Nonsurgical Treatment of Pelvic Organ Prolapse

Ingrid E. Nygaard

While surgery is considered the primary treatment for pelvic organ prolapse (POP), pessaries have been used to reduce prolapse for centuries and continue to fill an important niche in treating this disorder. Additionally, there is some, albeit scant, evidence that pelvic muscle exercises may hinder prolapse regression.

In 2001, 86% of American gynecologists queried prescribed pessaries, though most received minimal training in this area in their residencies. Further, 77% of American Urogynecologic Society members responding to a questionnaire about pessary use reported using them as first-line therapy for prolapse; 12% used pessaries only when surgery was contraindicated.

Some patients choose to wear a pessary as primary therapy for POP, while others use one temporarily when awaiting surgery. For some women, the option of a pessary allows flexibility in scheduling surgery. Others may wear a pessary only when doing an activity that exacerbates symptoms such as exercise.

A pessary may useful diagnostically. Patients generally have a variety of symptoms that may or may not be related to POP. By reducing the bulge for several days with a pessary, the patient and clinician get clues about whether reducing the prolapse surgically is likely to resolve symptoms that the patient may have, such as pelvic and back pain, urinary urgency and frequency, or voiding dysfunction. This may improve the chance that the patient has reasonable expectations of what surgery can and cannot “fix.”

Limited data from a small study by Handa suggest that wearing a pessary may have a therapeutic effect in women with POP: 19 of 56 women fitted with a pessary continued its use for at least 1 year. Four women had an improvement in stage of prolapse, and no women had worsening.

Choosing a Pessary

Today's pessaries are made from medical-grade silicone, which is not allergenic or toxic, does not absorb odors, can be sterilized, and lasts for several years.

Some pessaries are easier for a woman to manage herself than are others. Pessaries can be loosely grouped into supportive pessaries, in which levator muscle tone is needed to keep the pessary in place (Fig. 50.1), or space occupying pessaries (Fig. 50.2), which, as their

name implies, keep prolapse reduced by filling the vagina. Space-occupying pessaries are particularly useful for women with advanced POP who have minimal levator muscle tone and wide genital hiatuses.

Wu found that 70% of women with POP were successfully fitted with a size 3, 4, or 5 ring pessary. Pott-Grinstein also reported that the ring and donut pessaries were the most common pessaries used. In contrast, Sulak fitted 96 of 107 women with symptomatic POP with a Gellhorn pessary and gave the following reasons why they chose this pessary: the design makes it easy to insert and remove, the base of the pessary is large enough to support the proximal prolapse without exerting excessive pressure in any particular area, the concave base provides suction, and this pessary can be removed by the patient "with minimal discomfort."

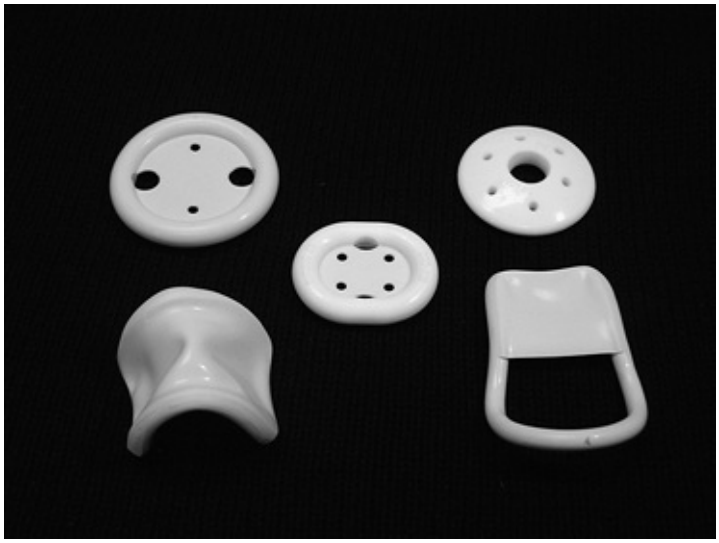

Figure 50.1 Support pessaries used to treat POP. **Top:** Ring with support (Milex Inc, Chicago, IL) **(left)**, Shaatz (Mentor Corporation, Santa Barbara, CA) **(right)**. **Middle:** Oval with support (Mentor Corporation, Santa Barbara, CA). **Bottom:** Gehrung (Milex Inc, Chicago, IL) **(left)**, Hodge (Milex Inc, Chicago, IL) **(right)**.

Most women can be fit successfully. In a prospective cohort study by Clemons and associates, 94 of 100 women with POP were fitted successfully in the office, while two women had pain and four expelled all pessaries tried. Clinicians tried an average of 2.2 pessaries per patient to achieve the best fit. The strategy of the clinic was to try a ring pessary with support first, followed by a Gellhorn if the ring was expelled. One week later, 54% of women were satisfied with the pessary, but it was expelled in 29% and caused pain or discomfort in 17%. Of the dissatisfied women, 29 were refit, 76% successfully. Overall, 73% of women had a successful 2-week pessary fitting trial. Women with a vaginal length of ≤6 cm and those with a wide introitus (four fingerbreadths wide or greater) had a lower chance of being successfully fitted. Ring pessaries with support were used in 100% of women with stage II prolapse and 71% of women with stage III prolapse. Gellhorn pessaries were used in 64% of women with stage IV prolapse.

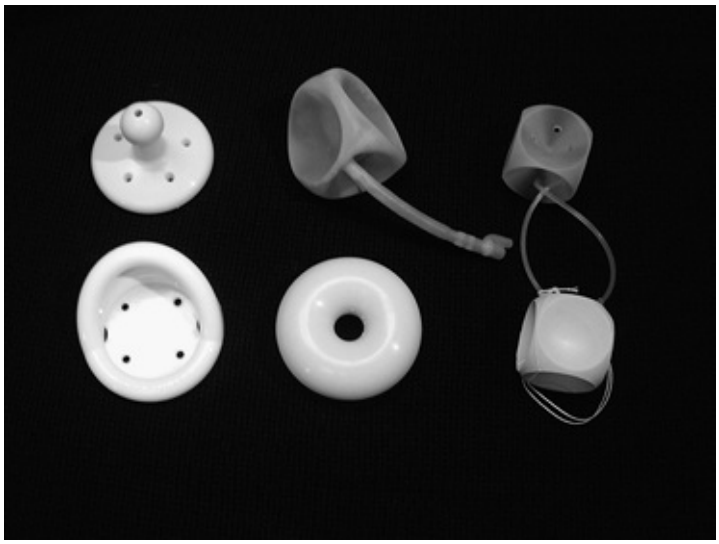

Figure 50.2 Space-occupying pessaries used to treat POP. **Top:** Gellhorn (Mentor Corporation, Santa Barbara, CA) **(left)**, Inflataball (Milex Inc, Chicago, IL) **(middle)**, cube with drainage holes (Mentor Corporation, Santa Barbara, CA) **(right)**. **Bottom:** Mar-Land **(left)**, doughnut **(middle)**, cube **(right)** (all three by Milex Inc, Chicago, IL).

Cundiff and colleagues conducted a randomized crossover design in which women with stages II or greater POP were initially randomly assigned to be fitted with a ring or a Gellhorn pessary and then 3 months later crossed over to the other type. In the first randomization, 71 and 63 women were assigned to the ring and Gellhorn pessary groups, respectively. In the ring group, 65 (92%) were fitted successfully, 51 at the initial visit and 14 after refitting. In the Gellhorn group, 57 (90%) were fitted successfully, 36 at the initial visit and 21 after refitting.

Thus, randomized trial evidence suggests that clinicians can successfully fit most women with either a ring or Gellhorn pessary. In our clinical experience, women find it easier to manage a ring pessary on their own than the Gellhorn.

Pessary Care

Before a pessary fitting session, the author treats women who demonstrate vaginal atrophy for 6 weeks with estrogen cream. The women are then instructed to come to the fitting session with a moderately full bladder so that it can be seen that the pessary induces stress incontinence and to ensure that the woman can void with it in place.

The author recommends that women remove the pessary at least weekly, leave it out overnight, and then reinsert in the morning. When removed, the pessary is simply washed with warm water. As seen by experience, women rarely develop excessive or foul-smelling vaginal discharge if they remove the pessary at this interval and thus have little use for creams other than occasionally estrogen. If women are unwilling or unable to remove the pessary, an attempt is made to estimate the best interval for office or visiting nurse visits for pessary removals. Women are examined 2 weeks after initial pessary insertion. If discharge is minimal and no erosions are present, the patient is examined at 4 weeks.

Similarly, if the examination is reassuring, the patient is examined again after 6 weeks and so on. The appropriate pessary interval is either a maximum of 3 months or the interval at which foul-smelling discharge or early erosion is seen.

Visiting nurses are a valuable resource for women who are unable to care for the pessary on their own. They are often able to visit the woman at home, remove the pessary in the evening, and return in the morning to replace it. The nurse can arrange follow-up if she sees excessive foul-smelling discharge or bleeding.

After an initial 2-week and 3-month check, the author examines women who manage their own pessary without difficulty on a yearly basis. (In premenopausal women,

women are generally seen only once after fitting and then yearly.) In those unable to remove the pessary themselves, the vagina is inspected visually at least twice yearly. It is important to examine the anterior and posterior vaginal walls during the examination (by turning the speculum 90 degrees) as well as the obvious lateral walls that are visible when the speculum is placed in the usual fashion. Several women have been seen with large rectovaginal or vesicovaginal fistulas caused by pessaries; in all cases, they were undergoing regular examinations by a physician. It is possible that unseen erosions under the speculum blades may have heralded the beginnings of such pressure ulcers.

Effectiveness of Pessaries in Treating Prolapse

Effectiveness of pessaries is usually described as either continued use or by reduced symptoms. In two separate studies by Wu and Sulak, each with about 100 women, 41% and 49% were still using the pessary a year or more later. Wu identified no clear factors that correlated with unsuccessful pessary use. Others reported that previous hysterectomy and previous prolapse surgery decreased the chance of success. However, a large enough number of women with prior surgeries were able to use a pessary successfully for several years to warrant trying this modality in women with this history.

Almost all women wearing a pessary for symptomatic POP report that the sensation of a bulge resolves; symptoms of pressure, discharge, splinting, urge incontinence, and voiding difficulty improve; and prolapse-specific quality of life improves.

Adverse Events

In Wu's series, in which pessaries were generally kept in situ for 3 months at a time, 8 of the 110 women developed vaginal erosions. Five were using a cube, and 3 others were using a ring pessary. Overall, 5 of 6 women using cube pessaries developed vaginal erosions, compared with 3 of 101 using ring pessaries. Ten women had pelvic pain with the pessary in place; 3 were using cube pessaries and 7 were using ring pessaries. Only 2 women discontinued pessary use because of discharge, while 1 did so because of difficulty evacuating the rectum. This study highlights the need for extra caution when using a cube pessary. The suction cups on each side of the cube allow this pessary to stay in when other pessaries fall out, but the same suction cups can cause significant ulceration in the vagina. The author has seen several postmenopausal women who developed large, weeping ulcers

after wearing the cube pessary for only 2 or 3 days. Anecdotally, some colleagues have not had similar experiences; however, based on the author's observation, the use of this type of pessary is now reserved for women with healthy vaginal tissue who are able to remove it nightly. Patients and clinicians must take care to release the suction by sweeping a finger between the pessary and the upper vaginal wall before attempting removal.

In the Clemons study, 6 of 73 women (8%) using a pessary discontinued it before 2 months because of severe stress incontinence (4 women), de novo voiding difficulty (1 woman), and de novo defecation difficulty (1 woman). Two women developed vaginal erosions that subsequently resolved with daily vaginal estrogen cream and continued pessary use.

Pelvic Muscle Exercises

In a 2006 Cochrane review by Hagen and associates, the authors found three trials that assessed the role of pelvic muscle exercises in treating prolapse. However, the trials were either very small or had substantial limitations that preclude the ability to draw any conclusions. Future research is needed to understand what role, if any, pelvic muscle exercises play in preventing or treating primary or recurrent POP.

Conclusion

Pessaries are an important part of the treatment armamentarium for POP. However, they are not without risk, and women using pessaries must be followed carefully. Whether pelvic muscle strengthening can prevent or retard prolapse progression must be studied in carefully designed trials.

Summary Points

- Most women with POP can be successfully fitted with a ring or Gellhorn pessary.
- One year after fitting, about half of women continue to use a pessary.
- While rare, pessaries can cause serious harm, and women using them must be followed closely.
- Data are insufficient to understand what role pelvic muscle strengthening may play in preventing or treating POP.

Female Urinary Incontinence: Epidemiology and Evaluation

Peggy A. Norton

Epidemiology of Urinary Incontinence

Urinary incontinence (UI) is a common problem in women that affects quality of life and results in over $16 billion in direct medical costs annually in the United States (1995 figures). UI can be surveyed by using standardized questionnaires, which have been used to estimate the prevalence of UI in the general population and in affected women seeking treatment. Unfortunately, severity of UI is not always correlated with level of bother: one woman may leak several times a day and not be bothered at all, while another would report an occasional leak as having severe impact on her quality of life. Thus, some measure of bother is considered when reporting UI.

Definitions

Rates vary in populations because of differences in definition, but good standardization with regular updates has been provided by the International Continence Society (ICS) for more than 20 years. The ICS has the following definitions for UI:

Urinary incontinence: the complaint of any involuntary urine leakage. The main types in women are stress, urge, and mixed.

Stress urinary incontinence (SUI): the complaint of involuntary leakage associated with effort or exertion or on coughing or sneezing. If the incontinence is diagnosed on urodynamic testing, this is termed *urodynamic stress incontinence* (USI).

Urge urinary incontinence (UUI): the complaint of involuntary loss of urine accompanied by or immediately proceeded by urgency. If the incontinence is diagnosed on urodynamic testing with increased detrusor pressures reproducing symptoms during filling, the diagnosis is *detrusor overactivity with incontinence* (DOI.) Because some women are bothered by frequency, nocturia, and urgency but do not actually leak urine with urge, a broader term, *overactive bladder*, may incorporate all of these symptoms.

Mixed incontinence: the presence of both stress and urge incontinence in the same patient.

Prevalence

The prevalence of any UI in community-dwelling women ranges from 10% to 40%; while this seems surprisingly high, women with UI often underreport or delay seeking treatment for UI for several years after the condition has become bothersome. Approximately one in four women with UI is considered to have “severe” UI: in studies that

differentiate “any” UI from “severe” UI, the prevalence is 29% (11% to 72%) versus 7% (3% to 17%), respectively. In institutional-dwelling adults, the prevalence of UI is 50% or higher. Overall, half of women with UI complain of pure SUI, 30% to 40% complain of mixed urinary incontinence (MUI), and 10% to 20% complain of pure UUI. However, these proportions vary with age: middle-age women complain of SUI, while MUI predominates in older women.

