adapted from Crowther CA. Hospitalization for bedrest in multiple pregnancy. In: Neilson JP, Crowther CA, Hodnett ED, et al., eds. Pregnancy and childbirth module. *Cochrane Database Syst Rev* [updated 03 June 1997] 1997; issue 3.)

Little evidence of efficacy of prophylactic tocolysis in triplets exists, although these data are obtained solely from retrospective review. The lack of efficacy in these retrospective studies may be biased if prophylactic tocolysis was used more often in triplets who were perceived to be at greater risk. The prophylactic use of oral tocolytic agents has not been associated with improved outcome or meaningful prolongation of pregnancy in either twin or triplet gestations.

Routine Hospitalization

Four prospective randomized trials of hospitalized bed rest for women with an uncomplicated twin pregnancy have been conducted. Published in the *Cochrane Database of Systematic Reviews*, these trials showed that neither stillbirth, neonatal death, or preterm birth were reduced by elective hospitalized bed rest (Fig. 14.8). In fact, significantly more women delivered VLBW infants and infants prior to

34 weeks gestation in the hospitalized cohort. This also was associated with an increased risk of early neonatal demise among the women who were routinely hospitalized with uncomplicated twins. Those patients at hospitalized bed rest did experience a lower frequency of maternal hypertension. One further study evaluated elective hospitalization by using a prospective sequential study design. A policy of elective hospitalization until 34 weeks was used between 1983 and 1985 encompassing 134 twin deliveries, followed by a policy of outpatient management between 1985 and 1987 encompassing 177 twin deliveries. There were no differences in prematurity or perinatal morbidity between the two groups. A study by Crowther in 1989 prospectively randomized 139 women with twins whose

pregnancies were complicated by preterm cervical dilation (CS <–2 at <34 weeks gestation). Despite the higher risk nature of this cohort, there were no differences seen in the risk of preterm birth, perinatal mortality, fetal growth, or other neonatal outcomes.

There is a single small prospective trial involving triplets born to 19 women who were randomized at 29 weeks gestation. The hospitalized group had a longer duration of pregnancy, fewer VLBW infants, and decreased neonatal morbidity. However, due to the small sample size, the observed differences were compatible with chance variation. A retrospective sequential cohort study of 34 triplets managed by elective hospitalization at 24 weeks between 1985 and 1993 were compared with 32 triplets managed by bed rest at home between 1993 and 1996. Routine hospitalization increased gestational age at delivery by 1 week, although this difference was not statistically significant.

There is no obvious benefit of routine hospitalization in twin gestations. In triplet gestations, there is a single prospective randomized trial, which suggested improved outcome with routine hospitalization but included too few patients to draw definitive conclusions. Definitive benefits will be necessary to outweigh the social and financial costs associated with routine hospitalization.

Intrapartum Management

Safe and successful intrapartum management of multiples requires attention to several important principles necessary to their care (Table 14.6). Most important is the presence of experienced and skilled obstetric, pediatric, anesthesia, and nursing personnel. The ability to successfully provide intrapartum care for laboring twin gestations is a reasonable measure of obstetrical quality and a highly functioning labor and delivery unit.

Intrapartum management plans for twin gestations will depend to a great degree on their relative presentations. During labor, both fetuses should be continuously monitored, as multiple gestations are at increased risk for intrapartum complications that may manifest as abnormal fetal heart rate tracings. Ultrasonography should be available to ascertain presentation, estimate relative fetal weights, and assist with fetal assessment during the interval between deliveries. When vaginal birth is attempted, the delivery room should be doubly set up for possible emergency cesarean, including immediate availability of anesthesia and neonatal services. Due to the relatively frequent need for emergency operative or manipulative obstetric procedures, continuous epidural anesthesia is preferred. Familiarity on the part of the obstetric attendants with the use of both obstetric forceps (Piper forceps if breech delivery is planned) and the vacuum extractor is recommended. A variety of medications also should be immediately available in the delivery suite, including a premixed oxytocin infusion for stimulation of labor since uterine inertia is often encountered following delivery of the first twin. Tocolytic agents such as subcutaneous terbutaline (0.25 mg) and intravenous nitroglycerine (50 to 100 μg) should be available for uterine relaxation. Women with multiple gestations also experience an increased mean blood loss with delivery, an increased cesarean rate, and are at increased risk of postpartum uterine atony. As a consequence, uterotonic agents such as methylergonovine maleate (Methergine) or 15-methyl prostaglandin F_2 (Hemabate) should be immediately accessible as well as the availability of blood products.

TABLE 14.6 Principles of Intrapartum Care for the Multiple Gestation

Presence of skilled obstetric attendants for labor and delivery
Sufficient nursing and neonatal care personnel
Dual-monitoring cardiotocograph
Intrapartum ultrasonic scanning capability
Intravenous access (16–18 gauge)
Premixed oxytocin infusion
Nitroglycerin or terbutaline for uterine relaxation
Methergine or 15-methyl $PGF_2\alpha$ readily available to treat postpartum hemorrhage
Obstetric forceps and vacuum extractor available
Immediate availability of blood and blood products
Anesthesiologist available at delivery and capability for emergency cesarean

$PGF_2\alpha$, prostaglandin F_2-alpha.

Timing of Delivery

The ideal time for delivery of uncomplicated multiple gestations is uncertain but is an important issue in terms of optimizing perinatal outcome. A retrospective population-based analysis of all live births and fetal deaths in the United States from 1983 to 1988 revealed that the lowest fetal death rate per 1,000 singleton conceptions was 0.9 at 3,700 to 4,000 g between 40 to 41 weeks. The lowest fetal death rate for twins was 3.3 per 1,000 conceptions at 2,500 to 2,800 g at 36 to 37 weeks gestation. The lowest fetal mortality rate for triplets was 5.2 per 1,000 conceptions at 1,900 to 2,200 g at 34 to 35 weeks gestation. The incidence of both stillbirth and early neonatal death gradually declined until 37 to 38 weeks gestation for multiples and increased thereafter. The lowest incidence of perinatal death (stillbirth plus early neonatal death) for multiples occurred at 38 weeks gestation. Most of the excess fetal mortality in twins was confined to infants with birth weights less than the tenth percentile. By 38 weeks gestation, asymmetric growth restriction is present in almost half of twin pregnancies and in an even larger percentage of triplets. Obviously, these population-based analyses should be supported by clinical studies determining the neonatal and postnatal risks of prematurity-related morbidity among multiples born during these presumed optimal birth-weight and gestational age windows.

Available data do not support the prolongation of a twin or triplet pregnancy beyond 38 or 36 weeks, respectively, in hopes of improving outcome. Elective delivery of twins and triplets at these gestational ages is not inappropriate. Beyond these points, multiples experience increased combined fetal and neonatal morbidity and mortality primarily related to growth restriction. At these advanced gestational ages, safely prolonging pregnancy requires reliable ultrasonographic evidence of adequate fetal growth, normal amniotic fluid volumes, and reassuring fetal testing as well as a stable maternal condition. The identification of IUGR, significant discordance, oligohydramnios, maternal preeclampsia, or any other significant maternal–fetal complication after 36 weeks with twins or after 34 weeks with triplets should be a specific indication for delivery. Unfortunately, the presumption that this will improve perinatal outcomes has not been subjected to prospective randomized analysis. In the absence of any of these maternal or fetal complications and with reassuring fetal testing, there is no contraindication to continued observation beyond 38 weeks for twins or beyond 36 weeks for triplets while awaiting spontaneous labor or a more favorable cervix.

Route of Delivery

The preferred route of delivery for multiples usually is determined based on presentation, which for twins is generally categorized into three large groups:

. Twin A vertex, twin B vertex

.. Twin A vertex, twin B nonvertex

. Twin A nonvertex.

Twin A Vertex/Twin B Vertex

Approximately 40% of twin gestations will present with both in a vertex presentation. Vaginal delivery should be anticipated for this group of twins, with high likelihood of success anticipated. More than 80% of vertex/vertex-presenting twin gestations are successfully delivered vaginally. The presentation of the second twin should be reconfirmed following delivery of the first as a change in the presentation may occur in 10% to 20% of cases. There is no evidence that perinatal outcomes for VLBW (<1500 gm) twins are improved by cesarean delivery. In fact, vaginal delivery is associated with a lesser degree of respiratory distress and pulmonary disease in the neonatal period. Nor is there evidence to support the need for a cesarean based on discordance in the size of the twins. Even if twin B is substantially larger than twin A, safe and successful vaginal delivery is still possible when twin B is in a vertex presentation.

Twin A Vertex/Twin B Nonvertex

Opinions diverge regarding the optimal mode of delivery for vertex/nonvertex-presenting twins, which represent another 40% of twins in labor. Reports of depressed Apgar scores and increased perinatal mortality during the 1970s and 1980s led to cesarean delivery being advocated by some whenever the second twin was in a nonvertex presentation. Since the

early 1980s, however, there has been a significant accumulation of primarily observational, nonrandomized clinical experiences that have not found an increased risk of adverse neonatal outcome when the nonvertex second twin is delivered vaginally. Only one prospective randomized trial, by Rabinovici and colleagues, has ever been performed. Sixty women in labor at 35 to 41 weeks in which the first twin was vertex and the second a nonvertex were enrolled. Of the 33 women assigned to vaginal delivery, two underwent cesareans, four second twins spontaneously converted to vertex, 14 had assisted breech extraction, and 13 had total breech extractions. Between twins delivered vaginally and those delivered by cesarean, there were no differences in Apgar scores or neonatal morbidity, and there was no birth trauma, stillbirth, or early neonatal death in either group. Women assigned to cesarean delivery had a significantly higher incidence of febrile morbidity and a trend toward greater receipt of general anesthesia (Fig. 14.9).

Supporting the Rabinovici trial, there have been at least ten observational studies that have looked at the outcomes for the nonvertex second twin. Although each study is limited by its lack of prospective randomization, and in some cases by size, none have found that the nonvertex second twin was disadvantaged by vaginal delivery, especially if the birth weight was greater than 1,500 g. Maternal morbidity is routinely higher and length of stay longer for the groups undergoing cesarean delivery.

Vaginal delivery of the nonvertex second twin by breech extraction or assisted breech delivery appears to be the best approach for infants over 1,500 g. There is no evidence that the increased maternal morbidity associated with routine cesarean is offset by improved neonatal outcome. A policy of routine cesarean whenever the second twin is not presenting as a vertex can be expected to increase maternal morbidity without beneficial effects in terms of maternal or infant outcome. Although not specifically studied, most clinicians would not recommend attempted breech

extraction if the second twin was anticipated to be significantly larger (>500 g) than the presenting twin.

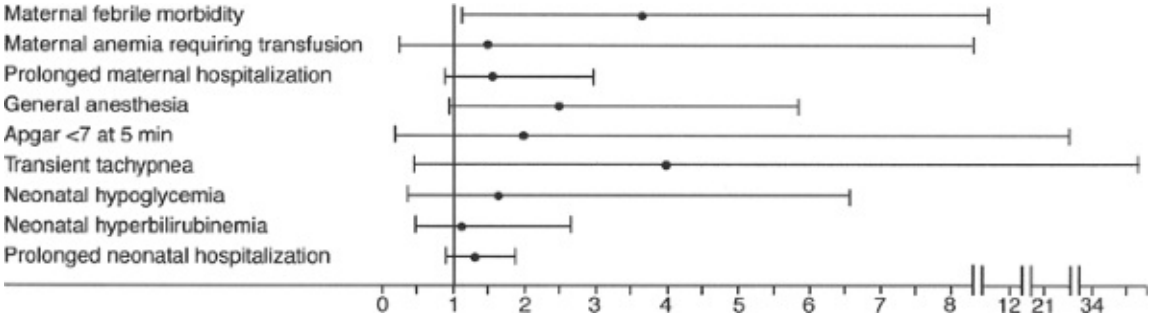

Figure 14.9 RR of selected obstetrical outcomes and the effect of cesarean delivery for the second twin. (Adapted from Rabinovici J, Barkai G, Reichman B et al. Randomized management of the second nonvertex twin: vaginal delivery or cesarean section. *Am J Obstet Gynecol* 1987;156:52–56.)

Recommendations for route of delivery for a nonvertex twin B whose birth weight is estimated to be less than 1,500 g is not so clear. A population-based study in Sweden encompassing 10 years of recorded deliveries allowed an assessment of 862 infants weighing less than 1,500 g delivered from 539 twin pairs. There was no significant difference in intrapartum or neonatal mortality related to the mode of delivery nor was there a difference of the subset of nonvertex second twins. Zhang and colleagues used a similar methodology in the United States but found somewhat different results. After controlling for maternal characteristics with multiple logistic regression, cesarean delivery was associated with a reduction in neonatal and infant death rates among all infants with a birth weight less than 1,000 g. The benefit of cesarean delivery was found primarily among second twins, whether vertex or nonvertex. Decisions on cesarean birth versus vaginal birth for nonvertex second twins less than 1,500 g should be based on the specific clinical situation and the experience of the staff involved. In the absence of an experienced operator comfortable with breech extraction, cesarean delivery should be performed.

External cephalic version for the nonvertex second twin after delivery of the first has been described. This approach has been popular among physicians who are less comfortable with breech extraction. Although no prospective trials have been performed comparing the efficacy and safety of second twin version versus breech extraction, several retrospective studies have addressed this issue. Chauhan and coworkers reviewed this literature, assembling 118 cases of external cephalic version for the nonvertex second twin. They found that despite a high rate of successful version, the rate of successful vaginal delivery was highly variable among reports (46% to 80%) with an overall success rate of 58%. There was a combined complication rate of 10%, including six cord prolapses, four episodes of fetal distress, one abruption, and one compound presentation. By way of comparison, the authors reviewed 683 second twin breech extractions in 11 published reports and reported a successful vaginal delivery rate of 98% with an overall complication rate of only 1%, which represented three fractured humeri, two episodes of fetal distress, and two cord prolapses.

Twin A Nonvertex

In approximately 20% of cases, twin A is in a nonvertex presentation. Vaginal delivery of twins with a nonvertex presentation of twin A is problematic, as little data exist evaluating its safety. Older retrospective reviews suggest an increased risk of perinatal loss when twin A delivers as a breech, although other relatively small retrospective reviews have found no significance difference in perinatal outcome between breech/vertex twins who are delivered vaginally and similar twins delivered abdominally. For twins presenting breech/vertex, the possibility of interlocking exists. While this complication is extremely rare, typically it is catastrophic. Another concern is that the breech twin A is free to extend its head during labor as a result of the space created by twin B or as a result of collision with twin B. Breech vaginal delivery with an extended fetal head is associated with an increased risk of cervical spine injury. When the first twin is presenting breech, the

most commonly employed mode of delivery is cesarean. Vaginal delivery may be an option based on the experience of the staff, the consent of the patient, and the capability for emergency cesarean delivery.

Triplets and Higher-Order Multiples

Cesarean is the most commonly recommended mode of delivery for triplets. A nationwide review of triplet births between 1985 and 1988 revealed that 94% of the deliveries were by cesarean, 4.5% were vaginal, and 1.5% were a combined vaginal/abdominal approach. Triplets and higher-order multiples are at significant risk for prematurity, growth retardation, and malpresentation. As a result, most clinicians prefer to deliver these pregnancies by cesarean rather than attempt a vaginal delivery, which may require complex manipulation of preterm infants. Successful vaginal delivery of triplets has been reported in several small series without any apparent compromise of perinatal outcome. If a vaginal delivery is planned, it is imperative that an experienced obstetric team be available, malpresentation anticipated, and preparations made for emergency cesarean delivery if necessary. It would

---

seem that optimal cases for vaginal delivery would be those with triplets estimated to weigh more than 1,500 g each and with at least the first two triplets in a vertex presentation.

Interval Between Deliveries

Older data suggested that time intervals between twin deliveries of more than 30 minutes would be associated with compromised outcomes. With the development of continuous electronic fetal monitoring and the intrapartum use of real-time ultrasonography, this no longer appears to be the case. Much of the data suggesting higher perinatal morbidity and mortality associated with long delays between deliveries are from an era when the presence of the second twin frequently was not apparent until after delivery of the first. Delays of more than 1 hour have not been associated with adverse outcomes for the second twin as long as continuous fetal heart rate monitoring is employed.

In some cases, there will be deterioration of the fetal condition following delivery of twin A. Both premature placental separation and prolapse of the umbilical cord are complications that are known to occur with increased frequency following the delivery of the first twin. Distress of the second twin usually should be managed by immediate cesarean or operative vaginal delivery. Internal podalic version and breech extraction should be considered only when emergency delivery is mandated and a cesarean is not immediately available. There are no current series documenting the safety of internal podalic version in cases of fetal distress. Due to the ever-present possibility of intrapartum fetal distress, the capability of immediate cesarean delivery should be considered the standard of care for multiples.

In the absence of any of the aforementioned complications, labor management for the second twin can be fairly aggressive. There often is a period of hypocontractility following delivery of the first twin. If labor has not resumed within a short time following delivery of

twin A, a previously prepared oxytocin infusion can be started and the dosage escalated in relatively rapid fashion until adequate uterine contractions are achieved. Once effective uterine contractions are reestablished, the woman is encouraged to bear down in order to achieve further descent. Once the vertex is dipping into the pelvic inlet, amniotomy can be performed during a contraction with moderate fundal pressure to help fix the vertex within the pelvis. The amniotic sac can be ruptured grossly if the fetal head is well applied to the cervix or leaked with a spinal needle if the vertex is not well applied.

Delayed Interval Delivery

Due to an increased risk of both extremely preterm and previable birth, multiple gestations occasionally present the opportunity for delayed interval delivery. The optimal situation occurs in a diamniotic, dichorionic twin gestation where the loss of the presenting fetus is the consequence of extrusion following either PPROM or true cervical incompetence. Other reported cases where delayed interval delivery has been employed successfully have been with separate implantations associated with müllerian anomalies, such as didelphic uterus. Less favorable circumstances would include those deliveries complicated by advanced preterm labor or vaginal bleeding suggestive of placental abruption. Contraindications to delayed interval delivery include significant hemorrhage, hemodynamic instability, intraamniotic infection, and monochorionic placentation. Although lifesaving prolongation of pregnancy has been reported in case reports and small series, the patient should be informed of the high failure rate associated with the procedure and risks including intrauterine infection, maternal sepsis, hemorrhage, and prolonged hospitalization.

Successful delayed interval delivery has been achieved both with and without the use of a rescue cerclage. Based on available case reports, however, adjunctive rescue cerclage appears to offer a better chance of greatly prolonging the interval between deliveries. Most protocols use aggressive perioperative tocolysis and broad-spectrum antibiotic coverage after delivery of the previable fetus, although there are no sufficient data to clearly establish the efficacy of either intervention. Given the early gestational age, many clinicians prefer perioperative indomethacin for prophylactic tocolysis. Specific pathogens such as gonorrhea, chlamydia, and group B streptococci should be identified and treated. Following delivery of the first fetus, the umbilical cord is tied, cut short, and allowed to retract back into the uterus. At that point, most clinicians place a 5-mm Merseline band using the McDonald technique as a rescue cerclage procedure. Tocolytic therapy, antibiotic coverage, and hospitalized observation are continued for variable periods of time along with intensive maternal and fetal surveillance. When successful, delayed interval delivery has allowed prolongation of pregnancy from a previable stage of maturation to viable gestation well within the third trimester and occasionally even to term.

Postpartum Management

Because of the potential risk of uterine atony and postpartum hemorrhage, the mother should be monitored closely during the initial hours after delivery. Intravenous oxytocin should be administered, and the uterine fundus should be regularly assessed to ensure that appropriate uterine tone is maintained. Lactation consultation may be useful to assist the

mother in initiating breast-feeding of her twins or triplets, particularly in cases of preterm or cesarean delivery. The maternal task of caring for multiple infants often is overwhelming. Follow-up and support for the mother in the early weeks after delivery are important, especially if the neonates require intensive care unit admission. Postpartum depression is more common in women who are delivering multiples, and surveillance for this important complication should be ongoing.

Summary Points

- Although multiples account for only a small percentage of all live births, they are responsible for a disproportionate share of all perinatal morbidity and mortality suffered in the United States.
- The dramatic increase in the frequency of DZ twinning in the United States is due, in part, to a national trend toward delayed childbearing, but the majority is a consequence of ovulation induction and ARTs.
- Women who are pregnant with multiples are more likely to be hospitalized antenatally for both an increased frequency and severity of pregnancy-related complications including preterm labor, PPROM, maternal anemia, placental abruption, preeclampsia, and urinary tract infections.
- The factors strongly correlated with both length of gestation and birth weight in multiples are maternal height; pregravid BMI; and maternal weight gain, especially early weight gain in underweight women.
- Preterm birth risk for multiples can be refined by using either digital cervical examination, TVCL measurement, or cervical/vaginal FFN. Application or avoidance of various preterm birth prevention strategies can be based on these risk refinement techniques.
- Data do not support prolongation of a twin or triplet pregnancy beyond 38 or 36 weeks, respectively, due to the increased combined fetal and neonatal morbidity and mortality associated primarily with high rates of IUGR.
- There is no evidence that the increased maternal morbidity associated with routine cesarean delivery is offset by improved neonatal outcomes for the nonvertex second twin over 1,500 g; therefore, vaginal delivery by breech extraction or assisted breech delivery is the preferred method of delivery in these cases.

Diabetes Mellitus and Pregnancy

E. Albert Reece
Carol J. Homko

The discovery of insulin in 1921 brought about a significant improvement in the overall outlook for women with diabetes and their reproductive potential. The incidence of both maternal and perinatal mortality has markedly decreased over the past 80-plus years as a result of this discovery as well as a multitude of other scientific advances, including fetal heart rate and blood glucose monitoring and neonatal intensive care. However, despite these advances, women with diabetes as well as their offspring remain at increased risk for a number of complications. The increased morbidity is directly related to the severity of maternal hyperglycemia. Therefore, the management goal of these pregnancies is strict glycemic control prior to conception and throughout gestation. This is best accomplished through the provision of multidisciplinary team care and targeted self-management education.

Fuel Metabolism

Pregnancy is recognized as having a profound effect on maternal fuel metabolism. These pregnancy-related alterations in maternal metabolism are necessary to meet the demands of the developing fetus. Studies of lean, healthy pregnant women have demonstrated a greater than normal sensitivity to the blood glucose–lowering effect of exogenously administered insulin during early pregnancy as compared with late gestation. In addition, insulin responses to an oral glucose load have been demonstrated to be increased in early pregnancy as compared with the nonpregnant state in the same glucose-tolerant women.

These increases in serum insulin levels and insulin sensitivity produce a milieu during early gestation that favors maternal fat accumulation in preparation for the rise in energy requirements associated with the rapid growth of the fetoplacental unit during late pregnancy (Fig. 15.1). Moreover, the increases in plasma concentrations of estrogen, progestins, and cortisol observed during early pregnancy also are likely to stimulate fat accumulation.

Late gestation is characterized by accelerated growth of the fetoplacental unit, rising plasma concentrations of several diabetogenic hormones including human placental lactogen and estrogens, and increasing insulin resistance. Several investigators have

demonstrated increased first- and second-phase insulin release during late gestation as well as increased plasma insulin and glucose ratios. Studies using the euglycemic-hyperinsulinemic clamp and minimal model techniques have reported that peripheral insulin sensitivity is reduced by 33% to 50% during late gestation. During the third trimester of pregnancy, insulin-stimulated carbohydrate oxidation is reduced out of proportion to the decrease observed in insulin-stimulated glucose uptake. Endogenous glucose production also is significantly less inhibited during the third trimester when compared with either the second trimester or the nonpregnant state. Thus, there appears to be general agreement that the second half of pregnancy is associated with increasing insulin resistance both in the periphery (muscle) and at the hepatic level.

The cause or causes of the increased insulin resistance during late pregnancy are not entirely clear (Fig. 15.1). The parallel development of insulin resistance and increases in blood levels of human placental lactogen, a hormone with strong lipolytic and anti-insulin action, suggests that human placental lactogen and perhaps other diabetogenic hormones, including cortisol, progesterone, and estrogens, may be responsible for much of the observed insulin resistance. In addition, there also is evidence to support a role

for plasma free fatty acids and inflammation in the development of insulin resistance during late pregnancy.

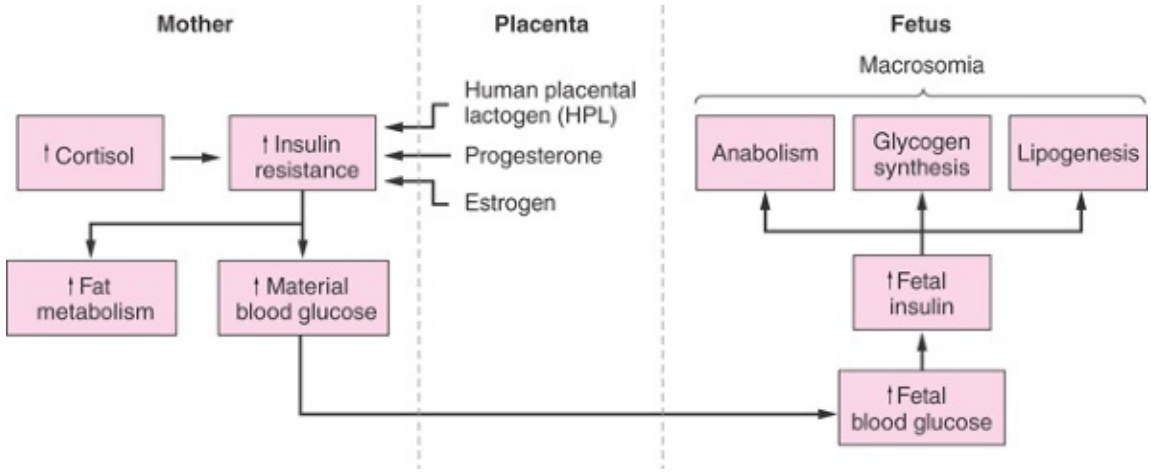

Figure 15.1 Schematic diagram of metabolic alterations in diabetes mellitus in late pregnancy (in absence of appropriate therapy).

The development of peripheral and hepatic insulin resistance after midpregnancy can be seen as an effort of the mother to adapt to the fuel needs of the rapidly growing fetus. During the third trimester of pregnancy, glucose uptake by the fetus has been estimated to be ~33 μmol/kg per minute. To satisfy this additional need, peripheral insulin resistance increases in pregnant women, thus reducing maternal glucose utilization. In addition, hepatic insulin resistance increases, which increases hepatic glucose production. Moreover, by decreasing carbohydrate oxidation, much of the glucose entering the muscle is shunted into alanine or lactate, which can be recycled into glucose.

Classifying Diabetes

Diabetes mellitus is generally classified into the following categories: type 1 or insulin-dependent diabetes mellitus, type 2 or noninsulin-dependent diabetes mellitus, and gestational diabetes mellitus (GDM). Approximately 10% of all individuals with diabetes mellitus have type 1 diabetes. Beta cell destruction, with resulting insulin deficiency, is the hallmark of this disorder. Onset is generally before the age of 30 years, and as a result, this type of diabetes is frequently encountered in women of childbearing age. It is estimated that type 1 diabetes complicates approximately 0.2% of all pregnancies in the United States annually.

Type 2 diabetes is the most common form of the disease, affecting nearly 90% of all individuals with diabetes. Type 2 diabetes is characterized by defects in both insulin action and secretion. It typically is seen in individuals over the age of 40 years and therefore in the past was felt to be uncommon in women of childbearing age. However, in recent years, the incidence of type 2 diabetes has been increasing steadily among younger individuals, and data from the National Maternal and Infant Health Survey indicates that type 2 diabetes complicates 0.3% of all pregnancies in the United States. *Gestational diabetes mellitus* is defined as carbohydrate intolerance of variable severity with onset or first recognition during the index pregnancy.

If the abnormality in glucose tolerance persists after pregnancy, the patient's diagnosis is revised to type 1, type 2, or impaired glucose tolerance (IGT).

Gestational Diabetes Mellitus

GDM is a common problem that complicates approximately 5% of all pregnancies in the United States. The likelihood of developing GDM is significantly increased among certain subgroups, including individuals with a positive family history of type 2 diabetes, advancing maternal age, obesity, and. nonwhite ethnicity. Excess risks for both GDM and IGT have been demonstrated in black, Hispanic, and Native American women as well as in women from the Indian subcontinent and the Middle East.

Screening and Diagnosis for Gestational Diabetes Mellitus

Screening of pregnant women for GDM remains a topic of great debate, both in this country and throughout the world. In 1998, the Fourth International Workshop-Conference on GDM acknowledged that there were certain populations of low-risk women in whom it may not be cost-effective to routinely screen for GDM. This low-risk group includes women who were not members of ethnic minorities, were less than 25 years of age, had no first-degree relatives with diabetes, and are of normal body weight. Although selective screening may be appropriate in certain populations with a low prevalence of type 2 diabetes, universal screening is advocated in most centers. The American College of Obstetricians and Gynecologists (ACOG) recommends that all pregnant patients be screened for GDM whether by patient's history, clinical risk factors, or a laboratory screening test. However, the American, Canadian,

and British Diabetes Associations recommend biochemical screening.

Screening should be performed between 24 and 28 weeks gestation, although women with significant risk factors may benefit from being screened earlier in pregnancy. A 50-g glucose challenge test is performed without regard to the time of day or interval since the last meal. A venous plasma glucose is measured 1 hour later, with a value of ≥140 mg/dL indicating the need for a 3-hour 100-g oral glucose tolerance test (OGTT). However, lowering the cutoff value to 130 to 135 mg/dL increases the yield of cases of GDM by 10%. Thus, by lowering the cutoff, the sensitivity is increased yet the number of false-positive screening tests increases as well. The use of either threshold is acceptable.

The OGTT is performed after an overnight fast and 3 days of an unrestricted carbohydrate diet. A fasting blood glucose level is drawn, and a 100-g glucose load is then administered. Plasma glucose levels are drawn 1, 2, and 3 hours following ingestion of the glucose solution. Diagnosis requires that at least two of the four glucose levels of the OGTT meet or exceed the upper limits of normal. Currently, there are two sets of diagnostic criteria in use in the United States—those of the National Diabetes Data Group and those of Carpenter and Coustan. The Fourth International Workshop Conference believed that there was sufficient evidence to suggest that the Carpenter-Coustan criteria, with its lower cutoff values, more accurately predict neonatal risks and has recommended the use of these criteria. ACOG guidelines support the use of either set of criteria.

In addition, the Fourth International Workshop-Conference acknowledged an alterative to the two-step screening/diagnostic procedure described previously. The evaluation of glucose intolerance during pregnancy may be made by using a one-step approach or 2-hour 75-g OGTT. This approach is considered most applicable in high-risk populations. Currently, studies are under way to establish the relationship between the various diagnostic criteria and perinatal outcomes in these pregnancies.

Women with GDM should be evaluated at the first postpartum visit by a 2-hour OGTT using a 75-g load. Greater than 90% of women will convert to normal glucose tolerance following delivery. However, studies indicate that the risk for overt diabetes may be as high as 20% to 50% in this population. Long-term annual follow-up is therefore indicated. GDM is influenced greatly by body weight, with the highest rate occurring in obese patients. Women with a history of GDM should be counseled regarding the use of lifestyle changes such as weight loss and regular exercise to reduce this risk.

Maternal Complications

Despite improvements in pregnancy outcomes, women with both GDM and pre-GDM are at greater risk for a number of pregnancy-related complications (Table 15.1). These include preterm labor, infectious morbidities, hydramnios, and hypertensive disorders. In addition, multiple investigators have reported a significant association between poor glycemic control and hypertensive disorders, preterm labor, and infections. Furthermore women with pre-GDM also are at risk for the acute complications of diabetes because of the metabolic alterations associated with pregnancy as well as the effects of strict glycemic control. The vascular alterations associated with long-term diabetes also contribute to the higher morbidity rates observed in women with diabetes. Both diabetic nephropathy and

retinopathy may progress during pregnancy and should be monitored closely.

TABLE 15.1 Pregnancy Complications in Diabetes

Long Term
Childhood obesity
Neuropsychologic defects
Diabetes

RDS, respiratory distress syndrome.

Current data would seem to indicate that pregnancy is an independent risk factor for diabetic retinopathy. Hypertension, poor control early in pregnancy, and rapid normalization all appear to be associated with the potential to accelerate retinal deterioration. Furthermore, women with more advanced forms of retinopathy and a longer duration of diabetes are at highest risk for progression. All women with type 1 diabetes for 5 years or more or type 2 diabetes at diagnosis require a thorough dilated ophthalmologic evaluation. This may necessitate preconception fluorescein angiography, as dye studies generally are contraindicated during pregnancy. Ideally, these evaluations should be completed prior to attempting conception. Laser therapy, if indicated, also needs to be completed prior to conception.

In contrast, most studies that have observed the effects of pregnancy on diabetic nephropathy have suggested that pregnancy is not associated with either the development

or progression of preexisting nephropathy in women with mild to moderate disease. However, diabetic nephropathy is the complication of diabetes that is most likely to affect pregnancy outcomes. There are increased risks for pregnancy-induced hypertension and/or a progression of already existing hypertension, intrauterine growth retardation resulting in small-for-gestational-age infants, preterm deliveries secondary to fetal distress, and a 10-fold increase in the incidence of stillbirth over women with diabetes but without nephropathy. Preeclampsia is the most frequent, serious complication of maternal nephropathy, with implications for both mother and fetus. Close monitoring of blood pressure, with addition or adjustment of antihypertensive agents as needed, is recommended. The drugs of choice are methyldopa, calcium channel blockers, and ß-blockers. Select calcium channel inhibitors, such as diltiazem, induce mild reductions in blood pressure but have a potent effect on decreasing excess protein excretion.

Neonatal Complications

The offspring of women with diabetes remain at increased risk for a number of complications, which includes congenital anomalies, fetal macrosomia, respiratory distress syndrome (RDS), and metabolic abnormalities as well as long-term sequelae (Table 15.1).

Perinatal Mortality

The two major causes of perinatal mortality are unexplained fetal death and congenital malformations. The causes of unexpected death are not well understood. In animal models, sustained hyperglycemia has been associated with increased insulin secretion, elevated fetal oxygen consumption, acidosis, and death. It has been postulated that fetal polycythemia and increased platelet aggregation could explain the increased incidence of intravascular thrombosis in infants of diabetic mothers and that thrombotic episodes could be the underlying cause for late unexplained intrauterine deaths.

Approximately 40% of perinatal deaths that occur among infants of women with diabetes can be attributed to malformations. Diabetes mellitus is one of the most common maternal conditions that results in anomalous offspring. The frequency of major congenital anomalies is increased two- to threefold over the general population. Great diversity is seen in the types of malformations associated with insulin-dependent diabetes mellitus. The most frequent types of malformations involve the central nervous system and cardiovascular, gastrointestinal, genitourinary, and skeletal systems, with cardiac malformations being the most common.

The defects most often associated with diabetes occur during organogenesis before 7 weeks gestation. Clinical series in humans have shown an association between malformations and glucose control early in pregnancy. In addition, other investigators have demonstrated that tight glucose control either prior to conception or very early during pregnancy can effectively reduce the rate of major malformations. As a result of these and other studies, the management goal for diabetic pregnancies has become the establishment and maintenance of near euglycemia beginning with the preconceptual period and continuing throughout gestation.

Altered Fetal Growth

Macrosomia is a classic hallmark of the pregnancy complicated by diabetes and is reported to occur in 20% to 25% of pregnancies complicated by diabetes. *Macrosomia* is defined as excessive birth weight (>90%) for gestational age or as a birth weight >4000 g. Increased adiposity is the primary cause of the increased birth weight seen in the offspring of diabetic women. Numerous studies have established a relationship between the level of maternal glucose control and macrosomia. Mothers of macrosomic infants usually have significantly elevated plasma glucose levels at term, indicating increased glucose availability to the fetus, with hyperinsulinemia a likely intermediate step, during the third trimester. Other factors associated with an increased risk for fetal macrosomia include increased maternal weight, increased parity, previous delivery of a macrosomic infant, and insulin requirements >80 U per day.

Macrosomic fetuses have higher perinatal and neonatal mortality and morbidity rates. Approximately 10% of infants weighing over 4,500 g at birth will require admission to a neonatal intensive care nursery. In addition, the reported perinatal mortality is two to five times higher in this group of children than in average-sized children. Delivery of a macrosomic infant is dangerous because of the risk for birth trauma to the head and neck. Fetal asphyxia and meconium aspiration may occur as a result of prolonged labor secondary to unrecognized cephalopelvic disproportion and shoulder dystocia.

At the other extreme, women with type 1 diabetes also are at increased risk for delivering a small-for-gestational-age infant. In general, the risk of growth retardation increases with the severity of the mother's clinical diabetes. Vascular complications, such as retinopathy and nephropathy, are believed to be associated with uteroplacental insufficiency in pregnant women with diabetes. Poor maternal renal function, hypertension, and placental lesions have all been associated with intrauterine growth retardation in the offspring of diabetic mothers. However, more recent evidence suggests that the growth retardation may be related to disturbances in maternal fuels during organogenesis.

Metabolic Abnormalities

Hypoglycemia occurs when plasma glucose levels fall below 35 mg/dL in the term infant and 25 mg/dL in the

preterm infant. Infants of diabetic mothers can develop hypoglycemia during the first few hours of life, particularly in cases of poor glycemic control. Macrosomic infants and infants with elevated cord blood C-peptide or immunoreactive insulin levels also are at increased risk. The incidence of hypoglycemia is reported to range from 25% to 40% in infants of mothers with diabetes. Both poor glycemic control during pregnancy and high maternal plasma glucose levels at the time of delivery increase the risk of its occurrence.

The incidence of hypocalcemia also is significantly increased in the infants of women with diabetes. Hypocalcemia generally occurs in association with hyperphosphatemia and occasionally with hypomagnesemia. *Neonatal hypocalcemia* is defined as a calcium level at or below 7 mg/dL. Serum calcium levels usually are lowest on the second or third day of

life. *Polycythemia* is defined as a venous hematocrit that exceeds 65% and is reported to occur in one third of neonates born to diabetic women. Polycythemia is believed to occur as a result of chronic intrauterine hypoxia, which leads to an increase in erythropoietin and consequently results in an increase in red cell production. Neonates born to women with diabetes also have a higher incidence of hyperbilirubinemia as compared with nondiabetic controls. Neonatal hyperbilirubinemia develops in approximately 20% to 25% of cases. Animal studies have demonstrated an association between fetal insulin and elevated levels of erythropoietin, which is the major regulator of erythropoiesis in the neonate.

Other Infant Morbidities

Offspring born to women with diabetes mellitus also are at increased risk of developing various hypertrophic types of cardiomyopathies and congestive heart failure. The exact incidence is not known, but one study reported that 10% of infants born to women with diabetes may have evidence of myocardial and septal hypertrophy. Thickening of the interventricular septum as well as the left or right ventricular wall can occur, and it is felt to be a result of the fetal hyperinsulinemic state. In the majority of cases, the infants are asymptomatic and the myocardial changes are detectable only by electrocardiogram or echocardiogram. In severe cases, left ventricular outflow obstruction can result and may lead to reduced cardiac output and congestive heart failure during the first few days of life. The abnormalities do not appear to permanently damage the myocardium, and in most cases, they regress by 6 months of age.

RDS is another common complication associated with diabetes. In the past, offspring born to women with diabetes had a four- to sixfold greater incidence of RDS at every week of gestation. This incidence was dramatically decreased with the initiation of strict metabolic control. More recent studies, in fact, seem to indicate that stringent metabolic control may reduce the incidence of RDS in neonates of women with diabetes to near background level in the population.

Lastly, there are long term consequences of diabetic pregnancies. These include childhood obesity, neuropsychologic deficits, and an increased tendency to develop overt diabetes.

Preconception Care

Care of women with type 1 or type 2 diabetes ideally begins before conception. Although numerous clinical trials have demonstrated that strict glycemic control prior to and during early gestation can reduce the rate of structural defects, the vast majority of women with diabetes still seek medical care only after they learn they are pregnant. Consequently, the rate of congenital malformations in infants of mothers with diabetes has continued to remain significantly higher than that of the general population.

A prepregnancy assessment should be undertaken to document a woman's overall fitness for pregnancy. This includes a careful history and thorough physical examination to assess the patient's vascular status. Baseline creatinine clearance and protein excretion levels should be evaluated and an electrocardiogram performed. These women also should be referred for an ophthalmologic consultation. Optimization of blood glucose control should be

achieved before the woman is advised to become pregnant. Women should receive appropriate contraceptive therapy while they are preparing for pregnancy. For patients who are not already following an intensive regimen, an extensive period of education and the institution of self–blood glucose monitoring is also necessary.

Prepregnancy counseling for women with GDM should begin immediately after delivery. These women need to be advised that they are at significant risk for developing GDM in subsequent pregnancies and that they are at increased risk for developing type 2 diabetes as they age.

Diabetes Management

The main goal of management for pregnancies complicated by either gestational diabetes or pre-GDM is to achieve and/or maintain euglycemia throughout gestation. The treatment approach requires a combination of diet, exercise, intensive insulin regimens, oral medications, and daily multiple blood glucose determinations.

Diet

Diet therapy is the cornerstone of diabetes management in pregnancy, just as it is in the nonpregnant state. The goal of diet therapy is to meet the additional nutritional requirements of pregnancy while at the same time maintaining good glycemic control.

TABLE 15.2 Preparation of a Diet for a Pregnant Woman with Diabetes

Determination of Calories	
Normal weight	30 kcal/kg/d
Underweight	40 kcal/kg/d
Overweight	24 kcal/kg/d
Components of Diets	
Carbohydrate	40%–45% of calories

Fat	Up to 40% of calories, with saturated fat limited to one third of calories
Protein	About 60 g, accounting for 12%–20% of calories

All pregnant women with diabetes should be seen by a nutritionist for individualized diet counseling. There are no universal recommendations for determining calories required during pregnancy. Most experts advocate an additional intake of 300 to 400 kcal per day to meet the needs of pregnancy. Recommendations regarding total caloric intake often are based on the mother's pregravid weight—30 kcal/kg of body weight per day for normal weight women with diabetes, 40 kcal/kg per day for underweight women, and 24 kcal/kg per day for overweight women (Table 15.2). Although it generally is agreed that pregnancy is not the time for weight reduction, obese women with type 2 or GDM should be encouraged to achieve a weight gain of no more than 15 pounds. Modest caloric restrictions have not been associated with either ketonuria or elevated plasma ketone concentrations.

The most current guidelines suggest that the composition of the diabetic diet be based on an individualized nutritional assessment. Since the postprandial blood glucose level has been shown to be a major factor in the development of neonatal macrosomia, a goal of nutrition therapy is to blunt postprandial hyperglycemia. The postprandial blood glucose level is most influenced by the carbohydrate content of the meal. Carbohydrate levels of 40% to 45% of total calories are considered appropriate during pregnancy. To achieve euglycemia, dietary fat can be liberalized up to 40% of calories. Saturated fats should be limited to one third of fat calories or less. The remaining calories should come from either monounsaturated or polyunsaturated fats. The recommended dietary allowance for protein in pregnancy is 60 g per day, and this typically ranges from 12% to 20% of total calories.

A number of different approaches to meal planning can be utilized and range from general guidelines for good nutrition to structured meal planning strategies and carbohydrate counting. The most appropriate approach will depend on the patient's type of diabetes, educational level, lifestyle habits, motivation, and economic restraints. Although the nutritional needs and distribution of calories for women with GDM and pre-GDM are similar, the number and timing of snacks will vary. Generally, two or more snacks are recommended for women with type 1 diabetes, while women with type 2 diabetes or GDM only require a bedtime snack. The bedtime snack should include a complex carbohydrate and protein to prevent late-night hypoglycemia and early morning starvation ketosis. Artificial sweeteners are considered safe to use during pregnancy, although no specific recommendations concerning intake levels exist.

Carbohydrate counting is another approach to meal planning that has gained popularity particularly among individuals on intensified insulin regimens (either insulin pumps or multiple daily injections). Carbohydrates affect blood glucose levels more than other forms of energy sources (proteins and fats). Both the amount and type of carbohydrate influence blood glucose values. Women are taught to measure the exact number of grams of carbohydrates in the food they eat and adjusted their short-acting or rapid analog insulin

doses (insulin-to-carbohydrate ratio) accordingly to achieve glycemic targets. With advanced carbohydrate counting, women also utilize correction boluses (supplemental doses of insulin based on their individual insulin sensitivity factor) as an adjunct to scheduled insulin to reduce glucose levels when elevated back into the target range.

Exercise

Although exercise has been demonstrated to be beneficial in nopregnant individuals, evidence regarding the risk and/or benefits of either periodic or regular exercise in pregnant women with diabetes is limited. Little has been published regarding exercise during pregnancy complicated by preexisting type 1 or type 2 diabetes. However, walking is possible for most women and has been reported to improve lipid profiles and blood glucose control.

Pregnancy is not a time to initiate a new exercise program, but women who have been exercising regularly prior to pregnancy can be counseled to continue. Appropriate exercises are those that use upper body muscles and place little mechanical stress on the trunk region. Women should be taught to palpate their uterus during exercise and stop the exercise if they detect contractions. Until additional studies are completed, however, medical supervision is recommended for all pregnancies complicated by diabetes. Women with type 1 diabetes are vulnerable to exercise-related hypoglycemia and therefore should monitor their blood glucose levels closely and always have a readily available source of glucose. Women should be cautioned against becoming dehydrated, overheated, tachycardic, or dyspneic. Exercise should not be prescribed for patients with hypertension or autonomic dysfunction with a diminished counter-regulatory response.

In regard to GDM, exercise has been recommended as an adjunct to nutritional therapy. Regular aerobic exercise has been shown to lower fasting and postprandial glucose

concentrations. Several randomized controlled trials have demonstrated that upper extremity exercise for 20 minutes three times per week can significantly lower blood glucose levels in women with GDM. In addition, these trials found no significant increase in either maternal or neonatal complications related to exercise.

Pharmacologic Therapy

The goal of insulin therapy is to achieve blood glucose levels that are nearly identical to those observed in healthy pregnant women. Therefore, multiple injections of insulin usually are required in women with preexisting diabetes. Human insulin is the least immunogenic of all insulins and is exclusively recommended in pregnancy. Insulin requirements may change dramatically throughout the various stages of gestation. In the first trimester, the maternal insulin requirement is approximately 0.7 U/kg of body weight per day. This is increased in the third trimester to 1.0 U/kg per day.

There are several different approaches to insulin administration that can be utilized during pregnancy. The superiority of one regimen over another has never been fully demonstrated. The new rapid-acting insulin analogs with peak hypoglycemic action 1 to 2

hours after injection offer the potential for improved perinatal outcomes. Studies support their safety during pregnancy and their ability to improve glycemic control.

The continuous subcutaneous insulin infusion pumps are another treatment option that have been utilized successfully during pregnancy. Insulin therapy delivered by a subcutaneous infusion pump more closely resembles that of physiologic insulin release. Insulin pumps deliver a continuous basal rate of insulin infusion with pulse-dose increments before meals. Published studies have demonstrated that comparable glucose control and pregnancy outcomes can be achieved by both conventional insulin therapy and pump therapy. However, it has been reported that A_1c (HbA_1c) levels were significantly lower 1 year after delivery in women who elected to remain on pump therapy after delivery as compared with women who had continued to use conventional insulin treatment. Other advantages of insulin pump therapy during pregnancy include more rapid and predictable insulin absorption, enhanced lifestyle flexibility, and simplified morning sickness management.

Pharmacologic therapy should be initiated in all women with GDM who fail to maintain euglycemia with diet. Historically, in this country, only insulin therapy has been utilized. As in pre-GDM, there is no generally accepted insulin regimen, so the woman's blood glucose levels should guide the doses and timing of insulin therapy. Over the past several years, glyburide therapy has been gaining popularity and is currently utilized in many obstetric settings throughout the world as an alternative to insulin therapy. In 2000, a randomized controlled trial in women with GDM found glyburide to be a safe and clinically effective alternative to insulin in achieving maternal blood glucose targets. These findings have been supported by both anecdotal data and evidence from multiple uncontrolled studies. However, glyburide should be used with caution in women who are obese, have elevated fasting blood glucose levels, and/or women diagnosed early in pregnancy. Approximately 5% to 20% of pregnant women who are started on glyburide will not respond adequately and will require insulin therapy.

Monitoring Metabolic Status

Self-Monitoring of Blood Glucose

Self-monitoring of blood glucose has become the mainstay of management for pregnancies complicated by diabetes mellitus. A variety of small, battery-powered blood glucose reflectance meters are available for home use. Accurate readings depend on performing the test correctly, but most of the newest models are less technique dependent. Some models are extremely sophisticated, having memories that permit the storage of results with the day and time they were collected, whereas others can even be downloaded onto a personal computer. Many systems also allow alternate site testing (palm, forearm, legs), which many people find more comfortable than finger sticks. However, it should be noted that alternate site testing should not be used if hypoglycemia is suspected or less than 2 hours following a meal. All women should be seen by a qualified nurse-educator for an individualized assessment to ensure that her technique is accurate. Ongoing education also is important to help the woman make necessary changes in her treatment plan to maintain

euglycemia throughout gestation.

Although it has been shown that self-monitored blood glucoses generally correlate very well with automated laboratories, reports have shown that sometimes patients falsely report blood glucose levels both during and outside of pregnancy. These findings are worrisome, as accurate information is essential for optimal management of the pregnancy complicated by diabetes. Therefore, verified blood glucose determinations (i.e., the utilization of blood glucose meters with memory) are recommended to enhance the reliability and accuracy of self-monitored blood glucose results.

Blood glucose measurements should be obtained at least 4 times a day (fasting and 1 to 2 hours after meals) in women with GDM and 5 to 7 times a day in women with preexisting diabetes (Table 15.3). In addition to this regular monitoring, patients also should test whenever they feel symptoms of either hyperglycemia or hypoglycemia. Detailed record keeping is useful to help identify glucose patterns. Daily urine ketone testing should be performed to ensure early identification of the development of starvation ketosis or ketoacidosis. Ketone testing also should be performed any time the blood glucose level exceeds

200 mg/dL, during illness, or when the patient is unable to eat.

TABLE 15.3 Monitoring the Diabetic Pregnancy

Maternal Surveillance
Self–blood glucose monitoring four to seven times daily
A_{1C}
Urinary ketones
Blood pressure
Retinal and renal status (for women with preexisting diabetes)
Fetal Surveillance
Level II ultrasound and fetal echocardiogram (for women with preexisting diabetes)
Serial assessment (4–6 wk) of fetal growth
Daily fetal movement counting
Weekly NST or BPP

NST, nonstress test; BPP, biophysical profile.

Blood glucose levels are measured in both the fasted and postprandial states. A randomized controlled trial compared the efficacy of preprandial and postprandial glucose

determinations in reducing the incidence of neonatal macrosomia and other complications in women with GDM. Women requiring insulin treatment were randomly assigned to have their diabetes managed according to the results of preprandial self–blood glucose monitoring or postprandial monitoring, which was performed 1 hour after meals. Both groups had similar success in achieving blood glucose targets and demonstrated similar degrees of adherence with the monitoring schedule. Nevertheless, the women in the postprandial monitoring group received significantly more insulin and achieved a greater decrease in glycoslyated hemoglobin values during treatment than those in the preprandial monitoring group. In addition, there was significantly less macrosomia and neonatal hypoglycemia among the offspring of the mothers in the postprandial monitoring group. These data suggest that adjustment of insulin therapy according to the results of postprandial blood glucose values improves glycemic control and pregnancy outcomes.

Previous studies in pregnant women with pre-GDM also have found that postprandial blood glucose levels are better predictors of fetal macrosomia than are fasting blood glucose levels. The Diabetes in Early Pregnancy Study demonstrated that third-trimester nonfasting glucose levels to be the strongest predictors of percentile birth weight in infants of diabetic mothers. Similar results have been reported by Combs and colleagues, who found that the incidence of macrosomia rose progressively with increasing postprandial glucose levels. Postprandial glucose levels of less than 130 mg/dL reduced the incidence of macrosomia, but levels of less than 120 mg/dL totally eliminated this complication. The Coombs group recommended a glucose level of 130 mg/dL as a reasonable target for 1-hour postprandial glucose levels.

Although it is widely accepted that the level of metabolic control achieved in the pregnancy complicated by diabetes significantly affects perinatal outcome, what constitutes optimal control has not been established. Emerging evidence suggests that a continuum of risk exists between carbohydrate intolerance and both perinatal and neonatal morbidity. In theory, then, the target ranges for blood glucose during pregnancy should be based on maternal plasma glucose levels in normal pregnancy. The logical approach is to achieve as near-normal glucose levels as possible without undue severe hypoglycemia. Current recommendations are that whole blood glucose levels should not exceed 95 mg/dL in the fasted state and 120 mg/dL after meals.

Although the current data demonstrate a relationship between metabolic control and neonatal complications, maternal glycemia may not be the sole parameter of optimal control. Buchanan and colleagues have suggested the use of fetal ultrasound to identify pregnancies at risk for fetal macrosomia and related morbidity in women with GDM. They have found that a fetal abdominal circumference of less than the 75th percentile for gestational age obtained in the late second trimester or early third trimester can distinguish pregnancies at low risk from those at high risk for producing large-for-gestational-age (LGA) infants. Their data suggest that maternal glucose concentrations alone may not accurately predict which fetuses are at high risk for excessive fetal growth and support the use of fetal criteria to direct metabolic therapies in GDM.

Glycosylated Hemoglobin

The glycosylated hemoglobin assay is an accurate, objective measure of chronic glycemic control in diabetes. It can be measured either as total glycohemoglobin or as the particular configuration known as HbA_1c or A_1c. Proteins undergo a nonenzymatic, postsynthetic modification that results in the attachment of glucose to various amino acids. This process, which is known as glycosylation, occurs slowly and is irreversible. The amount of hemoglobin that becomes glycosylated depends on the concentration of glucose over the time of the exposure and therefore is not significantly influenced by recent or transient blood glucose excursions. Because erythrocytes in the peripheral circulation have a half-life of 100 days, the glycosylated hemoglobin levels reflects glycemic control over the preceding 2 to 3 months. As in the nonpregnant state, most studies have found positive correlation between A_1c values and other parameters of glucose control during gestation.

Several investigators have reported an association between malformations and glucose control early in pregnancy. The higher the woman's glycosylated hemoglobin level, the greater is her risk of having a severely affected infant. The risk of miscarriage also has been shown to be increased with marked elevations in first-trimester glycosylated hemoglobin. Ideally, glycosylated hemoglobin

---

levels should be measured before conception, and pregnancy should be delayed until normal levels are reached. Unfortunately, the majority of pregnancies in both women with and without diabetes are not planned. Therefore, the A_1c level can be obtained at the first prenatal visit and reassessed every 4 to 6 weeks to document the degree of glycemic control maintained throughout the pregnancy. While elevations in first-trimester glycosylated hemoglobin levels indicate an increased risk for congenital malformations, an elevation in the second half of pregnancy appears to identify infants at risk for perinatal morbidity and mortality. Several investigators have demonstrated an association between A_1c and neonatal hypoglycemia, neonatal hyperbilirubinemia, perinatal death, and macrosomia. In women with GDM, however, A_1c levels have not been found to be useful as either a screening or diagnostic tool.

Fetal Assessment

All pregnancies that are complicated by diabetes require additional fetal evaluation and assessment (Table 15.3). Ultrasonography provides the clinician with essential information about the fetus and its development. A first-trimester scan should be performed to date the pregnancy and establish viability. All women with pre-GDM also should be evaluated for possible fetal anomalies. Although the risk for delivering an anomalous infant cannot be fully determined by a glycosylated hemoglobin level, an elevated A_1c should alert the practitioner to an increased risk for structural defects. Evaluation includes a targeted ultrasound to survey general fetal anatomy and fetal echocardiography at approximately 20 to 22 weeks gestation. In addition, the maternal serum alpha-fetoprotein screening test should be performed between 16 and 18 weeks gestation because of the increased risk of neural tube defects.

Since women with diabetes are at risk for fetal growth aberrations, frequent ultrasound scans are recommended to identify states of altered growth. Ultrasound examinations

should be performed at 4- to 6-week intervals during the second and third trimesters of pregnancy to assess not only fetal growth but amniotic fluid volume as well.

Fetal death is more common in pregnancies complicated by diabetes than in the general population. The goal of antepartum surveillance is avoidance of intrauterine death by early detection of fetal compromise. The nonstress test (NST) has become the preferred antepartum fetal heart rate test for screening the fetal condition in pregnancies complicated by diabetes. The NST evaluates the presence of accelerations from the baseline fetal heart rate. An alternative fetal test is the fetal biophysical profile (BPP), which also is utilized to evaluate the significance of a nonreactive NST. Because the BPP employs ultrasound, it permits evaluation of amniotic fluid volume and may detect major fetal malformations in patients who have not been studied earlier in pregnancy. Maternal evaluation of fetal movement counts also should be integrated into the surveillance program. Women with diabetes are instructed to count fetal movements beginning as early as 28 weeks gestation. Although the false-positive rate is high, the technique is inexpensive and simple and augments the total antepartum surveillance program.

Most perinatal centers institute a program of weekly fetal monitoring beginning at 32 to 34 weeks gestation. Since fetal death is more common in women with poor glycemic control, hydramnios, fetal macrosomia, hypertension, or vasculopathy, these women receive twice weekly NST testing. Patients with diet-controlled GDM who maintain normal fasting and postprandial glucose levels are probably at low risk for an intrauterine death and are not tested as early or frequently. However, women with GDM and chronic hypertension, a previous history of stillbirth, and preeclampsia and those who require insulin therapy receive more intense surveillance.

Timing and Mode of Delivery

It is generally accepted that if a pregnant diabetic patient is in good metabolic control and is receiving fetal surveillance on a regular basis, delivery may be safely delayed until term or the onset of spontaneous labor. Women with poor metabolic control, worsening hypertensive disorders, fetal macrosomia, growth retardation, or polyhydramnios may be electively delivered after fetal lung maturity has been confirmed. If an elective delivery is planned before 38 weeks gestation, amniocentesis should be performed for confirmation of fetal lung maturity. Fetal lung maturation is better predicted by the amniotic fluid phosphatidylglycerol content than by the lecithin:sphingomyelin ratio.

Cesarean section should be performed on most diabetic patients with an estimated fetal weight of greater than 4,500 g to prevent shoulder dystocia and birth trauma. Management should be individualized for patients with an estimated fetal weight between 4,000 and 4,500 g. The decision is based on the size of the pelvis and progress of labor as well as the patient's obstetric history. A history of shoulder dystocia often is an indication for repeat cesarean section.

During labor and delivery, good blood glucose control should be maintained to prevent neonatal hypoglycemia. Blood glucose levels should be maintained at a level below 100 mg/dL with the use of an insulin infusion. After delivery, insulin requirements tend to dramatically fall as a result of the significant decrease in level of placental hormones.

Once the patient is able to eat regular meals, she should receive subcutaneous insulin at approximately one half of her prepregnancy dose.

Breast-feeding

Breast-feeding should be encouraged in women with both preexisting diabetes and GDM. For women with diabetes

in good glycemic control, it has been demonstrated that the quality of breast milk is not substantially affected. Increasing evidence suggests that breast-feeding may give the offspring protection from type 2 diabetes as well as a decreased likelihood of developing obesity in childhood and young adulthood. Most recently, the Nurses Health Study found that the duration of breast-feeding was inversely associated with the risk of type 2 diabetes in two large cohorts of women.

Contraception and Family Planning

The use of contraception in all women with diabetes or a prior history of GDM cannot be emphasized strongly enough. This is the only way to ensure that preconception care can be provided. There are a variety of contraceptive methods currently available. Barrier methods of contraception create mechanical and/or chemical barriers to fertilization and include diaphragms, male condoms, spermicidal foam, jelly or foam, cervical caps, and female condoms.

Although these methods pose no health risks to women with diabetes, they are user dependent, require correct application or insertion before intercourse, and have a high failure rate of 12% to 28% in the first year because of improper use. With experience and motivation, these failure rates may be reduced to levels of 2% to 6%.

Oral contraceptives remain the most popular form of birth control despite controversy over potential side effects. The main reasons for their popularity are their failure rate of generally less than 1% and ease of use. Low-dose formulations are preferred and are recommended only for patients without vascular complications or additional risk factors such as smoking or a strong family history of myocardial disease. Progestin-only (“mini-pill”) oral contraceptives are an option for women with contraindications to the estrogen component, such as hypertension or thrombosis.

An intrauterine device is the most effective nonhormonal device. It should only be offered to women with diabetes who have a low risk of sexually transmitted diseases, as any infection might place the patient with diabetes at risk for sepsis and ketoacidosis. Patient education should include the early signs of sexually transmitted diseases such as increased and abnormal vaginal discharge; dyspareunia; heavy, painful menses; lower abdominal pain; and fever.

Depo-Provera is a long-acting progestin that provides highly effective pregnancy prevention. It is administered intramuscularly every 3 months and works by inhibiting ovulation. The high efficiency and long period of action of Depo-Provera makes it an attractive option for women with diabetes, especially women with a history of poor

medication taking. Unfortunately, this long-acting progestin has not been studied in women with diabetes.

Permanent sterilization, including tubal ligation and vasectomy, may be considered by the patient or her partner when they desire no more children.

Conclusion

The diagnosis of diabetes mellitus during pregnancy has certain implications for the well-being of both the mother and the fetus. Advances in medical and obstetric care have dramatically improved the outlook for women with diabetes and their offspring. However, both mother and child remain at increased risk for a number of complications. Research indicates that the majority of these complications are associated with hyperglycemia. The achievement and maintenance of euglyemia has therefore become the major focus of management.

Summary Points

- The development of insulin resistance during late pregnancy is a normal physiologic adaptation that shifts maternal energy metabolism from carbohydrate to lipid oxidation and thus spares glucose for the growing fetus.
- All pregnant women should be screened for GDM between 24 and 28 weeks gestation.
- Women with diabetes and their offspring are at greater risk for a number of pregnancy-related complications.
- Strict blood glucose control prior to conception and throughout gestation can reduce and or eliminate the excess risk for both mother and baby.
- All diabetic women of childbearing age should be counseled regarding the importance of preconception care and planning of their pregnancies.

Hypertensive Disorders of Pregnancy

Mounira Habli
Baha M. Sibai

Hypertensive disorders are the most common medical complications of pregnancy, affecting 5% to 10% of all pregnancies. These disorders are responsible for approximately 16% of maternal mortality in developed countries. Classification of hypertensive disorders in pregnancy include chronic hypertension and the group of hypertensive disorders unique to pregnancy including gestational hypertension and preeclampsia. Approximately 30% of hypertensive disorders in pregnancy are due to chronic hypertension, and 70% are due to gestational hypertension. The spectrum of disease ranges from mildly elevated blood pressures with minimal clinical significance to severe hypertension and multiorgan dysfunction. The incidence of disease is dependent on many different demographic parameters, including maternal age, race, and associated underlying medical conditions. Understanding the disease process and the impact of hypertensive disorders on pregnancy is of the utmost importance because these disorders remain a major cause of maternal and perinatal morbidity and mortality worldwide.

Definitions and Classifications

Making an appropriate diagnosis can at times be difficult in the gravid patient; however, adhering to the following definitions and classification schemes will help to eliminate confusion. *Hypertension* is defined as a systolic blood pressure (SBP) of 140 mm Hg or greater or a diastolic blood pressure (DBP) of 90 mm Hg or greater. These measurements must be present on at least two occasions at least 6 hours apart but no more than 1 week apart. In order to reduce inaccurate readings, an appropriate size of cuff should be used (length 1.5 times upper arm circumference or a cuff with a bladder that encircles 80% or more of the arm). Pressure should be taken with the patient in an upright position, after a 10-minute or longer rest period. For patients in the hospital, the blood pressure can be taken with either the patient sitting up or in the left lateral recumbent position with the patient's arm at the level of the heart. The patient should not use tobacco or caffeine for 30 minutes preceding the measurement. *Abnormal proteinuria in pregnancy* is defined as the excretion of 300 mg or more of protein in 24 hours. The most accurate measurement of proteinuria is obtained with a 24-hour urine collection. However, in certain instances, semiquantitative dipstick measurement may be the only mode available to assess urinary

protein. A value of 1+ or greater correlates with 30 mg/dL. Proteinuria by dipstick is defined as 1+ or more on at least two occasions at least 6 hours apart but no more than 1 week apart. The accuracy of semiquantitative dipstick measurements on spot urine samples as compared with 24-hour urine collections is highly variable. Therefore, should time allow, a 12-hour or 24-hour urine collection should be performed as part of the diagnostic criteria to define proteinuria. When obtaining urine protein measurements, care should be taken to use a clean sample, because blood, vaginal secretions, and bacteria can increase the amount of protein in urine.

Edema is a common finding in the gravid patient, occurring in approximately 50% of women. Lower extremity edema is the most typical form. Pathologic edema is seen in nondependent regions such as the face, hands, or lungs. Excessive, rapid weight gain of 5 pounds or more per week is another sign of fluid retention.

The classification system of hypertension in pregnancy was proposed originally by the American College of Obstetricians and Gynecologists Committee on Terminology in 1972. Further modifications by the National High Blood

Pressure Education Program Working Group in 2000 arrived at the classification scheme used today, which offers simple, concise, and clinically relevant features for each of the four categories. This system recognizes four major categories of hypertension in pregnancy—gestational hypertension, preeclampsia or eclampsia, chronic hypertension, and preeclampsia superimposed on chronic hypertension. Table 16.1 lists these categories and the features of each.

TABLE 16.1 Classification of Hypertension in Pregnancy with Definitions

Disorder	Definition
Gestational hypertension	Hypertension developing after 20 weeks gestation or during the first 24 hours postpartum without proteinuria or other signs of preeclampsia
Transient hypertension	Hypertension that resolves by 12 weeks postpartum
Chronic hypertension	Hypertension that does not resolve by 12 weeks postpartum

Preeclampsia or eclampsia	Hypertension typically developing after 20 weeks gestation with proteinuria; eclampsia is the occurrence of seizure activity without other identifiable causes
Chronic hypertension	Hypertension diagnosed prior to pregnancy, prior to 20 weeks gestation, or after 12 weeks postpartum
Preeclampsia superimposed	The development of preeclampsia or eclampsia in a woman with preexisting or chronic hypertension

Gestational Hypertension

Gestational hypertension is the most frequent cause of hypertension during pregnancy. The rate ranges between 6% and 17% in healthy nulliparous women and between 2% and 4% in multiparous women. It is considered severe if there is sustained SBP to at least 160 mm Hg and/or DBP to at least 110 mm Hg for at least 6 hours without proteinuria. Treatment generally is not warranted, because most patients have mild hypertension. However, approximately 46% of women diagnosed with preterm gestational hypertension will develop proteinuria and progress to preeclampsia. In general, the majority of cases of mild gestational hypertension are diagnosed at or beyond 37 weeks and have a pregnancy outcome similar to term normotensive pregnancies. However, a higher rate of induction and cesarean rate is seen in pregnancies complicated with gestational hypertension.

Preeclampsia and Eclampsia

The rate of preeclampsia ranges between 2% and 7% in healthy nulliparous women. The rate is substantially higher in women with twin gestation (14%) and in those with previous preeclampsia (18%). The symptoms of preeclampsia are headaches, visual changes, and epigastric or right upper quadrant pain plus nausea or vomiting. In the absence of proteinuria, preeclampsia should be considered when gestational hypertension is associated with persistent cerebral symptoms, epigastric or right upper quadrant pain with nausea or vomiting, fetal growth restriction, or thrombocytopenia and abnormal liver enzymes.

Preeclampsia may be subdivided further into mild and severe forms. The distinction between the two is made on the basis of the degree of hypertension and proteinuria as well as the involvement of other organ systems. The criteria for mild preeclampsia and severe preeclampsia are presented in Tables 16.2 and 16.3, respectively. Close surveillance of patients with either mild preeclampsia or gestational hypertension is warranted, because they may progress to fulminant disease. A particularly severe form of preeclampsia is the HELLP syndrome, which is an acronym for *h*emolysis, *e*levated *l*iver enzymes, and *l*ow

*p*latelet count. This syndrome is manifest by laboratory findings consistent with hemolysis, elevated levels of liver function, and thrombocytopenia. The diagnosis may be deceptive, because hypertension and proteinuria might be absent in 10% to 15% of women who develop HELLP and in 20% to 25% of those who develop eclampsia. A patient

diagnosed with HELLP syndrome is automatically classified as having severe preeclampsia. Another severe form of preeclampsia is eclampsia, which is the occurrence of seizures not attributable to other causes.

TABLE 16.2 Criteria for the Diagnosis of Mild Preeclampsia

SBP >140 mm Hg and/or DBP >90 mm Hg on two occasions at least 6 hours apart, typically occurring after 20 weeks gestation (no more than 1 week apart)
Proteinuria of 300 mg in a 24-hour urine collection or >1+ on two random sample urine dipsticks at least 6 hours apart (no more than 1 week apart)

SBP, systolic blood pressure; DBP, diastolic blood pressure.

TABLE 16.3 Criteria for the Diagnosis of Severe Preeclampsia

SBP >160 mm Hg and/or DBP >110 mm Hg on two occasions at least 6 hours apart
Proteinuria of 5 g or higher in a 24-hour urine specimen or 3+ or greater on two random urine samples collected at least 4 hours apart
Oliguria <500 cc in 24 hours
Thrombocytopenia—platelet count <100,000/mm^3
Elevated liver function test results with persistent epigastric or right upper quadrant pain
Pulmonary edema
Persistent, severe cerebral or visual disturbances

SBP, systolic blood pressure; DBP, diastolic blood pressure.

Chronic Hypertension

Hypertension that complicates pregnancy is considered chronic if a patient is diagnosed with hypertension before pregnancy, if hypertension is present prior to 20 weeks gestation, or if it persists longer than 12 weeks after delivery.

Chronic Hypertension with Superimposed Preeclampsia

Women with chronic hypertension are at risk of developing superimposed preeclampsia, with the reported rate of superimposed preeclampsia ranging from 10% to 25%. *Superimposed preeclampsia* is defined as an exacerbation of hypertension with new onset of proteinuria or symptoms of headache or epigastric pain or laboratory abnormalities such as elevated liver enzymes. Exacerbation of hypertension is confirmed if there is an increase in blood pressure to the severe range (SBP of 160 mm Hg or more; DBP of 110 mm Hg or more) in a woman whose hypertension has been well controlled.

Preeclampsia

Preeclampsia is a multisystem disorder of unknown cause that is unique to human pregnancy. The incidence is reported to be between 2% and 7%, depending on the population. Preeclampsia occurs more frequently in primigravidas. The reported rate ranges from 6% to 7% in primigravidas and from 3% to 4% in multiparous patients. Several risk factors for preeclampsia have been identified and are listed in Table 16.4. Generally, preeclampsia is regarded as a disease of first pregnancy. Advanced maternal age (>35 years) is another risk factor, especially if conception was secondary to assisted reproductive technology. Obesity is another important factor. An overall increased rate of thrombopilia has been seen in women with preeclampsia compared with controls.

TABLE 16.4 Risk Factors for Preeclampsia

Nulliparity
Chronic or vascular disease (pregestational diabetes, renal disease, chronic hypertension, rheumatic disease, connective tissue disease)
Molar pregnancy
Fetal hydrops
Multifetal gestation
Obesity and insulin resistance
Prior pregnancy complicated by preeclampsia
Antiphospholipid antibody syndrome and thrombophilia
Family history of preeclampsia or eclampsia
Fetal aneuploidy

Maternal infections
Maternal susceptibility genes
Extremes of maternal age
Partner-related factors (limited sperm exposure, donor insemination [oocyte and embryo donation])

Etiology

The etiologic agent responsible for the development of preeclampsia remains unknown. The syndrome is characterized by vasospasm; hemoconcentration; and ischemic changes in the placenta, kidney, liver, and brain. These abnormalities usually are seen in women with severe preeclampsia. Theories as to the causative mechanisms include placental origin, immunologic origin, and genetic predisposition, among others. A list of etiologic theories is shown in Table 16.5. A great deal of research is dedicated to solving the etiologic enigma of preeclampsia. Without a definitive etiology, predicting patients at risk for the development of preeclampsia and effecting a treatment for this morbid disease remain difficult.

TABLE 16.5 Etiologic Theories in Preeclampsia

Abnormal or increased immune response
Genetic predisposition
Abnormal coagulation or thrombophilias
Abnormal angiogenesis
Endothelial cell injury
Alterations in nitric oxide levels
Increased oxygen free radicals
Abnormal cytotrophoblast invasion
Abnormal calcium metabolism
Dietary deficiencies

Pathophysiology

Cardiovascular

The hypertensive changes seen in preeclampsia are attributed to intense vasoconstriction with segmental spasm that occurs particularly in arterioles and is thought to be due to increased vascular reactivity. The underlying mechanism responsible for the increased vascular reactivity is presumed to be alterations in the normal interactions of vasodilatory

(prostacyclin, nitric oxide) and vasoconstrictive (thromboxane A_2, endothelin) substances. These changes lead to higher arterial blood pressures (afterload). Another vascular hallmark of preeclampsia is hemoconcentration. Patients with preeclampsia have lower intravascular volumes and less tolerance for the blood loss associated with delivery. It is thought that endothelial damage promotes leakage of intravascular fluid and protein into the interstitial space, leading to lower intravascular volume. The heart in a healthy woman with preeclampsia is normal in function and contractility.

Hematologic

Several abnormalities of the coagulation system can occur. The most common hematologic abnormality in preeclampsia is thrombocytopenia (platelet count <100,000/mm^3). The suggested pathophysiology likely is vascular endothelial damage or activation and higher levels of thromboxane A_2. Another possible hematologic abnormality is microangiopathic hemolysis, as seen in HELLP syndrome, and can be diagnosed by schistocytes seen on peripheral smear and increased lactate dehydrogenase (LDH) levels. Interpretation of the baseline hematocrit in a preeclamptic patient may be difficult. A low hematocrit may signify hemolysis, and a falsely high hematocrit may be due to hemoconcentration.

Renal

Vasospasm in preeclampsia leads to decreased renal perfusion and subsequent decreased glomerular filtration rate (GFR). In normal pregnancy, the GFR is increased up to 50% above prepregancy levels. Because of this, serum creatinine levels in preeclamptic patients rarely rise above normal pregnancy levels (0.8 mg/dL). Close monitoring of urine output is necessary in patients with preeclampsia, because oliguria (defined as <500 cc in 24 hours) may occur due to renal insufficiency. Rarely, profound renal insufficiency may lead to acute tubular necrosis. The pathognomonic renal lesion in preeclampsia is called *glomerular capillary endotheliosis*, which is swelling of the glomerular capillary endothelial and mesangial cells.

Hepatic

Hepatic damage associated with preeclampsia can range from mildly elevated liver enzyme levels to subcapsular liver hematomas and hepatic rupture. The latter usually are associated with HELLP syndrome. Approximately 20% of maternal mortality in preeclampsia is related to hepatic complications. The pathologic liver lesions seen on autopsy are periportal hemorrhages, hepatocellular necrosis, ischemic lesions, intracellular fatty changes, and fibrin deposition.

Central Nervous System

Eclamptic convulsions are perhaps the most disturbing central nervous system (CNS) manifestation of preeclampsia and remain a major cause of maternal mortality in the Third World. The exact etiology of eclampsia is unknown but is thought to be attributed to coagulopathy, fibrin deposition, and vasospasm. The most common finding in the brain is

edema, which likely is due to vascular autoregulation dysfunction. Radiologic studies may show evidence of cerebral edema and hemorrhagic lesions, particularly in the posterior hemispheres, which may explain the visual disturbances seen in preeclampsia. Other CNS abnormalities include headaches and visual disturbances such as scotomata; blurred vision; and rarely, temporary blindness.

Fetus and Placenta

The hallmark placental lesion in preeclampsia is acute atherosis of decidual arteries. This is due in part to the abnormal adaptation of the spiral artery–cytotrophoblast interface and results in poor perfusion. This may lead to poor placental perfusion, resulting in oligohydramnios; intrauterine growth restriction; placental abruption; fetal distress; and ultimately, fetal demise.

Prediction

No good screening test exists for the prediction of preeclampsia. Several methods have been proposed but have not been found to be cost-effective or reliable (Table 16.6). Given that nulliparity has a 5% to 7% risk of preeclampsia

and multiparity carries only a 3% risk, an accurate and thorough maternal history with identification of risk factors is the most cost-effective screening method available. Doppler ultrasonography is a useful method to assess the velocity of uterine blood flow in the second trimester. Abnormal velocity waveform is characterized by a high resistance index or an early diastolic notch (unilateral or bilateral). Data still do not support this test for routine screening. Recently, investigators have begun to examine soluble FMS-like tyrosine kinase-1 receptors (sFlt-1) and placental growth factor as early markers for preeclampsia. Future studies using proteomic and other markers such as soluble endoglin and FMS-like tyrosine kinase receptors (sFlt) are still ongoing.

TABLE 16.6 Proposed Methods of Prediction of Preeclampsia

Maternal serum uric acid levels
Uterine artery Doppler determinations
Elevated second-trimester MSAFP, β-hCG levels, inhibin A
Elevated sFlt-1 and endoglin
Reduced placental growth factors
Plasma fibronectin values
Midpregnancy blood pressure measurements
Urinary calcium excretion
Urinary kallikrein concentration
Platelet activation
Excessive weight gain

Calcium-to-creatinine ratio

MSAFP, maternal serum α-fetoprotein; ß-hCG, ß-human chorionic gonadotropin.

TABLE 16.7 Methods to Prevent Preeclampsia

Method	Pregnancy Outcome	Recommendation
Diet and exercise (I); protein or salt restriction (II)	No reduction in preeclampsia	Insufficient evidence to recommend[a]
Magnesium or zinc supplementation (I)	No reduction in preeclampsia	Insufficient evidence to recommend[a]
Fish oil supplementation and other sources of fatty acids (I)	No effect in low- or high-risk populations	Insufficient evidence to recommend[a]
Calcium supplementation (I)	Reduced preeclampsia in those at high risk and with low baseline dietary calcium intake; no effect on perinatal outcome	Recommended for women at high risk of gestational hypertension and in communities with low dietary calcium intake
Low-dose aspirin (I)	19% reduction in risk of preeclampsia; 16% reduction in fetal	Consider in high-risk pregnancies

	and neonatal deaths	
Heparin or low-molecular-weight heparin (III-3)	Reduced preeclampsia in one trial	Insufficient evidence to recommend[a]
Antioxidant vitamins (C, E) (I)	No reduction in large trials	No evidence to recommend
Antihypertensive medications in women with chronic hypertension (I)	Risk of women developing severe hypertension reduced by half; no reduction in the risk of preeclampsia	No evidence to recommend for prevention

[a]Insufficient evidence refers to small trials or inconclusive results.
Levels of evidence (I–IV) as outlined by the U.S. Preventive Task Force.
Sibai BM. Preeclampsia. *Lancet* 2005;365(9461):785–799.

Prevention

Preventive interventions for preeclampsia could impact maternal and perinatal morbidity and mortality worldwide. As a result, during the past decade, several randomized trials reported several methods to reduce the rate and/or severity of preeclampsia. Several trials assessed protein or low-salt diets, diuretics, bed rest, zinc, magnesium, fish oil, or vitamin C and E supplementation and heparin to prevent preeclampsia in women, but results showed minimal to no effect (Table 16.7). Recently, the results of two large randomized clinic trials using vitamin C and E in both healthy women and women at high risk showed no reduction in the risk of preeclampsia, intrauterine growth restriction, or the risk of death or other serious outcomes in their infants. Furthermore, the World Health Organization (WHO) conducted a randomized trial of calcium supplementation among low-calcium-intake pregnant women. The study showed that 1.5 g per day of calcium does not prevent preeclampsia but did reduce its severity, maternal morbidity, and neonatal mortality. On the other hand, a new evidence-based review of the available scientific evidence in regard to calcium intake and hypertensive disorder in pregnancies did not

support a benefit.

Maternal and Perinatal Outcome

Maternal and neonatal outcome in patients with preeclampsia relates largely to one or more of the following factors: the gestational age at delivery, severity of disease, quality of management, and presence of preexisting disease. Perinatal mortalities are increased in those who develop the disease at <34 weeks gestation. Risk to the mother can be significant and includes the possible development of disseminated intravascular coagulation (DIC), intracranial hemorrhage, renal failure, retinal detachment, pulmonary edema, liver rupture, abruptio placentae, and death (Table 16.8). Therefore, experienced clinicians should be caring for women with preeclampsia.

Mild Preeclampsia

Diagnosis of Mild Preeclampsia and Gestational Hypertension

The diagnosis of mild preeclampsia requires the presence of hypertension and proteinuria in pregnancy. Once the diagnosis is made, treatment is delivery. The decision for active management versus expectant management depends on several factors: severity of disease, gestational age, fetal and

maternal status, presence of labor, and the wishes of the mother. Because the spectrum of disease in preeclampsia is variable, it is important to monitor patients for the development of severe preeclampsia. Patients with mild preeclampsia are at risk of developing eclampsia, potentially suddenly, without warning, and with minimal blood pressure elevations. Another risk is abruptio placentae. However, both of these risks are less than 1%.

TABLE 16.8 Maternal and Fetal Complications in Severe Preeclampsia

Maternal
Abruptio placentae (1%–4%)
Disseminated coagulopathy/HELLP syndrome (10%–20%)
Pulmonary edema/aspiration (2%–5%)
Acute renal failure (1%–5%)
Eclampsia (<1%)
Liver failure or hemorrhage (<1%)
Stroke (rare)
Death (rare)
Long-term cardiovascular morbidity

Fetal
Preterm delivery (15%–67%)
Fetal growth restriction (10%–25%)
Hypoxia–neurologic injury (<1%)
Perinatal death (1%–2%)
Long-term cardiovascular morbidity associated with low birth weight (fetal origin of adult disease)

HELLP, hemolysis, elevated liver enzymes, low platelet count.
Sibai BM. Preeclampsia. *Lancet* 2005;365(9461):785–799.

Management of Mild Preeclampsia

Ideally, a patient who has preeclampsia should be hospitalized at the time of diagnosis. Management of the patient with mild preeclampsia should include baseline laboratory evaluation, including a 24-hour urine collection for protein, hematocrit, platelet count, serum creatinine value, and aspartate aminotransferase (AST) level. At the time of diagnosis, ultrasonography should be performed to evaluate amniotic fluid volume and estimated fetal weight and to confirm gestational age.

The only definitive cure for preeclampsia is delivery. The main objective of management of preeclampsia must always be the safety of the mother and a mature newborn who will not require intensive and prolonged neonatal care. In patients diagnosed with mild preeclampsia at term (>37 weeks), the general consensus is delivery especially since perinatal outcome is similar to normotensive pregnancy. For the patient who is preterm (<37 weeks), controversy arises regarding management with respect to level of activity, diet, antihypertensive medications, and delivery. Usually, these patients do not require immediate delivery, and expectant management is warranted. Hence, the clinical decision making in patients with mild preeclampsia is twofold. If expectant management is chosen, the second question then becomes where to manage the patient—in the hospital or at home?

TABLE 16.9 Criteria for Home Management of Mild Preeclampsia

Ability to comply with recommendations
DBP ≤100 mm Hg
SBP ≤160 mm Hg
Normal laboratory tests and no maternal symptoms
Reassuring fetal status with appropriate growth

Urine protein of 1,000 mg or less in 24 hours

DBP, diastolic blood pressure; SBP, systolic blood pressure.

In the past, once diagnosed with mild preeclampsia, a woman was either delivered immediately or managed in the hospital for the remainder of the pregnancy. Several studies have shown that a management plan including immediate delivery may not be justified. Sibai and colleagues studied 200 women with preeclampsia who were managed as inpatients with unrestricted activity, and they were randomized to receive labetalol or no medications. The mean pregnancy prolongation was 21 days. The rate of placental abruption was 1.1%, and the perinatal mortality rate was 5.4 per 1,000. Another study by Matthews and colleagues evaluated the effect on preeclampsia of bed rest versus unlimited activity. They also found no significant difference in maternal or fetal outcomes.

At-home management of these patients or use of a day care setting is appropriate in most cases, provided the patient is compliant, has readily available transportation, and is reliable with follow-up (Table 16.9). These women are instructed to restrict their activity and to follow a low-salt diet. The authors do not recommend the use of antihypertensive medications in order not to mask the potential diagnosis of severe preeclampsia. Using this approach, it is important to educate patients regarding the signs and symptoms to report (Table 16.10). They should be advised to return immediately to the hospital if any of these arise. If the disease progresses from mild to severe or if there is any indication

of fetal compromise—including nonreassuring fetal heart rate test results, oligohydramnios, or growth restriction—the patient should be hospitalized and evaluated for delivery. Serial laboratory evaluation of platelet counts and liver enzyme values should be performed every 3 to 7 days to monitor for worsening disease. Significant abnormalities in any of these laboratory criteria warrant hospitalization. Antenatal surveillance should include at least twice weekly nonstress tests (Table 16.11).

TABLE 16.10 Signs and Symptoms of Preeclampsia That Warrant Prompt Evaluation

Nausea and vomiting
Persistent severe headache
Right upper quadrant or epigastric pain
Scotoma
Blurred vision
Decreased fetal movement
Rupture of membranes

Vaginal bleeding
Regular contractions

TABLE 16.11 Maternal and Fetal Evaluation in Mild Preeclampsia

Maternal
Daily weight
Urine dipstick daily; 24-hour protein once weekly
Monitoring for severe preeclampsia symptoms
Prenatal visits twice per week
Lab tests (liver function tests, hematocrit, platelet count once or twice per week)
Fetal
Daily fetal movement
Nonstress test twice per week or biophysical profile once per week
Ultrasound for growth every 3 to 4 weeks

Optimal timing of delivery is dependent on maternal and fetal status. In the preterm pregnancy, the sole benefit of expectant management is for the fetus. Once a pregnancy reaches term, the plan should be for delivery. Induction of labor is indicated in those patients with a favorable cervix (Fig. 16.1). At 37 weeks or beyond, if the cervix is unfavorable, there are two options: either cervical ripening and delivery or continued expectant management with maternal and fetal evaluation. The preferred mode of delivery remains vaginal. A cesarean section should be performed for obstetric indications only.

In the past, while in labor, patients with mild preeclampsia received intravenous magnesium sulfate ($MgSO_4$) for seizure prophylaxis. A regimen for $MgSO_4$ administration is presented later in this chapter. The exact point in labor at which to start $MgSO_4$ remains unknown. There is no support in the literature for the need or the optimal timing to begin the $MgSO_4$ infusion, and this should be left to the discretion of the physician. There are only two double-blind, placebo-controlled trials evaluating the use of $MgSO_4$ in patients with mild preeclampsia. In both trials, patients with well-defined mild preeclampsia were randomized during labor or postpartum, and there was no difference in the percentage of women who progressed to severe preeclampsia (12.5% vs. 13.8%; relative risk [RR] 0.90; 95% confidence interval [CI] 0.52 to 1.54). There were no instances of eclampsia among 181 patients assigned to placebo. Thus, the authors recommend to individualize each case for

the use of $MgSO_4$.

Pain management in labor should be individualized as well. Intravenous narcotics and regional anesthesia are both appropriate options. Close monitoring of blood pressure intrapartum is necessary. Antihypertensive medications may be needed in order to keep blood pressure values below 160 mm Hg systolic and below 110 mm Hg diastolic. The most commonly used intravenous medications for this purpose are labetalol and hydralazine. The recommended dosages of medications for the immediate treatment of hypertension are listed in Table 16.12. Care should be taken not to drop the blood pressure too rapidly, because a marked decrease in mean arterial pressure may lead to reduced renal perfusion and reduced placental perfusion. Preeclamptic women who receive $MgSO_4$ also are at risk for postpartum hemorrhage due to uterine atony.

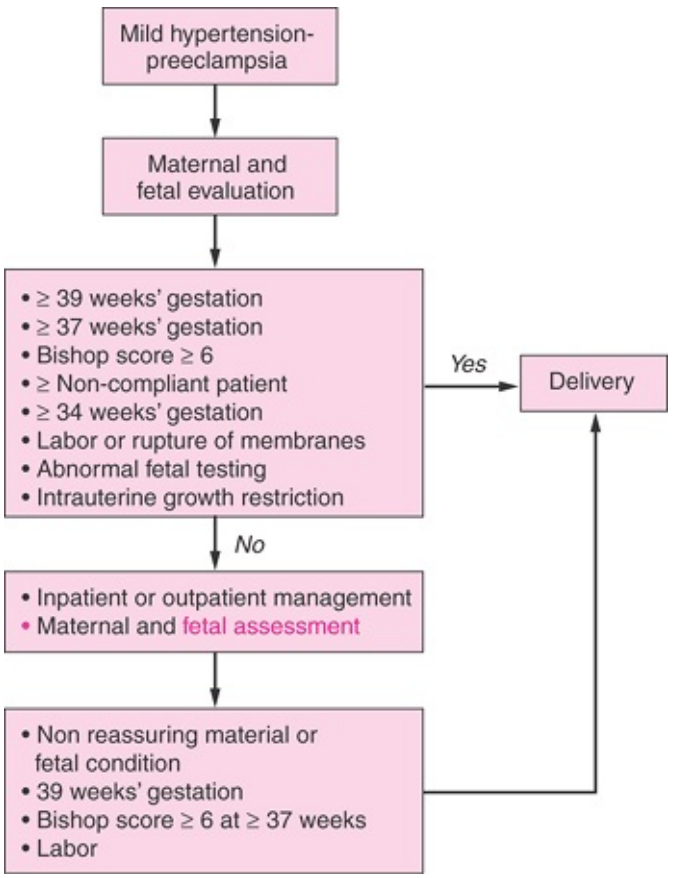

Figure 16.1 Recommended management of mild gestational hypertension or preeclampsia.

Patients should be monitored closely for at least 12 to 24 hours postpartum. Postpartum eclampsia occurs in 25% of patients. It is not clear if $MgSO_4$ should be continued in the postpartum period. There is no need for continued seizure prophylaxis beyond 24 hours postpartum.

Severe Preeclampsia

Management of Severe Preeclampsia

Any patient with severe preeclampsia should be admitted and observed initially in a labor and delivery unit (Fig. 16.2). Workup should include assessment for fetal well-being, monitoring of maternal blood pressures and

symptomatology, and laboratory evaluation. Laboratory evaluation should include 24-hour urine collection for total protein, hematocrit, platelet count, and serum creatinine and AST levels. Intravenous $MgSO_4$ should be initiated at time of admission. An initial ultrasonographic examination with umbilical artery Doppler studies for fetal growth and amniotic fluid index should be obtained as well.

TABLE 16.12 Indications and Precautions for Antihypertensive Medications

Drug	Starting Dosage	Maximum Dosage	Comments
Acute treatment of severe hypertension			
Hydralazine	5–10 mg i.v. every 20 min	30 mg[a]	—
Labetalol	20–40 mg i.v. every 10–15 min	220 mg[a]	Avoid in women with asthma or congestive heart failure
Nifedipine	10–20 mg p.o. every 30 min	50 mg[a]	—
Long-term treatment of hypertension			

Methyldopa	250 mg b.i.d.	4 g/d	Rarely indicated
Labetalol	100 mg b.i.d.	2,400 mg/d	First choice
Atenolol	50 mg q.d.	100 mg/d	Associated with IUGR
Propanolol	40 mg b.i.d.	640 mg/d	To be used with associated thyroid disease
Hydralazine	10 mg t.i.d.	100 mg/d	To be used in cases of left ventricular hypertrophy
Nifedipine	10 mg b.i.d.	120 mg/d	To be used in women with diabetes
Diltiazem	120–180 mg q.d.	540 mg/d	—
Thiazide diuretic	12.5 mg b.i.d.	50 mg/d	Use in salt-sensitive hypertension and/or CHF; may be added as second agent; not to be used if preeclampsia develops or IUGR is present
ACE inhibitors/ARB	—	—	Not to be used after 16–18 wk

IUGR, intrauterine growth restriction; CHF, congestive heart failure; ACE, angiotensin-converting enzyme; ARB, angiotensin-II receptor blockers

[a]If desired blood pressure levels are not achieved, switch to another drug.

It is well accepted that delivery is considered in all women with severe preeclampsia at >34 weeks, because prolonging the pregnancy may be hazardous to the mother with little benefit to the fetus. In patients at 33 to 34 weeks gestation, steroids should be administered and delivery planned within 48 hours unless otherwise indicated.

In patients with severe prematurity (24 0/7 and 32 6/7 weeks), expectant management significantly improves neonatal outcome. The goal in these patients is to gain at least 48 hours so that antenatal glucocorticoids can be administered for fetal benefit. Patients should be selected carefully to undergo expectant management. They should be counseled regarding the risks and benefits of expectant management. Guidelines for expectant management are outlined in Table 16.13. Fetal well-being should be assessed on a daily basis by the use of nonstress testing and the biophysical profile, if indicated, and weekly amniotic fluid index determinations and umbilical artery Doppler. The patient also should be instructed on fetal movement assessment. Ultrasonography for fetal growth should be performed every 2 to 3 weeks. Maternal laboratory evaluation should be done daily or every other day. If a stable maternal and fetal course is maintained, expectant management may be continued until 34 weeks. The development of any worsening change in maternal or fetal status warrants delivery regardless of gestational age, as shown in Table 16.14. A woman with a nonviable fetus should be presented with the option of pregnancy termination. In the United States, it typically is accepted that the fetus is potentially viable at 23 weeks, and at this gestation, expectant management may be considered. Consultation with the neonatology team may aid in making this decision.

Maternal blood pressure control is essential during either expectant management or during delivery. Medications can be given either orally or by the intravenous route, as necessary, to maintain a desired blood pressure range between 140 and 160 mm Hg systolic and 90 and 110 mm Hg diastolic. Drugs typically used in the management of acute hypertension are hydralazine and labetalol. The dosage of each is presented in Table 16.12. Once again, care must be taken to avoid a sudden drop in maternal blood pressure precipitating cerebral ischemia, decreased renal perfusion, and decreased placental perfusion. These patients typically do not require invasive hemodynamic monitoring. However, in patients with pulmonary edema and in those with underlying cardiac disease, consideration should be given to the use of invasive hemodynamic monitoring.