Incidence and Regression

It was thought previously that UI was a progressive condition, but some recent reports have highlighted the fact that a certain number of women develop UI and a certain number resolve UI at any given time. It is less known whether the resolution of UI is a direct result of effective medical and surgical intervention or due to the waxing and waning of UI in any single woman. Why would UI resolve in the absence of treatment? It may be that some modifying factor has improved, such as weight loss or change in job, or that the natural history of UI is variable in its severity.

Risk Factors

Most of the studies of risk factors have involved cross-sectional studies, with the best-studied factors being parity, age, and obesity. Specific risk factors for UI type are more developed for SUI (all of those mentioned), but risks for urge incontinence may include childbirth and obesity.

Pregnancy and childbirth are the most significant risk factors: half of all women experience UI increases during pregnancy, and leakage both before and during pregnancy seems to be associated with parity, age, and body mass index (BMI). Multiple studies demonstrate that episiotomy is not protective. Current epidemiologic studies suggest that cesarean delivery is somewhat but not completely protective. Although some UI resolves during the postpartum period, women who still experience UI at 3 months postpartum are likely to be incontinent 5 years later. Increasing parity and birth weight may be additive, but there is conflicting data in the literature.

Most epidemiologic studies demonstrate that increasing age is associated with increasing UI, but surprisingly, the highest prevalence of UI peaks first at age 50 years (Fig. 51.1). SUI predominates in middle-age women, but urge incontinence increases with age. This is not to say that UI is a normal part of aging; rather, factors that contribute to UI are increased with age as well. Obesity defined as >20% over ideal weight or BMI >30 is a risk factor for both urge and stress incontinence, the mechanism in stress being increases in intra-abdominal pressure. UUI is also increased in women with obesity.

Several recent studies in differing populations indicate that family history of UI in first-degree relatives increases the risk of UI four to six times for individual women. Sexual abuse has been identified recently as an important contributor to overactive bladder symptoms.

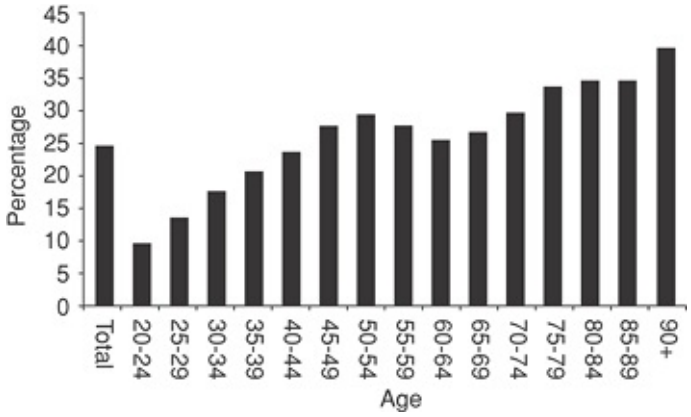

Figure 51.1 Prevalence of any UI by age from the Norwegian EPINCONT study. (From Hannestad YS, Rortveit G, Sandvik H, et al. A community-based epidemiological survey of female urinary incontinence: the Norwegian EPINCONT study. *J Clin Epidemiol* 2000;53:1150–1157, with permission.)

It is less clear whether UI is affected by the menopause and hysterectomy, and there is conflicting evidence as to the role of estrogen replacement. Other risk factors include functional and cognitive impairment, constipation, smoking, and pelvic organ prolapse.

Prevention

Some of the mentioned risk factors are potentially modifiable. Weight loss has been shown to reduce the severity of UI in women with BMI >30. With increasing request for cesarean delivery, more information is needed as to whether cesarean performed solely to prevent pelvic floor damage is really effective in defined patient populations. Few studies of primary prevention of UI have been undertaken, but women with a family history of UI may be an ideal group to study with regard to childbirth interventions such as elective cesarean. Smoking cessation and resolution of constipation have general benefits in addition to possibly preventing UI.

Evaluation of Urinary Incontinence

UI is so common that evaluation and treatment cannot be limited to specialists and subspecialists. UI continues to be embarrassing for some women to report, and this leads to delay and underreporting of symptoms to health care providers. Most of the basic evaluation of UI is within the scope of primary care providers, and many first-line treatments are readily available without specialized instructions or training. The main role of the primary care provider in basic evaluation of UI is to arrive at a presumptive

diagnosis and to exclude complicating factors that would necessitate referral for a more complex evaluation. Thus, a woman

complaining of UI may undergo basic triage by any interested clinician, who may be able to arrive at some initial treatment options or who may decide that more complex evaluation is needed.

Basic Evaluation

Most UI is diagnosed on history alone, with lesser contributions from the exam or testing. It has been argued that a simple questionnaire to evaluate UI subtypes and a review of potentially complicating factors is all that is required of the primary care provider. Several such questionnaires are included in Table 51.1.

History

The history is the most important basic evaluation of UI in women and focuses on the type and desire for treatment. Important questions include the frequency of UI episodes; the degree of bother; stress versus urge symptoms; and relationships to medications, voiding habits, or fluid intake.

Reversible causes of UI should be explored, including medications, comorbidities, stool impaction, or acute urinary tract infection (UTI). Pharmacologic agents that contribute to incontinence are listed in Table 51.2. Conditions such as poorly controlled diabetes mellitus or diabetes insipidus may result in excess urine output, thus overwhelming the normal continence mechanism. Gastroesophageal reflux disease (GERD) can lead to a chronic cough. Stool impaction distends the distal sigmoid and rectum and inhibits sacral parasympathetics, resulting in inadequate detrusor contractility and compromised bladder emptying.

TABLE 51.1 Questionnaires for the Evaluation of Urinary Incontinence

Sandvik Incontinence Severity Index: Sandvik et al 1995

1. Do you lose urine during sudden physical exertion, lifting, coughing or sneezing?
2. Do you experience such a strong and sudden urge to void that you leak before reaching the toilet?
   (1) SUI: 0.66 sensitive, 0.88 specific for SUI. (2) UUI: sensitive, 0.96 specific for UUI. (1) and (2) MUI: 0.84 sensitive, 0.66 specific for MUI.

31Q: Brown et al 2000

1. During the past month, have you leaked urine (even a small amount?)
2. id you (a) leak urine when you were performing some physical activity such as coughing, sneezing, lifting, or exercise? (b) when you had the urge or feeling that you needed to empty your bladder but you could not get to the toilet fast enough? (c) without physical activity and without a sense of urgency?
3. Did you leak urine most often with a, b, c, or equally a and b?

(a) SUI, 0.86 sensitive, 0.60 specific for SUI; (b) UUI, 0.75 sensitive, 0.77 specific for UUI; (c) unclear incontinence; (a) and (b) MUI.

TABLE 51.2 Medications Affecting Bladder Function, Type of Urinary Incontinence Associated with the Drug, and Presumed Mechanism

ACE-inhibitors	SUI: produce chronic cough in 15% of women
Alpha-blockers	SUI: decrease urethral tone
Anticholinergics	Voiding problems: reduce bladder contraclility
Diuretics	UUI: rapid bladder filling and fluid overload to bladder
Lithium	UI: causes excess fluid
Sedatives	Voiding problems: produces overflow incontinence

UI urinary incontinence; SUI stress urinary incontinence; UUI urge urinary incontinence

Acute UTI usually presents with typical symptoms of dysuria, frequency, and urgency but sometimes with urge incontinence. Asymptomatic bacteriuria detected in a woman undergoing evaluation for UI is a management dilemma: if the urge incontinence is a symptom of UTI, then the primary care physician should treat the infection and evaluate for improvement in UI. But asymptomatic bacteriuria otherwise is not treated in women unless they are pregnant, and in truth, few individuals see dramatic resolution of their UI with a course of antibiotics.

A relatively full bladder increases the likelihood of urine loss and decreases bladder control. However, many women drink excessive amounts of fluid in an effort to treat constipation, incontinence, or bladder infections or for weight loss. The Food and Drug Administration (FDA) recommends that in the absence of other factors, normal fluid intake for adults should be the equivalent of six to eight 8-oz glasses of fluid per day, much of which can be in the form of solid food. Urine output in excess of the normal 1,300 to 1,500 mL may lead to frequency, urgency, or UI.

The primary care physician should screen for the presence of these exacerbating or reversible factors, and in fact, most women presenting with a complaint of UI will have few or none of these issues. When such factors are present and are beyond the scope of the primary care physician, these patients should be referred for a complex evaluation with a specialist or subspecialist.

Exam

The physical exam is somewhat less helpful in the evaluation of UI compared with the history, but essential elements include visualization of urine loss *per urethrum*, confirmation of history, and exclusion of UTI or hematuria. Pelvic organ prolapse and vaginal atrophy are modifiable physical

findings that when treated may affect continence. Evidence of vaginal atrophy may be seen in loss of rugae or urethral caruncle. The strength of the pelvic floor muscles (pubococcygeus muscles) should be assessed during the bimanual examination. The patient should be able to voluntarily contract the muscles around the examining fingers and sustain the contraction for several seconds. Patients can be categorized those with good pelvic floor strength who would benefit from skill training, those with poor pelvic floor muscular strength who would benefit from strength training, or those with absent (possibly denervated) pelvic floor musculature who need further assessment. SUI should be demonstrated as leakage *per urethrum*, asking the patient to cough vigorously while the clinician watches for leakage of urine. This can be done in the standing position over a disposable absorbent pad, and/or in the supine position with the cautious examiner directly observing the urethra. Women who demonstrate urine leakage in the supine position with an empty bladder relatively are thought to be at increased risk of having a severe degree of stress incontinence. The bimanual examination should evaluate for pelvic mass and should include a rectal examination to check anal sphincter tone and, for fecal impaction, the presence of occult blood or rectal masses.

Tests

Some tests to consider in a basic UI evaluation include a frequency/volume diary, urinalysis, possible postvoid residual (PVR), and possibly simple cystometry.

The frequency/volume chart or bladder diary is the simplest and most important initial evaluation tool. These charts may recorded over 2 to 3 days, may record intake and output, and may allow the clinician to distinguish women who void 2 to 3 oz from the women who void 20 oz at time. Both groups of women may complain of urgency and urge incontinence, but the recommended treatments will be different. Both groups should have normal voided volumes of 7 to 10 oz without incontinence, but the former need bladder retraining and anticholinergic medications while the latter need to reducing voided volumes, possibly by normalizing fluid intake and urine output ("normal" is 50 to 70 oz intake and 40 to 50 oz output). Other simple tests include evaluation for UTI, assessment of PVR by catheterization or ultrasound, and simple cystometry. For clinical purposes, a PVR <50 mL is considered normal, while >200 mL is considered abnormal. In older women, residuals <100 mL are considered normal.

Any clinician may perform cystometry (measurement of bladder pressure during filling). The test is not required for diagnosis and initiation of treatment but carries low risk and may augment information obtained from the history and physical examination. Simple cystometry can be done by using minimal equipment (measuring bladder pressure only) with demonstration of normal filling volumes and type of leakage. A catheter is inserted to determine the PVR. The bladder is then filled with room-temperature water or saline, noting first the sensation of filling (usually 150 mL), of fullness (300 mL), and of capacity (400 to 600 mL). Abnormal pressure increases can occur with untimely detrusor contractions or abnormal compliance. In general, a "normal" simple cystogram gives reassuring information about normal bladder capacities and the ability to inhibit detrusor contractions. Abnormal findings need to be explored further, with a referral for complex evaluation and often urodynamic testing.

Diagnosis

At completion of a basic evaluation for UI, either a *presumptive diagnosis* is reached and the clinician can proceed with initial treatment options or a need for further assessment (complex evaluation) has been identified. Possible diagnoses after simple evaluation may include stress incontinence (consider pelvic floor reeducation, vaginal devices, or primary surgery), urge incontinence (consider bladder retraining and anticholinergics), mixed incontinence (consider treating dominant symptom first), or complex presentation requiring further evaluation. An algorithm for this evaluation is suggested in Figure 51.2.

Complex Evaluation

A referral for complex evaluation should occur in patients with mixed, unclear symptoms; failed initial treatments; complicating factors such as possible neurologic disease; voiding dysfunction; and pelvic organ prolapse. In these patients, more time and expertise is

required to tease out contributing factors and to assessment lower urinary tract anatomy and function. In some cases, referral may be for treatment instead of evaluation, such as surgery for stress incontinence if initial assessment by the primary care provider and discussion with the patient suggest treatments available only through a specialist or subspecialist. Since many gynecologists act as primary care physicians for their patients, this distinction may be less important than for surgical specialists who do not perform primary care. Some gynecologists may prefer consultation with a urogynecologist who performs these evaluations on a daily basis.

History

As in the case of basic evaluation, the history is the most important component of the complex evaluation of UI. Clinical and surgical records may need to be obtained prior to the consultation, but often the specialist is simply a set of ears tuned to the variations in the clinical presentation of UI. It may be necessary to schedule additional time to allow patients to relate unusual or confusing symptoms or to assess risks and benefits associated with treatment. In the complex evaluation, it is presumed that there will be more difficult presentations with more confounders of prior surgery, treatment failures, and mixed or unclear symptoms, but as

with basic evaluations, the most important issues are to understand patient-directed goals.