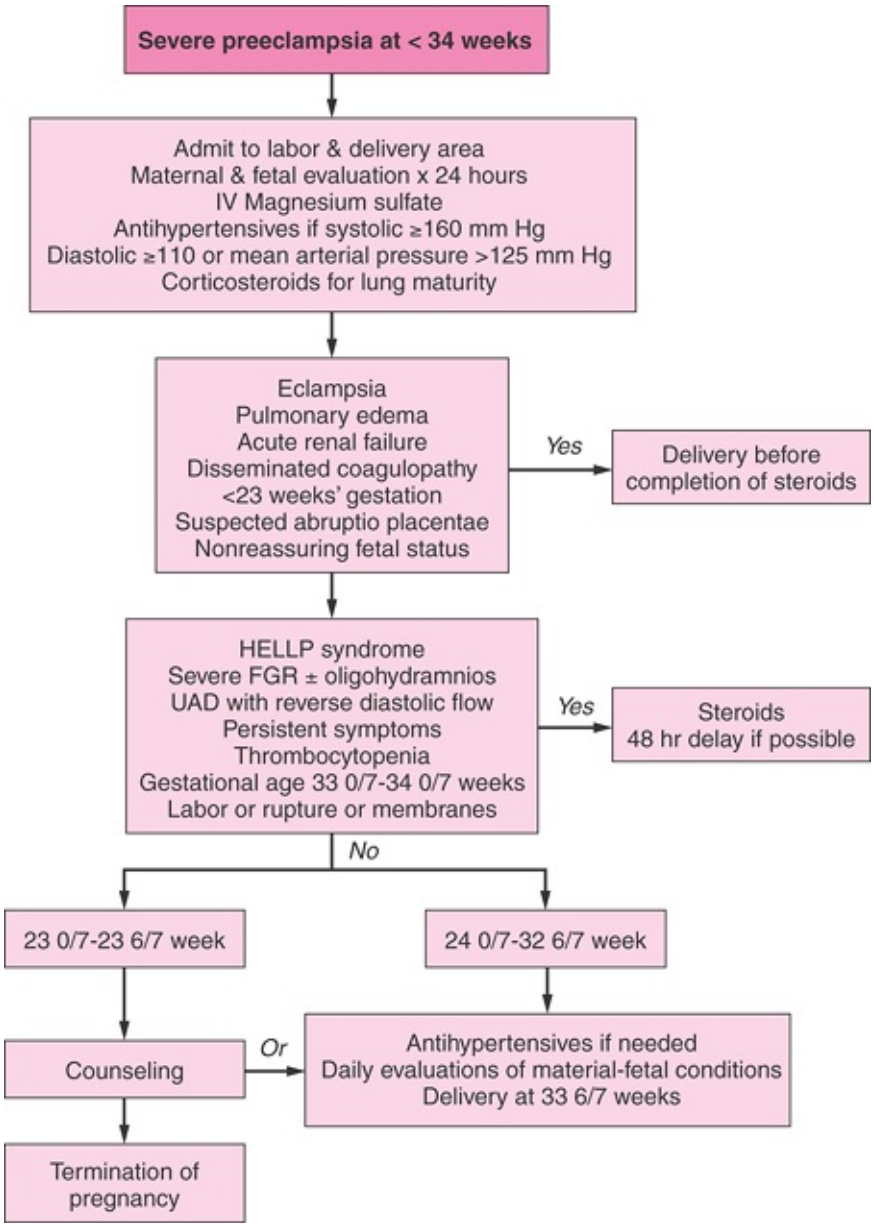

Figure 16.2 Management of severe preeclampsia. (FGR, fetal growth restriction; UAD, umbilical artery Doppler.) (From Sibai BM. Expectant management of severe preeclampsia. *Am J Obstet Gynecol* 2007, with permission.)

TABLE 16.13 Guidelines for Expectant Management in Severe Preeclampsia

Maternal evaluations
Monitoring blood pressure, urine output, cerebral status and epigastric pain, tenderness or vaginal bleeding
Daily weight

Antihypertensive drugs to maintain blood pressure between 140/90 and 159/109 mm Hg
Laboratory evaluation daily, or in case of developing new maternal symptoms, include platelet count, liver function test, and creatinine
Fetal evaluations
Continuous fetal monitoring for the first 48 hours, then daily biphasic profile
Ultrasound assessment; include weekly amniotic fluid measurement with biweekly umbilical artery Dopplers
Ultrasound for growth every 2 weeks

Friedman SA, Schiff E, Lubarsky SL, et al. Expectant management of severe preeclampsia remote from term. *Clin Obstet Gynecol* 1999;42(3):470–478.

Intrapartum management should include close blood pressure control, continuous fetal monitoring, and intravenous $MgSO_4$ administration. An indwelling urinary catheter should be placed in order to closely monitor fluid balance. Urine output should be >100 cc every 4 hours. A trial of labor is indicated in patients with severe preeclampsia. However, an appropriate time frame should be established during which to achieve active labor. Pain management should be dealt with on an individual basis. Epidural anesthesia is a reasonable option, provided the patient is without a coagulopathy. Patients with preeclampsia tolerate blood loss poorly due to volume contraction, and type-specific blood should be readily available for transfusion if needed. Appropriate steps should be taken to minimize postpartum hemorrhage in patients who develop uterine atony while receiving continuous $MgSO_4$ infusion. Methylergonovine (Methergine) is contraindicated in these patients.

$MgSO_4$ infusion should continue for 24 hours postpartum. The patient should be kept under close observation for

24 hours after delivery to monitor blood pressure, reflexes, and fluid status. Most patients will show improvement in the disease process within the first 24 hours postpartum. On the other hand, approximately 30% of HELLP cases develop postpartum, and all patients with severe preeclampsia should be monitored for the development of HELLP syndrome after delivery. If hypertension persists after delivery, the patient may need to continue taking antihypertensive medication after being discharged. Patients should be seen every week or two as outpatients until they become normotensive. If the hypertension persists beyond 12 weeks postpartum, the diagnosis of chronic hypertension should be considered.

TABLE 16.14 Guidelines for Expeditious Delivery within 48-72 Hours in Severe Preeclampsia

Maternal
Uncontrolled severe hypertension (SBP ≥160 mm Hg, DBP ≥110 mm Hg) despite maximum doses of antihypertensive (i.v. labetalol [220 mg], hydralazine, and oral nifedepine)
Eclampsia or persistent cerebral symptoms
Pulmonary edema
Placenta abruption
Thrombocytopenia (platelet count less than 100,000) or elevated liver enzymes (HELLP syndrome)
Serum creatinine of 1.5 mg/dL or more or oliguria (<0.5 mL/kg per hour)
Fetal
Severe fetal growth restriction (<5th percentile for gestational age)
Persistant oligohydramnios (amniotic fluid index of <5 cm on at least two occasions >24 hours apart)
Umbilical artery Doppler studies with persistent reverse end-diastolic flow
Biophysical profile <4 on two occasions at 4 hours apart
Repetitive late deceleration or severe variable deceleration or loss of variability

SBP, systolic blood pressure; DBP, diastolic blood pressure; HELLP, hemolysis, elevated liver enzymes, low platelet count.
Friedman SA, Schiff E, Lubarsky SL, Sibai BM. Expectant management of severe preeclampsia remote from term. Clin Obstet Gynecol. 1999 Sep;42(3):470–8.

HELLP Syndrome

Diagnosis of HELLP Syndrome

The term *HELLP syndrome* is used to describe preeclampsia in association with hemolysis, elevated liver enzyme levels, and low platelet count. It is found in about 10% of pregnancies complicated by severe preeclampsia. The diagnosis is not always clear, and the syndrome may be confused with other medical conditions. Any patient diagnosed with HELLP syndrome should be considered to have severe preeclampsia.

TABLE 16.15 Criteria for the Diagnosis of HELLP Syndrome

Hemolysis
Abnormal peripheral smear
LDH >600 U/L
Bilirubin >1.2 mg/dL
Elevated liver enzymes
Serum AST >70 U/L
LDH >600 U/L
Low platelets
Platelet count <100,000/mm^3

HELLP, hemolysis, elevated liver enzymes, low platelet count; LDH, lactate dehydrogenase; AST, aspartate aminotransferase.
Sibai BM. The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): much ado about nothing? *Am J Obstet Gynecol* 1990;162:311–316, with permission.

In the past, the diagnostic criteria for HELLP syndrome were variable and led to inconsistent diagnoses. The newer criteria used for the diagnosis of HELLP syndrome are those reported by Sibai and include specific laboratory abnormalities demonstrating hemolysis, elevated liver enzyme levels, and low platelet count as shown in Table 16.15.

The clinical picture of patients with HELLP syndrome is highly variable. However, in general, patients with HELLP are multiparous white females who will be diagnosed at less than 35 weeks gestation. The typical symptomatology of these patients consists of vague complaints, further skewing the diagnosis. A large percentage of patients will have a history of general malaise for the few days prior. Other complaints include epigastric or right upper quadrant pain (67%), nausea or vomiting (30%), and nonspecific viral syndrome–like complaints. Thus, any pregnant woman with suspected preeclampsia who makes these complaints should undergo a minimum workup of a complete blood count with platelet count and liver enzyme levels.

Sibai has noted that hypertension may be absent (20%), mild (30%), or severe (50%) in women diagnosed with HELLP syndrome. Therefore, the diagnosis of HELLP syndrome cannot necessarily be ruled out in the normotensive patient who has other signs and symptoms consistent with preeclampsia.

Differential Diagnosis of HELLP Syndrome

HELLP syndrome may be easily confused with many other medical conditions, particularly when the patient is normotensive. It is important to be aware of the differential diagnosis of HELLP and to be able to discern this condition from others. A list of the differential diagnosis is found in Table 16.16. HELLP syndrome also can easily be confused with two other specific medical conditions—acute fatty liver of pregnancy and thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP/HUS). The

differentiation among the three entities is made largely based on specific laboratory findings. Table 16.17 presents detailed laboratory comparisons among the three disorders.

TABLE 16.16 Differential Diagnosis of HELLP Syndrome

Acute fatty liver of pregnancy
Appendicitis
Cerebral hemorrhage
Diabetes insipidus
Gallbladder disease
Gastroenteritis
Glomerulonephritis
Hemolytic uremic syndrome
Hyperemesis gravidarum
Idiopathic thrombocytopenia
Pancreatitis
Pyelonephritis
Systemic lupus erythematosus
Thrombophilias
Thrombotic thrombocytopenic purpura
Viral hepatitis, including herpes

Sibai BM. The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): much ado about nothing? *Am J Obstet Gynecol* 1990;162:311–316, with permission.

Management of HELLP Syndrome

The initial evaluation of women diagnosed with HELLP syndrome should be like that for severe preeclampsia. The patient should be cared for at a tertiary care center. Management initially should include maternal and fetal assessment; control of severe hypertension, if present; initiation of $MgSO_4$ infusion; correction of coagulopathy, if present; and maternal stabilization. A potentially life-threatening complication of HELLP

syndrome is a subcapsular liver hematoma. If the suspicion for a subcapsular liver hematoma is high, then it is appropriate to proceed with obtaining a computed tomography scan.

TABLE 16.17 Clinical and Laboratory Findings in HELLP Syndrome, Thrombotic Thrombocytopenic Purpura/Hemolytic Uremic Syndrome, and Acute Fatty Liver of Pregnancy

	HELLP	TTP/HUS	AFLP
Ammonia	Normal	Normal	Elevated
Anemia	Present	Severe	Normal
Antithrombin III	May be reduced	Normal	Decreased in all cases
Aspartate transaminase	Elevated	Usually normal	Elevated
Bilirubin	Elevated, mostly indirect	Elevated	Elevated, mostly direct
Creatinine	May or may not be elevated	Significantly elevated	Significantly elevated
Fibrinogen	Normal	Normal	Decreased in all cases
Glucose	Normal	Normal	Decreased
Hypertension	Present	May or may not be present	May or may not be present

LDH	Elevated	Significantly elevated	Elevated
Proteinuria	Present	May or may not be present	May or may not be present
Thrombocytopenia	Present	Present	May or may not be present

HELLP, hemolysis, elevated liver enzymes, low platelet count; TTP/HUS, thrombotic thrombocytopenic purpura/hemolytic uremic syndrome; AFLP, acute fatty liver of pregnancy; LDH, lactate dehydrogenase.

Immediate delivery should be performed in patients >34 weeks gestation. In patients less than 34 weeks and without proven fetal lung maturity, glucocorticoids should be given for fetal benefits and delivery planned in 48 hours provided no worsening of maternal or fetal status occurs. Multiple studies have been done using steroids, volume expanders, plasmapheresis, and antithrombotic agents in patients with HELLP to attempt to prolong gestation. These studies show only marginal results. Some evidence exists as to the benefit of steroid therapy for improvement in maternal condition. In a study by O'Brien and colleagues, the antepartum use of glucocorticoids showed a dose-dependent prolongation in latency, reduction in liver enzyme abnormalities, and improvement in platelet count in patients with HELLP syndrome. Five randomized trials comparing the use of high-dose dexamethasone with either no treatment or with betamethasone in women with presumed HELLP syndrome (Table 16.18). The results of these studies demonstrate improved laboratory values and urine output in patients receiving dexamethasone but provide limited evidence of reduced maternal morbidity. However, because most of these trials were performed postpartum, the true extent by which glucocorticoids can influence outcomes has yet to be determined. The suggested recommended doses include 10 mg intravenous dexamethasone every 6 hours for two doses, then followed with 6 mg every 6 hours for an additional two doses; the other regimen is 20 mg of intravenous dexamethasone every 6 hours for four doses.

Conservative management of HELLP syndrome has significant risk, including abruptio placentae, pulmonary

edema, adult respiratory distress syndrome (ARDS), ruptured liver hematoma, acute renal failure, DIC, eclampsia, intracerebral hemorrhage, and maternal death. It is the authors' opinion that expectant management longer than 48 hours after glucocorticoid

administration is not warranted for the potential minimal fetal benefits when weighed against the profound maternal risk.

TABLE 16.18 Randomized Trial of Corticosteroids in Women with ELLP or HELLP Syndrome

Author	Dexamethasone (number)	Control (number)	Key Findings
Magann et al.	12[a]	13	Improved PLT, ALT, LDH in the treated group
Magann et al.	20	20	Improved PLT, ALT, LDH, urine output mean arterial pressure in the treated group
Vigil-De gracia	17[b]	17	Improved PLT in the treated group
Yalcin et al.	15[b]	15	Improved PLT, AST, urine output mean arterial pressure in the treated group
Isler et al.	19[a]	21[c]	Improved AST, LDH, urine output mean arterial pressure in the treated group
Fonseca et al.	66	66	No significant difference in the time of improvement in PLT, LDH

Sibai BM. Diagnosis and management of HELLP syndrome. *Obstet Gynecol* 2004.

Patients with a favorable cervix and a diagnosis of HELLP syndrome should undergo a trial of labor, particularly if they arrive in labor. HELLP syndrome does not automatically mandate cesarean delivery. An operative delivery in some situations may even be harmful. Any patient with a favorable cervix, regardless of length of gestation, should undergo induction of labor with either oxytocin or prostaglandins. Elective cesarean section should be considered in patients in very early gestation who have an unfavorable cervix. A management paradigm is presented in Table 16.19 for patients with HELLP undergoing cesarean section.

TABLE 16.19 Perioperative Management of a Patient with HELLP Syndrome Requiring Cesarean Section

1. Control severe hypertension
2. Initiate intravenous $MgSO_4$ infusion
3. Glucocorticoids for 24–48 hours for fetal benefit if <34 weeks
4. General anesthesia for platelet count <75,000/mm^3
5. Platelets 5–10 U before surgery if platelet count <50,000/mm^3
6. Leave vesicouterine peritoneum (bladder flap) open
7. Subfascial drain
8. Secondary closure of skin incision or subcutaneous drain
9. Postoperative transfusions as needed
10. Intensive monitoring for at least 48 hours postpartum

HELLP, hemolysis, elevated liver enzymes, low platelet count; $MgSO_4$, magnesium sulfate.

Pain management of the patient with HELLP during labor should be discussed between the obstetrician and the anesthetist. The anesthetist should be made aware of the patient's condition due to the potential of laryngeal edema and difficulties with intubation or extubation. Typically, the decision of whether to use epidural anesthesia is at the discretion of the anesthetist. Regional anesthesia should be used with caution in patients with particularly low platelet counts. A study by O'Brien and coworkers supported the use of glucocorticoids to improve platelet counts and to allow a more liberal use of regional anesthesia in patients with HELLP syndrome. The anesthetist should be updated as to the trend in platelet count of patients with HELLP. Intravenous narcotics can be given to achieve analgesia. Local infiltration can be used without concern during vaginal deliveries and for perineal repairs. Pudendal blocks should be avoided due to the potential for unrecognized bleeding into this area.

If a patient with HELLP syndrome requires cesarean delivery, precautions should be taken to minimize adverse outcomes. Platelet transfusion of approximately 5 to 10 U should be done en route to the operating room for patients with severe thrombocytopenia. Platelet consumption is rapid with a platelet transfusion, and the effects are temporary. Intraoperative considerations should include drain placement—either subfascial, subcutaneous, or both—due to anticipated generalized oozing. The choice of skin incision should be made entirely on the surgeon's best clinical judgment. In a study by Briggs and colleagues, patients with HELLP syndrome undergoing cesarean section were evaluated for wound complications. No statistical difference was found between midline incision versus a Pfannenstiel incision, whether primary or delayed closure.

Another potential life-threatening complication of HELLP syndrome is a subcapsular liver hematoma. Clinical findings consistent with subcapsular hematoma include physical examination with peritoneal irritation and

---

hepatomegaly and referred pain from the phrenic nerve. Pain to the pericardium, peritoneum, pleura, shoulder, gallbladder, and esophagus are consistent with referred pain from the phrenic nerve. Confirmation of the diagnosis can be made by computed tomography, ultrasonography, or magnetic resonance imaging. Conservative management in a hemodynamically stable patient with an unruptured subcapsular hematoma is an appropriate plan, provided that close hemodynamic monitoring, serial evaluations of coagulation profiles, and serial evaluation of hematoma status by radiologic studies are performed. If the patient decompensates hemodynamically, the diagnosis of ruptured subcapsular hematoma should be considered.

If rupture of a subcapsular liver hematoma is suspected, immediate intervention is necessary. Liver hematoma rupture with hemodynamic shock is a life-threatening surgical emergency. Treatment at this point is from a multidisciplinary approach and should involve general surgeons and vascular surgeons to perform a laparotomy. Furthermore, correction of coagulopathy and massive blood product transfusion is essential. The rupture typically involves the right lobe of the liver. Maternal and fetal mortality is over 50% with immediate intervention. The recommendation in the literature for rupture of a subcapsular liver hematoma in pregnancy is packing and drainage. According to a study by Smith and coworkers, overall survival reached 82% with this method.

Postpartum management of the patient with HELLP should include close hemodynamic monitoring for at least 48 hours. Serial laboratory evaluations should be done to monitor for worsening abnormalities. Most patients will show reversal of laboratory parameters within 48 hours postpartum. Small studies have shown a more rapid reversal in laboratory abnormalities with postpartum administration of plasma exchange and steroids.

Eclampsia

The rate of eclampsia in the United States is 0.05% to 0.10%. The rate is much higher in developing countries. Eclampsia continues to be a major cause of maternal and perinatal morbidity and mortality worldwide. The maternal mortality rate is approximately 4.2%. The perinatal mortality rate is higher, ranging from 13% to 30%. Eclampsia can occur antepartum (50%), intrapartum (25%), or postpartum (25%). Patients with eclampsia can exhibit a wide spectrum of signs and symptoms, from mild isolated hypertension to multiorgan failure. Prevention of eclampsia is one of the goals in treating preeclamptic patients with $MgSO_4$.

Management of Eclampsia

During the eclamptic seizure, the main therapy is supportive care. This includes avoiding injury, maintaining oxygenation, and minimizing the risk of aspiration. An outline of specific steps to care for an eclamptic patient are shown in Table 16.20. Most seizures are self-limited, lasting 1 to 2 minutes. However, some patients may have repeated convulsions, which can result in hypoxia or acidosis both in mother and fetus. $MgSO_4$ is the drug of choice for the prevention of eclamptic seizures and should be used for the prevention of recurrent seizures. Approximately 10% of eclamptic women receiving $MgSO_4$ will have further seizures.

TABLE 16.20 Management of the Eclamptic Patient

1. Avoid injury
   1. Padded bedside rails
   2. Physical restraints
2. Maintain oxygenation to mother and fetus
   1. Oxygen at 8–10 L per minute by face mask
   2. Monitor oxygenation and metabolic status with transcutaneous pulse oximetry or arterial blood gas measurements
3. Minimize aspiration
   1. Lateral decubitus position
   2. Suctioning of vomitus and oral secretions

3. Obtain chest x-ray after cessation of convulsion to rule out aspiration
4. Initiate $MgSO_4$ to prevent recurrent seizures
5. Control severe hypertension
6. Initiate the delivery process

$MgSO_4$, magnesium sulfate.

Immediately following an eclamptic seizure, it is common to see abnormalities in the fetal heart rate pattern. These include fetal bradycardia, decreased variability, late decelerations, and reflex tachycardia. These abnormalities typically resolve within 5 to 10 minutes after the convulsion. It is important not to proceed directly to cesarean delivery after a seizure. Stabilization of the mother is the priority. Generally, the fetus will respond favorably once the mother is treated. If prolonged signs of fetal compromise occur indicating possible abruptio placentae, consideration should be given to proceed with operative delivery.

Vaginal delivery is the preferred route after an eclamptic seizure. Cesarean delivery should be performed only for obstetric indications. Induction of labor should be performed with oxytocin or prostaglandins. The patient should be maintained on $MgSO_4$ throughout her labor. Careful attention must be made to the overall fluid status of the patient. Patients with eclampsia have profound hemoconcentration. Because of this, close hemodynamic monitoring is required with the use of epidural anesthesia and in case of severe blood loss. Patients who are hypovolemic will not respond well to acute blood loss, in contrast to healthy parturients. It also is important to limit fluids, because these patients have capillary leakage and are predisposed to developing pulmonary edema.

TABLE 16.21 Trials for seizure prophylaxis in preclam

Author Antihypertensive Therapy	Recurrent Seizures	Relative Risk (95% confidence interval)	$MgSO_4$ (number)

[b]Lytic cocktail.
[c]Phenytoin.
Sibai BM. Magnesium sulfate prophylaxis in preeclampsia: evidenc randomized trials. *Clin Obstet Gynecol* 2005;48(2):478–488.

$MgSO_4$ should be continued for 24 hours postpartum. Intracranial imaging typically is not warranted unless coma or focal neurologic signs or persistent headache or the diagnosis is uncertain. Most patients are normotensive at discharge and do not require medication. Eclamptic patients should be evaluated in the outpatient setting within 1 week of discharge.

Postpartum eclampsia offers a diagnostic dilemma. Any woman seizing in the postpartum period should be considered to have a diagnosis of eclampsia, although other disorders must be ruled out. Late postpartum eclampsia, defined by Sibai as occurring more than 48 hours after delivery, happens in 56% of postpartum eclampsia. Patients who develop postpartum eclampsia usually will have symptoms prior to seizure activity, including severe persistent headache, blurred vision, photophobia, epigastric pain, nausea and vomiting, and transient mental status changes. Therefore, it is important to educate patients about reporting these symptoms to health care providers. All such women should receive preeclamptic evaluation. These patients should receive $MgSO_4$ for 24 hours after seizure activity. If the patient has normal laboratory values and hypertension is controlled, she can be discharged after $MgSO_4$ treatment to return in 1 week for outpatient evaluation.

Magnesium Sulfate

$MgSO_4$ is used in the management of preeclamptic patients for the prevention of eclamptic seizures. The exact mode of action of $MgSO_4$ for preventing seizures is unknown, although it has been in use since the early 1900s. Multiple studies have been done that show $MgSO_4$ to be superior to both phenytoin and diazepam or another lytic cocktail for the prevention of seizures (Table 16.21). The most notable of these is the Collaborative Eclampsia Trial, in which women with eclampsia were randomized to receive $MgSO_4$, phenytoin, or diazepam. The trial found that $MgSO_4$ was superior to both phenytoin and diazepam in the prevention of recurrent seizures and of maternal and perinatal death.

The administration of $MgSO_4$ usually is intravenous. The therapeutic range is considered to be a serum plasma level from 4 to 8 mg/dL. Multiple regimens have been prescribed to achieve these levels. The recommended regimen is presented in Table 16.22. The intravenous route is the preferred method, because intramuscular injections of $MgSO_4$ are painful and occasionally can cause gluteal abscess formation. Lidocaine at the injection site may decrease discomfort. The intramuscular route should be reserved for rare situations when intravenous infusions may not be possible, such as lack of intravenous access, unavailability of infusion pumps, or during patient transport.

TABLE 16.22 Recommended Regimens of Magnesium Sulfate in the Treatment of Eclamptic Convulsions

Loading dosage: 6 g i.v. over 20–30 min (6 g of 50% solution diluted in 150 cc D5W)
Maintenance dosage: 2–3 g i.v. per h (40 g in 1 L D5LR at 50 cc/h)
Additional 2 g over 5–10 min (1–2 times) can be given with persistent convulsions
If convulsions persist (2% of cases), give 250 mg sodium amobarbital i.v. over 5 min
In status eclampticus: intubation and muscular paralysis
Intramuscular dosage: 10 g i.m. (20 mL of 50% $MgSO_4$, one half of the dose in each buttock)

$MgSO_4$, magnesium sulfate.

TABLE 16.23 Serum Magnesium Levels and Associated Clinical Findings

Clinical Finding	Serum Level
Loss of patellar reflex	8–12 mg/dL
Feeling of warmth, flushing	9–12 mg/dL
Double vision	—
Somnolence	10–12 mg/dL
Slurred speech	10–12 mg/dL
Muscular paralysis	15–17 mg/dL
Respiratory difficulty	15–17 mg/dL
Cardiac arrest	30–35 mg/dL

$MgSO_4$ is not an entirely benign medication. Any member of the health care team caring for a patient receiving $MgSO_4$ should be familiar with potential side effects and complications of its administration. Patients receiving $MgSO_4$ are at increased risk for postpartum hemorrhage due to uterine atony. This should be anticipated, and steps should be taken to prepare cross-matched blood if the need arises. Monitoring patients for signs of magnesium toxicity should be done throughout the course of administration. This includes eliciting deep tendon reflexes, assessing mental status, and checking respiratory rate. Table 16.23 lists the clinical findings associated with various serum magnesium levels. If a patient develops signs of magnesium toxicity, the infusion should be stopped immediately. The patient should then be evaluated for respiratory compromise by examination and pulse oximetry, oxygen administered, and a serum magnesium level obtained. If magnesium toxicity is diagnosed, the patient should be treated with 10 cc of 10% calcium gluconate (1 g) slow push intravenously. Calcium competitively inhibits magnesium at the neuromuscular junction and decreases the effect of the magnesium. The effect of the calcium is transient, and the patient should be monitored closely for continued magnesium

toxicity. If respiratory or cardiac arrest occurs, immediate resuscitation including intubation and mechanical ventilation should be performed. A summary of the treatment of magnesium toxicity is seen in Table 16.24.

TABLE 16.24 Management of Magnesium Toxicity

Discontinue $MgSO_4$ infusion
Begin supplemental oxygen administration
Obtain serum magnesium level
Administer 1 g calcium gluconate (10 cc 10% calcium gluconate) by slow intravenous push
Repeat calcium gluconate administration, if necessary
If respiratory arrest occurs, begin cardiopulmonary resuscitation

$MgSO_4$, magnesium sulfate.

Counseling

Any patient diagnosed with preeclampsia is at significantly greater risk of having an underlying medical condition than is a normotensive gravidae. A study by Dekker and Sibai found that 39% of patients with a history of early-onset severe preeclampsia developed chronic hypertension. Another study by Nisell and coworkers found that 37% of patients with a history of pregnancy-induced hypertension and 20% of patients with a history of preeclampsia were noted to have hypertension at 7-year follow-up. It is thus essential that women diagnosed with preeclampsia receive close follow-up.

With regard to future pregnancies, patients with preeclampsia are at increased risk of developing preeclampsia during subsequent gestations. The risk is dependent on the severity of preeclampsia as well as gestational age at onset in the index pregnancy. The recurrence rate is 65% if preeclampsia develops in the midtrimester and 20% if it develops at term. Sibai and associates reviewed recurrence rates of preeclampsia and HELLP syndrome in patients who had pregnancies complicated by HELLP. Their findings noted that the recurrence risk for preeclampsia in the otherwise normotensive group was 19%, and the risk for recurrence of HELLP was 3%. This is in contrast to a group of patients with underlying chronic hypertension who had recurrence rates of preeclampsia and HELLP of 75% and 5%, respectively. The rate of recurrence of eclampsia is about 1% to 2%.

Chronic Hypertension

Chronic hypertension is defined as elevated blood pressure occurring prior to pregnancy or

elevated blood pressure measurements prior to 20 weeks gestation. The rate of chronic hypertension is 1% to 5% in pregnancy. This number is effected by many factors, including maternal age and race. The incidence of chronic hypertension among blacks is 2.5% in comparison to 1.0% among other racial groups. The Third National Health and Nutrition Examination Survey, which took place from 1988 to 1991, studied the incidence and stratification of patients with chronic hypertension. The results of this study showed that the rate of chronic hypertension among women ages 18 to 29 was 2.0% for blacks, 0.6% for whites, and 1.0% for Mexican Americans. In the 30 to 39 age category, the rates were 22.3%, 4.6%, and 6.2%, respectively. From 40 to 49 years of age, the prevalence was 30.5%, 12.7%, and 10.6% for each group. Given the trend in delayed childbearing as women pursue career and educational goals, increasing numbers of pregnancies will be complicated by chronic hypertension.

Determination of associated underlying medical conditions and the classification of hypertension is important in the management and counseling of patients with chronic hypertension in pregnancy. The etiology of chronic

---

hypertension can be either primary or secondary. Primary hypertension, also referred to as idiopathic hypertension or essential hypertension, occurs in 90% of pregnancies. Secondary hypertension occurs in the remaining 10% of pregnancies and is associated with the following underlying medical conditions: renal disease, endocrine disease, collagen vascular disease, and coarctation of the aorta.

Women with chronic hypertension in pregnancy are at increased risk for the development of superimposed preeclampsia, abruptio placentae, intrauterine growth restriction, and preterm delivery. The rate of superimposed preeclampsia in women with chronic hypertension is 25%. If the patient has chronic hypertension of over 4 years duration, renal insufficiency, or had hypertension in a prior pregnancy, the rate of superimposed preeclampsia increases. Overall, abruptio placentae occurs in 1.5% of pregnancies complicated by chronic hypertension. This rate varies from 1% in women with uncomplicated chronic hypertension to 3% in women with superimposed preeclampsia. Proteinuria is an independent risk factor for adverse perinatal outcome, regardless of the development of superimposed preeclampsia. A maternal serum creatinine greater than 1.4 mg/dL at conception is another risk factor for increased fetal loss and progressive worsening of maternal renal disease. Fetal loss is increased 10-fold in women with uncontrolled chronic hypertension and impaired renal function at conception as compared with normotensive women and women with well-controlled hypertension. Therefore, management of women with chronic hypertension should begin prior to conception.

Women with chronic hypertension should be counseled regarding the increased risk of adverse maternal and fetal outcomes as previously described. These patients also should be evaluated for end-organ damage such as retinopathy, renal disease, and left ventricular hypertrophy. The possibility of worsening maternal condition during pregnancy must be discussed with the patient. Blood pressure control prior to pregnancy should be optimized and lifestyle changes initiated, if possible. Patients should be discouraged from tobacco or alcohol use, because both of these may exacerbate hypertension, not to mention other known obstetric risks. Daily salt intake should be limited to 2 g. Appropriate

antihypertensive medications should be prescribed. This would include the discontinuation of angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor antagonists, if the patient was previously taking these medications. In addition, atenolol should be discontinued early in pregnancy.

The diagnosis of superimposed preeclampsia may be difficult to make in the patient with chronic hypertension, particularly with baseline nephropathy. To make the diagnosis, the patient should have increasing or difficult-to-control blood pressure, HELLP syndrome, new-onset proteinuria, or significant increase in preexisting proteinuria. Any patient with chronic hypertension who develops headache, right upper quadrant pain, or visual disturbances requires further evaluation for superimposed preeclampsia. If superimposed preeclampsia is suspected in a patient with chronic hypertension, she should be hospitalized for close maternal and fetal evaluation.

Management

The management of pregnancies complicated by chronic hypertension differs for the low-risk group versus the high-risk group. Patients considered to be in the low-risk group have, by definition, mild hypertension without evidence of organ damage. The high-risk group has either severe hypertension (SBP 160 mm Hg or DBP >110 mm Hg) or mild hypertension with evidence of organ involvement.

Patients with low-risk chronic hypertension who do not develop superimposed preeclampsia have pregnancy outcomes similar to those of the general population. Studies have shown that antihypertensive treatment in this group does not affect perinatal outcome and is not necessary, provided they remain in the mild hypertension range by blood pressure criteria. Antihypertensive use may be discontinued at the first prenatal visit in any patient with mild hypertension. These patients should be observed closely throughout gestation, because they may become high risk at any time. Pharmacologic agents should be reinstituted if the SBP reaches 160 mm Hg, DBP reaches 105 mm Hg, or target organ damage develops. Prenatal care should include 24-hour urine collection for total protein determination in the first trimester and at least monthly visits in the first and second trimester. Visits should be every 1 to 2 weeks after 32 weeks, looking carefully for the development of superimposed preeclampsia. Fetal surveillance should include interval ultrasonography for fetal growth and amniotic fluid assessment every 4 weeks beginning at 32 weeks, unless there is suspicion of poor fetal growth, and then testing should be started earlier. Weekly fetal heart rate testing with nonstress tests should begin at 34 weeks. Fetal well-being assessment should be increased to twice weekly with evidence of growth restriction or oligohydramnios. The patient also should be instructed on fetal movement counts. Timing of delivery should be determined on an individual basis. Patients in the low-risk group may continue their pregnancies up to 41 weeks, provided that blood pressure remains controlled and no evidence of superimposed preeclampsia or fetal growth restriction develops.

Central to the management of the high-risk chronic hypertensive pregnancy is the use of antihypertensive pharmacotherapy. The choice of agent is dependent on its pharmacologic actions and will be covered in the next section. Prenatal care of the high-risk patient

includes a first-trimester 24-hour urine collection for total protein level. The frequency of visits in the first and second trimesters should be every 2 to 3 weeks, then weekly in the third trimester if clinically indicated. Fetal surveillance should include ultrasonography for estimated fetal weight and amniotic fluid volume every 4 weeks starting at 26 weeks. Weekly nonstress testing or biophysical profile assessments should begin at 28 weeks. The frequency of prenatal care

visits and fetal testing may need to be increased dependent on clinical findings such as increasing hypertension, superimposed preeclampsia, decreased amniotic fluid volume, or fetal growth restriction. If superimposed preeclampsia is suspected or uncontrolled hypertension develops, the patient should be hospitalized, preferably at a tertiary care center. The timing of delivery is dependent on the development of confounding complications and gestational age. In general, pregnancies in patients with high-risk chronic hypertension should not be continued past 40 weeks.

Antihypertensive Agents

Many agents are available for the control of hypertension. It is important to be familiar with the maternal and fetal side effects, as well as mode of action, in order to choose the most effective agent for the patient. Antihypertensive agents exert their activity through the following five methods: they decrease cardiac output, decrease peripheral vascular resistance, decrease blood pressure centrally, diurese, and inhibit angiotensin production. Commonly used drugs in pregnancy are listed in Table 16.25. For the postpartum patient who is breast-feeding, little information is known about most drugs regarding excretion in breast milk and neonatal effects. In general, ACE inhibitors are discouraged secondary to potential renal effects on the neonate.

Centrally Acting Drugs

Methyldopa

Methyldopa is the most commonly used antihypertensive in pregnancy. Its mode of action is by central inhibition of the sympathetic drive. The safety and efficacy of methyldopa is well established. Studies have documented no known congenital malformations or adverse long-term follow-up of children exposed in utero. Maternal side effects include tiredness, dry mouth, and somnolence. In addition, about 5% to 10% may have elevated liver enzyme values. Methyldopa is the agent of choice for long-term, nonemergent oral therapy.

Clonidine

Clonidine is not commonly used, and there is limited data regarding the safety and efficacy of its use. Limited studies regarding congenital defects associated with the use of clonidine reveal no increased risk.

TABLE 16.25 Antihypertensive Drugs Commonly Used in Pregnancy

Medication	Dosage	Maximum	Half-life
Methyldopa	250–500 mg p.o. q6–12h	4 g/24 h	2 h
Labetalol	100 mg p.o. b.i.d.	2,400 mg/24 h	5–8 h
Thiazide diuretic	12.5 mg p.o. b.i.d.	50 mg/24 h	3 h
Nifedipine	10–20 mg p.o. q4–6h	240 mg/24 h	2 h

ß-Blockers

The main mode of action of ß-adrenergic blockade is through the reduction in cardiac output. The drugs in this group are a heterogeneous mixture exerting their effects dependent on receptor selectivity, lipid solubility, and intrinsic sympathomimetic activity. Fetal effects of ß-blockers may include growth restriction and neonatal hypoglycemia. Atenolol given in the first trimester, in particular, has been linked to intrauterine growth restriction. Labetalol is a nonselective ß-blocker and a postsynaptic ß-1 blocker. It has lower ß-blocking effect than other ß-blockers, which does not reduce cardiac output. Thus, it is probably less responsible for fetal growth restriction. The side effects are tremors, headache, and scalp tingling. The use of labetalol should be avoided in patients with asthma and acute congestive heart failure.

Calcium Channel Blockers

Calcium channel blockers act by inhibiting extracellular calcium influx into cells through slow calcium channels. This, then, reduces peripheral vascular resistance. Studies have found no increase in congenital malformations associated with the long-term use of calcium channel blockers. However, adverse maternal and fetal outcomes have been associated with sublingual use of nifedipine, including maternal myocardial infarction and profound hypotension. Maternal side effects are flushing, headache, and palpitations.

Vasodilators

Hydralazine

Hydralazine works through direct and potent vasodilatation. It may be used orally but is most effective as an intravenous agent to control hypertensive crisis. No congenital defects have been associated with hydralazine. It may cause hypotension in hypovolemic patients, so giving intravenous fluids may be warranted. Side effects include fluid retention, tachycardia, palpitations, headache, lupuslike syndrome, and neonatal thrombocytopenia.

Diuretics

Diuretics, in general, are not contraindicated in pregnancy. There is no increased risk of congenital defects with their

---

use, but their efficacy is uncertain. It is recommended that women receiving diuretics prior to pregnancy be continued on them throughout pregnancy. However, diuretics should be discontinued in patients with preeclampsia or oligohydramnios or if there is evidence of reduction in uteroplacental flow.

Thiazide

The thiazide diuretics have minimal effect on lowering blood pressure in pregnancy and are rarely used. Limited studies show no increased congenital anomalies with the use of thiazide. The side effect profile includes maternal and fetal hyponatremia and acute pancreatitis, rise in blood uric acid levels, and neonatal thrombocytopenia. It also can precipitate hyperglycemia and glycosuria in the diabetic patient.

Furosemide

Furosemide is rarely used as a sole pharmacologic agent but is useful in conjunction with other antihypertensives. Studies showed no increase in congenital anomalies with use in the second and third trimesters, but first-trimester use may be associated with hypospadias. Furosemide use in pregnancy should be limited to postpartum management of fluid overload and pulmonary edema in the preeclamptic patient.

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors act by inhibiting the production of angiotensin II and by reducing peripheral vascular resistance. The use of ACE inhibitors has been associated with an increased risk of intrauterine demise, renal dysgenesis, oligohydramnios, pulmonary hypoplasia, fetal growth restriction, and neonatal renal dysfunction. The mechanism of action is thought to be due to continuous inhibition of the renin-angiotensin system, leading to the development of tubular dysfunction. Therefore, ACE inhibitors are contraindicated in pregnancy, mainly during the second and third trimesters. However, ACE inhibitors may be an excellent choice for hypertensive control in the postpartum period.

Contraception

Women with hypertensive diseases in pregnancy, whether preeclampsia or chronic hypertension, will seek advice regarding contraceptive methods postpartum. It is important to be familiar with options available to patients and to be able to discuss potential risk factors.

No contraindications exist with the use of barrier methods with regard to hypertension. The user failure rate, however, may be significant if failure results in a pregnancy with increased morbidity due to hypertensive disease. There are no contraindications for hypertensive patients desiring to use an intrauterine device. It is important to be aware of any associated underlying medical problems or therapies that the patient may have that would prohibit the use of an intrauterine device. Natural family planning continues to be an acceptable form of contraception when used appropriately.

The greatest concern in finding appropriate contraception for the hypertensive patient is with regard to hormonal contraception. Oral contraceptive pills are the most widely used reversible form of birth control in the United States. Combination oral contraceptives are known to elevate blood pressure minimally, increase clotting factors, and increase total cholesterol levels. Once again, it is extremely important to be familiar with any coexisting disease in a hypertensive patient. Hypertension may have associated underlying antiphospholipid syndrome, for example, which would be a contraindication to combination oral contraceptives, given the increased risk for thromboembolic phenomena. Progestin-only contraceptive methods may be a suitable alternative for women with underlying hypercoagulability because they do not interfere with coagulation. Overall, the contraceptive choices given to hypertensive patients are basically the same as in normotensive patients. The risks and benefits of contraception must be weighed and patients counseled accordingly. Avoiding the morbidity associated with pregnancy in some patients may be a benefit that outweighs the risk of contraceptive use.

Summary Points

- Making an appropriate diagnosis is essential in caring for women with hypertensive disease in pregnancy.
- There is no known etiology, prevention, or screening method for preeclampsia.
- The use of $MgSO_4$ is warranted in patients with preeclampsia and eclampsia to prevent seizures. In patients with mild preeclampsia, the need for $MgSO_4$ may be individualized.
- Fetal outcome in patients with preeclampsia is based largely on gestational age at delivery; as such, prolonging pregnancies in patients with preeclampsia should be done with close maternal and fetal observation.
- Blood pressure >170 mm Hg systolic and >110 mm Hg diastolic requires intervention.
- Any patient with symptoms of HELLP syndrome should have laboratory evaluation performed, regardless of blood pressure

measurements.
- Evaluation of a patient with chronic hypertension should include monitoring for target organ damage. Management of these patients is dependent on the degree of hypertension.
- Any patient with chronic hypertension is at increased risk of developing superimposed preeclampsia.

Medical and Surgical Complications of Pregnancy

Deborah Krakow

Hematologic Disease

Anemias

Anemia is defined as a hemoglobin (Hb) concentration <12 g/dL in nonpregnant women. Anemia can be either acquired or inherited. During pregnancy, plasma volume expands proportionately more than Hb or red blood cell volume, resulting in Hb dilution, such that anemia is defined as a Hb concentration <10 g/dL. In addition to blood loss, anemia can result from decreased production or increased destruction of red blood cells. The initial workup consists of a history and physical examination as well as an examination of the red blood cell indices and a peripheral smear, with additional tests as indicated (Fig. 17.1).

Iron Deficiency Anemia

Iron deficiency is an acquired anemia and is the most common cause of anemia in gravid women, occurring in 15% to 25% of all pregnancies. Iron deficiency is suspected when the mean corpuscular volume (MCV) is <ã80/mm^3 and is confirmed by demonstrating an elevated total iron-binding capacity (TIBC), a low serum iron level, a serum iron-to-TIBC ratio <20%, or a low ferritin level. Effects of iron deficiency on the fetus are usually minimal, although the incidence of neonatal anemia is increased. Iron is transported actively across the placenta, and fetal iron and ferritin levels are three times higher than maternal levels. While mild anemia is not a significant risk factor, severe anemia (Hb <8 g/dL) is associated with intrauterine growth restriction (IUGR). In pregnant women, iron deficiency can cause symptoms including fatigue, headache, lightheadedness, and reduced exercise tolerance. Blood loss at delivery may be tolerated poorly in anemic patients, and postpartum tissue healing may be compromised. For these reasons, treatment during pregnancy is recommended.

The total iron requirement of pregnancy is 1,000 mg: 500 mg increases the maternal red blood cell mass, 300 mg is transported to the fetus and placenta, and 200 mg compensates for blood loss at delivery. The iron requirements of pregnancy increase steadily toward

term but average 3.5 mg per day. Even though iron absorption efficiency increases during pregnancy, excess iron must be ingested to ensure sufficient dosage. Recommended supplementation for nonanemic gravidas is 300 mg of ferrous sulfate per day, which contains 60 mg of elemental iron. Anemic gravidas (Hb of 8 or 9 g/dL) should take 300 mg ferrous sulfate two or three times per day. Patients who cannot tolerate iron tablets may take an enteric-coated tablet or a liquid suspension (Table 17.1). Vitamin C facilitates iron absorption. Therapeutic results can be expected after 3 weeks of therapy.

The severely anemic patient (Hb <8 g/dL) may require parenteral therapy in the form of intramuscular or intravenous iron dextran. Because 0.2% to 0.3% of patients have an anaphylactic response to iron dextran, all patients should receive a small test dose 1 hour before the initiation of treatment, and therapy should be provided in an area with ready access to resuscitative medication and equipment. Adequate parenteral therapy should result in

a marked increase in the reticulocyte count within 7 to 14 days.

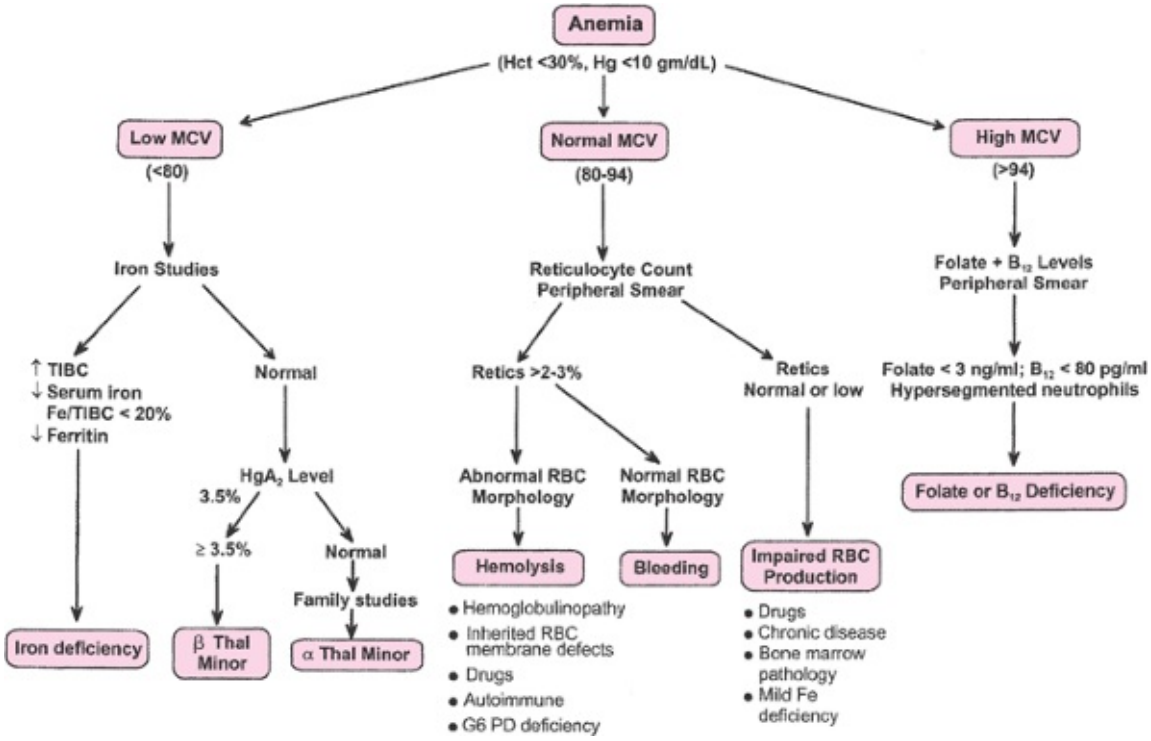

Figure 17.1 Workup of anemia in pregnancy. (MCV, mean corpuscular volume; Hct, hematocrit; Hg, hemoglobin; TIBC, total iron-binding capacity; Fe, iron; HgA_2, hemoglobin A_2; RBC, red blood cell; G6PD, glucose-6-phosphate dehydrogenase.)

Megaloblastic Anemia

Megaloblastic anemia is characterized by red blood cells with increased MCV and white blood cells with altered morphology (hypersegmented neutrophils, anisocytosis, and poikilocytosis). It complicates up to 1% of pregnancies and usually is caused by folate

deficiency, although it can occur after exposure to sulfa drugs or hydroxyurea or, rarely, because of vitamin B_{12} deficiency.

Folate deficiency can develop over a relatively short time, as liver stores of folate are sufficient to meet the body's needs for only 1 to 2 months. Malnutrition (e.g., alcoholism), malabsorption, anticonvulsant therapy, oral contraceptive use, or pregnancy can rapidly deplete the body's folate stores. Hypersegmented neutrophils (more than 5% of neutrophils having five or more lobes) appear after 7 weeks of deficiency, red blood cell folate is reduced after 18 weeks, and anemia occurs after 20 weeks. The daily folate requirement for a nonpregnant individual is 50 to 100 mg; a pregnant woman needs 300 to 400 mg. This dosage may be difficult to achieve through dietary manipulation because folate is found primarily in fresh fruits and vegetables and is destroyed by cooking. In addition, some individuals need excess folate to prevent neural tube defects. For these reasons, women who are contemplating pregnancy should be advised to ingest a daily folic acid supplement (0.4 mg per day if there is no family history of neural tube defects; 4.0 mg per day if there is a family history) beginning before conception and continuing throughout the first trimester of pregnancy.

TABLE 17.1 Iron Preparations and Dosages

Preparations Iron (milligrams)	Elemental Iron Content (%)	Dose Containing 60 mg Elemental
Ferrous fumarate	30	200
Ferrous gluconate	11	550
Ferrous sulfate	20	300

In contrast, vitamin B_{12} deficiency is rare because very little of the body's stores are used each day. Ingested vitamin B_{12} is bound to an intrinsic factor produced by the parietal cells of the stomach and then absorbed through the mucosa of the distal ileum. Patients who have had a gastrectomy, ileitis, or ileal resection or who have pernicious anemia, pancreatic insufficiency, or intestinal parasites eventually may develop vitamin B_{12} deficiency.

When megaloblastic anemia is suspected, the history should be reviewed for predisposing factors. The peripheral smear should be examined both to confirm altered cell morphology and to rule out a mixed (i.e., folate and iron) deficiency. Serum folate and vitamin B_{12} levels should be measured. A fasting folate level <3 ng/mL or a vitamin B_{12}

level <80 pg/mL indicates deficiency. Folate deficiency responds to 0.5 to 1.0 mg folate orally per day, while a B_{12} deficiency requires vitamin B_{12}, 1 mg intramuscularly, weekly for 6 weeks.

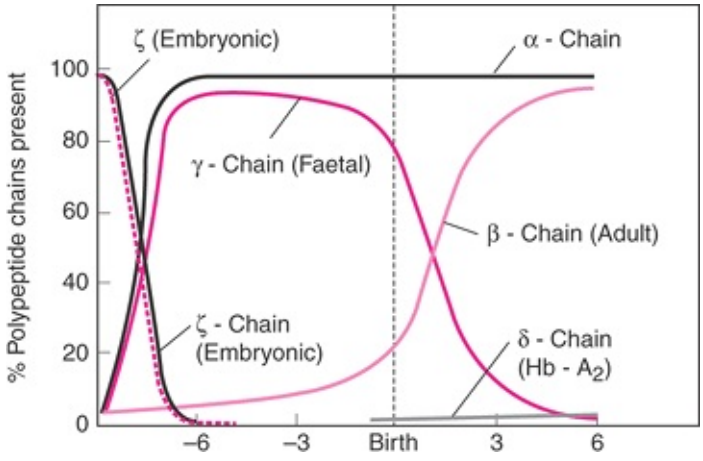

Figure 17.2 roduction of Hb polypeptide chains in relationship to gestational age. (From Rucknagel DL, Laros RK. Hemoglobinopathies: genetics and implications for studies of human reproduction. *Clin Obstet Gynecol* 1969;12:4, with permission.)

Hereditary Anemias

The most commonly encountered hereditary anemias in pregnancy are the thalassemias and sickle cell variants. Hb is a tetramer composed of two copies each of two different polypeptide chains; the identity of the chains determines the type of Hb produced. During embryonic and fetal life, genes directing production of different types of polypeptide chains, and thus different types of Hb, are switched on and then off sequentially. At birth, a normal individual produces α and ß chains, along with very small quantities of other Hbs (Fig. 17.2). Normal adults primarily produce hemoglobin A (HbA), composed of two α and two ß polypeptide chains.

TABLE 17.2 Hemoglobin Electrophoresis Findings in Various Hemoglobinopathies

Disorder	HbA (%)	HbA_2 (%)	HbS (%)	HbF (%)	HbC (%)
Sickle cell trait	55–60	2–3	40–45	1	—
			85–95		

Sickle cell disease	0	2–3		5–15	—
Sickle/ß-thalassemia	10–20	3–5	60–80	10–20	—
Hemoglobin SC disease	0	2–3	45–50	1	45–50
ßß—Thalassemia trait	82–94	4–8	—	2–3	—
Normal	96–97	2–3	—	1	—

HbA, hemoglobin A; HbA_2, hemoglobin A_2; HbS, hemoglobin S; HbF, fetal hemoglobin; HbC, hemoglobin C.

Thalassemias

Thalassemias are characterized by impaired production of one or more of the peptide chains. Thalassemia has a high incidence in certain ethnic groups, especially those originating in the Mediterranean basin, the Middle East, Africa, Asia, and India. Four clinical syndromes are associated with α-thalassemia, and two syndromes are associated with ß-thalassemia.

Two genes direct ß-chain production, both on chromosome 11. Over 100 different gene mutations have been identified that either prevent or diminish ß-chain transcription; if an individual carries an abnormal allele, then ß-chain production will be reduced by one half, and abnormally low quantities of Hb will be produced. This results in ß-thalassemia minor. The excess α chains combine, instead, with δ chains, producing a molecule called hemoglobin A (HbA_2), or with v chains, producing fetal hemoglobin (HbF). If ß-thalassemia minor is suspected because the patient has microcytic anemia without iron deficiency, Hb electrophoresis should be performed. Levels of HbA_2 >3.5% and HbF ≥2% confirm the diagnosis (Table 17.2). The gravid patient with ß-thalassemia minor generally tolerates pregnancy well. She should receive folic acid supplementation but not iron supplementation unless iron deficiency also is diagnosed. Patients with mutations preventing transcription of both ß-chain genes have ß-thalassemia major (ß-thalassemia), or Cooley anemia. Erythropoiesis is ineffective because there is no ß-chain production, and resultant α chains precipitate, causing red blood cell destruction. Occasionally, the mutations allow some ß-chain production, resulting in a less severe reduction of Hb synthesis. Aggressive intervention in infancy by using transfusion therapy ultimately leads to iron overload and hemosiderosis, with multiple organ system dysfunction and infertility.

Increasing numbers of pregnancies in this population are being reported by virtue of aggressive transfusion and iron chelation therapy. Such pregnancies can be complicated by an increased risk of cardiac arrhythmias and congestive heart failure secondary to severe anemia, chronic hypoxemia, and myocardial hemosiderosis. The safety of iron-chelating agents such as deferoxamine

---

has not been established in pregnancy and in theory could have an effect on fetal bone development. Prenatal diagnosis is available, and such pregnancies show improved outcome with stable maternal disease.

Before assessing whether a fetus has thalassemia major when the mother is a carrier of thalassemia minor, the father of the fetus should be offered testing. If the father has a normal Hb electrophoresis, the fetus has a 50% chance of having ß-thalassemia minor and a 50% chance of being unaffected. If the father has ß-thalassemia minor, the fetus has a 25% chance of having ß-thalassemia major, a 50% chance of thalassemia minor, and a 25% chance of having normal Hb. Prenatal testing of the fetus should be offered to high-risk couples. Alpha-chain production is directed by four genes, each residing as pairs on chromosome 16. Mutation in only one of the genes results in no clinical or laboratory abnormalities and is thus referred to as the silent carrier state. Mutations in two of the four genes results in ß-thalassemia minor, a condition characterized by mild microcytic hypochromic anemia. These patients have a low MCV but normal levels of HbA_2. The patient with these laboratory results should be referred for genetic evaluation and family studies to confirm the diagnosis, but typically they tolerate pregnancy fairly well.

Mutation of three of the four α genes results in hemoglobin H (HbH) disease. Affected patients have some HbA and a large percentage of HbH (four ß chains). The clinical course is characterized by chronic hemolytic anemia that may worsen during pregnancy. Loss of all four ß-chain genes causes ß-thalassemia major, resulting in fetal hydrops and perinatal death. As with ß-thalassemia, testing of the father is crucial for accurate genetic counseling. Consideration of the patient's ethnic background also is important. Asians with ß-thalassemia minor usually have the two mutant genes on the same chromosome (cis position) and thus have a 50% risk of passing on both affected genes with each conception. In contrast, patients of other ethnic origins usually carry the mutant genes on opposite chromosomes (trans position), so only one affected gene can be transmitted with each conception. All forms of ß-thalassemia can be diagnosed by prenatal invasive methods and should be offered to at-risk couples.

Hemoglobinopathies

Hemoglobinopathies involve mutations in the genes encoding Hb. These Hb variants generally have either reduced oxygen transport capabilities or produce hemolytic anemia. Hemoglobin S (HbS) and hemoglobin C (HbC) are the most frequent variants, and they can occur in association with thalassemia as well (Table 17.3).

Sickle Cell Disease

A mutation leading to a single amino acid substitution of valine for glutamic acid at the

sixth amino acid residue on the ß chain protein changes normal Hb to sickle Hb. An individual who is homozygous for this mutation has sickle cell anemia, or sickle cell disease, producing only HbS and a small quantity of HbF but no HbA. Sickle Hb functions well in the oxygenated state but aggregates, forming rod-shaped polymers, in the deoxygenated state. Polymerized Hb precipitates in the red blood cell, changing the cell from a biconcave disc to an elongated crescent or sickle shape. Sickled red blood cells are not deformable and cannot squeeze through the microcirculation. Microvascular obstruction results in local hypoxia that leads to a vicious cycle of further sickling and obstruction. Localized ischemia and infarction cause tissue damage.

TABLE 17.3 Frequency of Sickle Hemoglobinopathies in Blacks

Hemoglobinopathy	Frequency
Sickle cell trait (HbSA)	1:10
Sickle cell disease (HbSS)	1:400
Hemoglobin SC disease (HbSC)	1:800
Hemoglobin S/ß-thalassemia	1:1,250
Hemoglobin C trait (HbAC)	1:35
Hemoglobin C disease (HbCC)	1:4,800

Patients with sickle cell anemia usually produce increased quantities of HbF. HbF is not distributed uniformly among all red blood cells but is present at levels of 0% to 20% per cell. In cells containing HbF, restoration of normal oxygen tension may reverse the sickling and halt the destructive process. Cells containing little or no HbF become irreversibly sickled and are rapidly cleared from the system in a process leading to hemolytic anemia. Patients with predominant HbS typically have hematocrits of 20% to 30% and reticulocyte counts of 10% to 25%. Hydroxyurea therapy has been shown to increase both the number of red blood cells containing HbF and the quantity of HbF per cell. However, the issues surrounding the use of hydroxyurea are controversial; not all patients respond to treatment, there are associated complications, and its safety in pregnancy has not been established. It is a known teratogen, although isolated case reports on exposure in humans have been associated with unaffected fetuses. There has been increasing interest in the use of bone marrow/stem cell treatment for this disease. Any pathologic state causing

acidosis, dehydration, or hypoxemia can precipitate sickling, hemolysis, vasoocclusion, and infarction. Pregnancy often is characterized by an increase in sickle crises and associated complications (e.g., pneumonia, pyelonephritis, pulmonary emboli, congestive heart failure) and by pregnancy complications (e.g., IUGR, preterm birth, preeclampsia). The goal of pregnancy management should be to maintain adequate hydration and oxygen delivery to the tissues and to avoid or rapidly control infections or other stressors that could precipitate a crisis.

Patients with sickle cell anemia should ingest 1 mg of folate per day to support increased erythropoiesis in the

---

face of chronic hemolysis and should receive the polyvalent pneumococcal vaccine because chronic splenic infarction leads to functional asplenia by adulthood. Iron supplementation should not be given prophylactically but should be prescribed if there is laboratory evidence of iron-deficiency anemia. All sickle cell patients should undergo a funduscopic examination, with laser therapy as needed, because they are at increased risk for proliferative retinopathy. Asymptomatic bacteriuria (ASB) and other infections should be treated aggressively.

One controversy concerns the possible benefit of antepartum prophylactic exchange transfusions. Available data indicate that although some women with sickle cell anemia may escape prophylactic transfusion because they have no associated organ damage, very few crises, and a high percentage of HbF, many will require antepartum transfusion. Even those patients who avoid transfusion during pregnancy should be transfused prior to delivery, because the stresses of labor, anesthesia, operative delivery, and any associated complications (e.g., preeclampsia, chorioamnionitis) can precipitate a serious crisis. Transfusions should be planned to achieve a hematocrit above 30% and an HbA above 50%, although lower values are advocated by some authors. Unless complications dictate otherwise, delivery can be at term, with cesarean section for obstetric indications only.

Substitution of lysine for glutamic acid at the sixth amino acid position of the Hb chain results in the production of HbC. HbC is less soluble than HbA and can cause a mild hemolytic anemia, but it is more stable than HbS under hypoxic conditions. Nonpregnant women who are compound homozygotes for HbS and HbC generally have less severe anemia and fewer pain crises than women with sickle cell disease (HbSS), but under the stress of pregnancy, they experience similar maternal morbidity and pregnancy complications. Additionally, severe bone pain frequently occurs in individuals with hemoglobin SC disease (HbSC), and acute respiratory compromise as the result of embolization of necrotic bone marrow has been reported. The antenatal management of women with HbSC should be comparable to that of women with HbSS.

If one ß-chain gene carries the sickle cell mutation and the other gene is functionally deleted, the patient has sickle cell ß-thalassemia. Pregnancy-related morbidity in these patients is the same as for sickle cell anemia, and they should be managed similarly. Patients with hemoglobin C disease (HbCC) or C-ß-thalassemia have a very mild anemia and usually do not experience hemoglobinopathy-related pregnancy complications.

Heterozygotes for the sickle Hb mutation are referred to as having sickle cell trait (HbSA).

Individuals with HbSA have red blood cells that sickle under conditions of markedly reduced oxygen tension. Hb electrophoresis confirms the presence of 55% to 60% HbA in addition to 35% to 40% HbS. Sickling does not occur in vivo, except under conditions of severe stress and hypoxia. Because the renal medulla is especially sensitive to reduced oxygen tension, patients with HbSA may have episodes of painless, self-limited hematuria. During pregnancy, HbSA individuals exhibit an increased susceptibility to urinary tract infections. Patients with HbSA should be offered genetic counseling, and the father of the fetus should be tested so that the precise risk to the fetus can be provided. Prenatal diagnosis is possible by direct DNA analysis by chorionic villus sampling (CVS) or amniocentesis. Generally, no special therapy is required during labor and delivery for these patients.

Congenital Hemolytic Anemias

Hereditary Spherocytosis, Elliptocytosis, and Pyropoikilocytosis

Hemolytic anemia can occur for a variety of reasons. It may result from a hemoglobinopathy; may be autoimmune, drug induced, or pregnancy induced (very rarely); or may occur as the result of inherited red blood cell membrane abnormalities. Hereditary spherocytosis, elliptocytosis, and pyropoikilocytosis result from congenital defects of different red blood cell membrane proteins. All are autosomal dominant disorders occurring at an incidence of 1 in 4,000 to 5,000 in the general population. All result in variant red blood cell shapes, such that affected red blood cells cannot pass readily through the spleen. While trapped in the spleen, the cell membranes are damaged, leading to red blood cell lysis, hemolytic anemia, jaundice, and splenomegaly. Splenectomy is the treatment of choice and effectively eliminates the anemia. Most women of reproductive age with these disorders will already have undergone splenectomy. Although the abnormality of red blood cell shape persists, affected women tolerate pregnancy, labor, and delivery well, with few associated problems. The rare patient who has not undergone splenectomy may experience hemolytic anemia sufficient to require red blood cell transfusions. All patients should receive the polyvalent pneumococcal vaccine and should ingest a folic acid supplement throughout pregnancy. Infection should be treated aggressively, as it may cause hemolysis. The offspring of affected individuals have a 50% chance of inheriting the condition. Affected neonates may experience severe neonatal jaundice requiring exchange transfusion or splenectomy.

Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an inherited disorder caused by a defect of an enzyme essential to the hexose monophosphate shunt. Because of this defect, when under oxidant stress, Hb sulfhydryl groups become oxidized and Hb precipitates in the red blood cell, leading to hemolytic anemia. The gene is most prevalent among individuals of African, Asian, Mediterranean, or Middle Eastern origin. Known stressors include viruses; bacteria; toxins; fava beans; and certain drugs such as antimalarial agents, sulfa drugs, and nitrofurantoin. Over 400 different gene mutations leading to G6PD deficiency have

been described; the A variant is most common and is present in 1 in 20 black men and 1 in 10 black women in the United States. Although G6PD deficiency is X-linked and males are affected preferentially, carrier females with this gene defect can be symptomatic. Some females have markedly reduced G6PD levels because of unfavorable lyonization, and homozygosity for G6PD deficiency in females can occur (in at least 1 in 400 black women). Precipitating drugs should be avoided in known carriers.

Platelet Disorders

Thrombocytopenia, defined as a platelet count <150,000 platelets/mm^3, occurs relatively frequently in pregnancy, complicating 7% to 8% of all pregnancies. The diagnosis of benign or essential gestational thrombocytopenia is one of exclusion, however, requiring that other pathologic forms of thrombocytopenia be ruled out. Thrombocytopenia in pregnancy can be caused by defective platelet production (bone marrow pathology such as leukemia, lymphoma, metastatic disease), sequestration (splenomegaly), or accelerated platelet destruction. Accelerated destruction is the most common mechanism of disease. Destructive processes unique to pregnancy (e.g., preeclampsia, placental abruption) may occur as part of sepsis or disseminated intravascular coagulation or may result from immunologic dysfunction (e.g., systemic lupus erythematosus, immune thrombocytopenic purpura). These causes of thrombocytopenia are discussed in other areas of the text.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is a disorder characterized by the pentad of thrombocytopenia, hemolytic anemia, fever, neurologic abnormalities, and renal failure. It is rare and usually of unknown etiology; however, a rare congenital form caused by mutations in the *ADAMTS13* gene that encodes the von Willebrand factor (vWF) cleaving protease have been reported. TTP affects individuals of all ages, although most commonly young women. The untreated mortality rate exceeds 90%. Patients typically experience bleeding (uterine, gastrointestinal, or other) along with a mild Coombs-negative hemolytic anemia, thrombocytopenia, and mild jaundice. Hypertension and renal failure occur later in the course of the disease. All disease signs and symptoms result from microvascular damage caused by platelet thrombi, fibrin deposition, and microaneurysms in arterioles. Endothelial cell function, including prostaglandin production, is abnormal, although it is not known whether this causes TTP or results from it. Immune dysfunction may play a role.

When TTP manifests in the third trimester, it may be difficult to distinguish from preeclampsia or the syndrome of hemolysis, elevated liver enzymes, and low platelets (HELLP syndrome). One distinguishing feature is that tests of coagulation (prothrombin time, partial thromboplastin time, fibrinogen, fibrin dimers) usually have normal results in TTP. The advent of a fever of unknown origin or transient neurologic symptoms, as well as nonspecific complaints of arthralgias, nausea, or abdominal pain, may aid in the diagnosis of TTP. End-organ damage worsens as the disease persists. Delirium, seizures, hemiparesis, visual field defects, and coma indicate a very poor prognosis and an increased risk of mortality.

Distinguishing TTP from preeclampsia in its various forms is vital, because management is dramatically different. TTP responds only to plasmapheresis or exchange transfusion, although delivery is eventually curative for preeclampsia. Steroids, heparin, splenectomy, and antiplatelet drugs have had only variable success in the management of TTP. Plasmapheresis should be initiated as soon as the diagnosis is made, regardless of the clinical severity. If the patient is at or near term, magnesium sulfate therapy and delivery also should be initiated because of the possibility that the actual diagnosis is preeclampsia. Cesarean delivery should be for obstetric indications only.

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome (HUS) is similar to TTP, with similar microangiopathy, except that the kidneys are primarily affected in HUS. The patient usually manifests hemolytic anemia, thrombocytopenia, hypertension, and oliguric renal failure. Laboratory evaluation reveals a normal coagulation profile and hemoglobinuria. The pathologic process usually is confined to the kidney, although some patients have mild neurologic symptoms. Postpartum renal failure is probably the same entity, except that the pregnancy has already ended. Treatment in both cases consists of dialysis and red blood cell transfusions to maintain the hematocrit above 20%. Maternal morbidity and mortality are significant, with death frequently resulting from uncontrollable hemorrhage.

Coagulation Defects Von Willebrand Disease

Von Willebrand disease is an inherited defect of vWF, one of the proteins in the coagulation cascade. vWF is a large glycoprotein synthesized by endothelial cells and megakaryocytes and serves two functions: it is the plasma carrier for factor VIII, and it allows normal platelet aggregation at sites of endothelial injury. These two functions are directed by two different regions of the molecule, and several different mutations in both of these domains have been identified. There are three forms of von Willebrand disease.

Type I (approximately 75% of cases) and type II von Willebrand disease (25%) are inherited as autosomal dominant traits. Affected individuals have one normal vWF gene in addition to the abnormal gene, and some normal vWF will therefore be produced. As a result, individuals with type I disease are mildly affected, exhibiting easy bruising or bleeding only after dental procedures. Individuals with type II disease usually experience more severe bleeding problems, such as menorrhagia or corpus luteum hemorrhage. Type III disease is autosomal recessive and extremely

---

rare. It usually is associated with severe symptoms due to no normal production of the protein.

If the diagnosis is not made before pregnancy, it may be considered after excessive bleeding from a surgical or episiotomy site. Retrospectively, the patient may describe easy bruising or heavy menses. Pedigree analysis frequently includes similarly affected family members. The diagnosis is confirmed by all or some combination of the following laboratory tests: a prolonged bleeding time; decreased vWF concentration; reduced ristocetin cofactor activity; reduced factor VIII activity; and in some cases, mutational

analysis.

Women with von Willebrand disease usually tolerate pregnancy well, in large part because the production of all coagulation factors is increased and vWF factor levels can approach near-normal levels. Despite this, the bleeding time may still be prolonged, and treatment may be required. If the bleeding time is prolonged at term, levels of vWF must be increased so that postpartum or surgical hemorrhage can be avoided. One way to increase the vWF level is to administer desmopressin acetate (DDAVP) for 48 hours prior to planned delivery. Patients with type I disease have the best response to desmopressin; those with type III disease usually do not respond at all. Thus, a trial of the therapy should be conducted in the second trimester. Alternatively, vWF replacement can be provided. Fresh frozen plasma contains all coagulation factors in equal proportions; cryoprecipitate contains factor VIII, vWF, and fibrinogen; and lyophilized factor VIII contains only that protein. For patients with von Willebrand disease, the recommended therapy is 15 to 20 U of cryoprecipitate given twice daily just prior to delivery and for 2 to 3 days afterward. Factor VIII concentrate can be administered instead. Effective treatment should normalize the bleeding time.

Women with type I or type II von Willebrand disease have a 50% risk of having an affected child; those with type III disease have minimal risk, unless they are related to their spouses. Prenatal diagnosis can be offered to at-risk pregnancies.

Hemophilias A and B

Hemophilias A and B are X-linked disorders of two genes that encode coagulation proteins. Hemophilia A results from mutations in a gene that is part of the factor VIII complex, while hemophilia B has mutations in the gene that encodes for factor IX. In female carriers, levels of these factors are thus reduced by one half or more. These decreased factor levels are adequate for normal hemostasis, and carrier women usually are clinically unaffected. In rare circumstances, a woman may exhibit all of the classic features of hemophilia (i.e., if she is homozygous for the mutation or if she is a carrier and has unfavorable lyonization). Such patients benefit from factor replacement.

Carrier females should be offered genetic counseling. Female offspring will be carriers, and one half of their sons will have hemophilia. Prenatal diagnosis is available. In ongoing affected pregnancies, knowledge that a male fetus carries a hemophilia gene allows the obstetrician to plan to avoid placing a scalp electrode during labor and to avoid vacuum-assisted or forceps-assisted vaginal delivery. Cesarean delivery should be for obstetric indications only, because atraumatic spontaneous vaginal delivery does not entail additional risk for the affected fetus.

Gastrointestinal Disease

Nausea and Vomiting

Mild and self-limited nausea and vomiting in the first trimester of pregnancy occur in 60% to 80% of women. Chronic nausea and vomiting, or hyperemesis gravidarum, complicates 1

in 200 to 300 pregnancies. This disorder is characterized by dehydration, electrolyte imbalance, and nutrition depletion and prompts medical intervention.

The etiology of hyperemesis is unclear. Theories have suggested the influence of human chorionic gonadotropin, the pituitary–adrenal axis, transient hyperthyroidism, psychogenic factors, and potential evolutionary benefit. Regardless of the cause, intervention is appropriate, ranging from intravenous hydration and antiemetic medications to nasogastric enteral feeding and hyperalimentation. Pregnancies complicated by mild or severe hyperemesis are not at increased risk for growth abnormalities, congenital anomalies, or prematurity (Table 17.4).

Gastrointestinal Reflux Disease

One half of all pregnant women complain of gastroesophageal reflux disease (GERD), commonly known as heartburn, sometime during pregnancy and particularly in the third trimester. Complaints include burning substernal discomfort with or without radiation, dysphagia exacerbated by meals, and increased intra-abdominal pressure, all worsening in the recumbent position. The differential diagnosis includes angina, achalasia, and structural or functional causes of dysphagia.

Risk factors for gestational GERD include heartburn prior to or in previous pregnancies, multiparity, and advanced gestational age. There is no association between GERD and race, prepregnancy weight, or weight gain during pregnancy. Treatment options are similar to treatment of the nonpregnant population, depend on the severity of symptoms, and are initiated sequentially beginning with lifestyle modifications and antacids. In severe refractory cases, cimetidine and metoclopramide are appropriate therapeutic interventions.

Peptic Ulcer Disease

Gastric secretion and motility are reduced and mucus secretion is increased during gestation. As a result, peptic ulcer disease (PUD) is uncommon in pregnancy, and its complications, such as hemorrhage and perforation, are quite rare. Patients with PUD often experience considerable improvement, if not remission, of disease in pregnancy. However, PUD recurs in most women within 2 years of delivery.

TABLE 17.4 Gastrointestinal Disease in Preg

Disorder	Frequency	Trimester	Symptoms	Treatme
Hyperemesis	Common	First	Nausea and vomiting	Antieme nutritio

Reflux esophagitis	Common	Third	Heartburn	Antacid
Peptic ulcer disease	Uncommon	—	—	—
Cholecystitis	Uncommon	Any	Postprandial pain, nausea, anorexia	Bowel r hydratio
Pancreatitis	Uncommon	Any	Midepigastric pain, anorexia, nausea, emesis	Bowel r hydratio relief
Inflammatory bowel disease	Common	Any	Bloody diarrhea, pain	Sulfasal immunc drugs
Hepatitis	Common	Any	Fever, nausea, emesis, fatigue, jaundice	Support
Acute fatty liver	Rare	Third	Malaise, nausea, vomiting, epigastric pain	Delivery support

IUGR, intrauterine growth restriction.

Upper Gastrointestinal Bleeding

Hyperemesis can be accompanied by gastrointestinal bleeding. Although gastrointestinal bleeding prompts a concern for PUD with hemorrhage, most pregnant women with hematemesis will prove to have Mallory-Weiss tears. These small, linear mucosal tears

near the gastroesophageal junction respond to iced saline lavage, antacids, and intravenous cimetidine. Endoscopy can be performed during pregnancy and will detect esophageal rupture with bleeding (Boerhaave syndrome), a much more serious diagnosis for which surgery and gastroenterology consultations are appropriate.

Cholelithiasis and Biliary Disease

Studies using serial ultrasonographic examinations over the course of pregnancy confirm that the risk of gallstones is increased, to an incidence of 2% to 10%, because pregnancy is characterized by decreased gallbladder motility and increased biliary sludge. Many women with cholelithiasis are relatively asymptomatic during pregnancy and require no intervention. However, acute cholecystitis complicates about 1 in 1,000 to 1,600 gestations. It is characterized by postprandial pain in the right upper quadrant or epigastric area, with radiation to the back or shoulder. This type of pain, with anorexia, nausea, emesis, low-grade fever, and leukocytosis, suggests stone obstruction of a duct. Ultrasonographic examination is very helpful, detecting approximately 95% of stones.

Management is the same as in a nonpregnant individual. Three fourths of patients with acute cholecystitis will respond to medical therapy consisting of bowel rest, nasogastric suction, intravenous hydration, antibiotics, and analgesics. The remainder will require surgical intervention for persistent pain, empyema, gangrene, or perforation. Open laparoscopic cholecystectomy during pregnancy is becoming more widely accepted. Although the second trimester is considered optimal for any surgical procedure, delay in treatment should be avoided regardless of gestational age.

Pancreatitis

Pancreatitis occurs with an incidence of 1 in 1,500 to 4,000 during pregnancy, with the majority of cases due to cholelithiasis. Other far less common etiologies include ethanol abuse, certain medications, trauma, and hypertriglyceridemia. Symptoms include midepigastric pain with back radiation, anorexia, nausea, and emesis. In normal pregnancy, serum amylase and lipase levels tend to increase only slightly with advancing gestation. The upper limits of normal for amylase and lipase in the first two trimesters are 100 U/dL and 200 U/dL, respectively. Significant elevations of these enzymes are therefore consistent with pancreatitis, although the degree of elevation does not correlate with disease severity. As in the nonpregnant population, pancreatitis is managed by bowel rest, nasogastric suction, analgesia, and intravenous hydration.

In most patients, inflammation subsides within 2 to 7 days. In the minority, abscess or pseudocyst formation prompts abdominal exploration. In this population, perinatal morbidity ranges from 5% to 15%, and perinatal mortality can be as high as 38%, most likely resulting from accompanying hypovolemia, hypoxia, and acidosis.

Inflammatory Bowel Disease

The term *inflammatory bowel disease* (IBD) refers to two forms of intestinal inflammation—

namely, Crohn disease and ulcerative colitis. These diseases share many features but usually can be differentiated. IBDs have a significant genetic component and a fall under the classification of complex inheritance. The greatest risk factor for IBD is a family history of IBD. When both parents have IBD, the risk to the offspring is as high as 36% and is unaffected by disease activity in either parent at the time of conception. Figures for healthy offspring, congenital abnormalities, spontaneous abortions, and fetal demise are the same in pregnancies complicated by IBD as in the control population. Some report an increased risk of low birth weight in patients with Crohn disease, particularly if there is ileal disease, a history of bowel resection, or current tobacco abuse.

Ulcerative Colitis

Ulcerative colitis is a mucosal disease, almost always involves the rectum, and extends proximally and continuously for a variable distance. Symptoms include diarrhea, often with bleeding, and some degree of abdominal pain. Affected individuals also may have arthritis, uveitis, or erythema nodosum. Colon cancer, specifically adenocarcinoma, is increased in this population. The clinical course is one of exacerbations and remissions. The most serious complication is toxic megacolon, which can necessitate an emergency colectomy. Management is rapidly evolving, and new treatment regimens are based on the underlying mechanisms of disease and complement the older traditionally used drugs that include sulfasalazine, 5-aminosalicylic acid, and prednisone. If ulcerative colitis is quiescent at the time of conception, only one third to one half of patients will experience reactivation, often in the first trimester. Active disease at the time of conception may have a worse prognosis. When the disease is active, aggressive medical management, including parenteral nutrition, is essential.

Crohn Disease

Crohn disease is a transmural granulomatous inflammatory process that involves the rectum about 50% of the time. It may involve any part of the gastrointestinal tract but most often involves the terminal ileum and colon. “Skip” areas are common. Diarrhea and hematochezia can occur, and abdominal pain is almost always a problem. Nutritional deficiencies are more common than with ulcerative colitis. Complications include toxic megacolon and fistula formation, which is problematic for vaginal delivery if the perineum is involved. Eighteen percent of patients develop de novo perineal involvement after vaginal delivery, most often if an episiotomy was performed. As in ulcerative colitis, the patient also may have arthritis, and the risk of cancer is increased. Cancer risk correlates with the extent of mucosal pathology (pancolitis confers the highest risk) and the duration of the disease. In patients with long-standing disease, the risk exceeds 1% per year. Quiescent disease at conception carries a good prognosis. Similar to ulcerative colitis, there has been significant advances in the medical management of the disease. Surgery is necessary in about 5% of such pregnant patients.

Hepatitis

Acute viral hepatitis in pregnancy is a systemic illness with fever, nausea, emesis, and

fatigue. Jaundice is common initially, and liver function tests are markedly elevated. With the exception of hepatitis E virus (HEV) infection, viral hepatitides do not occur more frequently or with greater severity in pregnancy. HEV infection is more dangerous in a pregnant patient, with a mortality of 15% to 20%. It is transmitted by the fecal–oral route and occurs most frequently in countries with poor sanitation (e.g., the Middle East, Africa, and India). Infection in the third trimester often is associated with fulminant hepatitis as well as preterm delivery and neonatal and maternal death.

Hepatitis A

Hepatitis A virus (HAV) is an RNA virus, with fecal–oral transmission and an incubation period of 15 to 50 days. This highly contagious disease is self-limited, with resolution over 2 to 3 weeks. Acute HAV infection is confirmed by a positive anti-HAV immunoglobulin M (IgM) antibody test. There are no chronic sequelae, and HAV does not cross the placenta. A single dose of hepatitis immune globulin is recommended as soon as possible after exposure. If the exposed pregnant patient becomes infected, close contacts, including the neonate, should be offered passive immunotherapy.

Hepatitis B

Hepatitis B virus (HBV) is a double-stranded DNA virus with worldwide distribution, transmitted by parenteral and sexual contact. Risk factors include multiple sexual partners, intravenous drug abuse, and receipt of blood products. Its incubation period is 40 to 100 days, and it can be recovered from all body fluids—most importantly, blood, breast milk, and amniotic fluid. HBV surface antigen (HBsAg) and anti-Hb core (anti-HBc) IgM antibody are seen in the early clinical phase of infection, before icteric changes or elevations in liver function tests. They indicate infectivity (Fig. 17.3). The presence of HBe antigen (HBeAg)

denotes active viral replication. Although HBeAg usually indicates acute infection, its persistence correlates both with the chronic carrier state and with the ultimate development of hepatocellular carcinoma. The risk of maternal–fetal transmission increases dramatically to 90% when acute infection occurs in the third trimester or in the presence of both HBsAg and HBeAg positivity and is a consequence of intrapartum exposure to blood and genital secretions. If the mother develops HBV infection remote from delivery and has developed anti-HB antibodies, the risk of fetal or neonatal infection is considerably less. The neonate's risk of active or chronic disease is reduced significantly by HB immune globulin and the HBV vaccine; these should be given at delivery. Breast-feeding does not increase the risk of infection in these infants. The absence of HBsAg excludes active or chronic infection, and there is no risk for neonatal transmission. In the at-risk patient who is HBsAg negative and antibody negative, vaccination should be offered, as it is not contraindicated in pregnancy.

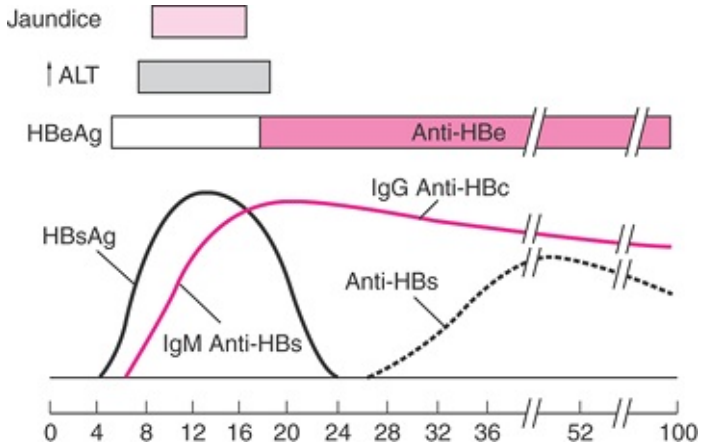

Figure 17.3 Timing of hepatitis B antigen and antibody production in acute hepatitis B infection. (ALT, alanine aminotransferase; HBeAg, hepatitis E antigen; HBsAg, hepatitis B surface antigen; IgG, immunoglobulin G; anti-HBc, antibody to hepatitis B core antigen; anti-HBs, antibody to hepatitis B surface antigen.) (From Dienstag JL, Isselbacher KJ. Acute hepatitis. In: Isselbacher KJ, Braunwald E, Wilson JD, et al., eds. *Harrison's principles of internal medicine*, 13th ed. New York: McGraw-Hill, 1994:1458, with permission.)

Hepatitis C

Hepatitis C virus (HCV) is the agent primarily responsible for non-A, non-B (posttransfusion) hepatitis. HCV is a single-stranded RNA virus. Principal risk factors for HCV transmission are blood product transfusion and intravenous drug use. Acute HCV infection follows an incubation period of 3 to 60 days, and only 25% of infected patients will be symptomatic. The presence of HCV antibody indicates chronic infection and does not confer immunity; approximately one half of those infected develop chronic liver disease. No specific therapy has been shown to be efficacious in decreasing the morbidity of the disease. Coinfection with HCV and HIV is thought to accelerate the progression of hepatic injury.

Seroprevalence studies in pregnant patients in the United States indicate an incidence of HCV of 2% to 4%. Vertical transmission is proportional to the maternal HCV RNA titer, and approximately 8% of patients transmit the disease to their offspring. Coinfection with HIV is associated with an increased rate of perinatal transmission of 23% to 44%. Breast-feeding in the HCV-positive patient is not contraindicated by virtue of the 4% transmission rate in breast- and bottle-fed infants.

Hepatitis D

Hepatitis D virus (HDV) is an RNA virus that is dependent on coinfection with HBV for replication. HDV is acquired as a coinfection with HBV or as a superinfection in a chronic HBV carrier. Coinfection rarely leads to chronic disease, whereas superinfection is associated with an 80% likelihood of chronic hepatitis. Perinatal transmission of HDV can be prevented by the immunoprophylaxis used for HBV.

Pregnancy Following Liver Transplantation

Following liver transplantation, most authorities recommend that pregnancy be avoided for at least 12 months so that graft viability can be assessed and immunosuppression can be achieved and maintained with the lowest possible medication dosages. Thirty-eight percent of liver transplant patients are hypertensive; pregnancy does not increase this incidence or hasten graft rejection. The incidence of spontaneous abortion is similar to that of the general pregnant population, and the incidence of preeclampsia is 13.5%. Anemia complicates 31% of pregnancies in liver transplant patients, and rejection develops or worsens in 9%. Fifty-eight percent deliver at term, and the majority deliver appropriately grown babies vaginally. Consultation with a specialist in hepatology is recommended in pregnancy.

Acute Fatty Liver

Acute fatty liver of pregnancy (AFLP) has an incidence of 1 in 13,000 deliveries. AFLP accounts for a large percentage of severe liver disease in pregnancy and is accompanied by a mortality of up to 25%. Primiparity, male fetal sex, and multiple gestation appear to confer a higher risk. The etiology is unknown, and liver biopsy reveals microvesicular fatty infiltrates.

Symptoms typically appear in the late third trimester and include malaise, persistent nausea, and vomiting. Right upper quadrant or epigastric pain is noted in 50% to 80%. Laboratory abnormalities include elevated liver function tests, increased ammonia and uric acid levels, hemolysis, hypoglycemia, and coagulopathy. Early recognition is essential; if untreated, AFLP progresses to multiorgan system failure and death. Once it is diagnosed, intensive supportive care

---

is provided, and delivery is necessarily accomplished. Under these circumstances, maternal and fetal mortality are <20%. Survivors have no long-term sequelae, and recurrence in subsequent pregnancies is a rarity.

Cardiovascular Disease

Physiologic Changes in Pregnancy

Normal pregnancy entails many physiologic changes that can stress the cardiovascular system. Plasma volume increases are measurable by 6 to 8 weeks gestation and 45% greater by 30 to 34 weeks. Red blood cell volume increases about 25%, resulting in a physiologic anemia. Cardiac output increases by 30% to 50% during the first half of pregnancy (as the result of an increase in both stroke volume and heart rate), by a further 30% during active labor, and by 45% during pushing. Systemic vascular resistance decreases during pregnancy, with both systolic and diastolic blood pressures falling during the second trimester and then returning to prepregnancy values in the third trimester. During labor, each uterine contraction results in an autotransfusion of 300 to 500 mL of blood. Cardiac output during this time is influenced by maternal vascular volume, maternal position, pain, and the

method of pain relief (epidural anesthesia, spinal anesthesia, or intravenous narcotics). Cardiac output rapidly increases at delivery as the result of autotransfusion and relief of caval compression by the involuting uterus.

Women with cardiovascular disease may tolerate these physiologic changes poorly. Knowledge of the pregnancy-associated risks and complications associated with each type of heart disease allows the physician to choose management that optimizes the chances for a good pregnancy outcome. For each patient, the prepregnancy cardiovascular status should be established and used as a reference in assessing any pregnancy-related cardiac changes. The New York Heart Association (NYHA) classification scheme is useful for quantifying symptomatology:

- Class I: patients are asymptomatic in all situations.
- Class II: patients are symptomatic with greater-than-normal exertion.
- Class III: patients are symptomatic with normal activities.
- Class IV: patients are symptomatic at rest.

Although useful for categorizing symptoms, this classification scheme does not necessarily predict pregnancy outcome. In one large retrospective study, for example, the majority of cases of pulmonary edema and maternal death occurred in women who were functional class I or class II. However, this scheme can be used to assess changes in cardiac function. Any change in cardiac classification during the pregnancy, even if only from class I to class II, can be ominous and should prompt a thorough evaluation and aggressive management. Bed rest or hospitalization often is required.

Rheumatic Heart Disease

Approximately 4% of reproductive-age women have heart disease. Although this number has remained fairly constant, the relative incidence of the various forms of heart disease has changed dramatically during the last few decades. During most of the 20th century, the majority of heart disease resulted from rheumatic fever (group A ß-hemolytic *Streptococcus*); the ratio of rheumatic heart disease to congenital heart disease was 20 to 1. During the last few decades, however, the prevalence of rheumatic heart disease has decreased significantly, while the number of adult survivors with congenital heart disease has increased; the ratio is now 3 to 1 or less. Nevertheless, rheumatic valvular disorders still account for a substantial proportion of heart disease in reproductive-age women.

Mitral Stenosis

Mitral stenosis is the most common form of rheumatic heart disease in women. Rheumatic fever typically occurs between ages 6 to 15 years. If myocarditis is present, mitral insufficiency will develop, followed in approximately 5 years by mitral stenosis. Symptoms usually do not begin for another 15 years after that, with severe complications such as right-sided heart failure occurring in another 5 to 10 years. The mean age for the initiation of symptoms is thus 31, with incapacity occurring at age 38 if the condition is not treated. Initial symptoms include fatigue and dyspnea on exertion, which progress to dyspnea at

rest and hemoptysis. Atrial arrhythmias, infection, or pulmonary embolism can lead to heart failure.

The stenotic mitral valve impairs left ventricular filling and thus limits any increase in cardiac output. Pregnancy-mediated cardiovascular changes, especially increased intravascular volume and increased heart rate, can exacerbate the impaired filling and lead to decompensation during pregnancy and especially during labor, delivery, and the puerperium. Left atrial volume and pressure increase, pulmonary venous pressure increases, and, eventually, features of pulmonary hypertension and right ventricular hypertrophy and failure can develop. The goals of management are to optimize cardiac output by preventing rapid ventricular rates and avoiding decreases in systemic vascular resistance, to reduce stress on the right ventricle by minimizing increases in blood volume, and avoiding situations in which pulmonary artery pressure is increased (i.e., hypercarbia, hypoxia, or acidosis). Two serious complications associated with mitral stenosis are atrial fibrillation and pulmonary edema. Both have been associated with maternal death.

Tachyarrhythmias that occur in the patient during pregnancy should be treated, because a rapid heart rate prevents adequate ventricular filling and decreases cardiac output.

ß-Blockers should be considered for the patient with a heart rate above 90 beats per minute. Digoxin and heparin may be required for the patient with atrial fibrillation. Rarely, surgery becomes necessary during the pregnancy, including balloon valvuloplasty and surgical commissurotomy. During labor, bedside cardiac monitoring is routine; central hemodynamic monitoring is routine if the patient is in NYHA class III to IV or the valve diameter is <2.5 cm^2. Pain must be managed effectively. Epidural anesthesia can be used if care is taken not to overload the patient with fluid beforehand and not to decrease systemic vascular resistance during the infusion. Fluid management must be meticulous, with extra attention given to the patient during the immediate postpartum period, when autotransfusion rapidly increases the central blood volume. Pulmonary function must be followed closely for pulmonary edema. A pulmonary artery catheter may assist in the management of patients with severe disease. Because the pulmonary capillary wedge pressure (PCWP) may not accurately reflect left ventricular filling pressure in severe mitral stenosis, the PCWP should be maintained in the high-normal to elevated range. If general anesthesia becomes necessary, agents that produce tachycardia (e.g., atropine, meperidine, ketamine) should be avoided. The high-risk period for severe decompensation continues for 24 to 48 hours postpartum.

Although the American Heart Association recommends antibiotic prophylaxis only for women who have a vaginal delivery in the presence of an infection or who undergo urethral catheterization, many clinicians provide prophylaxis to all cardiac patients. Subacute bacterial endocarditis (SBE) prophylaxis usually includes ampicillin 2 g and gentamicin 1.5 mg/kg intravenously 30 minutes before delivery and ampicillin 1 g intravenously or amoxicillin 1 g orally 6 hours after delivery. Penicillin-allergic patients should receive vancomycin.

Mitral Insufficiency

Mitral insufficiency results in regurgitation of blood from the left ventricle back into the left atrium, with resulting left atrial enlargement. Most patients tolerate mitral insufficiency well and remain asymptomatic for 30 to 40 years. However, because pulmonary edema or embolism, atrial tachycardia, and infective endocarditis can occur during pregnancy, patients with mitral insufficiency should be monitored closely. Anything that stresses or impairs the function of the left ventricle should be avoided. Increases in systemic vascular resistance, atrial fibrillation, bradycardia, or myocardial depressants can all result in left ventricular decompensation. During labor, pain should be treated effectively and fluid management calculated to maintain left ventricular volume without increasing it. Epidural anesthesia can be very effective, as long as preprocedure hydration is conducted cautiously. SBE prophylaxis should be given. Occasionally, surgical valve replacement is necessary during pregnancy.

Aortic Insufficiency

Aortic insufficiency (AI) usually occurs 7 to 10 years after an episode of rheumatic fever myocarditis, and the patient remains asymptomatic for another 7 to 10 years. The regurgitant valve causes a chronic increase in left ventricle volume, eventually leading to increased compliance, increased end-diastolic pressure, and pulmonary congestion and edema. Most pregnant women with AI are relatively asymptomatic. This is, in part, because the decreased systemic vascular resistance and increased heart rate typical of pregnancy tend to increase forward flow through the insufficient valve. However, cardiovascular changes occurring during labor and delivery can lead to decompensation, especially if intravascular volume is increased markedly or systemic vascular resistance is increased by pain or other stressors.

Epidural anesthesia is ideal for such patients, as it eliminates pain and decreases systemic vascular resistance. However, care must be taken not to reduce diastolic blood pressure or provoke a bradycardic episode, because left ventricular output will decrease as a result. Myocardial depressants should be avoided, and fluids must be managed carefully to maintain adequate volume but not overload the left side of the heart. Frequent pulmonary examinations to rule out pulmonary congestion may be helpful. SBE prophylaxis should be given.