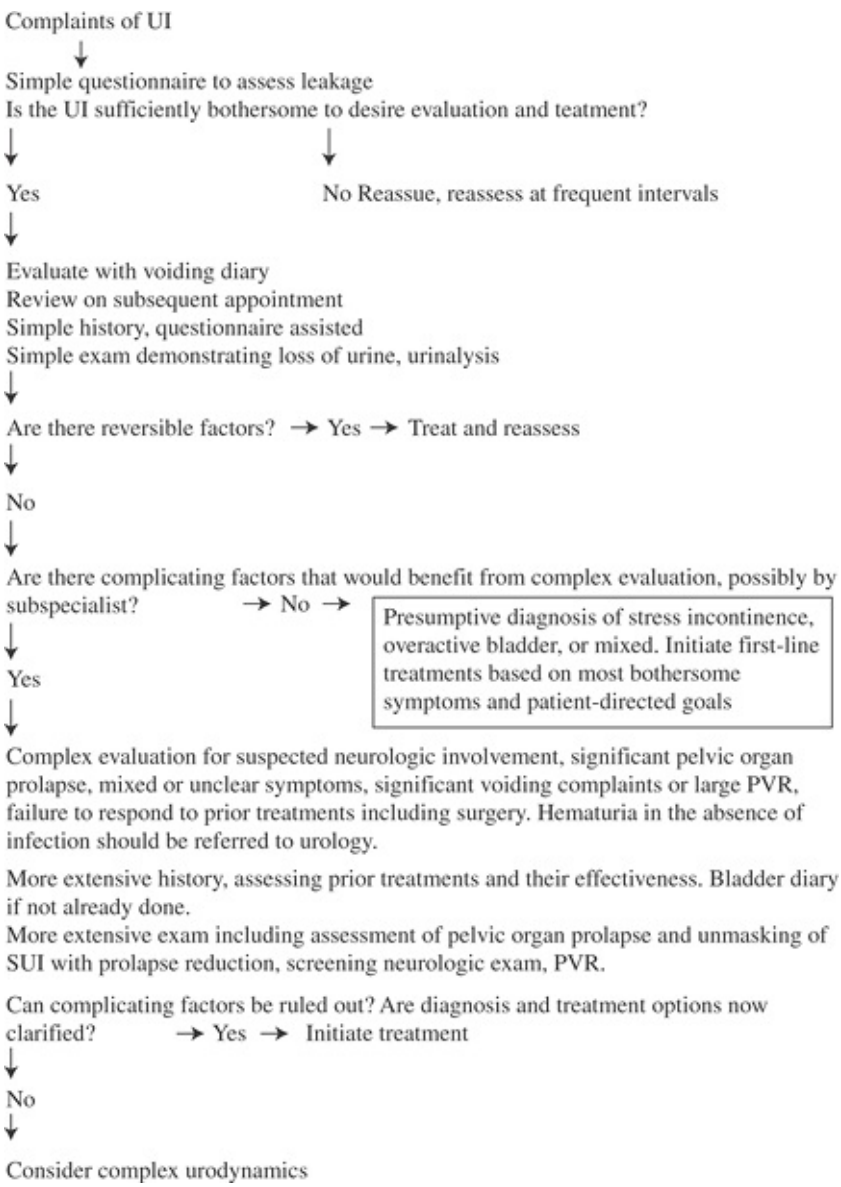

Figure 51.2 An algorithm for simple and complex evaluation of UI. (UI, urinary incontinence; PVR, postvoid residual; SUI, stress urinary incontinence.)

Exam

The physical exam may need to assess complicated factors of prolapse, potential neurologic disease, bladder neck support, and exclude outside factors. The examination is directed at organ systems that may be involved in UI: a general exam for endocrine abnormalities or peripheral edema that might explain fluid excesses or nocturia; a neurologic screen for upper motor neuron lesions such as multiple sclerosis and Parkinson disease; and a neurologic screen for lower motor neuron lesions such as spinal cord tumor or stenosis. Abnormal gait, increased PVR, or detrusor unde or overactivity may be an indication of neurologic involvement. A directed neurologic screening exam is performed: hyperreflexic deep tendon reflexes and/or absent bulbocavernosis reflexes should alert the clinician to possible underlying neurologic lesions. More common but less specific are sensation in sacral nerve roots 2, 3, and 4 (postaxial thigh, genitofemoral fold, and perianal) and anal wink; these can be absent in some elderly women without distinct

neurologic impairment.

The pelvic examination should include an evaluation for estrogen deficiency and pelvic mass. A more complete assessment of pelvic organ prolapse is expected, often using the pelvic organ prolapse quantification (POP-Q) system of measurement (Chapter 48). Reduction of significant anterior wall prolapse (to or beyond the hymeneal ring) may unmask SUI hidden by the sharp kinking of the urethra in such prolapse; the reduction is done manually, with large cotton swabs, or with a vaginal pessary. Bladder neck hypermobility may be seen in continent women, and the significance of urethral mobility is undergoing reassessment at this time, but some clinicians believe that an elevated bladder neck is less likely to benefit from typical bladder neck surgery. A urethral diverticulum is usually identified as a distal bulge under the urethra. Gentle massage of the area will frequently produce a purulent discharge from the urethral meatus.

Tests

Among the tests to be considered in complex evaluations are the frequency/volume diary, urinalysis, PVR, and simple or complex urodynamics. Even for subspecialists, the bladder diary provides insight into patient fluid management and bladder volumes in typical home and work settings; plus, it is the last free medical test in America. While a PVR may be impractical in some primary care settings, it is recommended in complex evaluations and performed either by bladder ultrasound or catheterization. The author uses a single female self-catheter, and the advantage is that sterile gloves do not need to be used with a reliable sample obtained for urinalysis and possible culture.

With more complex symptoms, subtracted urodynamics may help to identify voiding dysfunction, confirm UI subtype in patients with confusing symptoms, and identify risk factors for treatment such as detrusor overactivity or poor compliance. The rationale for this is based largely on the unproven assumption that cystometric findings are an accurate reflection of lower urinary tract function whereas symptoms (that correlate poorly with urodynamics) are not. In particular, symptoms resulting from involuntary detrusor activity may be difficult to distinguish from those due to sphincter weakness, and many patients have both. Many studies have found that women with symptoms of MUI often have only SUI on urodynamics, and it is apparent that in some instances, the symptom of urgency may result from sphincter weakness rather than detrusor overactivity. To further complicate the situation, more severe SUI may increase the likelihood of the subject also complaining of urgency.

Complex cystometry (either multichannel subtracted cystometry or videourodynamics) requires equipment that records of the intravesical pressure separate from the intra-abdominal pressure. These are studies that are generally available through incontinence specialists, including urologists, urogynecologists, and clinicians with special interests in continence from specialties such as nursing, geriatrics, rehabilitative medicine, and the like. Such investigations are performed in women with suspected voiding difficulties or neuropathy, in whom previous treatments have failed, or in whom invasive or surgical treatments are considered.

Stress incontinence can be evaluated with abdominal leak point pressures and urethral pressure profiles. Abdominal leak point pressure is the amount of bladder pressure that overcomes the continence mechanism with Valsalva or cough: in general, women with good sphincteric function should be able to Valsalva to high intra-abdominal pressures without leakage, while those with poor function will leak at lower pressures. Urethral pressure profiles measure the force vectors via a measuring catheter withdrawn through the urethra during coughing. While these two tests are widely employed, their real role remains elusive. Several large multicenter randomized trials are currently under way that may help us to identify how urodynamic testing can be used to improve patient care. It is unlikely that universal urodynamic testing will be beneficial, and it may not be needed in women undergoing primary surgery for stress incontinence. Urethral function may be assessed by electrophysiologic studies, real-time ultrasonography, and/or magnetic resonance imaging (MRI). These tests are often used in research settings and are beyond the scope of this review.

Another important goal of urodynamic testing is to distinguish symptoms due to detrusor contractions from those due to sphincter dysfunction. However, the value of urodynamics in making this distinction and improving outcome is not proven. Detrusor overactivity is often underdiagnosed during cystometry, and in women with mixed symptoms, the finding of SUI only should be interpreted with caution. For example, a woman with urge predominant MUI may have SUI as her only demonstrable urodynamic finding, but surgery for SUI in such a woman may only help a minority of her symptoms. Patient symptoms must always trump the urodynamic findings, especially when they are in disagreement.

Finally, pressure-flow studies evaluate the complex coordination of urethral relaxation and detrusor contraction; the diagnosis of bladder outlet obstruction (low flow, high detrusor voiding pressures) is made on these studies, but their value in predicting voiding dysfunction after bladder neck surgery is unproven.

Diagnosis

At the end of a complex evaluation, a more accurate and detailed diagnosis should be possible. As in the basic evaluation, reversible conditions should have been identified and corrected; hematuria is evaluated by IVP and cystoscopy, usually by a urologist.

SUI may be identified as a symptom only, reproduced as a sign, or demonstrated on urodynamic testing (USI.) Patients with bladder neck hypermobility often have high leak point pressures and urethral pressure profiles and are considered for all treatments of SUI, including surgery. Those with evidence of poor sphincter function (SUI despite relatively immobile bladder neck, low leak point pressures, and urethral pressure profiles) are often termed *intrinsic sphincter deficiency* and may benefit less from surgeries aimed at supporting the bladder neck.

UUI may be identified as a symptom, sign, or urodynamic diagnosis. Neurologic disorders affecting bladder filling or emptying should have been identified, including multiple sclerosis and Parkinson disease. In idiopathic detrusor overactivity, the filling volume that triggers detrusor contractions is considered, and anticholinergics and/or bladder retraining and fluid management are begun. In patients who have failed several anticholinergics,

neuromodulation and botulism toxin A injections to the bladder are increasingly considered.

MUI continues to be a therapeutic dilemma. Most experts recommend treating the most bothersome

component first, with a realistic discussion about treatment outcomes being more modest in such women. Patients with voiding dysfunction and significant residuals should be distinguished into bladder neck outlet obstruction after surgery (a takedown of the surgery should be considered), or due to detrusor underactivity (intermittent self-catheterization or neuromodulation may prove helpful) or lack of coordination between the detrusor and urethral sphincter (biofeedback may be tried.)

Conclusion

Incontinence is a common medical condition by any definition that has significance on quality of life. Some risk factors are modifiable. Incontinence is too common to be evaluated and treated in the hands of specialists only. Basic evaluation of patients can be undertaken in women who are bothered by their incontinence symptoms by most primary care health providers. Patients who are more complex or who fail initial efforts to diagnose and treat their incontinence may be better served by specialists who can look for more unusual causes of UI and consider more specialized forms of treatment.

Summary Points

- Some degree of UI affects 29% (range in studies is 11% to 72%) of women, and 7% of all women (range is 3% to 17%) have severe urinary leakage.
- Pregnancy and childbirth are the most significant risk factors. Episiotomy does not decrease the risk of UI. Cesarean delivery is somewhat but not completely protective, but this protective effect dissipates when women become older.
- Other well-established risk factors for UI include age and obesity.
- The most useful elements of an incontinence evaluation are a careful history and bladder diary.
- After the basic evaluation for UI, the clinician can reach a presumptive diagnosis and proceed with initial treatment options.
- Consider referral for complex evaluation in patients with unclear symptoms; worrisome findings (such as hematuria); failed initial treatments; and complicating factors such as possible neurologic disease, voiding dysfunction, and severe pelvic organ prolapse.

Operative Management of Urinary Incontinence

Charles W. Nager
Amy R. Kane

Stress Urinary Incontinence Surgery

General Principles

Urinary incontinence, in simple hydrodynamic terms, occurs whenever the bladder pressure exceeds the urethral pressure. Urge urinary incontinence (UUI) occurs because involuntary bladder contractions increase bladder pressure and overwhelm the urethral resistance. Stress urinary incontinence (SUI) occurs in spurts when there is a sudden increase in intra-abdominal pressure from coughing, sneezing, laughing, exercising, or straining. This intra-abdominal pressure is transmitted passively to the bladder, and in normal circumstances, a pelvic floor reflex causes the pelvic floor muscles to contract and produce a similar increase in urethral pressure/resistance. While the explicit cause of stress incontinence remains unclear, two theories predominate. Petros and Ulmsten's integral theory of female incontinence proposes that a single anatomic defect in the anterior vaginal wall, a “lax vagina,” causes dysfunction in urethral and bladder neck closure, thereby causing both SUI and UUI. The purported vaginal laxity contributes to urge incontinence mediated by altered stretch receptors in the urethra and bladder, while the mechanism underlying SUI is compromised connective tissue or pubourethral ligaments. Alternatively, the hammock hypothesis proposed by DeLancey developed after cadaveric dissections proposes that a hammocklike mechanism lies under the midurethra. Urine leakage during increased intra-abdominal pressure is prevented by coaptation of the urethra against this hammock comprised of vaginal wall, endopelvic fascia, the levator ani, and the arcus tendineus fascia pelvis. If the urethra is poorly supported by its vaginal support, the proximal posterior urethra funnels open and leakage occurs during these conditions of “stress.” Most SUI surgical procedures are designed to provide support to the posterior urethra in the proximal or midurethral regions.

Surgery is the most successful treatment for SUI. Conservative SUI treatments that focus on strengthening the pelvic floor muscles often result in improvement but rarely result in “cure” or “dry” results. Since urinary incontinence is a quality-of-life condition that is not life threatening, it is better to try conservative treatments first and reserve surgery for

those who fail or are dissatisfied. Although SUI surgery usually is more successful than conservative treatments, it also has greater risks, and these risks have to be weighed by the patient and her provider against the potential benefit.

Traditional Procedures

Hundreds of procedures have been developed over the last century to treat SUI, and because new ones are being developed at a faster rate than at any time in history, it is important to understand what has been tried and worked and what has been tried and failed. Traditional procedures for SUI can be grouped into urethral plications, retropubic suspensions, sling procedures, and transvaginal needle bladder neck suspensions (Table 52.1).

TABLE 52.1 Stress Incontinence Surgical Procedures

Traditional Procedures	Newer Procedures
Urethral plication/Anterior repair	Laparoscopic Burch procedures
Retropubic suspensions: Urethropexy/Colposuspension	Midurethral synthetic slings: retropubic or transobturator
Sling operations	Urethral bulking injections
Transvaginal needle bladder neck suspensions	Other procedures: allograft slings, xenograft slings, bone anchors, artificial urinary sphincters

Urethral Plications/Anterior Repair

A suburethral placation, first described by Kelly in 1914 and modified by Kennedy in 1937, involves dissecting the urethra from the vaginal wall and plicating the fibromuscular tissue (endopelvic fascia) at the level of the urethrovesical junction. The goal of this surgery was to provide some support to the proximal urethra or bladder neck so that intra-abdominal pressure would not produce a posterior displacement and opening of the urethra. For many decades, this was the preferred method by gynecologists for SUI surgical correction. Because medium-term success rates are inferior to sling and retropubic urethropexy procedures, urethral plication is no longer commonly done and is not recommended for SUI

surgery.