Aortic Stenosis

Aortic stenosis (AS) resulting from rheumatic fever rarely complicates pregnancy, because the time lag between the rheumatic fever episode and the occurrence of stenosis is usually 35 to 40 years. However, AS can occur in reproductive-age women, and those who are symptomatic (e.g., angina, syncope, shortness of breath) have a risk of sudden death out of proportion to the severity of their symptoms; left ventricular failure and infective endocarditis are other serious complications.

The normal cross-sectional area of the aortic valve is 2.6 to 3.5 cm^2; an orifice <2.6 cm^2 usually is heralded by a loud systolic murmur, while an orifice <1 cm^2 produces symptoms of dyspnea, chest pain, and syncope. AS results in a relatively fixed stroke volume that is dependent on both adequate diastolic filling and heart rate. Although some increase in

heart rate helps to maintain an adequate cardiac output, tachycardia >140 beats per minute, bradycardia, and decreased systemic vascular resistance are poorly tolerated.

For these reasons, use of epidural anesthesia is controversial for pain relief during labor, and the patient could instead be managed with parenteral narcotics and pudendal block. Fluid management must be meticulous, taking care to maintain an adequate intravascular and thus end-diastolic volume. A pulmonary artery catheter may be quite helpful in directing fluid management. Because hypovolemia is a far greater threat to this patient than is pulmonary edema, the pulmonary artery wedge pressure

---

should be maintained in the range of 14 to 16 mm Hg to provide a margin of safety against unexpected peripartum blood loss.

Congenital Heart Disease

Congenital heart disease accounts for the majority of all heart disease in reproductive-age women. Many women now reach adulthood without surgical correction of their lesions, while for others, early surgery has been lifesaving. Women who have undergone surgical correction, have normal hemodynamics, and are completely asymptomatic generally tolerate pregnancy, labor, and delivery well without special considerations. Women with uncorrected lesions, however, require special management. The most common uncorrected heart abnormalities seen in pregnancy are atrial septal defect (ASD), patent ductus arteriosus (PDA), ventricular septal defect (VSD), pulmonic stenosis, congenital AS, coarctation of the aorta, and tetralogy of Fallot.

Both maternal and fetal outcomes depend on the nature of the cardiac lesion, the patient's functional capacity, the history of surgical repair (if any), and the presence or absence of pulmonary hypertension or cyanosis. In the presence of cyanosis, there is an increased risk of functional deterioration, congestive heart failure, maternal mortality, IUGR, preterm birth, miscarriage, and stillbirth. In one series, only 55% of pregnancies in cyanotic mothers resulted in a live birth.

A woman with congenital heart disease should receive genetic counseling regarding the etiology of the lesion and risks to her fetus. Isolated congenital heart malformations are considered multifactorial in origin and thus have a general recurrence risk of 3% to 10% in first-degree relatives. However, a more precise recurrence risk can be provided if the heart defect is categorized according to the aspect of abnormal cardiac development. Many structural cardiac defects can be identified by second-trimester ultrasonographic examination or fetal echocardiogram.

Mitral Valve Prolapse

Mitral valve prolapse (MVP) is the most common congenital valvular lesion, with an incidence of 5% to 10% in the general population. The majority of patients with MVP are asymptomatic and tolerate pregnancy, labor, and delivery well. Arrhythmias occur occasionally. Although the patient's cardiovascular status should be monitored closely, usually no special therapy is required other than SBE prophylaxis, although this is

controversial and should be based on the recommendations of a cardiologist.

Left-to-Right Intracardiac Shunts

Left-to-right intracardiac shunts can result from ASDs, VSDs, or PDAs. Small shunts often are well tolerated for many years. If there is no pulmonary hypertension and the patient is asymptomatic, pregnancy does not impose significant increased risk and may actually improve cardiac hemodynamics, as the decreased systemic vascular resistance encourages forward flow. Increased systemic vascular resistance or increased maternal heart rate may increase the shunt and should be avoided; epidural anesthesia for labor and delivery can be helpful. Patients with ASDs are at increased risk of developing supraventricular dysrhythmias that should be controlled with medication.

If, however, the shunt is substantial, resulting in many years of increased pulmonary blood flow, pulmonary hypertension and right heart failure can develop, and the shunt reverses. The combination of pulmonary hypertension and right-to-left shunt through any communication between the systemic and pulmonary circulation is known as Eisenmenger syndrome. This condition is life threatening in the pregnant patient, with a maternal mortality of 40% to 60%. Death is due to congestive heart failure and thromboembolic phenomena. The outcome for the fetus also is exceptionally poor, with a perinatal mortality exceeding 28% and a 55% incidence of preterm birth. Women with Eisenmenger syndrome should be strongly discouraged from becoming pregnant or carrying a pregnancy. Management of the gravid patient with this condition includes hospitalization, oxygen therapy, prophylactic anticoagulation, and treatment of heart failure with digoxin and diuretics. Delivery usually requires pulmonary artery catheterization, intrathecal morphine provides excellent analgesia without significant motor or autonomic effects, and shortening of the second stage of labor with forceps delivery is common. SBE prophylaxis is routine, and many consider minidose heparinization postpartum.

Tetralogy of Fallot

Right-to-left shunting is seen also in tetralogy of Fallot, which describes the association of VSD, right ventricular outflow tract obstruction, right ventricular hypertrophy, and overriding aorta. The amount of right-to-left shunting is determined by both the size of the VSD and the degree of right ventricular outflow tract obstruction. Uncorrected tetralogy of Fallot is a cyanotic condition characterized by decreased arterial oxygen saturation and polycythemia. Pregnancy can cause further decompensation, because the decreased systemic vascular resistance increases the right-to-left shunt; shunting is increased as well by a rise in the pulmonary vascular resistance resulting from the stress of labor. With uncorrected tetralogy of Fallot, 40% of women develop heart failure during pregnancy, and 12% die; the fetal mortality rate is high. Pregnancy is discouraged in those with uncorrected tetralogy. Poor prognosis is associated with several factors, including a prepregnancy hematocrit of over 65%, a history of syncope or congestive heart failure, electrocardiographic evidence of right ventricular strain, and a peripheral oxygen saturation of <80%. Pregnancy management includes bed rest, oxygen therapy, and isotopic support as necessary. Because any decrease in systemic vascular resistance can be life

or spinal anesthesia should be avoided. Intravenous medication and pudendal block can be used, and the second stage of labor should be shortened.

Congenital Aortic Stenosis

Congenital AS accounts for 5% of all congenital heart disease, with bicuspid aortic valve being the most common malformation. Many patients with bicuspid aortic valve are completely asymptomatic and tolerate pregnancy, labor, and delivery well. For those who are symptomatic, management considerations are the same as for AS resulting from rheumatic heart disease. Bicuspid aortic valves can be a heritable trait.

Coarctation of the Aorta

Coarctation of the aorta rarely complicates pregnancy, because most affected women undergo surgical correction as children. During pregnancy, patients with uncorrected coarctation face an increased risk of aortic dissection and rupture, and thus an increased risk of maternal (up to 9%) and fetal (20%) death, as well as bacterial endocarditis and cerebral hemorrhage (associated with intracranial aneurysms). Because the coarctation results in a fixed stroke volume, management is similar to that for AS.

Pulmonic Stenosis

Pulmonic stenosis can be either valvular, which usually does not progress until late in life, or subvalvular, which can become steadily worse during the reproductive years. The right ventricle becomes hypertrophic to maintain output but eventually decompensates, leading to left ventricular failure as well. Right ventricular output is dependent on preload and heart rate, and systemic vascular resistance typically increases to compensate for any reduction in left ventricular output. During labor and delivery, fluids must be managed carefully so that preload is neither increased nor decreased, and bradycardia must be avoided. Because increased systemic vascular resistance is an important compensatory mechanism, epidural or spinal anesthesia should be used very cautiously, if at all.

Other Cardiac Abnormalities

Primary Pulmonary Hypertension

Primary pulmonary hypertension leads to right ventricular hypertrophy and eventually to right ventricular and then left ventricular failure. Pregnancy exacerbates this condition, resulting in a maternal mortality rate as high as 50%. Management is similar to that for Eisenmenger syndrome. Use of Viagralike drugs may improve the prognosis for this condition, but at the present time, they should not be used in pregnancy.

Hypertrophic Cardiomyopathy and Asymmetric Septal

Hypertrophy

Hypertrophic cardiomyopathy and asymmetric septal hypertrophy are relatively well tolerated in pregnancy. The increased intravascular volume of pregnancy tends to distend the left ventricle and reduce the degree of outflow obstruction. However, decreased systemic vascular resistance may increase the left ventricular ejection force and thus increase outflow obstruction.

Management goals include avoiding significant increases or decreases in intravascular volume, avoiding tachycardia, avoiding any decrease in systemic vascular resistance, and avoiding anything that increases myocardial contractility. Pain relief during labor can best be provided with intravenous medication or pudendal block or both.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy is a global congestive heart failure characterized by dilation of all four chambers of the heart, low cardiac output, and pulmonary edema. Arrhythmias may develop, along with pulmonary or systemic embolism. By definition, peripartum cardiomyopathy arises in the last month of pregnancy or in the first 5 months postpartum, and there is no other discernible etiology. The patient may complain of orthopnea, dyspnea, edema, weakness, and palpitations. The chest radiograph, echocardiogram, and electrocardiogram (ECG) are all consistent with cardiomegaly. The left ventricle and left atrium are enlarged, the ejection fraction is markedly reduced, and pulmonary congestion often is present. Up to 50% show evidence of pulmonary or systemic embolic phenomena.

Management consists of aggressive treatment of heart failure with digitalis, diuretics, and vasodilators as necessary; strict bed rest; and full anticoagulation. The prognosis is poor. If heart size and function do not return to normal within 6 months, the mortality rate is high (up to 85% in some series), and survivors often are left with a dilated cardiomyopathy that imposes significant morbidity. A proportion of patients experience a complete normalization of heart size and function within 6 months of the onset of disease and then remain at NYHA cardiac functional class I or II status. These patients should be counseled that the risk of recurrence of cardiomyopathy in future pregnancies approaches 50% and that complete recovery from a second episode cannot be assured.

Myocardial Infarction

The risk of myocardial infarction (MI) in a reproductive-age woman is low (1 in 10,000). Contributing factors include atherosclerosis, thrombosis, and vasospastic disease. The risk of death is highest at the time of the MI and is gestational-age dependent; maternal morality is approximately 23% in the first and second trimesters but 50% in the third. The risk of death also is high if delivery occurs within 2 weeks of the infarction. In the event of a cardiac arrest in a pregnant patient, cardiopulmonary resuscitation

---

(CPR) should be administered. Uterine displacement toward the left, maintenance of Pao_2 >70 mm Hg, cardioversion (having removed all metal monitoring devices from mother and fetus), and consideration of a cesarean section to increase the effectiveness of

resuscitative efforts are appropriate.

Management of a pregnant woman with an MI includes bed rest to minimize cardiac workload and myocardial oxygen consumption. Nitrates, aspirin, ß-blockers, and calcium channel blockers have been used successfully. Attempts should be made to stabilize the patient and prolong the time from MI to delivery as long as possible. Epidural anesthesia should be provided during labor and delivery, along with supplemental oxygen and left lateral tilt position. Troponin should be used to document an MI, because myoglobin, creatine kinase, and creatine kinase myocardial bands are increased twofold after delivery. Patients should be advised not to become pregnant for at least 1 year after an MI, and then only if normal ventricular function is confirmed by echocardiography, coronary angiography, or radionuclide studies.

Thromboembolic Disease

Venous thromboembolism occurs in 1 in 1,000 to 2,000 pregnancies and is a leading cause of maternal mortality in the United States. Venous stasis, which is aggravated by uterine compression of the pelvic veins, is a major predisposing factor. Levels of coagulation proteins are also altered unfavorably in pregnancy. Factors II, VII, and X and fibrin increase; levels of protein S decrease; and the fibrinolytic system is inhibited. Years ago, when postpartum ambulation was discouraged, the majority of thromboses occurred after delivery. Now, however, 50% or more of all thromboses occur during the antepartum period, making diagnosis and therapy a challenge.

Superficial Thrombophlebitis

Superficial thrombophlebitis involves only the superficial saphenous veins and is a relatively benign condition, often associated with varicosities. It is treated symptomatically with analgesia, rest, and elastic support.

Deep Venous Thrombosis

Deep venous thrombosis (DVT) is a pathologic condition that can be life threatening, with an absolute risk of symptomatic DVT during pregnancy of 0.5 to 3.0 per 1,000 women. It occurs most commonly in the iliofemoral region or in the veins of the calf and is characterized by edema and lower extremity aching and limb discoloration. Most DVT in pregnancy occurs on the left side and can complicate an otherwise unremarkable pregnancy, with diagnosis requiring a search for predisposing factors and a high index of suspicion. Most DVTs can be accurately diagnosed noninvasively. Impedance plethysmography is both highly sensitive and specific for identifying obstruction of the proximal veins (iliac, femoral, and popliteal). Likewise, real-time sonography and duplex Doppler sonography reliably detect proximal vein thrombosis, although they may fail to identify calf vein obstruction. During any examination after the late second trimester, the uterus should be displaced off the vena cava to prevent lower extremity engorgement leading to false-positive results. If ultrasonography is performed properly, however, a positive result after any of these three tests should be considered confirmatory and sufficient to warrant the initiation of therapy. If these studies are equivocal or negative

and suspicion is high, venography can be performed and findings are considered highly accurate. The amount of fetal radiation exposure associated with unilateral venography without an abdominal shield is 0.30 rad (0.0030 Gy); a limited venogram requires <0.05 rad (0.0005 Gy).

Pulmonary Thromboembolism

Pulmonary thromboembolism (PTE) is characterized by dyspnea, tachypnea, tachycardia, pleuritic chest pain, cough, and anxiety. In pregnancy, PTE usually is caused by emboli from a DVT and appears to occur more frequently in the postpartum period. Arterial blood gases confirm hypoxemia and hypocapnia, the ECG shows tachycardia with right heart strain, and the chest radiograph reveals subsegmental atelectasis. If there is a strong clinical suspicion of PTE, intravenous heparin therapy should be initiated immediately. The patient is thus protected from further compromise while awaiting confirmation of the diagnosis by spiral computed tomography (CT) or a ventilation/perfusion (V/Q) scan. Perfusion defects that are unmatched by ventilation defects indicate a high probability of PTE, while a normal V/Q scan excludes the diagnosis. Intermediate results, however, do not rule out a PTE and should try to be resolved by other modalities such as spiral CT or pulmonary angiography. Pulmonary angiography can be performed while the patient is receiving heparin. As with DVT, necessary diagnostic procedures should not be withheld because the patient is pregnant. The combination of chest radiograph, V/Q scan, and pulmonary angiography exposes the fetus to a radiation dose of only 0.5 rad (0.005 Gy).

Risk factors for a thromboembolic event include a history of DVT, a mechanical heart valve, atrial fibrillation, trauma, prolonged immobilization, major surgery, antiphospholipid antibody syndrome, and several hereditary thrombophilias. Some individuals carry a gene mutation that predisposes them to a thromboembolic event. Women who are heterozygous for protein C or protein S deficiency have an approximately 3% to 10% risk of antepartum thromboembolism and an 7% to 19% risk postpartum. The risk for heterozygotes for antithrombin III deficiency is 12% to 60% during pregnancy and 11% to 33% during the puerperium. A mutation in the gene that encodes factor V Leiden produces a single amino acid substitution that prevents factor V destruction and causes activated protein C resistance.

Women who carry this mutation have a 28% incidence of pregnancy-associated thromboembolism. These mutations are all inherited in an autosomal dominant fashion with variable expressivity. Most affected individuals have affected family members who display varying degrees of pathology.

Laboratory tests to diagnose all of these deficiencies are available and should be considered in the workup of a patient with a history of thromboembolism, especially if there is a strong family history and no clear predisposing factors. Tests for protein C, protein S, and antithrombin III deficiencies cannot be performed while the patient is anticoagulated. Factor V Leiden mutation is identified by molecular analysis, however, and can be diagnosed at any time. Although knowledge of such mutations would not affect management of an acute thromboembolic event, it would have a profound effect on the

patient's future medical management. As noted previously, antiphospholipid antibody syndrome also imposes an increased risk of thromboembolism and should be considered in the workup for thromboembolic disease.

Treatment for PTE with unfractionated heparin consists of intravenous administration for 5 to 10 days, followed by subcutaneous heparin every 12 hours or three times a day for the remainder of the pregnancy. Heparin is a large molecule that does not cross the placenta and has few reported side effects (mild thrombocytopenia or reversible osteoporosis after long-term therapy). The dosage should be titrated to achieve a midinterval activated partial thromboplastin time (aPTT) 1.5 to 2.5 times normal or a plasma heparin level of 0.1 to 0.2 IU/mL within 24 hours of the acute event; failure to do so increases the risk of recurrent thromboembolism by a factor of 15. Most patients require a minimum of 24,000 IU per 24 hours. Unfractionated heparin also can be administered by continuous subcutaneous pump. Fractionated or low-molecular-weight heparin has a longer half-life than ordinary heparin and thus can be administered once daily, and it is associated with reduced bleeding, osteoporosis, and thrombocytopenia that can complicate standard heparin administration. Low-molecular-weight heparin does not cross the placenta, and experience in pregnant patients is increasing. It is necessary to monitor peak antifactor Xa levels periodically when twice-daily dosing is used, because the aPTT does not correlate well with the anticoagulant effect of low-molecular-weight heparin. Warfarin sodium derivatives can be used after the second trimester, although historically it has not been used. First-trimester exposure imposes the highest risk due to the resultant warfarin embryopathy. Unfractionated heparin has a short half-life (60 to 90 minutes) and can be reversed with protamine sulfate. Because the half-life of low-molecular-weight heparin is much longer, most practitioners convert their anticoagulated patients to unfractionated heparin therapy in the last month of pregnancy. When delivery is planned or the patient enters labor, heparin should be discontinued and the aPTT checked. Most patients can undergo epidural anesthesia or cesarean section within 4 to 6 hours of their last unfractionated heparin dose, and protamine can be administered if reversal of anticoagulation is required sooner. Heparin should be resumed 6 to 12 hours postpartum, depending on the type of delivery and the occurrence of any complications, with warfarin sodium administered simultaneously. Once a therapeutic level is reached, warfarin alone should be continued for at least 6 weeks.

The recurrence risk of PTE in a subsequent pregnancy is 4% to 15%; the risk is much higher if the patient has a predisposing gene mutation or other known risk factors. Prophylactic heparin therapy should therefore be provided in subsequent pregnancies, although the ideal heparin dosage and duration of treatment remains controversial.

Mechanical Heart Valves

Women with mechanical heart valves require therapeutic anticoagulation during pregnancy. As noted previously, coumarin derivatives should be avoided during embryogenesis. Women with mechanical valves can be switched to therapeutic subcutaneous heparin before attempting conception or can be switched immediately after conception is verified (i.e., 1 to 2 weeks after the first missed period). The optimal agent

for anticoagulation from 14 to 39 weeks is controversial. The advantages of heparin include its inability to cross the placenta and its rapid reversibility. Disadvantages include difficulty in maintaining a therapeutic dosage and failure to prevent all valve thromboses. Although warfarin may provide more consistent anticoagulation, its effects cannot be readily reversed and may extend to the fetus; thus, consultation with the patient's cardiologist may be helpful.

Pulmonary Disease

Asthma

Asthma manifests as a spectrum of illness from infrequent, spontaneously resolving symptoms to repetitive, severe, life-threatening attacks. Symptomatic asthma involves fluctuating degrees of wheezing, dyspnea, chest tightness, and cough associated with reversible obstructive airway disease or bronchial hyperreactivity. Reversibility is defined objectively as an increase in forced expiratory volume in 1 second (FEV_1) of 12% and at least 200 mL after inhalation of a short-acting β_2 agonist.

Pathophysiologic mechanisms suspected as causal in asthma include genetic predisposition and airway hyperreactivity with a tendency toward bronchoconstriction, airway inflammation, and abnormal mucociliary function. Triggering factors include allergen exposure, respiratory infections, exercise, aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), and environmental irritants (e.g., tobacco smoke, pollutants).

Asthma may improve, worsen, or remain unchanged during pregnancy. Typically, the more severe the disease, the more likely it is to worsen. The course of asthma in a previous pregnancy is fairly predictive of the course in a subsequent pregnancy in about 60% of women. The peak incidence of asthma exacerbations is 24 to 36 weeks gestation, with relative improvement during the last month of pregnancy. Severe or uncontrolled asthma is associated with an increased risk of preeclampsia and maternal mortality as well as IUGR, preterm delivery, and perinatal mortality. It is apparent that perinatal outcome is much improved when optimal control is achieved.

Therapy of this chronic disease, which is characterized by acute exacerbations, should include education in the use of a peak flow meter, the importance of compliance with medications, and the avoidance of known triggers. Mild intermittent disease, with symptoms fewer than two times per week, is treated with an inhaled β_2 agonist such as albuterol. Mild persistent asthma, with symptoms more than two times per week, is treated with an inhaled glucocorticoid. Use of a long-acting β_2 agonist or a leukotriene antagonist is a second-line additive therapy to inhaled glucocorticoids for moderate and severe persistent asthma with daily or continuous symptoms. Systemic glucocorticoids for refractory severe exacerbations in the form of oral prednisone, 40 to 60 mg per day, is recommended until acute symptoms resolve, followed by tapering for 10 to 14 days.

Acute asthma attacks in pregnancy should prompt a thorough evaluation. Blood gas analysis in the normal pregnant woman typically reveals a pH of 7.35 and a higher Po_2 (102 to 106

mm Hg) and lower Pco_2 (28 to 30 mm Hg) than in nonpregnant patients. During the early stages of an asthma attack, the blood gas results often are consistent with hyperventilation, with an even lower Pco_2 and an elevated pH. After a prolonged attack, the patient will tire and may eventually hypoventilate. Therefore, a Pco_2 >35 mm Hg or a Po_2 <70 mm Hg indicates severe respiratory compromise.

In addition to arterial blood gas analysis, the evaluation should include a complete blood cell count, electrolyte levels, spirometry, and a chest radiograph (Table 17.5). A respiratory therapist should be involved. Initial management consists of intravenous hydration and inhaled oxygen to maintain a Po_2 >70 mm Hg and adequate urine output (in the face of alkalosis), followed by a nebulized $ß_2$ agonist, such as albuterol, up to three doses in the first 60 to 90 minutes and then 1 to 2 hours thereafter. Next, intravenous methylprednisolone 1 mg/kg every 6 to 8 hours is added, with tapering as clinical improvement occurs. Some clinicians also give intravenous aminophylline, 6 mg/kg loading dose and 0.5 mg/kg per hour maintenance dose, to keep blood levels between 8 and 12 mg/mL. Patients should receive intravenous antibiotics in the event that an infection is confounding. Finally, terbutaline, 0.25 mg per hour subcutaneously for three doses, is offered. In the absence of clinical response, transfer to an intensive care setting is considered, as respiratory support may become necessary.

TABLE 17.5 Treatment of Acute Asthma Attack

1. Arterial blood gas, complete blood cell count, electrolytes, peak flow meter, chest radiograph
2. Call respiratory therapy
3. Intravenous hydration, supplemental oxygen therapy to maintain Po_2 >70 mm Hg; monitor urine output
4. Albuterol, nebulized, three doses in initial 60–90 min
5. Methylprednisolone 1 mg/kg i.v. q6h
6. Aminophylline 6 mg/kg i.v. loading dose, then 0.5 mg/kg/h maintenance
7. Antibiotic i.v.
8. Terbutaline 0.25 mg s.c.
9. Transfer to intensive care for respiratory support and or/ventilation in absence of improvement

Antepartum management in patients with well-controlled mild to moderate asthma should be like that of an uncomplicated pregnant patient. However, in those patients with poorly controlled severe asthma, the pregnancy should be monitored for IUGR and preeclampsia, and weekly tests of fetal well-being should be instituted if these complications occur. Of

treated asthmatic women, 10% experience pulmonary symptoms in labor, in which case they are treated as outlined previously. For those patients on a maintenance glucocorticoid or for those who received a steroid course during the pregnancy, supplemental hydrocortisone, 100 mg intravenously every 8 hours for three doses, is recommended to avoid the unlikely occurrence of an addisonian crisis.

Medications to be avoided in the asthmatic patient include ß-blockers and prostaglandins. NSAIDs should be avoided in aspirin-sensitive patients. Magnesium sulfate and calcium channel blockers are well tolerated. Epidural anesthesia is preferred to general anesthesia.

Tuberculosis

Pregnancy does not worsen the course of tuberculosis (TB), and TB does not alter the overall outcome of pregnancy. However, it is important to diagnose and treat infected patients aggressively, because congenital TB can develop if a tubercular infection and bacteremia develop in a pregnant patient.

TB screening consists of the purified protein derivative (PPD) tuberculin test or Mantoux test. Forty-eight to 72 hours following intradermal injection, the presence or absence of induration at the injection site is determined. In patients with immunologic dysfunction (e.g., HIV infection), no reaction may be elicited. Therefore, a control skin test, such as for *Candida*, is placed as well. Most women have been exposed, and those who are not anergic will react. Reaction at the site of the control, not at the site of

---

the PPD test, indicates a negative PPD result. Induration ≥5 mm is considered positive in an HIV-positive patient, in anyone in recent contact with an active TB case, or in anyone with clinical or radiologic evidence of TB. Induration ≥10 mm is considered positive in health care workers, chronic alcoholics, or institutionalized individuals. Finally, induration ≥15 mm on the PPD test is considered positive in all low-risk patients. When a skin test is positive, a chest radiograph should be done; with shielding, this procedure involves minimal fetal radiation exposure. If the chest radiograph result is normal, or abnormal but inconsistent with TB, the patient is offered treatment to prevent disease development: isoniazid (INH) 300 mg every day for 6 months. Pyridoxine (vitamin B_6) at 50 mg daily is recommended as well to decrease the incidence of peripheral neuropathy and to protect the fetus from the neurotoxic effects of INH. Liver function tests are checked at baseline and then monthly to detect INH-induced hepatitis. If values increase twofold, the medication is discontinued. Patients on INH are instructed to avoid alcohol and acetaminophen. If the chest radiograph is consistent with old TB and further evaluation fails to reveal active TB, the patient should receive INH 300 mg every day for 12 months after delivery.

If the chest radiograph findings are consistent with TB (adenopathy, multinodular infiltrates, upward medial retraction of hilar markings), further workup to confirm the diagnosis is necessary. The workup should include a thorough history, physical examination, drug sensitivity testing, and a sputum smear and culture. The sputum test results confirm the diagnosis. Treatment for 6 to 9 months with two or more drugs is required, as in nonpregnant patients. Because of increasing resistance to antibiotics in individuals with TB,

consultation with an infectious disease or pulmonary consultant may be warranted. Household contacts of any patient with active TB should be identified, evaluated, and treated as necessary.

Maternal treatment does not treat the infant. Recognition of congenital TB can be difficult, and unrecognized active disease has significant mortality. Treatment in infants is similar to that in adults. Isolation of the uninfected infant from any potential close infectious contact is recommended until effective treatment is under way, although the infant may breast-feed.

Viral Pneumonia

Varicella Pneumonia

Varicella pneumonia can complicate 0.3% to 50.0% of all primary varicella infections in adults. Pregnant women are at increased risk of this complication, which has a mortality of up to 40%. Respiratory symptoms typically develop 2 to 5 days after the onset of fever, rash, and malaise. The physical examination findings can be unimpressive. Any pregnant woman with varicella and respiratory symptoms should be thoroughly evaluated and hospitalized if pneumonia is suspected. Aggressive treatment with intravenous acyclovir (Zovirax), a DNA polymerase inhibitor, has decreased mortality in the pregnant population by 50%, without an increase in fetal anomalies.

Of primary varicella infections occurring at <20 weeks gestation, 2% to 5% are associated with congenital varicella syndrome. This syndrome includes microphthalmia, hypoplastic limbs, nasal hypoplasia, and skin lesions. Infants born within 5 days of the development of maternal rash can develop disseminated neonatal varicella, with a 60% to 70% morbidity rate and a 5% to 20% mortality rate. In such cases, delivery should be delayed, if possible, to allow maternal antibodies to reach the fetus.

Cystic Fibrosis

Experience with pregnant patients who have cystic fibrosis (CF) is increasing because the median age of survival is now increasing, and these patients are surviving to reproductive age. Most patients with CF have chronic obstructive pulmonary disease and pancreatic insufficiency, but this heritable, autosomal recessive disorder has a broad spectrum of clinical manifestations. Progressive bronchopulmonary disease is the predominant cause of morbidity and mortality in CF. It is characterized by exacerbations of chronic endobronchial infection, bronchiectasis, and airway obstruction. *Pseudomonas* is the most common organism to colonize the respiratory tracts of patients with CF.

Prospective controlled studies of CF in pregnancy are lacking. Counseling regarding the effects of pregnancy on the disease process is therefore difficult. In general, progressive pulmonary deterioration with hypercapnia–hypoxemia with or without cor pulmonale or pulmonary hypertension contraindicate pregnancy. Several reports indicate that patients with good nutritional status and pancreatic sufficiency tolerate pregnancy well. The perinatal mortality rate is increased in patients with CF secondary to preterm delivery

reported at 5.9% to 35.0%. This increased rate is felt to be due to poor weight gain, low maternal prepregnancy weight, and chronic hypoxia. Management of the pregnant patient with CF stresses nutrition, maintenance of baseline pulmonary and cardiovascular status, and prompt treatment of exacerbations and deterioration. Counseling is essential; the patient with CF should understand that the fetus will be an obligate carrier. Paternal testing will reveal the fetal risk of disease. Unaffected couples also should be counseled regarding the risk of disease according to American College of Obstetricians and Gynecologists (ACOG) guidelines.

Renal Disease

Urinary tract infections are a common complication in pregnancy, occurring in 10% to 15% of women. Pregnancy-associated urinary stasis, glucosuria, and vesicoureteral reflux are predisposing factors. Responsible organisms

include *Escherichia coli* (75% to 90%), *Klebsiella* (10% to 15%), and *Proteus* (5%) species. *Pseudomonas*, *Streptococcus*, and *Staphylococcus* species are seen less frequently.

Renal Infections

Asymptomatic Bacteriuria

ASB is defined as >10,000 organisms per milliliter of urine in an asymptomatic woman. The incidence of ASB in the pregnant population is 6%, the same as in nonpregnant, sexually active women. The incidence is twice as high in women with HbSA. Failure to identify and treat pregnant women with ASB will result in an incidence of pyelonephritis of 25% to 40%, but treatment reduces this risk 10-fold. Treatment typically consists of empiric antibiotic therapy, such as 10 to 14 days of ampicillin or nitrofurantoin or therapy based on in vitro bacterial sensitivities. A culture should be repeated 1 week following therapy completion, because 30% of infections recur.

Cystitis

Cystitis is symptomatic bacteriuria without flank pain or fever. Urinary urgency, frequency, and dysuria are the most common complaints. Diagnosis and treatment do not differ from those of ASB. Occasionally, the same symptoms are associated with sterile urine; in this situation, the infecting agent is likely to be *Chlamydia trachomatis* and will respond to erythromycin therapy.

Pyelonephritis

Renal parenchymal infection, or pyelonephritis, complicates 1% to 3% of pregnancies. Patients with acute pyelonephritis typically are febrile. Symptoms can include chills, urgency, dysuria, and nausea and vomiting. Other signs include costovertebral angle tenderness, pyuria, and bacteriuria. Most cases of pyelonephritis are right sided or bilateral. Disease limited to only the left side suggests an anatomic abnormality. Bacterial

endotoxins and cytokines produced by activated macrophages are responsible for many of these symptoms. Hospitalization is recommended routinely, although outpatient management may be effective and safe in selected pregnant women. The risk of preterm labor is increased significantly with pyelonephritis. Once a urine culture is obtained, intravenous antibiotic therapy and vigorous intravenous hydration are started. The antibiotic of choice usually is a cephalosporin, because a large proportion of *E. coli* strains are ampicillin resistant. If the patient is afebrile within 24 hours, oral antibiotic treatment is started. If she remains afebrile for another 24 hours, she can be discharged home to complete a 10-day antibiotic course. If she remains febrile, changing or adding antibiotics to the regimen must be considered. If the urine culture and sensitivity results are available, they can be used to guide selection of drugs. If the organism is sensitive to the original antibiotic, gentamicin should be added. If no clinical improvement is seen, a renal ultrasonographic examination should be performed to rule out calculi or abscess.

Recurrent pyelonephritis occurs in 10% to 18% of patients. To reduce this risk, chronic suppressive therapy consisting of nitrofurantoin 100 mg each night often is recommended. Urine is obtained for culture and sensitivity every month or with patient complaints. Documented recurrent infection is treated with a 10-day course of antibiotics. For the patient with recurrent or persistent disease, a urologic evaluation, including intravenous pyelogram and voiding cystogram, is recommended 3 months postpartum.

Urinary Calculi

Urinary calculi occur in 1 in 1,000 pregnancies. Pregnancy does not affect the risk or severity of calculi formation. However, calculi do increase the incidence of urinary tract infections to 20% to 45%. Patients with known calculi typically are placed on suppressive nitrofurantoin therapy throughout the pregnancy. Urine cultures are performed every month, and infection is treated aggressively.

Urolithiasis should be suspected if the patient experiences colicky flank pain, tenderness, hematuria, or unresolved bacteriuria. The diagnosis can be confirmed by ultrasonography in 60% of patients and in 96% by using a single-view intravenous pyelogram, which exposes the fetus to minimal radiation (about 50 mrad). Acute urolithiasis is treated with analgesia and vigorous intravenous hydration. If infection is documented, antibiotic therapy is instituted. A ureteral stent or percutaneous nephrostomy may be required to relieve persistent obstruction.

Chronic Renal Disease

The effect of pregnancy on chronic renal disease varies with the degree of renal insufficiency. Mild renal insufficiency, defined as a serum creatinine <1.4 mg/dL, can be associated with a decline in renal function, increased proteinuria, and hypertension. However, renal function typically returns to prepregnancy levels after delivery.

Moderate renal insufficiency is defined as a creatinine >1.4 mg/dL but <2.5 mg/dL. Several series suggest that 10% of women with moderate renal insufficiency experience accelerated deterioration of renal function during pregnancy; women whose prepregnancy creatinine is

>2 mg/dL are at greatest risk. Hypertension typically escalates, and its control is essential for good outcome. Although methyldopa is prescribed frequently, the lag between dose and effect may make it a suboptimal choice. ß-Blockers, such as labetalol, and calcium channel blockers, such as nifedipine, have been shown to be effective.

Less information is available regarding pregnant patients with severe renal insufficiency (creatinine >2.5 mg/dL). Within 12 to 24 months postpartum, 30% to 40% of these patients experience a decline in renal function to end-stage disease.

Patients with renal insufficiency are at high risk of perinatal mortality (up to 15%), preeclampsia (more than 50%), preterm delivery (30% to 80%), and IUGR (up to 57%). Monitoring of baseline and subsequent laboratory values, routine urine cultures with prompt treatment for infection, serial ultrasonographic examinations for fetal growth, and formal tests of fetal well-being are indicated.

Acute Renal Failure

Acute renal failure is a rare but potentially devastating complication of pregnancy. It has many causes, including preeclampsia, hemorrhage, and placental abruption. Although typically characterized by persistent oliguria, diuretic therapy is not helpful because it does not correct the cause of the renal failure. In the presence of azotemia and severe oliguria, dialysis usually is initiated and continued until renal function returns. Fortunately, morbidity and mortality from renal failure have decreased as obstetric recognition and intervention have become more prompt and intensive supportive therapy has become more widely available.

Dialysis

Although most women with severely impaired renal function are infertile, chronic hemodialysis or peritoneal dialysis may make pregnancy possible. Hemodialysis usually is initiated earlier in the pregnant patient than in the nonpregnant patient because the risk for intrauterine fetal demise increases at a blood urea nitrogen (BUN) level >80 mg/dL. The goal of dialysis is to maintain the BUN at 50 to 60 mg/dL while limiting volume changes and episodes of hypotension. Peritoneal dialysis may be superior to hemodialysis because it minimizes fluid shifts and does not require maternal anticoagulation, although data to support its preferential use in pregnancy are limited. Because dialysis often is accompanied by contractions, magnesium sulfate can be added to the dialysate to maintain a serum level of 5 mEq/L. Increased numbers of hours on hemodialysis and increased frequency of treatments are recommended, as these improve management of weight and diet issues.

Renal Transplantation

Most pregnancies that occur after a renal transplantation are successful. Patients typically are advised to avoid pregnancy for 2 years following surgery to allow recovery, stabilization of graft function, and confirmation of graft survival on maintenance doses of immunosuppressive agents (prednisone up to 15 mg/day, azathioprine up to 2 mg/kg per

day). Once pregnancy is achieved, maternal–fetal complications can include an increased incidence of preeclampsia, infection (both viral [cytomegalovirus, herpes, hepatitis] and urinary tract [40%]), parathyroid dysfunction, and preterm birth. The incidence of prematurity is 45% to 60%, and of these babies, about 20% are growth restricted. Preterm premature rupture of the membranes is more common as well, likely due to long-term steroid therapy. However, pregnancy outcome is considered successful in 80% to 90% of these patients. These pregnancies need intense monitoring. Suspicion of graft rejection is high in the presence of fever, oliguria, graft enlargement, tenderness, and decline in renal function. Because the differential diagnosis also includes severe preeclampsia, pyelonephritis, and recurrence of glomerulopathy, renal biopsy may be necessary to confirm rejection. The immunosuppressive agents typically prescribed, including prednisone, azathioprine, and cyclosporine, are considered to be safe in pregnancy.

Neurologic Disorders

Neurologic diseases occur frequently in the general population and in reproductive-age women, and pregnancy can provoke or exacerbate certain neurologic abnormalities.

Headache

Headache is a common complaint during pregnancy, and the overwhelming majority are tension headaches. Tension headaches typically persist for hours and are characterized by a tight, sore feeling in the back of the head and neck. The pain usually responds to rest, application of heat or ice packs to the neck, massage, anti-inflammatory drugs, or a mild tranquilizer such as chlordiazepoxide. Strategies to relieve stress are important to prevent recurrence. Depression headaches usually occur in association with other symptoms of depression and respond to antidepressant medication and counseling.

Migraine Headache

Migraine headaches are seen commonly in pregnancy, and 15% of women with migraines experience their first one when pregnant. However, 64% of women with a history of menstrual migraine headaches experience a dramatic improvement in symptoms during pregnancy. Migraines are noteworthy for cerebral artery vasoconstriction and decreased blood flow. There is a 3-fold to 6-fold increased incidence of ischemic stroke in the population with migraines, which is increased to 10-fold to 14-fold with tobacco abuse.

There are at least four types of migraine headaches. Common migraine is characterized by a frequently unilateral headache lasting several hours, nausea and vomiting, and scalp tenderness. There often is a family history of similar headaches. Classic migraine has the same symptoms but is preceded by premonitory sensory phenomena, such as visual scomata or hallucinations. Basilar migraine includes symptoms of vertigo, dysarthria, or diplopia, while

---

complicated migraine involves more serious neurologic symptoms, mimicking an ischemic event.

The diagnosis of new-onset migraine headaches during pregnancy usually is one of exclusion. Other disorders such as brain tumor, stroke, and epilepsy need to be ruled out. The patient can undergo the same evaluation as a nonpregnant individual, usually consisting of a thorough history and neurologic examination and sometimes including CT or magnetic resonance (MR) imaging or awake and asleep electroencephalograms. Immediate treatment also is similar in the pregnant patient and can include aspirin or acetaminophen, with or without caffeine or butalbital, narcotics, phenothiazine antiemetics, or sumatriptan succinate (Imitrex). Ergotamine should not be given during pregnancy because it is a potent vasoconstrictor that can adversely affect uterine and placental blood flow. NSAIDs should be avoided in the third trimester. If headaches are chronic, the patient may benefit from suppressive amitriptyline or nortriptyline, propranolol, or verapamil. Valproic acid (Depakene) may be prescribed after the first trimester, when the fetal neural tube is completely formed.

Epilepsy

Epilepsy affects 0.5% to 2.0% of the population and complicates 1 in 200 pregnancies. Seizures usually are classified according to whether they are idiopathic or acquired (e.g., trauma, infection, space-occupying lesion, metabolic disorder) or are partial or generalized as well as by a description of the seizure itself. Absent seizures, or petit mal, involve loss of consciousness without any accompanying motor activity. Although both progesterone and estrogen have been shown to influence seizure activity, the relationship of pregnancy and seizure activity is unclear; 46% of women experience no change in seizure frequency, 20% experience a reduction, and 34% experience an increase in seizure activity during gestation. Factors that increase the frequency of seizures during pregnancy include discontinuation of antiepileptic medication in the belief that it harms the fetus, subtherapeutic drug levels because the dosage was not adjusted to compensate for expanding maternal vascular volume, inability to ingest medication because of nausea and vomiting, and lowering of the seizure threshold by sleep deprivation and stress.

The new onset of seizures during pregnancy is concerning. Although gestational epilepsy is probably a distinct entity, it is a diagnosis of exclusion. A complete workup should be performed as for a nonpregnant individual. Status epilepticus is a medical emergency, and the pregnant woman should be treated in the same manner as a nonpregnant individual. The airway must be secured and protected, and intravenous fluids, along with a glucose bolus and thiamine 100 mg, should be given. Intravenous phenytoin, phenobarbital, or diazepam should be administered. If possible, a wedge should be placed under one hip to displace the uterus off the vena cava. Although fetal heart rate abnormalities may be present during the seizure, the mother should be stabilized before any fetal intervention is contemplated. In most cases, resuscitation of the mother resuscitates the fetus. A thorough workup, including a toxicology screen and anticonvulsant drug levels, should be initiated following maternal stabilization.

Most epileptic women require seizure medication to remain seizurefree. For many anticonvulsant drugs, the benefit of preventing seizures outweighs any potential risks to the fetus. Some medications are clearly teratogenic and should be avoided, if possible;

these include valproic acid before 8 weeks gestation. However, women with epilepsy are at increased risk for fetal malformations, whether or not they ingest anticonvulsant medication. Although women taking multiple medications are at highest risk, it is not clear whether the increased risk is due to fetal drug exposure or whether it correlates with severity of maternal disease. Fetal factors play a role as well. For example, fetuses with epoxide hydrolase deficiency are at high risk for fetal hydantoin syndrome. The epileptic gravida should be counseled that her disease increases the risk of birth defects from the background rate of 3% to approximately 7%.

The lowest medication dosage associated with seizure prevention should be prescribed. Stressors should be minimized, and the patient should ingest a multivitamin with folate. A second-trimester targeted ultrasonographic examination, including fetal echocardiogram, with other ultrasonographic examinations as needed to assess fetal growth, is warranted. During labor, antiseizure medications should be continued, and pain relief should be excellent so that hyperventilation with pain does not lead to a respiratory alkalosis that could lower the seizure threshold. The patient may breast-feed. The anticonvulsant content of breast milk is inversely proportional to the degree of protein binding. However, even drugs that are not highly protein bound (e.g., carbamazepine, phenobarbital, primidone [Mysoline]) are present at low levels, so the total dosage ingested by the infant usually is negligible.

Subarachnoid Hemorrhage

Intracranial vascular anomalies can become symptomatic during pregnancy. Rupture of such malformations, resulting in subarachnoid hemorrhage, occurs in 1 in 75,000 pregnancies. Subarachnoid hemorrhage is characterized by sudden intense headache, visual changes or cranial nerve abnormalities, focal neurologic deficits, or an altered level of consciousness. In addition, the patient often complains of nausea, vomiting, and photophobia. The examination reveals signs of meningeal irritation, tachycardia, hypertension, slight fever, and mild leukocytosis and proteinuria. Subarachnoid hemorrhage may result from a ruptured cerebral angioma, saccular aneurysm, or arteriovenous malformation (AVM); aneurysm rupture reportedly

---

occurs three times more often than rupture of an AVM. The mortality rate is reported to be as high as 35%.

If intracranial hemorrhage is suspected during pregnancy, the patient should undergo a CT scan to confirm the hemorrhage and localize the bleeding. If the CT scan is normal but hemorrhage is strongly suspected, examination of the cerebrospinal fluid may be indicated to confirm the presence of blood, followed by angiography to locate the lesion. Treatment consists of bed rest, sedation, and analgesia; surgical correction often is recommended. Aneurysms that have bled once are very likely to bleed again within weeks of the first bleed, and 5% to 7% of AVMs bleed again during the first year. Therapy should not be withheld from the patient because she is pregnant. Hypothermia during neurosurgery usually is well tolerated by the fetus, although hypotension should be avoided if at all possible. If the patient requires neurosurgery near term, cesarean section just prior to the

craniotomy may avoid fetal compromise if the fetus is mature. Otherwise, there is usually no maternal benefit to terminating the pregnancy. Patients who experience an intracranial hemorrhage within 2 months of delivery or who have an unrepaired aneurysm should not perform the Valsalva maneuver during labor. Epidural anesthesia and assisted vaginal delivery are indicated.

Ischemic or Thrombotic Stroke

Ischemic (thrombotic) stroke is uncommon in reproductive-age women, occurring in 1 in 7,000 to 11,000 pregnancies; however, it can occur in association with hypertension, diabetes, hyperlipidemia, antiphospholipid antibody syndrome, HbSS, rheumatic heart disease, septicemia, and tobacco abuse. Cerebral artery thrombosis most often is associated with atherosclerosis and may be preceded by transient ischemic attacks. Cerebral artery embolism usually is associated with cardiac arrhythmia. In either case, the affected patient experiences the sudden onset of severe headache, hemiplegia or other neurologic deficits, or new-onset seizures. A thorough workup should be performed, including complete blood cell count, sedimentation rate, serum lipid profile, ECG or echocardiogram, and head CT scan or cerebral angiography, as necessary. Therapy includes rest, analgesia, aspirin, and heparin. Heparin may be discontinued prior to vaginal delivery and restarted postpartum. Cesarean section should be reserved for obstetric indications.

Cerebral Venous Sinus Thrombosis

Cerebral venous sinus thrombosis usually is a puerperal complication, occurring in association with preeclampsia, sepsis, or a coagulation defect. The patient complains of severe headache, drowsiness, and confusion and may have convulsions, focal neurologic deficits, hypertension, or papilledema. The diagnosis is made by CT scan or angiography. Treatment consists of mannitol or dexamethasone to reduce intracranial edema, along with antiepileptic medication if seizures have occurred. Heparin may be given if hemorrhage has been ruled out. If sepsis is a cofactor, the source must be identified and the infection treated aggressively. The mortality rate can be as high as 30%; poor prognostic factors include obtundation, coma, accompanying subarachnoid hemorrhage, or rapid deterioration. However, the prognosis for survivors is excellent.

Primary central nervous system (CNS) malignancies occur in 3 to 5 per 100,000 people per year. Although pregnancy does not alter this incidence, intracranial malignancies account for 10% of all maternal deaths. The malignancy may arise during pregnancy, or the physiologic changes of pregnancy may induce symptoms in a previously asymptomatic tumor. Symptoms typically include headache, vomiting, altered levels of consciousness, seizures, and hypertension. The presence of papilledema helps to distinguish intracranial pathology from other entities such as preeclampsia. Diagnosis is by CT or MR imaging. If an operable tumor of high malignant potential is suspected (e.g., high-grade gliomas, choroid plexus papillomas, posterior fossa tumors) or if there are significant neurologic complications such as seizures or progressive hydrocephalus, surgery should be performed without delay. Intraoperative hypothermia usually is well tolerated by the fetus, although hypotension should be avoided, if possible. In contrast, minimally symptomatic lesions of

low malignant potential (e.g., meningioma) may be followed and treated definitively postpartum.

It should be kept in mind that a proportion of intracranial malignancies are metastatic from other sites, primarily breast, lung, or gastrointestinal or genitourinary tracts. Therefore, a complete history and physical examination is crucial. Choriocarcinoma may manifest intracranial findings, and pituitary tumors may become symptomatic in pregnancy.

If intracranial malignancy is diagnosed early in pregnancy, pregnancy termination is not warranted but may be considered in patients with uncontrollable seizures or progressive loss of consciousness. Patients who have undergone craniotomy within 2 months of delivery should not perform the Valsalva maneuver during the second stage of labor. Epidural anesthesia and assisted vaginal delivery are indicated. Cesarean section should be for obstetric indications only.

Pseudotumor Cerebri

Pseudotumor cerebri is defined by increased intracranial pressure, papilledema, and headache without focal neurologic abnormalities. The etiology is unknown. Although pregnancy does not increase the incidence, the majority of cases occur in obese women of reproductive age. Pregnancy complications experienced by such women are likely to be related to their obesity and not their neurologic diagnosis. Women with pseudotumor cerebri should be followed with

---

serial visual field and acuity testing. Treatment typically consists of repeated lumbar punctures, shunting, glucocorticoids, or acetazolamide (Diamox); all can be used safely in pregnancy. Although weight loss and diuretics also may be helpful, they should be deferred until postpartum.

Multiple Sclerosis

Multiple sclerosis (MS) is a multifocal demyelinating disease of CNS white matter, characterized by chronic inflammation, selective demyelination, and scarring. The etiology is unknown but may involve a virus-triggered autoimmune phenomenon in a genetically susceptible individual. There are three forms of MS: relapsing MS, which is defined by recurrent attacks of neurologic abnormality followed by greater or lesser degrees of recovery; chronic progressive MS, which gradually worsens from the onset without remission; and inactive MS, in which patients have fixed neurologic deficits that neither progress nor resolve. Because it is most commonly seen in 20- to 40-year-old white women and does not impair fertility, MS can first manifest coincidentally with pregnancy. Symptoms and signs include weakness, hyperreflexia, paresthesia, hypesthesia, ataxia, visual loss resulting from optic neuritis, diplopia, facial nerve palsy, vertigo, urinary urgency, or incontinence. None of the symptoms or signs can be explained by a single anatomic lesion. The diagnosis is one of exclusion, with MS confirmed by cerebrospinal fluid abnormalities and MR imaging. In many patients, MS has been diagnosed before conception, and medical therapy has been initiated. Patients with chronic progressive MS

or severe relapsing MS may require more aggressive therapy with immunosuppressive drugs such as cyclosporine, azathioprine, or cyclophosphamide. All of these drugs may be continued during pregnancy if there is clear maternal benefit. Affected patients also may require an antispasmodic agent, urinary tract infection prophylaxis, and physical therapy.

Women with MS should be counseled that pregnancy increases the likelihood of urinary tract infections and constipation and may exacerbate fatigue and mobility problems. Women with paraplegia or quadriplegia are at risk for unmonitored, precipitous delivery. Women with a lesion at or above T6 are at risk for autonomic dysreflexia. Although some women experience relatively little symptomatic progression during pregnancy, flares are common during the first 3 months postpartum. Flares may preclude breast-feeding, and the patient may require assistance with infant care.

Myasthenia Gravis

Myasthenia gravis is a chronic autoimmune neuromuscular disease characterized by easy fatigability of facial, oropharyngeal, extraocular, and limb muscles. The primary defect is immunoglobulin G (IgG)-mediated destruction of striated muscle acetylcholine receptors. The diagnosis is made with the edrophonium chloride test (edrophonium inhibits acetylcholinesterase, which allows acetylcholine levels to increase and improves strength in myasthenic muscles), nerve stimulation tests, and measurement of acetylcholine receptor antibodies. The incidence of myasthenia gravis is 1 in 10,000 in the general population. Women are affected more often than men and experience a peak occurrence in their 20s and 30s. Symptoms typically wax and wane and are not altered by pregnancy, although postpartum exacerbation is common. Thymectomy usually is performed shortly after diagnosis, because it results in symptomatic improvement and may ultimately eliminate the need for medical therapy.

Pregnant women with mild disease usually require only adequate rest and the avoidance of strenuous activities. More seriously affected women require medical therapy in the form of pyridostigmine bromide or neostigmine bromide, glucocorticoids, or immunosuppressive drugs. Plasmapheresis can relieve acute symptoms by mechanically removing the pathologic antibodies and can be performed during pregnancy if care is taken to avoid maternal hypotension or hypovolemia. Because the disease does not affect smooth muscle, labor and delivery proceed normally. The patient may receive oxytocin and analgesics, but care should be taken to avoid extensive regional blocks that could compromise maternal respiration. Certain drugs are tolerated poorly and should be avoided. These include magnesium sulfate, aminoglycosides, certain antiarrhythmic agents (e.g., quinine, quinidine, and procaine), procaine anesthetics, curare, succinylcholine, and large doses of narcotics. Because the antireceptor IgG antibody easily crosses the placenta, the neonate will be transiently symptomatic in approximately 10% of cases and will require tertiary care.

Myotonic Dystrophy

Myotonic dystrophy is an autosomal dominant, multisystem disease characterized by muscle stiffness (myotonia); progressive dystrophic changes in muscles of the face, neck,

and distal limbs; and posterior subcapsular cataracts. It occurs in 3 to 5 per 100,000 individuals and usually is diagnosed in late childhood or early adulthood, with the development of progressive muscle weakness and atrophy. Affected patients have characteristic facies (drooping eyelids, bitemporal wasting, and weakness, with diminished expressivity of the mouth known as a flattened smile), weakness and atrophy of small hand muscles, and respiratory and gastrointestinal difficulties. Although menstrual irregularities and infertility are common, affected patients can become pregnant. Such pregnancies can be complicated by polyhydramnios, preterm labor, dysfunctional labor, and postpartum hemorrhage. Maternal deaths related to aspiration pneumonia or cardiac failure have been reported. Symptoms usually are worse in the last half of pregnancy and often improve after delivery.

The molecular defect is a region of CTG trinucleotide repeats in the myotonin gene on the long arm of chromosome 19. The number of repeats in this region determines the severity of the symptoms; expansion of the region, along with an increase in symptom severity, can occur with each generation. The fetus of an affected mother is thus at risk of inheriting an expanded form of the gene and having the severe congenital form of the disease. Infants with congenital myotonia are floppy at birth, have diminished suck and cry reflexes, and have serious respiratory compromise. Prenatal diagnosis is available. Severely affected women and their affected infants usually require tertiary care.

Spinal Cord Injury

Spinal cord injury resulting in paraplegia or quadriplegia occurs in 1 in 10,000 individuals per year in the United States. Reproductive-age women with spinal cord injuries generally tolerate pregnancy well, although pregnancy may exacerbate bowel dysfunction or pressure necrosis of the skin and may increase the incidence of urinary tract infections. Women with lesions below T10 to T12 feel uterine contractions normally. Women with lesions above this level, however, usually do not feel their contractions and are at risk for a precipitous, unattended delivery. Such women should be taught to palpate their uterus for contractions on a regular basis during the third trimester.

Women with lesions above T6 are at risk for autonomic hyperreflexia. In this condition, any number of stimuli (labor, urethral catheterization, cervical or rectal examination) can provoke afferent nerve impulses that enter the cord and initiate focal segmental reflexes that are not modulated or inhibited by higher centers, resulting in stimulation of the sympathetic nervous system. Symptoms include pilomotor erection, excessive sweating, facial flushing, dilated pupils, severe headache, paroxysmal hypertension, and bradycardia. Epidural anesthesia can prevent or control such sympathetic stimulation and therefore is a crucial component of planned labor management. Vaginal delivery is possible for some patients with spinal cord injury, because the expulsive forces of the uterus are sufficient to bring down the fetal head for an assisted vaginal delivery. If cesarean section is required, regional anesthesia is ideal.

Endocrinology

Pituitary Tumors

The pituitary gland normally enlarges by 30% during pregnancy, and compression of the optic chiasm infrequently results in bitemporal hemianopsia. Pituitary secretions are altered by pregnancy: follicle-stimulating hormone and luteinizing hormone levels are decreased, and corticotropin and prolactin are increased. Thyroid-stimulating hormone (TSH) concentrations, however, vary with gestational timing.

Pituitary adenomas are benign neoplasms of anterior pituitary cells. Adenomas can secrete hormones, such as prolactin or adrenocorticotropic hormone (ACTH), and cause hypopituitarism or headache or visual problems. They are classified by size as microadenomas or macroadenomas, with the former being <10 mm. They also can be classified by the hormone they secrete, with prolactin-secreting adenomas being the most prevalent at 26%. Diagnosis is confirmed by MR imaging or CT scan. Hyperprolactinemia can manifest as galactorrhea, menstrual disorders, infertility, hirsutism, headache, and visual field defects.

Treatment options include medical, surgical, or radiation therapy. Medical treatment is with the dopamine agonist bromocriptine, which decreases prolactin levels to normal in up to 90% of treated patients. Bromocriptine is not known to be teratogenic, but treatment during pregnancy typically is discontinued. As the normal pituitary enlarges during pregnancy, the potential for enlargement of an adenoma exists as well. Pregnant women should be educated about and monitored for the symptoms of expansion, such as headaches and visual field changes. This occurs infrequently, because only 2% of microadenomas and 15% of macroadenomas show signs or symptoms of tumor growth during pregnancy. An initial visual field examination early in the pregnancy is routine, but serial exams typically are not useful because visual field losses are acute. Instead, the patient should be made aware of the possibility of visual field loss, with the recommendation made to seek prompt evaluation if it occurs. Surgery and radiation are alternative treatment modalities for adenomas, with surgery reserved for patients with very large tumors in whom medical therapy fails. Breast-feeding is unaffected by hyperprolactinemia. Bromocriptine is reinstituted at its completion.

Diabetes Insipidus

Diabetes insipidus (DI) involves water loss secondary to inadequate renal tubule reabsorption. Polyuria, polydipsia, and excessive thirst are characteristic. There are three causes of DI (Table 17.6). Hypothalamic (central) DI results from inadequate arginine vasopressin (AVP) secretion in response to stimuli and can be genetic (rare) or

acquired. Acquired central DI occurs as the result of tumor, trauma, infection, Sheehan syndrome, or autoimmune disease. Nephrogenic DI results from decreased renal sensitivity to normal or elevated AVP levels and can be familial or acquired. Lithium also causes this type. Primary polydipsia, typically psychogenic in origin, involves excessive fluid intake and AVP suppression.

TABLE 17.6 Causes of Diabetes Insipidus

- Hypothalamic
  Genetic
  Acquired
- Nephrogenic
- Primary polydipsia

DI is diagnosed with a water deprivation test. In a pregnant patient with a viable fetus, this test is performed with continuous fetal monitoring. Dehydration in DI will be accompanied by rising serum osmolality and an inability to concentrate the urine. Intranasal administration of DDAVP prompts urine concentration and confirms the diagnosis. Its use is not associated with maternal or fetal complications.

Thyroid Disease

Maternal Thyroid Function during Normal Pregnancy

Normal pregnancy results in modest thyroid enlargement, which is detectable on physical examination. Serum levels of TSH and thyroid-releasing hormone (TRH) are the same in the pregnant patient as in the nonpregnant patient, while levels of thyroid-binding globulin (TBG) increase due to estrogen-enhanced hepatic production. Total thyroxine (T4) and triiodothyronine (T3) are increased, but free biologically active T3 and T4 concentrations are unchanged in normal pregnant women.

Maternal Hypothyroidism

Most pregnant patients who are treated for hypothyroidism during pregnancy are diagnosed before pregnancy and already are on replacement therapy. In these patients, the dosage should be checked to determine if it is adequate and should be followed through pregnancy. A patient also may develop hypothyroidism during pregnancy. The most common cause of hypothyroidism is Hashimoto thyroiditis, which is confirmed by demonstrating the presence of circulating antithyroglobulin and antimicrosomal antibodies. Women who have undergone thyroid ablation for Graves disease and are receiving inadequate replacement also may be hypothyroid. Symptoms include excessive fatigue, dry skin, cold intolerance, constipation, bradycardia, and irritability. Myxedema is rare. Laboratory evaluation reveals low free T4 and high TSH levels. The goal of therapy is to provide enough T4 to normalize the TSH and the pulse rate, which should be checked every 2 to 3 weeks. A typical replacement dosage is 150 mg of levothyroxine per day. At least 75% of all hypothyroid patients will require a higher dosage during pregnancy. The dosage typically is

increased in 50 mg increments. Unrecognized or inadequately treated hypothyroidism is associated with an increased risk of miscarriage, preeclampsia, intrauterine fetal demise, postpartum hemorrhage, and fetal effects.

TABLE 17.7 Causes of Hyperthyroidism

Graves disease
Acute (subacute) thyroiditis
Hashimoto disease
Toxic nodular goiter
Toxic adenoma
Gestational trophoblastic disease

Maternal Hyperthyroidism

Hyperthyroidism complicates 1 in 500 pregnancies. Etiologies include Graves disease, acute or subacute thyroiditis, toxic nodular goiter, toxic adenoma, and gestational trophoblastic disease (Table 17.7). Patients with Hashimoto thyroiditis also may exhibit signs of hyperthyroidism if they make antithyroid antibodies (a combination of Graves disease and Hashimoto thyroiditis, or Hashitoxicosis) or if they make anti-TSH receptor antibodies.

The most common cause of hyperthyroidism in pregnancy is Graves disease. The diagnosis is based on a triad of manifestations, including hyperthyroidism with diffuse goiter, ophthalmopathy (particularly exophthalmos), and dermopathy. Graves disease is an autoimmune disorder in which circulating thyroid-stimulating immunoglobulins (TSIs) bind to thyroid follicular cell TSH receptors, stimulating excess thyroid hormone synthesis and secretion. The patient may have other autoimmune diseases, including systemic lupus erythematosus, myasthenia gravis, and immune thrombocytopenia.

The diagnosis of hyperthyroidism can be difficult, because the patient may report symptoms that are seen commonly in a normal pregnancy. These include shortness of breath, palpitations, and heat intolerance. Signs and symptoms of hyperthyroidism that are not typical of pregnancy, and thus aid in its diagnosis, include weight loss or poor weight gain and increased bowel frequency. Laboratory evaluation confirms the diagnosis. Free T4 levels are high in hyperthyroid patients. Rarely (in 3% to 5%), the T4 level may be normal and free T3 elevated. TSH is uniformly suppressed. Autoantibodies confirm the autoimmune nature of the disease and may have fetal implications.

Hyperthyroidism can be treated with antithyroid medications, surgery, or radioactive sodium iodine (^{131}I). All medications have some contraindications in pregnancy. Propylthiouracil (PTU) and methimazole (Tapazole) are thioamides that inhibit thyroid

hormone biosynthesis. PTU lowers T4 levels faster than methimazole, giving it an advantage for therapy. The recommended dose of PTU is 300 to 450 mg initially, followed by a 50- to 300-mg daily maintenance dose, usually divided into a three-times-a-day dosage regimen. Both PTU and methimazole cross the placenta and can have inhibitory effects on fetal thyroid function. Once a high-normal free T4 level has been achieved, the PTU dosage should be reduced to the smallest amount

---

that maintains this level, thus decreasing the risk of fetal hypothyroidism. During therapy, maternal thyroid function should be evaluated every 3 to 4 weeks to guide dosage adjustments.

Before initiation of therapy, a baseline white blood cell count and differential should be obtained. Adverse reactions to PTU include skin rash (2% to 8%), bronchospasm, drug fever, hepatitis, oral ulcers, and idiopathic agranulocytopenia. Idiopathic agranulocytopenia usually occurs during the first 3 months of therapy (1 in 500 patients) and is reversible after stopping PTU. An adverse reaction to one thioamide does not necessarily predict a similar reaction to another.

Both PTU and methimazole are taken up by the fetal thyroid gland after the first trimester. At PTU dosages of 300 mg or greater daily, fetal goiter and hypothyroidism have been reported; at dosages lower than 300 mg daily, fetal clinical outcome usually is improved; and at dosages lower than 200 mg daily, fetal T4 levels can be normal. Aplasia cutis has been described in some fetuses exposed to methimazole, which may make PTU preferable during pregnancy. After birth, women taking these antithyroid medications may pass physiologically significant dosages of the medication into their milk. However, PTU is more strongly plasma protein bound and therefore is preferable for the patient who desires to breast-feed. The patient should be reminded to take the medication after feeding or pumping and to notify her pediatrician that she is taking the medication. The infant's thyroid function should be checked periodically to prevent undiagnosed neonatal hypothyroidism.

ß-Blockers may be useful in decreasing the sympatheticlike symptoms of hyperthyroidism while thyroid hormone levels are being reduced by other forms of therapy. In addition, propranolol has an inhibitory effect on the peripheral conversion of T4 to T3 and thus lowers circulating thyroid hormone levels. This action is additive to the effects of the thioamides. The recommended propranolol dose for this indication is 20 to 40 mg orally three to four times a day.

Surgical thyroid ablation, or thyroidectomy, may be necessary during pregnancy if very high dosages of PTU (>300 mg daily) are needed long term to control maternal hyperthyroidism. Medical thyroid ablation with ^{131}I should not be considered during pregnancy because of the possibility of simultaneous fetal thyroid ablation. Antenatal treatment with ^{131}I at the usual dosage results in 0.75 to 1.50 rad (0.0075 to 0.0150 Gy) of fetal radiation exposure. Patients with inadvertent first-trimester exposure can be reassured that the fetal thyroid gland does not begin concentrating iodine until 10 to 12 weeks gestation, and maternal thyroid ablation before this time would not be expected to affect the fetus. Exposure after 12 weeks gestation, however, may result in congenital hypothyroidism. Theoretically, 10

days of maternal PTU administration after accidental exposure may benefit the fetus by decreasing uptake of ^{131}I iodine into the fetal thyroid gland.

TABLE 17.8 Treatment of Thyroid Storm

Propylthiouracil: 600 mg p.o. (n.g.), then 300 mg q6h
Sodium iodide: 1 g/500 empc i.v. q.d.
Propranolol: 40–60 mg p.o. q4–6h
Dexamethasone: 1 mg p.o. i.m. q6h
Oxygen, acetaminophen, fluid replacement

n.g., nasogastric tube administration.

Adequate treatment of hyperthyroidism is important to decrease the risk of preeclampsia and preterm delivery as well as that of fetal demise, growth restriction, and fetal or neonatal thyroid dysfunction. The patient with a very serious complication of Graves disease, thyroid storm or crisis, can experience tachycardia, hyperpyrexia, circulatory collapse, and death. Thyroid storm involves a massive release of thyroid hormones and often is precipitated by a stressor, such as infection (e.g., pyelonephritis), thyroid gland palpation, or labor and delivery. Thyroid storm is an emergency and must be treated aggressively to prevent maternal decompensation (Table 17.8). Treatment may require the administration of multiple agents for up to 1 to 2 weeks. PTU should be given in large doses: 600 mg orally initially followed by 300 mg orally every 6 hours. The thioamides can be administered through a nasogastric tube if the patient cannot tolerate oral medications. In addition, sodium iodide, 1 g in 500 mL of fluid, should be given daily to inhibit the release of stored hormone. Propranolol may be added for control of tachycardia and other sympatheticlike symptoms if there is no evidence of cardiac failure. The initial propranolol dosage is 40 to 80 mg orally every 4 to 6 hours or 1 mg per minute intravenously for 2 to 10 minutes with concurrent maternal cardiac monitoring. The dosage may be adjusted, depending on the patient's cardiac response. Dexamethasone, 1 mg orally or intramuscularly every 6 hours, or hydrocortisone, 100 mg intravenously every 8 hours, can further inhibit peripheral T4 to T3 conversion. Oxygen, digitalis, fluid replacement, and acetaminophen (as an antipyretic) should be given as needed.

Thyroid Nodules and Cancer

Evaluation of thyroid nodules discovered during pregnancy should begin with a complete physical exam, evaluation of thyroid function tests, and ultrasonography to document the nodule's presence and size. This is followed by a fine-needle aspiration, and if elected, surgical removal, preferably in the mid second trimester. Thyroid cancer is suspected if there is rapid growth unaccompanied by tenderness or hoarseness. Thyroid function test

results usually are normal. Thyroid cancer is more likely in a population irradiated in childhood; in this group, 30% of those with a thyroid nodule will have thyroid cancer at the time of surgery. In the pregnant patient, papillary cancer

predominates and is no more aggressive than in the nonpregnant patient. Importantly, a delay in surgery does not alter outcome. In the presence of either a hyperfunctioning benign nodule or documented papillary carcinoma, thyroid function typically is suppressed with levothyroxine until definitively treated. In the presence of a more malignant cell type, such as medullary or undifferentiated carcinoma or lymphoma, some practitioners recommend pregnancy termination to pursue aggressive management with surgery, adjuvant radiation, and chemotherapy.

There is no evidence that pregnancy affects the progression of thyroid cancer or that thyroid cancer affects the outcome of pregnancy. As a result, thyroid cancer or a history of it is not an absolute contraindication to pregnancy. Although pregnancy is not a contraindication to thyroid surgery, it is a contraindication to ^{131}I treatment.

Fetal Thyroid Function

The fetal thyroid gland is first gland that is capable of hormonal activity by the end of the first trimester, and there is normally a gradual increase in fetal T4 concentrations during pregnancy. This increase represents fetal production rather than transplacental transfer, because both T3 and T4 cross the placenta only minimally. However, iodides, antithyroid medications, and TSIs cross the placenta easily.

Thyroid hormone deficiency during fetal development or during the first 2 years of life can cause irreversible brain damage, with the degree of disease related to the severity, duration, and gestational age at which the hypothyroidism occurs. Although neonatal hypothyroidism is not common (1 in 4,000 live births in the United States), it is a potentially treatable cause of mental retardation and thus is now included in newborn blood screening programs.

Fetal hypothyroidism can be treated antenatally by direct hormone injection of the fetus via amniocentesis. Fetal hyperthyroidism also can be diagnosed before birth and may respond to prenatal treatment. Fetal or neonatal thyrotoxicosis occurs in 1 of 70 thyrotoxic mothers. It results from the transplacental transfer of TSIs and is a potentially serious disease, with mortality rates of 10% to 16% due to prematurity and congestive heart failure. Hyperthyroid pregnant patients should be evaluated frequently for fetal tachycardia, and appropriate interval fetal growth should be confirmed. Fetal goiter may be identified on ultrasonographic examination, and fetal thyroid function can be assessed with fetal blood sampling. Because PTU and methimazole cross the placenta, maternal dosage can be adjusted to correct the fetal hyperthyroidism; replacement T4 can then be given to the mother if necessary.

The diagnosis of neonatal thyrotoxicosis usually is clinically apparent, as the infant may have a goiter, exophthalmos, tachycardia, irritability, and growth restriction. The mother likely has a history of hyperthyroidism and may have had previous infants affected by this

disease. Mild cases of neonatal thyrotoxicosis require no treatment; the symptoms resolve as maternal TSIs are cleared from the infant's system. Severely symptomatic babies are treated with propranolol and PTU.

Parathyroid Conditions

The parathyroid glands function to maintain maternal calcium and phosphate homeostasis. Total calcium levels decline during pregnancy because the binding protein albumin declines, but the level of ionized, biologically active calcium is unchanged. The fetus contains approximately 30 mg of calcium, which is transported actively across the placenta. Maternal calcium requirements increase from 0.5 mg per day to 1.5 mg per day at term. Serum parathyroid hormone (PTH) levels gradually increase during pregnancy, reflecting the increased calcium transfer to the fetus plus the increases in extracellular fluid volume and glomerular filtration rate.

Hyperparathyroidism

Hyperparathyroidism is a condition caused by excessive PTH production, often due to a clinically inapparent parathyroid adenoma. Hypercalcemia results and causes symptoms of fatigue, weakness, polyuria, polydipsia, nausea, anorexia, and constipation. During pregnancy, affected women may have prolonged nausea and vomiting. Increased renal excretion of calcium may predispose to nephrocalcinosis, renal calculi, and symptomatic bony resorption. Although serum calcium measurements remain the best single diagnostic test, the physiologic changes of pregnancy may make the diagnosis of hyperparathyroidism difficult. A total calcium concentration of 10.5 mg/dL or greater in late pregnancy must be considered suspicious, and a total calcium concentration of 12.0 mg/dL or greater is definite evidence of hyperparathyroidism. Palpable parathyroid adenomas are extremely uncommon.

Hyperparathyroidism is associated with an increased incidence of perinatal morbidity and mortality; therapy is recommended. Up to 50% of infants of untreated mothers will develop hypocalcemia and tetany, which may be the first indicator of maternal disease. If the diagnosis is first established during pregnancy, surgical resection of the adenoma generally is indicated, although oral phosphate therapy (1.0 to 1.5 g daily in divided doses) may occasionally be attempted. Pregnancy termination need not be considered except in the rare case of advanced renal involvement.

Hypoparathyroidism

Hypoparathyroidism results from inadequate production of PTH and is characterized by weakness, fatigue, mental status changes, numbness and paresthesias of the extremities, muscle cramps, and tetany. It must be distinguished from pseudohypoparathyroidism, in which parathyroid function is normal but end organs do not respond to PTH. The signs and symptoms of hypoparathyroidism are the result of a decreased serum ionized calcium level and increased neuromuscular irritability. It occurs most commonly as the result of parathyroid gland injury or removal

in association with thyroid surgery or irradiation, but it can be idiopathic. The increased calcium requirements of pregnancy may make patients with hypoparathyroidism more symptomatic. In addition, relative unavailability of calcium for the fetus may lead to secondary neonatal hyperparathyroidism. Symptomatic hypocalcemia can be prevented with calcitriol (1,25-dihydroxyvitamin D_3), dihydrotachysterol, large doses of vitamin D, and calcium gluconate or lactate. The patient should be on a low-phosphate diet and consultation with an endocrinologist and a dietitian is warranted.

Adrenal Disease

In normal pregnancy, plasma concentrations of adrenal steroid hormones typically increase with advancing gestation. Because the amount of cortisol bound to nuclear receptors actually is decreased slightly (due to competition by progesterone), both total plasma cortisol and cortisol-binding globulin levels increase. Free cortisol levels are increased, and a diurnal variation is maintained. Aldosterone levels also rise, although the factor or factors responsible remain unclear; no consistent correlations exist with observed elevations in angiotensin II or progesterone. Adrenal function tests are unaltered. As with other endocrine disorders, abnormalities in adrenal function usually are associated with infertility. However, adrenal insufficiency and hyperfunction can complicate pregnancy.

Adrenal Insufficiency

Inadequate production of adrenal corticosteroids can be either chronic or acute. Although most cases of adrenal insufficiency are diagnosed outside of pregnancy, the disease may first occur during pregnancy and present a diagnostic challenge. The chronic form may become apparent with numerous nonspecific signs and symptoms, whereas the acute form may manifest as vascular collapse.

The signs and symptoms of chronic adrenocortical insufficiency during pregnancy are identical to those in the nonpregnant state and include fatigue, hyperpigmentation, weakness, anorexia, nausea, vomiting, and weight loss. Because all of these problems may be encountered during the course of an otherwise normal gestation, the clinical diagnosis of adrenocortical insufficiency in pregnancy may be difficult. However, persistent weight loss or nausea and vomiting beyond the first trimester, particularly in association with any of the aforementioned signs or symptoms, should raise suspicions. The diagnosis and appropriate treatment of adrenocortical insufficiency during pregnancy are important because of the risks associated with the added stress of pregnancy and delivery and because of the increased likelihood of adrenal crisis, particularly during the puerperium.

Adrenal insufficiency can be primary (Addison disease), due to autoimmune adrenal destruction or TB, or secondary, due most often to exogenous glucocorticoid intake (Table 17.9). When Addison disease is suspected, a blood sample for plasma cortisol and ACTH levels should be obtained. A cortisol level <20 mg/dL is consistent with Addison disease. Treatment should be started promptly, consisting of intravenous hydrocortisone 100 mg every 6 hours. When chronic adrenal insufficiency is suspected or confirmation of the diagnosis of acute adrenal insufficiency is needed, an ACTH challenge test can be performed and a 24-hour urinary free cortisol level determined. Long-term replacement

thereafter consists of hydrocortisone 12 to 15 mg/m^2 per day and, if necessary (as guided by serum potassium), fludrocortisone acetate (Florinef) 100 g per day for mineralocorticoid activity.

TABLE 17.9 Causes of Adrenal Insufficiency

- Primary (Addison disease)
  Autoimmune
  Tuberculosis
- Secondary
  Exogenous glucocorticoids

Additional cortisol replacement is recommended during periods of major stress, with criteria being fairly vague and liberal (e.g., injury, fever, surgery). In these instances, the dosage is increased to at least 200 mg per day until the stress has passed. For periods of minor stress (e.g., nausea, vomiting, low-grade fever), the routine daily dosage is doubled. Because some glucocorticoids cross the placenta, transient suppression of the newborn hypothalamic–pituitary–adrenal axis may be observed, and the neonate may require cortisol replacement and treatment of hypoglycemia. Neonatal outcome is otherwise unaffected.

Cushing Syndrome or Hypercortisolism

Elevated levels of glucocorticoids can result from bilateral adrenal hyperplasia, benign or malignant adrenal adenomas, or exogenous corticosteroid therapy. If adrenal hyperplasia occurs in response to an ACTH-producing pituitary tumor, the diagnosis is Cushing disease. Affected individuals are obese, hypertensive, and hirsute, with common complaints of weakness, easy bruising, and emotional lability. Classically described features of Cushing syndrome include round faces and full cheeks, with increased centripetal fat distribution. Further, glucose intolerance, acne, and osteoporosis commonly are seen in untreated patients.

The diagnosis of Cushing syndrome in pregnancy may be difficult, as many of the previously mentioned signs and symptoms may be seen in normal pregnancy. However, hirsutism and acne generally are not seen in pregnancy and suggest another biologic process. These patients have elevated plasma cortisol levels, without diurnal variation, that are not suppressed with dexamethasone. Because of the possibility of adrenal carcinoma, any such patient must be evaluated carefully by appropriate laboratory and

imaging studies. With Cushing symptomatology, adrenal cancers are typically very large (6 cm) and easily detectable on CT scan.

Cushing syndrome in pregnancy is associated with an increased incidence of miscarriage, premature labor, diabetes, hypertension, and stillbirth. Consequently, careful fetal surveillance is mandatory.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is the result of one of several enzyme defects in cortisol biosynthesis. The majority of patients have 21-hydroxylase deficiency, although 11ß-hydroxylase deficiency or 18-hydroxysteroid dehydrogenase deficiency may be encountered rarely. Because these enzyme deficiencies are inherited in an autosomal recessive fashion, the patient with this diagnosis has a negligible chance to have an affected child, unless she is related to the child's father or comes from a high-risk ethnic group.

Approximately 90% of patients with CAH during pregnancy have a partial or complete deficiency of the 21-hydroxylase enzyme. The resultant decrease in cortisol production leads to increased ACTH stimulation, which then results in both increased production of androgenic cortisol precursors (e.g., 17ß-hydroxyprogesterone) and decreased production of aldosterone. Because these androgenic steroids readily cross the placenta, pregnancies complicated by significant maternal 21-hydroxylase deficiency are at increased risk for fetal virilization. Such virilization is most apparent in female infants, although male infants also may have somewhat enlarged external genitalia. The risk of fetal virilization is reduced if pregnant patients with CAH receive adequate basal glucocorticoid replacement together with additional glucocorticoid in times of stress. Mineralocorticoid replacement should be continued as well.

Sometimes, the pregnant patient does not have CAH but has had a previous child with the disorder. The diagnosis of CAH in the fetus historically has been made on the basis of amniotic fluid measurement of 17ß-hydroxyprogesterone. However, direct molecular genetic techniques are available for evaluation of fetuses at risk by sampling of chorionic villus cells or amniocytes. The affected fetus will produce high levels of androgenic steroids that can cause virilization. Fetal treatment consisting of maternal oral dexamethasone twice daily, beginning at 6 to 7 weeks, may prevent this, although this is not 100% effective. The treatment is discontinued if CVS or amniocyte analysis confirms that the fetus does not carry the enzymatic defect.

A newborn with ambiguous genitalia requires rapid diagnosis, treatment, and gender assignment. The karyotype, electrolytes, 17ß-hydroxyprogesterone, and urinary 17-ketosteroids should be evaluated expeditiously. The clinical manifestations of cortisol and aldosterone deficiency can include hypoglycemia, hyperpigmentation, apneic episodes, seizures, emesis, hyperkalemia, dehydration, hypotension, vascular collapse, and shock. Resuscitation requires hydrocortisone administration and saline-glucose hydration. Elevated plasma renin activity indicates the need for mineralocorticoid replacement as well. Eventually, maintenance therapy with hydrocortisone (glucocorticoid) and fludrocortisone (mineralocorticoid) is guided by 17ß-hydroxyprogesterone and plasma renin

activity measurements, respectively. Undertreatment is accompanied by premature skeletal maturation, whereas overtreatment leads to slowing of skeletal maturation. It is hoped that using clinical variables such as height velocity and weight to guide replacement therapy will improve the mean adult height in patients with this disorder (i.e., 4th percentile for men and 25th percentile for women).

Pheochromocytoma

Pheochromocytoma is a rare but extremely serious complication of pregnancy, with increased maternal and perinatal morbidity and mortality rates. Hypertension is present in the majority of patients and may be either paroxysmal or sustained. Only a minority of patients have classic pheochromocytoma episodes, characterized by extreme hypertension, headache, diaphoresis, weakness, tremor, and palpitations. Such patients often are initially considered to have hyperthyroidism.

The diagnosis of pheochromocytoma is best made by measurement of 24-hour urinary catecholamine levels; normal values are unaffected by pregnancy. If the diagnosis is established by laboratory criteria, the tumor should be localized, using a combination of imaging studies and selective venous sampling as clinically indicated. Eighty percent of these tumors are located in one adrenal gland, 10% to 15% are bilateral, and 10% are found in other locations, including the renal hilus, the organ of Zuckerkandl, and the periaortic sympathetic chain.

Because of the high morbidity and mortality associated with this condition, surgical removal during pregnancy is indicated when the diagnosis is established. The patient should be pretreated with α- and ß blockers, usually phenoxybenzamine and propranolol, for 1 to 2 weeks before surgery to increase the likelihood of intraoperative symptomatic control. Multidisciplinary management is essential to maximize maternal and fetal outcomes.

Dermatologic Disease

Physiologic Changes during Pregnancy

The systemic changes of pregnancy affect the skin in many ways. Effects can be transient or permanent. Striae gravidarum, or stretch marks, develop in the majority of women, and although they may fade postpartum, they seldom disappear. Ninety percent of all pregnant women experience some degree of hyperpigmentation, the cause of which is unknown. It may involve melanocyte-stimulating hormone and estrogens or other unestablished factors. Hyperpigmentation is more marked in darker-skinned women

---

and more often permanent in lighter-skinned women and involves the nipples, perineum, umbilicus, and the linea alba (nigra). Facial pigmentation, or melasma, is seen in at least 50% of pregnant women. It is melanin related and aggravated by sunlight. Benign or melanocytic nevi commonly enlarge and darken and can be confused with malignant melanoma. Vascular changes are prominent and may manifest as spider angiomas, palmar erythema, and venous varicosities. Finally, scalp hair growth is altered, with an increased

proportion of growing hairs to resting hairs. This is reversed after delivery with the onset of telogen effluvium, which is an abrupt hair loss 1 to 4 months postpartum. By 6 to 12 months, normal hair growth is restored.

Pregnancy-specific Dermatologic Disease Intrahepatic Cholestasis of Pregnancy

Intrahepatic cholestasis of pregnancy is the second most common cause of jaundice in pregnant women (hepatitis is the most common cause) and can produce intense pruritus (Table 17.10). There may be a several-fold increase in maternal serum bile salts, alkaline phosphatase, aspartate aminotransferase (serum glutamic-oxaloacetic transaminase), alanine aminotransferase (serum glutamic-pyruvic transaminase), and bilirubin. Treatment is symptomatic but not always effective. Topical antipruritics, antihistamines, dexamethasone, and cholestyramine seem to have little effect, and ursodeoxycholic acid has been used with variable success. The pruritus and laboratory abnormalities typically resolve promptly after delivery, but one half of patients will experience recurrence in subsequent pregnancies or with oral contraceptive use. Cholestasis is associated with an increased risk of adverse fetal outcome. Antepartum tests of fetal well-being and consideration of delivery on documentation of fetal lung maturity are recommended.

TABLE 17.10 Dermatologic Diseases in Pregnancy

Disorder	Frequency Clinical	Perinatal Treatment	Findings	Outcome
Intrahepatic cholestasis	Common	Jaundice, pruritis, abnormal liver function tests, elevated bile salts, high recurrence risk	Increased morbidity	UDCA
Herpes gestationis	Rare	Severe pruritus, papules, plaques,	Increased morbidity	Antiprur antihista steroids

		bullae		
PUPP of pregnancy	Common	Papules, plaques	No increased morbidity	Antiprur steroids
Impetigo herpetiformis	Rare	Pustules	Parallels severity of maternal disease	Antibioti supporti
Acne vulgaris	Common	—	Unaffected	Tretinoir benzoyl peroxide
Malignant melanoma	Rare	Pigmented cutaneous lesions	Placental metastases reported	Surgery

UDCA, ursodeoxycholic acid; PUPP, pruritic urticarial papules and plaques.

Herpes Gestationis

Herpes gestationis, or pemphigoid gestationis, is a rare, serious, autoimmune dermatologic disease seen in pregnancy (Table 17.10). Typically, the onset is in mid to late pregnancy but occasionally occurs postpartum. It is characterized by severe pruritus, with urticarial papules, plaques, erythema, and vesicles and bullae involving the abdomen and extremities. It is occasionally generalized, and exacerbations and remissions are common. Treatment for these pruritic lesions typically includes antihistamines and topical steroids, with oral steroids considered in severe cases. Biopsy with histologic examination reveals subepidermal edema with inflammatory infiltrate, and immunofluorescent staining confirms complement and IgG deposition at the basement membrane. This complement-fixing IgG can cross the placenta and cause dermatologic manifestations in about 5% of newborns; these typically resolve within several weeks. Herpes gestationis has been associated with adverse fetal outcome, so fetal antepartum testing is appropriate. Recurrence is seen in subsequent pregnancies, and it is often more severe and occurs earlier in gestation.

Pruritic Urticarial Papules and Plaques of Pregnancy

Pruritic urticarial papules and plaques (PUPP) of pregnancy is the most common pruritic

dermatosis of pregnancy (Table 17.10). An intensely pruritic disorder, PUPP appears late in pregnancy, with a frequency as high as 1%. It is more common in nulliparas and is not known to recur. The papules and plaques can be generalized or patchy, involving the abdomen, buttocks, thighs, and arms. On biopsy and immunofluorescent staining, the absence of antibody or complement deposition distinguishes PUPP from herpes gestationis; instead, there is a nonspecific lymphocytic perivasculitis. Treatment consists of antipruritics and topical steroids. In severe cases, oral steroids may be

considered, although these treatment modalities have limited success. There is no associated increase in perinatal morbidity.

Impetigo Herpetiformis

Impetigo herpetiformis, which some consider to be pustular psoriasis, is a rare disease with an onset late in pregnancy (Table 17.10). It initially involves intertriginous surfaces but can extend to involve the entire skin surface and mucous membranes. It classically appears as erythematous patches surrounded by sterile pustules that can become secondarily infected. Systemic symptoms and signs include fever, malaise, gastrointestinal distress, and hypocalcemia. Maternal sepsis is not uncommon. Treatment is supportive, with maintenance of fluid and electrolyte balance, correction of hypocalcemia, and antibiotic therapy as needed. The utility of steroids is uncertain. Delivery is not necessarily accompanied by resolution. Perinatal morbidity and mortality parallel the severity of maternal disease and antepartum testing is warranted in severe cases.

Non-Pregnancy-Specific Dermatologic Disease

Malignant Melanoma

Malignant melanoma, a relatively common disease of women of childbearing age, complicates about 3 in 1,000 births. Melanoma should be considered if a skin lesion is enlarging and unusually colored with bleeding or irregular borders (Table 17.10). The most significant risk factor is sun exposure. Diagnosis is by biopsy. Pregnancy is not thought to affect survival and, as in the nonpregnant population, tumor size and thickness are the most important qualifiers for prognosis. Interestingly, placental metastases have been reported. Treatment primarily is surgical, with adjuvant chemotherapy or immunotherapy. Because the majority of recurrences manifest within 5 years, most experts recommend a delay in future pregnancies.

Acute Abdomen and Surgical Disease in Pregnancy

Excluding ectopic pregnancy, pregnancy does not increase the risk of surgical illness or malignancy and does not increase the risk of adverse outcome after an uncomplicated surgical procedure. Surgical diseases in the pregnant woman can be life threatening, however, because the physiologic changes of pregnancy and the presence of a gravid uterus may delay accurate diagnosis and can make many surgical procedures more technically difficult. Although elective surgery should be postponed until after delivery if at all

possible, a surgical emergency in a pregnant woman should prompt the same aggressive treatment considered for the nonpregnant individual.

Appendicitis

Laparotomy is required during 1 in 500 to 1,000 pregnancies; appendicitis is the most common diagnosis. Pregnancy does not increase the risk of appendicitis. It occurs with equal frequency in all three trimesters, and appendectomy can be performed safely throughout pregnancy. However, acute appendicitis has been associated with a maternal mortality rate as high as 5% and an increased risk of preterm labor and fetal loss. These complications most often result from a delay in diagnosis.

Intra-abdominal pathology can be difficult to diagnose in the gravid woman. The bowel is progressively displaced upward and backward as the gravid uterus grows during pregnancy. Because bowel sounds normally are heard only in the upper abdomen, the absence of bowel sounds may not be appreciated. The appendix also assumes an increasingly more cephalad position, and associated inflammation and pain are therefore not typically localized to the right lower quadrant after the first trimester. Anorexia, nausea and vomiting, a change in bowel habits, and even epigastric or abdominal pain can be part of normal pregnancy and thus may not suggest pathology. Laboratory evaluation may not be helpful, because a mild leukocytosis is common in pregnancy. Nevertheless, it is in the patient's best interest to have a high index of suspicion, as delayed diagnosis can be catastrophic.

The patient typically has periumbilical or right flank pain that is increased by uterine manipulation. Placing the patient on her left side allows the uterus to fall away from the right flank and may facilitate examination. Thirty percent of appendices are retrocecal in location; in this situation, the initial complaint may be right flank or leg pain or pain on rectal examination, and the patient may have psoas or obturator muscle symptoms. Anorexia, nausea, and vomiting usually are increased relative to normal pregnancy. The white blood cell count may be elevated significantly, and the patient may be febrile, especially if rupture or generalized peritonitis is present. Sonographic examination can help to rule out other diagnoses but generally cannot confirm appendicitis itself, because ultrasound waves penetrate gas-filled structures poorly. A plain radiograph to identify air–fluid levels or free air in the abdomen can be very helpful, and most centers now use CT to evaluate the appendix, although no test is always conclusive. If appendicitis is strongly suggested, laparotomy or laparoscopy in earlier gestation should be performed, avoiding a rupture and the risk of sepsis.

Intestinal Obstruction

The second most common nonobstetric indication for abdominal surgery is intestinal obstruction, which complicates 3 in 10,000 pregnancies. Risk factors include previous pelvic inflammatory disease and previous intra-abdominal surgery. The incidence of intestinal obstruction increases

---

as pregnancy advances because the enlarging uterus displaces the bowel upward and backward, placing preexisting adhesions on tension and increasing the risk of volvulus. As

stated previously, pregnancy makes assessment of bowel function difficult and may contribute to a delay in diagnosis. Maternal mortality as high as 10% to 20% has been reported, due primarily to maternal shock associated with unrecognized bowel infarction. As with appendicitis, once bowel obstruction that is unresponsive to conservative management has been diagnosed, surgical intervention should not be delayed.

Cholecystitis

Acute abdomen may be due to cholecystitis. Cholecystitis occurs in 1 in 1,000 to 1,600 pregnancies; over 90% of cases are caused by cholelithiasis. Patients typically seek treatment for nausea, vomiting, and the acute onset of colicky midepigastric pain. Laboratory evaluation and ultrasonographic examination are helpful in making the diagnosis. The treatment primarily is medical, especially in the first and third trimesters. Surgery is considered for the patient with repeated severe episodes of cholecystitis and unremitting pain, systemic toxicity, or persistent or recurring pancreatitis. The second trimester is preferable for elective surgery, as the risks of surgery-associated fetal loss, preterm labor, or fetal compromise are lowest at this time. Further, although the pregnancy is well established, the uterus is still small enough to allow adequate visualization of the operative site without extensive uterine manipulation. Open laparoscopic second-trimester cholecystectomy has been reported with good results. Maternal mortality is minimal, and fetal mortality usually is <5%.

Pancreatitis

Pancreatitis can result in acute abdomen. In pregnancy, the most common cause of pancreatitis is cholecystitis, with alcohol abuse, viral infection, and hyperlipidemia accounting for a small proportion of cases. Treatment primarily is medical, as outlined previously, with surgery considered only if symptoms do not improve rapidly (1 to 2 days) or an abscess or pseudocyst develops. As with cholecystitis, ultrasonographic examination may be helpful in making the diagnosis and ruling out other entities. The patient should be followed closely, with careful attention given to fluid management. Fetal loss can occur in complicated cases as a result of acidosis, hypovolemia, and hypoxia.

Liver Disease

Abdominal pain, particularly right upper quadrant pain, may be due to liver disease. Most commonly, liver pathology in pregnancy is due to preeclampsia, hepatitis, or acute fatty liver. Very rarely, pregnancy is complicated by cirrhosis or portal hypertension. Because pregnancy increases the risk of bleeding from esophageal varices, such patients may require endoscopic sclerotherapy during pregnancy.

Maternal Trauma

Physiologic Changes in Pregnancy

Accurate assessment of the pregnant trauma victim requires knowledge of the physiologic

changes that normally occur during gestation. No organ system is unaffected, but the functions of the cardiovascular and respiratory systems are altered most dramatically. Plasma volume increases by 50%, while red blood cell mass increases by 25%, resulting in a physiologic anemia. Leukocytosis normally occurs, peaking in the third trimester with a white blood cell count of 12,000 to 18,000/mm^3 and 25,000/mm^3 in labor. Cardiac output increases by 4.5 to 6.0 L per minute (30% to 50%), primarily as a result of a gradual increase in stroke volume to 50% above nonpregnant levels. The majority of pregnant women have a widely split first heart sound, a third heart sound, and a systolic ejection murmur. Over 10% of cardiac output goes to the uterus at term, and veins in the pelvis and lower extremities are engorged. Renal blood flow increases by 30%, leading to a 30% to 50% increase in the glomerular filtration rate. As a result, the BUN and creatinine fall and should not be higher than 13 mg/dL and 0.8 mg/dL, respectively, during pregnancy. A hormonally mediated decrease in vascular resistance leads to a midtrimester decrease in both systolic and diastolic blood pressure. All of these changes are affected by maternal position. In the supine position, the uterus compresses the vena cava, resulting in decreased venous return, decreased cardiac output, a drop in blood pressure, bradycardia, and syncope.

Hyperventilation begins as early as the first trimester, probably in response to increased progesterone levels. Because of gradual elevation of the diaphragm by the enlarging uterus, functional residual capacity, residual volume, and expiratory reserve volume all decrease, while inspiratory reserve volume increases. The normal gravida at term has a chronic respiratory alkalosis with a resting carbon dioxide tension below 30 mm Hg. Seventy-five percent of gravidas experience dyspnea in the third trimester. Although arterial oxygen tension generally rises toward term, a moderate hypoxemia can occur in the supine position. Thus, the midtrimester gravida who is lying supine in the emergency room may be hypotensive, bradycardic, relatively hypoxemic, and anemic, all because of normal physiologic changes.

The ABCs

Taking into consideration the physiology of pregnancy, the pregnant trauma patient should be assessed initially as any trauma victim is assessed, according to the ABCs: airway, breathing, and circulation. In a rapid assessment of the

---

patient's status, airway patency and adequacy of respirations should be established. Supplemental oxygen should be administered to all patients; the patient who is not breathing spontaneously should be intubated and mechanically ventilated. A wedge should be placed under the right hip to displace the uterus off the vena cava. Pregnancy significantly slows gastrointestinal motility, so all pregnant women should be assumed to have a full stomach. The conscious patient should be given sodium citrate or a similar antacid, while the airway of the unconscious patient should be protected.

If cardiac function is adequate, attention should be turned to maintaining adequate circulating volume. One or two large-bore intravenous lines should be established and Ringer's lactate solution given. Infusion of large volumes of sodium chloride should be avoided, as it can lead to hyperchloremic acidosis that would exacerbate lactic acidosis

caused by poor perfusion. If the patient is bleeding, appropriate replacement products should be administered as soon as possible.

If cardiac arrest has occurred, full resuscitation should be initiated as for any other patient. CPR at most generates only 30% of the normal cardiac output; CPR of a pregnant woman in left lateral tilt will be even less effective. The patient must therefore remain supine, and someone must be assigned to elevate the uterus manually off the vena cava. It can be assumed that perfusion to the uterus will be negligible during CPR. The general consensus is that a fetus can survive total asphyxia for at most 4 to 6 minutes. If cardiac function has not been restored within 4 minutes of arrest and the fetus is still alive, an emergent, nonsterile, classic cesarean section should be performed without anesthesia at the bedside, and the uterus and abdominal incisions should be closed as rapidly as possible. If cardiac arrest has persisted for more than 6 minutes but fetal cardiac activity continues, delivery should still be performed. In addition to possibly saving the fetus, evacuation of the uterus will facilitate CPR by improving cardiovascular dynamics.

The ACOG recommends that any pregnant woman sustaining trauma beyond 22 to 24 weeks gestation undergo fetal monitoring for a minimum of 4 hours. If more than four contractions per hour are observed; if rupture of membranes, bleeding, fetal arrhythmia, or fetal heart rate decelerations occur; or if the mother is seriously injured, the patient should be admitted with continuous fetal monitoring for at least 24 hours.

Abdominal Trauma

Motor vehicle accidents are the leading cause of blunt abdominal trauma (especially if the woman is unrestrained or is not wearing her lap belt as low as possible under her uterus), followed by falls and direct assaults. Placental abruption is the most common severe complication of blunt trauma, occurring with 1% to 5% of minor injuries and 20% to 50% of major injuries. Findings may include vaginal bleeding, uterine tenderness, or contractions as well as fetal tachycardia, decelerations, acidosis, and death. Direct fetal injury is less common but most often involves fetal skull and brain injury as a result of maternal pelvic fracture. Rupture of the liver or spleen can accompany blunt trauma, and rupture of the uterus occurs in less than 1% of cases. Bladder injury or rupture is more common after 20 weeks, when the bladder assumes an intra-abdominal position and no longer is protected by the pelvis. Bladder injury also may result from pelvic fracture.

A patient with any signs of shock or peritoneal irritation is appropriately suspected to have major intra-abdominal injury. Intra-abdominal bleeding can be detected with intraperitoneal lavage, just as in the nonpregnant patient. Bladder injury is suspected when a urinary catheter cannot be passed, fails to return urine, or returns grossly bloody fluid. Bowel injury is uncommon, except at points of fixation. Uterine rupture usually results in vaginal bleeding, hypotension, absent fetal heart tones, and hematuria if the rupture involves the anterior uterine wall. If significant injury is suspected, the patient should be stabilized and a laparotomy performed as rapidly as possible. Extent of injuries, gestational age, and assessment of fetal well-being are considerations for fetal delivery. Appropriate counseling should be provided regarding the possibility of hysterectomy, and blood products obviously should be available.

However, if the patient is stable and a CT scan or other radiologic studies are necessary for diagnostic purposes, they should be performed. If at all possible, the patient should be positioned with a wedge under one hip to deflect the uterus off the vena cava. The amount of radiation exposure resulting from standard radiologic procedures is less than the minimum dose associated with fetal teratogenicity or growth effects. The fetus is most susceptible before 15 weeks gestation, when radiation doses of 10 rad (0.1 Gy) or greater can cause mental retardation. At 16 to 25 weeks, the risk is considerably less, and radiologic procedures at 25 weeks or beyond pose minimal to no risk. Most authorities recommend limiting fetal exposure to <5 rad (0.05 Gy). Most plain radiographs entail doses of <1 rad (0.01 Gy); an abdominal CT scan exposes the fetus to 2.0 to 2.6 mrad (0.020 to 0.026 Gy). MR imaging does not require ionizing radiation and thus does not entail risk at any gestational age. Medical and surgical care should not be compromised in any way because the patient is pregnant. If the woman is Rh negative and unsensitized, $Rh_0(D)$ immune globulin will protect her if there was fetal–maternal bleeding, and appropriate doses should be calculated.

Penetrating Abdominal Trauma

Gunshot and knife wounds are responsible for most cases of penetrating abdominal trauma in pregnancy. As the

uterus grows out of the pelvis, it becomes more likely that the uterus will be a site of injury. Penetration of the uterus results in maternal mortality in <5% of cases, but in fetal injury in 59% to 89% of cases, with fetal death in 41% to 71%. After penetrating abdominal trauma, the pregnant patient should be assessed as noted previously and attempts made to determine the exact site(s) of injury and associated organ damage. The initial evaluation and subsequent surgical management should be the same as for the nonpregnant patient. If the uterus is the primary site of injury, exploratory laparotomy likely will be required. Bullet wounds must be explored surgically, as deflection of the bullet off intra-abdominal structures can cause extensive damage and make it impossible to determine the projectile path. Knife wounds may require exploration, as the enlarged uterus compresses other intra-abdominal organs and prevents structures underlying the wound from sliding away from the blade, as they would in the nonpregnant state. Ultrasonographic examination of the fetus to determine age and assess viability is essential.

Decisions regarding whether or not to empty the uterus should be individualized. If there is extensive intrauterine damage, if the pregnancy is near term, if there is a strong suspicion of fetal hemorrhage, or if uteroplacental insufficiency is present, the fetus should be delivered and the uterus thoroughly explored. If the uterus is uninjured or the injury can be repaired without entering the uterine cavity, if the fetus is previable or dead, and if uterine size does not preclude adequate exploration of the abdominal cavity, hysterotomy may be avoided as long as hemostasis is achieved.

Intra-abdominal organs are compressed into the upper abdomen as pregnancy advances. Penetrating wounds in this area are especially traumatic because multiple organs are injured. In decreasing order of frequency, the small bowel, liver, colon, and stomach are

damaged most often. For this reason, many authorities recommend that upper abdominal wounds be explored by laparotomy in all pregnant patients. Broad-spectrum antibiotics should be administered, and tocolytic therapy can be used with caution during the postoperative period. ß-Mimetic agents have maternal and fetal cardiovascular effects that may confuse postoperative assessment, while magnesium sulfate is associated with maternal nausea, vomiting, and dizziness. Maintenance of normal intravascular volume and close attention to fluid balance are crucial.

Head Trauma

The gravida with head trauma should be evaluated and treated in the same way as the nonpregnant patient. Assessment begins with the ABCs. The head and neck should be immobilized as a unit in case there is cervical spine injury. In the stable patient, gestational age and viability should be assessed. Unless precluded by vertebral fractures, the uterus should be rolled off the vena cava by placing a wedge under the backboard. Mannitol, steroids, and other medications should be given as necessary. Because fluid restriction, osmotic diuresis, maternal hypotension, and hypothermia induced during neurosurgery may reduce uteroplacental blood flow, the viable fetus should be monitored and therapeutic adjustments made as required.

Burns

Burns are described as being partial or full thickness and are quantitated according to the percentage of surface area affected. Extensive full-thickness burns result in severe thermal instability and dramatic fluid loss. Hypovolemic shock can occur, especially within the first 36 hours. Airway management and treatment of the burn itself should be the same for pregnant and nonpregnant patients. The pregnant burn victim, however, requires meticulous attention to fluid management, with consideration of the expanded intravascular volume and altered cardiovascular dynamics associated with pregnancy. Fetal status is related directly to the adequacy of uteroplacental perfusion; poor outcome is associated with inadequate fluid resuscitation. If more than 50% of the patient's surface area is affected, immediate delivery of the viable fetus should be considered. However, in some cases, aggressive fluid resuscitation and close fetal monitoring may allow delivery to be deferred.

Thermal injury causes elevated prostaglandin levels and increased susceptibility to infection. These factors often contribute to preterm labor. Because complications that typically are associated with tocolytic therapy may not be tolerated by the gravid burn victim, tocolytics should be used cautiously, if at all. Indomethacin (Indocin) may be the safest agent for use before 32 weeks. If fetal surveillance (24 or more weeks gestation) indicates fetal compromise despite optimal maternal resuscitation, the fetus should be delivered.

Electrical Injury

There are very few reports of electrical injury during pregnancy. Because the uterus and amniotic fluid offer low resistance, current entering an upper extremity and exiting a

lower extremity may traverse the uterus and fetus. Maternal cardiac and respiratory status should be assessed and treated as in any injured patient. Ultrasonographic examination and fetal monitoring should guide pregnancy management. Fetal survival without specific intervention has been reported, although immediate fetal death also is possible.

Summary Points

- Severe anemia in pregnancy has many etiologies and is associated with intrauterine growth retardation.
- Hyperemesis gravidarum, which complicates 1 in 200 pregnancies, is characterized by dehydration, electrolyte imbalance, and nutrition depletion.
- Because pregnant women have decreased gallbladder motility and increased biliary sludge, gallstones affect 2% to 10%; however, acute cholecystitis complicates only about 1 in 1,000 pregnancies.
- Peripartum cardiomyopathy is a global congestive heart failure characterized by dilation of all four chambers of the heart, low cardiac output, and pulmonary edema.
- The mortality rate for pregnant women with varicella pneumonia is up to 40%. Aggressive treatment with intravenous acyclovir, a DNA polymerase inhibitor, decreases mortality in pregnant women by 50%, without increasing fetal anomalies.
- Unrecognized or inadequately treated hypothyroidism is associated with an increased risk of miscarriage, preeclampsia, intrauterine fetal demise, postpartum hemorrhage, and fetal effects.
- The obstetrician-gynecologist must be thoroughly familiar with the normal physiologic changes of pregnancy because these changes affect the clinical pictures of many diseases as well as their management.
- Although many disease processes are unchanged by pregnancy, the course of some diseases is altered. This alteration often affects diagnosis and therapy.
- The obstetrician-gynecologist should recognize the heritability of some disorders and should refer patients for adequate genetic counseling.
- Necessary imaging procedures can be performed during pregnancy and should not be withheld.
- Very few medications need to be restricted in pregnancy.
- In general, pregnant and nonpregnant women with a medical or surgical disease should receive comparable care, although fetal well-being must be kept in mind if fetal viability has been reached.
- For a pregnant woman with thromboembolism, tests to diagnose an

underlying thrombophilia should be considered, especially if there is a family history and if there are no clear predisposing factors for the thromboembolic event.
- The effect of pregnancy on chronic renal disease increases with the severity of the disease. For woman with mild renal disease (serum creatinine <1.4 mg/dL), renal function typically returns to prepregnancy levels after delivery.
- Because cholestasis of pregnancy is associated with an increased risk of adverse fetal outcome, antepartum tests of fetal well-being and consideration of delivery on documentation of fetal lung maturity are recommended.

Immunologic Disorders in Pregnancy

D. Ware Branch
Robert M. Silver
Kjersti Aagaard-Tillery

Reproductive Immunology

The physiologic mechanisms that protect the fetus and its placenta from attack by the maternal immune system are complex, and many remain poorly understood. Nevertheless, the practicing obstetrician should be familiar with the immunologic aspects of the maternal–fetal relationship as well as the profound impact that aberrations in immunologic function have on pregnancy outcome.

Fundamental Immunobiology

The primary function of the immune system is to protect against foreign pathogens, primarily by distinguishing biologic “self” from “nonself” (the clonal selection model of immunity). In the early stages of development, immune cell precursors are educated to recognize self. T cells that recognize self-antigens are killed or rendered inactive while T cells with specific receptor types against foreign pathogens continue to develop. The immune system has two primary effector mechanisms, which though overlapping and coordinated are classified for the sake of discussion as either innate or adaptive. The *innate* immune response is a continuous and relatively nonspecific process that recognizes foreign material as nonself, allowing it to operate effectively without prior exposure to a microorganism or its antigens. Components of the innate system include physical and biochemical barriers, primary effector cells such as mononuclear phagocytes, natural killer (NK) cells, and polymorphonuclear leukocytes and circulating biochemical factors such as the complement proteins. Recognition of foreign pathogens by membrane receptors on effector cells is followed by phagocytic destruction and induction of apoptosis by NK cells (Fig. 18.1). One family of pathogen recognition receptors, called *Toll-like receptors* (TLR), appears to play an important role in mediating the inflammatory responses in the reproductive tract. As membrane receptors on inflammatory cells, they initiate a nonspecific response to bacterial antigens and also may function to facilitate adhesion of immune cells on endothelium.

The hallmark of *adaptive* immunity is precise specificity of antigen recognition and

memory so that repeated exposures to a specific antigen elicit an enhanced immune response. The adaptive response includes several stepwise processes that occur in the lymphatic system (Fig. 18.1). The primary adaptive effector cells are B cells, precursors of plasma cells that secrete specific antibodies that circulate through the bloodstream and destroy target cells in concert with complement or antibody-dependent cellular cytotoxic cells. Antibodies are heterogeneous proteins produced by gene rearrangement, a process that creates myriad possible immunoglobulin antigen-recognition sites. The first antibody to be produced in a primary response is immunoglobulin M (IgM), which is soon superseded by a predominantly immunoglobulin G (IgG) response.

As proliferating T cells mature, they differentiate into an array of subtypes that have diverse functions. CD4+ helper cells promote the proliferation of other immune cells and help B cells produce antibodies. CD4+ inducer cells control the subsequent development of other T cells. CD8+ cytotoxic cells lyse foreign or virus-infected cells, and CD8+ suppressor cells prevent an uncontrolled immune response. T-cell subsets destroy and remove foreign tissues and organisms by direct binding and secretion of cytokines that recruit and activate macrophages. Cytokines are a means of communication between immune cells. Interleukin (IL)-1 is produced by macrophages and monocytes

and promotes multiplication and activation of lymphocytes. IL-2, produced in response to lymphocyte activation, is the major T-cell growth factor for the proliferation of activated T cells.

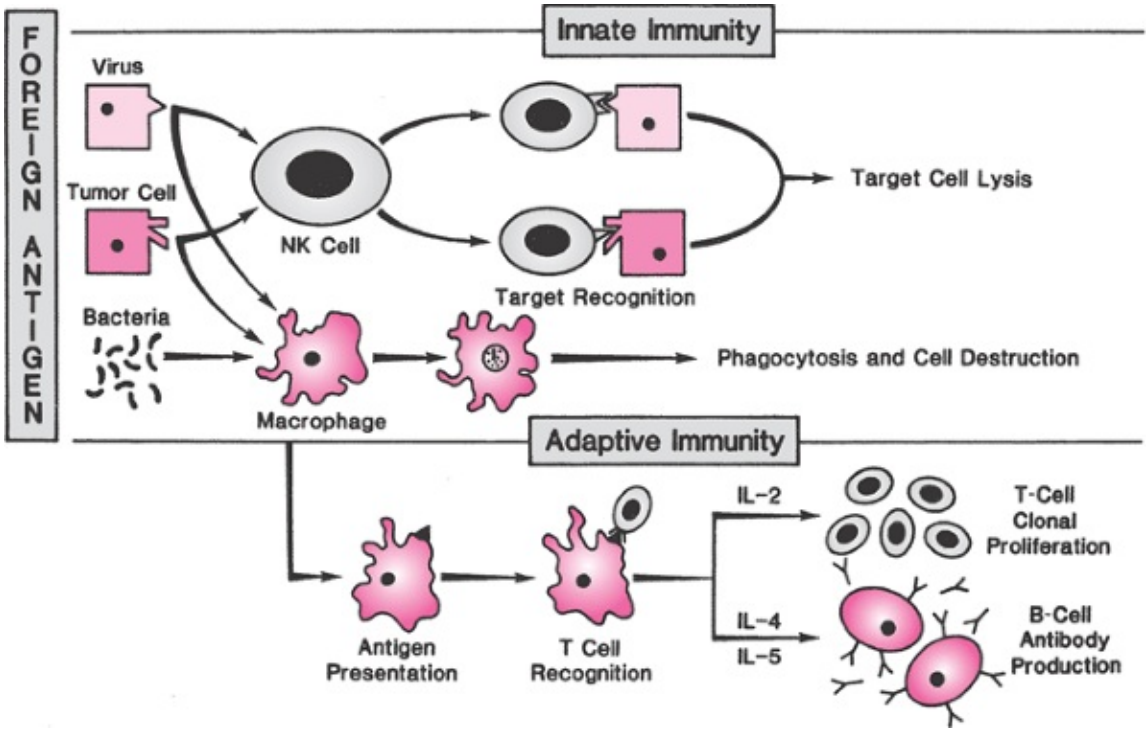

Figure 18.1 Schematic view of innate and adaptive immune systems. Phagocytic cells of the innate immune system recognize foreign antigen. The foreign antigen can be a microbial pathogen, viral antigen, or tumor antigen. Innate immune responses result in direct cytotoxicity or destruction of the pathogen. Activation of the adaptive immune system depends on interaction with processed antigen provided by cells of the innate

immune system. T-cell and B-cell activation results in T-cell clonal proliferation and B-cell antibody production, respectively. (NK, natural killer; IL, interleukin.) (From Dudley DJ. The immune system in health and disease. *Balliere's Clin Obstet Gynaecol* 1992;6:393.)

Cells of the innate immune system act as secondary effector cells in the adaptive response through T-cell recognition of human leukocyte antigens (HLAs), which are products of the major histocompatibility complex (MHC) located on the short arm of chromosome 6. Class I MHC antigens are expressed by nearly all nucleated cells and are identified by cytotoxic T cells. Class II MHC antigen expression is restricted to B cells, monocytes, macrophages, and activated T cells but is important for presenting antigen to helper T cells.

Embryologic Development of the Immune System

The development of the immune system begins at conception and continues throughout pregnancy and into the newborn period. During weeks 4.5 to 6.0 of gestation (menstrual weeks), pluripotential stem cells in the yolk sac and aortic-gonad-mesonephros form the precursors for all the blood cell series. Migration of these cells, probably in a series of migratory waves, to the liver, thymic bud, and eventually to the bone marrow and spleen establish the functioning immune system. The thymus develops in the human embryo at 6 weeks gestation, and lymphocyte differentiation proceeds in the absence of foreign antigens. Small lymphocytes appear in the peripheral blood at week 7 and around lymphocyte plexuses by week 8. As early as 13 weeks gestation, T cells that can respond to mitogens and recognize histoincompatible cells begin to appear. By 20 weeks gestation, the human fetus has the ability to respond to congenital infections by producing plasma cells and antibodies. Monocytes first appear in fetal blood at 18 to 20 weeks gestation and form approximately 5% of the circulating cells by 30 weeks. Polymorphonuclear cells (PMNs) are identifiable in the fetal liver and bone marrow in the mid-second trimester but are a relatively small component of circulating cells in utero and at birth. Circulating concentrations increase dramatically at birth, peaking at 12 to 24 hours and declining somewhat by 72 hours after birth in the term infant.

The presence of an intact trophoblastic cellular barrier prevents the movement of large numbers of immunocompetent cells into or out of the fetus during pregnancy. In contrast, maternal IgG, by virtue of its Fc fragment, is specifically selected for placental transfer (Fig. 18.2). Fetal IgG concentrations are about 10% of adult levels by the middle of the first trimester (Fig. 18.3). Adequate humoral immunity in the neonatal period depends on the circulating immunoglobulins that have crossed the placenta, and fetal blood levels of IgG reflect maternal levels. The specific antibody protection depends on the mother's own antigenic experience. The primary role of maternal antibodies is to protect the neonate from infections. However, several maternal autoimmune disorders are characterized by production of IgG antibodies and can be harmful to the infant.

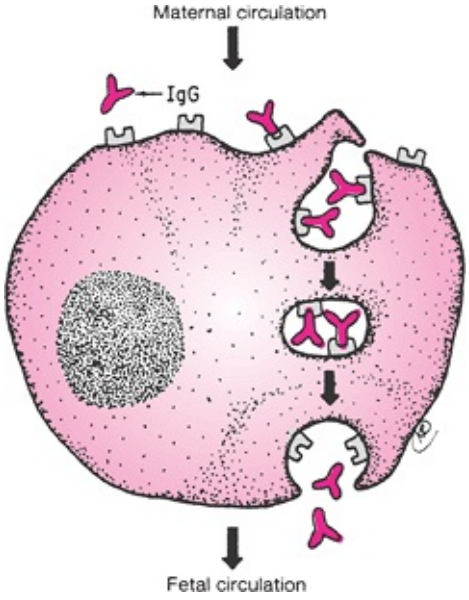

Figure 18.2 The transport of maternal IgG across the trophoblast and into the fetal circulation is an active process. Maternal IgG binds to Fc receptors on the surface of the trophoblast and is internalized into vacuoles. These receptors are specific for the Fc portion of IgG and do not bind other classes of immunoglobulins. The interaction of IgG with the receptors probably protects the antibody from digestion during the transport of the vacuole across the cell. On the fetal side, IgG is released into the fetal circulation. (From Scott JR, Rote NS, eds. *Immunology in obstetrics and gynecology*. Norwalk, CT: Appleton-Century-Crofts, 1985:70.)

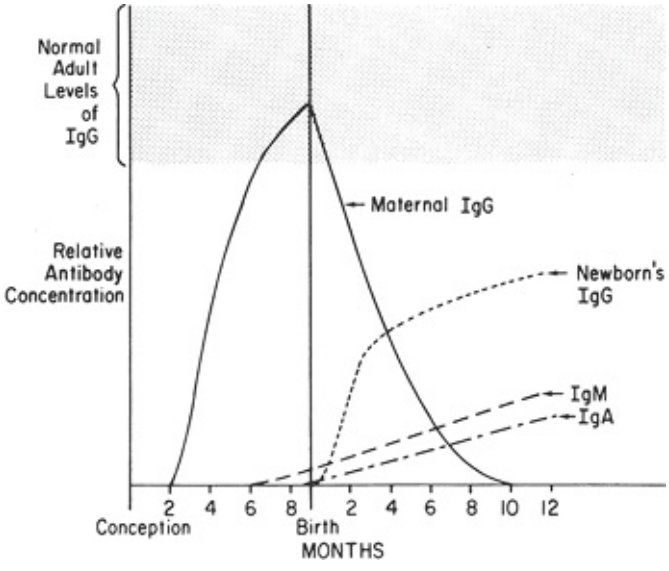

Figure 18.3 Levels of antibody in the cord blood and neonatal circulation. Early in gestation, maternal IgG crosses the placenta and enters the fetal circulation. At the time of birth, the fetal circulation normally contains a near-adult level of IgG, which is almost exclusively maternal, and small amounts of fetal IgM and IgA. After delivery of the child, maternal IgG is rapidly catabolized, whereas neonatal IgG production increases. (From Scott JR, Rote NS, eds. *Immunology in obstetrics and gynecology*.

Norwalk, CT: Appleton-Century-Crofts, 1985:69.)

Pathogenesis of Autoimmune Disease

The myriad specificities of the response of B cells and T cells to the wide array of antigenic material presented by nature results from various random combinations of the many genes coding for antigen binding sites on cellular receptors. It is estimated that this process can produce 10^9 different T-cell receptors. Not surprisingly, some of these millions of binding sites recognize, at least to some degree, antigenic structures present on the cells of normal tissues (autoantigens). The immune system is normally regulated so that cells capable of producing an immune response to self-antigens are suppressed; this process is often called *immune tolerance*.

Failure of immune tolerance may result in autoimmunity and autoimmune disease. A failure in B-cell tolerance would appear to result in the production of autoantibodies responsible for Graves disease, for example, because they bind to and stimulate the thyrotropin receptor. Autoantibodies also are the likely culprits in several other autoimmune disease, including pemphigus vulgaris, autoimmune hemolytic anemia, and autoimmune thrombocytopenia. A failure in T-cell immune tolerance likely is a primary cause of autoimmune thyroiditis, systemic lupus erythematosus, multiple sclerosis, and type I diabetes mellitus.

A complete discussion of the possible mechanisms of immune cell tolerance and the defects that may lead to a failure of B- or T-cell immune tolerance is beyond the scope of this chapter. Briefly, autoreactive B cells are normally deleted in the bone marrow or in the T-cell zones of the spleen or thymus, with the latter mechanism requiring the participation of the T-cell system. Autoreactive B cells also may be functionally inactivated in the periphery via the development of anergy or receptor editing.

Similarly, autoreactive T cells may be deleted in the thymus, where they encounter self-antigens presented in the context of MHC molecules. Those autoreactive cells with high affinity for the self-antigens undergo apoptosis—they are negatively selected by a process in thymus that requires self-antigen complexes, known as central tolerance. Autoreactive T cells in the periphery may be blocked from reacting with pertinent tissues via physiologic separation, for example, the blood–brain barrier, or by the binding of the autoreactive T cells to Fas ligand, which induces apoptosis and thus deletes the potentially damaging T-cell clone in periphery. Also, autoreactive T cells are regulated by “regulatory” T cells, likely composed of several cells types producing a variety of regulatory cytokines.

Autoimmune diseases result from a breakdown in normal regulatory mechanisms that allow the distinction between self and nonself. Autoimmunity is characterized by

persistent activation of immunologic mechanisms that affect the function and integrity of certain cells and organs. The process may be initiated in genetically susceptible individuals by environmental agents, such as infection, but is probably sustained by persistent T-cell activation that overrides normal tolerance of self-antigens.

Autoimmune diseases have a predilection for women of reproductive age and are often encountered during pregnancy. The effects of pregnancy on autoimmunity, and vice versa, depend to some degree on whether a condition is primarily cellular (T cell) or humoral antibody (B cell) in nature and to what degree the aberrant immune system might affect placentation or the fetus. Certain diseases with strong cellular pathophysiology, such as rheumatoid arthritis (RA) and multiple sclerosis, may be associated with remission during pregnancy and have little impact on the placenta or fetus, whereas autoantibody-mediated autoimmune diseases such as neonatal lupus may directly effect the fetus via the transplacental passage of autoantibodies.

Maternal-Fetal Immunology

Maternal immunologic reaction to the genetically dissimilar cells of the conceptus begins at fertilization and continues throughout pregnancy as differentiated fetal trophoblast cells interact with maternal uterine tissue and blood. The normal immunologic relationship between mother and fetus appears to be healthy and growth promoting rather than the usual allogeneic model of destruction.

Several mechanisms likely play a role in protection of the fetus from immunologic damage. Circulating blocking factors have been theorized to attenuate maternal immunologic reaction. One progesterone-induced blocking factor suppresses production of lymphocytes and proinflammatory cytokines. In addition, so-called blocking antibodies may prevent lymphocytic destruction by binding to receptors on fetoplacental tissues. Alternatively, blocking antibodies may be directed against antigen-specific combining sites (idiotypes) on maternally produced antibodies that prevent them from assisting lymphocytes in targeting cells on the conceptus. While the concept is appealing, the relevance of blocking antibodies and other alleged circulating pregnancy-maintaining factors remains unsettled. Not only do agammaglobulinemic women without antibody production have normal pregnancies, so-called blocking antibodies do not frequently appear until late in the first or second trimester of the first pregnancy.

Immunotolerance during pregnancy probably results from interactions at the local maternal–fetal interface rather than from generalized maternal immunosuppression. Before conception, endometrial stromal cells transform into decidual cells that contain T-cell subtypes with immunosuppressive activity. One T-helper cell subset secretes cytokines that are beneficial or neutral to the presence of the fetus. Another is thought to prevent colonization with microbial pathogens. Additional evidence suggests that some subsets of the decidual T cells promote growth of the placenta through the secretion of cytokines that suppress inflammation. Hormones, enzymes, growth factors, and endometrial proteins within maternal decidual tissue also have potent immunomodulatory properties that promote a favorable interaction between the conceptus and the mother.

The presence of large granular lymphocytes in luteal phase and early- to mid-pregnancy deciduas has generated considerable interest among reproductive immunologists. Under normal circumstances, these nonspecific innate immune effector cells, similar to NK cells, kill standard NK-cell targets with the notable exception of trophoblastic cells. Some experts find that alternations in uterine NK-cell numbers are associated with pregnancy

loss.

The placenta also plays an active role in protection of the fetus from maternal immune responses. Villous cytotrophoblasts and syncytiotrophoblasts escape destruction because both express nonclassic MHC antigens that prevent trophoblast destruction through inhibition of lysis by activated NK cells, limitation of leukocyte cytotoxic activity, suppression of proinflammatory cytokine production, and induction of T-cell death. Nonclassic MHC antigens, specifically HLA-G, also promote trophoblast proliferation and invasion. Altered expression of nonclassic MHC antigens has been linked to recurrent miscarriage and preeclampsia.

Placental expression of a protein known as the Fas ligand also may play a role in pregnancy success through selective deletion of antifetal T-cell clones. In animal studies, binding to the Fas ligand causes death and removal of autoreactive T cells.

The placenta also may inhibit T-cell proliferation by sequestering nutrients. Placental indolamine 2,3-dioxidase (IDO) inactivates the amino acid tryptophan, which is essential for the proliferation of T cells. The role of IDO in recurrent pregnancy loss (RPL) in humans has not yet been widely investigated.

The inhibition of complement activation also may play a role in maternal–fetal tolerance. Mice lacking a protein that inhibits complement have a high rate of pregnancy loss characterized by placental inflammation. If complement is removed, the mice reproduce normally. Complement activation also has been shown to be important in the pathophysiology of pregnancy loss in women with antiphospholipid syndrome (APS).

Erythroblastosis Fetalis (Red Cell Alloimmunization)

Although the first description of erythroblastosis fetalis (hemolytic disease of the newborn) dates back to 1609, it was not until the early 1900s that the role of alloimmunization in the pathogenesis of erythroblastosis was

established. In this condition, the Rh-negative mother becomes alloimmunized by exposure to Rh-positive fetal erythrocytes during pregnancy or delivery. Maternally produced antierythrocyte antibodies, recognizing the Rh D antigen, pass across the placenta to the fetus where they react with the Rh-positive fetal erythrocytes, causing their destruction. In the past, Rh alloimmunization also has been referred to as Rh sensitization or Rh isoimmunization.

Many other erythrocyte antigens have been described since the discovery of the Rh D antigen, but only a few are clinically important causes of maternal alloimmunization. However, with the widespread use of Rh immune globulin prophylaxis and the decline in Rh D alloimmunization, the overall importance of the “minor antigens” in red cell alloimmunization has increased.

Genetics of the Rh Antigen

The Rh blood group was so named because rabbits immunized with rhesus monkey

erythrocytes produced an antibody that agglutinated erythrocytes from 85% of whites. This antibody, initially known as the Rh factor, is directed against an erythrocyte surface antigen of the rhesus blood group system. The Rh blood group system has a high degree of polymorphism, with five major antigens and many variant minor antigens. While three systems of nomenclature have been suggested, the Fisher-Race system is probably best suited to understanding the inheritance of the Rh antigen and the clinical management of Rh alloimmunization. It assumes the presence of three genetic loci, each with two major alleles, lettered C, c, D, E, and e. No antiserum specific for a "d" antigen has been found.

The Rh gene complex is described by the three appropriate letters with eight possible combinations (listed in decreasing order of frequency among whites): CDe, cde, cDE, cDe, Cde, cdE, CDE, and CdE. Genotypes are indicated as pairs of gene complexes, such as CDe/cde. Certain genotypes, and thus certain phenotypes, are more prevalent than others. Although the alleles are always written in the order C(c), D, E(e), the actual order on chromosome 1 is of the genes coding for the antigens D, C(c), E(e). Anti-C, anti-c, anti-D, anti-E, and anti-e designate specific antibodies directed against the respective antigens. Because the majority of Rh D alloimmunization resulting in overt clinical disease results from incompatibility with respect to the D antigen, common convention holds that *Rh positive* indicates the presence of the D antigen and *Rh negative* indicates the absence of D antigen on erythrocytes.

Unique Rh antibodies have been used to identify more than 30 antigenic variants in the Rh blood group system, the most common of which is the Du antigen, now commonly referred to as *weak D*. This heterogeneous group of clinically important D-antigen variants most often is found in blacks. At least some weak D–positive patients are capable of producing anti-D, which could presumably result in a weak D–positive mother becoming sensitized to her D-positive fetus, but such an occurrence is exceedingly rare.

The Rh D antigen appears very early in embryonic life and has been demonstrated on the red blood cells of a 38-day-old fetus. The Rh erythrocyte glycoproteins are ancient in origin and occur widely in eukaryotic cells. They probably function in membrane ammonia homeostasis and also interact with cellular skeletal structure to help maintain the mechanical properties of the cell membrane. Rh_{null} individuals have a compensated hemolytic anemia with multiple red cell membrane abnormalities.

Pathophysiology of Rh Alloimmunization

The pathophysiology of Rh D alloimmunization is the best studied of the antierythrocyte alloimmunizations and thus may serve to illustrate the major principles of erythrocyte alloimmunization.

Rh D alloimmunization can occur only in the presence of three conditions: (a) the fetus must have Rh-positive erythrocytes, and the mother must have Rh-negative erythrocytes; (b) the mother must have the immunogenic capacity to produce antibody directed against the D antigen; and (c) a sufficient number of fetal erythrocytes must gain access to the maternal circulation.

Incidence of Rh D Incompatibility and Subsequent Alloimmunization

About 15% of whites, 5% to 8% of blacks, and 1% to 2% of Asians and Native Americans are Rh negative. In terms of risk, an Rh-negative woman has about an 85% chance of mating with an Rh-positive man, 60% of whom are heterozygous and 40% of whom are homozygous at the D locus. Assuming that one half of the conceptions of heterozygous men will be Rh D positive, the chance of an Rh-positive man producing an Rh-positive fetus is about 70%. An Rh-negative woman has about a 60% chance of bearing an Rh-positive fetus (0.85 × 0.70). About 10% of pregnancies are Rh incompatible (0.15 × 0.60). However, fewer than 20% of Rh-incompatible pregnancies result in alloimmunization because fetomaternal hemorrhage sufficient to trigger a maternal antibody response does not occur in every case. About 16% of untreated Rh-negative women become alloimmunized in their first Rh-incompatible (ABO-compatible) pregnancy. Half produce detectable anti-D antibody within 6 months of delivery, while the rest have undetectable amounts until early in the next incompatible pregnancy. Overall, even before the introduction of Rh immune globulin prophylaxis, only about 1% of pregnant women had anti-D antibody.

Maternal Immunologic Response

The probability and severity of Rh D alloimmunization varies depending on individual patient characteristics. As many as 30% of Rh-negative individuals appear to

be immunologic “nonresponders” who will not become sensitized. In addition, ABO incompatibility diminishes the risk of alloimmunization to about 1.5% to 2.0% after the delivery of an Rh-positive fetus. This is possibly due to rapid clearance of ABO-incompatible fetal cells from the maternal circulation or alteration or damage to the fetal Rh antigen so that it is no longer immunogenic. The effect is most pronounced if the mother is type O and the father is type A, B, or AB.

Fetomaternal Hemorrhage

Fetal red cells may gain access to the maternal circulation during pregnancy, delivery, and the immediate postpartum period. Fetomaternal hemorrhage in a volume sufficient to cause alloimmunization is most common at delivery, occurring in 15% to 50% of births. The amount of fetal blood entering the maternal circulation is usually less than 0.1 mL but may be greater than 30 mL in 0.2% to 1.0% of cases. Risk factors for excessive postpartum fetomaternal hemorrhage include cesarean delivery, multiple gestations, bleeding placenta previa or abruption, manual removal of the placenta, and intrauterine manipulation. However, the majority of cases of excessive fetomaternal hemorrhage occur after uncomplicated vaginal delivery.

Antepartum events also can result in fetomaternal hemorrhage in sufficient volume to cause alloimmunization in 1% to 2% of cases, even without obvious disruption of the choriodecidual junction (Table 18.1). Fortunately, asymptomatic antepartum sensitization rarely occurs before the third trimester.

TABLE 18.1 Antepartum Events Associated with Fetomaternal Hemorrhage

Event or Procedure	Dosage of Rh D Immune Globulin
First-trimester miscarriage	50 μg
Ectopic pregnancy	50 μg
Threatened first-trimester miscarriage[a]	50 μg
Molar pregnancy	50 μg
Induced second-trimester abortion[b]	300 μg
Fetal death (>10 weeks gestation)[b]	300 μg
Amniocentesis	300 μg
CVS	50 μg
External cephalic version[b]	300 μg
Abruption/bleeding placenta previa[b]	300 μg
Abdominal trauma[b]	300 μg
Vaginal bleeding of unknown origin in second or third trimester[b]	300 μg

CVS, chorionic villus sampling.

[a]The risk of fetomaternal hemorrhage and alloimmunization is uncertain, and the benefit of prophylaxis is uncertain in this situation.

[b]A test for the presence and volume of fetomaternal hemorrhage should be performed to determine the dose of Rh immune globulin.

Rh D Immune Globulin and the Prevention of Rh D Alloimmunization

The prevention of alloimmunization to a specific antigen by the passive administration of antibody is termed *antibody-mediated immune suppression*. In the case of Rh D alloimmunization, a high degree of protection was first achieved by administering anti-D immune globulin (Rh D immune globulin) to Rh-negative male volunteers who had been infused with Rh-positive red cells. It was later established that the amount of Rh D immune globulin necessary to prevent alloimmunization varies according to the size of fetomaternal hemorrhage:

- 300 µg of Rh D immune globulin for exposure to 10 mL of fetal blood
- 20 µg of Rh D immune globulin for exposure to 1 mL of fetal erythrocytes
- 10 µg of Rh D immune globulin for 1 mL of whole fetal blood.

Postpartum Alloimmunization Prophylaxis

The early Rh D alloimmunization prevention trials found that administration of Rh D immune globulin within 72 hours of delivery reduced alloimmunization to less than 1.5% in Rh-negative women, a 7- to 10-fold decrease in alloimmunization compared with untreated controls. Although 300 µg of Rh D immune globulin was used (and continues to be the standard in the United States), it has subsequently been shown that a dose of 100 µg to 150 µg probably is adequate for routine use.

Rh D immune globulin should be given as soon as possible after exposure to Rh D–positive blood (delivery or other event associated with fetomaternal hemorrhage) and *before* the primary immune response is established. While 72 hours is the standard recommendation, it is an artifact from the early studies performed using inmates, during which prison officials would allow visits only at 3-day intervals. Prophylaxis beyond 3 days has never been extensively studied, but if for some reason Rh D immune globulin prophylaxis does not occur within 72 hours after exposure, susceptible Rh D–negative women should be treated up to 14 to 28 days. Further, if the neonatal Rh status is unknown 3 days after delivery, Rh D immune globulin should be given rather than waiting for the neonatal results.

Antepartum Alloimmunization Prophylaxis

During pregnancy, 1% to 2% of susceptible Rh D–negative women become sensitized despite postpartum Rh D immune prophylaxis. Most failures can be attributed to antepartum fetomaternal hemorrhage that often is not clinically apparent. Prophylactic administration of Rh D immune globulin at 28 weeks gestation reduces the incidence of alloimmunization from 1.8% to 0.1%. Initial concerns about potential adverse effects of antenatal Rh D immune globulin prophylaxis have been refuted by

decades of experience with Rh D immune globulin without reports of maternal or fetal complications. Further, routine antepartum prophylaxis is much less expensive than the neonatal intensive care required for severely anemic infants.

Management of the Unsensitized Rh-Negative Pregnant Woman

Prenatal care for Rh D–negative women without evidence of alloimmunization is straightforward (Fig. 18.4). Every woman should have her ABO blood group, Rh type, and antibody screen checked at the first prenatal visit of all pregnancies. If she is Rh-negative or weak D–negative and has no demonstrable antibody, she is a candidate for 300 µg Rh D immune globulin prophylaxis at around 28 weeks gestation and again immediately postpartum. The American Association of Blood Banks recommends obtaining another antibody screen before administration of Rh D immune globulin, including antepartum prophylaxis. The cost and inconvenience of this test must be weighed against documenting the rare case of Rh D sensitization in the first or second trimester in asymptomatic women.

After delivery, another antibody screen is routinely performed. If negative and the newborn is Rh D positive or weak D positive, women should be given 300 µg of Rh D immune globulin. In addition, because a small number of deliveries (0.1% to 1.0%) result in a fetomaternal hemorrhage greater than 30 mL (the largest volume of fetal blood adequately covered by a standard 300 µg dose of Rh D immune globulin), a screen for “excessive” fetomaternal hemorrhage should be performed routinely. Most laboratories use the erythrocyte rosette test, a simple and sensitive method for detecting fetomaternal bleeding. If the rosette test is positive, the volume of fetal red cells in the maternal circulation can be calculated by using the Kleihauer-Betke test. If the volume of fetomaternal hemorrhage is greater than 30 mL whole blood, an additional 10 µg of Rh D immune globulin should be administered for each additional milliliter of fetal blood.

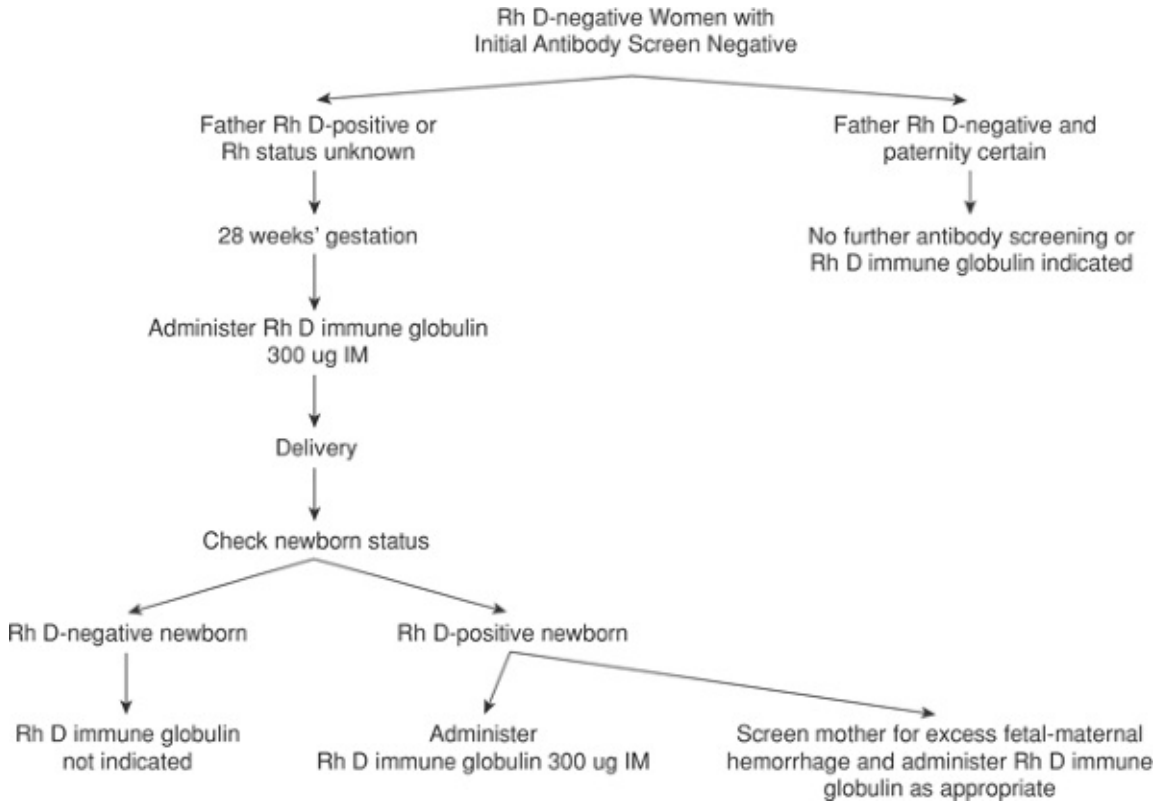

Figure 18.4 Diagram outlining the management of Rh D–negative, nonalloimmunized pregnancy.

A weak D–positive mother who delivers an Rh-positive infant is not at significant risk of Rh alloimmunization, probably because the weak D antigen actually is an incompletely expressed D antigen. Therefore, weak D–positive mothers usually do not require Rh D immune globulin. Occasionally, a woman previously typed as Rh negative is unexpectedly found to be weak D positive during pregnancy or after delivery. In this situation, the clinician should be suspicious that the patient's "new" weak D–positive status actually is due to a large number of Rh D–positive fetal cells in the maternal circulation. Appropriate diagnostic studies should be performed, and if fetomaternal hemorrhage is found, the mother should be treated with Rh D immune globulin.

Several antepartum complications and procedures also may result in fetomaternal hemorrhage (Table 18.1). First-trimester complications, including spontaneous miscarriage, elective abortion, and ectopic abortion, may result in fetomaternal hemorrhage sufficient to result in alloimmunization.

Fetomaternal hemorrhage also has been demonstrated in up to one half of women with threatened first-trimester miscarriage but only occasionally is associated with alloimmunization.

An Rh-negative, unsensitized patient who has antepartum bleeding or suffers an unexplained second- or third-trimester fetal death should receive Rh D immune globulin prophylaxis and be evaluated for the possibility of massive fetomaternal hemorrhage. Several procedures also may result in fetomaternal hemorrhage sufficient to cause

alloimmunization, including chorionic villus sampling (CVS), amniocentesis, and external cephalic version.

For first-trimester pregnancy complications and procedures, 50 µg of Rh D immune globulin is protective. Beyond 12 weeks, a full 300-µg dose is indicated, even in the absence of detectable hemorrhage. In addition, because excessive fetomaternal hemorrhage may occur with any complication or procedures performed in the second and third trimester, an assessment of the volume of fetal whole blood should be performed, and the appropriate amount of Rh D immune globulin should be given. Cases of chronic bleeding present a dilemma with regard to the optimal dose of Rh D immune globulin. An indirect antibody screen may be performed after the initial dose of Rh D immune globulin. A positive result likely indicates that enough antibody was administered (circulating unbound anti–Rh D). A negative result indicates antigen (fetal red blood cells) in excess of the antibody given and more Rh D immune globulin should be administered.

Failure to administer Rh D immune globulin when indicated is responsible for one fourth of new cases of alloimmunization. This oversight may be due to the following:

- Failure to type the patient's blood at the first prenatal visit or to order Rh D immune globulin when indicated
- Error in transmitting the proper blood type to the mother's chart and to the physician
- Error in typing the mother, father, or baby's blood
- Failure to administer Rh D immune globulin when ordered
- Unrecognized fetomaternal hemorrhage during pregnancy
- Inadequate Rh D immune globulin for the volume of fetomaternal hemorrhage
- Patient refusal.

Management of the Rh D-Alloimmunized Pregnancy

Obstetric History

A well-documented obstetric history is essential to guide the management of an alloimmunized pregnancy. Fetal hemolytic disease tends to become more severe in subsequent pregnancies. If hydrops occurred in a previous pregnancy, the next Rh-incompatible fetus has an 80% to 90% chance of becoming hydropic as well. With this in mind, patients are grouped into one of three categories:

- mildly affected fetuses, which can be allowed to remain in utero until they have achieved pulmonary maturation
- moderately to severely affected fetuses, which may need intrauterine treatment (transfusion) and very likely will require delivery prior to pulmonary maturation.

In general, hemolysis and hydrops develop at about the same time or somewhat earlier in subsequent pregnancies; this can be used as a rough guide for timing initial fetal studies

and transfusions. For Rh D alloimmunization, fetal hydrops seldom develops in a first sensitized pregnancy.

Maternal Antibody Titers

Severe erythroblastosis or perinatal death does not occur if antibody levels remain below 1:16. Some centers use an anti-D titer of 1:8 as the critical threshold of concern because of variations in reliability and methods of titration. In general, women with anti-D titers of 1:8 or less and no history of a previously affected infant can be safely followed with anti-D titers every 2 to 4 weeks and serial fetal ultrasound assessment. Those with anti-D titers of 1:16 or greater should be referred for further evaluation regarding possible fetal anemia.

Once the critical anti-D antibody titer has been reached in a sensitized pregnancy, more antibody titers are not useful in the current pregnancy or subsequent pregnancies. Titers may remain stable in up to 80% of severely affected pregnancies. Variability between maternal antibody levels and severity of fetal disease is explained by the fact that antibody concentration is only one factor influencing the degree of anemia. Other factors include antibody subclass and degree of glycosylation, placental transfer of antibody, antigen expression on fetal erythrocytes, functional maturity of the fetal reticuloendothelial system, and the presence of HLA-related antibodies that inhibit fetal erythrocyte destruction.

Determination of the Fetal Antigen Status

The possibility that the fetus is Rh D negative (not at risk) should always be considered. Assuming the male partner is the father of the fetus, a reasonable first step in this process is to determine paternal Rh D–antigen status:

- If the father is Rh D negative, the fetus must also be Rh D negative and no further testing is necessary.

- If the father is Rh D positive but has previously fathered Rh D–negative children, he is heterozygous and the probability that this fetus is Rh D negative is 50%.
- If the father is Rh D positive without other Rh D–negative children, zygosity can be established by using either DNA analysis or Rh antisera. If the father is homozygous, this fetus is Rh D positive and no other testing is necessary.

In the past, determination of fetal blood type required direct analysis of fetal blood obtained by umbilical cord blood sampling with its attendant risks of fetal loss and fetomaternal hemorrhage. The development of DNA tests that use polymerase chain reaction (PCR) has made it possible to determine fetal Rh status from uncultured amniocytes obtained from as little as 2 mL of amniotic fluid or 5 mg of chorionic villi. Though highly accurate, DNA testing for fetal Rh status is equivocal in about 1% of cases, probably because of the presence of gene rearrangements near the Rh D locus that can be missed by standard DNA primers used for PCR.

If the father of the fetus is heterozygous for the D antigen or if his D-antigen status is

unknown, fetal antigen testing from amniocytes has become routine at most centers in the United States. Alloimmunized women having CVS or second-trimester amniocentesis for other unrelated conditions can have fetal antigen typing done in association with these procedures. If the DNA test indicates an Rh D–negative fetus, the small likelihood of misdiagnosis should be discussed and the patients offered standard antenatal surveillance.

Amniotic Fluid Optical Density Analysis

Assessment of amniotic fluid in Rh D alloimmunization is based on the original observations that spectrophotometric determinations of amniotic fluid bilirubin correlated with the severity of fetal hemolysis. Bilirubin, a by-product of fetal hemolysis, is excreted into the amniotic fluid through fetal pulmonary and tracheal secretions and by diffusion across the fetal membranes and the umbilical cord. Using a semilogarithmic plot, the curve of optical density of normal amniotic fluid is approximately linear between wavelengths of 525 and 375 nm. Bilirubin causes a shift in the spectrophotometric density, with a peak at a wavelength of 450 nm. The amount of shift in optical density from linearity at 450 nm (the ΔOD450) is used to estimate the degree of fetal red cell hemolysis (Fig. 18.5).

Amniotic fluid ΔOD450 values can be correlated with newborn outcome by dividing a semilogarithmic graph of gestational age versus ΔOD450 into three zones (Fig. 18.6), according to the work of Liley. Unaffected fetuses and those with mild anemia had ΔOD450 values in zone I (the lowest zone), while severely affected fetuses had ΔOD450 values in zone III (the highest zone). Fetuses with zone II values (the middle zone) had disease ranging from mild to severe, indicated primarily by the trend of the determinations of amniotic fluid bilirubin. Because there is a tendency for amniotic fluid bilirubin to decrease as pregnancy advances, the boundaries of the zones slope downward as gestational age increases.

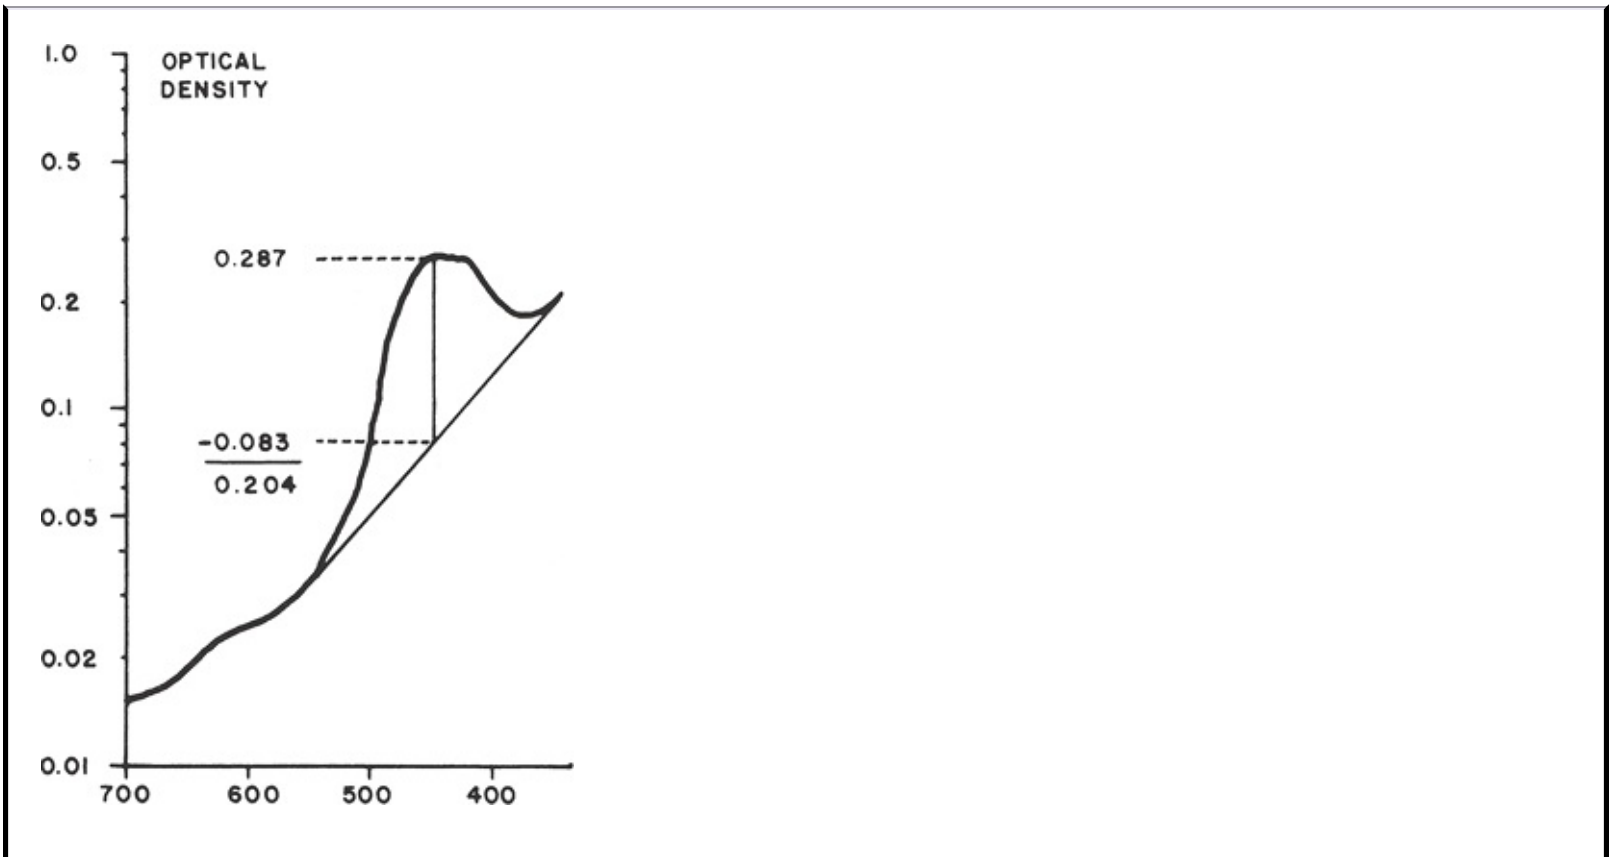

Figure 18.5 Spectrophotometric scan of amniotic fluid containing bilirubin. An arbitrary line (*thick line*) has been drawn to show where the scan would have been traced if there had been no increase in bilirubin. The peak absorption of bilirubin occurs at 450 mm. The difference between the peak and the arbitrary line equals 0.204.

Although the introduction of the method of fetal analysis substantially reduced perinatal mortality, the spectral

analysis of amniotic fluid is now primarily of historical interest. The current trend is management of alloimmunized pregnancy by primarily using fetal middle cerebral artery (MCA) Doppler imaging to assess for fetal anemia. However, amniotic fluid ΔOD450 measurement is sometimes performed in order to confirm or refute concern about fetal anemia in confusing clinical situations, such as an elevated MCA Doppler measurement after 34 to 35 weeks gestation.

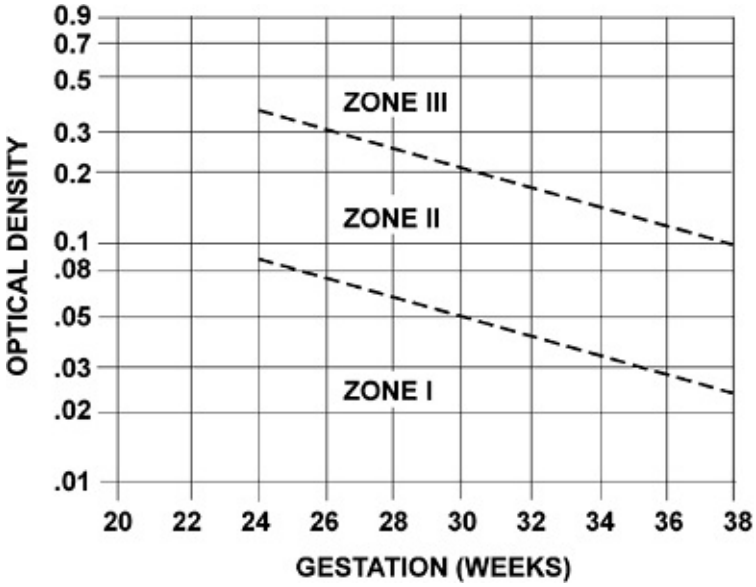

Figure 18.6 This modified Liley graph allows plotting of ΔOD450 measurements against gestational age, dividing them into zones of fetal risk for anemia and transfusion.

Ultrasound and Doppler Studies

Ultrasonographic examination of the fetus has become an extremely important adjunct in the management of the Rh D alloimmunized pregnancy, primarily as a guide for amniocentesis, cordocentesis, and intrauterine transfusion (IUT). Sonographic fetal findings also have been studied in an effort to identify those with severe anemia and reduce the need for invasive procedures. However, other than identifying frank hydrops, ultrasound is not sufficiently reliable in distinguishing mild from severe hemolytic disease.

Doppler flow velocity waveforms of fetal cardiac output and red cell flow in numerous fetal blood vessels have been extensively investigated as noninvasive predictors of fetal anemia. Doppler flow waveforms of the fetal MCA have been established as the most useful in the management of Rh D alloimmunized pregnancies. Several investigators have reported that fetal MCA peak systolic velocity waveforms consistently identify fetuses with moderate or severe anemia when velocities are greater than 1.5 times the median of values derived from normal controls (Fig. 18.7), with a sensitivity of 100% and a false-positive rate of 12%. Though an element of controversy persists, fetal MCA peak systolic velocity also can be used to assess fetuses that have undergone IUT. The major limitation to this methodology is a higher false-positive rate after 34 to 35 weeks gestation—that is, a fetus with mild to moderate anemia is identified as more severely anemic by MCA peak systolic velocity assessment. As long as this caveat is taken into account, fetal MCA peak systolic velocity measurements may be used to monitor pregnancies complicated by Rh (and other erythrocyte) alloimmunzation.

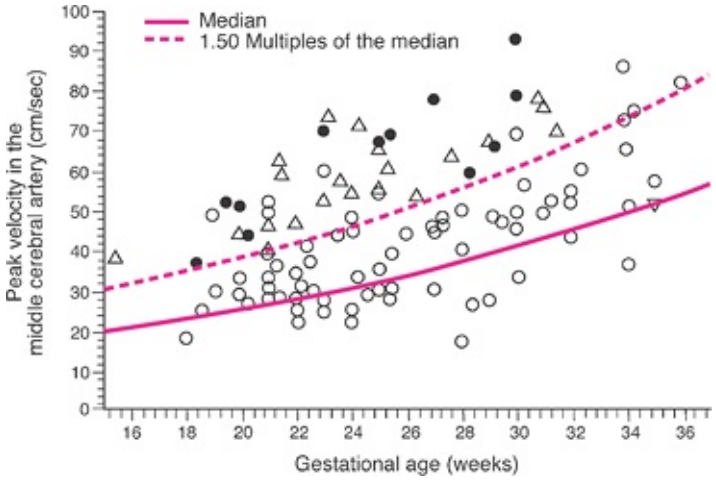

Figure 18.7 Peak velocity of systolic blood flow in the MCA in 111 fetuses at risk of anemia due to maternal red cell alloimmunization. *Open circles* indicate fetuses with either no anemia or mild anemia (0.65 multiples of the median hemoglobin concentration). *Triangles* indicate fetuses with moderate or severe anemia (<0.65 multiples of the median hemoglobin concentration). The *solid circles* indicate the fetuses with hydrops. The *solid curve* indicates the median peak systolic velocity in the MCA, and the *dotted curve* indicates 1.5 multiples of the median. (From Mari G, Deter RL, Carpenter RL, et al. Noninvasive diagnosis by Doppler ultrasonography of fetal anemia due to maternal red-cell alloimmunization. *N Engl J Med* 2000;342:9–14.)

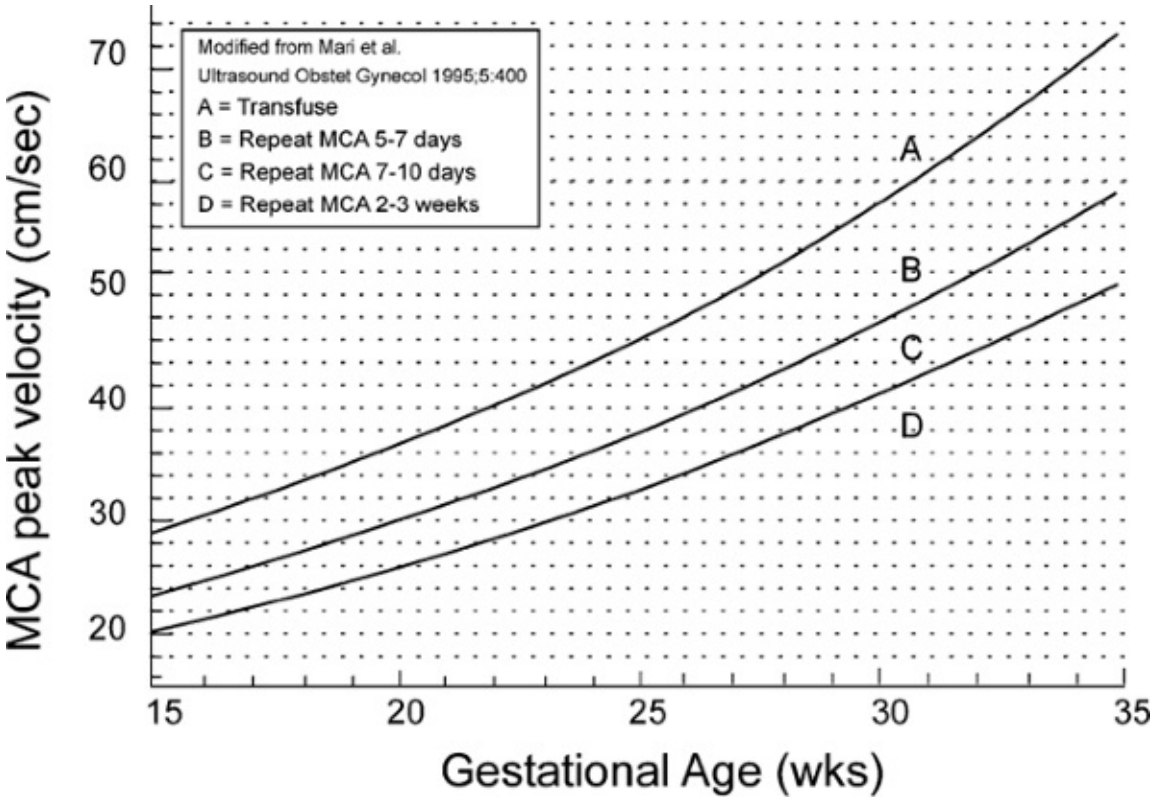

Figure 18.8 Fetal MCA peak velocity as a function of gestational age. This graph is used to manage red cell alloimmunized pregnancies as indicated in the figure. (MCA, middle cerebral artery.) (Modified from Mari G, Andrignolo A, Abuhamad AZ, et al. Diagnosis of fetal anemia with Doppler ultrasound in the pregnancy complicated by maternal blood group immunization. *Ultrasound Obstet Gynecol* 1995;5:400–405.)

The graphic tool used in fetal MCA peak systolic velocity measurements at the University of Utah is shown in Figure 18.8 and is based on the work of Mari and colleagues. As in the Liley graph, results are plotted in one of several zones, with established guidelines as to when to repeat the assessment and when to move to direct fetal blood analysis and transfusion.

Fetal Blood Analysis

Ultrasound-guided umbilical cord sampling (cordocentesis) should be performed to assess the degree of fetal anemia in severely alloimmunized pregnancies. The procedure is successful in greater than 95% of cases, with fetal loss rates between 0.5% and 2.0% per procedure. Fetomaternal bleeding may occur at the time of cordocentesis, resulting in worsened maternal alloimmunization. Traversing an anterior placenta with the sampling needle is thought to result in increased sensitization in as many as 50% of cases. Other complications also have been described, including acute refractory fetal distress, umbilical cord hematoma, amnionitis with maternal adult respiratory distress syndrome, and placental abruption.

The primary role of cordocentesis in the management of alloimmunization is assessment of the fetus known to be

antigen positive and suspected of having moderate to severe anemia. Because of the technical difficulty and increased hazard (both immediate and remote) associated with the procedure, umbilical cord blood sampling should be used with caution and performed only by properly trained personnel.

Intrauterine Transfusion in Rh Alloimmunized Pregnancies

Determining the Need for Transfusion

About one half of susceptible infants of Rh D alloimmunized pregnancies have mild to moderate hemolytic disease and do not require IUT or extensive extrauterine therapy. Reasonable management for these patients includes serial ultrasound examinations of the fetus every 2 to 4 weeks from 15 to 20 weeks gestation until delivery, along with serial fetal MCA peak systolic velocity determinations to determine the degree of fetal anemia (Fig. 18.8). A history of severe alloimmunization with early hemolysis and fetal hydrops is predictive of a similarly bad outcome in the current pregnancy. Indeed, if ultrasound reveals any evidence of fetal hydrops, severe fetal anemia (hematocrit <15%) can be assumed, and cordocentesis and IUT should be arranged immediately.

The goals of IUT are to correct fetal anemia in an effort to improve fetal oxygenation and to reduce extramedullary hematopoietic demand, which in turn should result in a fall in portal venous pressure and improved hepatic function.

Intrauterine Intravascular Transfusion

Historically, severe fetal anemia was managed with intraperitoneal transfusion. More recently, direct access to the fetal circulation via the umbilical cord (or hepatic venous circulation) is used and offers some major advantages. The initial fetal hematocrit can be measured, allowing a more precise calculation of the volume of blood required for transfusion. In some cases, the fetus will have a higher hematocrit than expected, and transfusion can be delayed. A post-transfusion hematocrit also can be obtained to determine whether the transfusion was adequate and when the next one should be scheduled. Further, transfusion into the fetal vascular system ensures complete uptake with a more rapid correction of fetal anemia, which is especially important for hydropic fetuses that often do not adequately absorb intraperitoneally transfused erythrocytes.

Disadvantages of intravascular fetal transfusion include the rare possibility of volume overload in the compromised fetus, procedure-related complications, and the risk of increasing the severity of maternal sensitization due to fetomaternal hemorrhage. The

perinatal survival of nonhydropic fetuses exceeds 90%, and approximately 75% of hydropic fetuses survive with intravascular transfusion (Table 18.2).

Several different methods of estimating the volume of blood needed for transfusion have been reported, with a goal of keeping the post-transfusion hematocrit at 40% to 45%. Following intravascular transfusion, the decline in the donor hematocrit is most dependent on the life span of the donor erythrocytes, the rate of fetal growth (and increased vascular volume), and the ratio of fetal-to-donor erythrocytes (since the fetal erythrocytes are subject to continued hemolysis). The latter is most influential between the first and second intravascular transfusions, when the ratio of fetal cells to donor cells is greatest. On average, the decline in the fetal hematocrit following the first transfusion is about

1.5% per day; following subsequent transfusions, the decline in fetal hematocrit is about 1.0% to 2.0% per day. Follow-up intravascular transfusions are scheduled to keep the fetal hematocrit above 20% to 25%.

Morbidity and mortality associated with intravascular transfusion are related to the technique of vascular access and transfusion. Fetal bradycardia is the most common problem, occurring in 8% to 12% of cases, although only rarely requires immediate delivery. Postprocedure infection and premature rupture of the membranes also have been reported. Overall, intravascular transfusion in experienced hands has a procedure-related complication rate of around 10% to 15% and a perinatal mortality rate of 1% to 5%.

Intraperitoneal Intrauterine Transfusion

Intraperitoneal transfusions were the mainstay of IUT therapy until the mid 1980s. Placement of erythrocytes in the fetal peritoneal cavity was found to reduce fetal anemia by gradual uptake of transfused red cells into the fetal circulatory system via subdiaphragmatic lymphatics. Success depended on the gestational age and the severity of fetal disease, particularly with regard to fetal hydrops (Table 18.2). In this day and age of intravascular transfusion, intraperitoneal transfusion occasionally is used after technical difficulties leading to failed intravascular transfusion and in severely alloimmunized pregnancies with severe fetal anemia prior to 18 to 20 weeks gestation (when intravascular transfusion may be difficult due to the small caliber of the umbilical vein).

Inadvertent transfusion into the bowel, liver, abdominal wall, and retroperitoneum may occur. Infection, premature rupture of the membranes, refractory preterm labor, and fetal distress necessitating immediate delivery are potential hazards of intraperitoneal IUT. The procedure should be performed only in well-equipped centers with appropriately trained personnel.

Other Therapies

A number of noninvasive alternatives to IUT have been investigated for the treatment of fetal hemolysis. Most have been aimed at modifying the maternal immune response. High-dose intravenous immunoglobulin (IVIG) has been used to treat women with severe Rh alloimmunization refractory to traditional treatment. Experience is limited to case reports

and small case series, all with different dosing regimens. The mechanism of action is uncertain but is most likely at the maternal or placental level since direct fetal administration is not effective. Plasmapheresis also has been used in refractory Rh alloimmunization and has been associated with a transient reduction in the anti-D titer during or immediately after treatment. However, no long-term, clinically significant reduction in antibody titer has been achieved. These modalities typically are used as an adjunctive therapy to transfusion in extremely severe cases resulting in hydrops in the early second trimester when transfusion is technically difficult.

Timing of Delivery

The timing of delivery should be based on individual case circumstances, including obstetric history and severity of Rh D alloimmunization. In mildly affected pregnancies, induction of labor at 37 to 38 weeks gestation is reasonable, unless fetal pulmonary maturity is documented earlier by amniocentesis. In severely sensitized pregnancies, the risks of continued cord blood sampling and transfusions must be weighed against the potential neonatal morbidity and mortality associated with preterm delivery. This has traditionally led to scheduling the last procedures at around 30 to 32 weeks gestation, with delivery between 32 to 34 weeks after maternal steroid administration to enhance fetal pulmonary maturity. In an effort to limit neonatal morbidity, IUT can be continued up to 36 weeks gestation with delivery between 37 and 38 weeks. At the University of Utah, last procedure generally is timed so that delivery can be carried out at about 36 or 37 weeks. Using this approach, neonatal survival in the nursery approaches 100%, and long-term morbidity from prematurity is exceedingly low.

Alloimmunization Caused by Minor Antigens

The reduction in Rh disease brought about by Rh D immune globulin prophylaxis has led to a relative increase in the number of cases of alloimmunization caused by other red blood cell surface antigens, known as “minor,” “atypical,” or “irregular” antigens (Table 18.3). Overall, alloimmunization due to minor antigens occurs in about 1.5% to 2.5% of obstetric patients, though the frequency depends on ethnicity of the population under study. Most cases result from incompatible blood transfusion because blood banks do not routinely assess donor–recipient compatibility for antigens other than ABO and Rh D. Some of the most common antibodies (i.e., anti-Lea, anti-Leb, and anti-I) do not cause fetal or neonatal hemolysis. However, other commonly encountered atypical antibodies (i.e., anti-E, anti-Kell, anti-c, anti–c + E, and anti-Fya [Duffy A]) may cause erythroblastosis fetalis and hydrops.

In general, management of pregnancies complicated by alloimmunization to one of the minor red cell antigens is similar to management of pregnancies complicated by Rh D alloimmunization. An exception to this rule is alloimmunization to the Kell antigen, which requires special vigilance because of its unpredictability and potential for severe fetal anemia, hydrops, and death. Its virulence may be related to its ability to suppress fetal erythropoiesis and activate the complement cascade in addition to hemolysis. Fortunately, only 9.0% of whites are positive for the Kell

antigen, and only 0.2% of pregnancies are complicated by Kell alloimmunization.

-, not a proven cause of hemolytic disease of the newborn; +, mild expectant, no further diagnostic testing or intervention is necess for Fetal Anemia, amniocentesis with amniotic bilirubin studies m *Source:* Adapted from Weinstein L. Irregular antibodies causing he newborn a continuing problem. *Clin Obstet: Gynecol* 1982;25;321.

Compared with Rh D alloimmunization, maternal antibody titers and amniotic fluid ΔOD450 values perform less well in predicting the degree of fetal hemolysis in cases of Kell alloimmunization. Severe anemia seems to occur with lower antibody titers and in zones of the Liley curve rather than with Rh D alloimmunization. However, MCA peak systolic velocity assessment appears effective in Kell alloimmunization and may be used reliably between 15 and 20 weeks gestation. In selected cases with particularly poor histories, some authorities suggest routine umbilical cord blood sampling as early as 20 weeks gestation if the father is Kell-positive or of uncertain status.

ABO Incompatibility

A comparison of Rh and ABO incompatibility is important because they are the most frequent causes of immune hemolytic disease in the neonatal period. In about 20% to 25% of pregnancies, ABO incompatibility exists between mother and infant, but a clinically recognizable hemolytic process in the infant occurs in only 10%. ABO hemolytic disease affects the firstborn child in about 50% of cases, and it is not uncommon for multiple siblings to be affected with comparable severity.

The pathophysiology involves the transplacental passage of maternal antibody and its interaction with fetal or neonatal red blood cell antigens, yielding erythrocyte destruction, variable anemia, and hyperbilirubinemia. Clinically, ABO hemolytic problems are confined almost exclusively to the A (specifically A1 rather than A2) or B infants of group O mothers. Anti-A and anti-B “natural” antibodies produced early in life by group A or B individuals are predominantly IgM. In contrast, group O individuals produce anti-A or anti-B that is predominantly IgG and capable of crossing the placenta. Yet, for reasons not completely understood, these antibodies seldom cause harm during pregnancy. There is no relationship between the antibody titer and the severity of hemolytic disease. The discordance between the high frequency of ABO-incompatible pregnancies and the low frequency of hemolytic disease as well as the broad spectrum of the severity has been attributed to such factors as immature, weak, nonspecific, or altered antigens on the fetal red blood cell; absorption of the antibodies by ABO antigens present in all body tissues; and the presence of soluble blood group substances in fetal plasma and tissue fluids that can neutralize maternal antibody. No single test exists that can forewarn the physician of impending ABO hemolytic disease.

Because this problem does not occur until after birth, amniocentesis and preterm induction of labor are not justified. The most common manifestations of ABO incompatibility in the neonate are early-onset jaundice (i.e., within 24 hours) and a variable elevation of the indirect bilirubin fraction. In contrast to Rh disease, kernicterus and anemia are rare. The cornerstones of management of ABO incompatibility are bilirubin surveillance, phototherapy (required in about 10% of infants); and, occasionally, exchange transfusion.

Platelet Alloimmunization

Like erythrocytes, platelets have specific surface antigens that sometimes result in maternal alloimmunization when there is an incompatibility between the fetus and the mother. In a situation analogous to Rh disease, fetal or neonatal alloimmune thrombocytopenia (NAIT) results from maternal production of antiplatelet antibodies followed by placental transfer of antiplatelet antibodies and subsequent platelet destruction. The maternal platelet count is normal, but fetal–neonatal thrombocytopenia is often profound.

Several different biallelic antigen systems may cause platelet alloimmunization, but most cases (75%) are due to sensitization to the HPA-1a (Pl^{A1}) antigen. Approximately 2.0% of whites, 0.4% of blacks, and less than 0.1% of Asians are negative for HPA-1a and thus are at risk for NAIT. Though fetomaternal incompatibility to platelet antigens is relatively common, only about 1:1,000 to 1:2,000 births are complicated by NAIT, probably because maternal HLA-antigen class II type influences susceptibility. Clinically, about 90% of affected newborns have diffuse petechiae, and 9% to 12% suffer intracranial bleeding with a neonatal mortality of 5% to 13%. Fetal thrombocytopenia has been detected as early as 20 weeks gestation, with 50% of intracranial hemorrhages (ICH) diagnosed at the time of prenatal ultrasound.

Unlike erythrocyte alloimmunization, platelet alloimmunization often occurs during the first pregnancy, with diagnosis after delivery of severely affected firstborn children. Maternal platelet antibody titers are not beneficial in predicting the severity of NAIT. Routine testing for HPA-1a antibody status during pregnancy has been proposed but probably is not justified because of the wide variation in the clinical expression of maternal–fetal platelet incompatibility and because 25% of cases of NAIT are due to antigens other than HPA-1a. The incidence of recurrent NAIT following delivery of an affected newborn is approximately 90% to 95%, and thrombocytopenia generally is equal or worse in severity. It is 100% in cases of HPA-1a alloimunization if the fetus is HPA-1a positive.

Obstetric Management

Umbilical cord blood sampling and direct measurement of fetal platelet count is the only method that accurately predicts disease severity. However, serial cordocentesis and

platelet transfusion are not recommended because of the high risk of procedure-related fetal loss. Based on the effectiveness of IVIG treatment for neonates with NAIT, antenatal protocols using maternally administered high-dose IVIG have been developed and widely

accepted. Some centers also add prednisone if the response to IVIG treatment is not adequate. The mechanism of IVIG treatment probably involves Fc-receptor saturation in the placenta and blockage of antibody transfer to the fetus. Direct fetal administration has not been successful. The use of high-dose IVIG in pregnancies at risk for NAIT is not without risk. Treatment with IVIG is expensive (over $2,000 per weekly infusion), occasional shortages have occurred, and there have been sporadic reports of acute hepatitis C associated with IVIG use.

The management of pregnancies at risk for NAIT is directed at prevention of hemorrhage in the fetus and newborn. As in erythrocyte alloimmunization, the paternal antigen status can be determined by using DNA diagnostic techniques. If the father is homozygous, the fetus is at risk and pregnancy management should proceed accordingly. If the father is heterozygous for the particular antigen, amniocentesis at 16 to 20 weeks can be performed to assess fetal antigen status. If the fetus is antigen negative, there is no significant risk of thrombocytopenia or ICH, and no fetal blood sampling is performed.

If the fetus is antigen positive, optimal management is controversial. Berkowitz and colleagues have performed several randomized controlled trials in cases of HPA-1a alloimmunization to determine the optimal therapy. They advise stratifying patients into groups based on their level of risk for NAIT. Women at “standard risk” for NAIT based on no prior infants with ICH may be treated empirically with either 2.0 g/kg per week of IVIG alone or 1 g/kg per week of IVIG plus 0.5 mg/kg per day of prednisone beginning at 20 weeks gestation. Cordocentesis may be performed at 32 weeks gestation, and if the platelet count is <50,000, salvage therapy with either steroids or a higher dose of IVIG is added. High-risk women, based on having a prior infant with ICH ex utero (or a fetal platelet count of <20,000, if determined), should be treated with 1 g/kg per week of IVIG and 1 mg/kg per day of prednisone. Salvage therapy (if fetal platelet count <50,000 cells/μL) consists of increasing the dose of IVIG. These regimens work well for most women at standard or high risk. Very high–risk women (prior infants with in utero ICH) may be treated with IVIG 1 or 2 g/kg per week beginning at 12 weeks gestation. Therapy is intensified (increased IVIG and/or adding steroids) if there is severe thrombocytopenia at 20 weeks. All but 1 of 15 very high–risk women did well in this protocol. One had ICH at 19 weeks gestation. Whether or not cordocentesis should be performed is controversial. The risk of the procedure (which is increased in cases of severe thrombocytopenia) must be weighed against the need to document NAIT and determine the need for salvage therapy. A reasonable approach is to start empiric therapy in cases of HPA-1a sensitization with an HPA-1a–positive fetus and assess the response at 26 to 32 weeks gestation when the risk of complications of cordocentesis lessens.

Although of unproven benefit, cesarean delivery is advised in cases of NAIT when the platelet count is <50,000 at term or is unknown. This may decrease the risk of intrapartum ICH in affected infants. A platelet count >100,000 cells/μL at 32 weeks gestation is likely evidence that a trial of labor is an appropriate option. In all cases at risk for NAIT, maternal platelets should be available for transfusion after delivery, regardless of the antenatal treatment or previously obtained fetal platelet counts.

NAIT associated with antigens other than HPA-1a is less well studied. Thrombocytopenia

associated with anti–HPA-1a is more severe than NAIT caused by other antigen incompatibilities. Thus, data regarding HPA-1a incompatibility cannot be generalized to other causes of NAIT. Cordocentesis to document thrombocytopenia may be useful in this subset of women.

Maternal Thrombocytopenia

Maternal thrombocytopenia is one of the most common hematologic disorders in pregnancy. Most cases of maternal thrombocytopenia are immunologically mediated, though thrombocytopenia also may be part of other systemic illnesses as well (Table 18.4). Normal values for platelets are unchanged during pregnancy; the mean platelet count for healthy pregnant women is 246,000 cells/μL. Platelet

counts <150,000 cells/μL occur in up to 7.6% of pregnant women, and counts less than 100,000 cells/μL occur in less than 1.0%. Thrombocytopenia may be categorized into mild (100,000 to 150,000 cells/μL), moderate (50,000 to 100,000 cells/μL), and severe (<50,000 cells/μL). Clinically significant bleeding usually does not occur until platelet counts drop below 10,000 cells/μL. Excessive bleeding associated with trauma or surgery is uncommon unless the patient's platelet count is less than 50,000 per milliliter.

TABLE 18.4 Causes of Thrombocytopenia in Pregnancy

Gestational thrombocytopenia
Pregnancy-induced hypertension
HELLP syndrome
Pseudothrombocytopenia (laboratory artifact)
HIV infection
Immune thrombocytopenic purpura
SLE
APS
Hypersplenism
Disseminated intravascular coagulation
Thrombotic thrombocytopenic purpura
Hemolytic uremic syndrome
Congenital thrombocytopenias
Medications (heparin, quinine, quinidine, zidovudine, sulfonamides)

HELLP, hemolysis, elevated liver enzymes, low platelet count; SLE, systemic lupus erythematosus; APS, antiphospholipid syndrome.

Gestational Thrombocytopenia

Gestational thrombocytopenia, also known as “essential thrombocytopenia” or “incidental thrombocytopenia,” is the most common type of mild thrombocytopenia in pregnancy. It is often diagnosed at the time of routine prenatal screening. Characteristics of gestational thrombocytopenia include the following:

- Thrombocytopenia is mild, usually greater than 70,000 cells/μL.
- Women with thrombocytopenia are asymptomatic with no history of bleeding diathesis.
- There is no history of thrombocytopenia, except in prior pregnancies.
- Platelet counts return to normal 1 to 2 weeks following delivery.
- There are no serious maternal or fetal consequences.

The mechanism of gestational thrombocytopenia is unknown but may involve accelerated platelet consumption. Many women with gestational thrombocytopenia have antiplatelet antibodies, but their presence is probably meaningless. Except for the addition of serial platelets counts (to exclude idiopathic thrombocytopenic purpura [ITP]), no change in prenatal care is necessary.

Autoimmune Thrombocytopenia

Autoimmune thrombocytopenia (ATP), also termed *idiopathic thrombocytopenic purpura*, is the most common autoimmune bleeding disorder encountered during pregnancy, affecting between 1 in 1,000 to 10,000 pregnancies. While acute ATP is a self-limited disorder of childhood, chronic ATP typically presents in the second or third decade of life with a female-to-male ratio of 3:1. Autoimmune thrombocytopenia is characterized by production of IgG antibodies directed against platelet membrane glycoproteins. The IgG antiplatelet antibodies bind to platelets, rendering them more susceptible to sequestration and premature destruction in the reticuloendothelial system. Thrombocytopenia occurs when the rate of destruction exceeds the ability of the bone marrow to produce new platelets. Though other sites also are involved, most antibody production and platelet destruction occur in the spleen.

The diagnosis of ATP should be based on clinical findings, after other causes of thrombocytopenia have been excluded. Characteristics include:

- Thrombocytopenia (platelet count <100,000 cells/μL) is present before and after pregnancy, with or without megathrombocytes on the peripheral smear.
- Bone marrow aspirates reveal normal or increased numbers of megakaryocytes.
- Patients usually but not uniformly have a history of bleeding, easy bruising, petechiae, menorrhagia, or other bleeding problems.
- Splenomegaly is absent.

The course of ATP is not substantially influenced by pregnancy. However, ATP may lead to

complications in pregnancy, the most serious of which is maternal hemorrhage around the time of delivery. No maternal deaths from ATP in pregnancy have been recorded since the early 1980s, but peripartum bleeding may result in serious morbidity. Because the placenta selectively transports maternal IgG antiplatelet antibodies into the fetal circulation, fetal thrombocytopenia may occur as well, sometimes leading to purpura, ecchymosis, or melena. Intracranial hemorrhage is rarely reported (less than 1% of cases) and may be unrelated to the mode of delivery.

Many women with ATP have elevated levels of platelet-associated antibodies and sometimes circulating antiplatelet antibodies. Assays for these antibodies are available commercially but should not be performed routinely because they are nonspecific, poorly standardized, and subject to a large degree of interlaboratory variation. Furthermore, levels of antiplatelet antibodies do not correlate well with the degree of fetal thrombocytopenia.

Treatment

Treatment of pregnant women with ATP is aimed at preventing bleeding by maintenance of the platelet count above 20,000 cells/μL in the antepartum period and over 50,000 cells/μL for delivery.

Glucocorticoids

Glucocorticoid drugs are the cornerstones of therapy for ATP in pregnancy. Prednisone (1 to 2 mg/kg per day in divided doses) for 2 to 3 weeks is the most typical regimen. An increase in platelet count to more than 50,000 cells/μL, accompanied by a decrease in clinical bleeding, is usually achieved within 21 days. More than 70% of patients have some response, and complete remission occurs in up to 25%. The prednisone dose is tapered by 10% to 20% decrements at 2-week intervals to a dose that maintains the platelet count above 50,000 cells/μL. Dexamethasone and betamethasone also cause an increase in platelet count, but both readily cross the placenta and have harmful fetal effects. The side effects of glucocorticoids in pregnancy include steroid-induced moon facies, gestational diabetes mellitus, psychosis, adrenocortical

---

insufficiency, osteoporosis, aseptic necrosis, hypertension, and uteroplacental insufficiency.

Intravenous Immunoglobulin

Given at high doses (i.e., 400 mg/kg per day for 5 days), IVIG usually induces a peak in platelet count within 7 to 9 days. More than 80% of patients achieve a platelet count greater than 50,000 cells/μL, and the response lasts for more than 30 days in 30% of patients. Only 2 to 3 days of IVIG therapy may be needed in some patients, and doses greater than 800 mg or 1 g/kg may suffice as a single or double infusion. Although expensive, IVIG therapy initiated 1 to 2 weeks before delivery or surgery may be useful in some obstetric patients who must undergo operative procedures or who develop bleeding problems and require emergency treatment. The exact mechanism of action of IVIG is unclear but may be related to decreased antiplatelet antibody production, interference

with antibody attachment to platelets, inhibition of macrophage receptor-mediated immune complex clearance, or interference with platelet receptor mechanisms in the reticuloendothelial system.

IgG is selectively transported across the placenta, and the amount transferred increases with gestational age and dose so that after 32 weeks gestation, maternally infused IgG sometimes has a beneficial effect on the fetal platelet count. No cases of HIV transmission have been reported with the use of IVIG, but adverse effects include thrombosis, alopecia, liver function disturbances, transient neutropenia, chills, nausea, flushing, tightness of the chest, wheezing, and anaphylactic reactions in patients with immunoglobulin A (IgA) antibodies.

Splenectomy

Splenectomy serves to remove the site of destruction of damaged platelets as well as the major source of antibody production. During pregnancy, it is used only for patients with ATP who are refractory to or cannot tolerate glucocorticoids and IVIG. A complete remission is obtained in 80% of patients. The postsplenectomy platelet count increases rapidly and often is normal within 1 to 2 weeks. The surgery is associated with a modest risk of spontaneous abortion or preterm labor and technically is more difficult late in gestation. If splenectomy is unavoidable, it is best performed in the second trimester; it has also been combined safely with cesarean section at term. Splenectomy does not always protect the fetus from thrombocytopenia, because antibodies to platelets also are produced in other lymphoid tissues.

Platelet Transfusions

Platelet transfusions are used only as a temporizing measure to control life-threatening hemorrhage or to prepare a patient for splenectomy or cesarean section. The survival of transfused platelets is decreased in patients with ATP, because antiplatelet antibodies also bind to donor platelets. In addition, patients with ATP do not respond as well as normal individuals to platelet transfusions, but 6 to 10 U is usually sufficient to temporarily control hemostasis.

Rh D Immune Globulin

Rh D immune globulin (anti–Rh D) has been used successfully to treat ATP in Rh-positive individuals. Indeed, immune globulin against Rh D (75 μg/kg of maternal weight) works as well as corticosteroids at initial presentation. It is more costly than steroids but has fewer side effects. There are concerns about the use of Rh D immune globulin during pregnancy because of a theoretical risk of fetal erythrocyte destruction. However, the antibody likely would bind maternal red blood cells before reaching the fetal circulation. Cases of successful and safe use of Rh D immune globulin during pregnancy (in Rh D–positive women) have been reported.

Other Treatments

Other agents have been used with some success in patients who are refractory to glucocorticoids, IVIG, and splenectomy. Those used most commonly, such as azathioprine, cyclophosphamide, Vinca alkaloids, and danazol, are to be avoided in pregnancy because of their toxicity and potential adverse effects on the fetus. Plasmapheresis has been tried as well, but the results of this treatment are variable.

Obstetric Management of Autoimmune Thrombocytopenia

Management of pregnancies complicated by ATP is controversial largely because of uncertainties regarding the actual risk of fetal thrombocytopenia. In the past, cesarean delivery was advocated in all women with ATP because of anecdotal reports of intracranial hemorrhage associated with vaginal delivery. Prompted by the fact that clinically significant bleeding is extremely unlikely in fetuses with platelet counts >50,000 cells/μL, some authorities recommended cesarean delivery only if the fetal platelet count was <50,000 cells/μL. However, this required measurement of the fetal platelet count. Fetal scalp sampling during labor was the first and most commonly performed method of obtaining the fetal platelet count, allowing 80% of fetuses with acceptable platelet counts to be safely delivered vaginally. Unfortunately, the procedure is technically difficult to perform in early labor, and falsely low platelets were sometimes obtained. Cordocentesis often replaced fetal scalp sampling because platelet counts were extremely accurate and the procedure could be performed before the onset of labor. However, cordocentesis is expensive and unavailable in centers without appropriate expertise and equipment. It also has several potentially serious complications, including fetal bradycardia, hemorrhage at the puncture site, and cord hematoma.

Both fetal scalp sampling and cordocentesis might be useful if there were any evidence that cesarean delivery reliably prevents intracranial hemorrhage in thrombocytopenic fetuses. However, it appears that early reports of ATP in pregnancy overestimated the risk of severe fetal thrombocytopenia and intracranial hemorrhage associated with vaginal delivery. In a recent, large, population-based study of almost 16,000 pregnancies, no infant born to a mother with ATP suffered intracranial hemorrhage, regardless of the route of delivery.

Because it appears that fetal scalp sampling, cordocentesis, and cesarean delivery contribute to cost and morbidity without preventing intracranial hemorrhage, many obstetricians have abandoned antenatal measurement of fetal platelet counts and reserve cesarean delivery for the usual obstetric indications.

Mothers with ATP do not require substantial alterations in prenatal care. Serial platelet counts should be obtained during the pregnancy. If the platelet count is <50,000 cells/μL in the weeks preceding delivery, patients with ATP should be treated with glucocorticoids or IVIG. Women requiring chronic glucocorticoid therapy during pregnancy should be carefully monitored for the development of gestational diabetes and should have serial ultrasounds to assess fetal growth. Women with prior splenectomy should be monitored for the development of infection. Delivery is best accomplished in a setting in which platelets, fresh frozen plasma, and IVIG are available. A neonatologist or pediatrician who is familiar

with the disorder should be present to promptly treat any hemorrhagic complications in the neonate. In the puerperium, salicylates and nonsteroidal anti-inflammatory drugs (NSAIDs) should be avoided. Though breast-feeding may theoretically induce neonatal thrombocytopenia because of the passage of antiplatelet antibodies in the colostrum, it is considered safe and reasonable by most pediatricians.

Other Causes of Thrombocytopenia in Pregnancy

Other than ATP, the most common serious conditions associated with maternal thrombocytopenia late in pregnancy are preeclampsia and HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count). Other conditions that can result in maternal thrombocytopenia at any gestational age include acute HIV infection, systemic lupus erythematosus (SLE), APS, sepsis, cocaine abuse, thrombotic thrombocytopenic purpura, transfusion reaction, blood dyscrasias, or certain medications (Table 18.4).

Pseudothrombocytopenia can result from laboratory artifacts such as platelet clumping induced by ethylenediaminetetraacetic acid (EDTA) in the collection tube, blood clotting related to techniques of blood withdrawal, and an inadequate amount of anticoagulant. These factors can be confirmed by examining a stained peripheral maternal blood smear. Once the diagnosis of pseudothrombocytopenia is established, no further treatment is needed for the mother or the infant.

Systemic Lupus Erythematosus

SLE is a chronic inflammatory condition that may impact virtually any organ system of the body. With a predilection for women of reproductive age, it is the autoimmune disease most commonly encountered during pregnancy. No specific gene mutation for SLE has been identified; it is likely that several genes are involved. An interval on chromosome 1, particularly 1q23-24, includes genes for C-reactive protein and is linked to SLE. Of individuals affected, 5% to 12% have another relative with SLE, and 25% to 50% of affected monozygotic twins are concordant for the disease. Several alterations in the HLA-antigen system have been linked to the development of SLE, and homozygous carriers of inherited complement deficiency disorders also appear to be predisposed to development of the disease.