Retropubic Suspensions: Urethropexy/Colposuspension

A major advance in the treatment of SUI was the development of the Marshall-Marchetti-Krantz retropubic urethropexy procedure in 1949. In this procedure, a Foley catheter is inserted in the bladder, and the retropubic space is exposed through an open abdominal incision. The surgeon's nondominant hand is placed in the vagina, and by using gentle traction on the Foley catheter, the urethra and lower bladder are clearly identified. Three sets of sutures are placed in the periurethral tissue adjacent to the proximal, middle, and distal urethra and then secured to the underside of the symphysis pubis in the periosteum or symphysis pubis cartilage. There is an approximate 3% risk of developing osteitis pubis from this procedure, so the Burch modification has replaced this as the main retropubic operation performed today. Burch modified this procedure in 1961 in 2 ways: (a) the lowest sutures were placed at the urethrovaginal (UV) junction, and additional sutures were placed in the paravaginal areas laterally and cranially to the UV junction so that a colposuspension instead of a urethropexy was performed; and (b) the sutures were attached to the iliopectineal (Cooper's) ligament instead of the periosteum.

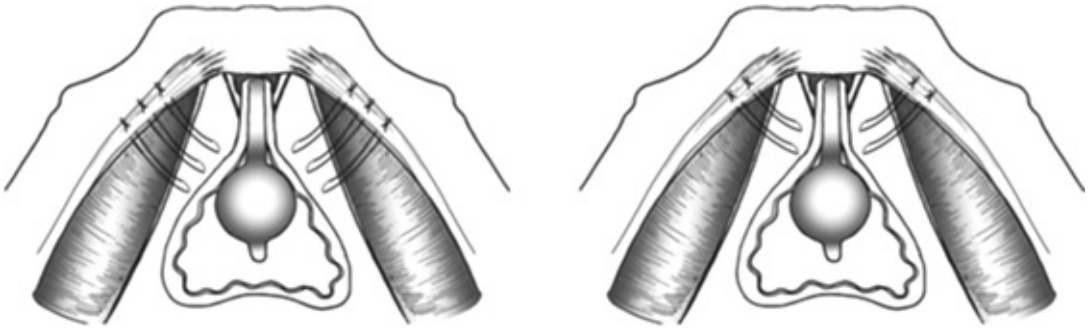

Figure 52.1 Through an open abdominal incision, the retropubic space is exposed. With a urethral catheter in the bladder and fingers from the surgeon's nondominant hand in the vagina, the appropriate bladder and urethral landmarks can be palpated. **Left:** Suture placement for the original Burch colposuspension. **Right:** Suture placement for the Tanagho-modified Burch urethropexy. All periurethral or bladder sutures are suspended to the iliopectineal line (Cooper's ligament). (Illustration by J. Tan-Kim, M.D.)

The Burch procedure became one of the standards for SUI surgery with cure rates typically in the 80% to 90% range and, as noted by Alcalay and colleagues, still in the 70% range at 20 years out. Tanagho modified the Burch procedure in 1976 by placing the two sets of urethropexy sutures lateral to the proximal urethra and lateral to the UV junction but still attaching them to the iliopectineal ligament. He allowed suture-bridging “banjo strings” to exist between the structures to reduce the risk of obstruction. The Tanagho-modified Burch

procedure became one of the most commonly performed retropubic urethropexies in the United States. The Burch and Tanagho-modified Burch procedure are illustrated in Figure 52.1

Sling Operations

Sling procedures actually predate Kelly's suburethral plication. The first pubovaginal sling operation was performed in 1907 by Von Giordano, using a gracilis muscle graft around the urethra. In 1914, Frangenheim introduced the use of autologous rectus abdominus muscle and fascia for pubovaginal slings. This was reformed by Aldridge, Millin, and Read in 1942, who corrected urinary incontinence by using fascial slings.

The suburethral sling described by Aldridge left rectus fascial strips attached to the anterior abdominal wall and

then sewed them together under the urethra. This rectus fascia technique later evolved into the current pubovaginal sling, which uses a free rectus fascia strip under the proximal urethra with the lateral arms secured to the anterior rectus fascia on each side. The traditional pubovaginal sling procedure is illustrated in Figure 52.2.

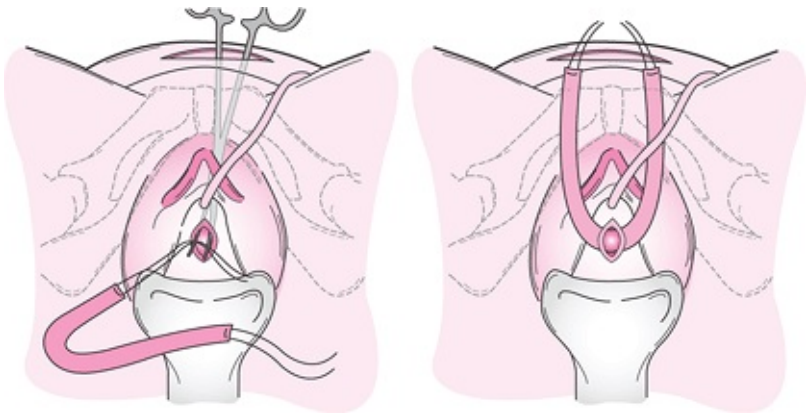

Figure 52.2 Pubovaginal sling procedure. A transverse strip of autologous rectus fascia has been harvested from the transverse abdominal incision, and the harvest site is closed. An incision in the vagina under the proximal urethral allows a finger dissection into the retropubic space so that a clamp can be passed from the abdominal incision under continuous and direct guidance. The clamp grasps the permanent sutures attached to the sling, the clamp is withdrawn, and the sling is secured to the rectus fascia. (Illustration by J. Tan-Kim, M.D.)

Durable cure rates of 80% to 92% have been obtained with this pubovaginal sling, and many would consider this procedure to be the one of the standards for SUI surgery. Alternatively, the autologous sling material could be harvested from the fascia lata on the lateral thigh. Since the 1960s, surgeons have looked for alternative sling materials that could avoid the time, morbidity, and potential complications of harvesting autologous material. Synthetic slings were introduced by Zoedler and Boeminghous in 1965. Synthetic materials (e.g.,

Silastic, polytetrafluoroethylene [Gore-Tex], polyethylene, and polypropylene) were more durable than autologous ones but were associated with higher rates of erosion, infection, and exposure complications.

A significant advance in the recent history of stress incontinence surgery was Ulmsten's 1996 description of the minimally invasive retropubic midurethral polypropylene sling known as tensionfree vaginal tape (TVT). Subsequent literature strongly supports the use of a macroporous monofilament polypropylene synthetic mesh for the midurethral sling (MUS). The larger, 75-µm pores allow passage of white blood cells to prevent infection as well as allowing ingrowth and incorporation of host tissue to the graft and lowering the risk of erosion. Polypropylene is inert, not antigenic, and produces induces minimal inflammatory reaction, theoretically lowering the risk of inflammatory complications such as erosion, infection, and pain. This technique, and the similar transobturator tape (TOT), will be discussed more fully later.

Transvaginal Needle Bladder Neck Suspensions

The first transvaginal needle bladder neck suspension was described by Pereyra in 1959 and involved using a long needle to pass paraurethral sutures to an abdominal puncture wound. Stamey advocated cystoscopic guidance and Dacron buttresses to the paraurethral sutures. Eventually, the modified Pereyra procedure included helical permanent polypropylene sutures in the paraurethral tissues passed to the abdominal wall with long needles and then sutured over a bridge of abdominal wall fascia with cystoscopic confirmation to ensure that the bladder had not been disrupted. Raz included the underside of the vaginal epithelium in his modification and popularized this technique with urologists.

Systematic Reviews in the 1990s

Several reviews of SUI surgery outcomes were published in the 1990s. Jarvis reported that the highest success rates for primary procedures were seen for retropubic procedures, slings, and endoscopic bladder neck suspensions, but the procedures with the highest cure rates and narrowest confidence intervals were slings and colposuspensions. Black and Downs found that colposuspension appeared to more effective and the effect more long lasting than that following anterior repair (urethral plication) and needle suspensions. The American Urological Association (AUA) convened a Female Stress Urinary Incontinence Clinical Guidelines Panel and reviewed 5,322 abstracts to extract data from 282 articles that had acceptable outcomes data. As reported by Leach and associates and demonstrated in Figure 52.3, the data indicate that after 48 months, retropubic suspensions (84% cure) and slings (83% cure) appeared to be more effective than transvaginal needle suspensions (67% cure) and anterior repairs (61% cure). Synthetic slings were associated with higher complication rates. Surgeons have responded to these reports by decreasing the number of transvaginal needle suspension procedures and urethral plications for SUI. Prior to the development of MUS procedures, the two gold standard traditional operations were considered to be the Burch colposuspension and the pubovaginal sling. These two operations were recently compared in the U.S. Urinary Incontinence Treatment Network's multicenter, randomized clinical trial of 655 women. Albo and coworkers reported that the

pubovaginal sling had slightly better efficacy but a higher rate of voiding complications than the Burch colposuspension.

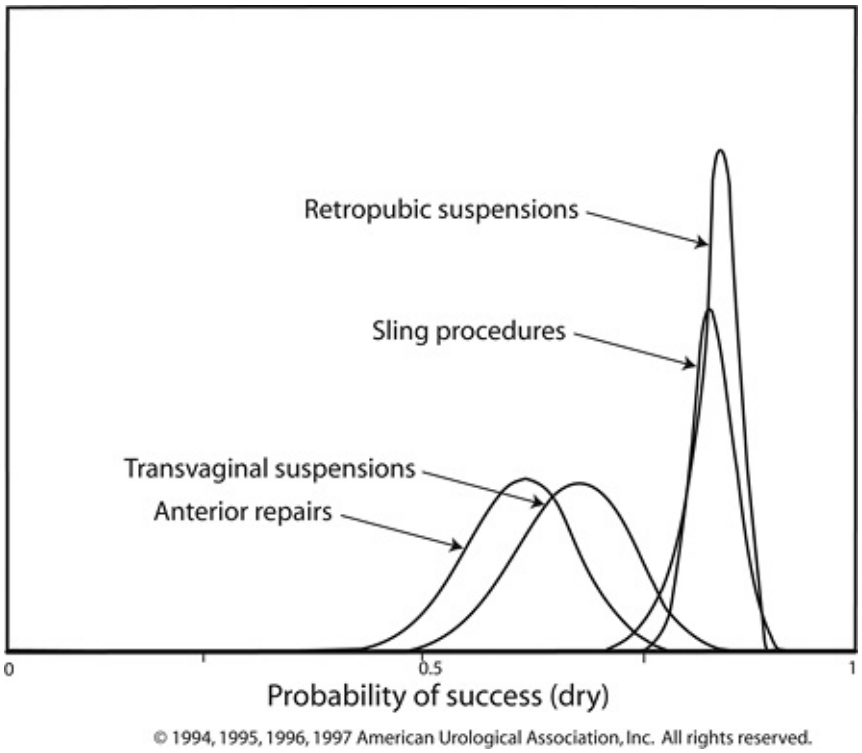

Figure 52.3 Probability of cure (dry) after 48 months for four categories of surgical procedures. Data comes from a systematic review done by the AUA Female Stress Urinary Incontinence Clinical Guidelines Panel. Retropubic suspensions and sling procedures were more efficacious than transvaginal needle bladder neck suspensions or anterior repairs. Newer Procedures for Stress Urinary Incontinence

Laparoscopic Burch Procedures

Laparoscopic Burch procedures became popular in the 1990s as a less invasive alternative to perform the Burch procedure. This procedure had a steep learning curve and longer operating times. Shortcuts were often introduced to make the procedure easier to perform, and when fewer sutures were used or staples instead of sutures were utilized, the results were often inferior to open techniques. However, when the laparoscopic procedure was performed similarly to open Burch procedures, it often demonstrated similar results. The popularity of the laparoscopic Burch procedure waned when equally or less invasive MUS were developed and shown to have comparable or better results.

Midurethral Sling: Retropubic or Transobturator

For descriptive purposes, the term *midurethral sling* will be used to describe a number of synthetic slings placed under the midurethra with small incisions using various trocar devices. This is in contrast to the traditional slings described earlier where slings were typically placed under the proximal urethra through larger incisions with an open technique without trocars. The two general categories of MUS are the retropubic and the transobturator (TOT).

Retropubic Midurethral Sling

TVT was the first and is the most commonly performed retropubic MUS. In 1996, Ulmsten and colleagues described this procedure as a modified intravaginal slingplasty for female SUI. The TVT technique is illustrated in Figure 52.4. Cystourethroscopy is performed after each pass of the trocar while the trocars are still in the retropubic space to evaluate for bladder or urethral injury. If bladder perforation is observed, the trocar is removed and redirected. Care is ensured to place the sling in a tensionfree application, and the excess mesh is trimmed on the suprapubic exit sites. Based on the integral theory of female incontinence, the sling, placed in a tensionfree fashion, is intended to approximate the compromised support of the pubourethral ligaments. In an observational study of 75 patients undergoing the TVT procedure, Ulmsten reported an objective and subjective cure rate of 84%, with no intraoperative or postoperative complications at a mean follow-up of 2 years. Kuuva and Nilsson published a 6-year follow-up demonstrating durable success. Because of its minimally invasive nature and high preliminary success rates, the retropubic MUS quickly gained popularity and throughout the world has rapidly replaced the Burch and pubovaginal sling procedures.

Figure 52.5 illustrates surgical trends in England in the first part of this century. Since the introduction of TVT, more than 1 million MUS have been implanted worldwide. An alternative top-down technique was developed in which the two stainless steel trocars are passed blindly behind the pubic bone and exit through a midurethral vaginal incision. A monofilament polypropylene mesh approximately 1 cm wide and 40 cm long is then attached to the end of the trocar, and the mesh is placed in the retropubic space when the trocars are withdrawn. Retrospective data suggested lower subjective and objective cure rates in the patients who underwent the top-down procedure, but one randomized clinical trial comparing the bottom-up and top-down methods by Andonian and associates demonstrated equivalent success and complication rates.