A number of environmental factors, including sunlight exposure, and several infections, such as Epstein Barr virus, may play a role in the development of SLE. With an increased awareness of the disease, more sophisticated diagnostic methods, and improved drug therapy, the 10-year survival rate now exceeds 90%.

Diagnosis

Initially, SLE may easily be overlooked because it often begins with mild and vague symptoms such as fatigue and is characterized by periods of exacerbation and remission. The presence of autoantibodies, characteristically against nuclear components, is a hallmark of the disorder. The American Rheumatism Association has set criteria for the diagnosis of SLE that incorporate immunologic abnormalities and improve disease

classification for purposes of clinical studies (Table 18.5). The most common clinical manifestations include arthralgia or arthritis (90%), dermatologic involvement (70% to 80%), renal disease (46%), hematologic abnormalities (50%), and cardiovascular disease (30% to 50%). The most frequent laboratory findings are thrombocytopenia, leukopenia, and the presence of autoantibodies. SLE also should be suspected when a woman in her reproductive years presents with glomerulonephritis, nephrotic syndrome, hemolytic anemia, leukopenia, or thrombocytopenia.

A positive antinuclear antibody (ANA) test is confirmatory in virtually all (98%) patients. This test has poor specificity at low or medium titers, because many healthy women may test positive for low levels of ANA antibodies. High titers of antibodies to double-stranded DNA and antibodies to the Smith (Sm) antigen are most specific for SLE.

TABLE 18.5 Diagnostic Criteria for Systemic Lupus Erythematosus[a]

Finding	Frequency (%)
Malar rash (fixed erythema over malar eminences)	85
Discoid rash (erythematous, raised patches with scaling)	15
Photosensitivity	Common
Oral or pharyngeal ulcers	50
Arthritis (nonerosive, involving two or more joints)	90
Pleuritis or pericarditis	25–46
Proteinuria, 0.5 g/d, or cellular casts	50
Seizures or psychosis	20

Anemia, leukopenia, thrombocytopenia	>95
Positive ANA titer	>95
Positive lupus erythematosus preparation, anti-DNA, anti-Sm, or false-positive test results for syphilis	>95

ANA, antiphospholipid antibody.

[a]The presence of any four criteria, serially or simultaneously, in any given period is sufficient to make the diagnosis of SLE.

Systemic Lupus Erythematosus and Pregnancy

Flare during Pregnancy

Considerable debate surrounds the incidence and severity of SLE flare during pregnancy. Studying flare in pregnancy is difficult because many of the signs and symptoms typically associated with SLE flare, such as worsening fatigue, commonly are encountered in normal pregnancy. In addition, studies have not consistently used the same criteria for flare or disease severity. Nevertheless, it appears that SLE flare occurs in 35% to 65% of pregnant women with otherwise well-controlled SLE. Most flares are mild to moderate in nature and easily are treated with glucocorticoids. Flares occur with similar frequency in all three trimesters and the puerperium.

Women at greatest risk for complications of SLE during pregnancy are undoubtedly those with preexisting lupus nephritis (LN). Approximately half of all SLE patients eventually develop LN as a result of immune complex deposition in the kidney with subsequent complement activation and inflammatory tissue damage. Patients typically present with proteinuria, hematuria, aseptic pyuria, and urinary sediment. Renal biopsy is necessary to confirm the diagnosis. Pregnancy places women with LN at risk for deterioration of renal function and increased proteinuria, especially if active nephritis or renal insufficiency is present at the time of conception. However, the risks of pregnancy may not be so serious for women with stable LN. About one third of women with LN experience flare during pregnancy, fewer than 25% have worsening renal function, and 10% of have permanent deterioration. The incidence of maternal death attributed to renal failure during pregnancy is less than 2%.

Obstetric Complications

Women with SLE are at risk of several obstetric complications. In 20% to 30% of women with

SLE, their pregnancies are complicated by preeclampsia. Women with secondary antiphospholipid syndrome (APS), underlying renal disease, chronic hypertension, or chronic steroid use are at particular risk. Uteroplacental insufficiency resulting in intrauterine growth restriction (IUGR) or neonates who are small for gestational age has been reported in 12% to 40% of pregnancies complicated by SLE. Renal insufficiency or hypertension increases the risk of IUGR.

The risk of pregnancy loss for women with SLE is uncertain, with reported rates ranging from 10% to 50% if one includes miscarriages. However, there appears to be a predilection for the second- and third-trimester losses among women with SLE, probably due to coexisting APS. Renal insufficiency increases the risk of fetal loss; moderate to severe renal insufficiency (serum creatinine >1.5 mg/dL) is associated with higher rates of severe prematurity and fetal loss.

Disease Activity and Risks of Pregnancy

The degree of disease activity at conception affects the risk of SLE flare and other complications during pregnancy. The rate of flare is lower for women with SLE in remission prior to conception. Renal deterioration is less likely and less severe in women with inactive LN in the 6 months prior to conception. Furthermore, nearly 90% of women with inactive SLE at conception have live births compared with 64% of those with active disease. Women with SLE who plan their pregnancies after disease remission have outcomes similar to those of the general population.

Neonatal Lupus Erythematosus

Neonatal lupus erythematosus (NLE) is a rare condition of the fetus and neonate, occurring in 1 in 20,000 live births and in fewer than 5% of all women with SLE. Dermatologic NLE is most common with lesions described as erythematous, scaling annular or elliptical plaques occurring on the face or scalp, analogous to the subacute cutaneous lesions in adults. Lesions appear in the first weeks of life, probably induced by exposure of the skin to ultraviolet light, and may last for up to 6 months. Hypopigmentation may persist for up to 2 years. Hematologic NLE is manifest as autoimmune hemolytic anemia, leukopenia, thrombocytopenia, and hepatosplenomegaly.

The most well-known expression NLE is congenital complete heart block (CCHB). This condition, caused by inflammation-mediated destruction of the conduction system in the area of the atrioventricular node, is associated with anti-SSA (anti-Ro) and anti-SSB (anti-La) antibodies in the mother. The diagnosis usually is made in the second

---

trimester when a fixed bradycardia, in the range of 60 to 80 beats per minute, is detected during a routine prenatal visit. Fetal echocardiography confirms complete atrioventricular dissociation with a structurally normal heart. There is no known treatment for prenatally diagnosed CCHB, though glucocorticoids, plasmapheresis, IVIG, digoxin, or some combination thereof have been tried. The prognosis for fetuses with CCHB varies, but hydrops fetalis may develop in the most severe cases. Because the damage is permanent, a pacemaker may be necessary for neonatal survival.

Anti-SSA antibodies are found in 75% to 95% mothers who deliver babies with NLE. A smaller percentage of mothers have anti-SSB, and some have both. About 15% of infants born to mothers with anti-Ro/SSA antibodies have dermatologic SLE; the incidence of CCHB is much smaller, no greater than several percent. However, with a previously affected infant, the risk of recurrence increases two- to threefold. Occasionally, women with no history of SLE give birth to babies with NLE. More than half eventually develop lupus.

Obstetric Management

Immunosuppressive Medications

Glucocorticoids

Glucocorticoid preparations are the group of drugs most commonly given to pregnant women with SLE, both as maintenance therapy and in “bursts” to treat suspected SLE flares. Dosing regimens in pregnant women are the same as those in nonpregnant patients. Prophylactic treatment with glucocorticoids is not necessary or prudent in women with inactive disease. Maternal side effects of chronic glucocorticoid therapy include weight gain, striae, acne, hirsutism, immunosuppression, osteonecrosis, and gastrointestinal ulceration. Pregnant women also are at risk for preeclampsia, uteroplacental insufficiency, glucose intolerance, and preterm premature rupture of membranes. Prednisolone or methylprednisolone should be used as maintenance therapy because of their conversion to relatively inactive forms in the human placenta. Glucocorticoids with fluorine at the 9a position (dexamethasone, betamethasone) are considerably less well metabolized by the placenta, and chronic use may lead to undesirable fetal effects.

Antimalarials

An accumulating body of evidence suggests that antimalarial drugs may be used safely for the treatment of SLE during pregnancy. Past concerns about teratogenicity including ototoxicity and eye damage appear to be unfounded. Many experts now believe that hydroxychloroquine during pregnancy is associated with fewer flares. Thus, women who are taking hydroxychloroquine prior to conception probably should continue the drug during pregnancy.

Cytotoxic Agents

Azathioprine, cyclophosphamide, and methotrexate are used to treat only the most severely affected patients with SLE. Azathioprine, a derivative of 6-mercaptopurine, is not a human teratogen but has been associated with fetal growth impairment and impaired neonatal immunity. Cyclophosphamide is a known teratogen and should be avoided during the first trimester. Thereafter, its use should be limited to women with severe, progressive proliferative glomerulonephritis or SLE-related central nervous system (CNS) disease. Methotrexate is well known to kill chorionic villi and cause fetal death. It is also a teratogen, and its use should be scrupulously avoided.

Nonsteroidal Medications

The most common types of analgesics used by women with SLE are NSAIDs. Unfortunately, they readily cross the placenta and should be avoided after the first trimester. Although short-term tocolytic therapy with indomethacin appears to be safe, long-term use of any NSAID has been associated with decreased fetal urinary output and oligohydramnios as well as neonatal renal insufficiency.

Other Treatments

Several new treatment regimens including cyclosporine, high-dose IVIG, mycophenolate mofetil, and thalidomide have been studied in the treatment of nonpregnant patients with SLE. Only IVIG has been used during pregnancy without reports of adverse fetal effects. Obviously, thalidomide is absolutely contraindicated during pregnancy.

Detection of Exacerbation (Flare)

Thorough and frequent clinical assessment remains essential for the timely and accurate detection of SLE flare. The most common presenting symptom in both flare and new-onset disease is extreme fatigue. In pregnancy, skin rashes are more frequent than musculoskeletal manifestations. Patients with LN exhibit worsening proteinuria along with pyuria, hematuria, and urinary casts, which can sometimes be confused with the onset of preeclampsia.

Laboratory evaluation of SLE activity should be used to confirm flare in confusing cases. Serial evaluation of complement levels has been suggested as a method of predicting SLE flare during pregnancy. However, the predictive value of complement activation has been inconsistent and has never been proven to be superior to thorough and frequent clinical assessment. The most specific laboratory test for disease activity is an elevation in the anti–double-stranded DNA (anti-dsDNA) titer that precedes SLE flare in more than 80% of patients and has been shown to correlate with the need for preterm delivery.

Treatment of Flare during Pregnancy

Mild to moderate symptomatic exacerbations of SLE without CNS or renal involvement may be treated with initiation or an increased dose of glucocorticoids. Relatively small

doses of prednisone (e.g., 15 to 30 mg per day) result in improvement in most cases. For severe exacerbations without CNS or renal involvement, 1.0 to 1.5 mg/kg per day of prednisone in divided doses should be used, and a good clinical response can be expected in 5 to 10 days. Thereafter, glucocorticoids may be tapered by several different approaches (Table 18.6).

TABLE 18.6 Suggested Methods for Tapering Prednisone

1. Consolidate to a single morning dose of prednisone. Reduce the daily dose by 10% per week, as tolerated. When a dose of 20 to 30 mg per day is reached, reduce by 2.5-mg increments per week. If the patient remains asymptomatic at a dose of 15 mg per day, reduce the dose by 1-mg increments per week to a dose of 5 to 10 mg per day.
2. Consolidate to a single morning dose of prednisone. Taper to 50 to 60 mg per day by reducing the dose by 10% per week. Thereafter, eliminate the alternate-day dose by tapering it 10% per week, as tolerated. Then, taper the remaining alternate-day dose by 10% per week, as tolerated.

Severe exacerbations, especially those involving the CNS or kidneys, are treated more aggressively. Intravenous-pulse glucocorticoid therapy should be given, usually in a dose of methylprednisolone at 10 to 30 mg/kg (about 500 to 1,000 mg) for 3 to 6 days. Thereafter, the patient is treated with 1.0 to 1.5 mg/kg per day of prednisone in divided doses and rapidly tapered over the course of 1 month. It can be expected that 75% of patients will respond favorably to this approach. This regimen may be repeated every 1 to 3 months in severe cases as an alternative to cytotoxic drugs. Hydoxychloroquine also may be initiated at a dose of 200 mg orally twice daily.

TABLE 18.7 Management of Systemic Lupus Erythematosus during Pregnancy

Testing Parameter	First Trimester	Second Trimester	Third Trimester
Blood count with platelets	×[a]	×	×
Microscopic urinalysis	×	×	×
24-h urine for protein, creatinine clearance	×	×	×
Urine culture	×	—	—
Lupus anticoagulant	×	—	—

Anticardiolipin	×	—	—
Anti-Ro and anti-La antibodies	×	—	—
Smooth muscle antibodies	×	—	—
Clinic visits	Biweekly	Biweekly	Weekly
Sonographic examination	Once	Monthly	Monthly
Fetal heart rate testing	—	—	Twice weekly

[a]The "×" denotes that the test should be performed in the trimester indicated.

The use of cytotoxic agents, plasmapheresis, and IVIG should be reserved for severe SLE exacerbations that do not respond to glucocorticoid therapy. Severe proliferative LN often is responsive only to cyclophosphamide.

Obstetric Care

Clinical precautions in pregnancies associated with SLE are similar to those required for other high-risk pregnancies. Recommended laboratory studies in addition to routine prenatal tests are listed in Table 18.7. The gestational age should be firmly established early in pregnancy. Serial sonography should be performed to assess fetal growth after 18 to 20 weeks gestation. Antenatal surveillance (e.g., nonstress tests, biophysical profiles, etc.) should be initiated in the third trimester to confirm fetal well-being. SLE per se is not an indication for cesarean delivery. Instead, the route of delivery should be based on appropriate obstetric indications.

Antiphospholipid Syndrome

The diagnosis of APS is based on the presence of one or more characteristic thrombotic or obstetric features of the condition in combination with positive serologic testing for antiphospholipid antibodies (aPL). Patients with bona fide APS must manifest at least one of two clinical criteria (vascular thrombosis or pregnancy morbidity) and at least one of three laboratory criteria (positive lupus anticoagulant [LA], medium to high titers of β_2-glycoprotein I–dependent IgG or IgM isotype anticardiolipin antibodies (aCL), or medium to high titers of anti-β_2-glycoprotein I IgG or IgM isotype antibodies (anti-β_2-GPI) confirmed on

two separate occasions at least 12 weeks apart (Table 18.8). APS may exist as an isolated immunologic derangement

(primary APS) or in combination with other autoimmune diseases (secondary APS), most commonly SLE.

TABLE 18.8 International Consensus Satement on Preliminary Criteria for the Classification of the Antiphospholipid Syndrome

Definite antiphospholipid syndrome may be diagnosed if at least one of the clinical criteria and at least one of the laboratory criteria are met.[a]

Clinical Criteria

1. *Vascular thrombosis*
   One or more clinical episodes of arterial, venous, or small vessel thrombosis, occurring within any tissue or organ. Thrombosis must be confirmed by imaging, Doppler studies, or histopathology, with the exception of superficial venous thrombosis for which clinical diagnosis is allowed. For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.
2. *Pregnancy morbidity*
   1. One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus, or
   2. One or more premature births of a morphologically normal neonate before the 34th week of gestation because of (i) eclampsia or severe preeclampsia defined according to standard definitions or (ii) recognized features of placental insufficiency,[b] or
   3. Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded.

In studies of populations of patients who have more than one type of pregnancy morbidity, investigators are strongly encouraged to stratify groups of subjects according to a, b, or c as described above.

Laboratory Criteria[c]

1. *Anticardiolipin antibodies*
   Anticardiolipin antibodies of IgG and/or IgM isotype in blood, present in medium or high titer,[d] on two or more occasions, at least 12 weeks apart, measured by a standardized enzyme-linked immunosorbent assay for β_2-glycoprotein I–dependent anticardiolipin antibodies.
2. *Anti-β_2-glycoprotein I antibodies*
   Anticardiolipin antibodies of IgG and/or IgM isotype in blood, present in medium or high titer,[d] on two or more occasions, at least 12 weeks apart, measured by a standardized enzyme-linked immunosorbent assay for β_2-glycoprotein I antibodies.
3. *Lupus anticoagulant antibodies*
   Lupus anticoagulant present in plasma, on two or more occasions, at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Hemostasis.
   These guidelines include the following steps:
   1. Prolonged phospholipid-dependent coagulation demonstrated on a screening test, e.g., activated partial thromboplastin time, kaolin clotting time, dilute Russell's viper venom time, dilute prothrombin time, Textarin time.
   2. Failure to correct the prolonged coagulation time on the screening test by mixing with normal, platelet-poor plasma.
   3. Shortening or correction of the prolonged coagulation time on the screening test by the addition of excess phospholipid.
   4. Exclusion of other coagulopathies, e.g., factor VIII inhibitor, or heparin, as appropriate.

[a]The current International Consensus suggests that no more than 5 years should separate the clinical event and the positive laboratory findings.

[b]Generally accepted features of placental insufficiency include (i) abnormal or nonreassuring fetal surveillance tests(s), e.g., a nonreactive nonstress test, suggestive of fetal hypoxemia; (ii) abnormal Doppler flow velocimetry waveform analysis suggestive of fetal hypoxemia, e.g., absent end-diastolic flow in the umbilical artery; (iii) oligohydramnios, e.g., an amniotic fluid index of 5 cm or less; or (iv) a postnatal birth weight less than the 10th percentile for the gestational age.

[c]The following antiphospholipid antibodies currently are not included in the laboratory criteria: anticardiolipin antibodies of the IgA isotype, anti-β_2-glycoprotein I antibodies of the IgA isotype, and antiphospholipid antibodies directed against phospholipids other than cardiolipin (e.g., phosphatidylserine, phosphatidylethanolamine) or against phospholipid-binding proteins (e.g., prothrombin, annexin V, protein C, protein S).

[d]The threshold used to distinguish "medium- or high-titer" from "low-titer" anticardiolipin antibodies has not been standardized and may depend on the population under study. Many laboratories use 15 or 20 international "phospholipids" units as the threshold separating low- from medium-titer anticardiolipin antibodies. Others define the threshold as 2.0 or 2.5 times the median titer of anticardiolipin antibodies or as the 99th percentile of anticardiolipin antibody titers within a normal population. The current International Consensus suggests >40 GPL or MPL units or >99th percentile.
Adapted from Branch DW, Khamashta MA. Antiphospholipid syndrome. In: Queenan J, ed. *High-risk pregnancy*. Washington, DC: American College of Obstetricians and Gynecologists, 2008.

Clinical Features

Original descriptions of women with APS featured fetal losses (>10 menstrual weeks gestation), and a high proportion of pregnancy losses reported by women with LA or medium- to high-positive IgG aCL occur in the fetal period. Since then, APS-related pregnancy loss has been extended to include women with early RPL, including those occurring in the preembryonic (<6 menstrual weeks gestation) and embryonic periods (6 to 9 menstrual weeks gestation). In addition, APS is associated with other pregnancy complications, including gestational hypertension or preeclampsia and uteroplacental insufficiency as manifested by fetal growth restriction, oligohydramnios, and nonreassuring

fetal surveillance. Obstetric complications other than pregnancy loss appear to persist despite treatment. There have been some attempts to link infertility and failure of in vitro fertilization (IVF) to the presence of aPL antibodies. However, the preponderance of evidence fails to support such a relationship.

Treatment

The goals of APS treatment during pregnancy are twofold:

. Improve maternal and fetal–neonatal outcome by preventing pregnancy loss and preeclampsia or placental insufficiency.

.. Reduce or eliminate risk of thromboembolism.

Initial attempts at treating women with APS during pregnancy involved immunosuppression with a glucocorticoid preparation, usually prednisone. Early enthusiasm for treatment of APS with glucocorticoids waned after publication of a small, randomized trial found maternally administered heparin to be as effective as prednisone, without the risks associated with chronic glucocorticoid use during pregnancy. At present, maternally administered heparin is considered the treatment of choice, usually initiated in the early first trimester after ultrasonographic demonstration of a live embryo. Daily low-dose aspirin usually is included as well. Live-birth rates among women with APS are generally greater than 70% with regimens including both heparin and aspirin. However, clinicians and patients must understand that other obstetric complications such as preeclampsia and placental insufficiency still may occur despite treatment.

The safe and effective dose of heparin for pregnant women with APS is debated but probably should depend on individual patient history. Women with APS and a history of thromboembolism should receive adjusted-dose anticoagulation with unfractionated heparin or low-molecular-weight heparin during pregnancy (Table 18.9). For women with APS without a history of thromboembolic disease, the choice of anticoagulation is less clear. Low-dose heparin prophylaxis may be sufficient for women with recurrent first-trimester loss and no history of fetal loss. However, women with a history of fetal death (>10 weeks gestation) may be at higher risk for thromboembolism during pregnancy and probably should receive higher doses of heparin prophylaxis. The authors treat such women with generous thromboprophylaxis (e.g., 7,500 to 10,000 U of standard heparin or 30 mg of enoxaparin twice daily). Recommendations for postpartum therapy vary, but most authorities recommend at least 6 weeks of some regimen of anticoagulation with unfractionated heparin, low-molecular-weight heparin, or warfarin.

TABLE 18.9 Subcutaneous Heparin Regimens Used in the Treatment of Antiphospholipid Syndrome during Pregnancy[a]

Prophylactic regimens:

These regimens are recommended in women with no history of thrombotic events—diagnosis is because of recurrent preembryonic and embryonic loss or prior fetal death or early delivery because of severe preeclampsia or severe placental insufficiency.
Standard heparin: (1) 7,500 to 10,000 U every 12 hours in the first trimester and 10,000 U every 12 hours in the second and third trimesters
Low-molecular-weight heparin: (1) Enoxaparin 40 mg once daily or dalteparin 5,000 U once daily, **OR** (2) enoxaparin 30 mg every 12 hours or dalteparin 5,000 U every 12 hours
Anticoagulation regimens:
These regimens are recommended in women with a history of thrombotic events.
Standard heparin: (1) >7,500 U every 8 to 12 hours, adjusted to maintain the midinterval heparin levels[b] in the therapeutic range
Low-molecular-weight heparin: (1) Weight-adjusted (e.g., enoxaparin 1 mg/kg every 12 hours or dalteparin 200 U/kg every 12 hours)

[a]See text for postpartum thromboprophylaxis recommendations.
[b]Heparin levels denotes anti-factor Xa levels. Women without a lupus anticoagulant in whom the activated partial thromboplastin time is normal can be followed by using the activated partial thromboplastin time.
Modified from Branch DW, Khamashta MA. Antiphospholipid syndrome. In: Queenan J, ed. *High-risk pregnancy*. Washington, DC: American College of Obstetricians and Gynecologists, 2008.

Healthy women with recurrent embryonic and preembryonic loss who have low or negative aPL titers do not require anticoagulation.

Women with APS should be counseled about the potential risks of heparin therapy during pregnancy, including heparin-induced osteoporosis (1% to 2%) and heparin-induced thrombocytopenia (HIT). Women who are treated with heparin should be encouraged to take daily supplemental calcium at a dose of 1,500 to 2,000 mg per day and vitamin D (e.g., prenatal vitamins) and perform daily axial skeleton weight-bearing exercise (e.g., walking).

Alhough uncommon, HIT potentially is very serious. Most cases have their onset 3 to 15 days after heparin initiation and are relatively mild in nature. A more severe form of HIT

paradoxically involves venous and arterial thromboses resulting in limb ischemia, cerebrovascular accidents, and myocardial infarctions as well as venous thromboses. The authors obtain platelet counts every several days for the first 2 weeks of heparin treatment and discontinue heparin if the platelet count falls to subnormal or by 50% from baseline.

Catastrophic Antiphospholipid Syndrome

Catastrophic APS is a rare but devastating syndrome characterized by multiple simultaneous vascular occlusions throughout the body, often resulting in death. The diagnosis should be suspected if at least three organ systems are affected and confirmed if there is histopathologic evidence of acute thrombotic microangiopathy affecting small vessels. Renal involvement occurs in nearly three fourths of patients. Most patients have hypertension, and 25% eventually require dialysis. Other common manifestations include adult respiratory distress syndrome (65%), cerebral microthrombi and microinfarctions (55%), myocardial microthrombi (50%), dermatologic abnormalities (50%), and disseminated intravascular coagulation (25%). Death from multiorgan failure occurs in 50% of patients. The pathophysiology of catastrophic APS is poorly understood. However, the onset may be presaged by several factors, including infection, trauma, surgical procedures, discontinuation of anticoagulant therapy, and the use of drugs such as oral contraceptives. The condition has been reported in a modest number of pregnant women, with about half of reported cases during pregnancy and about half in the postpartum period. Severe preeclampsia may be a trigger for catastrophic APS.

Early and aggressive treatment of catastrophic APS is necessary to avoid death. Patients should be transferred to an intensive care unit where supportive care can be provided. Hypertension should be treated aggressively with appropriate antihypertensive medication. While no one treatment has been shown to be superior to another, a combination of anticoagulants (usually heparin) and high-dose steroids plus either plasmapheresis or IVIG has been successful in some patients. Streptokinase and urokinase also have been used to treat acute vascular thrombosis. Women suspected of catastrophic APS during pregnancy probably should be delivered.

Rheumatoid Arthritis

RA is a chronic inflammatory process that primarily involves synovial-lined joints, resulting in swelling and pain. Established criteria are used to make the diagnosis of classic, definite, and probable or possible RA and include morning stiffness, pain and tenderness in at least one joint, swelling of at least one joint, swelling of at least one other joint, symmetric joint swelling, subcutaneous nodules, x-ray changes typical of RA, a positive test result for rheumatoid factor, and other features. Though many cases are mild and may be treated with NSAIDs, the disease may be characterized by intermittent exacerbations with ultimate progression over many years to typical joint deformities.

Pregnancy is associated with clinical improvement in at least 50% of patients, a phenomenon that may be related to elevated blood levels of free cortisol or to enhanced phagocytosis of immune complexes. Rheumatoid factor (IgM antibodies against autologous IgG) do not cross the placenta, and there is no fetal or neonatal involvement.

Management of RA during pregnancy should include an appropriate balance of medication, rest and exercise, heat, and physical therapy. Obviously, methotrexate, now widely used in the treatment of RA, must be discontinued prior to pregnancy. Inhibitors of tumor necrosis factor-α also are efficacious for the treatment of RA. Although experience with these drugs during pregnancy is limited, preliminary evidence is that they are not teratogenic; they are Food and Drug Administration (FDA) pregnancy category B agents. The basic reliance on large doses of salicylates, NSAIDs, and analgesics must be modified during pregnancy. Low-dose steroids (e.g., prednisone 5 mg per day) and low-dose aspirin are recommended. Though gold compounds cross the placenta, no fetal adverse effects or teratogenicity have been reported. Gold therapy can be continued in selected pregnant patients with RA who are unresponsive to glucocorticoids. Other NSAIDs and penicillamine are not recommended because of potential detrimental fetal effects. As in SLE, antimalarials (hydroxychloroquine) appear to be another safe option during pregnancy.

Specialized antenatal surveillance is unnecessary for women with RA. Serial ultrasounds and antenatal surveillance should be reserved for the usual obstetric indications. Joint deformities rarely preclude vaginal delivery, but mechanical obstacles may occur in women with hip deformities. Cesarean delivery usually can be reserved for standard obstetric indications. The type of anesthesia (regional vs. general) chosen depends on the presence of skeletal deformities or special problems such as atlantoaxial subluxation.

Other Rheumatic (Collagen Vascular) Diseases

Most disorders of undetermined origin, which are characterized by inflammation of various tissues, have been termed *systemic rheumatic* or *collagen vascular diseases*. More

recently, many have been classified as autoimmune disorders because of their association with the production of autoantibodies and other immunologic aberrations. This group includes mixed connective tissue disorder, Sjögren syndrome, polyarteritis nodosa, dermatomyositis, and scleroderma.

The risk of serious maternal and perinatal complications, including death, is concerningly elevated in patients with polyarteritis nodosa and scleroderma complicated by renal disease or cardiopulmonary disease. Scleroderma worsens in at least 10% of women during pregnancy. At least 5% have life-threatening complications, usually related to renal or cardiopulmonary disease.

Myasthenia Gravis

Myasthenia gravis (MG) is a chronic neuromuscular autoimmune disease characterized by fatigue and weakness, usually involving the extraocular, facial, pharyngeal, and respiratory muscles. It is worsened by exertion and relieved by rest and anticholinesterase drugs. Antibodies to human acetylcholine receptors (AChR) are detectable in up to 90% of patients with MG. The anti-AChR antibodies are involved in complement-dependent destruction of the postsynaptic membrane of the myoneural junction, resulting in decreased nerve impulse transmission. Thymoma, thymic hyperplasia, and other autoimmune diseases often accompany MG. The functional abnormalities associated with the disease are similar to

those induced by curare. The course during pregnancy is variable, although there may be a tendency for relapse during the puerperium.

The cholinesterase inhibitors and their equivalent doses most commonly used to alleviate symptoms are 0.5 mg of intravenous neostigmine, 1.5 mg of subcutaneous neostigmine, 15 mg of oral neostigmine, 60 mg of oral pyridostigmine, and 5 mg of oral ambenonium. Drugs are adjusted to the dose at which the patient's muscle strength is optimal with a minimum of cholinergic adverse effects. Oral pyridostigmine, or a sustained-release preparation of pyridostigmine, is the most commonly used medication for MG. Overmedication results in unpleasant effects such as abdominal cramps, flatulence, diarrhea, nausea, vomiting, and excessive secretion of saliva and tears. Toxic levels of pyridostigmine lead to a myasthenic crisislike syndrome involving profound muscle weakness and eventually respiratory failure. Treatment with high-dose glucocorticosteroids also has been used successfully in some patients. Regular rest periods with limited physical activity should be prescribed for the pregnant patient with MG. Infections should be treated aggressively because of their propensity to exacerbate MG.

Careful plans should be made for drug therapy during pregnancy, labor, delivery, and the postpartum period. Some antibiotics, such as the aminoglycosides, may produce a myasthenic crisis and should be avoided. Other medications also may be harmful in women with MG (Table 18.10). Many patients with MG are sensitive to sedatives, analgesics, tranquilizers, and narcotics. Muscle relaxants should be avoided. Local or regional anesthetics are preferable. Magnesium sulfate is contraindicated because the drug diminishes the acetylcholine effect and has been known to induce a myasthenic crisis.

TABLE 18.10 Medications That May Exacerbate or Cause Muscle Weakness in Patients with Myasthenia Gravis

Aminoglycosides
Barbiturates
Cholistin
Ether
Halothane
Lincomycin
Lithium salts
Magnesum salts
Penicillamine
Polymyxin B
Procainamide
Propranolol
Quinine
Tetracycline
Trichlorethylene

Labor typically progresses normally because smooth muscle is unaffected. Cesarean delivery should be reserved for obstetric reasons. Assisted ventilation should be available in the event of respiratory difficulty. During labor, the patient's oral dose of anticholinesterase should be discontinued and replaced with an intramuscular equivalent.

Approximately 12% to 20% of infants born to women with MG exhibit neonatal MG, which lasts from a few hours to several days. The manifestations are caused by the transplacental transfer of acetylcholine-blocking factor. The classic features of neonatal MG differ from those seen in adults. The symptoms usually do not develop until day 1 or 2 of life, probably because of some protection to the infant from the maternal blood levels of anticholinesterase agents. A high index of suspicion is necessary to recognize this phenomenon, because an infant who appears healthy at birth may later develop respiratory failure with asphyxia. The involved infant shows generalized muscle weakness and hypotonic limbs and is limp and motionless. The Moro reflex often is weak or absent, and there may be a feeble cry, inability to suck, and associated difficulty in swallowing and breathing. Arthrogryposis (i.e., joint contractures), which may develop as a result of reduced intrauterine movement, has been reported in several infants born to mothers with MG.

Summary Points

- Rh immune globulin should be given to Rh D–negative, unsensitized women at 28 weeks gestation, within 72 hours after delivery, and in the event of antenatal procedures and complications associated with fetomaternal hemorrhage.
- Rh D alloimmunized women with anti-D titers 1:16 or greater should be referred for assessment of possible fetal anemia.
- MCA Doppler peak systolic velocity measurements are used to evaluate fetuses at risk for significant fetal anemia.
- Intravascular IUT is most efficacious for the treatment of severely anemic fetuses with hydrops.
- Platelet alloimmunization results in severe fetal and neonatal thrombocytopenia, which may be ameliorated with maternal administration of IVIG.
- Gestational thrombocytopenia is a benign disorder that is characterized by mild thrombocytopenia (>70,000 per mL), no history of excessive bleeding, no history of thrombocytopenia, resolution of thrombocytopenia 1 to 2 weeks after delivery, and no serious risk to the mother or the fetus.
- Autoimmune thrombocytopenia is characterized by thrombocytopenia before and after pregnancy, megathrombocytes on peripheral smears, bone marrow aspirate with normal or

increased numbers of megakaryocytes, history of excessive bleeding, and absence of splenomegaly.

- Antiplatelet antibodies are not useful in differentiating between gestational thrombocytopenia and autoimmune thrombocytopenia.
- Autoimmune thrombocytopenia is not associated with a significant risk of fetal thrombocytopenia leading to intracranial hemorrhage.
- The diagnosis of SLE is based on specific clinical criteria.
- A positive ANA test is confirmatory in 98% of patients, but elevated levels of antibodies to double-stranded DNA are most specific for disease activity.
- Most SLE flares during pregnancy are easily treated with glucocorticoids.
- Prophylaxis with glucocorticoid medication is not indicated to prevent flare during pregnancy.
- SLE flare during pregnancy is best detected by frequent and thorough clinical assessment.
- Congenital cardiac heart block associated with neonatal lupus is characterized by fetal bradycardia diagnosed in the second trimester in a fetus with a structurally normal heart.
- The diagnosis of APS should be based on the presence of thromboembolism or pregnancy morbidity in combination with the presence of LA or medium to high titers of β_2-glycoprotein I–dependent IgG or IgM isotype aCL or medium to high titers of anti-β_2-GPI.
- A regimen of heparin and low-dose aspirin reduces the risk of pregnancy loss in women with APS.
- Pregnancy is associated with clinical improvement in at least 50% of patients with RA.
- MG is a chronic neuromuscular autoimmune disease characterized by fatigue and weakness, usually involving the extraocular, facial, pharyngeal, and respiratory muscles.
- Women with MG should avoid magnesium sulfate and aminoglycoside preparations, narcotics, and muscle relaxants.
- Neonatal MG occurs in 12% to 20% of infants born to mothers affected with MG.

Obstetric and Perinatal Infections

Jill K. Davies
Ronald S. Gibbs

In this chapter, six important infections are discussed—group B streptococci (GBS), varicella-zoster virus (VZV), parvovirus B19, toxoplasmosis, cytomegalovirus (CMV), and herpes simplex virus (HSV)—focusing on their relevance during pregnancy to both the mother and the fetus. In addition, two common peripartum infections will be reviewed—intra-amniotic infection (IAI) and postpartum endometritis.

Group B Streptococci

In the 1970s, GBS became recognized as the leading cause of neonatal infection and an important cause of maternal genital tract infection. Prior to the mid 1990s, early-onset neonatal GBS disease incidence ranged between 1.5 to 2.0 cases per 1,000 live births. As prevention measures then came into practice, disease incidence declined by 70% to a rate of 0.5 cases per 1,000 live births. Most recent surveillance data indicates the rate of early onset is now 0.34 cases in 1,000 live births, and the rate of late onset disease decreased to 0.38 cases in 1000 live births.

In 1996, the first national consensus guidelines were released. Based on new evidence from a large retrospective cohort study, new national prevention guidelines from the Centers for Disease Control and Prevention (CDC), American Academy of Pediatrics (AAP), and American College of Obstetricians and Gynecologists (ACOG) were released in 2002, recommending a single prevention strategy—namely, universal antenatal culture-based screening at 35 to 37 weeks gestation.

Epidemiology

It is estimated that 20% to 30% of all pregnant women are GBS carriers, but colonization can be intermittent or transient. Prenatal screening for GBS at 35 to 37 weeks gestation is recommended by the 2002 national guidelines.

In newborns, the most common GBS infections are sepsis, pneumonia, and meningitis (Fig. 19.1). Early-onset disease occurs within the first week of life; late-onset disease occurs after the first week. Outcome survival has improved recently. For term infants, survival for

GBS sepsis is about 98%, but for preterm infants the survival is lower, at 90% for cases at 34 to 36 weeks gestation and 70% for cases at less than 33 weeks.

Risk factors for early-onset disease are maternal GBS colonization, prolonged rupture of membranes, preterm delivery, GBS bacteriuria during pregnancy, birth of a previous infant with invasive GBS disease, maternal chorioamnionitis as evidenced by intrapartum fever, young maternal age, African American race, Hispanic ethnicity, and low levels of antibody to type-specific capsular polysaccharide antigens.

Manifestations of maternal GBS infection include urinary tract infection, chorioamnionitis, endometritis, bacteremia, and stillbirth.

GBS are isolated in 15% of cases of amnionitis, 15% of cases of endometritis, 2% to 15% of infected abdominal wounds after cesarean delivery, and about 15% of cases of bacteriuria in obstetric patients.

Diagnosis

The 2002 CDC guidelines provide directions for collecting and processing these specimens (Table 19.1). These guidelines recommend a rectogenital specimen to obtain optimal yield of GBS.

There has been intense interest in tests for rapid identification of GBS. In one study, a polymerase chain reaction

(PCR) test reported excellent sensitivity, specificity, positive predictive value, and negative predictive value when compared with conventional anovaginal cultures. The reported laboratory turnaround time was 40 to 100 minutes for these PCR methods. The FDA approved an intrapartum rapid PCR test (IDI-Strep B, Infection Diagnostic Inc., Quebec, Canada). However, there are “real-world” limitations to this test, including turnaround time on a 24-hour, 7-day per week basis and inability to determine antibiotic susceptibility in women who cannot take penicillin or a cephalosporin. One role for PCR tests may be in testing women whose GBS status is unknown on admission in labor.

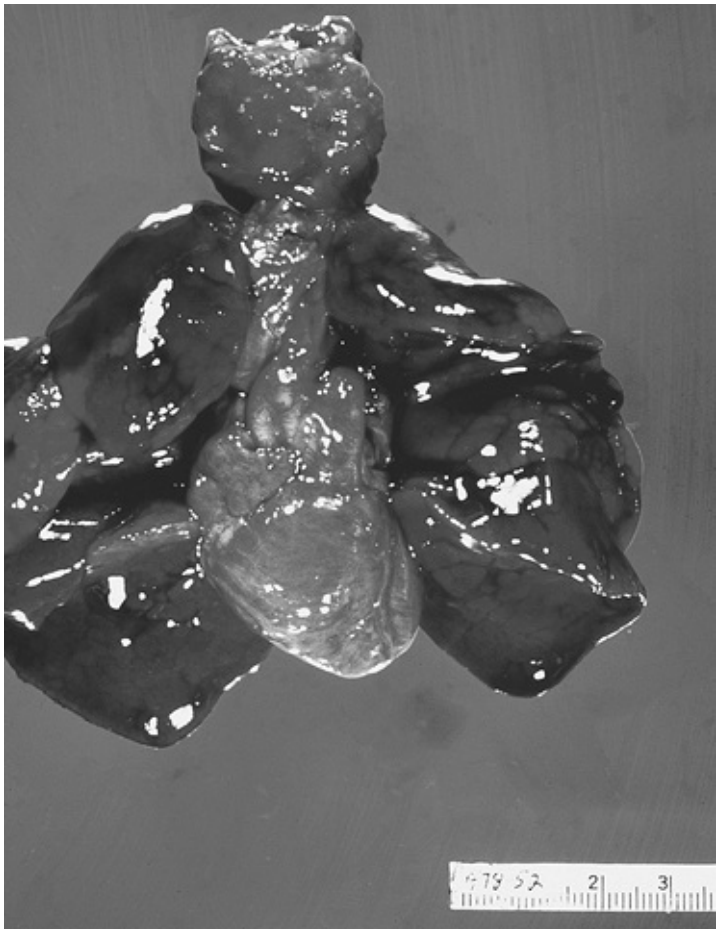

Figure 19.1 Neonatal autopsy showing congenital pneumonia due to GBS. (From Gibbs RS, Schrag S, Schuchat A. Perinatal infections due to group B streptocci. *Obstet Gynecol* 2004;104[5]:1064.)

Tests from genital specimens other than PCR (such as antigen detection) are not sufficiently sensitive for clinical use.

Therapy

Because resistance to penicillin or ampicillin has not been detected in GBS, penicillin, because of its narrow spectrum of activity, remains the agent of choice for GBS prophylaxis, with ampicillin as an alternative. Resistance to clindamycin and erythromycin among GBS isolates is widely prevalent, ranging from 7% to 30% for erythromycin and 3% to 15% for clindamycin. Resistance to also has been detected.

These resistance trends led to a revision of the first- and second-line antibiotics (Table 19.2). Because of the possibility of inducible resistance, the 2002 guidelines recommend that clindamycin or erythromycin be used only if a given patient's GBS isolate was shown to have in vitro susceptibility to both. If there is in vitro resistance to either in a patient at high risk for penicillin anaphylaxis, then vancomycin should be used. For women at high risk of penicillin allergy colonized by clindamycin-resistant or erythromycin-resistant isolates, the 2002 guidelines recommend vancomycin. Because vancomycin use is restricted due to concerns regarding emerging vancomycin resistance, vancomycin should be

reserved, in GBS prophylaxis, for highly penicillin-allergic women with isolates of unknown susceptibility and isolates with resistance to either erythromycin or clindamycin.

Because of its uniform activity, penicillin G remains the drug of choice for clinically evident maternal infection with GBS. Ampicillin is used widely and is an acceptable alternative. The usual dose of penicillin G is 5.0 million units intravenously initially, then 2.5 million units intravenously every 4 to 6 hours. Note that for prevention of GBS perinatal infections, the dosing interval is every 4 hours until delivery. For ampicillin, the usual adult dose is 2 g intravenously initially, then 1 g intravenously every 4 to 6 hours. Again, note that for GBS prophylaxis, the dosing interval is every 4 hours until delivery.

Prevention

The indications for prophylaxis under this universal prenatal screening strategy are shown in Figure 19.2.

Obstetric Procedures

Membrane sweeping (or stripping) among term patients hastens the onset of labor, with no increases in overall perinatal or peripartum infection. However, because studies using this technique did not report GBS status, there are no data to advise whether this procedure should or should not be avoided in GBS-positive women. Nevertheless, because the benefits of membrane sweeping are limited (such as a significantly greater likelihood of onset of labor within 48 hours). The authors avoid membrane sweeping in GBS-positive women. If there is an indication for delivery, there are many alternative interventions to membrane sweeping, such as vaginal prostaglandin preparations.

Vaccine Development

Immunization holds promise to prevent a larger burden of disease, protecting against both early- and late-onset

infections. Moreover, vaccination may prevent some adverse pregnancy outcomes associated with GBS, such as preterm delivery, spontaneous abortion, or stillbirth, particularly if vaccination of adolescent girls before pregnancy is a viable strategy. Additionally, immunization strategies would not contribute to emerging antimicrobial resistance among GBS. Promising GBS vaccine candidates now exist but are not available commercially.

TABLE 19.1 Procedures for Collecting and Processing Clinical Specimens for Group B Streptococcal Culture and Performing Susceptibility Testing to Clindamycin and Erythromycin

Procedure for collecting clinical specimens for culture of group B streptococcus at 35–37 weeks' gestation

- Swab the lower vagina (vaginal introitus), followed by the rectum (i.e., insert swab through the anal sphincter) using the same swab or two different swabs. Cultures should be collected in the outpatient setting by the healthcare provider or the patient herself, with appropriate instruction. Cervical cultures are not recommended and a speculum should not be used for culture collection.
- Place the swab(s) in to a non-nutritive transport medium. Appropriate transport systems (e.g., Amies or Stuart's without charcoal) are commercially available. If vaginal and rectal swabs were collected separately, both swabs can be placed into the same container of medium. Transport media will maintain GBS viability for up to 4 days at room temperature or under refrigeration.
- Specimen labels should clearly identify that specimens are for group B streptococcal culture. If susceptibility testing is ordered for penicillin-allergic women (Table 19.2), specimen labels should also identify the patient as penicillin allergic and should specify that susceptibility testing for clindamycin and erythromycin should be performed if GBS is isolated.

Procedure for processing clinical specimens for culture of group B streptococcus

- Remove swab (s) from transport medium.* Inoculate swab(s) into a recommended selective broth medium, such as Todd-Hewitt broth supplemented with either gentamicin (8 µg/ml) and nalidixic acid (15 µg/ml), or with colistin (10 µg/ml) and nalidixic acid (15 µg/ml). Examples of appropriate commercially available options include Trans-Vag broth supplemented with 5% defibrinated sheep blood of LIM broth.†
- Incubate inoculated selective broth for 18–24 hours at 35°–37°C in ambient air or 5% CO_2. Subculture the broth to a sheep blood agar plate (e.g., tryptic soy agar with 5% defibrinated sheep blood).
- Inspect and identify organisms suggestive of GBS (i.e., narrow zone of beta hemolysis, gram-positive cocci, catalase negative). Note that hemolysis may be difficult to observe, so typical colonies without hemolysis should also be further tested. If GBS is not identified after incubation for 18–24 hours, reincubate and inspect at 48 hours to identify suspected organisms.

- Various treptococcus grouping latex agglutination tests or other tests for GBS antigen detection (e.g., genetic probe) may be used for specific indentification, or the CAMP test may be employed for presumptive identification.

Procedure for clindamycin and erythromycin disk susceptibility testing of isolates, when ordered for penicillin-allergic patients.‡

- Use a cotton swab to make a suspension from 18–24 hour growth of the organism in saline of Mueller-Hinton broth to match a 0.5 McFarland turbidity standard.
- Within 15 minutes of adjusting the turbidity, dip a sterile cotton swab into the adjusted suspension. The swab should be rotated several times and pressed firmly on the inside wall of the tube above the fluid level. Use the swab to inoculate the entire surface of a Mueller-Hinton sheep blood agar plate. After the plate is dry, use sterile forceps to place a clindamycin (2 µg) disk on to half of the plate and an erythromycin (15 µg) disk onto the other half.
- Incubate at 35°C in 5% CO_2 for 20–24 hours.
- Measure the diameter of the zone of inhibition using a ruler of calipers. Interpret according to NCCLS guidelines for *Streptococcus* species other than *S. pneumoniae* (2002 breakpoints:‡ clindamycin: ≥19 mm = susceptible, 16–18 = intermediate, ≤15 = resistant; erythromycin: ≥21 mm = susceptible, 16–20 = intermediate, ≤15 = resistant).

*Before inoculation step, some laboratories may choose to roll swab(s) on a single sheep blood agar plate or CNA sheep blood agar plate. This should be done only in addition to, and not instead of, inoculation into selective broth. The plate should be streaked for isolation, incubated at 35–37°C in ambient air of 5% CO_2 for 18–24 hours and inspected for organisms suggestive of GBS as described above. If suspected colonies are confirmed as GBS, the broth can be discarded, thus shortening the time to obtaining culture results.

†Sources Fenton, LJ, Harper MH. Evaluation of colistin and nalidixic acid in Todd-Hewitt broth for selective isolation of group B streptococci. J Clin Microbiol 1979;9:167–9. Although Trans-Vag medium is often available without sheep blood, direct comparison of medium with and without blood has shown higher yield when blood is added. LIM broth may also benefit from the addition of sheep blood, although the

improvement in yield is smaller and sufficient data are not yet available to support a recommendation.

‡Source NCCLS, Performance standard for antimicrobial susceptibility testing. M100-S12, Table 2H, Wayne, Pa.: NCCLS, 2002, NCCLS recommends disk diffusion (M-2) or broth microdilution testing (M-7) for susceptibility testing of GBS. Commercial systems that have been cleared or approved for testing of streptococci other than *S. pneumoniae* may also be used. Penicillin susceptibility testing is not routinely recommended for GBS because penicillin-resistant isolates have not been confirmed to date.

From Centers for Disease Control and Prevention. Prevention of perinatal group B streptococcal disease. *MMWR* 2002;51(RR-11):4.

Varicella-zoster Virus (VZV)

VZV, a member of the herpesvirus family, is the etiologic agent that causes chicken pox, an almost universal infection of children and adolescents. Its reactivation is the cause of herpes zoster. Ninety percent of individuals will be immune prior to adulthood. Infection during pregnancy complicates 0.7 per 1,000 pregnancies. The incubation period

for varicella zoster is 10 to 21 days, and infected individuals are contagious from 1 to 2 days before the rash begins until all of the skin lesions are crusted over. The lesions are classically described as “dew drops on a rose petal.” During the prodrome and early infection, there is characteristic fever and malaise followed by development of the pruritic rash. Following varicella-zoster infection, the virus lays dormant in the dorsal horn cells of the spinal cord. Reactivation causes herpes zoster.

TABLE 19.2 Recommended Regimens for Intrapartum Antimicrobial Prophylaxis for Perinatal Group B Streptococci Disease Prevention*

Recommended	Penicillin G, 5 million units IV initial dose, then 2.5 million units IV every 4 hours until delivery
	Ampicillin, 2 g IV initial dose,

Alternative	then 1 g IV every 4 hours until delivery
If penicillin allergic†	
Patients not at high risk for anaphylaxis	Cefazolin, 2 g IV initial dose, then 1 g IV every 8 hours until delivery
Patients at high risk for anaphylaxis‡	
GBS susceptible to clindamycin and erythromycin§	Clindamycin, 900 mg IV every 8 hours until delivery
	OR
	Erythromycin, 500 mg IV every 6 hours until delivery
GBS resistant to clindamycin or erythromycin or susceptibility unknown	Vancomycin,¶ 1 g IV every 12 hours until delivery

GBS, group B streptococci.

*Broader-spectrum agents, including an agent active against GBS, may be necessary for treatment of chorioamnionitis

†History of penicillin allergy should be assessed to determine whether a high risk for anaphylaxis is present. Penicillin-allergic patients at high risk for anaphylaxis are those who have experienced immediate hypersensitivity to penicillin including a history of penicillin-related anaphylaxis; other high-risk patients are those with asthma or other diseases that would make anaphylaxis more dangerous or difficult to treat, such as persons being treated with beta-adrenergic-blocking agents.

‡If laboratory facilities are adequate, clindamycin and erythromycin susceptibility testing (Table 19.1) should be performed on prenatal GBS isolates from penicillin-allergic women at high risk for anaphylaxis.

§Resistance to erythromycin is often but not always associated with clindamycin resistance. If a strain is resistant to erythromycin but appears susceptible to clindamycin, it may still have inducible resistance to clindamycin.

¶Cefazolin is preferred over vancomycin for women with a history of penicillin allergy other than immediate hypersensitivity reactions, and pharmacologic data suggest it achieves effective intraaminiotic concentration. Vancomycin should be reserved for penicillin-allergic women at high risk for anaphylaxis.

From Centers for Disease Control and Prevention. Prevention of perinatal group B streptoccal disease. *MMWR* 2002:51(RR-11):10.

Most women are immune to varicella prior to adulthood due to a history of typical varicella infection as a child, which is considered sufficient for immunity. As most women are immune to varicella before reproductive age, most who do not specifically recall a history of chicken pox infection as a child are immune as well. Varicella vaccine (Varivax, Merck, Whitehouse Station, NJ) is now available and recommended for administration during childhood. Thus, the overwhelming majority of pregnant women are immune to varicella prior to pregnancy. Immunocompetent individuals will not get chicken pox again.

Varicella Exposure and Management

When exposure occurs in a pregnant woman, it is important to obtain her history regarding prior varicella infection. The diagnostic approach to the pregnant woman with possible varicella exposure is shown in Figure 19.3. With a prior history of typical chicken pox infection, she can be reassured. No serologic confirmation is required. In the setting of an inconclusive maternal history, a VCV immunoglobulin G (IgG) level should be checked urgently. Most laboratories can provide results of this in a day or so. If a woman's IgG is positive shortly after exposure, this indicates prior immunity and she can be reassured. If her IgG is negative, she is susceptible to infection from the exposure. A significant exposure to varicella consists of a household contact, a face-to-face contact with an infected individual for at least 5 minutes, or an indoor contact with chicken pox or herpes zoster for at least 1 hour. If the woman meets these criteria, her varicella immunoglobulin M (IgM) antibody level should be measured. If her IgM is negative, immune globulin should be given to prevent transmission of the virus or lessen its severity. She should be given postexposure prophylaxis with varicella-zoster–specific immune globulin (VariZIG, FFF Enterprises, Temecula, CA). The adult dosage of VZIG is 625 U and is most effective when given within

96 hours of exposure. If VZIG is not available, 0.6–1.2 mL/kg of intravenous immune globulin (IVIG) can be given. In one trial, administration of VZIG to pregnant women within 96 hours of exposure was demonstrated to be highly efficacious in preventing 80% (20 of 25) of clinical infection. The 16 of 18 women who did not receive VZIG contracted infection. In addition, when VZIG was given between 3 and 10 days after exposure, the same group described attenuation of maternal infection.

Natural History and Pathophysiology

Although most pregnant women will have self-limited infection, VZV during pregnancy has been associated with increased morbidity and mortality compared with nonpregnant adult infection (*http://www.fda.gov/cber/ infosheets/mphvzig092005.htm*). Symptomatic therapy with antipyretics and antipruritic agents that are safe during pregnancy can be used. Because of the high infectivity of

this virus, the patient should be properly isolated from other susceptible pregnant women. When diagnosis of maternal varicella is made, patients should be treated with acyclovir 800 mg orally five times daily for 7 days to decrease severity of infection, as it has been associated with a decrease in time to lesion healing and lessens fever and other symptoms. Five percent of women in the National Institute of Child Health and Development (NICHD) review of maternal varicella developed varicella pneumonia. Women with VZV infections during pregnancy should be given strict respiratory precautions, as a significant minority of women who develop varicella pneumonia will develop respiratory failure warranting mechanical ventilation, and their respiratory status can rapidly decompensate. Respiratory symptoms most likely will develop on the second day of rash, often consisting of dry cough, hemoptysis, pleuritic chest pain, and shortness of breath. Chest radiographs most often will show a miliary or diffuse nodular pattern. Varicella pneumonia should be treated aggressively with acyclovir 10 to 15 mg/kg given intravenously three times daily for 7 days. Higher doses of acyclovir are needed to treat varicella due to its lower specificity for VZV compared with HSV.

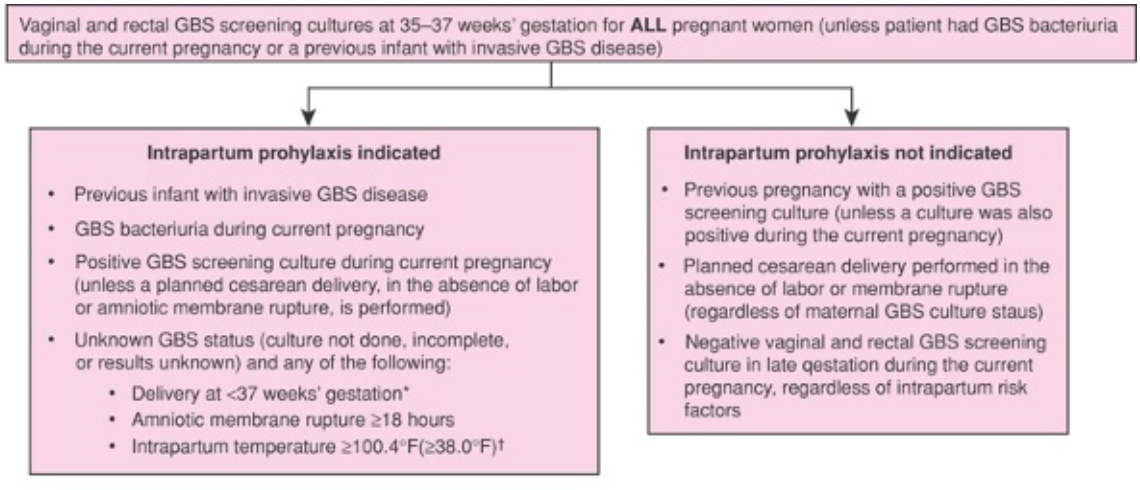

Figure 19.2 Indications for intrapartum antibiotic prophylaxis to prevent perinatal GBS disease under a universal prenatal screening strategy based on combined vaginal and rectal cultures collected at 35 to 37 weeks gestation from all pregnant women. (GBS, group B streptococci.) (From Centers for Disease Control and Prevention. Prevention of perinatal group B streptococcal disease. *MMWR* 2002;51[RR-11]:8.)

Neonatal Varicella

Newborn infection can occur if maternal infection with rash and symptoms develop from approximately 5 days before delivery until 2 days after delivery. This is the period in which there is insufficient time for maternal IgG antibody development and passive transfer to protect the fetus. Infection in the neonate usually will occur within 5 to 10 days of life and is of variable course but can be quite severe. Passive immunization of the exposed neonate with 125 U of VZIG is recommended if maternal varicella infection occurs within 5 days of delivery to 2 days following delivery as well as to any exposed neonate born at less than 28 weeks gestation, as IgG antibody transfer at premature gestational ages is less efficient. Although VZIG will not protect all neonates from varicella, it should reduce the severity of infection. Appropriate isolation of exposed infants should occur as well.

Fetal Effects and Prenatal Diagnosis

Varicella has been shown to cause fetal effects. Although first-trimester infection is associated with a low risk for miscarriage and anomalies (0.4%), the second trimester between approximately 12 and 20 weeks is the highest risk for vertical transmission causing serious fetal abnormalities (congenital varicella syndrome). Although vertical transmission has been estimated to be as high as 10%, more recent studies suggest this risk to be less than 2%. Fetal abnormalities include skin scarring, a variety of fetal central nervous system (CNS) abnormalities,

ophthalmologic effects, limb anomalies, and gastrointestinal abnormalities. These fetal effects are thought to be as a result of immaturity of the fetal immune system as well as intrauterine herpes zoster resulting in a predilection for neuronal cells and their downstream innervated tissues. There is no clear information regarding whether maternal administration of VZIG or acyclovir will lessen or prevent these fetal effects.

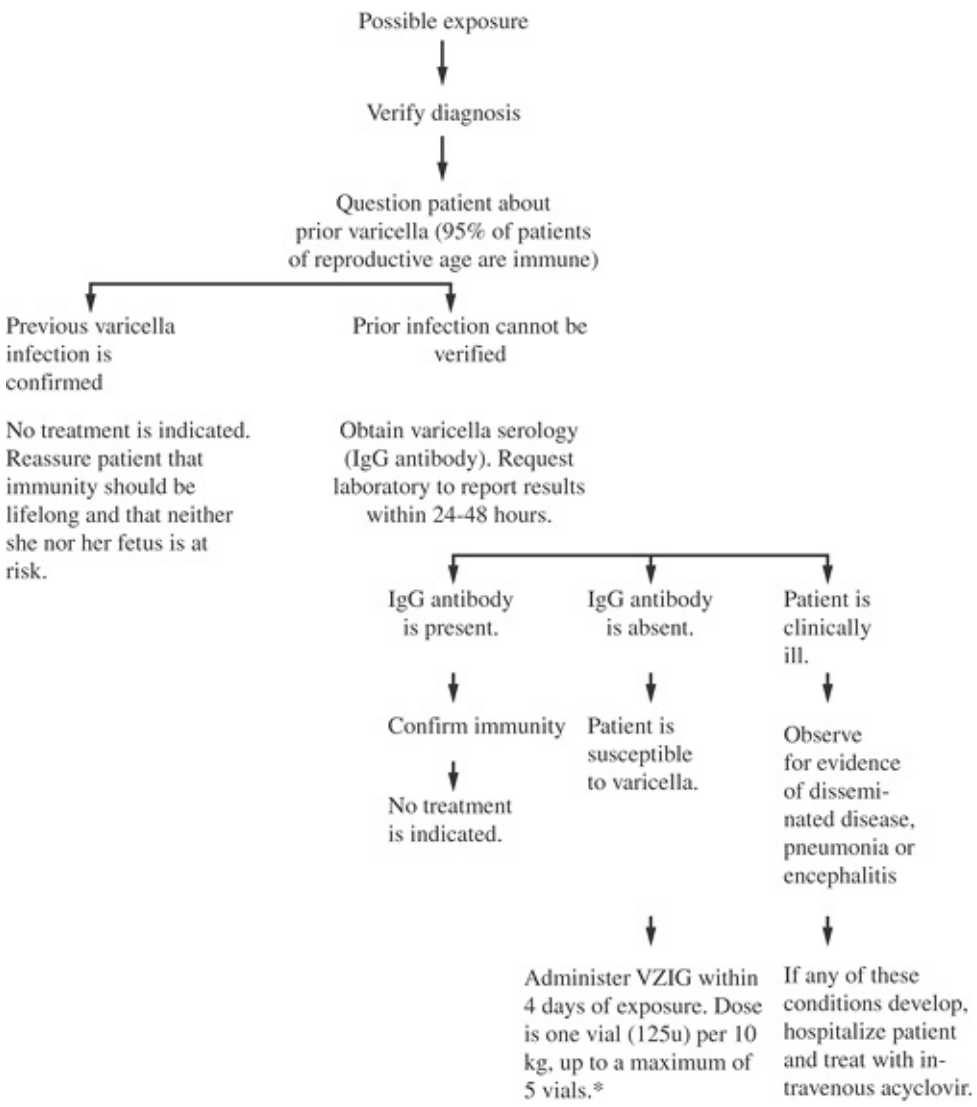

Figure 19.3 Algorithm for assessment and management of varicella exposure in pregnancy. (IgG, immunoglobulin G.) (From Chapman SJ. Varicella in pregnancy. *Semin Perinatol* 1998;22:344.)

* VZIG is not currently available in the US although available with IRB approval through FFF Enterprised (Temecula, California). Sample release forms are available through http://www.fda.gov/cber/infosheets/ mphvzig 020806form-pdf.

Approximately 4 to 6 weeks following resolution of maternal varicella infection, detailed ultrasound exams to evaluate for fetal effects should be performed. A subsequent ultrasound should be performed between 8 and 12 weeks to look for delayed effects.

Herpes Zoster

Herpes zoster represents a reactivation of VZV and is commonly known as shingles. Although herpes zoster may be contagious to a nonimmune person by skin-to-skin contact, it is not spread by respiratory secretions. Fetal effects are not reportedly seen, as most herpes zoster infections do not result in viremia. Depending on dermatomal reactivation, intrauterine infection theoretically could be possible if the uterus were involved with reactivation of T10-L1 (which innervates the uterus). In most recent reviews, in utero

transmission has not been reported without dissemination. These painful infections should be treated with acyclovir.

Prevention

Postpartum vaccination of varicella-nonimmune women should be offered when breast-feeding has been completed. Since it is a live, attenuated vaccine, the ACOG and AAP recommended that women avoid conception for 1 month following vaccine administration, although the manufacturer recommends a 3-month delay (*http://www.merck.com/product/usa/pi_circulars/v/varivax/varivax_pi.pdf*). However, since vaccine virus has not been found to be excreted into breast milk, it has been suggested that vaccine administration not be delayed in nonimmune breast-feeding women.

Parvovirus B19

Epidemiology

Erythema infectiosum and fifth disease are two common names for parvovirus B19 infection. B19 is the only parvovirus known to cause human infection. It was not until 1984 that parvovirus B19 was first described as a cause of fetal infection and nonimmune hydrops. Only 30% to 60% of adults are immune to this virus. The incidence of parvovirus B19 seroconversion during pregnancy is 1% to 2% but may be higher than 10% during epidemics.

Pathophysiology

Parvovirus is a highly contagious infection, with an attack rate of 60% to 80% of susceptible household contacts, whereas only 20% to 30% of susceptible schoolteachers or day care workers will become infected following exposure. Infection is most common in late winter or spring and is transmitted by respiratory droplets and contaminated blood. Transplacental fetal transmission occurs in one third of cases, with risk of adverse fetal outcome in approximately 10%. Parvovirus is a strong inhibitor of hematopoietic cells, including liver, myocardium, and erythroid precursor cells. The P antigen on the red blood cell is a receptor for parvovirus B19; fetal cardiac myocytes are another receptor for the P antigen. Although maternal infection can be asymptomatic, some will develop symptoms including fever, myalgias, and malaise initially followed by arthralgias and sometimes pruritis and rash—commonly a “slapped cheek”–appearing rash in children. Uncommonly, meningoencephalitis, hepatitis, or myocarditis may occur with seroconversion. Symptomatic fetal infection is seen in approximately 10% and is associated with myocarditis; nonimmune hydrops; fetal demise; spontaneous loss; and rarely, neurologic complications. When hydrops occurs, it usually does so within 2 to 6 weeks of fetal infection, although the reported range is 1 to 12 weeks, with the maximal risk for development of fetal hydrops between 17 and 24 weeks gestation. Although the mechanism behind development of hydrops is incompletely understood, severe anemia leading to high-output cardiac failure is the likely pathophysiologic mechanism.

Diagnosis

Diagnosis of maternal parvovirus B19 infection initially is made by serologic methods with enzyme immunoassay of B19 IgM and IgG. Antibodies of the IgM class will become measurable in 7 to 10 days following maternal infection, peaking at about 14 days then declining over 2 to 3 months. The IgG antibodies will rise more slowly, not peaking until about 4 months following acute infection. When IgG is positive on the initial specimen following exposure and IgM is negative, the patient demonstrates evidence of past infection. Immunity is lifelong, and she can be reassured that there is no fetal risk. If the first serum sample demonstrates negative IgM and IgG, acute seroconversion still may be occurring. Thus, repeat titers should be repeated 1 to 2 weeks after the initial titers were collected to study the evolution of the titers. To compare the sets of IgM/IgG antibodies most accurately, the laboratory should freeze the serum after running the first specimen to run together with the second specimen. Maternal B19 viremia will be present during acute seroconversion by DNA PCR, but persistent low-level viremia may persist for years following acute seroconversion. Thus, PCR testing for the virus is a less specific and a more expensive method of detection. New on the horizon include parvovirus B19 IgG avidity assays as well as IgG epitope specificity assays. These assays likely will be most useful in those patients with low-level parvovirus B19 IgM levels that may signify nonrecent seroconversion and may be associated with less, if any, fetal risk. Because fetal immunologic response is less pronounced, fetal and cord blood examinations should be confined to B19 DNA PCR.

Prenatal Diagnosis and Fetal Management

Following confirmation of acute maternal seroconversion, fetal ultrasound examinations should be serially performed for 10 to 12 weeks following seroconversion to evaluate for fetal anemia as well as hydrops and other signs of fetal viral infection such as calcifications in the liver and myocarditis. Similar to Rh isoimmunization, anemic fetuses from parvovirus B19 infection will demonstrate increased blood velocity, as measured by peak systolic velocity in the middle cerebral artery. Ultrasound evidence of anemia usually will precede the development of fetal hydrops, allowing for optimization of fetal procedures such as percutaneous umbilical blood sampling (PUBS) and intrauterine transfusion (IUT). Hydrops, defined as fluid in two or more fetal body cavities, traditionally was defined as pleural effusions, pericardial effusions, ascites, and scalp edema but also may manifest as placental edema and be accompanied by amniotic fluid abnormalities. IUT to support the fetus during the parvovirus B19 suppression of hematopoiesis can prevent hydrops formation or cause it to resolve. Resolution of hydrops may take weeks despite correction of fetal anemia with IUT. Spontaneous recovery of parvovirus-induced hydrops has been described but is uncommon. Fetal mortality is higher when hydrops is present and is lessened with IUT. Prognosis following fetal recovery from in utero parvovirus infection usually is quite good, and only rare neurodevelopmental, cardiac, and hematologic sequelae have been reported.

Toxoplasmosis

Primary maternal toxoplasmosis occurs in approximately 1 of every 900 pregnancies in the United States. This estimate

is based on a prospective study of sera from 23,000 pregnant women done in early and late gestation. That study, conducted by the National Institutes of Health, also showed that 38% of the women tested had antibodies to *Toxoplasma gondii*, indicating previous infection with the organism. More recent data suggest that the seroprevalence may now be somewhat lower (15% among women of childbearing age); this reduction may be due to improved hygiene, education, and meat practices. In earlier data, the presence of antibodies correlated with increasing patient age and was twice as frequent among blacks as among whites. None of the mothers tested had evidence of significant clinical disease. It has been estimated that between 400 and 4,000 babies are born with congenital *T. gondii* infections each year. Some data suggest that congenital infections occur in approximately 1 in 10,000 births.

Microbiology: Transmission

Cats

The cat is the definitive host for *T. gondii*, which is a protozoan parasite (Fig. 19.4). About one half of the cats tested in the United States have antibodies to *T. gondii*. It is thought that cats acquire infection by eating infected wild rodents and birds. A week after infection, the cat begins to shed oocysts in its feces. Shedding of the oocysts persists for about 2 weeks only, then the cat recovers spontaneously. These animals are susceptible to reinfection and also may shed toxoplasma oocysts when infected with other organisms.

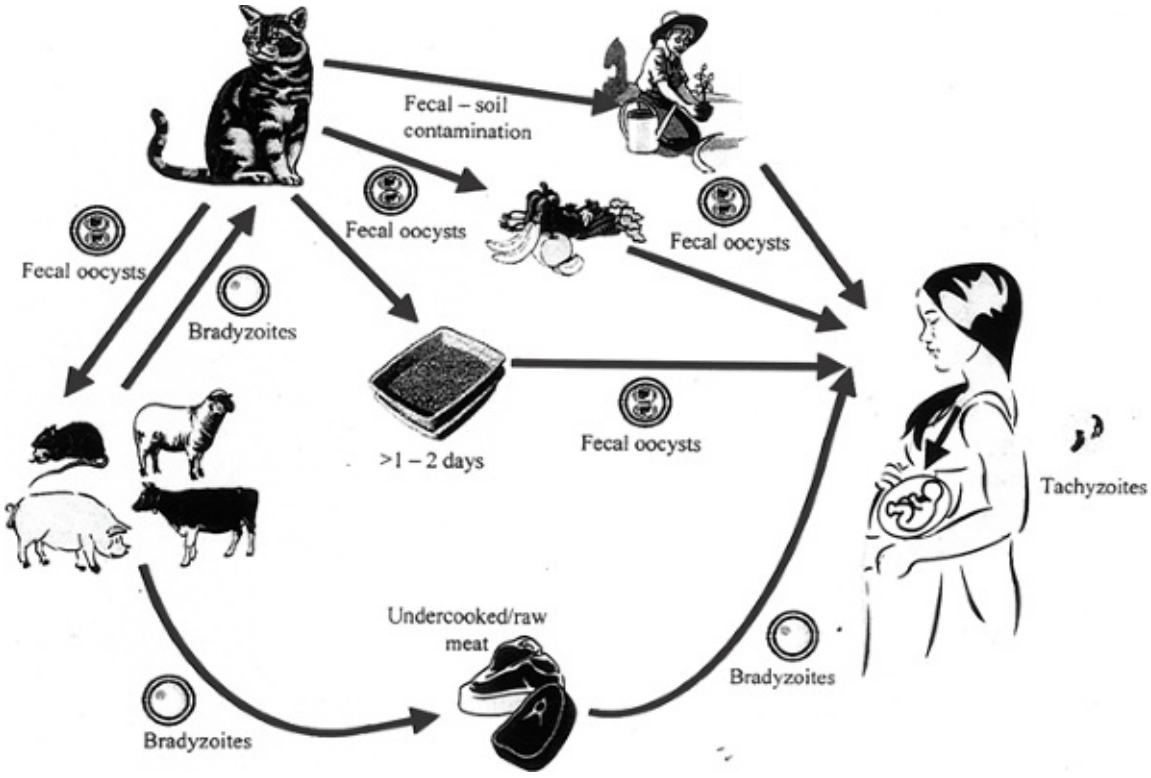

Figure 19.4 *T. gondii* in trophozoites or proliferative form. (From Jones JL, Lopez A, Wilson M, et al. Congenital toxoplasmosis: a review. *Obstet Gynecol Surv* 2001;50:297, with permission.)

Although the cats excrete unsporulated (i.e., noninfectious) oocysts in their feces, within days to weeks these oocysts sporulate and become extremely infectious. The fecal oocysts are an important source of infection to humans through inadvertent ingestion. Because sporulation of the organism occurs after days to weeks in cat litter, it is recommended that pregnant women not change the litter and instead it is changed daily by a nonpregant person. Care must be taken in disposing of cat litter because the oocysts can remain infectious for long periods in favorable climates.

Food

In Europe, where the use of refrigeration is more limited and foods usually are not frozen, ingestion of contaminated food is an important cause of toxoplasmosis. Although meat is the most common infected food source discussed, produce from oocyte-contaminated soil as well as unpasteurized milk and unfiltered water sources also are at risk. In the United States, most meat is frozen at some point during storage or transport. Freezing is probably one of the factors responsible for the difference in incidence of toxoplasmosis here and in Europe. Worldwide, about 1% of cattle, 20% of hogs, and 30% of sheep have toxoplasmosis.

To avoid contamination from meat, it should be cooked thoroughly at adequate temperatures. To avoid contamination of fruits and vegetables from potentially contaminated soils, thorough washing of fruits and vegetables is recommended. In addition, proper hand hygiene, prevention of cross contamination of cooking surfaces, and

cleaning of food preparation areas and kitchen knives is crucial. Organ transplantation is another less common risk factor.

Epidemiology

T. gondii has a worldwide distribution and has been reported from wherever cats are found. It is somewhat more common in tropical and coastal regions and is less common in regions that are cold, warm and arid, or at high elevation. The infection rate in the United States is significantly lower than that in France. Within the United States, seroprevalence rates are lower in the western central and mountain states and higher in eastern Atlantic and eastern central states.

Pathophysiology

Acute toxoplasmosis generally is well tolerated in immunocompetent adults but may result in vertical infection to the fetus and lead to potentially serious consequences. In the immunocompetent adult host, symptoms usually are mild or inapparent. In about 10%, fever, fatigue, malaise, headache, myalgias, and lymphadenopathy will be present. These symptoms will resolve in weeks to months without specific therapy. In immunosuppressed adult patients, signs and symptoms often will be more pronounced and can result in significant ocular and CNS abnormalities. Reactivation infection in immunosuppressed pregnant women also can cause fetal infection.

T. gondii exists in three forms: trophozoites or proliferative form (Fig. 19.4), tissue cysts, and oocytes. The organism undergoes a substantial portion of its life cycle in the cat, where after between 5 and 8 days of infection, there is peak oocyte production. As many as ten million oocysts per day can be shed in feces for periods varying between 7 and 20 days. These oocytes sporulate within 1 to 3 days and can remain infectious for several months in moist soil. At that point, they may be carried from point of deposition by other animals (e.g., flies) and deposited in food. It also has been suggested that they can become airborne from a dried-out litter box and lead to human infection. Eating undercooked or raw meat that contains tissue cysts causes approximately one half of infections in most humans. In the human, the trophozoite form of *T. gondii* is seen in the acute phase of the infection, and it is during this phase that host cells are invaded. Thereafter, the organism multiplies every 4 to 6 hours until the cytoplasm becomes so filled with trophozoites that the cells rupture, releasing organisms to invade other cells.

In Utero Transmission

Newborns with congenital toxoplasmosis become infected in utero by transplacental passage of the parasite when the mother has acute infection. Chronic infections (onset precedes pregnancy) do not lead to congenital infection except in the rare circumstance of an immunocompromised host (e.g., patient with systemic lupus erythematosus taking steroids, HIV infection) with reactivation. In general, the likelihood of fetal infection increases with each trimester of pregnancy, being approximately 15%, 25%, and 60% in the first, second, and third trimester, respectively. The severity of damage associated with congenital toxoplasmosis also is related to the timing of maternal infection, but in this

situation, the risks decrease toward term. Severe fetal disease or fetal death occurs in about 10% of cases when infection occurs during the first trimester and is extremely rare with infection during the third trimester. Mild damage is more frequent in the second and third trimesters (about 5%). Subclinical infections increase from about 2% with first-trimester infections to 50% with third-trimester infections. The results of a case-control study of women with poor pregnancy outcomes and controls suggested that acute infection could be associated with preterm delivery and stillbirth but not with spontaneous abortion. Chronic infections were not associated with any untoward outcomes.

Diagnosis in Pregnancy

Maternal Infection

Maternal infection with *T. gondii* usually is asymptomatic, although 10% to 20% of infected mothers have lymphadenopathy. Posterior cervical lymphadenopathy is the most frequent finding associated with acute maternal toxoplasmosis. The infection also can result in a mononucleosislike syndrome with fatigue and lassitude and, rarely, can cause encephalitis. Acute toxoplasmosis should be considered in any pregnant woman who has lymphadenopathy, particularly involving the posterior cervical chain, or mononucleosislike symptoms. The vast majority, however, of those acutely infected with *T. gondii* are asymptomatic. The clinical picture can be much more severe in immunocompromised adults.

Because of the wide clinical spectrum of toxoplasmosis, clinicians are forced to rely on serologic tools for the diagnosis of toxoplasmosis in pregnancy. The diagnosis of primary infection with *T. gondii* during pregnancy requires either (a) the demonstration of a seroconversion to this organism, (b) a significant rise in antibody titer obtained from maternal sera taken at two different times, or (c) the detection of toxoplasma-specific IgM antibody. Adults with primary infection develop IgG and IgM antibody to toxoplasma rapidly. Toxoplasma-specific IgG antibody develops within 2 weeks after infection, peaks in 6 to 8 weeks, drops down over the subsequent several months, and then

---

persists for life. Toxoplasma-specific IgM develops within 10 days after infection and remains elevated for 6 months to more than 6 years.

Because IgM antibody remains elevated for many months, IgM titers may not provide useful information to document recent primary infection in pregnant women. The enzyme-linked immunosorbent assay (ELISA) test for IgM frequently shows the development of high titers of IgM antibody that can persist for many months and even years. Indirect immunofluorescence antibody (IFA) tests for toxoplasma-specific IgM usually show high titers for only about 6 months after infection; thereafter, the titer rapidly drops. The IFA test, then, frequently is more useful than ELISA in differentiating remote from recent primary infection of a pregnant woman. In any case, the presence of IgG and the absence of IgM suggest an infection that is probably at least a year old.

Because of difficulties with the reliability of some commercially available tests for IgM, it has been recommended that all positive test results be confirmed in a reference

laboratory. The authors recommend the laboratory of Jack Remington and colleagues, who can be reached at 650-853-4828 or *toxolab@pamf.org*. Up to 40% of positive toxoplasma-specific IgM results from commercial laboratories are false positives.

Avidity testing is a newer type of testing that particularly can be helpful for testing for several of the infections discussed in this chapter, including toxplasma, CMV, and parvovirus. When antibodies are initially produced to a new antigen, the antibodies have low avidity for the antigen. As the antibody response matures, the avidity of the antibody increases. Avidity testing usually is expressed as an index, the percentage of the antibody bound to antigen following denaturation. Some researchers have suggested that the presence of high-avidity IgG antibodies exclude acute infection within the previous 3 months, thereby making it a useful test for first-trimester infections with serious fetal consequence such as toxoplasma and CMV, particularly when the IgM is elevated. If the IgM is falsely elevated, as reflected by nonprogression of acute and convalescent serum titers as well as high-avidity IgG antibodies, then there should be little fetal risk and much maternal anxiety can be averted.

Approximately 50% of placentas of congenitally infected infants will show *T. gondii* cysts on histologic slides, and their presence supports the diagnosis of acute infection in the mother during pregnancy. Additional cases can be detected by the presence of parasites in the cord blood. The organism also has been isolated from placental tissue of acutely infected mothers in 2% to 25% of cases. Recovery was more frequent when infection occurred later in pregnancy. Isolation of organisms from tissue specimens, buffy coat heparinized blood, and body fluids can be used for diagnosis as well. These specimens produce the organism after inoculation into the intraperitoneal cavities of mice or into tissue culture.

Prenatal Diagnosis

Antenatal diagnosis of fetal toxoplasmosis previously relied on culture of amniotic fluid (15 to 20 cc) or fetal blood (1.5 to 3.0 cc) obtained at the time of diagnostic amniocentesis or cordocentesis, respectively. The specimen commonly was cultured in mouse or fibroblast cells. The main difficulties with culture techniques have been that some assays may take up to several weeks to get complete results, and few laboratories are able to perform the assay. In addition, amniocentesis performed too early in gestation occasionally can be falsely negative.

Toxoplasma-specific IgM, when present in fetal blood from cordocentesis, also has been used to diagnose fetal infection prenatally. Unfortunately, fetal-specific IgM antibody frequently does not develop until after 21 to 24 weeks gestation and is positive in only about 50% of infected cases. Additionally, cordocentesis is a procedure that entails some risk.

More recently, the PCR has been used to detect *T. gondii* in amniotic fluid and has been shown to be useful in the detection of in utero infections. In one large series, PCR performed better than conventional tests (sensitivity 97.4% vs. 89.5%; negative predictive value 99.7% vs. 98.7%). In a more recent study, higher parasite concentrations (>100 per mL) were associated with more severe congenital infection outcomes. This information in particular may be useful for prenatal counseling. To a large extent, PCR of amniotic fluid

has rendered cordocentesis unnecessary for the purpose of diagnosing toxoplasma infections.

Prenatal ultrasound also may demonstrate abnormalities. Many of these visualized abnormalities will signify a poor postnatal prognosis. Ventriculomegaly and hydrocephalus as well as microcephaly will be poor prognosticators. Intracranial calcifications, placentomegaly, hepatomegaly cataracts, and hydrops may be other signs. Intracranial replication of toxoplasma tachyzoites as well as its proinflammatory cytokine response will cause necrosis and then the development of the periventricular calcifications. Resultant ventriculomegaly occurs secondary to relative obstruction of cerebrospinal fluid outflow through narrow areas such as the foramina of Monro and the cerebral aqueduct.

Due to the difficult nature of interpretation of this testing and the certain anxiety of the implications of a diagnosis of possible congenital toxoplasmosis, consultation with an expert is recommended for proper interpretation of serologic results and subsequent management recommendations.

Neonatal Infection

Most congenitally infected newborns are asymptomatic at birth. Literature has shown that detection of toxoplasma-specific immunoglobulin A (IgA) may be a reliable method for the diagnosis of toxoplasmosis in the newborn. A number of these asymptomatic, untreated infants will go on to have delayed and potentially serious manifestations. The

---

20% with clinically obvious symptoms at birth will exhibit multiple findings. The most frequent clinical findings are chorioretinitis, jaundice, fever, and hepatosplenomegaly. Hydrocephaly or microcephaly and cerebral calcifications can be seen in severe cases. Demonstration of toxoplasma-specific IgM infection may be diagnostic, although in newborns, approximately 20% of infections are not detectable by toxoplasma-specific IgM at birth.

Treatment and Prevention

Treatment of acute toxoplasmosis in immunocompetent, nonpregnant adults is primarily supportive. In general, the prognosis following acute infection is good, except in cases of profound immunosuppression.

The treatment in pregnancy is a bit more complex. In Europe, where the seroprevalence and, hence, the clinical experience is greater, spiramycin is the first-line agent used. However, that agent generally does not cross the placenta, and if fetal infection is detected, women also are treated with a combination of pyrimethamine, folinic acid, and a sulfonamide. Although not definitive, treatment with these regimens may prevent maternal-to-fetal transmission of the infection or improve the outcome among infected fetuses. In one study from France, 163 mothers diagnosed with toxoplasmosis prior to 28 weeks gestation were treated with spiramycin (23 also received pyrithiamine and sulfadiazine). Three fetuses died in utero, and 27 were diagnosed with congenital toxoplasmosis. All 27 were free from symptoms and had normal neurologic development at

15 to 71 months. Most studies that control for gestational age at the time of infection suggest that transmission rates are not altered markedly by therapy, but the degree of fetal sequelae may be.

The standard dosage is 25 mg of pyrimethamine by mouth given daily and 1 g of sulfadiazine by mouth four times daily for 1 year. Pyrimethamine is a folic acid antagonist and therefore may have teratogenic effects when given in the first trimester. Whenever possible, treatment with pyrimethamine in the first trimester should be weighed against the potential risk of drug teratogenicity to the infant. Folinic acid, 6 mg given intramuscularly or by mouth every other day, should be used to correct the depletion of folic acid induced by pyrimethamine.

Spiramycin can be obtained in the United States through the CDC. It is used more commonly in Europe, and hence, there are no good controlled studies of its efficacy in this country. It has not been found to be teratogenic in humans or animals.

Case-control studies in France, where women routinely receive serial assessments to detect seroconversion, have revealed that risk factors for acquisition of infection include poor hand washing, eating undercooked beef or lamb, and owning a cat. Based on these data, the CDC has recommended that serosusceptible pregnant women should be counseled to avoid eating raw or undercooked meats, which may contain *T. gondii* cysts. This can be accomplished by using a food thermometer to ensure that the meat is cooked all the way through. Fruits and vegetables should be peeled and washed before eating. Gloves should be used for gardening and during any contact with soil or sand because cat waste might be found there. Pregnant women should avoid close contact with cat feces, such as by avoiding changing cat litter. The CDC also highlights the need for obstetricians to educate pregnant patients about these important preventive steps.

In countries such as France, with high seroprevalence rates, routine serologic screening programs have proven successful in diagnosing recent seroconverters, allowing for prenatal diagnosis of fetal status and either termination of pregnancy or prenatal therapy. There is no consensus for routine screening in the United States. Because of the low prevalence of the disease and the possibility of false-positive results, the ACOG does not recommend routine screening.

Most recently, programs have been undertaken that focus on screening of newborns and the institution of treatment during the neonatal period to minimize the morbidity that would otherwise accrue to congenitally infected children. Many infections in children that otherwise would be missed on routine clinical examination can be detected with IgM assays. Treatment of these infected infants has been associated with very low rates of subsequent neurologic or retinal disease. Routine screening of newborns in the United States is not yet recommended.

Cytomegalovirus

CMV, a member of the herpesvirus family, is the largest virus that infects humans. It can code for over 200 proteins, through which it can lead to substantial down regulation of the immune system and many diseases, such as infectious mononucleosis in young adults. It

also causes the most common congenital viral infection, affecting approximately 1% of all live births, which comprises about 35,000 infants annually in this country. Congenital CMV infection is acquired by the fetus in utero when the mother develops primary CMV infection while pregnant or with reactivation of a prior maternal infection. Although reactivated disease in the pregnant woman accounts for more than one half of the congenital infections, primary maternal CMV infection is much more likely to result in a severely affected and symptomatic infant. Passive in utero transfer of maternally derived CMV-specific IgG antibody appears to provide some protection to the fetus when CMV is reactivated during pregnancy.

The majority of infants with congenital CMV are asymptomatic (90%), but some have evidence of disease during the newborn period (10%). About 10% of the symptomatic group has full-blown cytomegalic inclusion disease. An additional 10% of infected infants who are asymptomatic at

---

birth later develop symptoms related to CMV infection. The most common late-onset symptoms in these cases are mental retardation and deafness. These infants usually shed high titers of virus in the urine and saliva for a number of months.

CMV infections can be acquired by the child during the postpartum period through (a) exposure of the infant to infectious maternal body fluids such as cervical secretions, urine, saliva, and breast milk; (b) following blood transfusion or tissue transplantation from an infected donor; or (c) most frequently, through contact with infected individuals, such as in the newborn nursery, day care centers, or from other family members in the household. These cases are called *acquired cytomegalovirus infections* in contrast to *congenital infections*.

Virology

CMV has a diameter of about 180 nm and is encapsulated by an icosahedral capsid containing 162 capsomeres. Within the capsid is double-stranded DNA of about 230 kb that is enclosed by a lipid bilayer envelope. The diagnosis of CMV requires laboratory confirmation and cannot be made on clinical grounds alone. Seroconversion, monoclonal antibody, and PCR are among the tools available for diagnosis.

Antibody response (whether maternal or fetal) may play a less important role in transmission and, subsequently, in the development of symptomatic disease than other viral factors, such as the amount of maternal viremia or the timing in pregnancy during which infection and subsequent maternal-to-fetal transmission occurs.

Epidemiology

Seroprevalence of CMV among adult populations shows significant geographic variability. Rates range from 40% to 100% depending on the region surveyed, with most infections being detected solely by serologic screening (i.e., asymptomatic). Countries or regions with low socioeconomic status usually demonstrate very high seroprevalence rates. The risk of seroconversion during pregnancy for a seronegative woman is approximately 2%. However,

because congenital infections can follow either primary disease (maternal seroconversion) or reactivation of disease, congenital infections may occur in a much higher percentage of cases. There are two periods in life when infection rates are particularly high—perinatal (related to mother-to-child transmission, breast-feeding, and child to child) and reproductive age (putatively related to sexual transmission).

Pregnant women acquire CMV infection either through exposure to infected children (the infected children shed virus in urine, saliva, and nasopharyngeal secretions and are infectious for a prolonged period) or through sexual contact. About 1% to 2% of women in the United States shed CMV from their cervix at any given time, although that number is higher in women with multiple sexual partners.

Pathophysiology

The incubation period for CMV is 20 to 60 days. Following primary infection, the virus goes into a latent phase within host tissues. Intermittent periods of reactivation occur frequently, and virus again is excreted in the nasopharynx, cervix, urine, saliva, and breast milk. Maternal viral shedding increases throughout pregnancy, and neonatal infection becomes increasingly likely as cervical shedding rates increase toward term.

Acquisition of disease by neonates at the time of birth is much more common than congenital infection but is much less devastating. Perinatally acquired infection comes from CMV carried in the cervix during the late stages of pregnancy as well as from CMV in breast milk. After primary infection during the prenatal period, the congenital infection rate has been reported to be as high as 55%. Although the majority of infants with congenital CMV are asymptomatic, infants with symptomatic infection at birth usually have findings associated primarily with the reticuloendothelial and central nervous systems. The severe cases of congenitally acquired symptomatic infection result from primary rather than recurrent infection in the pregnant woman and from infections occurring early in pregnancy. The most common findings in these severe cases include hepatosplenomegaly, jaundice, a generalized petechial rash, microcephaly, and growth restriction. Less common findings include chorioretinitis with or without optic atrophy, pneumonitis, cerebral calcifications, microphthalmia, microcephaly, seizures, and cerebral and cerebellar atrophy. The mortality of newborns with symptomatic disease is approximately 30%. Most deaths are due to disseminated intravascular coagulation, hepatic disease, and bacterial superinfection. In those neonates with sequelae at birth, 13% will have mental impairment.

Diagnosis

Maternal Infection

The majority of primary maternal infections with CMV are asymptomatic and unrecognized. When symptoms do occur, they often are not recognized as being indicative of CMV because they appear as a mild, infectious, mononucleosislike illness, with lymphadenopathy, fatigue, and slight fever. Even though CMV is hepatotropic, elevations in liver enzyme levels rarely are seen in primary or recurrent infections. In primary infections, lymphocytosis may be present with increases in atypical lymphocytes and

thrombocytopenia. A diagnostic approach to the pregnant woman following CMV exposure is outlined in Figure 19.5. About one third to two thirds of all pregnant women have IgG antibodies to CMV, indicating previous infection. Detection of CMV-specific IgM during the acute phase of infection

is useful for making the diagnosis of CMV infection, but only 80% of women with primary infection demonstrate this antibody. In addition, more than one third of mothers with recurrent CMV from latent infection will be positive for CMV-specific IgM. CMV-specific IgM antibodies may persist up to 18 months, and some test methods may give false-positive results because of cross reactions with other herpesviruses, antinuclear antibody, or rheumatoid factor. A microneutralization assay may be of some utility. In one study, antibodies did not appear until 15 weeks after infection and persisted thereafter. Thus, its absence, shortly after a presumed infection, can help to rule out infection. In a recent report from a referral center in Italy, about one half of pregnant women with a diagnosis of preliminary referring CMV infection had no evidence of active infection. Clinicians should be thoughtful in analyzing commercially available tests results for IgG and IgM anti-CMV antibodies.