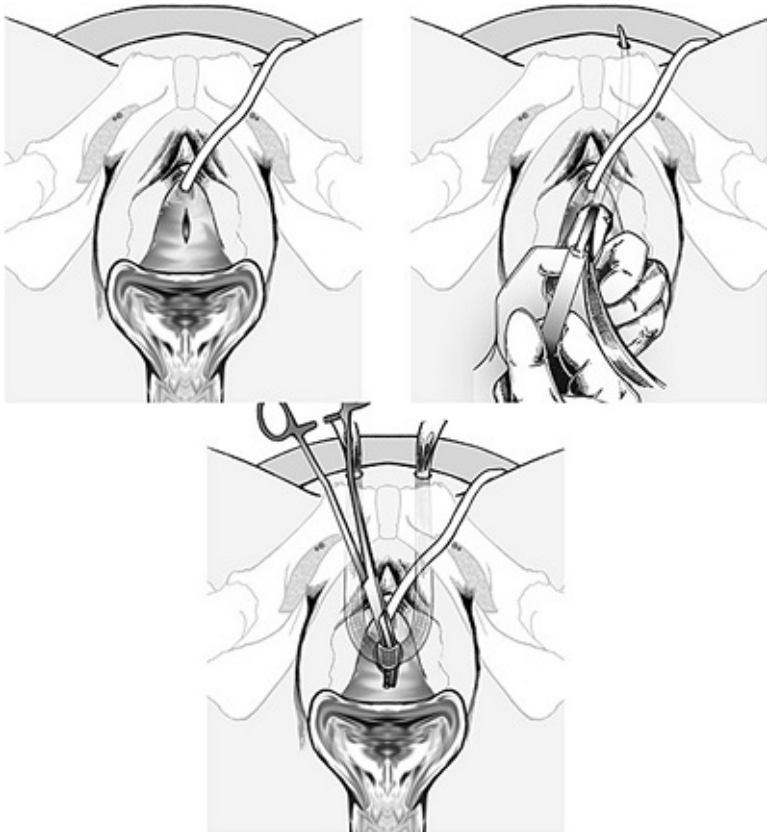

Figure 52.4 Retropubic MUS, or more specifically, the TVT procedure. A synthetic large pore polypropylene mesh ribbon is attached to trocars on each end. Through a small vaginal incision under the midurethra, the trocars traverse the retropubic space behind the pubic bone and exit through small suprapubic incisions. Not shown in the illustration, an assistant uses a rigid catheter guide to deviate the bladder to the contralateral side of the advancing trocar to avoid urethral or bladder perforation. The mesh is trimmed on the abdominal wall. The sling is secured by tissue ingrowth. The procedure is intended to be performed under local anesthesia with conscious sedation. Success rates are comparable to traditional open surgical procedures. (Illustration by J. Tan-Kim, M.D.)

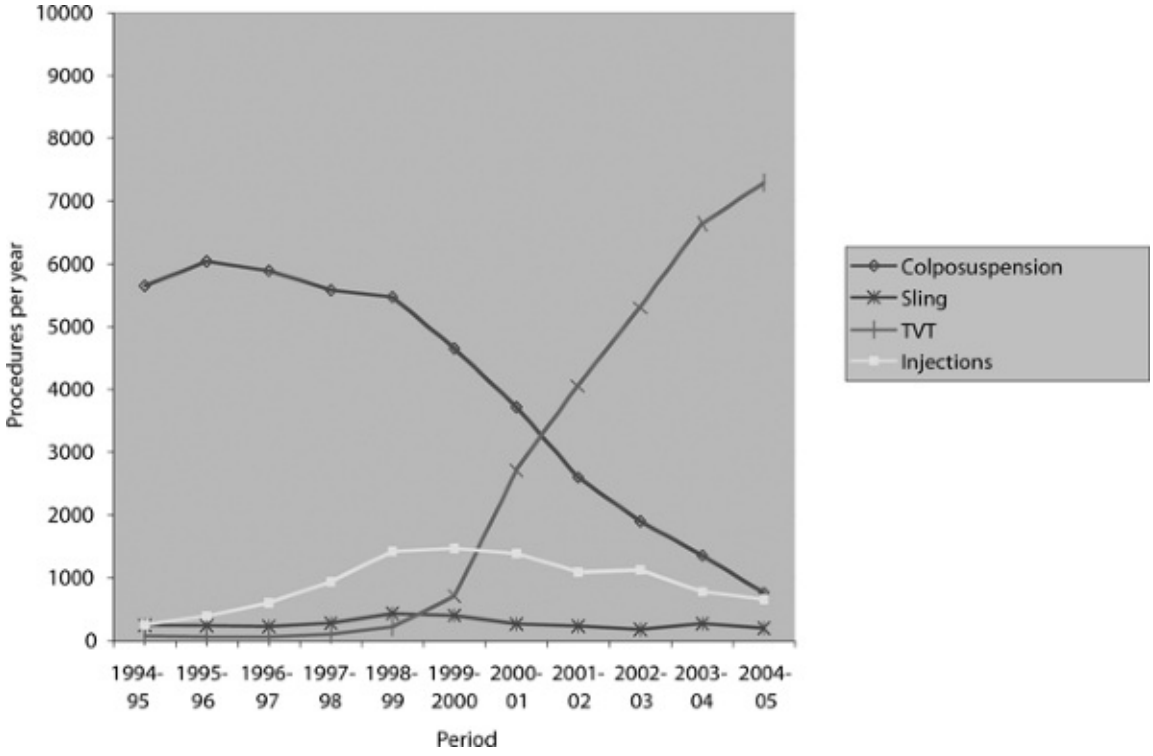

Figure 52.5 This graph illustrates the trends in surgery for SUI in England after the introduction of the TVT procedure. (*TVT*, tensionfree vaginal tape.) (Graph modified from a figure in National Collaborating Centre for Women's and Children's Health. *Urinary incontinence: the management of urinary incontinence in women.* Commissioned by the National Institute for Health and Clinical Excellence (NICE). RCOG Press. October 2006.)

Randomized trials have consistently demonstrated comparable cure rates with retropubic MUS and both open and laparoscopic Burch colposuspension. Objective cure rates for the retropubic MUS range from 63% to 95%. Ward and Hilton reported a prospective multicenter randomized trial in the United Kingdom and Ireland comparing the Burch procedure with TVT in 344 women without previous anti-incontinence surgery, severe prolapse, or voiding dysfunction. Objective cure rates at 2-year follow-up, defined as a negative 1-hour pad test, were 63% in the TVT group and 51% in the Burch group. Excluding withdrawals from the analysis, objective cure rates were 81% and 80% for TVT and Burch, respectively. In another smaller randomized trial of retropubic MUS and the Burch procedure, El-Barky and coworkers found similar objective cure rates (72% at 6 months). Notably, there was a statistically significantly shorter mean operative time for the retropubic MUS; 20 minutes for the retropubic MUS versus 57 minutes for the Burch procedure. In addition, 8% of Burch procedures, but none of the retropubic MUS procedures, were complicated by wound infection. Current data clearly suggest that the TVT retropubic MUS is comparable in efficacy to the Burch procedure.

To date, there have been two prospective randomized studies comparing the retropubic MUS to the laparoscopic Burch procedure. In 2003, Ustun and colleagues found equivalent cure rates of 83% for either procedure. Cure was defined as a negative cough stress test

and no need for pads. The laparoscopic Burch had longer operative times, hospital stay, and duration of catheterization. A prospective randomized trial by Paraiso and associates with 21 months of follow-up demonstrated more incontinence symptoms and longer operating times in the laparoscopic Burch group. Length of hospitalization and catheterization were equivalent.

Transobturator Tape Midurethral Sling

Despite the encouraging literature on the retropubic MUS, the blind passage of the trocar through the retropubic space led to rare but serious complications of bowel injury, significant retropubic bleeding, and even death from bleeding or sepsis. Developed by Delorme in 2001, the first TOT MUS is similar to the retropubic MUS in its support of the midurethra in a tensionfree fashion; however, the TOT traverses the obturator canal instead of the retropubic space. When performed in an out-to-in manner, incisions are made at the genitofemoral fold at the level of the clitoris bilaterally. The trocars are passed through these incisions and rotated through the obturator membrane to their exit point through the midurethral vaginal incision. As the trocar is passed blindly through the obturator membrane, the surgeon carefully hugs the inferior pubic ramus to avoid contact or damage to the obturator nerves and vessels that lie centimeters away. In theory, the passage of trocars through the obturator space would eliminate the small risk of bowel injury because the peritoneal space should never be entered and bladder injury rates would be lower than the retropubic MUS. In addition, sling insertion through the transobturator muscles was thought to reapproximate a more natural urethral suspension, and perhaps this flatter sling would be less obstructive and decrease the risk of obstruction or postoperative de novo detrusor instability. Of the first 40 women who underwent the procedure, 15 were cured, without serious intraoperative or postoperative complications.

Two years after Delorme published his out-to-in TOT procedure, an in-to-out procedure was introduced by de Leval in 2003. Figure 52.6 illustrates the in-to-out technique. This procedure can be performed with a smaller vaginal incision than the out-to-in technique because a finger is not inserted in the incision to guide the trocar coming from the outside. Of the 107 women who initially underwent inside-out sling placement, none suffered from bladder or urethral injuries.

The necessity for cystourethroscopy at the completion of TOT is controversial. Although bladder injuries are rare, urethral injuries have been reported with TOT procedures.

Preliminary data reports equivalent success rates of the TOT and retropubic MUS. Debodinance found comparable efficacy and safety profiles for the outside-in and the inside-out procedures. Published cure rates for the transobturator approach range from 83% to 95%. A prospective randomized trial by Sivaslioglu and coworkers comparing the transobturator sling with Burch revealed comparable objective and subjective cure rates with follow-up at 1 and 2 years. Mean operating time and duration of hospital stay were significantly longer with the Burch procedure. The investigators reported no difference in intraoperative complications rate, de novo urge symptoms, or voiding dysfunction.

In a randomized controlled trial conducted in Finland by Laurikainen and colleagues, 267 women were randomly assigned to either the retropubic or transobturator route. This study

reported objective cure rates (defined as negative cough stress test); of 98.5% with retropubic sling and 95.4% with transobturator sling, however, these findings were at 2-month follow-up. Patient undergoing transobturator sling had significantly more requirements for opiate anesthesia and postoperative groin pain. Operative time and blood loss were equivalent in both groups. The rate of de novo urge symptoms was low for both groups (2.2% retropubic and 2.3% transobturator). In another randomized trial by Liapis and associates, cure rates were equivalent, but a significantly longer operating time was noted for the retropubic procedure.

At this time, the Urinary Incontinence Treatment Network is conducting a randomized trial comparing the retropubic and transobturator approaches for mid-urethral sling placement. This study will allow comparison of both effectiveness and adverse events.

Urethral Bulking Injections

Urethral bulking injections are an alternative form of operative management of SUI used primarily for women

with limited urethral hypermobility. This treatment is based on the theory that urethral mucosal coaptation can be improved by bulking the submucosal tissues. As Figure 52.7 demonstrates, this procedure is typically performed under direct cystoscopic (actually urethroscopic) guidance with injections done through an operating channel of the cystoscope (transurethral technique). Alternatively, injections are done with a long needle inserted periurethrally and then advanced nearly parallel to the cystoscope until the tip resides in the proximal urethra submucosa. Injections usually have to be repeated, with results lasting 12 to 24 months. Numerous materials have been investigated as bulking agents, including collagen, carbon-coated zirconium oxide beads, ethylene vinyl copolymer, calcium hydroxyapatite, silicone microimplants, dextranomer–hyaluronic acid, polytetrafluoroethylene (Teflon), autologous fat, and more recently autologous skeletal muscle cells. An ideal agent that is safe and durable over the long term has not been developed. In general, biodegradable materials (like collagen) have fewer complications than permanent materials, and since no product has ever been conclusively shown to be more durable than collagen, it remains the most commonly used material.

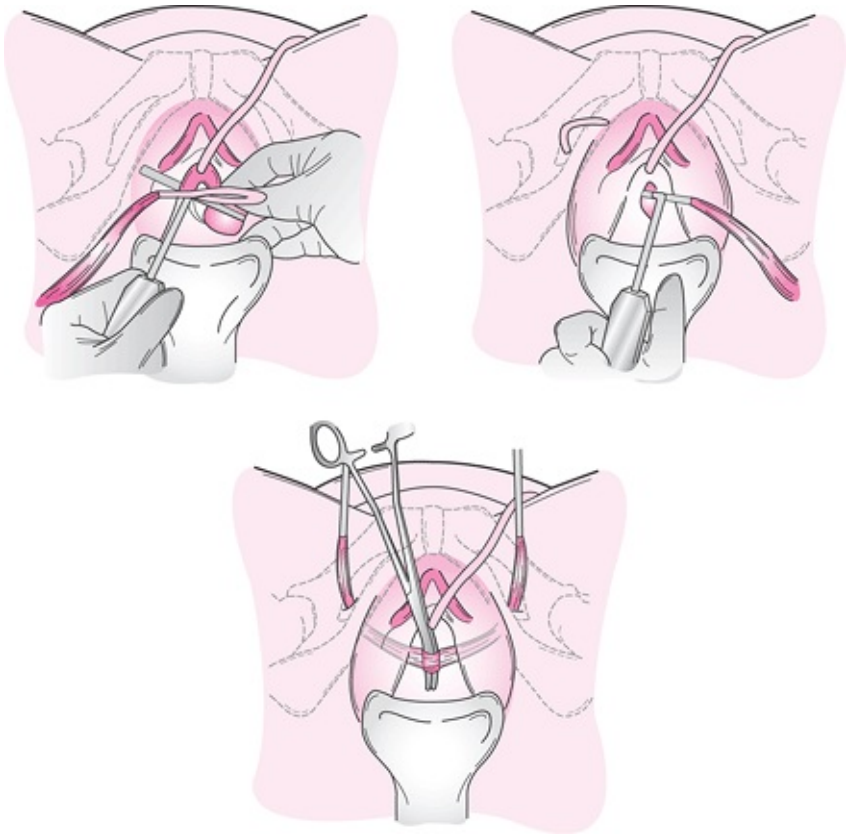

Figure 52.6 A TOT procedure performed with the in-to-out technique. A synthetic large pore polypropylene mesh ribbon is attached to trocars on each end. Through a small vaginal incision under the midurethra, a winged guide directs the trocar into the obturator canal region. The trocars then penetrate the obturator canal posterior and medial to the obturator vessels and exit through small incisions near the genitofemoral fold at the level of the clitoris. The mesh is trimmed at the exit sites and secured by tissue ingrowth. Similar to the TVT, this is an outpatient procedure typically performed with local anesthesia and conscious sedation. (Illustration by J. Tan-Kim, M.D.)

Since these procedures often have to be repeated for a lifetime, the ideal candidates for this procedure are thought to be older women and/or women who are poor candidates for conventional surgery because of frailty, previously failed surgery, or limited urethral hypermobility. The 1996 Medicare guidelines for reimbursement indicated that urethral immobility and low leak point pressures were required, although some investigators have found that the procedure works as well in urethral hypermobility patients. In a review of 15 articles, the Second International Consultation

on Incontinence found a 48% dry rate and a 76% success rate. Gorton and coworkers found that very few women have durable results at 5 years. Nevertheless, this procedure remains a reasonable minimally invasive option with very few complications.