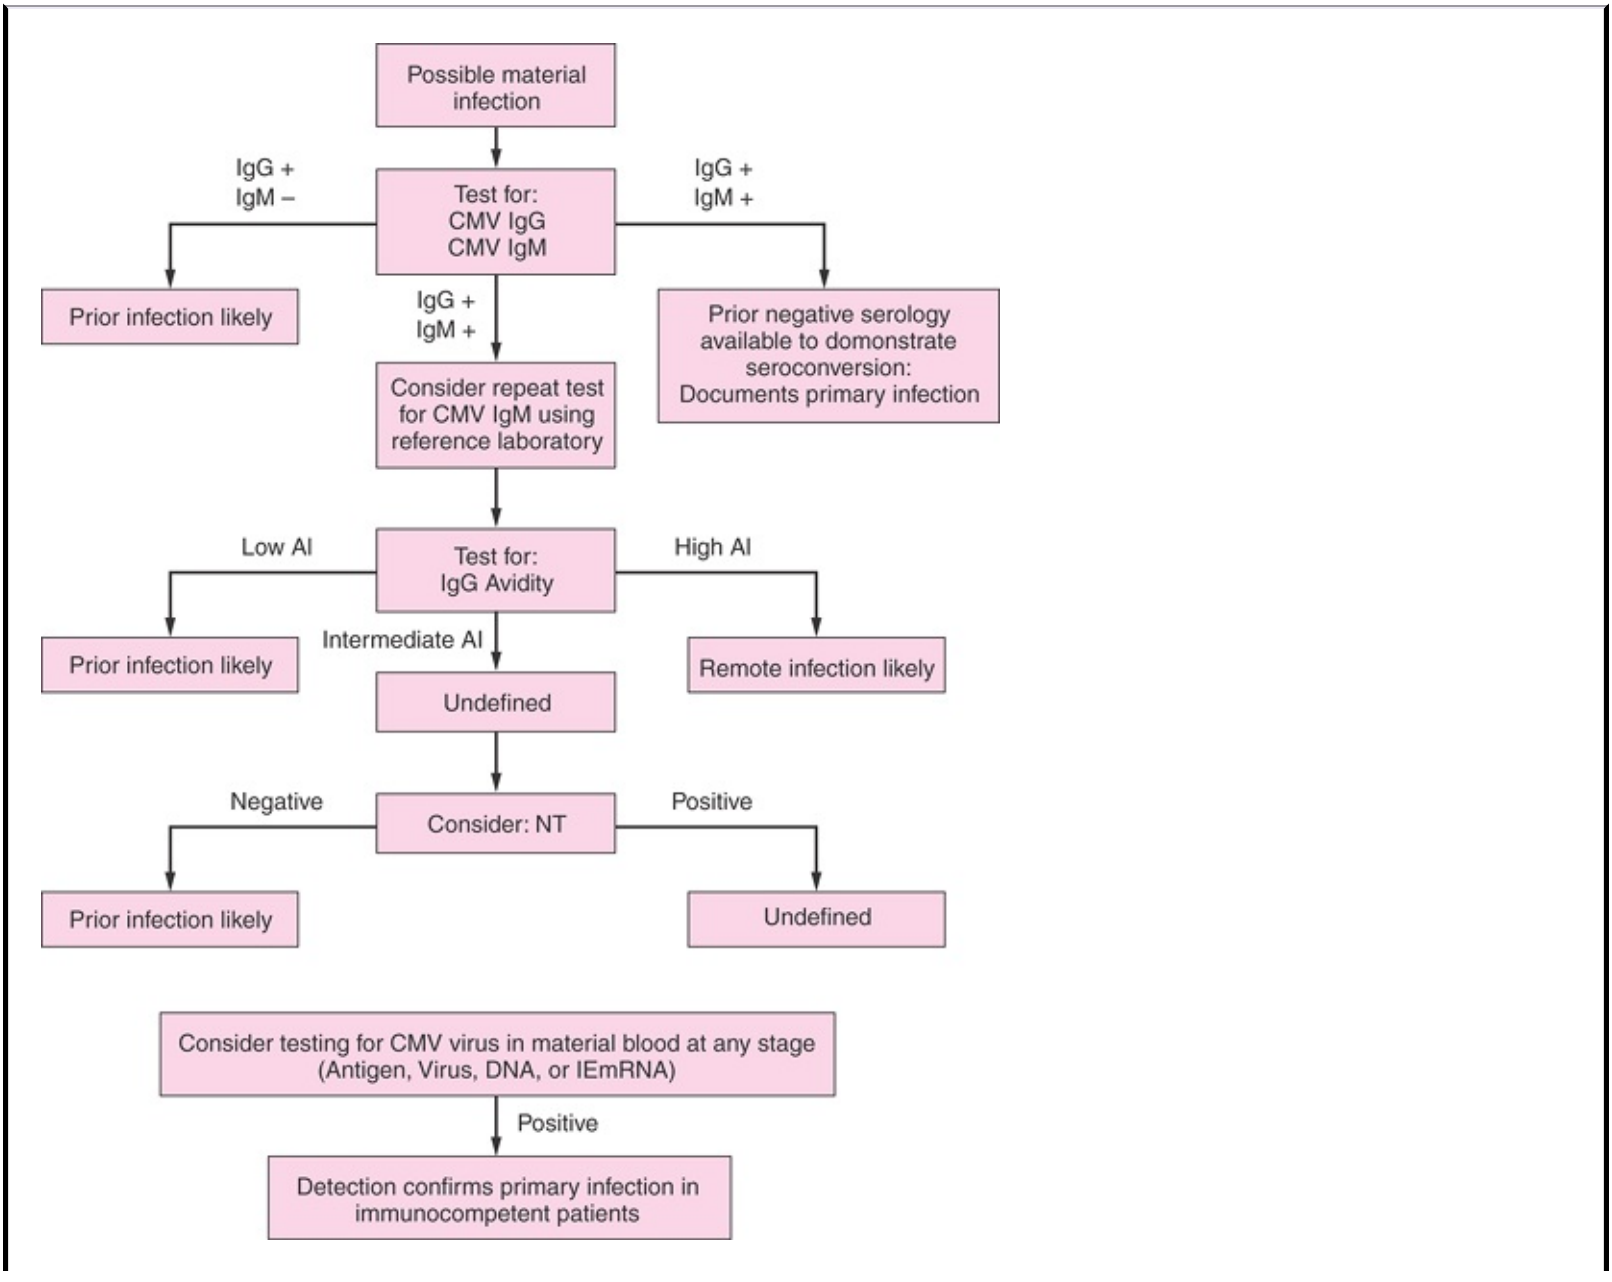

Figure 19.5 Diagnosis of maternal CMV infection. (CVM, cytomegalovirus; IgG, immunoglobulin G; IgM, immunoglobulin M; AI, avidity index; NT, neutralization test; IEmRNA, intermediate-early messenger RNA.) (From Hollier LM, Grissom H. Human herpes viruses in pregnancy: cytomegalovirus, Epstein-Barr virus, and varicella zoster virus. *Clin Perinatol* 2005;32:674; adapted from Revello M, Gerna G. Diagnosis of congenital HCMV infection. *Clin Microbiol Rev* 2002;15[4]:680–715, with permission.)

Avidity studies, with similar methodology to that described previously for toxoplasmosis, also can be performed with CMV IgG to try to differentiate between primary and reactivation infection. Again, when antibodies are first made to an antigen, they are of low avidity. With time, as antibodies mature, the avidity increases. Thus, the presence of high avidity shortly after a suspected infection makes recent infection (and the highest fetal risk) highly unlikely.

Viral culture is the gold standard for the diagnosis of CMV infection. Virus usually is detected in the cervix, nasopharynx, and urine of infected individuals. However, culture results are positive with both primary and recurrent infections. PCR also has proven to be quite useful in the detection of CMV. Quantitative PCR testing has been particularly useful in the management of AIDS and transplant in patients whose high serum levels augur complications, and it offers an early opportunity for the initiation of antiviral therapy.

Fetal Infection

Sonography may be useful for identifying some abnormalities in the fetus that may be related to CMV infection. A

spectrum of sonographic findings including fetal hydrops, intrauterine growth restriction, polyhydramnios, fetal ascites, and specific CNS anomalies (e.g., ventriculomegaly, periventricular calcifications, and microcephaly) as well as intra-abdominal pathology (hepatosplenomegaly, intra-abdominal calcifications) may suggest an intrauterine infection, possibly CMV, and invasive fetal testing should be considered. When multiple ultrasound markers are found (microcephaly in particular is worrisome), prognosis is often poor, whereas if only isolated markers are found such as isolated hepatic calcifications, prognosis may be better.

Lynch and others reported the successful prenatal diagnosis of fetal infection by a combination of amniotic fluid culture and measurement of total and CMV-specific IgM and γ-glutamyl transpeptidase in fetal blood samples. In a study of 189 pregnancies with known outcome, Enders and colleagues reported 89.5% sensitivity with the use of amniotic fluid and fetal blood assessments for virus and anti-CMV IgM. They noted that the correct diagnosis of in utero infection with CMV by amniotic fluid analysis could be expected after 21 weeks gestation and at least 6 weeks following the diagnosis of infection in the mother. Other authors have reported similar sensitivities and have pointed out that those instances of false-negative results often are associated with infants with minimal stigmata of disease. Further studies are needed on the sensitivity and specificity of these methods in

identifying infected infants prior to birth.

More recently, quantitative PCR from the amniotic fluid has been used to give additional direction to counseling when congenital CMV is diagnosed in the fetus by amniocentesis. Guerra and associates showed that if <103 organisms per milliliter were present in the amniotic fluid, then 81% would have no evidence of infection at birth. If there were ≥103 but <105 organisms per milliliter in the amniotic fluid, there was a 92% probability that the fetus or newborn would be asymptomatic. If there were ≥105 organisms per milliliter, then there was 100% probability that the fetus or newborn would be symptomatic.

Neonatal Infection

The definitive diagnosis postnatally is best made through the detection of viruria during the first week of life. The presence of IgM antibodies in cord serum is suggestive but not sufficiently specific to make a definitive diagnosis.

Management

Mother

Susceptible pregnant women have a 2% risk of seroconverting while pregnant. Routine serologic testing of pregnant women is not recommended because of this relatively low risk of infection, there is a somewhat low rate of possible damage to the fetus, and no effective therapy is available to infected infants.

Probably the single most important method of preventing primary infection during pregnancy is minimizing exposure in high-risk areas, such as nurseries, day care centers, and other places that have a high concentration of young children. Careful hand-washing techniques as well as proper handling of potentially infectious body fluids should be instituted to minimize spread of the infection. Specific education to a known seronegative individual is helpful in preventing CMV acquisition during pregnancy.

Secondary prevention with maternal IVIG recently has been suggested in a small, nonrandomized trial to be efficacious in treatment of pregnant women with evidence of recent seroconversion or in women with positive amniotic fluid studies. In the treatment arm of the trial, only 3% had symptomatic disease at birth and handicap at 2 years of age in the child compared with 50% of those not offered IVIG during pregnancy. In the prevention arm, 16% had congenital CMV infection with IVIG compared with 40% who did not receive IVIG. Results of a controlled trial to confirm these favorable nonrandomized results are anticipated, as IVIG therapy is quite expensive.

There are no protocols for the use of antiviral agents (acyclovir and ganciclovir) during pregnancy to decrease the risk of mother-to-child transmission of CMV. Although gangiclovir has been administered in case reports both intravenously and into the amniotic fluid of two different fetuses, one was stillborn and the other still had symptomatic CMV disease at birth. Ultimately, it is hoped that a vaccine will be developed that will prevent CMV. Some authors have suggested that in order to target both the mothers most likely to transmit to infants and those most likely to transmit to pregnant women, young unmarried mothers

and all toddlers and preteen children should be considered for vaccination.

Infant

Clinically evident infection in newborns and infants is treated symptomatically. In the most severe cases of neonatal infection, antiviral agents such as acyclovir and ganciclovir have been used to suppress the infection, but discontinuation of the medication results in reappearance of the infection. Foscarnet (phosphonoformic acid) has been used in primary symptomatic neonatal disease and has been effective in reducing viral shedding. All of these medications have a narrow therapeutic index, and none has achieved substantial success in the amelioration of symptomatic disease.

Herpes Simplex Virus

HSV causes an extremely common sexually transmitted disease (STD), with potentially devastating consequences for the perinatally infected neonate. Management of these infections in pregnancy has undergone substantive evolution.

Microbiology

HSV is an encapsulated double-stranded DNA virus that infects susceptible mucosal surfaces. The DNA-containing core is surrounded by an envelope containing viral proteins that are important for attachment to host cell receptors, cell penetration, and immune escape mechanisms. There is approximately a 50% homology in the DNA sequences of HSV type 1 (HSV-1) and HSV type 2 (HSV-2). HSV-2 predominantly is genital, and HSV-1 predominantly causes oral lesions, although HSV-1 causes an increasing percentage of genital lesions as well. Either virus can cause serious illness in the neonate. Immunity to one virus leads to an attenuated illness if an individual becomes infected with the other.

Epidemiology

Whereas only approximately 5% of the reproductive-age population gives a history of clinical herpes infections, serologic surveys suggest that up to 20% to 25% of adults have unequivocal evidence of HSV-2 infection. That represents a 30% rise in the age-adjusted risk since the late 1970s (Fig. 19.6). A large majority of those individuals who are seropositive will shed virus intermittently for many years after the initial infection. The rate of shedding does not vary significantly between those with and those without a history of genital herpes. The reason that most seropositive women are unaware of their status may be related to the presence of antibody to HSV-1, which offers sufficient protection from HSV-2 to mute any symptoms. However, with proper education, a large percentage of women can be trained to recognize recurrences. The infection is transmitted from both symptomatic and asymptomatic individuals, with the latter being the cause of the majority of new infections. Transmission occurs with greater facility from men to women. However, condoms seem to be more effective in preventing transmission from men to women than from women to men. There is little evidence to suggest that pregnancy, in itself, increases

either the frequency or the severity of genital HSV infections. In one study, in an unselected patient population, HSV shedding occurred in only 0.1% to 0.4% of all deliveries. In other studies of pregnant women with histories of HSV, positive culture results have been found in 0.2% to 7.4% of asymptomatic women. It has been estimated that if PCR were used in lieu of cultures, shedding would be detected about eight times as frequently. The rate of shedding at term is no higher than at other times in pregnancy. Unfortunately, from the therapeutic perspective, most women who shed viruses are not aware that they are shedding or that they are seropositive for HSV.

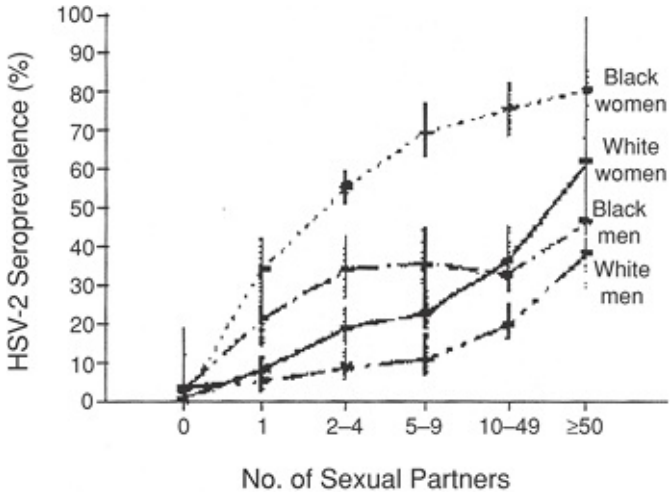

Figure 19.6 HSV-2 seroprevalence according to the lifetime number of sexual partners, adjusted for age, for black and white men and women in the National Health and Nutrition Evaluation Survey (1988–1994). *Bars* indicate 95% confidence intervals. (HSV-2, herpes simplex virus type 2.) (From Fleming DT, McQuillan GM, Johnson RE, et al. Herpes simplex virus type 2 in the United States, 1976–1994. *N Engl J Med* 1997;337:1105–1111, with permission.)

Pathophysiology

HSV has an incubation period of 2 to 10 days, followed by a primary infection that is characterized by focal vesicle formation and a pronounced cellular immune response. The infection enters a latent phase, with the virus ascending peripheral sensory nerves and coming to rest in nerve root ganglia. Recurrent exacerbations occur intermittently, stimulated by poorly understood mechanisms. Infection may be primary, recurrent, or nonprimary first episode. Primary infection poses the greatest risk to both mother and infant. Clinically, it is not possible to distinguish the kind of infection. Proper identification requires isolation and typing of the virus and type-specific antibody testing of the patient. About 40% of infants born vaginally to mothers with a primary infection will themselves have HSV infection compared with only 0% to 4% of those born to mothers with recurrent infection. Viral shedding occurs for a significantly longer period with primary infection (1 to 2 weeks) than with recurrent infection (3 to 5 days).

Type-specific antibodies appear approximately 7 days following the onset of primary

infection, reaching a peak in 2 to 3 weeks, and generally remain detectable for life. Titers do not rise significantly with recurrent infections. The significant difference in infection rates in neonates born to mothers with primary infections versus those born to women with recurrent infections suggests that maternal antibodies provide some protection.

Disseminated primary HSV infections in pregnant women are rare. When these infections become disseminated during pregnancy, mortality is high for both the mother and fetus, and systemic antiviral therapy is recommended.

Although HSV shedding occurs in approximately 0.1% to 0.4% of deliveries, the frequency of neonatal infection is 10-fold or lower. The reason for this difference in infection between mother and newborn probably is related to

---

both a protective benefit of maternal antibodies and to the size of the viral inoculum to which the fetus is exposed during birth. The viral inoculum associated with asymptomatic shedding is several logs less than that associated with primary infection. Because of the absence of protective maternal antibodies (given transplacentally to the fetus), maternal infection late in pregnancy is the time most likely to result in an infected neonate.

Neonatal infection may result from either HSV-1 or HSV-2. The majority of cases of neonatal HSV infections, however, are caused by HSV-2, with approximately 76% of isolates from infected neonates being HSV-2. It is estimated that approximately 90% of cases of neonatal HSV infections can be traced to a maternal source of infection and are secondary to either ascending infection with ruptured membranes or to colonization during the actual birth process.

As noted, approximately 40% of mothers delivering vaginally with a primary genital HSV infection will give birth to an infant with HSV infection. Of these infected neonates, 60% will die during the neonatal period. Of equal concern is that approximately 50% of the survivors will have significant sequelae, such as microcephaly, mental retardation, seizures, microphthalmia, retinal dysplasia, chorioretinitis, meningitis, encephalitis, hypertonicity, apnea, and coma. Although less common, the neonate also may acquire infection from exposure during the neonatal period from either or both parents or from other family members, other infected infants, or infected health care workers.

“Congenitally infected” fetuses resulting from transplacental infection (in maternal primary infection) with malformations are rare. Congenital infections have been defined by the presence of skin vesicles or scarring, chorioretinitis, hydranencephaly, microphthalmia, microcephaly, or an abnormal computed tomographic (CT) scan of the brain within the first week of life.

Diagnosis

When typical clinical signs are present, the diagnosis of HSV infection is relatively easy. Generally, there are multiple painful ulcers on an inflamed surface. The lesions progress to ulcers, and there may be accompanying painful adenopathy and fevers. Other ulcerative lesions (e.g., syphilis, chancroid) should be considered as well. However, HSV can present atypically as recurrent fissures and recurrent itching, without vessicles or ulcers. Further,

most women with unequivocal serologic evidence of HSV-2 infection have not been diagnosed clinically. Virus isolation by tissue culture is one method of confirming the diagnosis of HSV infection but has limited sensitivity. Culture positivity decreases with the duration of the lesion. Cytologic tests such as Pap smear and Tzanck preparations should not be used for diagnosis because they tend to be less accurate. Rapid accurate tests for HSV, such as PCR, have been demonstrated to have utility in research settings and undoubtedly will eventually establish a role in clinical medicine. PCR is several-fold more sensitive than culture.

Reliable type-specific antibodies for HSV-1 and HSV-2 have been approved by the Food and Drug Administration (FDA) and have acceptable sensitivity (80% to 98%) and specificity (>96%). These are based on antibodies to glycoprotein G.

Management

There are many treatments now available to the nonpregnant individual that will shorten the course of HSV or ameliorate symptoms. Even before antiviral therapy is instituted, there are some therapies that can be offered. Application of topical cool compresses with Burow's solution for 15 minutes four to six times daily may be helpful for patients with extensive erosions on the genitalia. For a first episode of HSV-2, several medications are available.

Severe cases may be treated with intravenous acyclovir 5 mg per kilogram, infused at a constant rate over 1 hour, every 8 hours for 7 days in patients with normal renal function or oral acyclovir, oral famciclovir, or oral valacyclovir, each for 7 to 10 days. The CDC offers recommendations for exact doses.

For episodic treatment of a recurrent lesion, the CDC recommends several choices. One is acyclovir (either 400 mg orally three times a day for 5 days, 800 mg orally two times a day for 5 days, or 800 mg orally three times a day for 2 days), generally started during the prodrome or within 2 days of onset of lesions. Famciclovir also is useful for treatment of recurrent genital herpes (125 mg orally every 12 hours for 5 days or 1,000 mg orally two times a day for 1 day), started at the first sign of symptoms. Valacyclovir (500 mg orally every 12 hours for 5 days or 1 g orally daily for 5 days) can be used as well.

As HSV is an STD, individuals diagnosed during pregnancy should be screened for other STDs. Moreover, cesarean delivery, even with intact membranes, will not prevent all cases of neonatal HSV infections secondary to maternal genital HSV infection. There are many reported cases of neonatal HSV infections in infants delivered by cesarean section with intact membranes.

Recommendations for pregnant women with HSV infections include the following:

- Cultures should be performed to confirm the diagnosis when a woman has active HSV lesions during pregnancy. If there are no visible lesions at the onset of labor, vaginal delivery is acceptable.
- Weekly surveillance cultures of pregnant women with a history of HSV infection but no visible lesions are not necessary, and vaginal delivery is acceptable.

- Amniocentesis in an attempt to rule out intrauterine infection is not recommended for mothers with HSV infection at any stage of gestation.

- Cesarean section should be performed if lesions are present or if there is a typical syndrome at the onset of labor.

Oral acyclovir prophylaxis in late pregnancy is effective in preventing recurrence and reducing the need for cesarean section both in women with a history of herpes in the current pregnancy as well as in women with a remote history. Cost savings with that strategy have been suggested based on decision analysis. Although acyclovir is a nucleoside that incorporates into DNA, registries have not revealed an untoward rate of adverse outcomes among exposed infants.

Intrapartum

It is recommended that term patients who have visible lesions, are in labor, and have ruptured membranes should undergo cesarean delivery. Among women with recurrent lesions, the presence of antibody may make the mother-to-child HSV transmission rate lower, but cesarean section in the presence of visible lesions is recommended regardless of the mother's history.

Although classically it has been taught that cesarean delivery of women with visible lesions should be performed only if membranes have been ruptured for less than 4 to 6 hours, not all neonates born to mothers with HSV infections become infected, even with membranes ruptured for more than 24 hours. In contrast, neonates born by cesarean delivery within 2 hours of rupture of membranes have developed HSV infection.

The management of patients with active HSV infections and premature rupture of membranes remote from term is based on small core series. The risk of extreme immaturity must be weighed against the risk of neonatal HSV infection. There have been several case reports of infants born without sequelae after prolonged periods of conservative management.

Because the use of scalp electrodes has been associated with neonatal infection, monitoring by fetal scalp electrode is relatively contraindicated in women with history of HSV infection but without lesions or symptoms.

Treatment

There is no known cure for HSV infection. The purine analogues acyclovir, valacyclovir, and famciclovir have been used to treat both primary HSV infection and to prevent recurrent HSV infection in nonpregnant women.

Prevention

Although it is not necessary to isolate the infant from the infected mother, the infected parturient should be counseled regarding hand washing and good hygiene to prevent infection of the infant. Every effort should be made to avoid direct contract of the

newborn with herpetic lesions.

Universal serologic screening has been recommended by some authorities, but this is an unproved approach. It is likely that this approach is be cost-effective.

Intra-amniotic Infection

IAI also is known as chorioamnionitis, amnionitis, intrapartum infection, and amniotic fluid infection. In this chapter, IAI is used to distinguish this clinical syndrome from bacterial colonization of amniotic fluid and from histologic inflammation of the cord or placenta. Prospective studies published in the last few years report rates of 4% to 10% among nonprivately insured and privately insured patients, respectively.

Pathogenesis

The ascending route is the most common pathway for development of IAI. A hematogenous or transplacental route of infection occurs with *Listeria monocytogenes*. Other virulent organisms, such as GBS, may lead to a similar blood-borne infection. IAI may occur infrequently as a complication of invasive diagnostic procedures such as amniocentesis or IUT.

In large investigations using logistic regression analysis, risk factors for IAI were identified as follows: low parity, prolonged duration of membrane rupture, prolonged duration of labor, larger number of vaginal examinations, and duration of internal fetal monitoring. With regard to the use of internal fetal monitoring, the authors feel that this technique should be used if it enables the practitioner to diagnose and treat labor abnormalities more efficiently.

Once IAI develops, the fetus may swallow and aspirate the infected fluid and is prone to develop pneumonia, enteritis, meningitis, and sepsis. Indeed, a clinical diagnosis of IAI is one of the most important risk factors for neonatal sepsis.

Microbiology

IAI is a polymicrobial infection, involving both aerobic and anaerobic bacteria. The most common isolates in the amniotic fluid of over 400 cases of IAI are shown in Table 19.3.

Diagnosis

The most common clinical criteria for IAI are fever, leukocytosis, and ruptured membranes; fetal and maternal tachycardia are noted in variable percentages of cases. Foul-smelling amniotic fluid and uterine tenderness, although more specific signs, occur in a minority of cases. In cases of clinical IAI, maternal fever was present in 85% to 99%, fetal tachycardia in 37% to 82%, maternal tachycardia in 19% to 37%, uterine tenderness in 13% to 16%, and foul-smelling amniotic fluid in 9% to 22%. The determination of amniotic fluid glucose concentration is a practical test for diagnosing clinical IAI. With an amniotic glucose concentration <5 mg/dL, the likelihood of amniotic fluid culture results being positive is

approximately 90%. On the other hand, when the amniotic fluid glucose concentration is >20 mg/dL, the likelihood of a positive culture result is approximately 2%. At intermediate values (e.g., 14 and 15 mg/dL), the likelihood of a positive amniotic culture result is 30% to 50%.

TABLE 19.3 Amniotic Fluid Isolates in 404 Cases of Intra-amniotic Infection

Organism[a]	Number (%)
GBS	59 (14.6)
Escherichia coli	33 (8.2)
Enterococci	22 (5.4)
Gardnerella vaginalis	99 (24.5)
Peptostreptococci	38 (9.4)
Bacteroides bivius	119 (29.4)
Bacteroides fragilis	14 (3.4)
Fusobacterium spp.	22 (5.4)
Mycoplasma hominis	123 (30.4)
Ureaplasma urealyticum	190 (47.0)

GBS, group B streptococci.
[a]For bacteria, all isolates shown were found in concentrations of $\geq 10^2$ cfu/mL. Genital mycoplasmas were cultured qualitatively.

permission.

Management

When IAI is diagnosed, there is a need for delivery of the fetus as well as antibiotics. With regard to timing of delivery, there has been excellent maternal–neonatal outcome without use of arbitrary time limits. Cesarean delivery has been performed for standard obstetric indications, not for IAI alone. In nearly all cases, delivery occurred within 8 hours following diagnosis of IAI, and the mean time was between 3 and 5 hours. No critical interval from diagnosis of amnionitis to delivery could be identified, as the duration of chorioamnionitis is not related to most adverse outcome measures. There is no compelling indication to perform cesarean delivery in the setting of chorioamnionitis unless there are other obstetric indications. Cesarean section rates are higher among patients with IAI, running two to three times greater than in the general population. The reason for the increase most likely results from two considerations. First, IAI commonly develops in patients who have dystocia as an underlying problem. Second, the uterus with IAI is less sensitive to oxytocin.

TABLE 19.4 Outcome by Maternal Treatment Group in Cases of Intra-amniotic Infection: Results of a Randomized Study

Characteristic	Maternal Treatment		
	Intrapartum (n = 26)	Postpartum (n = 19)	P
Maximum maternal temperature postpartum	99.8 ± 0.8	100.3 ± 1.1	.050
Maternal postpartum hospital stay (d)	4.0 ± 1.0	5.0 ± 1.9	.050
Early neonatal sepsis (No., %)	0	4 (21)	.030
Neonatal pneumonia or sepsis (No., %)	0	6 (32)	.003
Neonatal hospital stay			

(d)[a]	3.8 ± 1.1	5.7 ± 3.0	.020

[a]Data are presented as mean ± SD.
Gibbs RS, Dinsmoor MJ, Newton ER, et al. A randomized trial of intrapartum versus immediate postpartum treatment of women with intra-amniotic infection. *Obstet Gynecol* 1988;74:562, with permission.

The benefits of intrapartum treatment have been well established. Intrapartum initiation of antibiotic treatment improves maternal outcome, decreases neonatal bacteremia, and does not result in delayed sepsis (Table 19.4).

As noted previously, the traditional antibiotic approach to treatment has been with combination therapy, primarily broad-spectrum penicillin with an aminoglycoside, plus clindamycin in some cases (such as cesarean delivery or apparent sepsis). Because of the expense and complexity of such therapy, there has been recent interest in single-drug treatment of IAI. In view of the well-described microbes involved, there would be several reasonable choices of single-agent therapy, but there have not been sufficient comparative trials to recommend alternative single-agent therapy. Studies have addressed the issue of duration of antibiotic therapy following delivery in the treatment of IAI. There is new, good evidence that short courses of treatment (even limited to treatment in labor plus a single postpartum dose) is equally effective when compared with longer courses.

Outcome

From descriptive studies largely from the early 1980s, several strong consistent observations may be made about

short-term outcomes of IAI. Maternal outcome was excellent, with bacteremia occurring in only 2% to 6%. Maternal outcome was more complicated in patients who had cesarean delivery. No critical diagnosis to delivery interval was demonstrable. Specifically, neither prenatal mortality nor maternal complications correlated with more prolonged intervals from diagnoses of IAI to delivery. Yet all patients delivered within 4 to 12 hours, and nearly all patients received intrapartum antibiotics. Although prenatal mortality was relatively high, little of this was directly attributable to infection because most of the prenatal mortality was due to accompanying prematurity. Prior to term pregnancy, neonates have a higher frequency of complications if they are delivered of mothers with IAI. The group with IAI had a significantly higher number with respiratory distress syndrome and any diagnosis of infection.

Thus, IAI has a significant adverse effect on the mother and neonate. Short-term outcome is dependent largely on the organisms in the amniotic fluid (with *Escherichia coli* and GBS more likely to result in maternal or neonatal bacteremia), low birth weight (with low-birth-weight infants faring more poorly), and timing of antibiotic therapy (with intrapartum

administration improving outcome).

Traditional complications of IAI have been maternal and neonatal sepsis, neonatal pneumonia and meningitis, and neonatal death. Recent studies indicate that complications of IAI should be expanded to include long-term outcomes such as periventricular leukomalacia, cerebral palsy, respiratory distress syndrome, and perhaps other neonatal complications. The hypothesized mechanism is that ascending infection leads to placental and congenital infection. This in turn leads to an overly exuberant production of inflammatory cytokines, which then leads to cell damage. Evidence for these expanded neonatal complications after IAI are as follows:

. Intrauterine exposure to maternal or placental infection is epidemiologically associated with an increased risk of cerebral palsy.

. Levels of inflammatory cytokines are increased in the amniotic of infants with brain white matter lesions or respiratory distress syndrome.

. Experimental intrauterine infection has led to brain white matter lesions in rabbits.

Prevention

Within in the last few years, several intervention strategies for preventing clinical IAI have been evaluated. These are summarized in Table 19.5.

Postpartum Endometritis

Seven decades into the antibiotic era, genital tract infections continue to pose a common, and occasionally severe, threat to women after childbirth. Although substantial progress has been made in the control of puerperal sepsis, infection still ranks as the fourth most common cause of maternal death.

TABLE 19.5 Clinical Measures to Irevent Intra-amniotic Infection

1. Identify dystocia promptly, and treat hypotonic dysfunctional labor promptly with oxytocin.
2. In patients with premature rupture of the membranes at term, induce labor with either oxytocin or prostaglandin preparations.
3. In patients with preterm premature rupture of membranes and without contractions, give broad-spectrum antibiotics such as ampicillin or amoxicillin plus erythromycin for 7 days.
4. Follow CDC and ACOG guidelines for prevention of perinatal

GBS infection.

5. For patients with preterm labor but without rupture of membranes, perinatal GBS guidelines should be followed; however, broad-spectrum antibiotics for the purpose of preventing chorioamnionitis have not been effective.

CDC, Centers for Disease Control and Prevention; ACOG, American College of Obstetricians and Gynecologists; GBS, group B streptococci.

The most common cause of puerperal fever is uterine infection, occurring in approximately 1% to 3% of women after vaginal delivery and up to 27% after cesarean delivery, even when prophylactic antibiotics are used. The infection is variously known as endometritis; endoparametritis; or simply, metritis. Criteria for endomyometritis include fever, uterine tenderness, and purulent or foul lochia; peripheral leukocytosis; and exclusion of another infected site. Nonspecific signs and symptoms such as malaise, abdominal pain, chills, and tachycardia may be present. In the vast majority of cases of uterine infection, initial signs and symptoms develop within the first 5 days following delivery.

Pathophysiology

The major risk factors for postpartum infection are summarized in Table 19.6. Cesarean section is the most important predisposing clinical factor for pelvic infection. The severity of infection also is increased in abdominal delivery. Those

patients with electively scheduled operations (with no labor and no rupture of membranes) have lower infection rates than those with emergency or nonelective procedures. This observation has been made nearly universally in a large number of studies.

TABLE 19.6 Major Risk Factors for Postpartum Infection

Duration of labor
Cesarean delivery, especially nonelective
Nonelective cesarean delivery, without prophylactic antibiotics
Duration of rupture of membranes
Failure to progress in labor
Number of vaginal examinations
Duration of internal fetal monitoring
Low socioeconomic status

Risk factors of labor, rupture of membranes, vaginal examinations, and internal fetal monitoring are intricately interrelated, and even sophisticated statistical techniques may not be able to discern which of these factors is an independent variable. Whether amniotomy increases postpartum infection has been the subject of many reports. Amniotomy, as part of a plan of active labor management, probably does not increase the risk. Regardless of race, indigent patients have higher puerperal infection rates than do middle-class patients. The cause is unclear, but differences in flora, hygiene, and nutrition have all been postulated as reasons. Diabetes is also a risk factor for endometritis, with diabetic patients having approximately a fourfold increase in risk. Among patients without labor or ruptured membranes, 9.1% (5/55) of diabetics developed endometritis or wound infection versus 1.8% (2/110) of nondiabetics (P = .042). Among patients with either labor or rupture of membranes or both, the infection rate for diabetics was 25.0% (6/24) versus 6.3% (3/48) for nondiabetics (P = .032). Endometritis most often is caused by a mixture of aerobic and anaerobic bacteria from the genital tract. Isolates from one carefully done study are shown in Table 19.6.

Diagnosis

The diagnosis of endomyometritis usually is based on symptoms of fever, malaise, abdominal pain, and purulent or foul lochia. Other sources of fever should be excluded. In clinical investigations, various temperature criteria have been used in the definition of endometritis. These include temperatures of 100°F (37.8°C) and 100.4°F (38°C) on two or more occasions. When there are signs of infection, multiple risk factors for infection, or persistence of low-grade fever in the puerperium, it is reasonable to presume that a genital tract infection is present and proceed with the workup and treatment. The authors believe that appropriate specimens include a complete blood count, blood cultures, and an aerobic uterine culture. Gram staining of the genital specimen may be helpful when hemolytic streptococci, clostridia, or other anaerobes are suspected.

Treatment

With supportive therapy and appropriate antibiotics, the vast majority of patients improve within 1 to 3 days. For patients with endomyometritis after vaginal delivery, the treatment should include good anaerobic coverage, probably using a single agent (such as broad-spectrum penicillin or cephalosporin or a penicillin–β-lactamase inhibitor combination).

Among patients with endomyometritis after cesarean section, response to antibiotics is poorer. Initial therapy for endometritis after cesarean section should consist of broad-spectrum antibiotics, with activity against anaerobes as well as gram-positive and gram-negative aerobes. In many clinical trials, the combination of clindamycin and aminoglycoside has been considered the standard for comparison for treatment in genital tract infections after cesarean section. A large number of new penicillins and cephalosporins have become available to treat postpartum infection. Although no single

agent provides activity against the entire bacterial spectrum, most have sufficient aerobic and anaerobic activity to merit use in endometritis. Specific regimens are shown in Table 19.7.

The new penicillins and cephalosporins usually are tolerated very well and have few side effects. Administration of a single agent requires less time and equipment, but the higher cost of most new agents also must be considered. Metronidazole has excellent anaerobic activity. Because it has little activity against aerobes, its use as single-agent therapy is unwise. Its use in combination with gentamicin still leaves the gram-positive aerobes (notably GBS and enterococci) uncovered. New antibiotics are being formulated that may replace gentamicin as initial therapy. The monobactams (e.g., aztreonam) have exquisite gram-negative activity, but they have little activity in the rest of the bacterial spectrum. These agents have the same spectrum as the aminoglycosides and have fewer side effects. Clinical trials of these monobactams in combination with clindamycin have shown excellent results, equivalent to clindamycin plus gentamicin.

For patients who respond promptly to parenteral antibiotics, some questions arise: How long should therapy be continued? Is oral therapy needed as an adjunct? It has been recommended that parenteral therapy should be continued for 24 to 48 hours after the patient becomes afebrile and asymptomatic. Then, intravenous antibiotics may be discontinued and the patient discharged without oral antibiotics, unless the patient has had staphylococcal bacteremia. The approach is based on several descriptive studies plus a randomized trial of oral antibiotic therapy after successful intravenous therapy in women with puerperal endometritis. Patients given placebo had similar subsequent courses to those of patients given oral amoxicillin (after parenteral therapy). Side effects also were similar in both groups (Table 19.8).

At the other end of the patient response spectrum, there are patients who do not respond within 48 to 72 hours of appropriate antibiotic therapy. Diagnostic considerations are (a) an infected “mass” such as abscess or hematoma of the wound or pelvis, extensive pelvic cellulitis, septic pelvic thrombophlebitis, or retained placenta; (b) a resistant organism such as enterococci in patients treated with cephalosporinlike antibiotics or with clindamycin plus gentamicin; (c) a nongenital source of infection such as pyelonephritis, pneumonia, or intravenous

catheter phlebitis; (d) a noninfectious fever such as drug fever or factitial fever; or (e) inadequate dosage or inadequate route of otherwise correct antibiotics (Fig. 19.7). Appropriate bedside examination and review of the chart and cultures often reveal the cause. In general, in patients who are stable and not seriously ill, an appropriate change in antibiotics (such as adding penicillin to clindamycin plus gentamicin to add coverage for enterococci) is effective in about 80% of those who have not responded in the initial 48 hours.

TABLE 19.7 Selected Regimens for Initial Parenteral Therapy

of Postpartum Endometritis

Regimen	Organisms Resistant to the Regimen	Comments
Clindamycin plus gentamicin	Mainly enterococci	Often a standard for comparison
Cefoxitin, cefotetan, or alternative cephalosporinlike antibiotics	Mainly enterococci	Avoid in cases of immediate hypersensitivity to penicillin
Ampicillin-sulbactam (Unasyn)	Some aerobic gram-negative rods	Contraindicated in cases of penicillin allergy
Ticarcillin-clavulanic acid (Timentin)	—	—
Piperacillin-tazobactam (Zosyn)	—	—
Piperacillin, mezlocillin, or other ureido penicillins	Some aerobic, gram-negative rods, some *Staphylococcus aureus*	Contraindicated in cases of penicillin allergy
Clindamycin plus aztreonam	Mainly enterococci	Alternative to gentamicin plus clindamycin
Metronidazole plus gentamicin	GBS, enterococci, and the other aerobic	Absence of streptococcal actively limits its

	streptococci	role in endometritis
Imipenem-cilastatin; meropenem,	Some clostridia, some *S. aureus* and other carbapenems	Because of usual spectrum of activity, reserve for treating difficult infections

GBS, group B streptococci.

In about 20% of cases, the initial failure to respond is due to resistant organisms, and in another 30%, no cause for the failure is identified. The authors believe that 48 hours is an appropriate point to change therapy unless the patient is unstable, when changes are needed more promptly. In the remaining 40% to 50%, the reason for poor response to initial therapy is an infected mass. If the mass or collection is present in the wound after cesarean section, physical examination usually identifies the source. In other cases, radiographic studies are helpful in identifying pelvic masses or deep-seated wound infection.

TABLE 19.8 Oral Amoxicillin after Intravenous Antibiotics for Postpartum Endometritis[a]

Variable	Placebo (n = 49)	Amoxicillin (n = 50)
Recurrent endometritis	0	0
Wound infection	0	0
Side effects—any	14%	10%
Side effects—stopped medications	2%	4%
Completed medication (5 d)	65%	52%

[a]Cefoxitin, clindamycin-gentamicin, or ampicillin-sulbactam.

Dinsmoor MJ, Newton ER, Gibbs RS. A randomized, double blind, placebo-controlled trial of oral antibiotic therapy following intravenous antibiotic therapy for postpartum endometritis. *Obstet Gynecol* 1991;77:60–62, with permission.

Ultrasonography or a CT study may reveal a mass in the pelvis. In patients with persistent pelvic infection after vaginal delivery, an ultrasonographic examination is helpful because it may reveal a pelvic mass, retained placental tissue, or septic pelvic thrombophlebitis. Sonography is readily available, inexpensive, and requires no special preparation. When patients are obese or have an open wound, ultrasonography provides a limited examination and CT is useful (Figs. 19.8, 19.9).

Prevention

Principles for use of antibiotic prophylaxis to prevent endometritis after cesarean delivery are well established. These are summarized in Table 19.9.

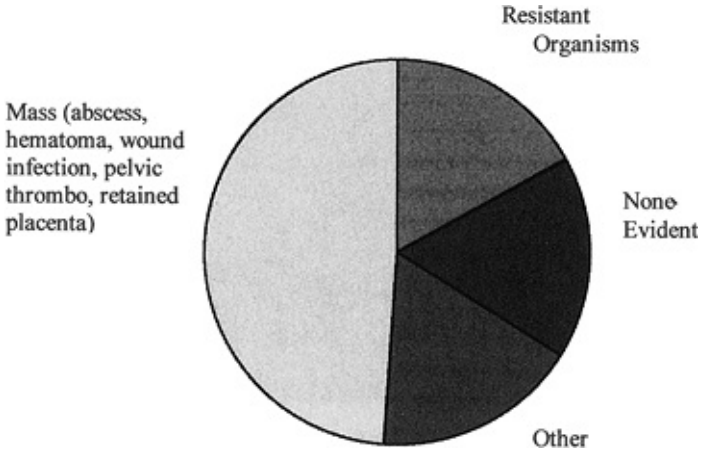

Figure 19.7 Causes of poor response to antibiotics. (From Sweet RL, Gibbs RS. Postpartum infection. In: Sweet RL, Gibbs RS, eds. *Infectious diseases of the female genital tract*. Philadelphia: Lippincott Williams & Wilkins, 2002:547, with permission.)

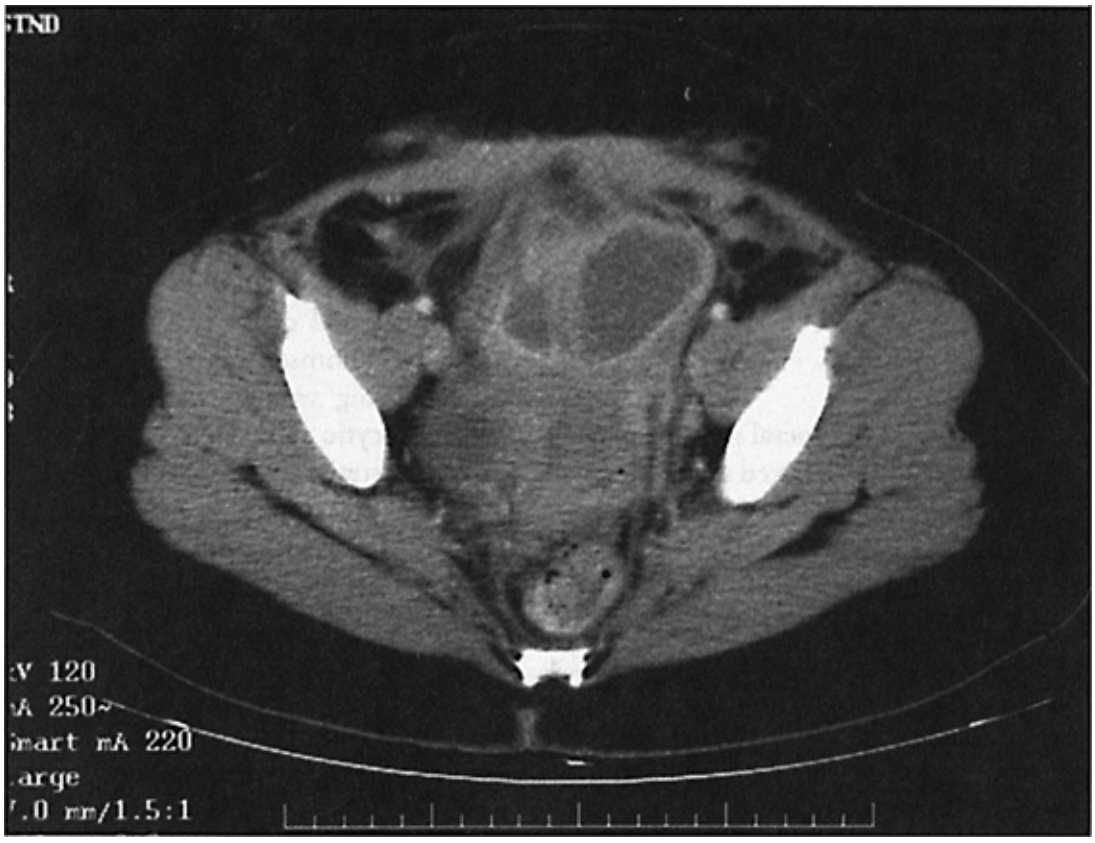

Figure 19.8 Left parauterine abscess in a patient after cesarean delivery. (From Sweet RL, Gibbs RS. Postpartum infection. In: Sweet RL, Gibbs RS, eds. *Infectious diseases of the female genital tract*. Philadelphia: Lippincott Williams & Wilkins, 2002:549, with permission.)

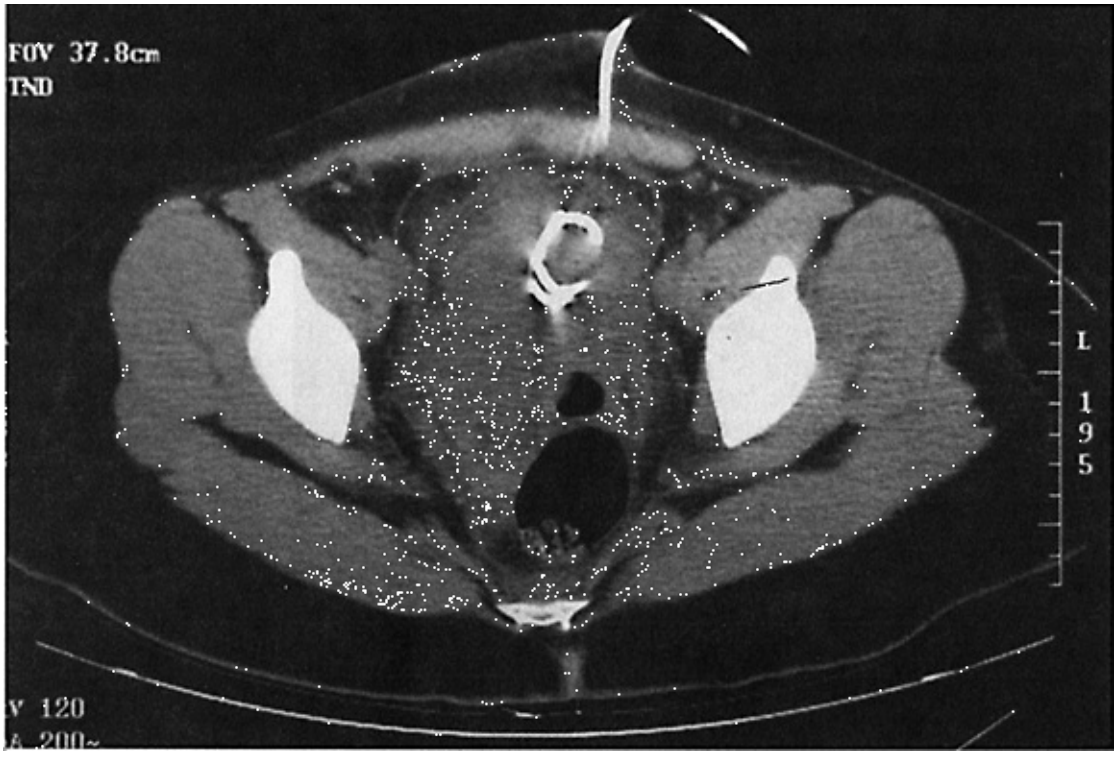

Figure 19.9 CT scans showing percutaneous placement of a pigtail catheter in an abscess after cesarean section. (From Sweet RL, Gibbs RS. Postpartum infection. In: Sweet RL, Gibbs RS, eds. *Infectious diseases of the female genital tract*. Philadelphia: Lippincott Williams & Wilkins, 2002:549, with permission.)

TABLE 19.9 Recommendations for Use of Prophylactic Antibiotics in Cesarean Section

1. Antibiotic prophylaxis is recommended for women undergoing nonelective cesarean section because such antibiotic use reduces the risk of endometritis and wound infections. Use of prophylaxis in this setting appears to be cost-effective.
2. Prophylaxis is not recommended routinely in low-risk patients, such as those with documented low infection rates, after undergoing an electively scheduled cesarean section.
3. Preferred antibiotics include a first-generation cephalosporin such as cefazolin (1 g i.v.) or ampicillin (1 to 2 g i.v.). Newer extended-spectrum cephalosporins or penicillins are no more effective and add cost to the prophylaxis.
4. Single-dose prophylaxis usually is sufficient, but in selected circumstances such as cesarean section after prolonged rupture of the membranes (e.g., 12 hours), a regimen of two- or three-dose prophylaxis is supported. Additional intraoperative doses of an antibiotic for prophylaxis should be given at intervals of 1 or 2 times the half-life of the antibiotic to maintain adequate levels of the antibiotic throughout the surgical procedure. Half-lives of representative antibiotics (in patients with normal renal function) are as follows: for cefazolin, 1.8 hours; cefoxitin, 60 minutes; cefotetan, 4 hours; and clindamycin, 3 hours.
5. The antibiotic used for prophylaxis should be initiated immediately after cord clamping (unless the rationale is to prevent perinatal GBS infection). This timing of antibiotic prophylaxis is equally effective as regimens beginning prophylaxis before cord clamping, and this regimen avoids direct and indirect adverse effects on the newborn.
6. Antibiotics used for prophylaxis dramatically shift upper

genital tract flora. Extended-spectrum antibiotics should not be used for prophylaxis. For patients who develop genital tract infection after prophylaxis, a culture for aerobes should be obtained to direct subsequent antibiotic therapy and to direct antibiotic policies in a given hospital. Antibiotics used for prophylaxis should not be used for therapy in the same patient. If a cephalosporin was used for prophylaxis, a treatment regimen active against enterococci should be considered. If ampicillin is used for prophylaxis, a treatment regimen active against *Kiebsiella* organisms should be considered.

7. For patients who have immediate hypersensitivity reactions to penicillin, antibiotic choices for prophylaxis are limited. One recommendation is to use a single dose of clindamycin (900 mg), either with or without gentamicin, in a dose of 1.5 to 2.0 mg/kg. If there is a contraindication to clindamycin, vancomycin may be used. The Infectious Diseases Society of America recommends vancomycin for prophylaxis instead of cefazolin or alternative cephalosporins in patients who are allergic to cephalosporins. Further, because vancomycin provides no activity against gram-negative bacilli, another antibiotic with gram-negative activity should be added to this regimen. Such an alternative includes aztreonam or aminoglycoside.
8. Direct adverse effects of antibiotics used for prophylaxis have been reported, including life-threatening complications such an anaphylaxis and pseudomembranous colitis.
9. Use of prophylactic antibiotics must not result in relaxation of standard infection control measures.
10. Antibiotics administered by irrigation are not more effective than those given by intravenous injection.

Summary Points

- National guidelines (2002) include recommendation for screening of all pregnant women at 35 to 37 weeks gestation.
- Special consideration must be given to antibiotic selection in patients who cannot receive penicillins.
- There is widespread resistance by GBS to both erythromycin and clindamycin.
- All pregnant women should be counseled regarding ways in which

to minimize the risk of acquiring infection with *T. gondii*.
- Pregnant women who acquire *T. gondii* infections should have studies performed to ascertain the status of the fetus.
- If congenital infection with *T. gondii* is diagnosed and the patient continues the pregnancy, antiparasitic therapy should be instituted.
- CMV is the most common congenital infection in the United States.
- Although patients with antibodies may have reactivation resulting in infected newborns, these children are less frequently and less severely infected then those whose mothers have primary infections.
- The highest risk of perinatal HSV occurs when there has been maternal infection late in pregnancy.
- Cesarean section should be performed if lesions are present or if there is a typical prodrome at the onset of labor.
- Nucleoside analogues in late pregnancy reduce the frequency of HSV viral shedding and, thereby, the need for cesarean section.
- Currently, routine serologic screening for HSV pregnancy cannot be recommended.
- Both IAI and endometritis are polymicrobial infections.
- Intrapartum treatment of IAI improves both maternal and fetal–neonatal outcomes.
- For patients with IAI at term, the route of delivery should be determined by standard obstetric indications.
  - IAI is associated with long-term neurologic adverse sequelae in the newborn.
- Preventative measures for IAI include prompt induction with premature rupture of the membranes at term and use of broad-spectrum antibiotics with premature rupture of the membranes remote from term.
- For patients with postpartum endometritis and a poor response to antibiotic therapy, the differential diagnosis includes an infected mass and resistant organisms.

Human Immunodeficiency Virus

Howard Minkoff

Human Immunodeficiency Virus

The HIV epidemic is a quarter of a century old and in that time frame has transformed from a uniformly lethal disease of unknown etiology to a manageable chronic disease, albeit one with complicated treatment regimens and mortality remaining an inherent risk. The success of treatment regimens has led to the emergence of two epidemics—one among those with access to highly active therapies as well as a larger one among those without. In this chapter, the pathophysiology and epidemiology of HIV will be summarized, and the management of obstetric and gynecologic patients who are infected will be detailed. Given the ability of U.S. providers to avail themselves of the most efficacious therapies, they should be able to assure their patients that perinatal transmission of HIV will be an extremely uncommon event and that gynecologic morbidities can be minimized.

Microbiology

HIV is a lentivirus, from the family of retroviruses, which characteristically have an RNA genome contained within a capsid and a lipid envelope. Retroviruses constitute a large and diverse family of enveloped RNA viruses that use the transcription of virion RNA into linear double-stranded DNA as a replication strategy, with subsequent integration into the host genome. The characteristic enzyme used for this process, an RNA-dependent DNA polymerase that reverses the flow of genetic information, is known as reverse transcriptase. The unique lifestyle of the retrovirus involves two forms, a DNA provirus and an RNA-containing infectious virion. Infection is initiated by the binding of a protein on the surface of the virus (gp120 Env protein) to the CD4 molecule found on some T-cells, macrophages, and microglial cells. CD4 was first shown to be a viral receptor in a number of studies showing the susceptibility of CD4-bearing cells to infection and the ability to block infection with anti-CD4 monoclonal antibodies in culture.

HIV is composed of core (p18, p24, and p27) and surface (gp120 and gp 41) proteins, genomic RNA, and the reverse transcriptase enzyme surrounded by a lipid bilayer envelope. The virion contains three structural genes (gag, pol, and env) as well as a complex set of regulatory genes (including tat, vif, nef, vpu, and ref) that control the rate of virion production. As noted, it preferentially infects cells with the CD4+ antigen,

particularly helper lymphocytes but also macrophages, cells of the central nervous system, and according to some evidence, cells of the placenta. At least two other cell surface molecules help HIV enter cells. These coreceptors for HIV, called CXCR4 and CCR5, are receptors for chemokines. Individuals who are homozygous for a deletion at the CCR5 gene appear less likely to acquire HIV, while deletion heterozygotes progress less rapidly if infected. On the basis of cell tropism, HIV strains can be broadly divided into two categories—macrophage-tropic (M-tropic) and T-cell tropic (T-tropic). M-tropic strains use CCR5 as a coreceptor and are referred as R5 viruses. They primarily infect macrophages and primary T cells and infect

poorly CD4+ T-cell lines. In addition, these viruses tend to be transmitted sexually more easily. T-tropic strains use the CXCR4 coreceptor, which is most expressed in CD4+ T cells. Also referred to as X4 viruses, they induce the formation of syncytia in the infected cells. Early in the course of HIV infection, the R5 strain viruses predominate; however, eventually, both X4 and R5 strains are recovered (Fig. 20.1).

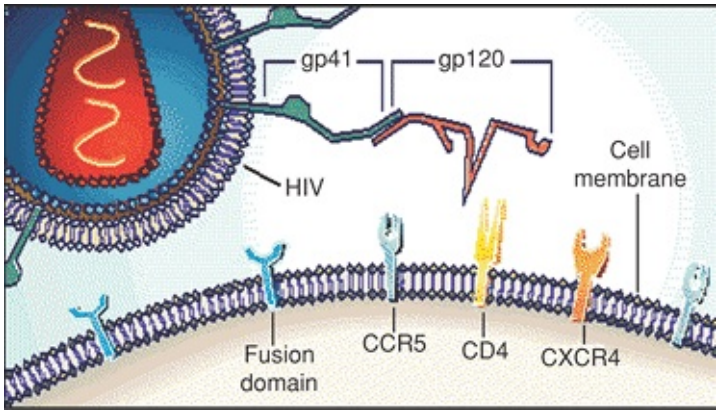

Figure 20.1 Early in the course of HIV infection, the R5 strain viruses predominate, but eventually both X4 and R5 strains are recovered. (From Levy JA. Infection by human immunodeficiency virus—CD4 is not enough. *N Engl J Med* 1996;335:1525–1527, Figure 1A. Illustrations © Massachusetts Medical Society, with permission.) (See Color Plate)

Epidemiology

By the end of 2003, approximately 1,039,000 to 1,185,000 persons in the United States were living with HIV/AIDS, an estimated 24% to 27% of whom were unaware of their infection, with approximately 25% being women. AIDS cases increased rapidly in the 1980s and peaked in 1992 (an estimated 78,000 cases diagnosed that year) before stabilizing in 1998; since then, approximately 40,000 AIDS cases have been diagnosed annually. Over the course of the epidemic, even before effective treatments were widely utilized, the number of AIDS cases decreased 47% from 1992 to 1998. The majority of AIDS cases continue to occur among males; however, the proportion of all AIDS cases for females increased from 15% in

1981 to 1995 to 27% in 2001 to 2004. Not coincidently, the vast majority of cases of pediatric AIDS are secondary to vertical transmission of HIV from mother to fetus. The proportion of all AIDS cases attributable to high-risk heterosexual contact (i.e., sexual contact with a person at high risk for or infected with HIV) from 1981 to 1995 was 10% and increased to 30% from 2001 to 2004. Among males and females, case rates among blacks (males: 131.6 per 100,000; females: 67.0 per 100,000) were 7 and 21 times higher, respectively, than rates for whites (males: 18.7 per 100,000; females: 3.2 per 100,000).

Other important trends characterize the epidemic in women. For example, an increasing proportion of AIDS cases are occurring in women in the South, perhaps reflecting the dramatic increase in other sexually transmitted diseases first seen in that region more than a decade ago. Poverty status also might vary with gender, with women substantially more likely to be covered by Medicaid and less likely to be privately insured. These data demonstrate, yet again, that poverty, drug use, and sexually transmitted diseases continue to fuel the HIV epidemic among women in the United States.

Pathophysiology

HIV infection induces a profound immune dysfunction, with abnormalities in every arm of the immune system. While studies of long-term nonprogressors (HIV-infected patients who are asymptomatic and have normal CD4+ T-cell counts in the absence of treatment) have revealed several immune mechanisms that are significant in controlling HIV infection, the virus has several inherent strategies by which to escape this vigorous immune response and to continue replicating. The most studied of these strategies are antigenic variation, down regulation of the surface expression of major histocompatibility complex (MHC) molecules, and reduction of specific CD8+ T cells. Once the immune system has become debilitated, infected individuals are rendered susceptible to opportunistic infections (e.g., *Pneumocystis carinii* pneumonia [PCP] and central nervous system toxoplasmosis) and neoplasias (e.g., Kaposi's sarcoma) that rarely afflict patients with intact immune systems. An HIV-infected patient with one of several specific opportunistic infections, neoplasia, dementia encephalopathy, or wasting syndrome is diagnosed as having AIDS. The diagnosis of AIDS can be made in the absence of laboratory evidence of infection if the patient has no other known cause of immune deficiency and has the definitive diagnosis of one of a number of indicator diseases. In 1993, the Centers for Disease Control and Prevention (CDC) changed the case definition to include all individuals with HIV infection whose CD4 counts drop below 200 cells/mm^3 as well as HIV-infected individuals with advanced cervical cancer, pulmonary tuberculosis, and recurrent pneumonia.

At the time of initial infection, an individual may be asymptomatic or may develop an acute mononucleosislike syndrome that can be accompanied by aseptic meningitis. There is then an immediate viremia of substantive proportions (up to ten billion viral particles turned over per day) and an equally impressive immune responsive with similar levels of T-cell turnover. Antibodies can be detected in almost all individuals at 6 to 12 weeks after exposure, but in rare circumstances, this latent period (the so-called “window phase”) can be longer. After seroconversion has occurred, an asymptomatic period of variable length usually follows. The median clinical latency in the absence of effective therapy is

estimated at approximately 11 years. Very few infected persons (<5%) develop AIDS within 3 years. Evidence of immune dysfunction may be followed by clinical conditions ranging from fever, weight loss, malaise, lymphadenopathy, and central nervous system dysfunction to infections such as herpes simplex virus or oral candidiasis. These nonspecific conditions usually are progressive and are a prelude to an opportunistic infection that is diagnostic of AIDS. Pre–HAART (highly active antiretroviral therapy) era studies of infected individuals reported that 5 years after infection was confirmed, up to 35% had progressed to AIDS. A study of subjects with hemophilia demonstrated that the incidence rate of AIDS after seroconversion was 2.67 per 100 person-years and was directly related to age (younger individuals developed AIDS at a slower rate). The level of virus in the plasma can provide an estimate of the probability that an individual will develop AIDS within 5 years. It should be noted that almost all of these statistics antedate the use of new, more powerful antiretroviral agents that have a significant effect on both clinical outcomes and surrogate markers of disease progression.

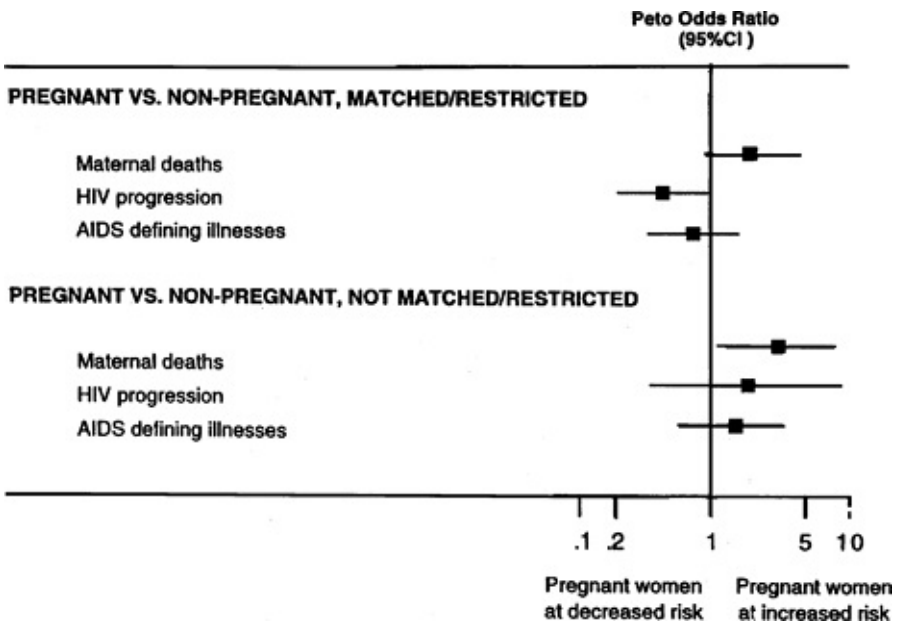

Figure 20.2 Summary odds ratio of studies that attempted to control for confounding by matching or restriction techniques compared with those which had not used matching or restriction. (CI, confidence interval.) (From French R, Brocklehurst P. The effect of pregnancy on survival in women infected with HIV: a systemic review of the literature and meta-analysis. *Br J Obstet Gynecol* 1998;105:827–835, with permission.)

From 1981 to 2004, a total of 522,723 deaths among persons with AIDS were reported to the CDC. In the era of highly active antiretroviral therapy, prognosis has improved even for those with AIDS at initiation of treatment. The time at which 25% of individuals had died after an AIDS diagnosis increased significantly from 0.56 years (95% confidence interval [CI] 0.50 to 0.64) in the no/monotherapy era to 5.08 years (95% CI 2.39 to 10.79) in the HAART era. The proportion of persons living at 2 years after AIDS diagnosis was 44% for those with

AIDS diagnosed from 1981 to 1992, 64% for 1993 to 1995, and 85% for 1996 to 2000. Survival for more than 1 year after diagnosis for persons with AIDS diagnosed from 1996 to 2003 was greater among Asians/Pacific Islanders, whites, and Hispanics than among blacks and American Indians/Alaska Natives. Viral load and CD4 counts can be used to predict the likelihood that an individual will develop AIDS during a given follow-up period. At the current time, appropriately controlled studies reveal no convincing evidence that the natural history of HIV infection is influenced by gender or pregnancy (Fig. 20.2). Clearly, medications have improved prognosis dramatically, though it must be recognized that they also have been associated with substantial morbidity (e.g., lipodystrophy).

Management

Monitoring

The guiding principle in the care of HIV-infected pregnant women continues to be strict adherence to the standards of care that apply to all other HIV-infected individuals. The first step in that care is the monitoring of immune status with CD4 counts and viral loads. Checking for viral resistance also has become a key component of monitoring regimens (vide infra). Viral loads can be checked every 3 to 4 months. Once a decision is made to initiate therapy, viral-load monitoring should occur monthly until virus is no longer detectable and then can be cut back to three or four times per year. With appropriate therapy, a drop of 1.5 to 2 logs within 1 month of initiation of treatment can be anticipated. The recommended timing of initiation of therapy (vis-a-vis CD4 counts and viral loads) has undergone several revisions over the last few years. This evolution reflects the awareness that despite the clear benefits of therapy, there also are well-recognized toxicities that make it difficult to maintain strict adherence. Some data suggest that no harm befalls patients who delay therapy until viral loads rise and CD4 counts drop further than had previously been recommended. Current guidelines are to start therapy in nonpregnant women when the viral load is >100,000 copies or when the CD4 count drops below 350 cells/mm^3. In the nonpregnant state, when those thresholds are passed, HAART should be initiated. The appropriate guidelines for initiating therapy in pregnancy follow.

Resistance Testing

Resistance testing has become a staple of care for HIV-infected individuals. The viral RNA is reverse transcribed

into complementary DNA (cDNA) by the viral reverse transcriptase through use of a cellular lysine tRNA molecule as a primer; subsequently, the RNAase activity of the reverse transcriptase degrades the viral RNA template. The reverse transcriptase incorporates an incorrect nucleotide every 1,500 to 4,000 bases, which explains the rapid occurrence of mutations. Some of the resulting mutations provide a survival advantage, leading to drug-resistant strains.

There is accumulating evidence that transmitted resistant mutants may persist for indefinite periods after initial infection, these viral variants may be detectable by standard

assays used in clinical practice, the prevalence of resistance in antiretroviral-naive patients is increasing, and baseline resistance may be associated with adverse virologic outcomes. For these reasons, baseline HIV resistance testing is now recommended for all patients with established infection, including pregnant women, prior to initiating treatment.

Most randomized trials of resistance testing have demonstrated that those assigned to study arms with access to resistance test results have a greater reduction in viral load after the initiation of salvage therapy, though follow-up generally has been short. These tests are recommended for individuals prior to commencing therapy or after failed therapy. *Treatment failure* is defined as the failure to attain an undetectable level of virus or the persistent presence of virus after it has become undetectable. Transient low-level viremia may not be the same as a drug failure, and sustained response to treatment can occur even in the setting of occasional low-level viremia. Blood for testing should be obtained before a failing regimen is discontinued lest wild-type virus overgrow before the test is performed. In that circumstance, an individual with no apparent resistance would still fail therapy when reexposed to drugs that favor the growth of the resistant virus over the wild-type strain. In essence, resistance testing is more useful for ruling out, than for ruling in, therapies to be utilized in a given patient. That is because, as noted, the absence of resistance may merely reflect the reemergence of a wild-type strain after an antiretroviral agent has been withdrawn. In that circumstance, the assays will not detect a low volume of a minority mutant strain. However, if the patient is reexposed to the offending agent, the resistant strain may again attain dominance. It is not possible to perform resistance studies if there are <1,000 copies of detectable virus.

Currently, two types of testing are available—genotypic and phenotypic—each with distinct advantages and disadvantages. Phenotypic testing compares the ability of the virus to replicate in various concentrations of an antiretroviral drug, with its replication in the absence of the drug. In general, if the amount of drug required to inhibit viral production by 50% is fourfold or greater for the patient virus than the control strain, then the patient's strain is considered resistant. Specific cutoffs for resistance for each drug are based on clinical correlation, and the serum levels usually are attainable for a given drug. Measurement of drug levels per se has not yet been shown to be useful addendums to standard monitoring.

Genotypic testing is directed at detecting mutations in the genes that encode reverse transcriptase and protease formation by the virus. Point mutations in the virus result in the substitution of amino acids in the proteins produced (i.e., reverse transcriptase or protease). The significance of these point mutations has to be determined by correlating specific mutations with phenotypic resistance as measured by viral susceptibility assays and correlation with clinical response to therapy. Genotypic changes leading to resistance are believed to result from the combination of the rapid turnover of HIV (10^7 to 10^8 rounds of replication per day) and the high error rate of reverse transcriptase when replicating the nearly 10,000 nucleotides present in the HIV genome. Genetic mutants with resistance to antiretroviral agents are then selected by evolutionary pressure when incompletely suppressive drug regimens are used. The rate at which resistance develops will depend on the number of mutations necessary for a significant change in susceptibility to occur. The

genetic basis for resistance must be understood before the impact of a specific mutation can be predicted. In addition, mutational interactions may make prediction of phenotype (i.e., susceptibility) difficult when multiple mutations are present. Prediction of cross resistance to other drugs within a class such as protease inhibitors (PIs) can be difficult to predict based only on genotype. In clinical practice, most clinicians will rely on algorithms developed by panels of experts or to online databases. Obstetricians should interpret and act on these results in consultation with an expert in the field.

During pregnancy, HIV drug-resistance testing is recommended for several subsets of women. All pregnant women who are not currently receiving antiretroviral therapy should be tested before starting treatment or prophylaxis. Additionally, all pregnant women who are receiving antenatal antiretroviral therapy and have virologic failure with persistently detectable HIV RNA levels or who have suboptimal viral suppression after initiation of antiretroviral therapy should undergo resistance testing. While it would be ideal to have results back before starting therapy in pregnancy, it has been recommended that in certain circumstances (e.g., late registrant), empiric initiation of antiretroviral therapy before results of resistance testing are available may be warranted, with adjustment as needed once the results are known. Ideally, the development of resistance would be avoided in the first instance. Several steps can be taken toward that end. The use of highly active antiretroviral combination therapy to maximally suppress viral replication during pregnancy is the most effective strategy to prevent the development of resistance and to minimize the risk of perinatal transmission. Finally, all pregnant women should be counseled about the importance of adherence to prescribed antiretroviral medications to reduce the potential for development of resistance.

Although perinatal transmission of resistant virus has been reported, it appears to be unusual, and there is little evidence that the presence of resistance mutations increases the risk of transmission when current recommendations for antiretroviral management in pregnancy are followed. In studies in which transmitting mothers had mixed viral populations of wild type and virus with low-level zidovudine (ZDV) resistance, only wild-type virus was found in the infants, and other studies have suggested that drug-resistance mutations may diminish the fitness of the virus, possibly leading to a decrease in transmissibility. Neither resistance to NVP that develops as a result of exposure to single-dose NVP nor exposure to single-dose NVP in a prior pregnancy have been shown to affect perinatal transmission rates.

Pharmaceutical Therapy

The standard approach to the medical treatment of HIV infection continues to evolve at a rapid pace (Table 20.1). An example of the rate of change in recommended treatments is the pace of new guidelines by the International AIDS Society–USA panel; they have been revised seven times since 1996. However, while the number of HAART regimens that have been shown to achieve persistently low viral loads continue to increase, they still fall into one of a few broad categories. The original regimens described in 1996 included dual nucleoside therapy accompanied by a PI; now, the nucleoside “backbone” may be

supplemented by a non-nucleoside, a “boosted” protease, or a third nucleoside. Currently, there are numerous nucleoside reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), and PIs approved for therapy, with many others in the pharmaceutical “pipeline.” So, theoretically, a large number of choices within these categories exist. However, certain medications should not be used in combination. For example, ZDV and stavudine (d4T) have overlapping toxicities. Didanosine (ddI) and zalcitabine (ddC) should not be used in combination, and ddI and d4T have been linked to several fatal cases of mitochondrial toxicity in pregnancy.

TABLE 20.1 Abbreviations for Commonly Used Drugs to Treat the Human Immunodeficiency Virus

NRTI	Nucleoside reverse transcriptase inhibitor
NNRTI	Non-nucleoside reverse transcriptase inhibitor
PI	Protease inhibitor
SGC	Soft gel capsule
HGC	Hard gel capsule
ZDV (formerly AZT)	Zidovudine
NVP	Nevaripine
ddI	Didanosine
d4T	Stavudine
ddC	Zalcitabine
3TC	Lamivudine

TABLE 20.2 Recommendations for Initiating Antiretroviral Therapy in Treatment-naive Adults with Chronic Human Immunodeficiency Virus Infection[a]

Measure	Recommendation
Symptomatic HIV disease	Antiretroviral therapy recommended
Asymptomatic HIV disease	
CD4 count <200 cells/mm^3	Antiretroviral therapy recommended
CD4 count <350 cells/mm^3 but >200 cells/mm^3	Antiretroviral therapy should be considered and decision individualized[b]
CD4 count >350 cells/mm^3 but <500 cells/mm^3	Antiretroviral therapy generally not recommended[c]
CD4 count >500 cells/mm^3	Antiretroviral therapy generally not recommended

[a]In nonpregnant adults only. For all individuals regardless of whether they are receiving treatment, intensive counseling to prevent secondary transmission is indicated.

[b]The closer the CD4 count is to 200 cells/mm^3, the stronger the recommendation, particularly if the plasma viral load is high (>100,000 HIV-1 RNA copies/mL) or if the CD4 count is declining rapidly (>100 cells/mm^3 per year).

[c]Consider treatment for patients with high plasma viral load (>100,000 HIV-1 RNA copies/mL) or with rapid decline of CD4 cell count.

Adapted from Hammer SM, Saag MS, Schecter M, et al. Treatment for adult HIV infection: 2006 recommendations of the International AIDS Society–USA Panel. *JAMA* 2006;296:829, with permission.

The clinician who is preparing to care for an HIV-infected individual must consider the following: when to start therapy, which therapy should be used, and when the regimen should be altered. The trigger for starting antiretroviral therapy in nonpregnant women is either symptomatic HIV disease or, for patients without symptoms, after the CD4 count declines below 350 cells/mm^3 but before it reaches 200 cells/mm^3 (Table 20.2). Individualization continues to guide the timing of treatment initiation, with consideration of patient readiness, rate of CD4 cell count decline, and plasma HIV-1 RNA level. Thus, with a count between 200 cells/mm^3 and 350 cells/mm^3, a provider might be more aggressive in promoting the initiation of therapy if the count is dropping rapidly or the viral load is >100,000 copies. In the near future, it can be anticipated that new formulations of antiretroviral drugs and combinations with improved tolerance and convenience may increase the patient and physicians' willingness to start therapy at an earlier point in the disease.

In regard to the choice of medication with which to begin therapy, several factors need to be considered. Since the number of new drugs continues to multiply, as does information about their benefits and toxicities, it has become increasingly difficult for busy clinicians to stay abreast. There

are several useful resources to assist in that endeavor. The International AIDS Society–USA panel publishes periodic updates to its guidelines. In addition, the Public Health Service (PHS) has established a website that is updated regularly. The expert panel that authors those update guidelines strongly recommends regimens that include either a protease or proteases (indinavir, nelfinavir, ritonavir + saquinavir, ritonavir + indinavir, ritonavir + lopinavir) or a non-nucleoside (efavirenz in the nonpregnant patient) in combination with one of several two NRTI combinations. The USA panel also suggests a combination of two NRTIs with either an NNRTI or a PI boosted with low-dose ritonavir. That panel goes on to state that given the high degree of comparability of the recommended components of these regimens in treatment-naive persons with drug-susceptible virus, the choice of drug centers on acceptability; predicted tolerance; pill burden; comorbid conditions; short-term, mid-term, and long-term adverse event profiles; and successful alternatives in the event the initial regimen fails and drug resistance emerges. The successful outcomes of several “switch studies” suggest that the initial choice of regimen does not preclude safely changing drugs once viral suppression is achieved. There is a great deal of clinical outcome data that support these approaches.

A critical factor to recognize is that often there are poor results with antiretroviral regimens when they are used after an initial regimen has failed. This fact suggests that the first regimen affords the best opportunity for long-term control of viral replication. Because the genetic barrier to resistance is greatest with PIs, many would consider a PI

with two NRTIs to be the preferred initial regimen. However, efavirenz (an NNRTI) with two NRTIs appears to be at least as effective as a PI with two NRTIs in suppressing plasma viremia and increasing CD4+ T-cell counts, and many would prefer such a regimen initially because it may spare the toxicities of PIs for a considerable time. However, concerns about efavirenz and teratogenicity, that have been demonstrated in animal models as well as by a case report of a myelomeningocele after in utero exposure in a human make this a poor choice for use in early pregnancy. Thus, although the demonstrated ability of efavirenz in combination with two NRTIs to suppress viral replication and increase CD4+ T-cell counts to a similar degree as a PI with two NRTIs supports a preference for efavirenz over other available NNRTIs, in pregnancy the choice of a different NNRTI may be appropriate. Abacavir, a new NRTI, with two other NRTIs (i.e., a triple NRTI regimen) has been used with some success as well. Such a regimen, however, may have short-lived efficacy when the baseline viral load is >100,000 copies/mL. Using two NRTIs alone does not achieve the goal of suppressing viremia to below detectable levels as consistently as does the other regimens discussed previously and should be used only if more potent treatment is not possible. Use of antiretroviral agents as monotherapy is contraindicated, except when there are no other options or in pregnancy to reduce perinatal transmission, as noted below. When initiating antiretroviral therapy, all drugs should be started simultaneously at full dose with the following three exceptions: dose escalation regimens are recommended for ritonavir; nevirapine (NVP); and in some cases, ritonavir plus saquinavir. Recent data confirm that four drugs are generally no better than three drugs when considering treatment with currently available NRTIs and PIs in treatment-naive patients who are not infected with drug-resistant virus.

In order to determine whether a change in therapy is appropriate, the patient must undergo monitoring for immunologic and virologic response as well as for drug toxicity and acceptability. The aim of antiretroviral therapy remains the maintenance of a plasma HIV-1 RNA level below the limits of detection of the most sensitive assays available commercially (i.e., <50 copies/mL). Effective regimens and high levels of adherence result in a decrease of at least 1.0 $\log_{10}$ copies/mL or 90% per month, and suppression of plasma HIV-1 RNA level to below 50 copies/mL will generally be achieved by 16 to 24 weeks, depending on pretreatment level. After antiretroviral therapy is initiated, the plasma HIV-1 RNA level should be checked relatively frequently (e.g., every 4 to 8 weeks) until it is below the limits of detection and regularly thereafter (e.g., three to four times per year). CD4 cell counts generally should be monitored at the same intervals. Resistance testing is recommended in the setting of virologic failure and ideally should be performed when the patient is taking the failing regimen, which maximizes selective pressure on the virus thus increasing the likelihood that resistance testing will detect any mutations that the patient harbors. Genotypic testing for HIV resistance is preferred over phenotypic testing in most settings because it is faster, readily available, and less expensive; phenotypic testing may be more useful for patients with virologic failure following two or more regimens.

There are several reasons to consider modifying a patient's regimen. One reason would be adverse drug effects. Intolerance or toxicity frequently occurs within the first several weeks of starting a new regimen. In a previously treatment-naive patient who is not expected to harbor archived drug-resistance mutations, if one offending drug can be

identified, changing only that drug in an otherwise successful regimen is virologically safe. With some acute toxic effects such as rash, hepatic dysfunction, and febrile systemic reactions, it may be best to stop all antiretroviral drugs. Therapy also may need to be changed because of treatment failure. Treatment failure may be defined virologically, immunologically (declining CD4 cell count), or clinically (HIV-related disease progression). Viral rebound should be confirmed to ensure that it is not transient (i.e., a blip). The fundamental principle for managing any regimen failure, regardless of how many prior regimens the patient has experienced, is to ensure that at least two, and preferably three, drugs used in the new regimen are likely to have activity based on integration of resistance test results and history of antiretroviral regimen use. In individuals in whom the first regimen fails and who were likely infected

with a drug-susceptible virus, a full assessment of adherence is the first step.

Pregnancy

Antiviral medications are used in pregnancy to achieve two goals—to maintain the mother's health and to prevent mother-to-child transmission (PMTCT) of HIV. In regard to the former, although therapeutic recommendations should not be modified *a priori* because of pregnancy, a few comments deserve particular mention. The initiation of antiretroviral therapy during the first trimester should be avoided if possible. However, in general, when an HIV-1 infected woman taking effective antiretroviral therapy becomes pregnant, antiretroviral drugs should not be discontinued, though an adjustment in the regimen based on the considerations outlined below may be in order. After the first trimester of pregnancy, the indications for the initiation of therapy are the same as in nonpregnant women with the exceptions noted below. Even if antiretroviral drugs are administered to women for PMTCT of HIV-1, they should be given in combinations intended to be fully suppressive, although some experts will allow for ZDV-only therapy if the viral load is undetectable at the time therapy is initiated (Table 20.3).

Assuming the virus is susceptible, ZDV and lamivudine (3TC) or emtricitabine are the preferred NRTIs. Other NRTIs may be substituted if resistance testing indicates that drug-resistant mutations are present. An increased risk of hepatotoxicity is associated with the use of NVP in pregnancy, especially if initiated in women with >250 CD4 cells/mm^3. In women who become pregnant while taking NVP, this risk is substantially lower.

Until more data are available that address concerns about bone formation in utero, tenofovir should be avoided unless resistance testing suggests that its use is advisable. Efavirenz is contraindicated in the first trimester of pregnancy. Nelfinavir has been used extensively in pregnancy, but concerns about its potency make it a less attractive agent. Ritonovir-boosted lopinavir remains an acceptable first-line option, although concerns about dosing have been raised and currently are being addressed.

When possible, ZDV should be used as part of the antiviral regimen. In Pediatric AIDS Clinical Trials Group (PACTG) Protocol 076, which utilized a regimen of ZDV given during pregnancy and labor and to the newborn for 6 weeks, the antenatal dosing of 100 mg administered orally five times daily was selected on the basis of the standard ZDV dosage

for adults at the time of the study. However, administration of ZDV three times daily will maintain intracellular ZDV triphosphate at levels comparable with those observed with more frequent dosing. Comparable clinical response also has been observed in some clinical trials among persons receiving ZDV twice daily. Thus, the current standard dosing for ZDV, whether used as a part of a HAART regimen or as single drug therapy for transmission prevention (discussed below), is 200 mg three times daily or 300 mg two times daily. While it is possible that these dosing regimens may not have equivalent efficacy to that observed in PACTG 076, a regimen of two or three times daily is likely to enhance maternal adherence.

Most data regarding the safety of ZDV have been reassuring. Almost 1,000 children have been tracked for 4 years with no increase in risks of neurodevelopmental delay or carcinogenesis. In regard to monitoring of the mother on ZDV, it only is necessary to measure the blood count and liver functions on a monthly basis. The only abnormality that occurs with any frequency is anemia.

Other NRTIs generally have been well tolerated and have not been demonstrated to be teratogenic in humans. However, concerns have been raised about potential adverse effects on both mothers and infants related to the avidity of these drugs for mitochondria. By binding to mitochondrial γ-DNA polymerase and interfering with replication, these drugs can induce mitochondrial dysfunction. ddC demonstrates the greatest inhibition of mitochondrial γ-DNA polymerase, followed in order by ddI, d4T, 3TC, ZDV, and abacavir. Clinical disorders associated with mitochondrial toxicity include neuropathy, myopathy, cardiomyopathy, pancreatitis, hepatic steatosis, and lactic acidosis.

In regard to potential maternal toxicity, several cases of lactic acidosis, three of which were fatal and two of which were accompanied by pancreatitis, have been reported among pregnant or recently delivered women who had been on ddI and d4T therapy along with a variety of third agents since before conception. Two cases of fatal liver failure in pregnant women on ZDV, 3TC, and nelfinavir also have been reported. These cases developed in late pregnancy, and in several cases, the presentation was similar to that seen with acute fatty liver of pregnancy, a condition that itself has been linked to mitochondrial fatty oxidation disorders in the fetus and mother. This has led to speculation that the metabolic changes of late pregnancy may enhance susceptibility to complications of nucleoside agents, especially those with greater inhibition of mitochondrial γ-DNA polymerase. That susceptibility is suggested both by the syndrome of acute fatty liver of pregnancy and animal data that demonstrate reduced mitochondrial fatty acid oxidation in late pregnancy and in animals treated with exogenous estradiol and progesterone to mimic pregnancy levels. However, many cases of death related to use of these medications outside of pregnancy have been reported as well. In any event, although these serious morbidities appear to be rare, providers caring for HIV-infected women receiving nucleoside analog agents should be cognizant of the risk and monitor accordingly. One approach would be to monitor hepatic enzyme levels during the last trimester and to aggressively investigate all new symptoms. Women with substantial elevations in transaminase levels above baseline or other new abnormalities, in the absence of other explanations such as preeclampsia, should have their nucleoside agents discontinued, either with substitution of agents from another class of antiretrovirals or discontinuation of all antiretrovirals. In view of the

reports of maternal

deaths and toxicity associated with prolonged use of d4T and ddI in pregnancy, this combination should be used in pregnancy with caution and only if other nucleoside agents cannot be used because of resistance or toxicity.

TABLE 20.3 Antiretroviral Drug Use in Pregnant HIV-Infe Pharmacokinetic and Toxicity Data in Human Pregnancy and R Use in Pregnancy

Antiretroviral Drug	Pharmacokinetics in Pregnancy	Concerns in Pregnancy
NRTIs/NtRTIs		

Recommended agents

Zidovudine*	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated.	No evidence of human teratogenicity. Well-tolerated, short-term safety demonstrated for mother and infant.
Lamivudine*	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated.	No evidence of human teratogenicity. Well-tolerated, short-term safety demonstrated for mother and infant.

Alternate agents

Didanosine	Pharmacokinetics not significantly altered in pregnancy; no change in dose	Cases of lactic acidosis, some fatal, have been reported in pregnant women receiving

	indicated.	didanosine and stavudine together.
Emtricitabine†	No studies in human pregnancy.	No studies in human pregnancy.
Stavudine	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated.	No evidence of human teratogenicity. Cases of lactic acidosis, some fatal, have been reported in pregnant women receiving didanosine and stavudine together.
Abacavir*	Pharmacokinetics are not significantly altered in pregnancy; no change in dose indicated.	Hypersensitivity reactions occur in ~58% of non-pregnant persons; a much smaller percentage are fatal and are usually associated with rechallenge. Rate in pregnancy unknown. Patient should be educated regarding symptoms of hypersensitivity

		reaction.
Insufficient data to recommend use		
Tenofovir†	No studies in human pregnancy. Phase I study in late pregnancy in progress.	Studies in monkeys show decreased fetal growth and reduction in fetal bone porosity within two months of starting maternal therapy. Clinical studies in humans (particularly children) show bone demineralization with chronic use; clinical significance unknown.
Not recommended		
Zalcitabine	No studies in human pregnancy.	Rodent studies indicate potential for teratogenicity and developmental toxicity.
NNRTIs		
Recommended agents		

Nevirapine	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated.	No evidence of human teratogenicity. Increased risk of symptomatic, often rash associated, and potentially fatal liver toxicity among women with CD4+ counts >250/mm^3 when first initiating therapy; unclear if pregnancy increases risk.
Not recommended		
Efavirenz†	No studies in human pregnancy.	FDA Pregnancy Class D; significant malformations (anencephaly, anophthalmia, cleft palate) were observed in 3 (15%) of 20 infants born to cynomolgus monkeys receiving efavirenz during the first trimester at a dose giving plasma levels comparable to systemic human

		therapeutic exposure; there are three case reports of neural tube defects in humans after first trimester exposure; relative risk unclear.
Delavirdine	No studies in human pregnancy.	Rodent studies indicate potential for carcinogenicity and teratogenicity.
Protease Inhibitors		Hyperglycemia, new onset or exacerbation of diabetes mellitus, and diabetic ketoacidosis reported with PI use; unclear if pregnancy increases risk. Conflicting data regarding preterm delivery in women receiving PIs.
Recommended agents		

Lopinavir/ritonavir	Pharmacokinetic studies of standard dose of lopinavir/ritonavir capsules (3 capsules twice daily) during 3rd trimester indicated levels were significantly lower than during postpartum period and in non-pregnant adults; an increased dose of 4 capsules of lopinavir/ritonavir twice daily starting in the 3rd trimester resulted in adequate lopinavir exposure; by 2 weeks postpartum, standard dosing was again appropriate. Pharmacokinetic studies of the new lopinavir/ritonavir tablet formulation are underway, but data are not yet	No evidence of human teratogenicity. Well-tolerated, short-term safety demonstrated in phase I/II studies.

Nelfinavir	Adequate drug levels are achieved in pregnant women with nelfinavir 1250 mg, given twice daily.	No evidence of human teratogenicity. Well-tolerated, short-term safety demonstrated for mother and infant. Nelfinavir dosing at 750 mg three times daily produced variable and generally low levels in pregnant women.

Alternate agents

Indinavir	Two studies including 18 women receiving indinavir 800 mg three times daily showed markedly lower levels during pregnancy compared to postpartum, although suppression of HIV RNA was seen.	Theoretical concern re: increased indirect bilirubin levels, which may exacerbate physiologic hyperbilirubinemia in the neonate, but minimal placental passage. Use of unboosted indinavir during pregnancy is not recommended.
Ritonavir	Phase I/II study in pregnancy showed lower levels during pregnancy compared to postpartum.	Limited experience at full dose in human pregnancy; has been used as low-dose ritonavir boosting with other PIs.
	Pharmacokinetic studies of saquinavir soft gel capsules (SGC) indicated that inadequate drug levels were observed in pregnant women given 1,200 mg of saquinavir-SGC as a sole PI three times daily *[275]*, but adequate levels were	

Saquinavirhard gel capsule [HGC] (Invirase®)/ritonavir	achieved when 800 mg saquinavir-SGC boosted with ritonavir 100 mg was given twice daily. However, saquinavir-SGC is no longer produced. Limited pharmacokinetic data on saquinavir hard gel capsule (HGC) suggest that 1,000 mg saquinavir-HGC/100 mg ritonavir given twice daily will achieve adequate saquinavir drug levels in pregnant women.	Well-tolerated, short-term safety demonstrated for mother and infant for both saquinavir-SGC and -HGC in combination with low-dose ritonavir.
Insufficient data to recommend use		
Amprenavir	No studies in human pregnancy.	Oral solution contraindicated in pregnant women because of high levels of propylene glycol, which may not be adequately metabolized during pregnancy.
Atazanavir	No studies in	Theoretical concern re: increased indirect bilirubin levels, which may exacerbate physiologic

	human pregnancy.	hyperbilirubinemia in the neonate, although transplacental passage of other PIs has been low.
Darunavir	No studies in human pregnancy.	No experience in human pregnancy.
Fosamprenavir	No studies in human pregnancy.	No experience in human pregnancy.
Tipranavir	No studies in human pregnancy.	No experience in human pregnancy.
Fusion Inhibitors		
Insufficient data to recommend use		
Enfuvirtide	No studies in human pregnancy.	No experience in human pregnancy

(Adapted from Perinatal Guidelines. AIDSinfo.nih.gov/guidelines)

In regard to infants, concern about mitochondrial toxicity initially was raised by a French report of eight cases of HIV-uninfected infants with abnormalities potentially related to mitochondrial dysfunction developing among 1,754 fetuses exposed to prophylactic nucleoside therapy. Two infants had progressive neurologic symptoms and died several months after completing in utero and neonatal courses of ZDV and 3TC. Three other infants had mild to moderate symptoms, and three had asymptomatic laboratory abnormalities. Mitochondrial abnormalities were not proven to be the cause of the abnormalities, and the relationship between these findings and in utero and neonatal nucleoside exposure has not been established. In response to these concerns, investigators from several large cohort studies in the United States reviewed all 353 deaths among more than 20,000 children born to HIV-infected women and found no deaths similar to those in the French cohort, although only 6% of the children had been exposed to the combination of ZDV and 3TC.

Combination therapy also has been linked to increased rates of prematurity in a few European studies, but these have not been confirmed in larger U.S. series. Recent reports have warned of an increased rate of neonatal febrile seizures in infants who had been exposed to antiretroviral therapy. Finally, as noted previously, efavirenz should not be recommended because of reported teratogenic effects in monkey models.

In regard to prophylaxis for opportunistic infections, if the count drops below 200 cells/mm^3, PCP prophylaxis should be instituted; below 50 cells/mm^3, *Mycobacterium avium* complex (MAC) prophylaxis should be given and an ophthalmology consult obtained. The specific details of management of the myriad infections to which these women are prone are beyond the scope of this chapter. If HAART therapy is successful in returning CD4 counts to levels above the threshold for opportunistic infection prophylaxis and those levels are maintained for 6 months, then the prophylaxis can be discontinued.

Preventing Perinatal Transmission

PACTG-THR 076 regimen has been demonstrated to reduce the risk of perinatal HIV-1

transmission by almost 70%, from 25% in the placebo group to 8% in the ZDV group. Subsequently, ACTG 185 demonstrated that similar results could be seen even among women who had previous exposure to ZDV or who had CD4 counts below 200 cells/mm^3. ZDV has been successfully integrated into clinical practice in the United States and Europe, and its widespread use has been accompanied by dramatic declines in perinatal transmission rates in these countries. As noted previously, the regimen consists of ZDV 300 mg two times a day in the antepartum period (beginning after 14 weeks). In the intrapartum period, a loading dose of 2 mg/kg over the first hour is followed by a maintenance dose of 1 mg/kg per hour thereafter. In the neonatal period, the infant receives ZDV syrup for 6 weeks at a dose of 2 mg/kg every 6 hours.

Currently, there is insufficient data to justify the substitution of any agent for ZDV in most circumstances, except perhaps for times when women have not received therapy prior to labor (vide infra). Even if there is evidence of ZDV resistance, which might make ZDV therapy for the prevention of mother-to-child transmission seem futile, ZDV might still have a role. The demonstration of transmission of escape mutants from mother to child suggests that an individual ZDV-susceptible virus might be transmitted even if the predominant strain(s) in the mother is (are) not susceptible. If the mother is intolerant of ZDV, it may be reasonable to consider using an alternative agent (which could potentially reduce viral load during the antepartum period) and then adding ZDV for the intrapartum (depending on the type of toxicity experienced by the mother) and neonatal periods. Thus, if the therapeutic regimen being used to treat a woman's HIV disease does not include ZDV, it would seem judicious to incorporate it if she becomes pregnant.

The recommendation to use ZDV, as opposed to other antiretroviral agents, for the prevention of mother-to-child transmission of HIV is based on two considerations. First, there is empiric data that strongly supports its use in that regard. No other agent has been similarly studied. Second, pharmacokinetic studies demonstrate that high levels of the drug are available in the fetal compartment. Similar information is unavailable for most other agents. The importance of placental passage of the drug is not certain. If viral load thresholds are truly central to transmission risk, then viral dynamics on the maternal side of the placenta might be as important as placental passage of the drug. Several publications (Fig. 20.3) suggest that a correlation exists between maternal viral load and rates of mother-to-child HIV transmission and further hint at the existence of a clinically relevant threshold. Although other researchers disagree, most data support the thesis that dropping viral loads as low as possible in the setting of pregnancy is a useful strategy. There is clear evidence that even if the viral load is low, those women on antiretroviral therapy will fare better than women with similar viral loads who are not on therapy, and recent data suggest that combination therapy is even more effective than ZDV alone in reducing rates of transmission. A French team reported that adding 3TC to ZDV reduced transmission rates to 1.6%. A longitudinal study in the United States found that 20% of women with no antiretroviral therapy transmitted HIV to their infant compared with 10.4% who received ZDV alone, 3.8% who received combination therapy without a protease, and 1.2% who received a combination that included a protease.

The vast majority of perinatal HIV-1 infection occurs in the developing world. Unfortunately, the PACTG 076 ZDV regimen is too costly and logistically complex for many

scale, and its efficacy in a breast-feeding population (where postpartum transmission remains a real concern) is unknown. An ideal preventive intervention would be cheap, nontoxic to the mother and fetus, easy to administer, only needs to be given once or for a limited period of time, and has utility in preventing postpartum transmission. The results of PACTG 076 have spurred the worldwide evaluation of multiple other modalities to reduce transmission.