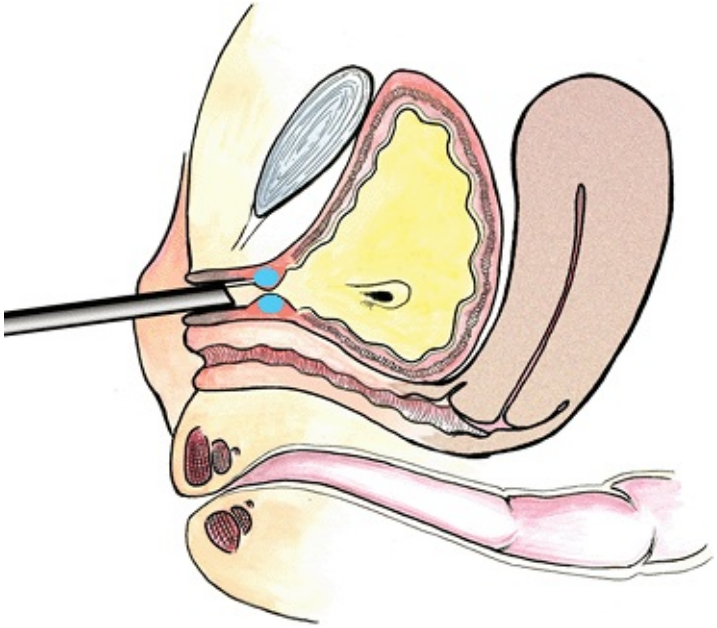

Figure 52.7 Under cystoscopic visualization, a transurethral needle injects a bulking agent into multiple submucosal sites in the proximal urethra to increase urethral resistance. (Illustration by J. Tan-Kim, M.D.) (See Color Plate)

Other Procedures

It is important for physicians to realize that current law in the United States allows many surgical devices to be legally marketed and distributed through the Food and Drug Administration (FDA) Premarket Notification 510(k) process without conducting human clinical trials. This process merely requires demonstrating that the device is substantially equivalent to other devices approved on the market. These other devices could have been approved by this same process! This means that devices can be marketed and sold without any safety, efficacy, or outcome data. The requirements for device approval are significantly less rigorous than for drugs, even though devices may be in the body forever. Surgeons should be skeptical and wary of new products that lack human study data. The history of stress incontinence surgical procedures is filled with bad ideas, bad devices, and subsequent human suffering. Synthetic multifilament or small pore sling materials have been withdrawn from the market when unacceptably high rates of erosion and infection have been found.

In attempts to reduce complications associated with synthetic grafts, biological materials—either allografts (human cadaveric fascia lata, dura mater) or xenografts (porcine dermis or porcine, small intestine submucosa)—are also marketed for such use. Despite the reduced antigenicity of these collagen scaffolds, there is nearly always some limited host versus graft inflammatory response to these allograft or xenograft materials. While the hope is that endogenous collagen replaces the foreign material before support is lost, as noted by FitzGerald and colleagues, in a significant number of human cadaveric allografts cases, unpredictable early autolysis led to early failure. There is significant concern about the durability of nonautologous, biological materials. The data for these alternative

biological sling materials is far less abundant than data for synthetic wide pore polypropylene mesh slings or autologous tissue.

In the search for minimally invasive procedures, suprapubic and transvaginal bone anchors have been employed for sling procedures. The use of these anchors has been quite controversial, because failures of slings are rarely at the point of suspension and these anchors can produce disabling pelvic pain or osteomyelitis in a small percentage of women.

The artificial urinary sphincter has a high rate of complications, including erosion, infection, and mechanical failure requiring replacement or revision. Its use in women (who have many more surgical options) is much less common than in men.

Complications of Surgery

Intraoperative Complications

Open procedures, laparoscopic procedures, and trocar procedures all have risks of bleeding, adjacent organ injury, and even death. In the AUA systematic review of traditional open procedures published by Leach and associates, transfusion rates ranged from 3% to 5% and the risk of death was estimated at 1 in 2,000. Bladder injury was more common with slings and transvaginal needle suspension procedures, but the more serious ureteral injury occurred with 1% of the retropubic procedures. Ureteral injury is extremely rare with MUS, but bladder perforation is common with the retropubic MUS, complicating 3% to 10% of procedures. If recognized immediately, bladder perforation is a relatively minor and easily managed complication, highlighting the importance of intraoperative cystourethroscopy. Bladder injury is more easily visualized by cystoscopy with a trocar in place and is managed by removing and redirecting the trocar and then allowing postoperative bladder drainage to heal the bladder perforation. Undiagnosed bladder and urethral injuries often present as dysuria or voiding dysfunction and may cause fistula formation as well as mesh erosion into those vital structures. In comparison to the retropubic approach, the transobturator sling rarely causes urinary tract injury, with rates of 0% to 1% making the necessity for intraoperative cystoscopy controversial. No difference exists between outside-in and inside-out approaches with respect to rate of lower urinary tract injury.

Bowel injury occurs rarely with open procedures or retropubic MUS. In a review of complications by Tamussino coworkers, only one bowel injury occurred from over 2,500 retropubic sling procedures. In another review of retropubic sling complications by Kuuva and Nilsson involving 38 Finnish hospitals, no bowel injuries occurred in over 1,400 procedures. At this time, there are no reports on bowel injury with the transobturator approach.

In the large series mentioned above, the risk of clinically significant bleeding and significant hematoma formation is approximately 2% to 3%. Barber and coworkers reported similar rates for retropubic and transobturator approaches. Blind passage of trocars through the highly vascular venous space of Retzius or through the obturator space in proximity to the obturator vessels probably account for the majority of bleeding

complications. Management of specific bleeding complications depends on the nature and extent of bleeding. Most retropubic bleeding complications are probably venous, self-limited, and confined to the space of Retzius and can be managed with observation only. Transfusion, hematoma drainage, and even laparotomy may be required, especially if the bleeding source is arterial.

A review of the literature by Deng and colleagues revealed that 0.8% of complications of MUS are major, including unrecognized bladder or urethral injury, bowel injury, major vascular or nerve injury, abscess

---

requiring drainage, transfusion, and significant bleeding or hematoma requiring surgical drainage. This rate is comparable to open procedures. Rare deaths have been reported with MUS, usually from bleeding, or sepsis after bowel injury, but this rate does not seem to be any higher than the 1 in 2,000 rate estimated for open procedures.

Postoperative Complications

Except for urinary tract infections, which are common with any incontinence operation, other sites of infection are uncommon. An obturator abscess is a rare and serious complication of the transobturator sling, and patients with symptoms related to abscess should undergo pelvic magnetic resonance imaging (MRI). Management may require surgical removal of the entire mesh as well as use of broad-spectrum intravenous antibiotics followed by a 2-week course of broad-spectrum oral antibiotics.

Mesh erosion is an uncommon complication with current wide pore monofilament mesh slings, with erosion into the vagina occurring at a rate of approximately 1%. Inadequate vaginal tissue coverage, close proximity to the urethra, poor tissue vascularity, and infection may contribute to mesh erosion. Symptoms of mesh erosion include dyspareunia, bleeding, discharge, and pain. The patient's sexual partner may detect the erosion during intercourse. Initial management may be conservative with vaginal estrogen to treat atrophic tissue. If the erosion is small, excision of exposed mesh can be done in an office setting. Larger erosions may require removal of more of the sling under general anesthesia. Erosion into the bladder or urethra requires resection of the mesh. Small pore or multifilament meshes can produce bacterial sanctuaries that are associated with higher erosion, exposure, and infection rates, and these materials, in general, should be avoided. Erosions with multifilament mesh may necessitate complete removal if infection develops.

The AUA review estimated the risk of temporary urinary retention lasting longer than 4 weeks to be 5% for open retropubic or needle transvaginal operations and 8% for slings. Similar rates have been seen for retropubic MUS, but Barber associates found lower rates for the transobturator MUS. While most postoperative urinary retention resolves with conservative management such as intermittent catheterization and time, unresolved voiding dysfunction ultimately requires intervention in the form of urethral dilation or, more commonly, sling transection.

Resolution of detrusor overactivity (DO), overactive bladder (OAB) symptoms, and UUI in patients with mixed incontinence has been reported after both types of MUS. In a retrospective review by Segal and coworkers, the majority of preexisting OAB and UUI

resolved in patients with mixed urinary incontinence after retropubic MUS. Despite improvement in mixed incontinence subjects, de novo DO and UUI have been associated with nearly all incontinence operations. Published rates of de novo UUI range from 5% to 25% after MUS.

Special Considerations

Occult Stress Incontinence

In women with advanced prolapse past the introitus, the urethra can be kinked, producing paradoxical continence in a patient who would have stress incontinence if she did not have prolapse. Surgically repairing her prolapse may unmask her occult incontinence. Preoperative efforts to predict whether a woman will develop stress incontinence after surgery have not been found to be either sensitive or specific. However, many clinicians do a cough stress test with the prolapse physically reduced, urodynamic testing with the prolapse reduced, or a pessary trial. In the Pelvic Floor Disorders Network multicenter study, Brubaker and colleagues demonstrated that in women without symptoms of stress incontinence, a Burch procedure should be added to an open sacrocolpopexy to prevent postoperative stress incontinence.

Recurrent Stress Urinary Incontinence

In a prospective observational study by Liapis and associates of patients who underwent retropubic MUS after another failed procedure (mostly anterior colporrhaphy), 70% were objectively cured. Of those with urethral hypermobility, the cure rate was 90%. Kuuva and Nilsson reported similar success rates, even with patients who had more than one prior procedure.

Concomitant Surgery

Most studies involving traditional procedures and MUS and concomitant surgery show no decline in success rates with the addition of other procedures. Tamussino and coworkers and Atherton and Stanton have reviewed this topic and have found success rates equivalent to those undergoing sling alone.

Absence of Urethral Hypermobility

Most women with SUI have urethral hypermobility. This can be assessed during an office exam with a cotton swab placed in the urethra and asking the patient to strain (Q-tip test) or, in a more sophisticated manner, with ultrasound measurements. Traditional open operations were designed to reduce this hypermobility, and Bergman and colleagues showed that the absence of urethral hypermobility preoperatively was a risk factor for failed surgery. This seems to be true for MUS as well. In patients with a history of prior incontinence surgery and a Q-tip angle <30 degrees, Deffieux and associates and Bakos and coworkers have reported lower cure rates in the 40% to 50% range. Lukacz and colleagues showed that after a retropubic MUS, there was a transient decrease in the Q-tip angle that

then returned to baseline over a year, but this regression to baseline did not affect success. Although a preoperative lack of hypermobility measured by the Q-tip test may be a risk factor for failure, the success of the MUS does not depend on

correction of urethral hypermobility, as measured by the Q-tip test.

Poor Urethral Function Tests: Intrinsic Sphincter Deficiency

There is much confusion in the literature about the term *intrinsic sphincter deficiency* (ISD). As described by Bump and associates, ISD should be diagnosed by a composite of findings including a low maximum urethral closure pressure (MUCP), a low Valsalva leak point pressure (VLPP), and a low Q-tip angle. Therefore, true ISD patients should have poor urethral function tests (MUCP or VLPP) and no urethral hypermobility. Unfortunately, some investigators do not include an assessment of urethral mobility when they use this term, so it is difficult to determine if their ISD patients really have true ISD of if they just have poor urethral function tests. Most of the data with MUS would suggest that the urodynamic measure of low MUCP in the presence of hypermobility does not significantly affect the results of the retropubic MUS. However, in comparing the two MUS approaches in subjects with hypermobility, Miller and coworkers found that low MUCP was a risk factor for failure with the obturator technique.

Subsequent Pregnancy

SUI surgery is best deferred until after childbearing is complete, because most of the urethral supporting surgeries could be disrupted by vaginal delivery. Since surgery is not typically done before completion of the family, there is little data to guide management on the mode of delivery if a woman becomes pregnant after SUI surgery. If the incontinence surgery has been working well, most experts recommend cesarean delivery to prevent jeopardizing a successful result, although this is not based on good evidence.

Elderly Women

With the aging population and the increase in prevalence of incontinence with age, the demand for safe, effective treatments for incontinence is increasing. Older women have lower urethral pressures and more urge incontinence; thus, success rates could be lower. Despite this concern, Liapis and colleagues and Ku and associates have reported that elderly women undergoing retropubic MUS have the same cure rates as younger women if they have urethral hypermobility. For older women with Q-tip angles <30 degrees, cure rates dropped to 42%. Operative complications were similar to younger patients. De novo urge symptoms were found to be higher in the elderly compared with those found in younger cohorts after MUS placement. In fact, postoperative urge symptoms were four times more common in women >65 years of age than those <65 years. For an elderly patient with multiple comorbidities, MUS performed under local anesthesia with conscious sedation is a good option.

Obesity

Obesity is a known risk factor for SUI. Noblett and coworkers demonstrated a correlation between body mass index and intra-abdominal pressure, suggesting that obesity may weaken the pelvic floor as a result of this long-standing increased pressure. Obesity also increases the risk of wound infection with open abdominal incisions, and obesity can limit exposure for open retropubic procedures. When comparing obese with nonobese women, Rafii and colleagues and Lovatsis and associates demonstrated similar success rates with retropubic MUS. Complication rates and operating times were equivalent as well. There was actually a trend toward more bladder injuries in thinner patients.

Problem Case

History. A 65-year-old gravida 4 para 4 woman presents to your office complaining of urinary incontinence. She leaks urine with coughing, sneezing, laughing, and exercising. She also leaks urine at night and in the early morning on the way to the toilet. The stress leakage bothers her much more than the early morning urinary leakage. Her urinary frequency is every 2 hours, and she typically has two episodes of nocturia each night. She wears two pads per day and one at night. She has had this incontinence problem for 20 years. Fifteen years ago, she had some type of needle bladder neck suspension, which helped for about 3 years, but now her incontinence is as bad as ever. Oxybutynin and tolterodine were prescribed by her primary care doctor, but those medications have not helped. Kegel exercises—three sets of ten repetitions each day—have not helped. She has no bowel or prolapse complaints. She thinks that she has a reasonably full bladder at the present time.

Evaluation. The patient is 5′6″ tall and weighs 100 kg. You perform a standing cough stress test and observe a spurt of urine coming from the urethral meatus synchronous with the second cough. She then voids 250 mL in a toilet hat, and her postvoid residual on catheterization is 40 mL. The dipstick urinalysis on this specimen is normal. She has a normal lower extremity and perineal neurologic exam and no significant pelvic organ prolapse. Her Q-tip test is 10 degrees at rest and 50 degrees with straining. She demonstrates a properly performed pelvic floor contraction when you ask her to show you her Kegel exercises. She asks for your help.