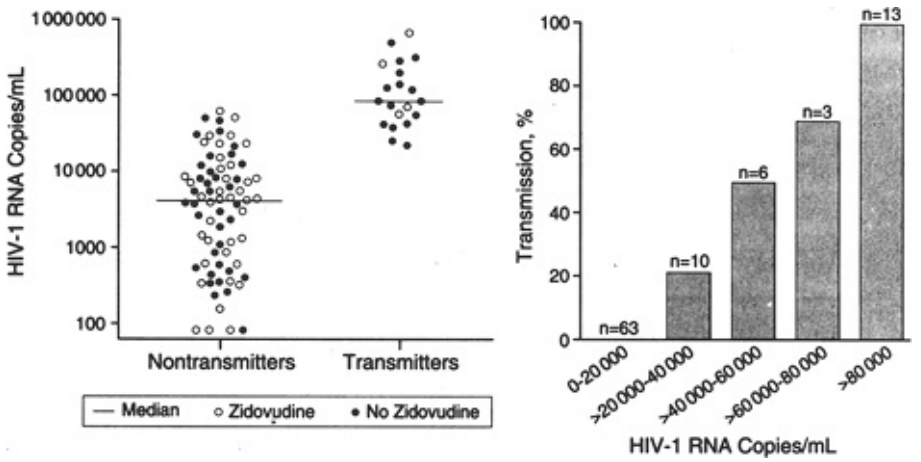

Figure 20.3 Left: Maternal HIV-1 RNA levels at delivery in infected nontransmitting and transmitting mothers. Mothers who received ZDV during gestation or labor and delivery are indicated by the *open circles*; mothers who did not receive ZDV during gestation, labor, or delivery are indicated by the *darkened circles*. *Horizontal bars* indicate the median for each of the measured variables. **Right:** Perinatal transmission rate according to HIV-1 RNA levels at delivery. (From Dickover RE, Garratty EM, Herman SA, et al. Identification of levels of maternal HIV-1 RNA associated with risk of perinatal transmission. *JAMA* 1996;275:599–605, with permission.)

In the developed world, where cost is a lesser consideration, regimens capable of maximally sustaining a drop of viral load (HAART) have gained greater favor for use during pregnancy. Clearly, any woman who would be a candidate for HAART if she were not pregnant should be on HAART while she is pregnant. If therapy is being initiated for the first time in pregnancy, consideration may be given to delaying initiation of therapy until 14 weeks gestation. Most experts also would recommend HAART for any pregnant woman whose viral load is >1,000 copies.

The pharmacologic approach to the patient whose viral load is <1,000 copies is less clear-cut. There are some experts who feel that even with HIV-1 RNA levels <1,000 copies/mL, combination antiretroviral regimens may further decrease perinatal transmission compared with ZDV alone. However, some women may wish to restrict exposure of their fetus to antiretroviral drugs during pregnancy while still reducing the risk of transmitting HIV-1 to their infants. Additionally, for women with HIV-1 RNA levels <1,000 copies/mL, time-limited

use of ZDV during the second and third trimesters of pregnancy is less likely to induce the development of resistance than in women with higher viral loads because of the limited viral replication in the patient and the time-limited exposure to the antiretroviral drug. To summarize, with a low viral load, the patient must balance potential benefits of HAART (potentially lowering the likelihood of developing resistant virus, maximally reducing rates of transmission, possibly avoiding the need for cesarean section) against possible risks (drug toxicities, unknown long-term risk to the exposed fetus).

If combination therapy is given principally to reduce perinatal transmission and would not have been necessary if the woman were not pregnant, consideration may be given to discontinuing therapy postnatally, with the option to reinitiate treatment at a later date according to standard criteria for nonpregnant women. Generally, when drugs are discontinued postnatally, all drugs should be stopped simultaneously. However, if the drugs have significantly different half-lives, such a strategy may result in functional monotherapy for a period of time and potential development of resistance. NVP has a particularly long half-life such that to avoid a period of functional monotherapy, some experts would continue the dual nucleoside analogue components of the regimen for a period of time after NVP discontinuation.

Many of the regimens designed for countries with fewer resources have attempted to achieve reduced numbers of infected children with shortened courses of antepartum and neonatal therapy. These regimens have included a Thai regimen of 4 weeks of antepartum ZDV combined with oral ZDV therapy during labor that reduced transmission to 9% compared with 19% in a placebo arm. Similar findings have been reported from the use of an abbreviated course of ZDV and 3TC in an African trial. An even more dramatic finding emerged from the HIVNET 012 trial, which revealed that a single does of NVP during labor and again to the neonate could reduce transmission at 6 weeks from the 21% seen in those receiving a short course of ZDV to only 12%. Unfortunately, the benefits of all these regimens are attenuated in populations that breast-feed after the regimens have been completed. An additional concern is that single-dose NVP has been associated with NVP-resistant virus in women as well as in infants who become infected despite receiving NVP, even when the mother receives additional antiretroviral drugs during pregnancy and intrapartum. NVP resistance mutations were detected at 6 weeks postpartum in 25% of the subset of women with detectable viremia who received single-dose intrapartum NVP in HIVNET 012. These mutations were no longer detectable in plasma virus at 13 to 18 months postpartum, in a setting where none of the women received postnatal antiretroviral therapy. NVP resistance mutations also were detected at 6 to 8 weeks of age in 11 of 24 (46%) infants who became infected despite receiving NVP. Genotypic NVP resistance

---

was detected at 6 weeks postpartum in 15% of women who received single-dose NVP and who had received ZDV alone or combination antiretroviral drugs during pregnancy and intrapartum. Further, women who received a single dose of NVP to prevent perinatal transmission of HIV-1 had higher rates of virologic failure with subsequent NVP-based antiretroviral therapy than did women without previous exposure to NVP. However, this applied only when NVP-based antiretroviral therapy was initiated within 6 months after receipt of a single, peripartum dose of NVP.

Perhaps of greater relevance to U.S. populations are data demonstrating that even patients whose serostatus is unknown until the peripartum period may benefit from pharmaceutical interventions. A review of the New York State experience found that the transmission rate from mothers who received no therapy was significantly lowered with the use of ZDV even when therapy was delayed to the first 24 hours postpartum (i.e., given only to the neonate). It was lowered to an even greater extent when therapy began during the intrapartum period. Several effective regimens are available for intrapartum therapy for women who have had no prior therapy.

. Intrapartum intravenous ZDV followed by 6 weeks of ZDV for the newborn.

.. Oral ZDV and 3TC during labor, followed by 1 week of oral ZDV/3TC for the newborn.

. A single dose of NVP at the onset of labor, followed by a single dose of NVP for the newborn at age 48 hours.

. The single-dose maternal–infant NVP regimen combined with intrapartum intravenous ZDV and 6 weeks of ZDV for the newborn.

If single-dose NVP is given to the mother, alone or in combination with ZDV, consideration should be given to adding maternal ZDV and 3TC as soon as possible (intrapartum or immediately postpartum) and continuing for 3 to 7 days, which may reduce development of NVP resistance.

Other efforts to prevent transmission have focused on attempts to reduce peripartum and postpartum exposure to the virus. Reduction of intrapartum exposure could include attempts to minimize the duration of ruptured membranes, which has been related to the rate of mother-to-child transmission of HIV (Fig. 20.4). Cesarean section is the one strategy that can guarantee the infant will not be exposed to ruptured membranes during parturition. Evidence has accumulated that cesarean section may be a beneficial addendum to pharmaceutical therapy. A meta-analysis performed on primary data from 15 prospective cohort studies including more than 7,800 mother–child pairs found that the rate of perinatal HIV-1 transmission in women undergoing elective cesarean delivery was 8.2% in those receiving no antiretrovirals and 2% in those receiving ZDV. Both rates were significantly lower than that seen among women delivered by either nonelective cesarean or vaginal delivery.

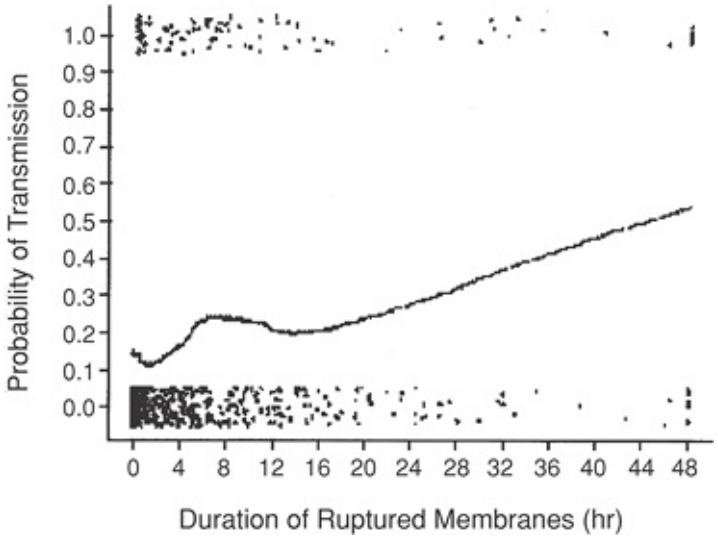

Figure 20.4 Probability of HIV-1 transmission in relation to the duration of ruptured membranes. The *dots* at the top represent women who transmitted HIV-1 to their infants, and those at the bottom represent women who did not transmit. (From Landesman S, Kalish L, Burns D, et al. The relationship of obstetrical factors to the mother-to-child transmission of HIV-1. *N Engl J Med* 1996;334:1617–1623, with permission.)

Subsequently, the results of a European randomized trial of cesarean section were reported (Table 20.4). The results were remarkably consistent with those reported previously. In the European study, HIV-infected women between 34 and 36 weeks gestation were randomly assigned elective cesarean delivery at 38 weeks or vaginal delivery. Three (1.8%) of 170 infants born to women assigned cesarean delivery were infected compared with 21 (10.5%) of 200 infants born to those assigned to vaginal delivery ($P < 0.001$). Seven (3.4%) of 203 infants of women who gave birth by cesarean section were infected compared with 15 (10.2%) of 167 infants born vaginally ($P = 0.009$). Unfortunately, the number of participants was too small to allow a separate analysis of the benefit of cesarean section in the setting of antiretroviral therapy, and HAART use was not reported from the cohort. There were few postpartum complications, and no serious morbidity was noted in either group. Despite the shortcomings of the trial, it does suggest that among women who were not optimally treated with HAART, cesarean section could have an important effect on reducing rates of mother-to-child transmission of HIV.

In summary, the cited studies indicate that compared with other types of delivery, cesarean delivery performed prior to the onset of labor and prior to rupture of membranes (elective or scheduled cesarean) significantly reduces the rate of perinatal HIV-1 transmission by odds ratios of 0.20 to 0.45. On the basis of the data, the American College of Obstetricians and Gynecologists published

a Committee Opinion that concluded that HIV-infected women should be offered scheduled cesarean section in order to reduce the rate of transmission beyond that which could be achieved with ZDV alone. They also pointed out that data are insufficient to demonstrate a

benefit for women with viral loads <1,000 copies/mL of plasma. They suggested that scheduled cesarean sections should be performed at 38 weeks gestation and that amniocentesis should not be performed in order to avoid contamination of the amniotic cavity with viral antigen from maternal blood. They also suggested that prophylactic antibiotics be employed because of concerns of heightened risks of postoperative infectious morbidity. The data supporting a heightened risk for postoperative morbidity among HIV-infected women is not robust; however, the evidence that all women undergoing an operative delivery face a greater risk of infectious morbidity is overwhelming. The liberal use of antibiotics in the setting of cesarean section and HIV infection therefore would seem reasonable.

TABLE 20.4 HIV-1 infection status of children according to allocated and actual mode of delivery

	Infection Status		
	Negative	Positive	Odds Ratio (95% CI)
Allocated mode			
Vaginal delivery	179 (89.5%)	21 (10.5%)	1.0[a]
Caesarean section	167 (98.2%)	3 (1.8%)	0.2 (0.1–0.6)
Actual Mode			
Vaginal delivery	150 (89.8%)	17 (10.2%)	1.0[a]
Caesarean section	196 (96.5%)	7 (3.5%)	0.4 (0.2–0.9)
Elective	165 (97.6%)	4 (2.4%)	0.3 (0.1–0.8)

Emergency	(91.2%)	3 (8.8%)	1.0 (0.3–3.7)

[a]Reference category.

Although not so compelling as the data just cited, there is some evidence that cesarean section could be beneficial even in the setting of viral loads <1,000 copies. Those data come from a meta-analysis of studies that focused exclusively on women who had viral loads <1,000 copies. In those women, antiretroviral therapy still played a major role in reducing transmission, dropping rates from approximately 10% to approximately 1%. Cesarean section apparently dropped the rate from 6% to 1.5%, but there was no control in that analysis for the use of antiretroviral therapy. To summarize, at the moment, there is no strong evidence that cesarean section will provide additional benefit to the HIV-infected woman who is on therapy and has an undetectable viral load.

Postpartum Hemorrhage

There is no evidence that HIV-infected women are prone to bleeding in the postpartum period. However, if excess bleeding does occur, the provider should be familiar with certain drug–drug interactions that could come into play in that setting and that could have deleterious consequences. Among the treatments still available for use in the setting of hemorrhage is oral or parenteral methergine or other ergot alkaloids as a first-line agent. Methergine should not be coadministered with PIs and the NNRTIs efavirenz and delavirdine because these drugs are potent CYP3A4 enzyme inhibitors. Their concomitant use has been associated with exaggerated vasoconstrictive responses. If a woman on one of these antiviral agents experiences postpartum hemorrhage, methergine should only be used if alternative treatments (e.g., prostaglandin F2-α, misoprostol, or oxytocin) are not available. If there are no alternative medications available and the need for pharmacologic treatment outweighs the risks, methergine should be used in as low a dosage and for as short duration as possible.

Human Immunodeficiency Virus and Gynecology

Preconception Care

Providing all women of childbearing age the opportunity to receive preconception counseling and care facilitates optimal perinatal outcomes. The purpose of preconception care is to improve the health of each woman prior to conception by identifying risk factors for adverse maternal or fetal outcome, providing education and counseling targeted to the patient's individual needs, and treating or stabilizing medical conditions to optimize maternal and fetal outcomes.

This is particularly true in the setting of HIV infection because in addition to the general components of preconception counseling and care that are appropriate for all women of reproductive age, HIV-1–infected women have specific needs that must be addressed. The

contraceptive methods to reduce the likelihood of unintended pregnancy. In choosing a method, the provider should be concerned not only with efficacy but with any potential interactions of antiretroviral drugs with hormonal contraceptives that could lower contraceptive efficacy as well. For example, with the PI fosamprenavir (fAPV), there will be an increase in ethinyl estradiol and norethindrone levels and a 20% decrease in amprenavir (APV) levels. It is therefore recommended that it should not be coadministered; rather, alternative methods of contraception should be used. With atazanavir (ATV), the levels of ethinyl estradiol and norethindrone increase markedly, so the lowest effective dose should be used or alternative methods found for contraception. With lopinavir/ritonavir, levels of ethinyl estradiol decrease and alternative contraception should be used. Since new drug–drug interactions are still being detected, it is important to consult up-to-date sources prior to beginning new medications for contraception.

It also is important for counseling to include a discussion about safer sexual practices in order to reduce the likelihood of HIV transmission to sexual partners and to protect women from acquiring sexually transmitted diseases. Clearly, these discussions will be more fruitful if the HIV status of partners is known. Clinicians should therefore encourage sexual partners to receive HIV testing and counseling and appropriate HIV care, if infected. These conversations may naturally lead into discussions about the safest way to conceive if a discordant couple desires a biologic child. In some circumstances, assisted reproductive technologies (ART) may be useful either to reduce risks to the uninfected partner or simply because the couple has difficulty conceiving (vide infra). In those circumstances, expert consultation is recommended. HIV status per se should not preclude the use of ART.

HIV-infected women may frequently use substances (e.g., alcohol, illicit drugs, and cigarettes) that can have deleterious effects on the fetus. The time prior to conception provides an ideal opportunity to prevent fetal exposure by engaging women in efforts to wean off these agents. It also is the appropriate time to start to engage in strategies to prevent fetal infection with HIV. Some studies suggest that smoking itself might heighten risks of prenatal exposure. Beyond that, getting HIV infection under optimal control by using medications that do not pose risks to an early gestation is an important strategy. Thus, if a woman is planning a pregnancy and is on efavirenz, it is important to switch regimens prior to conception. Whatever regimen ultimately is chosen, it should be capable of attaining a stable, maximally suppressed maternal viral load prior to conception. The woman also should be evaluated for any therapy-associated side effects that may adversely impact maternal–fetal health outcomes (e.g., hyperglycemia, anemia, hepatic toxicity). If the woman has a low CD4 count, she also may be a candidate for prophylaxis for opportunistic infections and administration of medical immunizations (e.g., influenza, pneumococcal, or hepatitis B vaccines), and such treatments should be instituted as necessary.

Family Planning

The advent of effective therapies has led to longer life spans for HIV-infected women, and

there is no evidence that pregnancy adversely influences the course of HIV infection. Coupled with increasingly effective means of preventing mother-to-child transmission of HIV, these facts have led many couples to consider childbearing in the context of HIV infection. That process may involve issues unique to HIV-infected couples, such as reducing the risks of infecting an uninfected partner, and issues applicable to all couples, such as choosing the optimal time to have a child and the best means of contraception until that time arrives. The HIV-infected woman will need an obstetrician/gynecologist who understands these issues and respects the rights of all such individuals to have children in order to guide them through these sometimes difficult issues.

The optimal time for an HIV-infected woman to become pregnant is when her infection is well controlled (i.e., no clinical manifestations) or when, through therapy, her viral load is undetectable. Using contraception to space and time pregnancies, as well as to prevent unintended pregnancies, is a critical aspect of short- and long-term care for the HIV-infected woman. Thus, contraception may be critical in achieving that goal as well as allowing patents to exercise choice in regard to when to have children. In choosing a method of contraception, the HIV-infected woman needs to consider both the efficacy of a technique for the prevention of pregnancy, the interaction of any medication she may be taking on hormonal therapies that she might consider (vide supra), and whether preventing HIV transmission as well as pregnancy should factor into her calculus when choosing a method. Since she is a potential source of infection and may be uniquely susceptible to sexually transmitted diseases and their consequences, discussions of the use of latex condoms should be routine. If the woman is certain that she no longer desires the possibility of bearing children, then sterilization should be an option.

If a woman is already on a method of contraception that she finds satisfactory and effective, it should be maintained if possible. She should be told of the advantage of adding condoms to that regimen. If condoms are her method of contraception, the limitations of that method should be discussed, and she should be educated about emergency contraception if it becomes necessary. Condom use with emergency contraceptive backup is recommended because studies among HIV-uninfected and HIV-infected persons show that attempts at consistent dual method use consisting of a condom plus use of a rigorous, client dependent, ongoing method of reversible contraception

---

(e.g. combined hormonal contraceptives or progestin-only hormonal contraception) often results either in inconsistent use of the condom or inconsistent use of the ongoing pregnancy prevention method. Currently, there is no evidence that any microbicide provides an advantage to condoms. If the patient is using hormonal contraception, then consultation with an HIV expert should be obtained to discuss potential interactions between antiretroviral regimens and various hormones.

There is limited empirical data on interactions between hormonal contraception and HIV disease. The Women's Interagency HIV Study found no associations between HIV RNA levels at baseline (or longitudinally) and no reductions in CD4 counts among HIV-infected women using the hormonal contraceptives Depo-Provera (injectable) and Norplant (implant). However, some data suggest that hormonal contraceptive use increases the risk of genital (cervical) shedding of HIV-infected cells, thus possibly increasing risk of transmission.

Clinicians should reemphasize condom use (for prevention of pregnancy and sexually transmitted infection) when prescribing courses of liver enzyme–inducing medications for HIV-infected women who are using hormonal contraception because variations in serum estrogen and progestin levels may result in reduced contraceptive efficacy. Although this advice is reasonable, it does err on the side of caution; hormonal contraception is progestin dominant in its contraceptive actions, and concerns about reduced efficacy remain theoretical and have not been borne out clinically. Finally, it should be remembered that oral contraceptive absorption can be affected by diarrhea and vomiting, which are side effects of many antiretroviral drugs.

The intrauterine device (IUD) may be a reasonable choice for some HIV-infected women. Only one cohort study has been conducted to assess the safety of copper IUD use among HIV-infected women. This study found no association between HIV infection and overall complications at 4 and 24 months following insertion. The overall prevalence of pelvic inflammatory disease was low. At 24 months, the difference in the incidence of pelvic inflammatory diseases between HIV-infected women and HIV-uninfected women (2.0% vs. 0.4%) was not statistically significant; however, the study was not adequately powered.

Some HIV-infected women may need to use ART in order to conceive. Since this chapter focuses on HIV-infected women, this discussion will not include considerations of the serodiscordant couple in which the female is the uninfected partner. In general, ART may serve one of two purposes: either to treat infertility or to allow conception while minimizing the risk of infecting a seronegative partner. For the first years of the HIV epidemic, reproductive endocrinologists were reluctant to utilize ART for HIV-infected women because of concern for their ability to remain healthy long enough to raise a child as well as concern about the high risk of transmission of HIV from mother to child. The advent of HAART has mitigated both these concerns and has made HIV similar in many regards to chronic illnesses that have, in the past, not precluded the use of ART. More recently, many reproductive endocrinologists have started to offer ART to HIV-infected women.

Infertile HIV-infected couples should undergo the same evaluation as noninfected couples. Since some of the risk factors associated with acquisition of HIV infection in the first instance (e.g., drug use) may also be linked to sexually transmitted diseases and pelvic inflammatory disease, evaluation of tubal patency should be one focus of that evaluation. For the male partner, the stability of the HIV infection should be assessed. Serum gonadotropins, testosterone, and prolactin should be performed because HIV infection can cause earlier and more severe central hypothalamic reproductive dysfunction in men compared with women. At least two semen analyses, performed at least 3 months apart, should be obtained after 2 to 5 days of sexual abstinence. Men receiving treatment with exogenous testosterone for HIV disease may have marked oligospermia or even azoospermia.

If the male partner is uninfected, then the clinician should recommend either self-insemination at home or intrauterine insemination in the office (with self-insemination between 12 and 36 hours after the evening on which the luteinizing hormone surge is detected). The couple can collect the man's ejaculated sperm, by using a clean glass or

plastic container, and deposit it in the woman's posterior vagina, by using a sterile, large-bore syringe.

Treatment of the infertile couple should mirror that for HIV-uninfected couples. Controlled ovarian hyperstimulation can be used as appropriate. In vitro fertilization (IVF) can be performed, if needed. In that case, modifications of infection control in the lab may be warranted. Universal precautions, face shields, and careful laboratory technique are required when laboratory staff handle the ova. If possible, and at the discretion of the laboratory, the oocytes and embryos of an HIV-infected woman should be cultured in a separate incubator and decontaminated after culture. If a couple has supernumerary embryos available for cryopreservation after the IVF cycle, the use of Food and Drug Administration (FDA)-approved embryo straws, which are nonporous and nonabsorbent, is recommended to eliminate the theoretical risk of contamination while stored in the liquid nitrogen. While there are not a great deal of data on outcomes, there is some suggestion of a lower success rate among HIV-infected couples, perhaps reflecting either lesser ovarian reserve or a higher prevalence of deleterious behaviors (e.g., smoking).

Human Papillomavirus

Cervical cancer is a clinical criterion for the diagnosis of AIDS. There are large numbers of reports documenting

---

that HIV-infected women have high rates of carriage of human papillomavirus (HPV), the causative virus of cervical neoplasia, and that they also have high rates of cervical cancer. These facts reflect both the high rates of behaviors that might predispose to the acquisition of HIV (e.g., multiple sexual partners, smoking) and the deterioration of immune factors that usually control HPV and accompany the progression of HIV disease. Studies have shown that severely immunosuppressed HIV-infected women are less likely to resolve HPV infection, and take longer when they do, than HIV-uninfected women. Higher HIV-1 RNA plasma levels have been associated with both an increased risk of HPV infection with oncogenic types and an increased risk of cervical dysplasia. While HAART might restore some of the host's ability to control HPV, women on or off HAART need assiduous monitoring. The clinical consequence of these facts is the requirement that clinicians perform a gynecologic examination, including a cytologic evaluation, in HIV-infected women during their baseline evaluation. The Pap smear should then be repeated at 6 months and then annually if the results are normal. Women with abnormal Pap tests, including ASC-US, ASC-H, or LSIL, should be referred for colposcopy and further evaluation that may include HPV DNA testing, cervical biopsy, cervical curettage, and endometrial biopsy, depending on cell type and the degree of cytological abnormality.

If an abnormality is diagnosed on colposcopy, clinicians should treat HIV-positive women based on the extent of the disease and follow the treatment protocols outlined by the American Society for Colposcopy and Cervical Pathology (ASCCP). HIV-infected women who have undergone ablation or excisional therapy for dysplasia should receive careful follow-up for disease recurrence because they have an increased rate of recurrence of dysplasia compared with HIV-uninfected women with all of these techniques, particularly

cryotherapy.

For women who are HIV-uninfected, HPV testing at the time of initial Pap test can be a useful adjunct when Pap test results are ASC-US. Those patients with a high-risk HPV subtype are referred to colposcopy more quickly and are monitored closely. However, since it is currently recommended that colposcopy be performed in HIV-positive women with any abnormal cervical cytology, at the current time the results of HPV testing do not change the management of women living with HIV infection. However, in one recent report, rates of any SIL were compared among HIV-infected and -uninfected women, all of whom were negative for HPV (oncogenic and nononcogenic). The investigators found a similar low cumulative incidence of any SIL among both groups when limiting the seropositive to those with CD4 counts >500 cells/mm^3 and who had normal cervical cytology at baseline. They concluded that similar cervical cancer screening practices might be applicable to both groups, although they cautioned that such a strategy warranted evaluation in an appropriate clinical trial.

Menstrual Irregularities

While a large number of studies have assessed the association between HIV infection and menstrual abnormalities, none has clearly demonstrated a link. Any such studies must consider a variety of confounding factors that might mediate such a relationship, such as weight loss (or gain secondary to HAART), smoking, or illicit drug use. One large study controlling for several of the aforementioned confounding factors demonstrated slightly shorter (<18 days) menstrual cycles in HIV-infected women, but menstrual function did not differ from the HIV-uninfected cohort by cycle length or menstrual variability. However, higher viral loads and decreased CD4 counts were associated with increased cycle variability and polymenorrhea. The authors later attributed the menstrual disorders to substance abuse rather than HIV seropositivity.

Several mechanisms can be considered as potentially causative of any irregularities. One such mechanism is the HIV-specific effect on the hypothalmic–pituitary–gonadal axis. Among asymptomatic HIV-infected women on no therapy, hyperresponsiveness of luteinizing hormone to gonadotropin-releasing hormone has been reported—a finding compatible with the thesis that the hypothalmic–pituitary axis may be altered early in HIV disease. Irregularities also may be attributable to opportunistic infections (e.g., cytomegalovirus or toxoplasmosis involving the pituitary and ovary); autoimmune ovarian failure; and comorbid conditions such as HIV-associated thrombocytopenia, hypermenorrhea associated with some PIs, and chronic endometritis.

Although there are relatively uncommon causes of menstrual abnormalities attributable to HIV, or to comorbid conditions or medications, the basic workup of a woman with menstrual abnormalities should proceed as it would for an HIV-uninfected woman. If hormonal therapy is chosen as the appropriate therapeutic approach, consultation with an HIV-expert should be obtained to account for potential drug–drug interactions.

Conclusion

HIV infection is now a chronic, treatable disease. However, the advances that have brought the epidemic to this stage are built on increasingly complex drug regimens and the coincident requirement for the obstetrician/gynecologist to keep abreast of a changing therapeutic landscape. Physicians also must continue to act as advocates for their patients, taking the necessary steps to assure that they have access to these treatments, and have an understanding of the critical need for life long adherence to treatment regimens. With the partnership of a committed patient and a dedicated clinician, the long-term prognosis for women, the chances for the birth of uninfected children, and the likelihood of prevention of gynecologic complications are better than they have ever been.

Summary Points

- Obstetricians should recommend HIV testing to all pregnant women, ideally using an opt-out approach.
- HIV-infected pregnant women should have regular monitoring of their CD4 count and viral load. They should undergo resistance testing before starting antiviral testing if there is detectable virus.
- Whenever possible, HIV-infected women should receive ZDV (per the PACTG 076 protocol), whether it is given as a component of HAART or, in rare circumstances, as monotherapy.
- Standards of care for HIV infection should be upheld during the prenatal period.
- During the intrapartum period, attempts should be made to minimize the duration of ruptured membranes among women with HIV infection.
- Pregnant women with viral loads >1,000 copies should be offered elective cesarean sections at 38 weeks but should not undergo amniocentesis. Prophylactic antibiotics should be given.
- Efavirenz should be avoided in the first trimester, and NVP should not be initiated as part of a HAART regimen for women with a CD4 count over 250 cells/mm^3.
- Women with unknown HIV status in labor should undergo rapid testing. If found to be positive, they should receive intrapartum therapy.
- Methergine should not be coadministered with PIs or with the NNRTIs efavirenz and delavirdine, because these drugs are potent CYP3A4 enzyme inhibitors.
- PIs may affect blood levels of hormones (and vice versa). Therefore, up-to-date sources on drug–drug interactions should be utilized prior to prescribing hormonal contraception.
- Condom use with emergency contraceptive backup is recommended because studies show that attempts at consistent

dual method use consisting of a condom plus use of a rigorous, client dependent, ongoing method of reversible contraception (e.g., combined hormonal contraceptives or progestin-only hormonal contraception) often results either in inconsistent use of the condom or inconsistent use of the ongoing pregnancy prevention method.

- Infertile HIV-infected couples should undergo the same evaluation as noninfected couples and have access to ART.
- HIV-infected women should have a baseline Pap smear, which should then be repeated at 6 months and then annually if the results are normal. Women with abnormal Pap tests, including ASC-US, ASC-H, or LSIL, should be referred for colposcopy and further evaluation that may include HPV DNA testing, cervical biopsy, cervical curettage, and endometrial biopsy, depending on cell type and the degree of cytological abnormality.

Placenta Previa and Abruption

Helen H. Kay

All bleeding during pregnancy should be investigated by an examination and imaging studies. There are many etiologies for bleeding in pregnancy, but the most clinically significant are placenta previa and placental abruption. These conditions can lead to serious fetal compromise and maternal death. Other causes of bleeding that should be excluded are cervical lesions such as carcinoma or polyps, vaginal lacerations from trauma or carcinoma, other uterine bleeding such as dehiscence of a prior cesarean section scar, and premature cervical dilation, although these usually do not present with large amounts of blood loss. The presence of either placenta previa or placental abruption places the patient in a high-risk situation that warrants close monitoring. A definitive diagnosis is extremely important because in many cases, both commit the patient to a prolonged period of bed rest and hospitalization.

Placenta Previa

Incidence

Placenta previa is encountered in approximately 0.50% to 1.00% of all pregnancies and is fatal in 0.03% of cases. Formerly, the diagnosis of milder degrees of placenta previa without hemorrhage may have gone unnoticed by clinical exam, but now with the widespread use of ultrasound scanning, the incidence appears to be rising. It is more common in multiparous than in nulliparous women, occurring in only 1 in 1,500 nulliparas and in as many as 1 in 20 grand multiparas. The incidence in the United States is declining, probably in part due to the smaller number of grand multiparous women.

Definition

The definition of placenta previa has been complicated because the original descriptions referred to the location of the placenta in relation to a dilated cervix (i.e., in labor) determined by digital exam. By this diagnostic methodology, a complete previa is present when the placenta extends over and beyond the internal os. A partial previa refers to a placenta with its edge partially over the dilated cervix, meaning that if the cervix were visualized with a speculum, placental tissue would be seen over some part of the dilated

cervical area but not all. The last type of previa, the marginal previa, refers to a placenta where the edge lies very close to and up to the edge of the os but does not cover any of the dilated cervix. In those original descriptions, the distance between the placental edge and the internal os was never defined in terms of centimeters (Fig. 21.1). However, with the advent of transvaginal ultrasound imaging, the cervix can be routinely imaged, even when not dilated, and the internal os is seen as a point, not a dilated cervix—hence the confusion over the terminology. In today's practice, any suspected low-lying placenta seen by transabdominal scan should be further evaluated by a transvaginal scan to determine the distance between the edge of the placenta and the internal os (Fig. 21.2). Those cases where the placental edge completely covers the cervical os are labeled as a complete previa. Those with the placental edge at the cervical os should be labeled as partial or marginal (partial/marginal), as it is impossible to determine whether those placentas will remain covered over the dilated cervix during labor or whether they will remain at the edge of the dilated cervix. The cases in which the placental edge is located within 1 to 2 cm of the internal os are the most confusing. Studies that have evaluated the situation where a placental edge

is <1 cm from the cervical os tend to result in cesarean sections because clinically, they are most like those found in placenta previa patients (i.e., with bleeding, and these are delivered by cesarean section). Patients with a placental edge >2 cm from the cervical os are considered to have normal placentas that are not previa. Patients with the placental edge between 1 and 2 cm of the internal os, however, remain in the gray zone. These patients will benefit from either a double setup at the time of labor or close observation in labor and an attempt for a vaginal delivery if there is no bleeding.

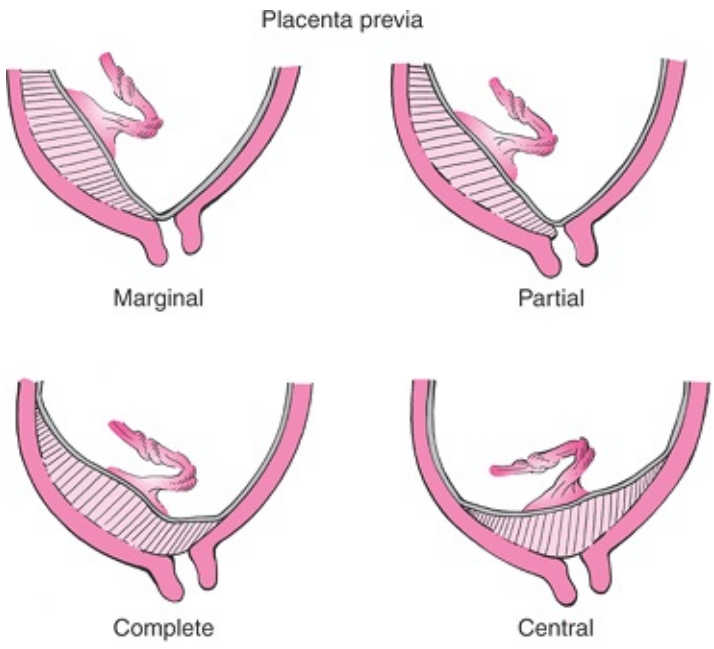

Figure 21.1 Diagrammatic illustration of the three classic types of previa: marginal, partial, and complete. These relate to diagnosis by digital or visual examination when the patient is in labor with a partially dilated cervix. The term *central previa* refers to a previa in which the central portion of the placenta lies directly over the cervical os.

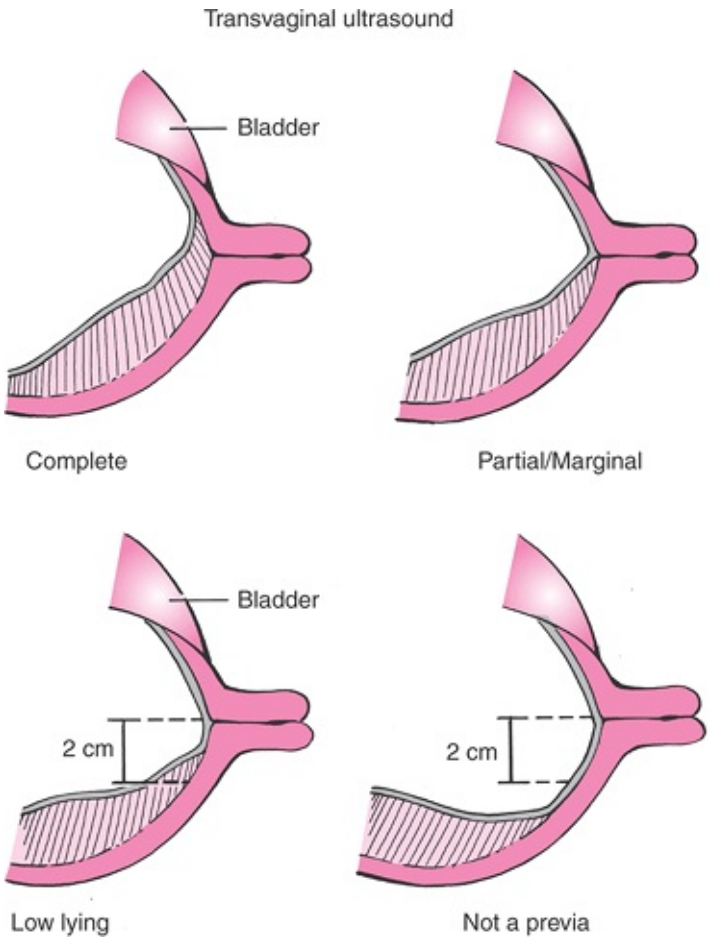

Figure 21.2 Diagrammatic illustration of the classes of placenta previa diagnosed by transvaginal ultrasound. In the nonlaboring patient, the internal os is seen as a point, and the distance between this and the lower edge of the placenta becomes the more critical reference.

Pathophysiology

Placenta previa is a condition of abnormal implantation (i.e., into the lower uterine segment rather than the corpus or fundal region). The exact pathophysiology is unknown, but because it is seen more frequently in patients who tend to be older, multiparous, and have had prior cesarean sections or prior uterine curettage, it is thought to result from scarring in the endometrium. This is theorized to lead to abnormal endometrial tissue, poor vascularization, thinner myometrium, and a less favorable location for implantation. Presumably, the embryo is attracted to healthier tissue, which would be the unaffected endometrium of the lower uterine segment. By this rationale, the anterior uterine segment after cesarean section would appear to be an unfavorable site for implantation, but for uncertain reasons, the uterine trauma from cesarean sections actually increases the risk of previa by as much as sixfold.

Risk Factors

Several risk factors have been found that are associated with placenta previa (Table 21.1). The most significant is a prior cesarean section (approximately 1 in 200 deliveries; the incidence is higher if a woman has undergone two or more cesarean sections). Black or minority patients seem to be at higher risk, as are women over 35 years of age. Other risks include increased gravidity and parity and cigarette smoking, with a 2.6- to 4.4-fold increase. Interestingly, meta-analyses have shown a preponderance of male

gender among the fetuses with placenta previa. The mechanism for this is unknown. Previous abortion has not been consistently shown to be associated with an increase in risk for previa.

TABLE 21.1 Risk Factors Associated with Placenta Previa

- Black and minority
- Advanced maternal age
- High gravidity
- High parity
- Previous abortion—induced and spontaneous
- Prior cesarean section
- Cigarette smoking

Diagnosis

The diagnosis of placenta previa can be made by transabdominal ultrasound. With the advent of the curvilinear probe, the cervical and lower uterine segment is much better imaged, and the relationship of the lower placental edge to the internal cervical os can be routinely visualized. However, the most common diagnostic pitfalls include a distended bladder and a lower uterine segment contraction that can lead to misdiagnosis. Of those placenta previas diagnosed in the second trimester, 90% to 95% resolve by the third trimester due to further development of the lower uterine segment, also referred to as “migration” of the placenta. However, if the placenta covers the internal os by 20 mm or more, meaning that it crosses the os by 20 mm, there is a 100% sensitivity rate for detection of previa at delivery, which requires a cesarean section. Three-dimensional scanning may further increase prenatal detection, but this technology remains a new investigational technique for previa at this time. Therefore, it is imperative that follow-up scanning be performed to determine if there is resolution of what appears to be a placenta previa. Marginal and partial placenta previa are significantly less likely to persist into the third trimester (i.e., <5% chance).

Although initially thought to be contraindicated in patients with suspected placenta previa, transvaginal scanning can be performed safely with the appropriate level of caution. In many cases, the relationship between the placental edge and the internal os can be difficult to assess, and only a close-up view with a transvaginal approach can make a definitive diagnosis (Fig. 21.3). This approach to scanning has been studied carefully and does not appear to lead to increased vaginal bleeding, in part because it is technically impossible to introduce the probe through the cervix. Another alternative approach is with translabial scanning, which has been reported to be 100% sensitive for detection of a previa. However, on occasion, bowel gas can interfere. When a clear diagnosis of placenta previa is made by a transabdominal or translabial scan, there is no need to perform a transvaginal scan. However, when a partial/marginal placenta previa or low-lying placenta is suspected, a transvaginal scan should be performed to confirm the diagnosis and measure the distance between the internal os and lower placental edge. Both types of scanning have greatly reduced the false-positive rate by transabdominal scanning alone, which is reported to be as high as 25%.

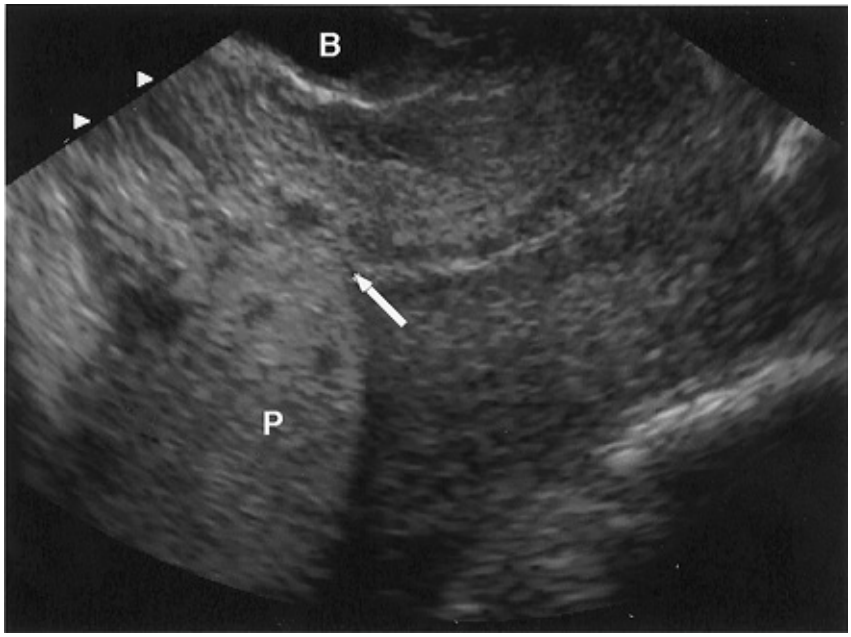

Figure 21.3 A transvaginal ultrasound image of a complete placenta previa. The *arrow* points to the internal os. (*P*, placenta; *B*, bladder.)

It is debatable whether transvaginal scanning has made the double setup examination obsolete, because the relationship between the placenta and cervix can be identified well by experienced scanners. However, likely there still is a place for the double setup exam, particularly in those patients who do not experience bleeding and have a placental edge between 1 to 2 cm from the internal os. The double setup can be used in labor to determine the relationship between the placental edge and the cervix by carefully introducing the examining finger into the cervix with the patient prepped and draped in the operating room so that if the placenta is encountered at the internal os, an immediate cesarean section can be performed, particularly when acute hemorrhage is precipitated by

the exam. If the cervix is dilated, a finger can be passed through the cervical canal to the internal os, and placental tissue can be palpated as gritty, fibrous tissue in contrast to the fetal membranes that are smooth to the touch, particularly when intact and enclosing amniotic fluid. If placental tissue is palpated that covers the os or is located easily within reach,

---

it is considered to be a previa. In this circumstance, the distance relationship (i.e., whether it is 1 or 2 cm from the os) is insignificant since that distance is only predictive when determined by ultrasound imaging. At that point, the patient would be managed by proceeding directly with a cesarean delivery. However, if the cervix is dilated, the membranes are ruptured allowing the fetal vertex to be well applied to the cervix, thus any bleeding may be tamponaded by the fetal head, enabling the patient to continue laboring, with or without pitocin augmentation, to achieve a vaginal delivery.

Clinical Features

Patients with placenta previa typically remain asymptomatic until they have vaginal bleeding. Many are detected during second trimester ultrasound screening, although they remain asymptomatic. It is becoming increasingly rare to have a patient present late in the third trimester with a newly made diagnosis. There are no means to predict which patients will bleed and when they will bleed. Approximately one fourth of patients do not bleed prior to 36 weeks gestation. Usually, the first episode of painless vaginal bleeding occurs without any precipitating event, although intercourse and strenuous physical activity by the patient may be inciting factors. Complete previas are more likely to present with vaginal bleeding earlier than partial or marginal previas. In most cases, the thinning lower uterine segment tears into the intervillous space of the placenta. This bleeding can bring about uterine irritability and, occasionally, preterm contractions. The amount of blood lost in this first bleeding episode tends to be variable, from slight to heavy, although usually it is unlikely to be heavy enough to prompt delivery. However, the amount of subsequent bleeds tends to be increasingly heavier as the cervix and lower uterine segment change as the pregnancy progresses. Blood seen on a patient's shoes is the classic indication of heavy vaginal bleeding.

Most patients stop bleeding with bed rest, particularly those in the second trimester. Many are placed on bed rest either at home or in the hospital until resolution of the bleeding. The episode of bright red bleeding usually ends as a brownish discharge. However, the amount of bleeding increases in the third trimester, and delivery often is prompted by one massive bleed following multiple earlier lighter bleeding episodes. The blood typically is of maternal origin, and therefore the fetus usually is not in jeopardy. In cases with massive bleeding, however, the fetal heart rate tracing may show signs of distress, usually with repetitive late decelerations.

Patients with placenta previa are at increased risk for placental abruption, cesarean delivery, fetal malpresentation, and postpartum hemorrhage. Although fetal growth restriction formerly was thought to be an outcome of placenta previa, more recent studies do support an association when comparisons are made with a well-matched control group

adjusted for gestational age at delivery. Although it is impossible to predict which patients will bleed and when, one report suggests that patients with elevated maternal serum alpha-fetoprotein (MSAFP) levels >2.0 multiples of the median (MoM) have a 50% chance of requiring hospitalization for bleeding before 30 weeks gestation, a preterm delivery before 34 weeks, and to be delivered for pregnancy-associated hypertension before 34 weeks. MSAFP elevations did not predict those with placenta accreta or emergent cesarean hysterectomy. Careful note of the MSAFP levels in the second trimester may help in targeting those patients who need to be cautioned more specifically about adverse outcomes in the presence of a placenta previa.

Management

Patients diagnosed in the second trimester should be cautioned about the possibility of experiencing bleeding. Intercourse should be avoided unless a follow-up scan reveals further migration of the placenta. Otherwise, patients may be allowed their usual activities but should avoid strenuous physical exertion. Approximately every 4 weeks, a repeat scan should be performed to determine the persistence or resolution of the previa. If further scans reveal resolution, no further evaluation is necessary. However, if follow-up scans show persistent placenta previa into the third trimester, the patient should be counseled further regarding her chances of bleeding and the need for a cesarean section. Decreased physical activity would be advisable and travel away from home discouraged.

Every patient who bleeds needs to be evaluated and the fetal status documented. Depending on the amount of bleeding, intravenous fluids should be started and blood should be cross matched or, at a minimum, typed and screened. Subsequently, continuous availability of cross-matched blood does not appear to be necessary, as few antepartum patients require emergent transfusion. Rh status should be checked, and RhoGam should be administered if patients are Rh-negative and unsensitized. A baseline blood count with hemoglobin and hematocrit should be determined to assess the degree of bleeding. These blood counts should be interpreted carefully in the context of the normal reserve in pregnancy as well as the hemodilution with intravenous hydration. Because pregnant women have a significant reserve, their vital signs and laboratory values may not directly reflect their vascular compromise until they have had a large amount of bleeding. Their status may be deceptively stable until they approach serious cardiovascular decompensation. If signs of hypovolemia are present, such as hypotension and tachycardia, the patient more than likely has had severe hemorrhage—significantly more than was clinically observed. Since it is rare to develop a coagulopathy with a bleed from a previa, a coagulation profile is not necessary at the onset. A Kleihauer-Betke test for fetal red blood cells in maternal blood also

---

is not necessary, as it is rare to find an abnormal test result.

If the fetus clearly is previable, continued monitoring and stabilization of maternal hemodynamics is the appropriate course. Blood can be transfused as needed to maintain the maternal blood count in a normal range (hematocrit >30) until fetal viability is reached. In patients who decline transfusions, erythropoietin may be a good option. In

addition, the use of autologous blood donation in these patients may be a safer option in some parts of the world if the blood supply is not routinely tested for infectious disease. If bleeding ceases, the patient may be a candidate for continued outpatient bed rest. Outpatient expectant management has been analyzed, and the cost–benefit ratio has been favorable, with no outcome difference between those managed as outpatients versus those managed as inpatients. Antenatal steroids for fetal lung maturity should be administered between 24 and 34 weeks gestation.

In the third trimester, the threshold for discharging the patient should significantly be higher. A period of prolonged bed rest and observation is warranted, and it is not unreasonable to consider hospitalization until delivery. If it appears that immediate delivery is not necessary, patients with intact membranes should be given a course of antenatal steroids from 24 to 34 weeks. Continuous fetal monitoring should be carried out until the bleeding is stable, then daily fetal assessment is appropriate. Additional episodes of bleeding, despite full bed rest, are not uncommon. Approximately 70% of patients treated expectantly will have a second episode of bleeding, and 10% will have a third bleed. Unless acute bleeding mandates an immediate preterm delivery, the patient can undergo semielective amniocentesis after 36 weeks and delivery if fetal lung maturity can be documented. Approximately 25% to 30% of patients will achieve 36 weeks gestation. If significant bleeding occurs after 34 weeks, a decision to proceed directly to delivery without amniocentesis is justified.

In the event of severe hemorrhage on admission, the medical team should prepare for immediate delivery if the fetus has reached a viable gestation. The anesthesiologist and neonatologist should be notified immediately. Two large-bore intravenous lines should be established, and blood should be cross matched promptly. A Foley catheter should be inserted to monitor urine output. A coagulation panel also is warranted. Continuous fetal monitoring should be performed while preparing for delivery and any decompensation should hasten the delivery process.

In about 20% of the women with placenta previa associated with bleeding, the uterus contracts and the additional problem of managing preterm labor needs to be confronted. A transvaginal or translabial ultrasound scan can be performed to assess the status of the cervix if bleeding is not too heavy. If fetal lung maturity is not documented or unlikely, efforts to arrest the labor should be attempted in order to begin a course of antenatal steroids. However, the use of tocolytics is considered controversial, and no studies have confirmed their benefit in these women. The choice of tocolytics should be weighed carefully. ß-Mimetics produce maternal tachycardia and hypotension and generally are contraindicated unless the bleeding appears to be stable. Calcium channel blockers can cause hypotension. Indomethacin generally is not recommended after 32 weeks because of possible premature closure of the fetal ductus arteriosus. Magnesium sulfate is a popular choice and is the most widely used.

Delivery should be by cesarean section for all categories of placenta previa when documented by transvaginal scan with an undilated cervix in the third trimester regardless of whether it is a complete, partial, or marginal previa. However, if the diagnosis cannot be established definitively, such as when vaginal scanning is unavailable, or there is a

suspected marginal or partial previa between 1 to 2 cm from the os without any bleeding, a double setup may be considered during or before labor. If no placenta tissue can be palpated, the membranes should be ruptured and the patient may be allowed to labor. Rupturing the membranes and allowing labor to progress could bring the fetal vertex down and tamponade any placental bleeding.

In the majority of cases, a low transverse uterine incision can be achieved, particularly with a posterior placenta and with a well-developed lower uterine segment. A transverse incision can be accomplished in skilled hands even when an anterior placenta is encountered by cutting quickly through the uterus and placenta and delivering the fetus as swiftly as possible before there is significant bleeding and a risk of fetal exsanguination. In a good percentage of cases, the placenta previa causes a fetal malpresentation such as transverse lie. In those cases, the best uterine incision would be a vertical, or classical, one.

Regional anesthesia may be used successfully for patients with placenta previa. It has been reported that the management of blood pressure for hemorrhage is not a problem and may be the preferred choice due to the lowered amounts of intraoperative blood loss compared with general anesthesia. With heavy bleeding preceding delivery, however, many anesthesiologists still opt to use general anesthesia because regional anesthesia in the presence of major hemorrhage may exacerbate hypotension and block the normal sympathetic response to hypovolemia.

Complications

Complications from placenta previa include a longer hospital stay, cesarean delivery, placental abruption, postpartum hemorrhage, fetal malpresentation, and maternal death from uterine bleeding and disseminated intravascular coagulation (DIC).

Placenta Accreta

Significant complications of placenta previa include placenta accreta, increta, and percreta, particularly with a prior history of a cesarean section. Placenta accreta refers to the placenta being directly attached to the myometrium, without intervening decidua, but not invading the muscle; increta is noted when the chorionic villi invade the myometrium; and percreta is present when the chorionic villi penetrate through the entire uterine wall and invade into the bladder or rectum. The presence of placenta previa in a patient with a prior cesarean section is associated with accreta in 10% to 35% of cases. With multiple cesarean sections, the risk may be as high as 60% to 65%.

During antenatal ultrasound scans, the lower uterine segment should be scrutinized for any evidence of a disruption in the demarcation between the placental fibrinoid base known as the Nitabuch layer and the uterine decidua basalis. Color Doppler assessment can be helpful by demonstrating marked or turbulent blood flow within the placenta and extending into the surrounding tissues, which is also described as lacunar flow. Similar, and perhaps better, scrutiny can be offered by magnetic resonance imaging (MRI), which can

demonstrate placental tissue extension through the uterus (Fig. 21.4). MRI diagnosis for placenta percreta may be quite accurate, but the diagnostic accuracy for placenta accreta—a lesser degree of myometrial invasion—is lower. The imaging features include a loss of the decreased signal intensity demarcation between myometrium and decidua basalis. More recent experience, however, suggests a sensitivity of 88% and a specificity of 100% for the diagnosis of placenta accreta, albeit with low numbers of patients. There are some reports of gadolinium-enhanced MRI that can more clearly distinguish a placenta accreta from a percreta. There is not enough data thus far to determine whether MRI is superior to ultrasound for diagnosing placental accreta and percreta.

In the presence of placental accreta, increta, and percreta, the risk of hemorrhage is extremely high. Careful attention should be paid to the lower uterine segment after delivery of the placenta. If bleeding persists despite the usual postpartum uterotonic agents and uterine or hypogastric artery ligation, hysterectomy must be considered. Complications are more likely to arise from delay in making the decision to proceed with hysterectomy. It may be a worthwhile exercise to attempt other methods to control the bleeding before hysterectomy such as oversewing the lower uterine segment, uterine artery ligation, ovarian artery ligation, B-Lynch suture and uterine packing, but all are associated with mixed results. If definitive hysterectomy is not performed, bilateral arterial embolization of the uterine arteries by utilizing currently available interventional radiology technology should be the next option of choice, although more experience is needed to determine the success rate of such a procedure for placenta percreta. Precautions to control hemorrhage in general should include intravenous access, blood products, and anesthesiology assistance. If these conditions are suspected by imaging studies prior to delivery, a planned cesarean section after uterine artery catheters are placed for possible embolization may be useful to avoid a hysterectomy. Plans should be made to deliver in an operating room where there is access to extra assistance and equipment in the event that a hysterectomy must be performed. The interventional radiologists should be notified of the possibility for embolization, and the proper equipment should be made available.

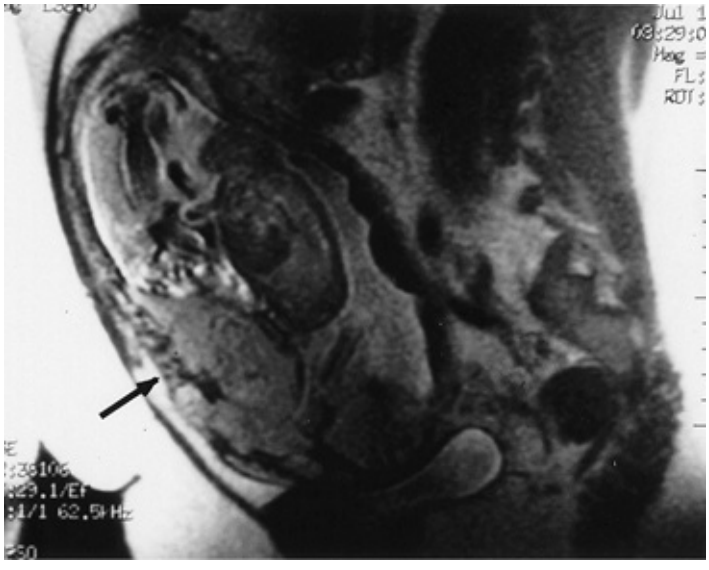

Figure 21.4 A sagittal T2-weighted MRI case of placenta percreta. The percreta is low anterior (*arrow*). (Courtesy Dr. Mark Kliewer.)

Other types of management have included methotrexate for placenta accreta tissue left in situ from bladder wall invasion, subendothelial vasopressin to control bleeding, and balloon occlusion in the hypogastric arteries before hysterectomy. These have been reported with mixed results, likely secondary to the variability of the pathology. Ongoing improvements in the management, once hemorrhage is recognized, will decrease overall morbidity to the patient.

Other complications in the presence of significant hemorrhage from placenta previa could include complications from hypotension such as acute tubular necrosis and Sheehan syndrome of pituitary infarction. Although maternal mortality is <1% and perinatal mortality is <5%, there can be significant morbidity for both. Lesser complications include the risk for hysterectomy, antepartum bleeding, intrapartum and postpartum hemorrhages, blood transfusion, septicemia, and thrombophlebitis. Cases of spontaneous uterine rupture attributable to placenta percreta without prior cesarean delivery also have been reported.

Outcomes

Many reports have suggested a causative effect between placenta previa and low birth weight. The association between placenta previa and fetal growth restriction has been assumed to a large extent. However, more recent studies that have controlled for the gestational age at delivery have found no significant association between previa and growth restriction, and the previously seen association most likely is due to preterm birth. Other neonatal outcomes of significance also include an increased risk of congenital anomaly, respiratory distress syndrome, and anemia. The mechanism for the increase in congenital anomalies is not known, but the increase in respiratory distress syndrome and anemia can be explained by the increased perinatal bleeding. Mortality, intraventricular hemorrhage, and low Apgar scores are not different, reflecting advances in obstetrics and neonatal treatments.

Recurrence risks for placenta previa are 2% to 3%, or six- to eightfold higher than the normal population. Cigarette smoking further increases these recurrence risks.

Prevention

There are no means to prevent placenta previa. However, some studies have suggested that a cervical cerclage placed between 24 and 30 weeks gestation may decrease the chance of bleeding and blood transfusion while prolonging the pregnancy, increasing the birth weight, and decreasing the hospital stay and costs and admission to the neonatal intensive care unit. The mechanism is thought to be due to stabilization of the lower uterine segment. However, this practice is evidence based, and there have been no large randomized trials to evaluate this intervention. Other trials found some benefits in a prolongation of pregnancy by 1 week, fewer readmissions for bleeding, fewer

hospitalization days, and higher birth weights, although none of these was statistically significant.

Vasa Previa

A vasa previa occurs in approximately 1 in 1,000 to 1 in 5,000 pregnancies and refers to a condition associated with a very high fetal mortality in the range of 33% to 100%. It is seen when a fetal vessel crosses and covers the internal os (Fig. 21.5). Patients at risk include those with bilobed placentas, succenturiate-lobed placentas, low-lying placentas, pregnancies resulting from in vitro fertilization, and multiple pregnancies. These conditions all increase the likelihood that fetal vessels in the membrane will rest over the cervical os. Technically, this only is possible in two circumstances. One is in the presence of a velamentous cord insertion, and the other is a placenta with a succenturiate lobe. In both cases, unprotected fetal vessels within the membranes can go undiagnosed, and at the time of artificial rupture of the membranes or with advanced labor, these fetal vessels can be ruptured, leading to fetal exsanguinations.

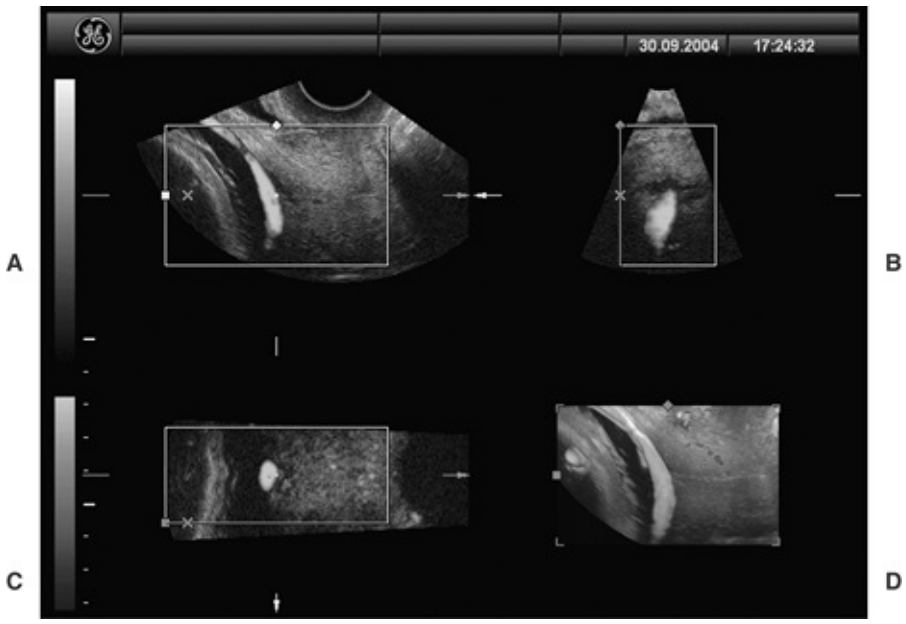

Figure 21.5 Multiplanar transvaginal 3D sonogram of the vasa previa at 34 weeks gestation. **A:** Sagittal view showing a vessel running in a sagittal direction over the internal os. The *arrow* points to the internal os. **B:** Coronal view showing a cross section of the vessel just behind the internal os. The *arrow* points to the internal os. **C:** Transverse view with the reference dot at the internal os showing the vessel crossing the cervix just at the level of the internal os, to which the *arrows* point. **D:** Three-dimensional reconstruction of the vasa previa. (From Canterino JC, Mondestin-Sorrentino M, Muench MV, et al. Vasa previa. *J Ultrasound Med* 2005; 24:721–724, with permission.)

When fetal blood is suspected, it may be confirmed quickly by doing a test for fetal hemoglobin. Because fetal hemoglobin is resistant to alkaline pH, several alkaline

denaturation tests have been developed such as the Apt, Ogita, and Loendersloot. These tests differ only in the time it takes to perform the test, but all take <10 minutes. Therefore, all of them are suitable for an acute situation prior to grossly obvious fetal deterioration. Fetal distress secondary to anemia may be represented by a sinusoidal pattern on the fetal heart monitor and should prompt consideration for immediate operative delivery.

It is prudent to identify the location of the cord insertion into the placenta and to look for the presence of a secondary placental lobe at the time of a routine second-trimester scan to avoid a disastrous outcome. Color Doppler scanning dramatically simplifies making this diagnosis, and when combined with either transvaginal or translabial scanning, it can distinguish a funic presentation (i.e., cord presenting ahead of the vertex) from a vasa previa. Reports also have suggested that three-dimensional ultrasonography and MRI may help in the diagnosis of vasa previa, but further benefit of these techniques needs to be demonstrated. Transvaginal scanning with color Doppler currently is the most effective means available.

Early recognition has been reported to be associated with decreased fetal mortality. It can assist in planning delivery and preventing iatrogenic harm such as that from artificial rupture of the membranes. Elective cesarean delivery decreases the perinatal mortality. In undiagnosed cases, a heightened sense of suspicion and aggressive intrapartum and neonatal management are the only means to achieve successful neonatal outcomes.

Placental Abruption

Placental abruption is a pathologic condition in which some part of the placenta prematurely separates from the uterus. It is one of the leading causes of fetal and neonatal mortality.

Incidence

Many factors may lead to placental abruption, and its incidence seems to be increasing. The current incidence is 0.5% to 1.0%. It is a leading cause of perinatal mortality, accounting for 10% to 15% of all perinatal deaths, although this rate may be decreasing with improved neonatal care.

Definition

The three types of placental abruption include the following:

1. Retroplacental—between the placenta and myometrium; severe is defined as 30% to 40% of the surface area, with a 50% fetal mortality if >60 mL of blood.
2. Marginal, subchorionic—between the placenta and membranes.
3. Preplacental, subamniotic—between the placenta and the amniotic fluid. These are of no clinical significance.

There are several categories of abruptions, and some are more dangerous than others (Fig. 21.6). The most significant abruption is a retroplacental abruption, which can compromise fetal oxygenation and perfusion. These can derive from a marginal abruption, which refers to those located at the edge of the placenta and considered a simple lifting of the placental edge away from the uterus. These can be serious when the abruption extends from the margin to the rest of the placenta. A concealed abruption is a retroplacental abruption in which there is no obvious discernible external bleeding.

Pathophysiology

The pathophysiology of an abruption depends on the etiology. An abruption is the clinically recognized end result when villi separate from the underlying decidua basalis. In blunt trauma, the cause is clearly a forceful shearing effect. In the majority of other cases, bleeding results from cell death (apoptosis) induced through ischemia and hypoxia. In patients with a thrombophilia, the higher tendency to clotting leads to a thrombotic event in the decidua basalis resulting in ischemia and hypoxia. In patients with chorioamnionitis, lipopolysaccharides and other endotoxins generated from the infectious agents induce the accumulation of cytokines, eicosanoids, and reactive oxygen species such as superoxide. All have cytotoxic potential that promotes ischemia and hypoxia. One of the cytotoxic actions of endotoxin is the induction of nitric oxide synthase (NOS) activity that produces nitric oxide (NO), a potent vasodilator and inhibitor of platelet aggregation. As NO is metabolized, peroxynitrite is generated, which is a longer-lasting oxidant capable of causing ischemia and

hypoxia through actions on vascular endothelial cells. As the beneficial effects of NO are outweighed by the overwhelming inflammation, ischemia and hypoxia result and thus lead to cell death and bleeding. The specific mechanisms involved in this final step are under active investigation.

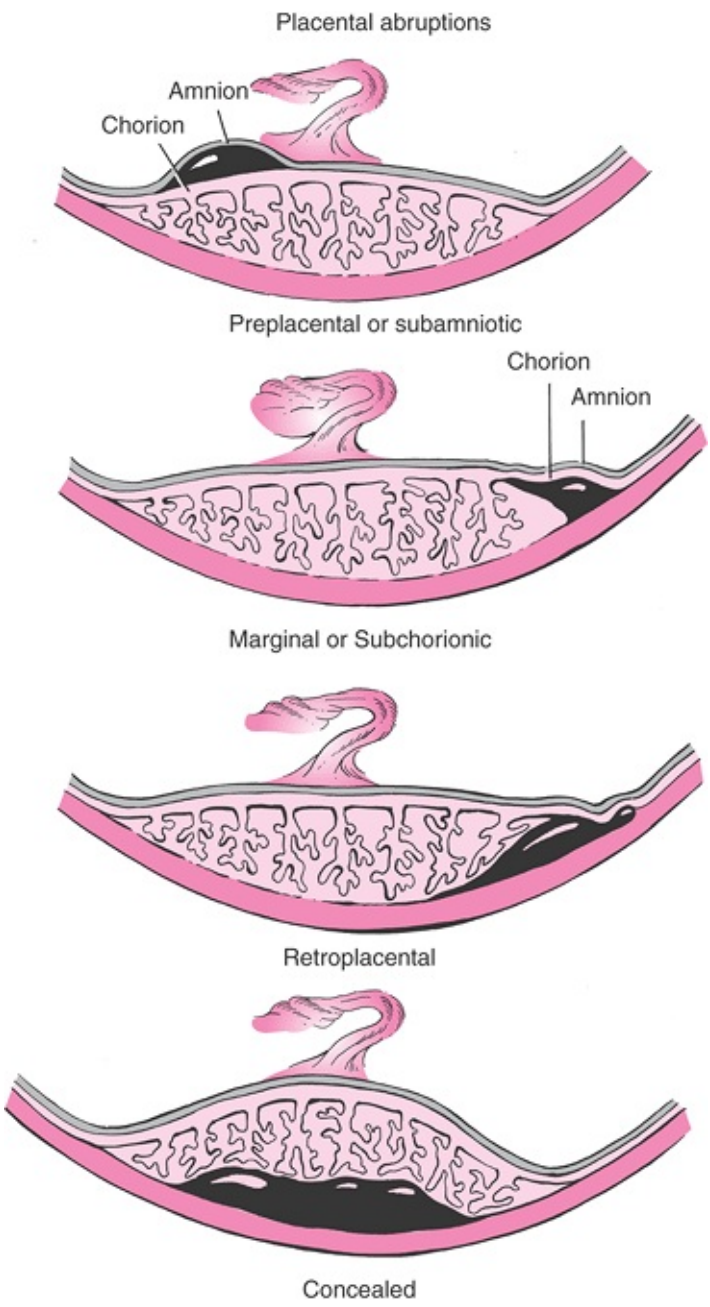

Figure 21.6 Diagrammatic representation of various degrees of placental abruption: preplacental or subamniotic (between the amnion and chorion), marginal or subchorionic (between the placenta and membranes), and retroplacental (between the placenta and myometrium).

Risk Factors

The many risk factors associated with placental abruptions have been studied extensively (Table 21.2). The first is socioeconomic factors such as young age, primiparity, single parenthood, and low education. Second is a prior abruption, with a recurrence risk ten times higher than in those without a prior history. Third is physical factors such as blunt abdominal trauma from domestic abuse or a motor vehicle accident. Fourth, a higher incidence of abruptions has been noted in patients with a retroplacental myoma, particularly if the myoma volume exceeds 200 cm^3 and is submucosal in location. Fifth is

the largest and most significant group, which includes maternal illnesses such as thrombophilias and hypertensive diseases. Finally, iatrogenic causes such as external cephalic version are noted rarely.

TABLE 21.2 Risk Factors Associated with Placental Abruption

Uterine
Myomas
Uterine septum
Uterine malformations
Demographic/Socioeconomic
High parity
Single parent
Low education
Infertility
Medical
Unexplained elevated MSAFP and hCG
Decreased inhibin A
Antiphospholipid syndrome
Pregestational diabetes
Hypertension—chronic and gestational
Preterm rupture of membranes with chorioamnionitis
Thrombophilias
Prothrombin 20210A mutation
Hyperhomocysteinemia
Factor V Leiden mutation
APCR
Protein C and S deficiency
MTHFR mutation
Dysfibrinogenemia
Iatrogenic
Sudden decompression of uterus (amniocentesis)
External cephalic version for breech
Cigarette smoking
Cocaine abuse
Blunt trauma
Incorrectly applied seat belt
Intrauterine pressure catheter placement
Heavy physical activity

MSAFP, maternal serum alpha-fetoprotein; hCG, human

chorionic gonadotropin; MTHFR, methylenetetrahydrofolate reductase; APCR, activated protein C resistance.

Maternal disease such as hypertension has been associated with an increased risk of abruption. In a large epidemiologic study of hypertensive women in Nova Scotia, only women with chronic hypertension with superimposed severe preeclampsia were at increased risk for abruption compared with women who had chronic hypertension alone, a relative risk of 3.8 for parous women and 1.6 for nulliparous women. Not surprisingly, the effects of smoking and hypertension appeared to be additive, if not higher.

Maternal illness due to chorioamnionitis secondary to premature rupture of the membranes has been strongly correlated with the incidence of abruptions based on epidemiologic reports as well as microbiologic and histopathologic studies of the placentas. Pathologic evidence to support this includes observations that lipopolysaccharides and bacterial endotoxins are elevated in the amniotic fluid of patients with chorioamnionitis. These agents, in turn, induce the formation of superoxide or free oxygen radicals, evidenced by an increase in the nitrites and nitrates in maternal serum. These are metabolites of NO, an antioxidant that appears to be increased under these infectious conditions. Immunohistochemical studies have demonstrated increased expression of NOS and nitrotyrosine, which are markers for NO metabolism, in placentas from patients with chorioamnionitis and abruptions. Additionally, evidence for apoptotic cell death has been identified in placentas from both conditions. This evidence supports a strong link between chorioamnionitis and placental abruption.

Over the past decade, new risk factors have been identified in association with placental abruptions. These factors are encompassed under the umbrella of thrombophilia defects and include anticardiolipin antibodies, the lupus anticoagulant, protein C and S deficiencies, antithrombin III deficiency, and the genetic causes such as the factor V Leiden mutation (also known as activated protein C resistance [APCR]), the methylenetetrahydrofolate reductase (MTHFR) mutation, and the prothrombin 20210A gene mutation as well as the more rare congenital dysfibrinogenemia.

The autoimmune antibodies, anticardiolipin antibodies, and lupus anticoagulant have been shown for many years to be associated with adverse pregnancy outcomes, including placental abruption. Because these are nonspecific antibodies, it is difficult to understand their pathophysiologic role in bleeding. Protein C and protein S deficiency are genetic disorders resulting in an increased risk for thrombosis. They have been implicated in preeclampsia and abruption. However, their levels may normally be decreased during pregnancy, making it difficult to fully understand their role in the pathophysiology of abruption.

More recently, research has focused on specific gene defects that predispose patients to coagulopathy.

APCR is the most common genetic factor predisposing to thrombosis, and it appears to be the most common identifiable cause. This resistance most often is caused by the factor V

Leiden mutation and in many cases is used synonymously, although patients can have APCR without the Leiden mutation. In this mutation, there is a nucleotide substitution of adenine for guanine, which results in an amino acid substitution of arginine for glutamine. Patients who are heterozygous for this mutation have fewer manifestations of clinical disease than those who are homozygous. Because patients with this mutation have an increased tendency to form clots, they also have a higher risk for abruption due to clotting in the placenta, primarily thought to be in the decidua basalis either early in pregnancy resulting in spontaneous abortions or in the latter half of pregnancy resulting in abruption. Furthermore, women with a hypofibrinolytic 4G/4G mutation of the plasminogen activator inhibitor 1 (PAI-1) gene, which is frequently associated with the thrombophilic factor V Leiden mutation, also have a predisposition to thrombosis. A study of women with adverse obstetric complications found that women with placental abruption more often were associated with homozygous and heterozygous factor V Leiden mutation, heterozygous G20210A prothrombin gene mutation, homocysteinemia, APCR, or anticardiolipin immunoglobulin G (IgG) antibodies. However, other studies have found a weaker link, and it is cautioned that these tests should not become standard and routine until larger studies further substantiate their relationship to placental abruption and other pregnancy complications. A concomitant search for therapeutic measures would further justify this type of testing of a beneficial treatment, if one can be found.

One etiologic factor that has been widely studied in association with placental abruption is the condition known as hyperhomocysteinemia. Homocysteine is metabolized from methionine and then re-methylated by an enzyme known as methylenetetrahydrofolate reductase (MTHFR) to methionine, with folate and vitamin B_{12} as cofactors. Mutations in the MTHFR gene, the two known as C677T and A1298C, prevent this normal remethylation, which leads to increased levels of homocysteine. These elevated levels of homocysteine can damage vascular endothelium, leading to thrombosis formation when they occur in veins or to placental abruption when they cause damage in the spiral arteries that supply flow to the placenta. Increased levels of homocysteine have been identified in the fasting state in patients with placental abruption and infarction. Hyperhomocysteinemia was found in 24% of Danish women with a history of placental abruption, intrauterine fetal demise, and fetal growth restriction. Increasing folate and pyridoxine intake successfully reduced the levels of homocysteine. Pathologic evaluation of the placentas from patients with hyperhomocysteinemia have identified an increase in pathologic features, including acute atherosis, infarction, retroplacental hematomas, accelerated villous maturity, and vascular thrombosis. These abnormalities further support the fact that hyperhomocysteinemia is an etiologic factor in placental abruption. Future randomized trials with folate, vitamin B_6, and vitamin B_{12} supplementation will be informative. For the present time, patients with placental abruptions with no obvious etiology should be considered for hyperhomocysteinemia screening.

A final category of risks includes iatrogenic causes. Iatrogenic agents such as nicotine from cigarette smoking and cocaine can both cause vasoconstriction that leads to ischemia and abruption. This alteration in uteroplacental blood flow most likely causes placental lesions (i.e., infarction, oxidative stress, apoptosis, and necrosis) that can bring about disruptions in the placental–uterine interface leading to the abruption. Cigarette smoking has been

associated with an adjusted odds ratio for abruption ranging from 1.7 in all patients to 3.5 for blacks, or an approximate twofold relative risk. It also has been reported that smoking a pack of cigarettes per day increases the risk by approximately 40%. In another analysis, approximately 15% to 25% of abruptions can be attributed to smoking. The pathophysiology is thought to be smoking-induced vasospasm. Similarly, cocaine use, which also causes acute vasospasm, has been associated with abruption.

Other etiologic factors that are less well studied or less frequent include the iatrogenic risks from cesarean section, extramembranous placement of intrauterine pressure catheters, external version, amniocentesis, incorrect placement of a seat belt, and possibly maternal physical activity. No large case-control study has been performed to settle these associations satisfactorily.

Circumvallate Placenta

One final risk for placental abruption is the abnormal placentation known as a circumvallate placenta. It is an abnormality in placental development that leads to a thickened placenta with an overall decreased surface area over the uterine wall. In this condition, the membranes of the chorion laeve do not insert at the edge of the placenta but at some distance closer toward the center. This leaves a rim of fibrin and blood in various stages of clotting at the membrane and placental junction. The unprotected villi beyond the rim tend to bleed. In addition to hemorrhage, this abnormal placentation can lead to placental abruption, fetal growth restriction, preterm labor, and preterm rupture of the membranes. Typically, a second-trimester ultrasound can identify such a placenta by its unusual shape with a raised placental margin that does not lay flat against the uterine wall. However, clinically observed bleeding usually is not seen until the end of the second trimester or the beginning of the third. Therefore, when suspicions are raised, the patient will need to be warned of the potential for bleeding and other complications and will need to be followed closely.

In summary, many risk factors have now been identified in association with placental abruption. Many are preventable, thus justifying programs that can assess an individual's risk in order to attempt modification of behaviors preconceptually or during pregnancy.

Diagnosis

The diagnosis of a suspected abruption usually is made clinically. The symptoms include vaginal bleeding, uterine pain, a tetanic contraction of the uterus, and fetal heart rate abnormalities including a sinusoidal pattern in severe abruption. Bleeding occurs in approximately 80% of cases, but the remaining symptoms may be present in <20% of cases. A definitive diagnosis can only be made retrospectively after delivery and inspection of the placenta because even ultrasound diagnosis is at best 50% sensitive, and hemorrhage can be difficult to visualize. MRI can detect blood through detection of methemoglobin, but it is not a practical modality for an acute problem such as abruption.

Diagnostic ultrasound usually is performed transabdominally but may be supplemented with

transvaginal scanning if the bleeding placental edge is low (Fig. 21.7). Careful examination of the retroplacental area is required. False-positive identification of the normal retroplacental complex—the normal vascular complex of uterine vessels, decidua, and myometrium—as an abruption has been reported. This complex appears hypoechoic on ultrasound. Acute bleeding may take on a variety of appearances from hypoechoic to isoechoic to hyperechoic, and diagnosis of an abruption may be confused by this complex. The hyperechoic retroplacental complex, which is usually no more than 2 cm in thickness, demonstrates very high amounts of blood flow by color Doppler imaging, excluding its likelihood of being a clot that should demonstrate no active flow. Other hypoechoic areas such as a myoma or a uterine contraction can be mistaken for an abruption; but again, color Doppler can assist in the distinction because contractions demonstrate a large amount of blood flow within them, and myomas demonstrate blood flow around most of their periphery and less within them. A repeat scan of a fresh bleed often is helpful, as the ultrasound appearance of a clot will change with time, becoming more echogenic at 48 hours and then hypoechogenic within 1 to 2 weeks. Aside from this retroplacental complex, an abruption often is difficult to distinguish from the placenta itself. Acute hemorrhage tends to be difficult to distinguish from the placenta, but with time the clot becomes hypoechoic compared with the placenta.

Figure 21.7 Transvaginal ultrasound image of a retroplacental abruption. The markers indicate the size of the clot, 3.5 × 1.0 cm.

Pulsed-wave Doppler is not a useful tool for abruption diagnosis, because the results have been inconsistent. Some studies evaluating the use of umbilical artery Doppler velocimetry have shown no abnormalities despite the presence of large retroplacental clots, while others have shown elevated resistive indices and waveforms in both the umbilical and uterine arteries in patients with third-trimester hemorrhage. These inconsistent findings probably reflect the heterogeneity of patients who presented with an abruption in the published studies. It also reflects the fact that none of the studies to date has had

sufficiently high numbers of patients with isolated abruptions. The majority of these studies have evaluated these markers in a heterogeneous group of patients with a wide number of pregnancy complications in addition to abruptions. Uterine artery Doppler studies between 22 and 24 weeks gestation are better for predicting subsequent preeclampsia and fetal growth restriction. Therefore, undertaking the use of either of these tests to predict subsequent abruption would not be a valued undertaking at this time. However, use of these tests to detect patients at higher risk for pregnancy outcome complications would be a meaningful exercise.

Other means to diagnose or detect placental abruptions include serum biochemical tests. Two markers that have been studied are MSAFP and maternal serum beta-subunit human chorionic gonadotropin (ß-hCG). Presumably, these proteins leak across the placenta when there is an abnormality in its physiologic and anatomic integrity. These markers are elevated in low-risk women with fetal or neonatal death, pregnancy-induced hypertension, placenta previa, preterm delivery, growth restriction, and perinatal complications but who did not have an a priori risk for a neural tube defect or a chromosomal abnormality. The risk of an unexplained elevated MSAFP has been associated with as high as a 10-fold increase of placental abruptions. Among women with third-trimester preterm labor, elevated levels of MSAFP at a MoM of 2.0 was observed when an abruption was present, with a sensitivity of 67% without bleeding and 100% with bleeding. The negative predictive value can be as high as 94% and 100%, respectively.

The latest serum marker to be studied in this context is inhibin A, a placental protein that currently is part of a

---

quadruple–serum-marker screen for the detection of Down syndrome, in which it tends to be increased. Although preliminary, some studies suggest that inhibin A is decreased in patients with systemic lupus erythematosus who also had placental abruptions.

One other marker worth discussion is a test for fetal hemoglobin in maternal blood such as the Kleihauer-Betke test, which is a stain for fetal hemoglobin. This test is ordered routinely for Rh-negative patients with a positive blood-screening test to determine how much RhoGam to administer to protect against sensitization. Studies, however, have shown that it is not a useful test to detect suspected placental abruption. This may be explained by the fact that most abruptions consist of maternal blood and originate in the retroplacental space, where there is no overlap of the fetal and maternal blood compartments as would be encountered with an intraplacental bleed where the fetal blood within villous vessels is in close proximity to maternal blood within the intervillous spaces.

Clinical Features

A patient with an abruption usually presents with either painless or painful vaginal bleeding. Approximately 20% will have no external bleeding. Typical symptoms include uterine tenderness and irritability. Uterine tone may be increased and may be difficult to distinguish from uterine contractions. Because of the amount of retroplacental clotting, women with abruptions can quickly develop a quite significant consumptive coagulopathy that requires immediate attention.

Management

The majority of abruptions are marginal, and patients tend to be quite stable. Large retroplacental abruptions usually are quite symptomatic and more easily diagnosed. They also require aggressive management to prevent disastrous adverse consequences. The probability of a marginal abruption extending to a large retroplacental hematoma is unknown. The decision to hospitalize a patient with any bleeding or with a diagnosed abruption in the latter half of the second trimester or in the third trimester after fetal viability is established should be an easy one. On admission, the patient should have blood drawn for a complete blood count and a type and cross or type and screen, depending on the amount of bleeding. With large bleeds, 4 U of packed red blood cells should be made available. A coagulation panel consisting of a prothrombin time (PT), partial thromboplastin time (PTT), fibrin degradation product, and fibrinogen level should be drawn if there is a large amount of bleeding. When the fibrinogen level is <150 mg/dL, blood in a red top tube may not clot within 6 minutes or forms and lyses within 30 minutes. With minimal bleeding, fetal monitoring and observation is appropriate. If the fetus is significantly previable, intermittent transfusions may be necessary to maintain the hematocrit above 30.

When there is a large amount of bleeding, fetal well-being should be documented by continuous fetal monitoring, a Foley catheter should be inserted to monitor urine output, frequent maternal vital signs should be performed, and a neonatologist and anesthesiologist should be notified of a potential emergent cesarean delivery. An ultrasound should be obtained to ascertain the amount and location of bleeding. Antenatal steroid treatment should be considered if membranes are intact and the fetus is between 24 and 34 weeks gestation. For any pregnant patient with bleeding, consideration for treatment with 1 mg folic acid and vitamins B_{12} and B_6 should be undertaken for the possible link between abruptions and hyperhomocysteinemia.

If the bleeding is minimal, the patient likely will resolve her symptoms and should be able to be discharged after an interval of time without any further bleeding, usually 2 to 5 days. However, the decision on when to discharge patients who have had a large bleed is more difficult, and there are no strict guidelines. Clearly, no decision on discharge should even be considered if the patient is symptomatic with either pain or contractions. Much of the decision also will rest on the patient's home support and whether she will be able to comply with bed rest. If the patient is noncompliant or if the home environment will not allow her to undertake bed rest, then it may be reasonable to keep the patient in the hospital until delivery. Whether the patient is an inpatient or an outpatient, some fetal monitoring program should be established.

Tocolytic use is debatable in a patient with uterine contractions and a known or suspected abruption. Although it formerly was taught that no tocolytics should be used in patients with undiagnosed bleeding, it has become acceptable to consider a short course of tocolytic therapy for patients with bleeding and contractions provided that the patient is stable, the abruption appears to be limited, fetal well-being is established, gestational age is preterm, and there is a controlled environment. The use of tocolytics also can be

justified if they can prevent labor until a full course of antenatal steroids can be administered and 48 hours posttreatment can be achieved. Because ß-mimetics can mask or blunt the patient's cardiovascular responses to volume depletion, terbutaline and ritodrine should be avoided. Calcium channel blockers may further reduce the blood pressure, so nifedipine should be used with caution. The most accepted agent at the present time is magnesium sulfate. As with patients with preterm labor, these agents should be used in the acute setting, and efforts should be made to discontinue them when there is a persistent period of quiescence.

Delivery can be either vaginal or cesarean section, depending on the degree of bleeding, the presence or absence of active labor, and the presence or absence of fetal distress. Operative deliveries have been used liberally, in excess of 50% of cases.

When abruption leads to fetal demise, there is a very high rate of DIC. The best marker of severity is the

---

fibrinogen level. Blood products should be administered as needed to correct the coagulopathy, and then plans for delivery should be made. Induction of labor and successful vaginal delivery has been reported. Cesarean section may seriously jeopardize the mother's health in the face of a significant coagulopathy and should be reserved for those cases where there is fetal distress or when it appears that labor and delivery will not be successfully achieved within a reasonable amount of time, between 12 to 18 hours.

Complications

One complication of placental abruption is uteroplacental apoplexy, also known as a Couvelaire uterus. It occurs rarely but is seen with severe placental abruption in which blood extravasates from the clot into the myometrium. The appearance is that of a blue-tinted, large, boggy uterus. This is an obvious visual diagnosis, but biopsies have confirmed the presence of heme throughout the myometrium. This leads to a hypotonic uterus, and on occasion a hysterectomy is needed in order to control the bleeding. In this setting, uterine artery embolization is likely not to be effective, although it has not been reported in the literature.

Another complication is DIC marked by a fibrinogen level <300 mg/dL and a prolonged PT and PTT. If this occurs, large-bore intravenous lines should be placed and crystalloid and blood products should be given as quickly as possible in the form of packed red cells, fresh frozen plasma, cryoprecipitate, and platelets. A Foley catheter should be placed to monitor urine output, and a central venous pressure catheter should be considered if urine output drops below 30 mL per minute.

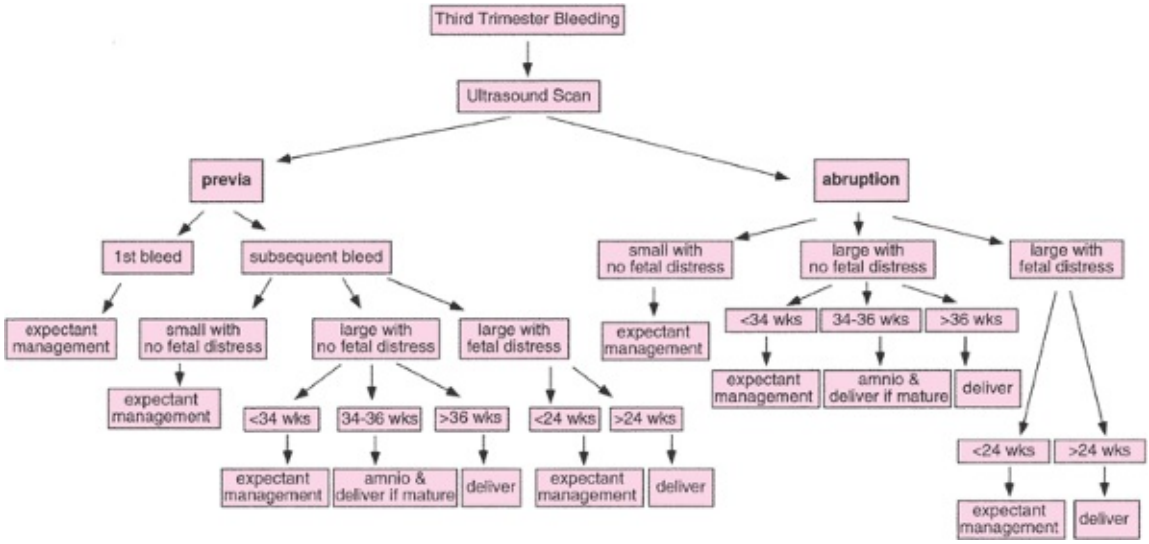

Figure 21.8 Flow diagram summarizing recommended clinical management for bleeding in the third trimester. Individualization is warranted, and the entire clinical picture must be factored into the management plan.

Outcomes

Several adverse outcomes have been seen in association with placental abruptions. In a large epidemiologic study of placental abruption in the United States from 1995 to 1996 that incorporated over 7 millions births, the perinatal mortality rate was reported to be 119 per 1,000 births with abruption compared with 8.2 per 1,000 in all other births. Although there was significant mortality attributed to prematurity and growth restriction, the high perinatal death rate persisted. Term babies of normal size had a 25-fold higher mortality with an abruption than those without abruption. The pathophysiology of this outcome remains to be determined. In another similar epidemiologic study, abruption also was found to be associated with a very high risk of stillbirth (8.9-fold), preterm birth (39.6%), and growth restriction (14.3%). The relative risk for stillbirth has been reported to be 31.5% for a 75% abruption and 5.5% for a 25% abruption.

Patients with an abruption should be counseled that there is an increased risk of recurrence with an adjusted odds ratio of 6.4 and possibly as high as 25%. Efforts should be made to identify any associated risk factors and to modify them. Fetal surveillance in subsequent pregnancies should be monitored starting at least 2 weeks before the gestational age at which the previous abruption was diagnosed in order to reduce the recurrence risk. Surveillance consists of serial ultrasound scans for fetal growth restriction and placental bleeds in combination with fetal biophysical profiles, depending on when the gestational age surveillance is initiated.

Other outcome measures such as intraventricular hemorrhage, cystic periventricular leukomalacia, and cerebral palsy have been evaluated. All were seen in higher frequency among infants delivered because of an abruption. However, many of these infants also were growth-restricted, making it difficult to discern whether these adverse outcomes

were attributed to the early gestational age, the abruption, or the growth restriction. Many of these studies also were plagued by the small numbers of infants studied.

Prevention

There is no established protocol for the prevention of primary or recurrent abruption. Based on the risk factors that have been identified, an effort should be made to educate patients on the signs and symptoms of an abruption, avoiding and reporting domestic abuse, the proper use of seat belts, and the adverse health effects of cigarette smoking and illicit drug use. A nutritional educational program can focus on how to increase the patient's folic acid and iron intake. A social service contact can be established for those at risk because of a poor home situation, for those engaged in hard physical activity, and to assist if any illicit drug use is noted. Ultrasound scanning should be used to scrutinize the integrity of the uterine wall in patients with a prior cesarean section and to identify other uterine or placental abnormalities, such as the presence of a myoma or septum and the placental location in relation to it. Finally, patients with medical illnesses such as hypertension should have them treated and be seen frequently to optimize the maternal and neonatal outcome.

Summary Points

- The workup of a patient who presents with third-trimester bleeding should be methodical and thorough in order to optimize the neonatal outcome. The two major etiologies, placenta previa and placental abruption, are better diagnosed by state-of-the art imaging. Best outcomes can be obtained by following a systematic approach. The risk factors for each should be identified in order to prevent similar future events.
- There are two ways to classify a placenta previa: (a) by visual inspection or digital exam—marginal, partial, or complete; and (b) by transvaginal ultrasound—<1 cm, between 1 and 2 cm, or >2 cm from the undilated internal cervical os.
- New imaging modalities including color Doppler ultrasound and MRI can improve on making the diagnosis of placenta previa, accreta, and abruption. These modalities have minimized the need for a double setup exam in the case of a previa.
- Arterial embolization is becoming a standard means to decrease the need for a hysterectomy due to postdelivery bleeding from a previa.
- There are many risk factors for placental abruptions, and the clinician should know them. When possible, the risks (i.e., cigarette smoking) should be modified to decrease the chance for abruption.
- Both placenta previa and placental abruption can lead to serious bleeding. However, placental abruption is more likely to lead to significant maternal coagulopathy.

- Expectant management is an acceptable plan for placenta previa and abruptions when the gestational age is preterm, there is no fetal distress, and the patient is stable.
- Amniocentesis should be used routinely in patients with placenta previa and abruption to document fetal lung maturity, and delivery should be planned as soon as possible in these potentially unstable situations.

Breech, Other Malpresentations, and Umbilical Cord Complications

Timothy E. Klatt
Dwight P. Cruikshank

Breech Presentation

Breech presentation, the most common obstetric malpresentation, complicates approximately 4% of deliveries.

Definitions

Breech presentation is a polar alignment of the fetus in which the fetal buttocks present at the maternal pelvic inlet. Three types are recognized: frank, incomplete, and complete. In frank breech presentation, the fetal hips are flexed and the knees extended so that the thighs are apposed to the abdomen and the lower legs to the chest (Fig. 22.1). The buttocks are the most dependent part of the fetus. Frank breech presentation accounts for 60% to 65% of breech presentations; it is more common at term. In incomplete breech presentation, the fetus has one or both hips incompletely flexed so that some part of the fetal lower extremity, rather than the buttocks, is the most dependent part (hence the terms *single footling* or *double footling*). This presentation accounts for 25% to 35% of breech presentations and is more common among premature fetuses. Complete breech presentation is the least common type, accounting for about 5% of breech presentations. In this situation, the fetal hips and knees are both flexed so that the thighs are apposed to the abdomen and the legs lie on the thighs. A significant proportion of these fetuses convert to incomplete breech presentations if allowed to labor. The position of the breech fetus is described with the fetal sacrum as the reference point; thus, it is right sacrum anterior, left sacrum posterior, left sacrum transverse, and so forth.