Investigation. Because she has mixed urinary symptoms and nighttime urine loss and has failed a previous incontinence surgery, urodynamic studies are indicated to exclude a dominant urge incontinence (DO) diagnosis. Overflow incontinence is excluded with her normal residual. The urodynamic studies show urodynamic stress incontinence with leak point pressures of 90 cm H_2O above atmospheric pressure, no evidence of DO, a maximum cystometric capacity of 400 mL, and complete voiding by detrusor without elevated detrusor pressure.

Diagnosis. Stress–predominant urinary incontinence (recurrent) with urethral hypermobility (an anatomic failure of her previous needle bladder neck suspension). Urodynamic stress incontinence. Mixed urinary incontinence symptoms. Nocturia. Normal bladder emptying.

Management discussion. The patient declines any further attempts at conservative therapy. Surgical options are discussed. The pros and cons of traditional operations and the newer MUS are reviewed. She asks what would you recommend for your mother, and you recommend the TVT MUS. She is told that the TVT has been around since 1996, it appears to be as effective as the Burch procedure, over a million of these procedures have been performed in the world, and it has good success rates reported out as long as 6 years. She is told that the newer transobturator MUS is also a reasonable option. Some data suggest that it has comparable efficacy to the TVT, but it has not been around as long and there is significantly less information about its safety and durability. Since she may have some scarring in her retropubic space from her previous needle bladder neck suspension, the TOT might have a lower risk of bladder injury, but she is told that this is managed with reinsertion of the trocars and a urinary catheter for 3 days and should have no long-term sequelae. She is also told that this surgery is designed to just treat stress incontinence, and it has about an 85% success rate for doing that. It does not reliably treat her other urge symptoms, and she will probably still have nocturia two times every night.

Management. The patient undergoes a TVT MUS under local anesthesia and conscious sedation as an outpatient procedure. The operating time is 25 minutes, and the patient is discharged from the recovery room without a urinary catheter after she demonstrates a postvoid residual <150 mL. She is seen in your office 3 days and 4 weeks later and denies any SUI. Her postvoid residual at each visit is <100 mL.

Urge Urinary Incontinence Surgery

First-line therapy for urge incontinence is conservative—primarily medications and behavioral therapy with or without biofeedback. Neuromodulation and, more recently, intravesical botulism toxin injection can be considered in refractory urge incontinence before more invasive and morbid procedures like enterocystoplasty or urinary diversion are performed.

Neuromodulation

The bladder is innervated by pelvic and pudendal nerves coming from S2, S3, and S4. The

most common type of neuromodulation is sacral neuromodulation. The exact mechanism on how the electrical stimulation improves urgency, frequency, and urge incontinence is not known. The first stage of the surgical procedure involves implanting a temporary or permanent electrode in the sacral foramina, typically S3, and then connecting it to a temporary external generator that stimulates the afferent and efferent pelvic plexus and pudendal nerves that innervate the bladder. If the patient receives a >50% reduction in her symptoms, then a permanent implantable pulse generator is surgically inserted subcutaneously in the upper outer buttocks. In a large cohort study, 70% of stage 1 patients were able to proceed to stage 2 implants on the basis of a good clinical response.

Botulism Toxin Detrusor Injections

The most recent surgical procedure for refractory urge incontinence is cystoscopically directed botulinum toxin injections into the detrusor muscle. At the time of this writing, botulinum toxin is not approved by the FDA to treat urinary symptoms. Although procedure-specific details for the optimal injection dose and injection sites are still being explored, this procedure appears to give a temporary (4 to 8 months) response in urgency, frequency, and urge incontinence symptoms.

Conclusion

When conservative therapy fails for SUI, surgery provides an option with high likelihood of success. Numerous procedures have been developed over the years, and traditional operations like the Burch and autologous fascia sling procedures are now being replaced with less invasive midurethral synthetic slings. The retropubic and transobturator MUS are the most commonly performed procedures at this time, and only randomized trials will tell which one of these is better. These procedures have shortened recovery and morbidity from surgery with no apparent reduction in efficacy. It is likely that more women will seek surgical treatment for stress incontinence now that there are less invasive options available. New procedures are being marketed at a rapid rate for stress incontinence surgery, often before any human safety and efficacy data is available. Physicians should be skeptical and look for outcome data before using them in individual patients. Neuromodulation and botulism toxin detrusor injections are promising new therapies for refractory urge incontinence.

Summary Points

- Surgery is the most successful treatment for SUI.
- Most SUI surgical procedures are designed to provide support to the posterior urethra, in the proximal or midurethral regions.
- In a large, multicenter randomized clinical trial of the two gold standard traditional operations, the pubovaginal sling was more effective than the Burch colposuspension, but there was a higher rate of voiding complications.
- During the last 10 years, retropubic MUS placed with trocars have largely replaced open surgical procedures and have comparable

efficacy rates as the Burch procedure.
- Transobturator midurethral trocar slings may have similar efficacy rates as retropubic MUS, with reduced rates of bladder and bowel perforation.
- Complications of stress incontinence surgeries include adjacent organ injury, infection, urinary retention, new-onset urge incontinence, and mesh erosion with synthetic meshes.
- New procedures are being marketed at a rapid rate for SUI surgery, often before any human safety and efficacy data is available. Physicians should be skeptical and look for outcome data before using them in individual patients.
- Urethral bulking injections have short-term efficacy and are used to treat women with limited urethral mobility.
- Refractory urge incontinence can be surgically treated with an implantable neuromodulation device.

Nonsurgical Management of Urinary Incontinence and Overactive Bladder

Baharak Amir
Alfred E. Bent

The key to successful management of urinary incontinence and overactive bladder should involve a multidisciplinary team, including the primary care physician, allied health professionals such as clinical nurse specialists in incontinence, and pelvic floor physiotherapists. This allows management of the patient's most troublesome symptoms, which may occur from a number of etiologies. The treatment plan should be stepwise, moving from the least invasive therapy available to more invasive therapies as necessary.

As illustrated in the previous sections of this text, it is important to understand what particular symptoms have brought a patient to seek care. Many treatments are aimed at reducing episodes of urinary incontinence. The incontinence, however, may only be a small factor in a larger picture of voiding concerns. Other symptoms such as urinary frequency occurring at work or several episodes of nocturia may have significantly impacted the patient's quality of life. A comprehensive history and physical examination will determine the symptoms and exacerbating factors. The aim of this section is to provide an overview of the nonsurgical management of stress and urge urinary incontinence and overactive bladder symptoms.

Definitions

The International Continence Society (ICS) defines *stress urinary incontinence* as “involuntary leakage on effort or exertion” and *urge urinary incontinence* as “involuntary leakage accompanied by or immediately preceded by urgency.” *Overactive bladder* is considered a clinical syndrome involving one or more of the following:

1. Urgency (sudden strong unavoidable desire to pass urine)
2. Frequency (more than eight voids in 24 hours)
3. Nocturia (waking more than once through sleeping hours to void)
4. Incontinence.

More than 40% of individuals with overactive bladder will also have the last criteria.

When measuring the efficacy of treatment for urinary incontinence, the focus of many clinical trials to date has been the reduction of incontinent episodes. As mentioned above, however, this measure may not accurately reflect the patient's view of how she has improved with therapy. Quality-of-life questionnaires and global assessment scales may be better suited to providing the patient's perception of how a therapy has helped her.

General Lifestyle Modifications

There have been several suggested strategies to manage and reduce urinary incontinence and overactive bladder symptoms. These include reasonable intake of fluid with limitation of evening intake. Although incontinence may not be related to fluid intake, the voided volumes during the course of a day are a reflection of how much the patient has consumed. Nocturia, in particular, may be directly related to how much the patient has had to drink prior to bedtime.

Caffeine reduction is another strategy that has been suggested. While the relationship between caffeine consumption and episodes of incontinence remains unclear, drinking caffeinated beverages does contribute to overactive bladder symptoms such as frequency and urgency. Very few studies have been published regarding caffeine reduction and improvement of incontinence. Table 53.1 depicts the general caffeine content in common foods and beverages.

Smoking cessation has also been put forth as a means of improving bladder symptoms. Epidemiologic studies have repeatedly demonstrated increased risk of urinary incontinence in older women who have chronic respiratory disorders. Although the relationship between cigarette smoking and urinary incontinence is unclear, there is certainly a relationship between smoking and development of chronic respiratory symptoms. Advocating smoking cessation in a patient with incontinence—in particular, stress urinary incontinence—may prevent worsening of her urinary symptoms.

Managing constipation is also advocated as a lifestyle modification to help urinary incontinence. Constipation is one of several associated risk factors for development of stress urinary incontinence. Lifelong significant straining to have a bowel movement may play a role in the development of stress urinary incontinence. There is growing evidence to support appropriate bowel management in women with and without urinary incontinence.

TABLE 53.1 Caffeine Content in Common Foods and Beverages

Food or Beverage	Serving Size (ounces)	Caffeine (milligrams)

Dark chocolate (bar)	1.5	31
Milk chocolate (bar)	1.5	10
Hot chocolate	8.0	5
Brewed coffee	8.0	135
Instant coffee	8.0	95–102
Decaffeinated brewed coffee	8.0	5
Decaffeinated instant coffee	8.0	3
Black tea (bag or leaf)	8.0	35–70
Decaffeinated black tea (bag or leaf)	8.0	4
Iced tea bottled drinks	16.0	40–50
Green tea	8.0	25–40
Instant tea	8.0	15
Herbal tea	8.0	0
Dark colas	12.0	22–58
Sports-energy drinks	16.0	130–160

Obesity has also been identified as a risk factor for the development urinary incontinence in women. There have been several studies to date that have demonstrated reduction in weekly episodes of incontinence with weight loss. One longitudinal study evaluating the association of lifestyle factors with overactive bladder and stress incontinence established a causal relationship with the development of these conditions and obesity, smoking, and

consumption of carbonated beverages.

Lifestyle modifications are aimed at healthy living and healthy choices involving dietary changes and exercise. Although there is a paucity of literature on the impact of these lifestyle modifications on urinary incontinence or other voiding problems, clinical experience has indicated that they are reasonable suggestions to make in the ongoing care of a patient.

Behavioral Therapy

Most experts agree that the first-line conservative treatment for urinary incontinence and overactive bladder is behavioral therapy, which includes bladder retraining and pelvic floor muscle exercises.

The goal of behavioral therapy is to correct abnormal voiding patterns and establish ways to improve bladder capacity and avoid urge incontinence. This form of therapy is founded on several general principles. First, the patient must be motivated to make changes to her schedule, in particular for voiding. Second, it is important to maintain a low bladder volume by voiding at reasonably frequent intervals. Third, an attempt is made to retrain the central nervous system as well as the pelvic muscles to inhibit detrusor contractions. With these principles, behavioral therapy can be utilized for either cognitively intact or impaired individuals.

Bladder Retraining

In the cognitively intact individual, bladder training involves timed voiding while awake. The initial frequency of voiding is set on the smallest time interval between voids as obtained by a urolog or bladder diary kept by the patient for a minimum of 48 hours (Fig. 53.1). The objective of therapy is to suppress any urge to void between scheduled voids by using a number of relaxation or distraction techniques. One example of such a technique to try and suppress an urge to void is to consider the urge like a wave that will eventually recede. The patient sits or stands still and undertakes his or her relaxation or distraction technique such as deep breathing and imagining the wave until the urge dissipates. Once a patient has been able to do this for several consecutive days at the given voiding frequency without any episodes of incontinence, she can increase her voiding interval incrementally by 15 or 30 minutes per week. The other premise is that as long as the bladder is emptied prior

---

to little or no sensation to void, then it will remain quiescent. This goes on until the patient can comfortably void every 3 to 4 hours without incontinence episodes. The patient needs to maintain a record of voiding times and leak episodes during initial training for a minimum of 6 weeks. She also has to indefinitely maintain some interval that allows her to empty without fear of the bladder going back to its old ways. The recommendation for behavioral therapy is based on expert opinion involving the World Health Organization and the International Consultation on Incontinence (ICI). A Cochrane review in 2000 concluded that although bladder retraining may be helpful in overactive bladder and urge

incontinence, there is no definitive evidence at the present time regarding its benefits compared with other therapies or no treatment at all. Figure 53.2 provides a sample protocol for bladder retraining.

Figure 53.1 Example of an urolog or bladder diary.

In cognitively impaired individuals, the only behavioral therapy with proven efficacy is prompted voiding. This therapy involves the patient being monitored closely by a caretaker to evaluate continence, with a regimented and closely followed schedule to void. The patient needs frequent positive reinforcement and encouragement. In the absence of a nurse or caretaker, prompted voiding can be accomplished by a timer set to go off during voiding times. The interval between voids may vary with the individual but is ideally set at

2 hours.

Bladder retraining has been shown to reduce incontinent episodes by over 50% in both genuine stress incontinence and overactive bladder. The quantity of urine loss has also been shown to be reduced by over 50%, particularly in patients with overactive bladder.

Pelvic Floor Muscle Exercises

Kegel first introduced pelvic floor muscle exercises in 1948. For incontinence, the objective is primarily to strengthen the urethral closure mechanism. Although pelvic floor exercises were first promoted for management of stress incontinence, they are also advocated for urge incontinence. These exercises involve a small number of isometric repetitions at maximal exertion. Women are instructed to contract the pelvic floor muscles and attempt to keep them maximally contracted for 5 to 10 seconds and then to relax for 10 to 15 seconds. The patient is asked to contract the vaginal muscles as she would to stop the flow of urine. The examiner can gauge the accuracy and strength of this contraction with two fingers in vagina while the patient is in the lithotomy position. The examiner should observe circumferential pressure that gently pulls the fingers upward toward the vaginal vault. There are numerous prescriptions for adequate muscle training. Kegel's original recommendation was up to 300 repetitions per day. Modifications to the original description now involve anywhere from 30 to 100 repetitions per day. Figure 53.3 describes a modification for the management of stress urinary incontinence.

a) The patient is given a diary to keep for 48 hours

b) Her voiding interval is set at 1 hour or greater, and she maintains this while awake for one week

c) She keeps a record of voiding times and leak episodes

d) Ideally she is seen by the therapist at one week for reinforcement and counsel

e) The interval between voids is increased at 15 minute intervals weekly until a two to two and a half hour interval is reached

f) If patients are already voiding more often than every hour, and are still having leaking episodes, a combination of medication and bladder retraining may prove of benefit.