A spontaneous breech delivery is one in which the entire infant delivers vaginally without manual aid. In the unusual circumstance of a vaginal delivery of a singleton breech, the recommended form is the assisted breech delivery, also known as partial breech extraction. In this delivery, the fetus is allowed to deliver by the forces of uterine contractions and maternal bearing-down efforts until the fetal umbilicus has passed over the mother's perineum. After this, delivery of the legs, trunk, and arms are assisted

manually; the head may be delivered manually or with forceps. A complete breech extraction, in which manual assistance is applied by traction in the groins or on the lower extremities before delivery of the buttocks, is contraindicated in singleton breech presentations.

Incidence

The incidence of breech presentation is closely associated with birth weight. Breech presentation accounts for 4% of births overall but occurs in 15% of deliveries of low-birth-weight (<2,500 g) infants. Furthermore, the smaller the

infant, the higher the incidence of breech presentation, rising to 30% among infants weighing 1,000 to 1,499 g and to 40% among those weighing <1,000 g. Viewed from another perspective, the association between breech presentation and low birth weight is even more striking. Only 70% of infants who present as breeches weigh >2,500 g; 30% weigh <2,500 g (compared with 5% to 6% of infants who are in vertex presentation), and 12% are of very low birth weight, weighing <1,500 g.

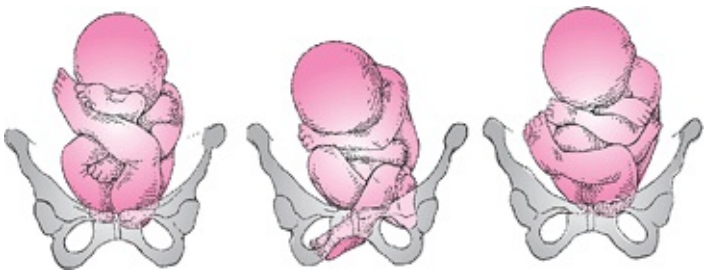

Figure 22.1 Fetal attitude in frank, incomplete, and complete breech presentations.

Cause

Factors that predispose to breech presentation are listed in Table 22.1. The importance of fetal anomalies cannot be overemphasized (Table 22.2). Malformations of the central nervous system complicate 1.5% to 2.0% of breech births: the incidence of hydrocephalus is tenfold greater, and that of anencephaly twofold to fivefold greater, than it is among infants presenting as vertex. Up to 1% of infants in breech presentation have a significant chromosomal abnormality: 1 in 200 has Down syndrome, and the incidence of other autosomal trisomies is increased as well. Of those infants presenting as breeches, the incidence of major congenital anomalies is 17% among premature infants, 9% among term infants, and 50% among term infants who die in the perinatal period. It is prudent to keep these numbers in mind when deciding on a method of delivery for a fetus in breech presentation and to discuss the risk–benefit ratio with the parents.

TABLE 22.1 Factors Predisposing to Breech Presentation

- Fetal anomalies
  Head anomalies
    Anencephaly
    Hydrocephalus
  Chromosomal anomalies
    Autosomal trisomies
  Multiple anomaly syndromes
- Uterine Anomalies
  Septate
  Bicornuate
  Unicornuate
- Uterine overdistension
  Polyhydramnios
  Multiple gestation
- High parity with lax abdominal and uterine musculature

For many years, an association between cerebral palsy and breech presentation (although not vaginal breech delivery) has been assumed. As it becomes apparent that most fetal insults leading to cerebral palsy occur before term, it appears that cerebral palsy is another cause of breech presentation. In fact, among term infants, the risk of cerebral palsy is not related to presentation after correcting for intrauterine fetal growth restriction. In >50% of cases, no causative factor for breech presentation can be identified.

Diagnosis

On abdominal examination, Leopold's first maneuver will identify the fetal head in the fundus. The third maneuver reveals the softer breech over the pelvic inlet. It is useful to remember that the head narrows down to the neck before attaching to the body, whereas there is no such tapering between the buttocks and body. Auscultation of fetal heart tones usually reveals them to be most easily detected in the upper quadrants of the uterus when the fetus is in breech presentation.

The diagnosis often is made by vaginal examination. In frank or complete breech presentation, the anal orifice may be identified, with the bony prominences of the ischial tuberosities directly lateral to it. Face presentation may be difficult to distinguish from frank breech presentation on

digital examination, with the fetal mouth being mistaken for the anus. It is helpful to remember that the mouth is surrounded by bone, whereas the anus is not. In incomplete

breech presentations, palpation of the feet on vaginal examination is diagnostic. During labor, any presentation that is not clearly vertex by vaginal examination should be confirmed by an intrapartum ultrasound.

TABLE 22.2 Congenital Malformations among Term Infants in Breech Presentation

Type of Malformation	Incidence (%)
Central nervous system	2.0
Hydrocephalus	0.6
Anencephaly	0.4
Trisomy 21	0.5
Cardiovascular	0.5
Gastrointestinal	0.5
Genitourinary	0.1
Overall	9.0
Overall among term infants who die	50.0

Perinatal Mortality

Perinatal mortality is higher in breech presentation than in vertex, being fourfold greater among term infants and twofold to threefold greater among premature infants. Much of this excess mortality is not currently preventable; 64% of deaths among term infants in breech presentation are due to malformations or infection. Among premature infants, malformations, infection, maternal disease, and intrauterine death before labor account for 56% of perinatal mortality, and complications of prematurity unrelated to the method of delivery account for another 11%. Thus, only about one third of perinatal deaths among breech infants are due to potentially preventable factors. These basically fall into two

categories: trauma and asphyxia.

Trauma to the head is a significant risk in both term and premature infants who present as a breech, regardless of the route of delivery. Unlike the situation in vertex presentation, in which the fetal head is in the maternal pelvis for hours or days during which molding can occur, the after-coming head of the breech fetus must come through the pelvis as is—there is no time for molding. Thus, minor variations in maternal pelvic architecture, which would be insignificant in vertex presentation, may become major risks for the after-coming head. This problem is compounded for the infant at <32 weeks gestation, in whom the head is the largest part. In these circumstances, the fetal body may deliver through an incompletely dilated cervix, which then entraps the head. Performance of a cesarean either before or during labor does not ensure an atraumatic delivery of the head. An inadequate uterine incision or suboptimal uterine relaxation may still result in head entrapment, leading to significant injury to the infant.

When extracting a breech presentation, damage to fetal muscles, soft tissue, and viscera may occur with delivery if the fetus is grasped in places other than its bony pelvis. Likewise, delivery may be associated with nerve injury if the arms are not delivered properly, especially if there are nuchal arms. Finally, trauma to the cervical spinal cord may occur with delivery of a breech fetus with hyperextension of the neck.

Asphyxia may be caused by prolapse of the umbilical cord past the body, as the head will compress the cord against the cervix and pelvic soft tissues. The incidence of cord prolapse in term fetuses in frank breech presentation is 0.4%. In complete breech presentation, the incidence is 5% to 6%, and with incomplete breech presentation, the incidence may be as high as 10%. Cord prolapse in incomplete breech presentation, although an indication for prompt cesarean delivery, often is not the devastating event that it is in vertex or frank breech presentation. Because the cord is prolapsed between the fetal legs, it often is not markedly compressed during subsequent uterine contractions. Not all asphyxia among fetuses in breech presentation is caused by overt cord prolapse. Abnormalities of the fetal heart rate pattern during labor are four to eight times more common in fetuses in breech presentation than in fetuses presenting vertex. An unknown percentage of this undoubtedly is due to occult cord prolapse and other forms of cord compression.

Antepartum Management

Breech presentation diagnosed before 32 weeks gestation should be managed expectantly. Recently, it has been confirmed that a significant percentage of preterm fetuses in abnormal presentations (breech, transverse and oblique) spontaneously convert to vertex presentation as the gestation approaches term (Table 22.3). Breech presentation that persists into the late third trimester should be evaluated by an ultrasound examination for congenital anomalies. When a breech presentation persists beyond 32 weeks gestation, some obstetricians have recommended attempts at converting the presentation to vertex by external cephalic version (ECV). Ranney reported his experience with 860 patients managed by external version. Attempts were made to turn the fetus to vertex whenever breech presentation was found in the third trimester, and some patients had repeated versions performed. Ranney was able to lower the incidence of breech presentation at

term to 0.6%, about one sixth the expected incidence, and encountered no fetal trauma or death and, specifically, no increase in the incidence of placental abruptions.

The report by Kasule and coworkers was less optimistic. All patients with fetuses in breech presentation after 30 weeks gestation were prospectively randomized to either

an external version group (310 patients) or a control group (330 patients). The subjects in the external version group had the procedure performed between 33 and 36 weeks gestation. If the first attempt failed, or if the fetus reverted to breech presentation, the procedure was repeated up to three times in subsequent weekly visits. No attempts at external version were made after 36 weeks gestation. Although their immediate success rate was 80%, 46% of fetuses spontaneously reverted to breech presentation. There were three perinatal deaths attributed to the procedure: two from abruptio placentae and one from premature labor and delivery. Most important, the incidence of breech presentation at delivery was 52% in the external version group and 51% in the control group, with 49% of fetuses in the control group converting to vertex presentation spontaneously before delivery. The authors surmised that many, if not all, of their successful external versions may have been in patients whose fetuses would have converted spontaneously had nothing been done. This hypothesis, coupled with the three perinatal deaths, led them to conclude that “there is no place for external cephalic version before 36 weeks gestation.”

TABLE 22.3 Incidence of Malpresentation from 28 Weeks Gestation through Term

Gestational Age (Weeks)	Fetuses Remaining in Abnormal Presentation (Breech, Transverse, and Oblique) (%)	
	Primigravidas	Multigravidas
28–29	100	100
30–31	72	57
32–33	45	42
34–35	41	30
36–37	38	19
38+	30	18

Adapted from Fox and Chapman. *Aust N Z J Obstet Gynaecol* 2006;46(4):341–344.

If external version at term is to be attempted, it should be done in the labor and delivery suite, using monitoring of the fetal position and heart rate by ultrasound. Both regional anesthesia and a dose of a tocolytic medication have been shown to increase the success rate of ECV. Epidural analgesia appears to be superior to spinal analgesia. The most recent Cochrane review found that ECV failure, noncephalic births, and cesareans were reduced in two trials with epidural but not in three with spinal analgesia. Two theories for this difference have been advanced. The large volume preloading associated with an epidural may increase the amniotic fluid volume. The local anesthetic doses used in the epidural studies also may have resulted in significant abdominal wall relaxation. This same Cochrane review concludes that, “there is evidence to support the use of tocolysis in clinical practice to reduce the failure rate of ECV at term. Whether tocolysis should be used routinely or selectively, when initial ECV attempts fail, has not been adequately addressed.” A number of the studies of tocolysis for ECV used intravenous ritodrine, an agent no longer available in the United States. One readily available agent on most labor and delivery units is terbutaline. In 1997, Fernandez and colleagues reported a prospective, randomized, controlled trial showing that terbutaline (0.25 mg) administered subcutaneously, 15 to 30 minutes before the attempt, doubled their ECV success rate.

In the authors' practice, terbutaline is used, and attempts at ECV are scheduled at 37 weeks gestation. Regardless of the fetal presentation after the attempt, the patient is then discharged and delivered at a future date. An alternative approach may be to attempt ECV at 38 weeks gestation after an epidural is placed. If the version is successful, proceed with induction of labor. If unsuccessful, cesarean delivery could then be performed with only a small risk of fetal lung immaturity.

The safety of ECV is well documented. In a recent review of 44 studies by Collaris, published between 1990 and 2002, with a total of 7,377 patients, the most frequently reported complications were transient abnormal fetal heart rate patterns (5.70%), fetomaternal transfusion (3.70%), vaginal bleeding (0.47%), emergency cesarean (0.43%), persisting pathologic fetal heart rate patterns (0.37%), and placental abruption (0.12%). The incidence of perinatal mortality was 0.16%. None of these studies used any anesthesia. In a review of six studies published within the same time period that included 1,170 patients in whom anesthesia was utilized, complications of ECV were more frequent, including transient abnormal fetal heart rate patterns (11.7%), persisting pathologic fetal heart rate patterns (4.36%), vaginal bleeding (3.67%), emergency cesarean (5.30%), and placental abruption (0.51%). The majority of these complications occurred in the study with the largest number of patients. If this study is excluded, the rates of these complications are similar to those in the studies in which anesthesia was not used.

Lau and associates reported a series of 243 women who underwent attempts at external version. Regression analysis identified three independent predictors of failed version: (a) engaged presenting part, (b) difficulty palpating the fetal head, and (c) nulliparity. The

chance of success was 0% if all three variables were present, <20% if any two were present, 30% to 60% if only one was present, and 94% if none was present. Interestingly, placental location, position of the fetal spine, attitude of the fetal legs, and maternal obesity were not significant variables for predicting successful version when controlling for the other variables.

The Cochrane Database review of ECV at term concludes that “the chance of breech birth and cesarean section may be substantially reduced by attempting ECV at term. There is sound reason to use ECV at term, with appropriate cautions.” The American College of Obstetricians and Gynecologists (ACOG) recommends, in Committee Opinion No. 340, July 2006, that “obstetricians should offer and perform external cephalic version whenever possible.” It should be noted that successful external version does not reduce the cesarean rate to that found in spontaneous vertex presentations. In 2004, Verzina and colleagues published a case-controlled study in which each patient who underwent successful ECV was compared with the next parturient of the same parity with a vertex presentation at term. The rates of cesarean delivery in the ECV groups of both nulliparous women (29.8% vs. 15.9%, P <0.001) and multiparous women (15.9% vs. 4.7%, P <0.001) were significantly higher when compared with the control groups. Earlier that same year, Chan and colleagues published a meta-analysis that concluded that the intrapartum cesarean delivery rate after successful ECV is twice the rate seen with spontaneous cephalic presentations.

Active labor and ruptured membranes are contraindications to the procedure. Relative contraindications include an engaged presenting part and an estimated fetal weight of ≥4,000 g. Whether a previous cesarean contraindicates

attempts at external version is uncertain, but in modern practice, delivery of breech fetus in a woman with a previous cesarean by elective repeat cesarean seems reasonable.

TABLE 22.4 Neonatal Morbidity, Planned Vaginal Delivery versus Planned Cesarean Typical (Odds Ratio and 95% Confidence Interval)

	Planned Cesarean	Planned Vaginal Delivery
Apgar <7 at 5 min	1.0	3.86 (2.22–6.69)
Birth trauma	1.0	3.96 (2.76–5.67)
Short-term morbidity	1.0	2.54 (1.74–3.71)

Long-term morbidity	1.0	2.88 (1.04–7.97)

From Cheng M, Hannah M. Breech delivery at term: a critical review of the literature. *Obstet Gynecol* 1993;82:605.

Management of Delivery

Term Breech Presentation

In 1993, Cheng and Hannah published a critical review of the literature on singleton term breech pregnancies, reviewing all articles in the English language literature between 1966 and 1992. They found that there were only 24 studies that presented outcome data in sufficient detail to be analyzable according to the intended mode of delivery. Of these 24 reports, only two were randomized trials[1]; eight were prospective cohort studies and 14 were randomized cohort studies. Twenty-two of these studies, including both prospective trials, did not demonstrate a statistically significant difference in corrected perinatal mortality between those patients for whom a vaginal delivery was planned and those for whom a cesarean was planned. Two series did show significantly worse outcome among those for whom vaginal delivery was planned. When the authors combined all of the data, they produced a "typical odds ratio" for perinatal mortality of 3.86, (95% confidence interval [CI] of 2.22 to 6.69) in the planned vaginal delivery group. Their data on low 5-minute Apgar scores, birth trauma, and short- and long-term neonatal morbidity were similar to the data on perinatal mortality, in that the majority of individual studies did not find a difference between those for whom vaginal birth was planned and those for whom cesarean was planned, but when the studies were combined, the planned vaginal delivery group fared worse in all categories (Table 22.4). The authors of this review carefully pointed out all of the flaws in the papers they reviewed and concluded that most of these studies were too poorly done to allow definitive conclusions. They ended their paper by stating that "the only way to obtain more definitive information regarding the effectiveness of a policy of elective cesarean vs. that of a trial of labor in women with breech presentation at term is to mount an appropriately sized, randomized controlled trial. In the absence of such a trial, a policy of elective cesarean delivery appears to be a reasonable option for the woman with breech presentation at term."

The Term Breech Trial organized by Hannah and associates is such a trial. The trial was carried out between January 1997 and April 2000 in 121 hospitals in 26 countries. Sixteen were industrialized nations with low perinatal mortality rates, and ten were underdeveloped countries with high perinatal mortality rates. The results of this trial were published in 2000 and will be presented here in considerable detail because of the uniqueness and importance of the study.

Patients were eligible for the trial if they were at 37 or more weeks of singleton gestation with a frank or complete breech. Women were excluded for clinical or radiographic

evidence of pelvic inadequacy (91% of subjects in both groups had only clinical evaluation of the pelvis), if the fetus was estimated to weigh >4,000 g either by clinical estimation or by ultrasonography (60% of subjects had sonography, 40% had clinical evaluations of fetal weight), if hyperextension of the fetal neck was felt to be present by clinical exam (31% of subjects) or ultrasonography (69% of subjects), if there was a contraindication to labor or vaginal delivery, or if there were fetal malformations incompatible with life or which might predispose to mechanical problems with vaginal delivery. The labor protocol permitted induction and augmentation of labor for usual indications and called for either continuous electronic fetal monitoring or intermittent auscultation every 15 minutes in the first stage of labor and every 5 minutes in the second. Adequate labor progress was defined as a rate of cervical dilatation of ≥0.5 cm per hour in the active phase, descent of the breech to the pelvic floor within 2 hours of the second stage, and imminent delivery within 1 hour of active pushing. The method of vaginal delivery was spontaneous or assisted; total breech extraction was not permitted. Most importantly, all vaginal deliveries were to be attended by a clinician experienced with vaginal breech delivery (self-defined with confirmation by the individual's department head).

The primary outcomes measured were perinatal/ neonatal mortality and serious neonatal morbidity. The secondary outcomes measured were maternal mortality and serious maternal morbidity (Table 22.5). Power analysis prior to the study calculated a required randomization of 2,800 subjects. An interim analysis of the first 1,600 births revealed a clear advantage for planned cesarean, and therefore, recruitment was stopped at 2,088 women (488

---

additional women had been enrolled while the interim analysis of the first 1,600 was in progress). In the final analysis, the rate of perinatal mortality and morbidity was 1.6% in the planned cesarean group and 5.0% in the planned vaginal delivery group (relative risk [RR] 0.33, 95% CI 0.19 to 0.56, P <0.0001). Considering perinatal mortality alone, the respective rates for cesarean and vaginal delivery were 0.3% and 1.3% (RR 0.23, 95% CI 0.07 to 0.81, P <.01). Similar data for neonatal morbidity alone were 1.4% and 3.8% (RR 0.36, 95% CI 0.19 to 0.65, P <0.0003). For every subcategory of neonatal morbidity, infants in the planned cesarean group fared significantly better than those in the planned vaginal delivery group. Most interestingly, the improvement in neonatal outcome with planned cesarean was better in the countries with already low perinatal mortality rates. The authors determined that in industrialized nations, one case of neonatal mortality or serious morbidity could be avoided for every seven additional cesareans, whereas in underdeveloped countries as many as 39 additional cesareans might be needed to avoid one dead or compromised baby. For the entire population studied, the number of additional cesareans needed to avoid one dead or seriously injured baby was 14. The authors' finding of a significant advantage for planned cesarean birth was maintained even after excluding labors that were prolonged, induced, or augmented and after correcting for whether or not epidural anesthesia was used. Finally, and equally importantly, the authors found no differences between the groups in terms of maternal mortality or serious morbidity; there were no differences in maternal morbidity whether the various morbid conditions were totaled or considered separately.

TABLE 22.5 Primary and Secondary Outcomes in the Term Breech Trial

Serious neonatal morbidity
Birth trauma
Subdural, intracerebral, or intraventricular hemorrhage
Spinal cord injury
Skull fracture
Peripheral nerve injury
Seizures at <24 h of age
Apgar score <4 at 5 min
Cord blood base deficit ≥15
Hypotonia for ≥2 h
Stupor or coma
Intubation and ventilation for ≥24 h
Tube feeding for ≥4 d
NICU admission > 4 d
Serious maternal morbidity
Postpartum hemorrhage >1,500 mL
Need for blood transfusion
D&C for bleeding or retained placenta
Hysterectomy
Cervical laceration extending into lower uterine segment
Vertical uterine incision
Vulvar/perineal hematoma
Deep venous thrombosis/pulmonary embolism
Pneumonia
Wound infection/breakdown
Bladder, ureter, or bowel injury
Genital tract fistula
Bowel obstruction
Febrile morbidity (standard definition)

NICU, neonatal intensive care unit; D&C, dilation and curettage.

From Hannah ME, Hannah WF, Hewson SA, et al. Planned caesarean section versus planned vaginal birth for breech presentation at term: a randomized multicentre trial. *Lancet* 2000;356,1375–1383.

There are many points on which the Term Breech Trial can be criticized. It is a good study, not a perfect study. Its merits and conclusions have been actively debated in the literature. Given today's medicolegal and social climate, the authors of this chapter believe that it is likely the best evidence that will ever be shown. Reitberg and associates recently published a compelling paper reporting on the effects that the publication of the Term Breech Trial had on medical practice and neonatal outcome in the Netherlands. Within 2 months of publication, the overall cesarean rate for breech presentation increased from 50% to 80%. In the group of infants ≤4,000 g, this was associated with a significant decrease in perinatal mortality from 0.35% to 0.18%, a decrease in the incidence of a 5-minute Apgar score <7 from 2.4% to 1.1%, and a decreased incidence of birth trauma from 0.29% to 0.08%. Also of interest is a paper published by Lowry and associates, who reported that in Ireland, the increased rate of cesarean delivery of breech infants, after publication of the Term Breech Trial, resulted in a lower incidence of developmental dysplasia of the hip among those infants delivered by elective prelabor cesarean compared with those delivered vaginally (3.69% vs. 8.11%, P <0.02).

Two fairly large retrospective studies of term breech delivery from Sweden are among the studies that confirm the findings of the Term Breech Trial. Herbst and Thorngren-Jerneck published a series of 1,050 term singleton breeches delivered at a single institution between 1988 and 2000. A planned vaginal delivery group of 699 women was compared with a planned cesarean group of 327. Acidemia at birth, low 5-minute Apgar scores, neonatal intensive care unit (NICU) admissions, and the rate of neonatal neurologic morbidity were all significantly greater among infants in the planned vaginal delivery group. Roman and colleagues studied 15,818 term singleton breeches delivered throughout Sweden between 1987 and 1993. A summary of their neonatal data is shown in Table 22.6 and demonstrates a clear advantage for cesarean delivery. Also, very importantly, the authors found the same rates of maternal morbidity for elective cesarean (1.7%) and vaginal delivery (1.8%). The maternal morbidity rate for emergency cesarean was 2.8%.

Since 2003, there have been many published retrospective studies that investigated the safety of vaginal breech delivery. By the authors' count, there have been six whose conclusions have supported the conclusions of the Term

---

Breech Trial. There also are eight retrospective studies that note excellent outcomes with vaginal breech delivery. These investigators followed very specific protocols, and inclusion criteria included a gestational age of at least 37 weeks, frank or complete breech presentation, the absence of fetal anomalies, documentation of an adequate maternal pelvis, an estimated fetal weight >2,500 g and <4,000 g, and documentation of a flexed fetal head. In some of these studies, short-term neonatal morbidity was reported to occur more commonly with vaginal delivery. Most of these studies concluded that vaginal delivery is as safe as cesarean delivery but not safer.

TABLE 22.6 Neonatal Outcome, Cesarean versus Vaginal Breech Delivery (Odds Ratio and 95% Confidence Interval)

	Elective Cesarean (n = 6,031)	Vaginal Delivery (n = 5,897)	Emergency Cesarean (n = 3,011)
Infant mortality	1.0	2.5 (1.1–5.9)	1.1 (0.4–3.4)
Apgar <7 at 5 min	1.0	9.5 (5.8–15.8)	4.7 (2.7–8.2)
Birth injury	1.0	12.2 (6.8–21.8)	2.0 (0.9–4.3)
Seizures	1.0	2.7 (0.9–8.1)	4.1 (1.4–12.0)

From Roman J, Bakos O, Cnattingius S. Pregnancy outcomes in mode of delivery among term breech births: Swedish experience 1987–1993. *Obstet Gynecol* 1998;92:945–950.

In 2004, the Term Breech Trial authors reported the risk of death and neurodevelopmental delay of the children 2 years after delivery. Those authors concluded that planned cesarean delivery is not associated with a reduction in the risk of death or neurodevelopmental delay in children at 2 years of age. Their follow-up data showed that the benefits of planned cesarean delivery are limited to reducing perinatal and neonatal mortality and serious neonatal morbidity during the first 6 weeks of life. These benefits remain important. The most recent update of the *Cochrane Database of Systematic Reviews* includes a review of the three randomized controlled trials of planned cesarean versus planned vaginal delivery for breech presentation and concludes that “planned cesarean section compared with planned vaginal birth reduced perinatal or neonatal death or serious neonatal morbidity, at the expense of somewhat increased maternal morbidity.”

The ACOG issued Committee Opinion No. 340 in July 2006, which recommends that “the decision regarding mode of delivery should depend on the experience of the health care provider.” This document also states that “planned vaginal delivery of a term singleton breech fetus may be reasonable under hospital-specific protocol guidelines for both eligibility and labor management. Before a vaginal breech delivery is planned, women should be informed that the risk of perinatal or neonatal mortality or short-term serious neonatal morbidity may be higher than if a cesarean delivery is planned and the patient's informed consent should be documented.”

Two points are pertinent. First, almost no obstetrician completing residency in the past 15 years has the training or experience to be skillful at vaginal breech delivery, and the cadre

of obstetricians capable of imparting these skills is dying, retiring, or giving up obstetrics. Second, the argument that vaginal delivery is significantly safer than cesarean for the mother is becoming more and more difficult to prove. A number of studies, including the Term Breech Trial, have shown that maternal morbidity and mortality is as good or better with planned cesarean delivery as with vaginal birth. On the other hand, emergency cesarean or cesarean after a trial of labor is clearly more morbid than either elective cesarean or vaginal delivery. In nearly all recent series, including those in the Cochrane database, 40% to 45% of women given a trial of labor for breech presentation eventually were delivered by cesarean, which greatly increases the overall risk of maternal morbidity and mortality in the total group for whom vaginal breech delivery is planned.

Given these recent data, the authors believe that it is time to consider the matter settled. Unless and until another large randomized controlled trial reveals different findings from these recent studies, the route of delivery for the term singleton breech, except in very rare circumstances, should be cesarean. One such circumstance is the woman whose breech delivery is imminent. The authors do not recommend physically preventing delivery while attempting to perform a cesarean. This may be more traumatic than the vaginal delivery of a breech.

Premature Breech Presentation

Almost no randomized prospective data have been published regarding delivery of the premature infant in breech presentation. Penn and coworkers attempted a multicenter randomized controlled trial in 26 hospitals in England, in an effort to determine the optimal mode of delivery for breech infants at gestational ages between 26 and 32 weeks. After 17 months of attempting to enroll patients, the study was abandoned because only 13 women from six hospitals had been recruited. The authors of this study stated that “the low accrual rate was due to clinicians' reluctance to

randomize eligible women.” Eller and VanDorsten polled the Maternal-Fetal Medicine Units network and found 7 of 11 centers willing to do a randomized controlled trial comparing cesarean to vaginal birth for breech infants between 24 and 28 weeks gestation; because of small numbers, they calculated that this study would require at least 10 years. No center in the network was even willing to study breech birth in pregnancies >28 weeks gestation. Therefore, management decisions regarding the premature breech must be made based on retrospective data, which suffer from serious shortcomings. These data, however, all point in the same direction and indicate that cesarean delivery is preferable for the premature breech.

The Effect of Parity

To separate primigravidas whose fetuses are in breech presentation as a group needing cesarean delivery is fallacious for two reasons. First, there are no data to suggest that primigravidas are at more risk than parous women for fetal injury, cord prolapse, difficult vaginal delivery, or perinatal death. Second, this philosophy implies that a parous woman in labor with a fetus in breech presentation is not at very high risk. The parous woman is at

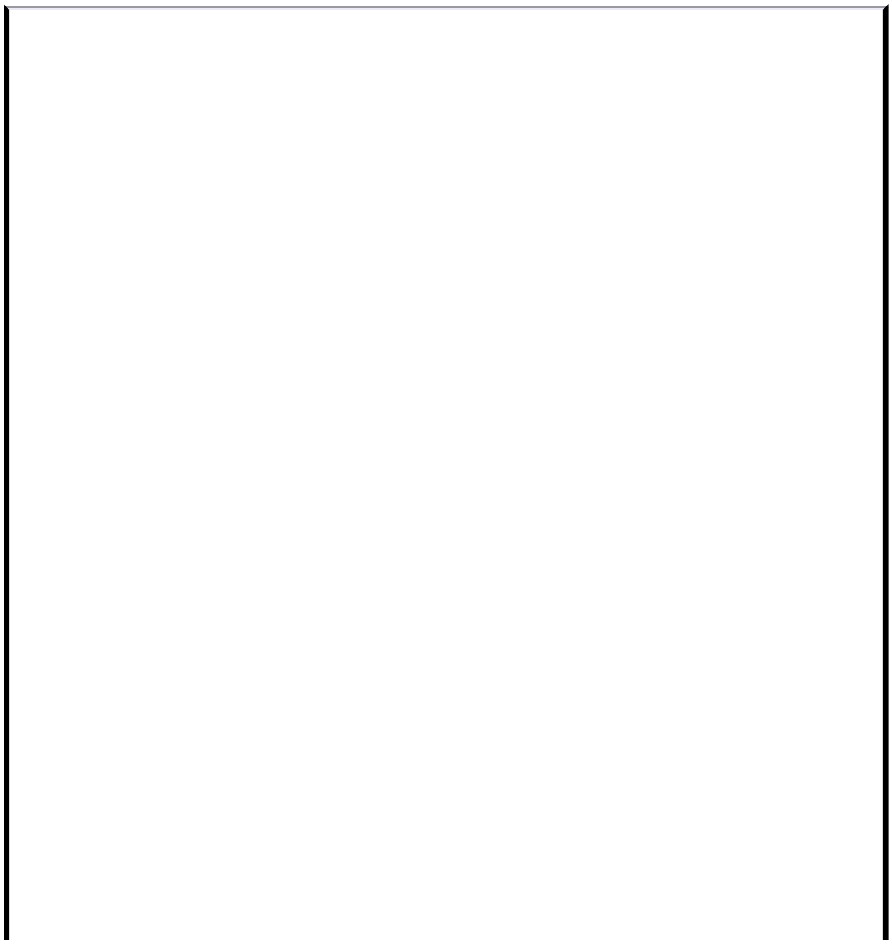
no less risk than the nulliparous woman, because a subsequent fetus is typically larger than previous infants delivered and because the pelvis may be adequate for vertex presentation but not for the unmolded head of a breech fetus.

Extension of the Fetal Neck

Ballas and Toaff demonstrated that when the fetal neck is hyperextended to an angle of >90 degrees (Fig. 22.2), vaginal delivery is associated with a 70% incidence of fetal spinal cord transection. This complication can be avoided by cesarean delivery, utilizing generous abdominal and uterine incisions and delivering the head slowly while attempts are made to flex the neck. Experience in such maneuvers is ideal but not often possible due to the rarity of this clinical situation.

Management of Vaginal Delivery

Occasionally, a patient will arrive at the hospital in the process of delivering a breech infant. In such circumstances, a vaginal delivery probably is less traumatic to both the infant and mother than a rushed cesarean under suboptimal emergency conditions. The Cochrane review anticipates this problem without providing a solution, stating that “one problem with a policy of routine cesarean section for breech presentation at term is that in time the skills of breech delivery will be lost, placing women who deliver before cesarean section can be carried out at increased risk.” To prepare as much as possible for such circumstances, given the paucity of actual experience with vaginal breech delivery, all obstetricians frequently should mentally review the principles of vaginal breech delivery and have their labor and delivery team participate in mock rehearsals.



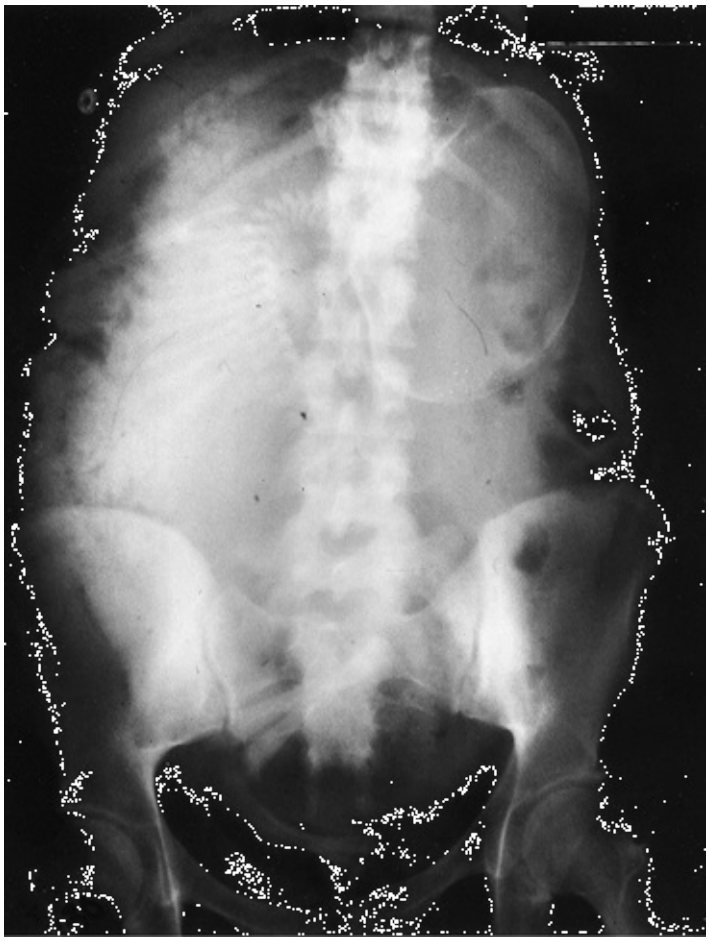


Figure 22.2 Hyperextension of the fetal neck.

Vaginal delivery of a fetus in breech presentation requires the attendance of at least an obstetrician and an anesthesiologist. It is preferable to have a pediatrician in attendance as well. The fetal monitor should be taken to the delivery room, and monitoring should be continued until the physician is committed to a vaginal delivery. Such a commitment occurs when the fetal umbilicus passes over the mother's perineum, at which time the fetal head is in the maternal pelvis and the umbilical cord may undergo compression. Traction on the fetus before that point constitutes a total breech extraction and should be avoided. The legs may then be delivered by flexing the knees and sweeping the legs out from in front of the fetus. A towel is placed around the fetal pelvis, which is then grasped, and downward traction is applied until the fetal scapulas pass under the maternal symphysis. Then, the fetal body is rotated so that the shoulders are in an anteroposterior position, and the anterior arm is flexed and swept out from under the symphysis. The fetus is then rotated 180 degrees in the direction that will keep the fetal back toward the maternal symphysis, and the other arm is swept out in a similar manner. During delivery of a breech, it is important that the fetus not be allowed to assume a position with the fetal face or abdomen toward the maternal symphysis.

If the breech infant is delivering so rapidly that cesarean birth is not feasible, the after-coming head usually delivers

spontaneously. Should this not occur, delivery of the fetal head with Piper forceps may be

necessary. An assistant must support the fetal body during application of these forceps (Fig. 22.3). The temptation to elevate the fetal body to provide better visualization must be resisted, because this maneuver hyperextends the neck. Rather, the fetal body should be supported parallel to the floor, and the operator should drop to the knee for application of the forceps. The application is pelvic rather than cephalic, with the forceps being applied to the lateral aspects of the maternal pelvis, not wandered around from the posterior using landmarks on the fetal head, as would be done in vertex presentation. Controlled delivery of the fetal head is then accomplished, with suctioning of the fetal airway as soon as the mouth passes over the perineum. If the obstetrician is unfamiliar with the use of Piper forceps or if they are not available, the Mauriceau-Smellie–Veit maneuver can be utilized. The baby is first placed astride one arm. The index and middle finger of this hand are positioned on the fetal maxilla, one on either side of the nose, to keep the head flexed. Placing a finger in the baby's mouth to facilitate gentle and controlled downward traction may be useful. The fingers of the other hand are applied to both fetal shoulders. An assistant may then apply gentle suprapubic pressure to help keep the fetal head flexed. Gentle downward traction is applied to the baby until the suboccipital region is visible under the symphysis pubis. At this point, the assistant should stop providing suprapubic pressure. The baby is then slowly elevated toward the maternal abdomen, guiding the face and forehead over the perineum. Finally, the occiput follows and the baby is delivered. A generous episiotomy is necessary for any vaginal breech birth. For the term-sized infant, a mediolateral episiotomy is appropriate.

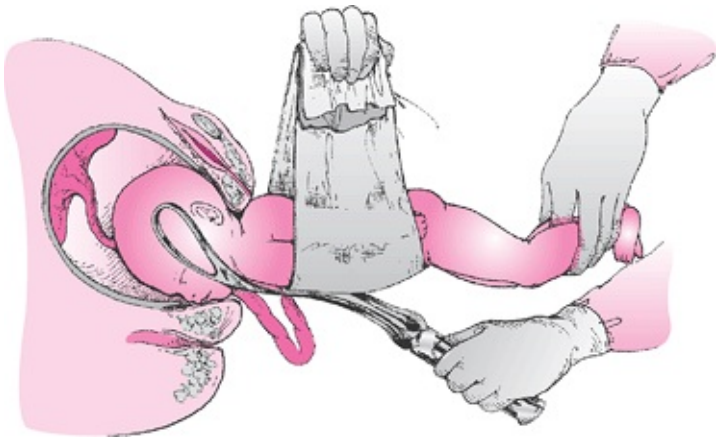

Figure 22.3 Breech delivery with Piper forceps to the after-coming head. Note that the infant's body is being supported parallel to the floor.

Management of Cesarean Delivery

Abdominal delivery does not guarantee an atraumatic birth of the fetus in breech presentation. Just as in vaginal delivery, it is important to grasp the fetal bony pelvis rather than soft tissue during extraction. The most serious complication is head entrapment by the uterus contracting down around the neck after delivery of the body through a low transverse uterine incision. Some physicians have advocated a vertical

uterine incision so that it may be extended if this occurs. This may be the best choice for the premature fetus accompanied by a poorly developed lower uterine segment. Because such an incision compromises future childbearing, the obstetrician should perform a low transverse cervical incision for the term fetus or the premature fetus when labor has resulted in a well-developed lower segment. Such an incision can be extended in a J-shaped (rather than a T-shaped) manner on one side, if necessary. A technique that may obviate the need for this in the face of head entrapment is general anesthesia with an agent that rapidly relaxes the uterus. The anesthesiologist should be alerted that this might become necessary and have made preparations, even if the cesarean is begun under regional anesthesia.

Face Presentation

In a face presentation, the fetal neck is hyperextended so that the occiput touches the back. The presenting part is that part of the fetal face between the orbital ridges and the chin (Fig. 22.4). The incidence is approximately 1 in 550 births.

Cause

Proposed causative factors of face presentation include anencephaly, high parity, contracted pelvis, large infant, small infant, and nuchal cord. It is interesting to note that in the majority of studies, one of the larger categories is that in which no causative factor can be identified; this varies from 2% to 97%, with an average frequency of 38%.

Anencephalic fetuses frequently present by the face if the fetal presentation is cephalic. However, because the course and mechanism of labor, management of delivery,

and perinatal outcome are entirely different in the absence of a cranial vault, these cases should be excluded from consideration of face presentation. The association between face presentation and anencephaly is important to remember, however, because when face presentation is suspected clinically, ultrasound studies are helpful to rule out this anomaly.

Figure 22.4 Face presentation.

Most series demonstrate an association between high parity and face presentation; whether this relation is causal remains unclear. The average reported incidence of contracted pelves in series of face presentations is 15%. In reality, the incidence is probably much lower because in most series, only those patients with arrested labor were studied radiographically. Contracted pelvis or cephalopelvic disproportion is probably diagnosed clinically with excessive frequency in face presentation because the extended head feels larger on abdominal palpation and because the head often is floating at the onset of labor. However, if large series of radiographically diagnosed contractions of the pelvis are examined, it is rare to find a case of face presentation, none being reported in three series of radiographically diagnosed pelvic contraction totaling >700 patients. The weight of evidence seems to indicate that contraction of the bony pelvis is not of causative significance in face presentation.

Some authors associate face presentation with large infants. This is based on the assumption that cephalopelvic disproportion may result from excessive fetal size despite a normal pelvis. The argument that large infants cause cephalopelvic disproportion, and thus face presentation, is weakened by the high proportion of vaginal deliveries in most series of face presentations. Furthermore, the average incidence of large infants (variously defined) in series of face presentations is 12%, which is not significantly different from that in the general obstetric population.

Many series have demonstrated an increased proportion of low-birth-weight infants among face presentations and ascribed causative significance to prematurity, although other studies have found no excess of low-birth-weight infants. Part of the discrepancy may result from the inclusion of anencephalic fetuses in many series—fetuses that usually are small for gestational age. The average incidence of low birth weight is 11% in those series of face presentation in which it is possible to exclude anencephalics; this is not significantly different from the incidence of low birth weight in the general population. Thus, it is difficult to conclude that low birth weight or prematurity are causative factors in face presentation. A nuchal cord occurs in approximately 25% of cephalic deliveries. The average incidence of nuchal cord in face presentation is 10%. Thus, a nuchal cord is not a cause of face presentation.

Of all the proposed causative factors in face presentation, there is no unanimity of opinion regarding their significance and, as reported by Cruikshank and Cruikshank, none can withstand careful scrutiny. There does seem to be an association between face presentation and high parity, but 34% of face presentations occur in primigravidas. All of the postulated causes presume that face presentation develops after the onset of labor. Cases of face presentation that occur before labor are called *primary face presentations* and are thought to be due to increased tone in the extensor muscles of the fetal neck. The usual attitude of the fetal neck is flexion caused by greater tone in the flexor muscles, but occasionally infants are seen in whom the extensors predominate. In addition to face presentation, hyperextension of the neck occurs in transverse lie (i.e., “flying fetus”) and in breech presentation; in fact, up to 5% of breech fetuses have hyperextended necks.

To ascertain the true incidence of primary face presentation, it is necessary to examine large series of x-ray films obtained before labor. In three such series, seven primary face presentations were found among 1,762 patients, an incidence of one face presentation in 251 cases, which is more than twice the reported incidence of face presentation at delivery. These data, coupled with the uncertainties surrounding the proposed causative factors, make it most likely that all face presentations are primary and intrinsic to the fetus and that there are no significant causative maternal factors. The preponderance of multiparas in series of face presentation is compatible with this theory. Increased extensor muscle tone cannot cause extension of the neck if the head is fixed in the pelvis; thus, face presentation is less likely to occur during the last 1 to 2 weeks of pregnancy in a primigravida with an engaged presenting part than in a multipara in whom the head often is not engaged until after the onset of labor.

Diagnosis

The diagnosis of face presentation usually is made by vaginal examination during labor followed by ultrasound studies. Face presentation is rarely diagnosed prior to the onset of labor, with 35% of cases being diagnosed in the first stage, 27% in the second stage, and 35% at the time of delivery. At the time of diagnosis, 60% of face presentations are mentum (chin) anterior (MA), 15% are mentum transverse (MT), and 25% are mentum posterior (MP).

Mechanism and Course of Labor

In face presentation, the presenting diameter is the tracheloparietal (trachelobregmatic), which is 0.7 cm longer than the presenting diameter in vertex presentation (the suboccipitobregmatic). Internal rotation in face presentation occurs between the ischial spines and the ischial tuberosities, lower than that for rotation of a vertex presentation. After internal rotation to MA has placed the fetal chin under the maternal symphysis, delivery occurs by flexion of the fetal neck. It is important to remember that in face presentation, the distance from the leading edge to the largest presenting diameter is greater than that in vertex presentation. Thus, engagement of the presenting part probably has not occurred until the face is at a +2 station.

Safe vaginal delivery of a term-sized persistent MP is impossible for two reasons: the short fetal neck cannot span the full length of the maternal sacrum, so the fetal head and shoulders must enter the maternal pelvis at the same time; even if this should occur, the persistent MP would have to deliver under the symphysis by extension, but the neck is already maximally extended. Many MPs will spontaneously rotate and convert to MA; the average reported rate is 35%. This may be an artificially low value because, as pointed out previously, rotation does not occur until the head is well down in the pelvis. Surgical intervention before that point would make the incidence of spontaneous rotation appear lower. In fact, some series report spontaneous rotation rates of 50% to 65%. When the face is MT at the time of diagnosis during labor, spontaneous rotation to MA usually occurs.

Most patients with face presentations have durations of the first stage of labor similar to

those of patients with vertex presentations, although there may be some prolongation in MP presentations. Likewise, the length of the second stage is similar to or only slightly longer than that in vertex presentation.

Management

The average reported incidence of spontaneous or elective low forceps delivery in face presentation is 72% (range, 40% to 90%). The average rate of cesarean delivery is 15% and in only two series was it >29%. In older series, up to 12% of face presentations were delivered by various operative vaginal procedures, including midforceps rotation, version and extraction, and manual conversion of face to vertex (Thorn maneuver). These procedures are associated with high perinatal mortality and maternal morbidity, and there is no place for them in the modern management of face presentation.

Face presentation alone is not a contraindication to oxytocin stimulation of labor, and it can be done for the same reasons and with the same precautions as in vertex presentation. Likewise, outlet forceps delivery in MA presentation can be accomplished by using the same criteria that would be used in vertex presentation, but midforceps delivery in face presentation should be abandoned. Because of the altered diameters of the presenting part, if the face is not bulging the perineum, any forceps delivery probably is a midforceps operation and should not be attempted. For obvious reasons, application of the vacuum extractor is contraindicated with face presentation.

The old adage “if a face is progressing, leave it alone” is still valid. This applies to MT and MP presentations as well as to MA because of the likelihood that these presentations will convert to MA. Rotation may not occur, however, until the presenting part is on the pelvic floor. In any face presentation, as in vertex presentation, if progress in dilatation and descent ceases despite adequate contractions, delivery should be accomplished by cesarean section. Conversely, as long as dilatation and descent continue, management should be expectant.

The only series using fetal monitoring extensively in the management of face presentation reported variable decelerations in 59% of 29 infants, severe variables in 29%, and late decelerations in 24%. Only 14% of patients in the study (4 of 29) had no fetal heart rate abnormality. It seems plausible that the increased incidence of fetal heart rate abnormalities is due in part to abnormal pressure on the extended head, neck, or eyes, similar to the mechanism of heart rate abnormalities described in occiput posterior presentations. Therefore, face presentation is an indication for electronic fetal monitoring. To avoid damaging the fetal eyes or scarring the face with an electrode, external monitoring should be used.

Brow Presentation

In brow presentation, the fetal neck is midway between flexion and hyperextension, and the presenting part is that portion of the head between the orbital ridges and the anterior fontanelle. Brow presentation is less common than face presentation; the reported incidence is approximately 1 in 1,400 births.

Cause

As in face presentation, numerous factors have been proposed as causative in brow presentation. Most series report a few cases of brow presentation associated with placenta previa, polyhydramnios, uterine anomalies, and fetal malformations, but these are no longer seriously proposed as causes of brow presentation. Likewise, the reported incidence of nuchal cord in brow presentation is lower than that in the general obstetric population, and the presence of a nuchal cord with a brow presentation is only by coincidence. The average incidence of low birth weight among brow presentations is 13%; yet this does not seem to be etiologically significant. However, most data suggests that cephalopelvic disproportion more commonly is associated with brow presentation than with face presentation.

Many authors believe that brow presentation, like face presentation, is nearly always primary (i.e., caused solely by factors intrinsic to the fetus). Others believe that brow is an unstable or transitional presentation, representing a head in the process of converting from vertex to face presentation or vice versa. If this is true, and if, as proposed previously, all face presentations are primary, then all brow presentations must likewise be primary. If so, how can the apparent association between brow presentation and cephalopelvic disproportion be explained? Two factors seem relevant: (a) “relative” cephalopelvic disproportion is more likely to occur in brow presentation because the presenting diameters of the fetal head are greater than in face or vertex presentation (see Mechanism and Course of Labor below) and (b)

---

persistent brow presentation probably selects for patients with smaller pelves, because in patients with larger pelves, the brow may convert to face or to vertex before being recognized.

Diagnosis

The diagnosis of brow presentation is nearly always made by vaginal examination or sonographic studies or both. Most cases are diagnosed in labor, with approximately one half diagnosed during the second stage. If labor is progressing, the diagnosis often is missed until late in the second stage of labor.

Mechanism and Course of Labor

When the fetal head engages as a brow presentation, there are three possible mechanisms of labor, depending on whether the brow converts to a face, converts to a vertex, or persists as a brow. Spontaneous conversion to face or vertex occurs in approximately 50% of cases, with 30% converting to face and 20% to vertex. However, in those series in which the brow presentation was diagnosed early in labor, spontaneous conversion rates of 67% to 75% have been reported. In fact, many occiput posterior presentations probably enter the pelvis as brows but are never diagnosed as such. Regardless of the eventual outcome, the brow usually engages transversely at the pelvic brim. The engaging diameter is the mentoparietal, which is about 1.5 cm longer than the engaging diameter in vertex

presentation and 0.8 cm longer than that in face presentation.

Most experts would agree that there is no mechanism of successful labor for a term-sized persistent brow under most circumstances, and therefore vaginal delivery is impossible. However, vaginal delivery can occur if the fetus is quite small or if the pelvis is very large. Not surprisingly, most series report a definite prolongation of labor with brow presentation, but the duration of labor in those patients who eventually convert to face or vertex is no different from the duration of labor with vertex presentation. It would seem that those cases destined to convert to face or vertex and deliver spontaneously have normal to slightly prolonged labor, whereas those destined to persist as brows often have very prolonged labors unless timely intervention is undertaken.

Management

The best recommendation for management of brow presentations is the same as that for face presentations. If dilatation and descent are progressing normally, expectant management is best. If progress ceases, delivery should be by cesarean section. The association of cephalopelvic disproportion with brow presentation probably contraindicates the use of oxytocin to stimulate labor. Forceps deliveries are acceptable if the brow converts to MA face or vertex. Once progress in labor has ceased, persistent brow presentations require a cesarean delivery, and all operative vaginal maneuvers are contraindicated. In assessing whether progress in labor has stopped, it is important to remember that if the fetus becomes arrested at the pelvic brim, tremendous caput succedaneum may form over the brow, giving a false impression of descent of the head.

Shoulder Presentation (Transverse Lie)

When the long axis of the fetus lies perpendicular to that of the mother, the condition is termed a *shoulder presentation* or *transverse lie*. This malpresentation complicates 1 in 300 births.

Definitions

In transverse lie, the fetal head lies in one maternal iliac fossa and the buttocks in the other. A better term for this would be *transverse presentation*, but this term is avoided, as it often is confused with transverse position of vertex presentation. Because the fetal shoulder usually lies over the pelvic inlet, the formal term is *shoulder presentation*, which should be considered synonymous with *transverse lie*. The fetal position is described with the fetal acromion used as a reference point and is termed *left* or *right acromion*, according to which side of the mother the fetal shoulder is directed. Because the fetal back may be directed anteriorly, posteriorly, superiorly, or inferiorly, the additional qualifying terms *dorsum superior*, *dorsum anterior*, and so on are used as well. Thus, a fetus with its head on the mother's left and its back toward the mother's head would be described as left acromion dorsum superior. If one fetal pole lies in a maternal iliac fossa and the other pole lies in the opposite upper quadrant of the uterus, the lie is said to be oblique or unstable.

Cause

The most common causative factors of shoulder presentation are high parity with lax abdominal wall and uterine musculature as well as conditions in which the fetus is small in relation to the volume of the uterus (i.e., prematurity and polyhydramnios). Shoulder presentation also may be caused by anything that prevents descent of a fetal pole into the maternal pelvis, such as pelvic contraction, placenta previa, lower uterine segment myoma, or an ovarian tumor in the cul-de-sac. These conditions should be kept in mind for any patient who presents with a transverse lie, but especially in the patient of low parity who has this malpresentation at or near term.

Diagnosis

The diagnosis of shoulder presentation usually can be made by physical examination of the maternal abdomen,

---

with the fetal head and buttocks palpable in the iliac fossas and no fetal pole at the pelvic inlet. A very high or unreachable presenting part on vaginal examination suggests transverse lie. All such findings should be confirmed by ultrasound.

Mechanism and Course of Labor

The tiny fetus in transverse lie may deliver by the mechanism of conduplicato corpore, in which the fetal body doubles up on itself and the fetal head and buttocks enter the maternal pelvis simultaneously. This often is associated with rupture of fetal abdominal viscera. If the fetal weight is greater than approximately 800 g, there is no mechanism of labor. Uterine contractions will wedge the fetal shoulder into the maternal pelvis, and eventually the membranes will rupture and the fetal arm will prolapse into the vagina. Such a condition is termed a *neglected transverse lie*. If labor is permitted to continue, there will be progressive thinning of the lower uterine segment, a Bandl retraction ring will form, the uterus will rupture, and eventually both the fetus and the mother will die.

Management

Shoulder presentations that are diagnosed before term should be managed expectantly, as most will convert to polar presentations before labor. If the patient is not at term but the cervix is significantly dilated (>3 cm), hospitalization at bed rest should be considered because the incidence of cord prolapse in such a patient is 10% to 15% should spontaneous rupture of membranes occur.

If the patient is at term (37 or more completed weeks gestation), external version may be attempted with the same techniques and precautions as described for breech presentation. If the version is successful and the cervix favorable, induction of labor may be undertaken immediately. External version also may be attempted in early labor, provided the membranes are intact and no fetal part has entered the pelvis. Before any version attempt, ultrasound should be used to rule out placenta previa or pelvic masses precluding

a successful external version.

If the patient is in active labor or has ruptured membranes and the fetus is of a gestational age to be considered viable, delivery should be by cesarean. Because of exceedingly high morbidity and mortality for both the mother and fetus, there is no role for internal version and extraction in the management of transverse lie in singleton gestation. Because the lower uterine segment may be poorly developed, vertical uterine incisions are often necessary. If, however, the fetus can be manipulated to a polar presentation after opening the abdomen but before entering the uterus, a low transverse incision may be performed. This usually is possible only if the membranes are still intact.

The patient with a neglected transverse lie is an obstetric emergency. Usually she is septic, and often the fetus has died. If the uterus is still intact, it is exceedingly thin because of the prolonged duration of contractions. Some patients will be completely dilated on arrival at the hospital, but the temptation to try vaginal maneuvers such as internal version must be resisted, as this often will result in uterine rupture and may lead to maternal death. Such patients should have basic laboratory studies, coagulation indices, and blood cultures obtained. Rapid intravenous hydration and antibiotic therapy should be instituted, type-specific blood should be available, and the patient should be taken promptly to the operating room for a cesarean delivery. Cesarean hysterectomy often is the best procedure for such patients, especially if the uterus has ruptured or is grossly infected. In the past, various vaginal fetal destructive procedures were described for treating the neglected transverse lie with a dead fetus. Given that obstetricians today have almost no training in such procedures, they should be abandoned in favor of cesarean delivery, even in the face of a dead fetus.

Compound Presentation

A compound presentation occurs whenever some part of a fetal extremity is prolapsed alongside the presenting part. By far the most common type is vertex/hand or vertex/arm, in which some part of the upper extremity is alongside the head. Much less common types are breech/arm and vertex/foot. The reported incidences range between 1 in 400 and 1 in 1,200 births.

Cause

The ultimate cause of a compound presentation is a situation in which the presenting part fills the pelvis poorly and predisposes to compound presentation. The most obvious and frequent reason for this is prematurity, which is associated with most compound presentations. In fact, the incidence of this complication among infants who weigh >1,500 g is only 1 in 1600 births.

Diagnosis

The diagnosis of compound presentation almost invariably is made by vaginal examination and generally late in the labor course, with at least 50% diagnosed in the second stage of labor. Whenever a fetal hand or arm is palpated on vaginal examination, the examiner

must be certain that the fetal head is in the pelvis as well before concluding that the presentation is compound. If the head is not easily palpated in the pelvis in such circumstances, most likely the diagnosis is shoulder presentation with a prolapsed arm, a much more serious and urgent obstetric condition.

Management

Management of vertex/arm and vertex/hand presentations should be expectant. One of three outcomes will occur: (a)

---

the prolapsed part will be withdrawn back up in to the uterus as labor progresses and the fetus descends; (b) the baby will deliver with the arm or hand alongside the head; or (c) progress in labor will cease, in which case a cesarean delivery is indicated.

The reported incidence of cord prolapse in compound presentation is 10% to 20%, but many of these are related to attempts to replace the prolapsed arm into the uterus, which often necessitates upward displacement of the fetal head. For this reason, attempts at replacement of the prolapsed part in compound presentation should be avoided. Because of the increased incidence of cord prolapse, electronic fetal monitoring should be used in these situations. Vertex/arm and vertex/hand presentations are not indications for a cesarean delivery in and of themselves. Indications for an operative delivery in such circumstances include failure to progress in labor, cord prolapse, and nonreassuring fetal status.

Cases of breech/arm presentation should be managed as any other breech presentation would be managed. Cases of vertex/foot presentation are rare, but those few reported cases have a perinatal mortality two to three times that of other compound presentations and are best managed by cesarean delivery. In essence, these are variants of shoulder presentation. There is no role for internal version and extraction in the modern management of compound presentation, although this was commonly done in years past.

Umbilical Cord Complications

The mean length of the umbilical cord at term is 55 to 60 cm, and the normal range (5th to 95th percentile) is 35 to 80 cm. The longest umbilical cord reported measured 190 cm. The length of the cord is related to fetal activity in the first two trimesters; there is little change in the length of the cord after 28 weeks gestation. At term, mean cord length is slightly (1.6 cm) but significantly longer in male fetuses compared with females, and is 4.5 cm greater in vertex infants compared with breech. There is no correlation between cord length and either fetal or placental weight.

Cord Prolapse

The reported incidence of prolapse of the umbilical cord varies between 0.2% and 0.6% of births. Cord prolapse virtually never occurs with cords shorter than 35 cm; the incidence is 0.4% with normal-length cords (35 to 80 cm) and 4% to 6% with cords longer than 80 cm. Besides excessive cord length, other causative factors include malpresentation in

approximately 50% of cases; low birth weight (<2,500 g) in 30% to 50% of cases; grand multiparity (more than five deliveries) in 10% of cases; multiple gestation in 10%; and obstetric manipulation, including artificial rupture of membranes, in 10% to 15%. Table 22.7 shows the association between cord prolapse and malpresentation, especially with nonfrank breech, compound, and shoulder presentations. Nearly 50% of cord prolapses occur during the second stage of labor.

TABLE 22.7 Incidence of Cord Prolapse

Presentation	Incidence (%)
Vertex	0.14
Breech	2.50–3.00
Frank	0.40
Complete	5.00
Incomplete	10.00
Shoulder (transverse lie)	5.00–10.00
Compound	10.00–20.00
Face/brow	Rare

The diagnosis of cord prolapse should be suspected in any patient who develops fetal heart rate abnormalities after rupture of the membranes, either spontaneous or artificial. The heart rate abnormalities usually observed are sustained bradycardia and, less frequently, profound variable decelerations (Fig. 22.5). All such patients should be promptly examined or reexamined and the diagnosis confirmed by palpation of the cord alongside the presenting part or in the cervix or vagina.

When cord prolapse is diagnosed, every effort should be made to prevent compression of the cord by the presenting part. The patient should be placed in steep Trendelenburg or the knee–chest position, and the presenting part should be manually elevated as far out of the pelvis as possible and held there until delivery is accomplished. Once the diagnosis is made, further palpation of the cord must be avoided because this may cause spasm of the

umbilical arteries, which would further compromise the fetus. Fetal cardiac activity should be confirmed by ultrasound rather than by cord palpation. In fact, ultrasound is the only certain way to confirm fetal viability. There are at least two reported cases in which nonpulsatile cords were palpated and no fetal heart tones were heard with Doppler or stethoscope, yet ultrasound revealed fetal heart rates of 50 to 80 beats per minute. In both cases, prompt delivery resulted in surviving infants.

Cesarean delivery is the treatment of choice in almost all cases if there is fetal cardiac activity. Even at complete dilatation, the perinatal outcome is better with cesarean delivery than with such maneuvers as breech extraction or high forceps. If the fetus is dead with no fetal cardiac activity present by ultrasound and the fetal lie is polar, the mother usually is better served by allowing continued labor and vaginal delivery.

In most series of cord prolapse, perinatal mortality is approximately 15%. Among term infants and among all infants delivered by cesarean within 10 minutes of cord prolapse, mortality is <5%. Murphy and MacKenzie reported a retrospective study of 132 consecutive cases of cord

prolapse in a single hospital. The overall perinatal mortality was 9% (12 of 132 infants). However, all but one death was due to either extreme prematurity or congenital malformations; the perinatal mortality rate attributable to asphyxia was 0.8 percent (one case). Of the 120 survivors they reported, only one infant had a major neurologic handicap.

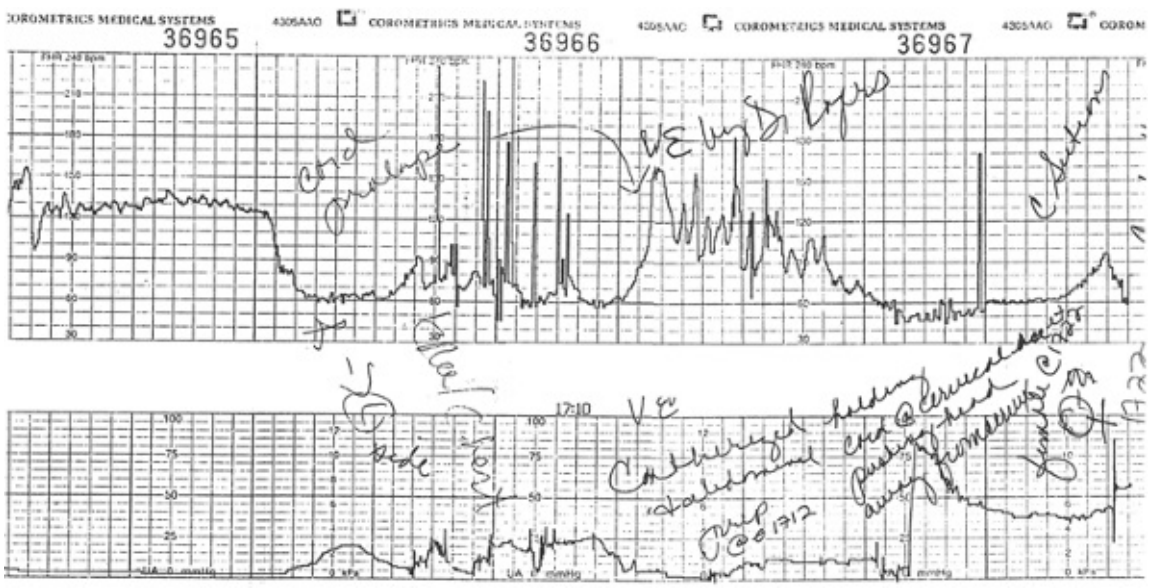

Figure 22.5 Fetal monitor tracing associated with umbilical cord prolapse.

True Knots

The reported incidence of true knots in the cord is 0.3% to 2.1% of births (excluding monoamniotic twins), the mean being about 1.0%. As is true of all cord accidents, true knots are more common if the cord is abnormally long. Ten percent of true knots occur in

cords >80 cm in length, and 3% of cords longer than 80 cm have true knots. However, many true knots must form early in pregnancy, as the incidence in aborted fetuses is 0.9%. True knots can be diagnosed only after delivery in the vast majority of cases, because unless the knot is pulled tight, there is no reduction of flow or increase in perfusion pressure, and thus no abnormality of the fetal heart rate or Doppler velocimetry. The patient with a tight knot will demonstrate a typical cord pattern of variable decelerations (Fig. 22.6) and will, of necessity, be managed like any other patient with fetal heart rate abnormalities. The Collaborative Study of Cerebral Palsy found no difference in 5-minute Apgar scores or neurologic abnormalities at age 1 year between controls and infants born with true knots in the cord. There is an association between true knots and antepartum stillbirths, however. About 4% to 5% of stillborns have true knots in the cord, compared with 1% of live-born infants.

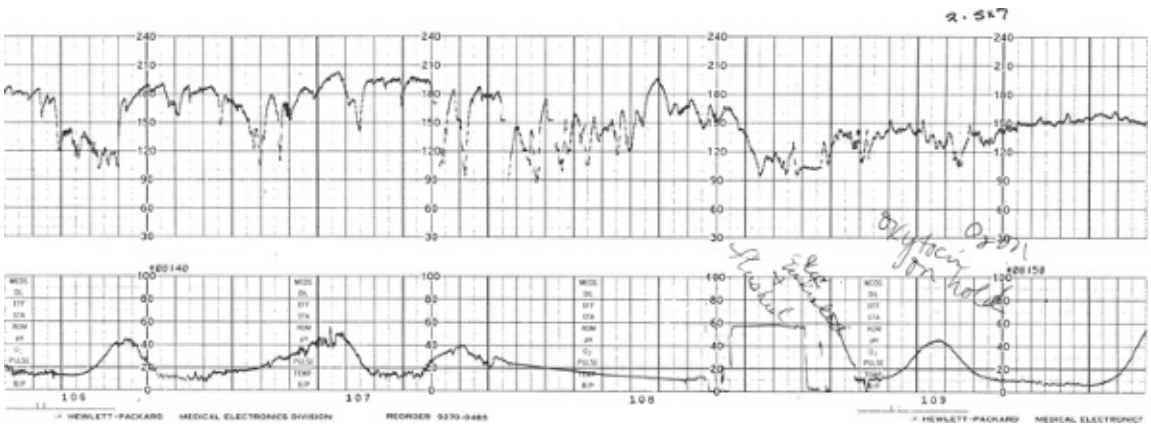

Figure 22.6 Monitor tracing of a fetus with a tight true knot in the umbilical cord.

Nuchal Cord

The incidence of loops of umbilical cord around the fetal neck is 33.7% of term infants at delivery, with 5.5% having two or more. In fact, 0.1% of fetuses have four or more loops of nuchal cord; the maximum reported number is nine. The incidence is 14% with short cords (<35 cm), 23% with normal length cords, and 53% with cords longer than 80 cm. There is no evidence that nuchal cords cause fetal death or significant fetal compromise. The Collaborative Study of Cerebral Palsy found no increase in the incidence of depressed 5-minute Apgar scores, perinatal mortality, or abnormal neonatal development among infants with nuchal cords. However, it did demonstrate reduced 1-minute Apgar scores in these infants. Although nuchal cords are at times diagnosed by ultrasound, the excellent outcome of these infants demonstrates that no alteration in management is indicated unless the fetus develops bona fide intolerance of labor.

Body Coils of Cord

The incidence of coils of umbilical cord around various parts of the fetal body other than

the neck is 0.5% to 2.0% and is more frequent with long cords. As with nuchal cords, body coils are not associated with any increase in low Apgar scores, perinatal mortality, or neonatal morbidity.

Giant Umbilical Cord

Giant umbilical cord is a rare malformation that usually is associated with a patent urachus (Fig. 22.7). The prenatal differential diagnosis includes abdominal wall defects, umbilical cord cysts, cystic expansion of the omphalomesenteric duct, and cystic degeneration of Wharton jelly. After delivery, the umbilical stump may detach spontaneously with leakage of urine occurring at the umbilicus. The authors recommend surgical consultation in the nursery.

Figure 22.7 Newborn with a giant, cystic umbilical cord and an unusually large umbilicus. (From Dr. Ricardo Pfister, with permission.)

Umbilical Cord Stricture

Umbilical cord stricture has been associated with fetal death, but the exact etiology remains unknown. Stricture occurs most frequently in the portion of the cord near the fetal insertion and cannot be reliably diagnosed prior to delivery. Pathologic examination of the umbilical cord should be performed after fetal death.

Umbilical Cord Coiling

The umbilical coiling index (UCI), the number of completed spirals per centimeter of cord length, varies progressively along the umbilical cord, with the most coiling noted at the fetal end. Hypocoiling of the cord, <0.07 spirals/cm, has been associated with an increased incidence of fetal death, small for gestational age infants, operative delivery for fetal intolerance of labor, fetal heart rate tracing abnormalities during labor, low Apgar scores at 5 minutes, spontaneous preterm delivery, aneuploidy, fetal anomalies, and chorioamnionitis. Hypercoiling of the umbilical cord, >0.3 spirals/cm, has been associated

with an increased incidence of fetal growth restriction, intrauterine fetal death, intrapartum fetal heart rate tracing abnormalities, umbilical pH <7.05, trisomies, vascular thrombosis, and stenosis of the umbilical cord. It is not clear whether hypo- and hypercoiling are the result or the cause of pathology or both. The clinical utility of antenatal ultrasonic evaluation of the UCI remains controversial.

Summary Points

- The singleton breech fetus at term should, except in very rare circumstances, be delivered by cesarean.
- The preterm singleton breech at 28 weeks gestation and beyond should be delivered by cesarean. There is no evidence about the optimal mode of delivery of the singleton breech at 24 to 27 weeks gestation.
- In the absence of contraindications, ECV should be attempted at term in singleton breech fetuses. At present, there is no role for ECV before term.
- Fetal anomalies and chromosome abnormalities are important causes of breech presentation. Likewise, fetuses that have sustained neurologic insults leading to cerebral palsy often present as breeches.
- Nearly all cases of face presentation and compound presentation should be managed expectantly and vaginal delivery anticipated. Persistent MP face, persistent brow, and essentially all cases of shoulder presentation should be delivered by cesarean.

Stillbirth and Intrauterine Fetal Demise

Robert M. Silver

Few obstetric complications are as emotionally devastating for families as antepartum stillbirth. Since the mid 20th century, there has been a tremendous decrease in the rate of stillbirth due to improved prevention and treatment of conditions such as diabetes, hypertension, and red cell alloimmunization. However, stillbirth rates have reached a plateau or have only modestly declined over the past several decades. This is in contrast to neonatal death rates, which continue to drop substantially. Currently, stillbirth after 20 weeks gestation affects over 1 in 200 pregnancies and is considerably more common than sudden infant death syndrome and intrapartum stillbirth in developed countries. Nonetheless, relatively more public attention and research have focused on infant rather than fetal mortality. Thus, fetal death remains a common, important, and poorly understood obstetric problem.

This chapter will review the nomenclature, epidemiology, causes, risk factors for, management of, and recurrence risk for stillbirth. Emphasis will be placed on clinically relevant issues, recent developments, and areas of controversy.

Terminology

The terminology of pregnancy loss can be confusing and often varies among and even within countries. Traditionally, abortions (or miscarriages) refer to pregnancy losses prior to 20 weeks gestation, while fetal deaths or stillbirths are used to describe losses after 20 weeks gestation. The threshold of 20 weeks is somewhat arbitrary, and it may be more useful to classify pregnancy losses by stages of gestational development. For example, pregnancy losses could be classified as pre-embryonic or anembryonic (conception to 5 weeks gestation), embryonic (6 to 9 weeks gestation), and fetal (after 10 weeks gestation) losses. In the past, anembryonic losses were termed *blighted ova*. This term is best avoided. Another approach would be to describe losses prior to 20 weeks gestation as early losses and those after 20 weeks gestation as late losses.

It is important to specify the timing in gestation and nature of pregnancy loss as accurately as possible. This can be difficult because death or failure of growth of the conceptus may precede clinical symptoms of miscarriage by days or weeks. Thus, ultrasound findings, histologic examination, and human chorionic gonadotropin (hCG) levels often are more

useful than clinical data when characterizing pregnancy losses. The etiologies of pregnancy losses vary over gestation. Genetic problems are more common in pre-embryonic or anembryonic losses, while antiphospholipid syndrome (APS) and heritable thrombophilias are more likely in losses after 10 weeks gestation. Also, the recurrence risk of pregnancy loss is influenced by gestational age. Pregnancy losses tend to recur at similar times during gestation, and in patients with recurrent pregnancy loss, those with fetal deaths after 10 weeks gestation have worse subsequent pregnancy outcomes than women with recurrent early losses.

Stillbirth often is defined as the death of a fetus after 20 completed weeks of gestation. In cases of uncertain gestational age, losses weighing >500 g are considered

stillbirths. However, others believe that a more useful definition would include death of a fetus past the age of viability. This has prompted the use of 24 or even 28 weeks gestation as a threshold for defining stillbirth. Another controversial issue is whether or not to include both antepartum and intrapartum deaths as stillbirths. Some but not all studies distinguish between the two. This is an important distinction, as causes and strategies to reduce antepartum and intrapartum losses are quite different. Intentional fetal death (e.g., pregnancy termination in the setting of fetal anomalies or preterm premature rupture of membranes) poses another problem for vital statistics. Pregnancy terminations often are excluded when counting stillbirths, but the issue remains controversial. It seems appropriate to exclude terminations as a distinct entity. However, in many cases, these fetuses would be stillborn if the pregnancy were allowed to continue. As such, their exclusion might alter the true impact of stillbirth on a population.

Epidemiology

In 2003, the stillbirth rate (after 20 weeks gestation) in the United States was 6.23 per 1,000 live births. This represents a slight and steady decline since 1990, when the rate was over 7.5 per 1,000 live births (Fig. 23.1). Just over one half of stillbirths in the United States occur between 20 and 27 weeks gestation. It is important to note that this may underestimate the true rate, as stillbirths are likely underreported. The scope of the problem is considerably higher in many parts of the world. Stillbirth rates are estimated to range from 5 per 1,000 births in rich countries to 32 per 1,000 births in southern Asia and sub-Saharan Africa. The estimated number of global stillbirths per year is 3.2 million.

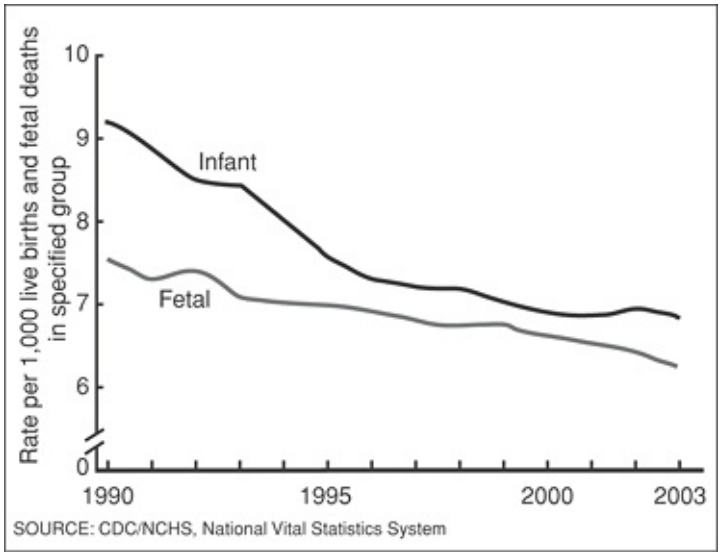

Figure 23.1 Thousands of fetal and infant deaths in the United States, 1990–1993. (MacDorman MF, Hoyert DL, Martin JA, et al. Fetal and perinatal mortality, United States, 2003. *Natl Vital Stat Rep* 2007;55:1–18.)

In the United States, stillbirth rates continue to be increased in non-Hispanic black women. In 2003, the fetal mortality rate for non-Hispanic blacks was 11.56 per 1,000 births compared with 4.94 per 1,000 births for non-Hispanic whites. Fetal mortality also is relatively higher for teenagers, unmarried women, and women over 35 years of age.

It is difficult to obtain an accurate estimate of the fetal death rate between 10 and 20 weeks gestation, because such data are not routinely collected. According to the National Survey of Family Growth, estimates of total fetal losses per year in the United States are about one million. The majority of these occur prior to 20 weeks gestation.

Classification

Numerous classification schemes have been used to catalog stillbirths based on etiology. This has proved difficult for several reasons. First, it often is difficult to be certain of a "cause" of death. Many risk factors such as diabetes, obesity, or heritable thrombophilias are associated with an increased risk of fetal death. However, the vast majority of women with these risk factors have live-born infants. Thus, it is difficult to be certain that these factors led to the stillbirth. Second, there may be more than one potential cause of stillbirth in the same patient. For example, what would be considered the etiology in a fetus with trisomy 18 that also has evidence of bacterial infection? Stillbirth may be due to the additive or interactive effects of several disorders. Finally, a cause of death often is never determined. In many cases, this is due to a lack of systematic evaluation into potential etiologies. However, a cause of death may not be found despite a comprehensive evaluation. This is especially true in cases of term stillbirth.

Because of these problems, no single classification scheme has been universally adopted, and new ones are being developed. Additional confusion arises from the use of different definitions for fetal death, the occasional inclusion of neonatal death, and different

standards regarding causes versus associations in the classification schemes. The Wigglesworth classification probably is in most widespread use today (Table 23.1). A problem with all of the classification systems is that many stillbirths remain unexplained. Recently, Gardosi and colleagues introduced a new system that explains a much larger proportion of fetal deaths than prior schemes (Table 23.2). However, many of the etiologies in the new system may be risk factors such as small-for-gestational-age fetus (SGA) rather than etiologies. Forthcoming international conferences hopefully will facilitate the development of uniform definitions and classification systems for fetal death.

TABLE 23.1 Wigglesworth Classification

1. Congenital defect/malformation (lethal or severe)
2. Unexplained antepartum fetal death
3. Death from intrapartum “asphyxia,” “anoxia,” or “trauma”
4. Immaturity
5. Infection
6. Death due to other specific causes
7. Death due to accident or nonintrapartum trauma
8. Sudden infant death, cause unknown
9. Unclassifiable

Hey EN, Lloyd DJ, Wigglesworth JS. Classifying perinatal death: fetal and neonatal factors. *Br J Obstet Gynaecol*, 1986;93(12):1213–1223.

Etiologies and Risk Factors

Fetal Conditions

Congenital Abnormalities

Genetic abnormalities and fetal malformations account for a significant proportion of stillbirths. Abnormal karyotypes are present in 6% to 12% of stillbirths after 20 weeks gestation. The rate of chromosomal abnormalities is considerably higher in first-trimester pregnancy losses and is probably intermediate in losses between 10 and 20 weeks gestation. This likely underestimates the true rate of chromosomal abnormalities, because karyotype is not always successfully obtained in cases of stillbirth. The odds of an abnormal karyotype are increased in the setting of fetal malformations, dysmorphic features, or SGA fetus. Conversely, the chances of an abnormal karyotype is low (about 2%) in stillbirths greater

than 20 weeks gestation with no apparent phenotypic abnormalities. The most common single abnormality in stillbirths is monosomy X (Fig. 23.2), occurring in 23% of cases with abnormal karyotype. Trisomies including 21, 18, and 13 also are common. This is in contrast to first-trimester losses, wherein trisomy 16 accounts for the majority of abnormalities.

Many fetuses have malformations or other congenital abnormalities without necessarily having chromosomal abnormalities. Up to 35% of stillborn infants undergoing perinatal autopsy have abnormalities including malformations, syndromes, and dysplasias. Approximately 25% of these will have an abnormal karyotype. However, it is likely that many of these fetuses have genetic abnormalities that are not identified by traditional karyotype.

Some fetuses may have microdeletions or additions that are too small to be identified by cytogenetics. Newer molecular genetic technology using a technique termed *comparative genomic hybridization* (CGH) may identify these smaller lesions. Similar abnormalities have been reported in cases of unexplained mental retardation with normal karyotype. Other cases of stillbirth are due to single gene mutations that require specific targeted assays for diagnosis. Many are autosomal recessive conditions such as glycogen storage diseases, hemoglobinopathies, and other metabolic disorders. There are probably several other single gene disorders responsible for some cases of stillbirth. Another potential genetic cause of pregnancy loss is confined placental

mosaicism. This refers to abnormal chromosomes in some or all of the placental tissue with normal fetal karyotype. In turn, this leads to abnormal placental function resulting in fetal growth impairment or death. Continued advancements in molecular genetic technology should enhance our ability to identify previously unrecognized genetic causes of stillbirth.

Infection

Infections are another biologically plausible, generally accepted cause of stillbirth, accounting for 10% to 25% of stillbirths in developed countries. The proportion of stillbirths due to infection (especially bacterial infection) is even higher in developing countries. It is important to be careful when attributing fetal death to infection. Mothers often have vaginal infection or colonization or systemic viral infections that may have nothing to do with a stillbirth. Fetal autopsy and placental histologic evaluation are extremely helpful in proving that infection truly is a cause of stillbirth. For example, positive cultures of group B streptococcus in fetal lungs is convincing evidence of causality, while positive maternal serology for cytomegalovirus (CMV) in a case with no evidence of infection on fetal autopsy is not.

Bacterial Infection

Bacterial infections implicated in stillbirth are most commonly due to ascending organisms from the genital tract. Bacteria such as *Escherichia coli*, *Klebsiella*, *Ureaplasma urealyticum*, *Mycoplasma hominus*, *Bacterioides* species, and group B streptococcus track from the vagina, through the cervix, and into the amniotic fluid, where they may be

swallowed by the fetus, sometimes leading to infection. Less commonly, bacteria such as *Listeria monocytogenes* can be hematogenously transmitted to the fetus. It is noteworthy that some organisms usually cause clinically apparent intra-amniotic infection, while other indolent organisms such as L. *monocytogenes* may cause vague symptoms that are difficult to diagnose. Although rare, fetal death also may occur because of severe systemic maternal infection. This is thought to be due to the propagation of inflammatory mediators leading to uterine ischemia, hypoxia, and preterm labor.

Viral Infections

The most common viral infection that has been linked to fetal death is parvovirus B19 (Fig. 23.3). This virus is trophic for erythrocyte precursors and myocardial cells. Death is thought to be caused by fetal anemia, hydrops, and/or myocardial dysfunction. Parvovirus is most likely to cause fetal death after infection in the first two trimesters. Late fetal death due to the virus is rare. The organism has been reported in up to 15% of cases of fetal death when polymerase chain reaction (PCR) was used to detect parvovirus nucleic acid in the fetus or placenta. However, parvovirus has been found in <1% of fetal deaths in series that did not systematically assess for the virus. The true proportion of fetal deaths due to parvovirus is likely somewhere in between these figures. Viruses are difficult to culture, and PCR

probably identifies cases that would have been otherwise missed. Conversely, finding viral nucleic acid in the fetus or placenta without histologic evidence of viral infection may be represent a false-positive result.

CMV is the most common fetal/neonatal viral infection. Although cases have been reported, CMV rarely causes stillbirth. Coxsackie A and B virsuses are associated with stillbirth. They appear to cause death through placental inflammation, myocarditis, and hydrops. Numerous other viruses may sporadically cause stillbirth, but none accounts for more than a handful of cases.

Other Infections

Other types of infection also may cause stillbirth. The risk of stillbirth from syphilis increases with advancing gestation as the responsible spirochete, *Treponema pallidum*, may cross the placenta and directly infect the fetus. Syphilis is a major cause of fetal death in developing countries and persists in some parts of the United States. Infections such as malaria, syphilis, and toxoplasmosis account for an important number of stillbirths in endemic areas. As with viruses, numerous other spirochetes and other organisms cause sporadic stillbirth.

Small-for-Gestational-Age Fetus

SGA fetus is a major risk factor for fetal death. The risk for stillbirth increases with decreasing birth-weight percentile and likely occurs through several mechanisms, including an increased risk of genetic abnormalities, placental insufficiency, and other factors. It is important to recognize that SGA is a risk factor rather than a cause of fetal death. Indeed, the vast majority of SGA fetuses are constitutionally small (healthy fetuses in the lower 10% for weight). Also, intrauterine growth restriction (IUGR), rather than SGA, is associated with stillbirth. However, it often is difficult to determine whether a fetus is growth restricted. This implies a downward inflection in the rate of fetal growth, which requires serial measurements that are not available for many pregnancies. Second, population-based growth curves or percentiles for fetal weight do not account for an individual fetsus's inherent growth potential. For example, a 6-pound infant may be growth restricted if its siblings all weighed 8 pounds at birth.

Nonetheless, SGA is a strong risk factor for fetal death. Also, the smaller the birth weight for gestational age, the higher the risk for fetal death. This dose-response curve provides robust evidence that SGA is a meaningful risk factor for stillbirth. The use of customized rather than population-based growth curves attempts to account for individual growth potential. A Swedish study using such growth curves noted an odds ratio for stillbirth of 6.1 (95% confidence interval [CI] 0.8 to 1.9) for SGA compared with average-for-gestational-age (AGA) fetuses. Umbilical artery Doppler velocimetry (or other antenatal surveillance) may help to distinguish between SGA fetuses that are constitutionally small and those at risk for stillbirth.

Maternal Conditions

Demographics

Race is one of the strongest risk factors for stillbirth. Non-Hispanic blacks have stillbirth rates that are over double that of non-Hispanic whites. The increase in the risk for fetal death persists, even when factors such as access to prenatal care are accounted for. In part, this may be due to relatively higher rates of medical and obstetric complications in blacks. However, other factors likely play a role as well. Approximately two thirds of the excess mortality in blacks occurs at 20 to 27 weeks gestation and one third at 28 weeks or more.

Advanced maternal age (>35 years of age) is associated with a progressive increase in the risk for stillbirth. In one population-based study, compared to women 20 to 34 years of age, the odds ratio for stillbirth in women 35 to 39 years of age was 1.28 (95% CI 1.24 to 1.32). It was 1.72 (95% CI 1.6 to 1.81) for those >40 years of age. Maternal age ≥35 years of age is an independent risk factor for stillbirth, even after adjusting for potential confounding variables such as genetic abnormalities or underlying medical conditions. This is of increasing concern, as a larger proportion of pregnancies are occurring in women ≥35 years of age.

Another risk factor for stillbirth that is increasing in frequency is obesity. Most studies have reported at least a twofold increase in the risk of fetal death in women with a body mass index (BMI) ≥30. A recent study of 25,000 women noted an odds ratio of 2.8 (95% CI 1.5 to 5.3) for stillbirth in women with BMIs ≥30 compared with a normal BMI of 18.5–24.9. Obese women have an increased risk for many other conditions such as diabetes and hypertension, which are known to be associated with stillbirth. However, after controlling for comorbidities, age, smoking, and other potential confounders, the adjusted odds ratio for stillbirth in obese women was 3.1 (95% CI 1.6 to 5.9).

There are several other maternal risk factors for stillbirth. Some but not all studies have reported an increased stillbirth risk in women with prior cesarean deliveries. Another risk factor is abnormal levels of maternal serum markers in cases with normal fetal karyotype. For example, low concentrations of pregnancy-associated plasma protein A in the first trimester and elevated maternal serum alpha-fetoprotein in the second trimester are associated with an increased risk of placental insufficiency and stillbirth. An excellent summary of available epidemiologic literature regarding risk factors for stillbirth is shown in Table 23.3.

Medical Disorders

Maternal medical diseases are estimated to contribute to 10% of fetal deaths. It is difficult to be certain as to whether these conditions are causes or risk factors for stillbirth, because most affected women do not have stillbirths. Also, medical and obstetric management can have a dramatic influence on pregnancy outcome in women with these conditions. Examples include the tremendous decrease in perinatal mortality due to diabetes and hypertension over the past 50 years.

TABLE 23.3 Estimates of Maternal Risk Factors and Risk of Stillbirth

Condition	Prevalence (%)	Estimated Rate of Stillbirth (Per Thousand)	Odds Ratio[a]
All pregnancies	—	6.4	1.0
Low-risk pregnancies	80	4.0–5.5	0.86
Hypertensive disorder			
Chronic hypertension	6–10	6–25	1.5–2.7
Pregnancy-induced hypertension			
Mild	5.8–7.7	9–51	1.2–4.0
Severe	1.3–3.3	12–29	1.8–4.4
Diabetes			
Treated with diet	2.5–5.0	6–10	1.2–2.2
Treated with insulin	2.4	6–35	1.7–7.0
SLE	<1	40–50	6–20
Renal disease	<1	15–200	2.2–30

Thyroid disorders	0.2–2.0	12–20	2.2–3.0
Thrombophilia	1–5	18–40	2.8–5.0
Cholestatis of pregnancy	<0.1	12–30	1.8–4.4
Smoking >10 cigarettes	10–20	10–15	1.7–3.0
Obesity (prepregnancy)			
BMI 25.0–29.9 kg/m^2	21	12–15	1.9–2.7
BMI >30	20	13–18	2.1–2.8
Low education attainment (<12 y vs. 12 y+)	30	10–13	1.6–2.0
Previous growth-restricted infant (<10%)	6.7	12–30	2.0–4.6
Previous stillbirth	0.5–1.0	9–20	1.4–3.2
Multiple gestation	2–3.5	—	—
Twins	2.7	12	1.0–2.8
Triplets	0.14	34	2.8–3.7

Advanced maternal age (reference <35 y)			
35–39 y	15–18	11–14	1.8–2.2
40 y+	2	11–21	1.8–3.3
Black women compared with white women	15	12–14	2.0–2.2

SLE, systemic lupus erythematosus; BMI, body mass index.
[a]Odds ratio of the factor present compared with the risk factor absent.

APS poses a very high risk (up to 70%) for fetal death in untreated women. This autoimmune condition is characterized by specified levels of antiphospholipid antibodies and clinical features such as fetal death, recurrent pregnancy loss, and thrombosis. Although many antiphospholipid antibodies have been described, the ones best characterized and in most common clinical use are lupus anticoagulant, anticardiolipin antibodies, and anti-ß2-glycoprotein-I antibodies. Fetal death is thought to occur due to thrombosis in the uteroplacental circulation, leading to infarction, necrosis, and in severe cases, death (Fig. 23.4). Thromboprophylaxis with heparin or low-molecular-weight heparin appears to decrease perinatal morbidity and mortality in women with APS.

Diabetes also is strongly associated with an increased risk for fetal death. Even with modern care, the risk of stillbirth is increased 2.5- to 4.0-fold in women with diabetes. A recent British study noted that the risk of fetal death was similar in women with type 1 and type 2 diabetes. In contrast, gestational diabetes does not confer an increased risk for fetal death. The risk of stillbirth associated with diabetes persists after controlling for congenital abnormalities and comorbidities such as hypertension and obesity. The mechanism of fetal death is uncertain but seems to be related to maternal hyperglycemia as well as abnormal fetal growth and possibly acidosis. Treatment with insulin during pregnancy has been convincingly shown to reduce the risk of stillbirth.

Many other medical conditions such as hypertension, renal disease, thyroid disease, cardiovascular disease, asthma, and systemic lupus erythematosus (SLE) are associated with an increased risk for fetal death. In general, stillbirth attributed to these conditions occurs in the setting of severe, clinically obvious disease. It is uncertain whether

asymptomatic or mild disease (e.g., biochemical abnormal thyroid function or glucose intolerance) increases the risk for fetal death. If so, the attributable risk likely is small.

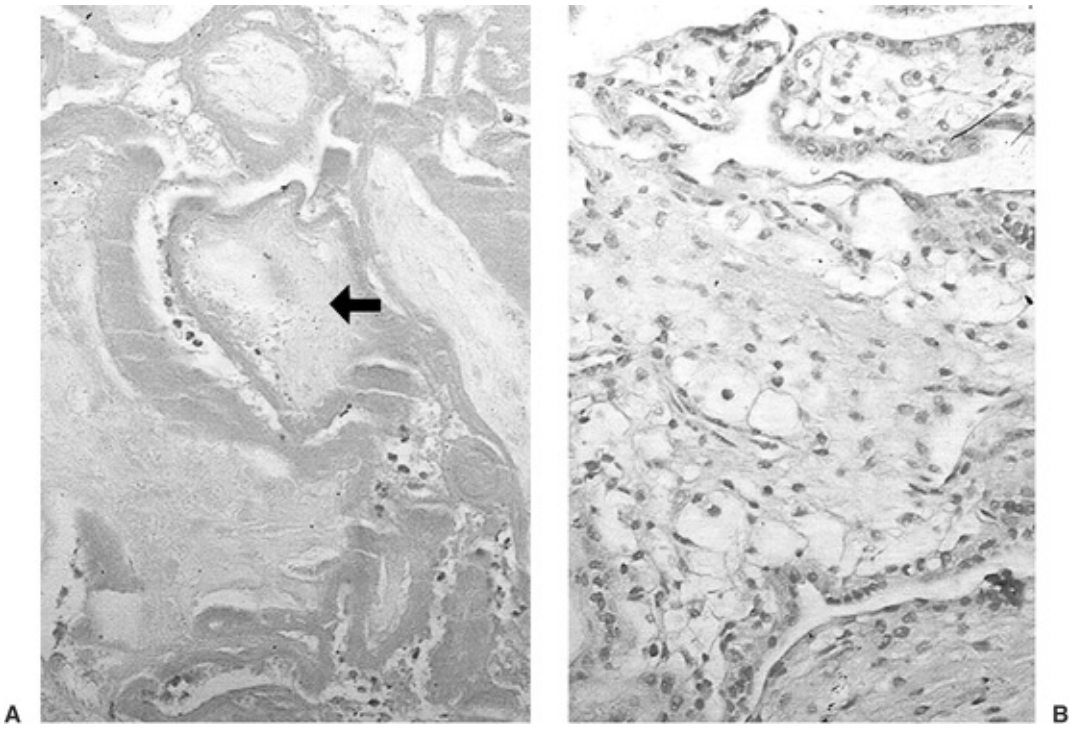

Figure 23.4 Placenta demonstrating villous infarction from a case of second trimester fetal death in a patent with APS shown on the left. Normal placenta is shown on the right for comparison. (Reprinted with permission from Silver RM. Fetal death. Obstet Gynecol 2007; 109:153–167.)

Intrahepatic cholestasis of pregnancy also is associated with stillbirth. The mechanism of fetal death is uncertain but may involve deposits of bile salts in the placenta. Stillbirth in women with cholestasis of pregnancy is particularly worrisome because they have been reported despite normal antenatal testing.

Exposures

Several maternal exposures have been associated with an increased risk for fetal death. Since most women with exposures do not suffer stillbirth, these should (in most cases) be considered risk factors rather than etiologies. The most common exposure is smoking, which increases the risk for stillbirth by 1.5-fold. The mechanism of fetal death is uncertain but may include an increase in fetal carboxyhemoglobin leading to vascular resistance and hypoxia as well as abruption. It is noteworthy that the risk of stillbirth can be reduced to the same as for nonsmokers in women who stop smoking after the first trimester.

Pesticides and other environmental exposures have been proposed as a potential cause of stillbirth. This possibility is of great concern but is hard to study because it is difficult to quantify the true level of exposure. The same is true for medications. Exposures probably

do not contribute to a meaningful proportion of fetal deaths.

Substance abuse is associated with many comorbidities and risk factors such as infection and low socioeconomic status, making it difficult to determine the isolated effect of the exposure on stillbirth. The recreational drug that most generally is accepted as increasing the risk for stillbirth is cocaine. Indeed, in cases of abruption associated with cocaine, it is likely causative. In contrast, methamphetamines have not been associated with fetal death (to date) despite having some of the same physiologic effects as cocaine. Despite the risk of fetal alcohol syndrome, it is unclear whether or not alcohol increases the risk of fetal death. Marijuana and heroin use have not been associated with stillbirth, although abrupt narcotic withdrawal may pose a theoretical risk.

Thrombophilias