Figure 53.2 Sample of bladder retraining protocol.

Pelvic floor muscle exercises require a motivated individual who is aware that it will require several months of therapy before any measurable improvement in symptoms is demonstrated. The patient can be instructed to use two fingers to identify the appropriate muscles to contract and test her own strength. She should be reminded that the appropriate contraction of pelvic floor muscles does not involve contraction of the buttock or abdominal muscles, nor should it involve a Valsalva effort. The health care provider

should avoid instructing the patient to start and stop a urinary stream, as this is not physiologic and may lead to further voiding problems stemming from incomplete emptying. Even with appropriate clinical instruction, a motivated patient may fail to learn the appropriate technique in pelvic floor exercises. In this instance, the use of biofeedback or referral to a pelvic floor physiotherapist may be helpful.

Biofeedback may be used as an adjunct to pelvic floor muscle training. It involves using a number of devices such as vaginal or anorectal probes with pressure-sensitive monitors or electromyography. These devices can help

patients to identify the correct pelvic muscles that need to be relaxed or contracted. One randomized controlled trial evaluating behavioral therapy with biofeedback demonstrated an approximately 63% reduction in incontinent episodes yet failed to demonstrate a significantly better outcome over other behavioral therapies.

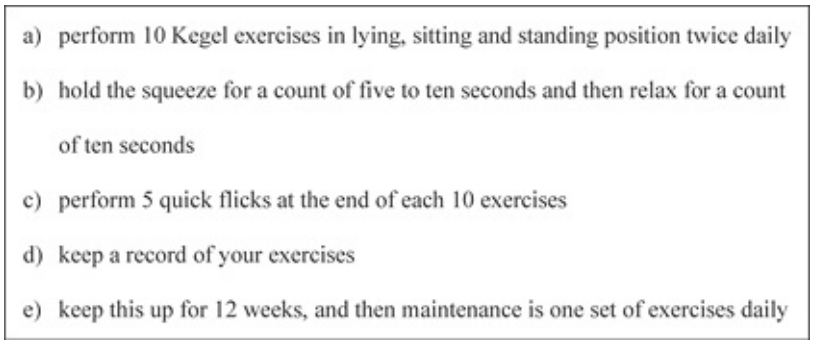

Figure 53.3 Example of a pelvic floor exercise regimen.

Pharmacotherapy

Normal Bladder Physiology

Bladder filling involves the concurrent relaxation of the detrusor muscle and contraction of the urethral sphincter. The sympathetic nervous system is the active neural participant in this phase of bladder function. During normal bladder emptying, there should be a coordinated contraction of the detrusor muscle preceded by relaxation of the urethral sphincter and the pelvic floor muscles. This part of the normal function of the bladder is directed by the parasympathetic nervous system. This sequence of bladder emptying does not occur in all patients. Some patients void only by urethral relaxation, while others mount a Valsalva with or without detrusor contraction and urethral relaxation in order to void.

Pharmacotherapy has been primarily used for individuals with urgency and urge incontinence and overactive bladder with or without incontinence. These medications

suppress bladder contractions, but a few also have direct action on the bladder muscle. At the present time there is little consensus with regards to medical therapy for stress urinary incontinence.

Use in Overactive Bladder and Urge Incontinence

Anticholinergics

Muscarinic acetylcholine receptors are one of seven transmembrane spanning cell receptors that are widely distributed in the central and peripheral nervous systems. There have been five muscarinic cell receptors cloned and defined pharmacologically. Bladder contractions are mediated mainly via stimulation of these muscarinic receptors expressed on the bladder smooth muscle. M2 and M3 immunoreactivity has been observed in the urothelium, nerve fibers, and detrusor muscles. The normal M2-to-M3 ratio of these receptors on the bladder is 3:1. Increase in the ratio has been identified in patients with clinical bladder syndromes such as overactive bladder and correlates with increased frequency and urgency scores.

When a patient continues to have symptoms of overactive bladder or urge incontinence despite efforts with lifestyle modifications and behavior therapy, the next step in management involves medical therapy. Anticholinergic medications with antimuscarinic effects are the medication most commonly prescribed for overactive bladder and urge incontinence. A systematic review in 2003 demonstrated that therapy with these agents results in a 40% higher cure or improvement over placebo.

Anticholinergic medication acts by suppressing contractions of the detrusor muscle through inhibition of the neurotransmitter acetylcholine from binding muscarinic receptors. A few of these agents also have direct antispasmodic effects on the detrusor smooth muscle. There are a number of medications in the class of anticholinergics that have been approved for use in North America for a variety of conditions. Currently, only a few are available in the market for the treatment of overactive bladder and urge incontinence (Table 53.2).

On average, anticholinergic therapy reduces weekly urge incontinence episodes by 70%. Therapeutic effect may be seen as early as 1 week, but generally the medication should be used for 1 month prior to adjusting dose and for 2 months before determining lack of efficacy. Side effects of this class of medication are related to the anticholinergic effects elsewhere in the body, such as the gastrointestinal tract and the central nervous system. Hence, patients may experience constipation, confusion, or blurred vision. The most common side effect of this class of medication is dry mouth. Estimates suggest that up to 30% of patients experience dry mouth while taking anticholinergic medication. The second most common complaint is constipation. Newer medications approved for use in North America are marketed as being “uroselective,” as they have improved selectivity for M3 receptors. Anticholinergics can potentially cause urinary retention in patients with detrusor hyperactivity and impaired contractility. These patients may present with overflow incontinence and recurrent urinary tract infections.

TABLE 53.2 Anticholinergic Medication Approved for Use i Overactive Bladder and Urge Incontinence

Medication	Dose	Metabolism	Muscarinic Receptor Selectivity	Other
Darifenacin	7.5–15.0 mg q.d.	Hepatic	Yes (M3)	—
Oxybutynin chloride IR ER Transdermal	2.5 mg b.i.d. t.i.d. (maximum 20 mg/d) 5–10 mg q.d. (maximum 30 mg/d) 3.89 mg (twice weekly)	Hepatic	No	Direct antispasr effects
Solifenacin	5–10 mg q.d.	Hepatic	Yes (M3)	—
Tolterodine tartrate IR ER	1–2 mg b.i.d. 2–4 mg q.d.	Hepatic	No	—
Trospium	20 mg b.i.d.	Renal	No	Water soluble, therefore crosses B poorly

IR, immediate release; ER, extended release; BBB, blood-brain

barrier.

Anticholinergics should not be given to patients with bowel obstruction. The health care provider should also try to avoid the use of these medications in patients with Alzheimer's disease. The only absolute contraindication to taking this class of medication is uncorrected narrow or acute angle glaucoma, as mydriasis is to be avoided in these patients.

Oxybutynin is available in both immediate release as well as extended release and is also available as a transdermal formulation. It has both direct antispasmodic and antimuscarinic effects. The quick-release formulations are useful when the effect is wanted at particular times, such as a single dose for an afternoon card game or bus trip. The efficacy of oxybutynin can continue to increase over the course of 2 weeks or more, and therefore, it is advised that any dose change or discontinuation be avoided before a 2-week trial. However, the immediate-release preparation has side effects that are intolerable in up to 70% of patients, and it is a very poor first-choice medication. The advantage of the transdermal preparation is the lack of dry mouth and constipation side effects in exchange for skin rash at the patch site. Generally, a 10-mg dose of the extended-release preparation is used for initial therapy.

Tolterodine and oxybutynin extended-release formulations have similar efficacy and side effect profiles. The starting dose of 4 mg of the extended-release preparation is tolerated well by almost all patients.

Trospium is approved for the treatment of overactive bladder and urge incontinence. In comparison to placebo, this medication produces a larger reduction in the incidence of incontinence. It is water soluble and therefore crosses the blood–brain barrier poorly and has been proposed for those who are cognitively impaired, including the elderly. Trospium is excreted by the kidneys and should be avoided in those patients with renal impairment. However, its metabolism does not compete with hepatic enzymes that most drugs rely on.

Solifenacin and darifenacin are also approved for treating symptoms of overactive bladder and urge incontinence. These two medications have more selective M3 receptor affinity. It remains to be proven whether this receptor selectivity actually translates to increased efficacy, as the only comparative trial with another medication was with tolterodine, and this trial did not demonstrate any significant difference in rates of dry mouth and constipation.

There are a number of older antimuscarinic agents that may also be used on occasion for overactive bladder. Some of these medications may be indicated and marketed for other purposes such as peptic ulcers and irritable bowel syndrome and can be less expensive. These include propantheline bromide, flavoxate hydrochloride, and hyoscyamine sulfate.

In summary, anticholinergics medications have similar efficacy. There may be individual differences and sensitivity to medication, and one preparation may work in one patient when another does not. Side effects are also similar, other than for the transdermal administration.

Botulinum Toxin

Schurch and colleagues first reported cystoscopic injection of the botulinum toxin into the detrusor muscle in 2000. They reported the use of botulinum toxin type A (BoNTA) in 19 spinal cord–injured patients with detrusor overactivity and incontinence. The goal for these patients was to allow them to empty their bladders through clean intermittent self-catheterization without intervening incontinence. By 6 weeks postinjection, 17 of the patients were continent

of urine. Since this initial report, there have been increasing reports of using botulinum injections as an alternative to long-term oral therapy or for refractory overactive bladder symptoms and urge incontinence.

Botulinum toxin is a neurotoxin produced by gram-negative coccus *Clostridium botulinum*. It works by binding to presynaptic nerve terminals and enters the cell through a process known as endocytosis. Once intracellular, the toxin inhibits the release of acetylcholine from the presynaptic nerve terminal, hence preventing acetylcholine from stimulating the muscle.

Scientific information regarding the appropriate sites of injection, dosing, and the number of injections is lacking. Although earlier reports recommended sparing of the trigone of the bladder to prevent vesicoureteral reflux, more recent reports suggest that there is no problem injecting this area. Many reports also recommend avoiding the dome of the bladder to avoid inadvertent injection of the toxin into the peritoneal cavity. In published reports, the numbers of injections range from 10 to 50, with most recommending on average 30 injections. The amount of toxin ranges from 200 to 5,000 U, with the average dilution recommended at 100 U per 10 mL of solution (Fig. 53.4).

Most studies using cystoscopic injection of botulinum toxin in idiopathic detrusor overactivity and overactive bladder have shown good efficacy with few side effects. The only significant side effect reported is urinary retention that occurs infrequently and is often transient and dose dependent, resolving by 2 months after treatment. There is very little information on the number of treatments that a patient may require. Several studies have shown significant improvement after only one instillation for up to 36 months, while another has demonstrated that patients may require an average of eight instillations over an 18-month period. A nonrandomized prospective study consisting of 25 patients failed to show botulinum toxin B (BTX B) as an effective treatment for refractory overactive bladder. Clearly, more studies using botulinum injections are warranted.

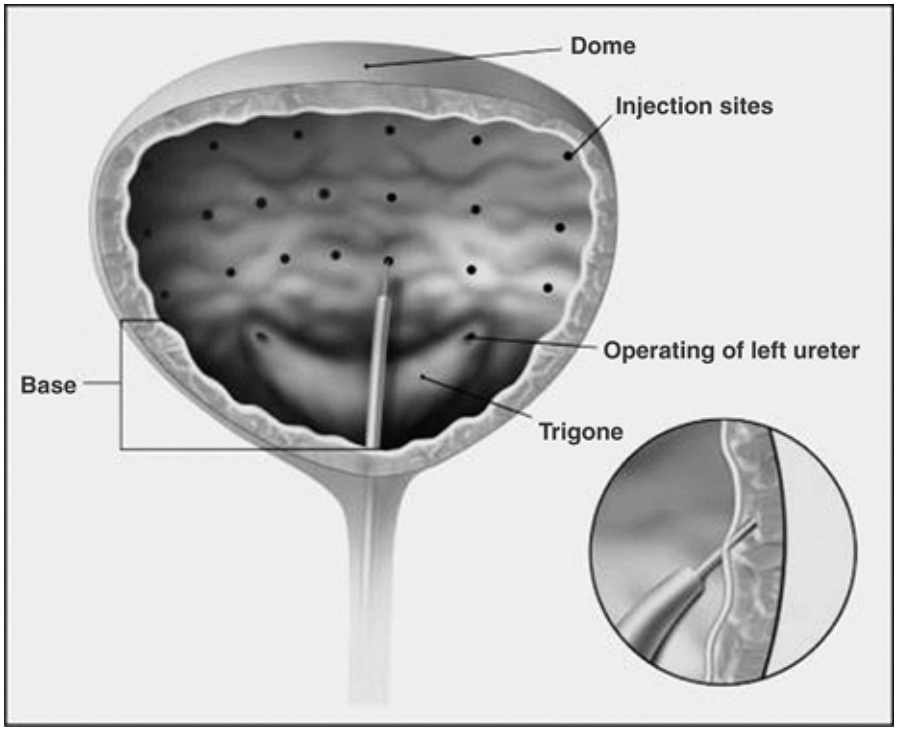

Figure 53.4 Example of an injection template for botulinum, with 20 injections and sparing of the trigone and dome. (From Nitti VW. Botulinum toxin for the treatment of idiopathic and neurogenic overactive bladder: state of the art. *Rev Urol* 2006;8(4):198–208.)

Use in Stress and Mixed Urinary Incontinence

Alpha-Adrenergic Agonists

Medications do not play a significant role in the treatment of stress urinary incontinence. α-Adrenergic agonists were once advocated for use in treating stress urinary incontinence. These agents stimulate urethral smooth muscle contraction and have demonstrated modest improvement of stress incontinence. However, this class of medication has been removed from the market, as it have been shown to increase the risk of hemorrhagic stroke.

Serotonin-Norepinephrine Reuptake Inhibitors

Several drugs that inhibit the reuptake of serotonin and norepinephrine have been advocated for use in the management of patients with mixed urinary incontinence. Imipramine is a tricyclic antidepressant that has both anticholinergic and adrenergic reuptake inhibitory effects. The adrenergic inhibitory reuptake effect increases the urethral sphincter contractive force via spinal cord modulation. This part of imipramine's action has allowed its use for treatment of stress urinary incontinence, and its anticholinergic properties allow it to be used in urge incontinence. There have been no randomized clinical trials to date that have evaluated the use of this medication in the treatment of mixed incontinence.

Duloxetine, which is approved for use in major depressive disorder and diabetic neuropathy, is the only medication in this class that has undergone phase III controlled trials and has shown efficacy in the treatment of stress incontinence. It is approved for the treatment of stress urinary incontinence in only Europe and Japan.

Estrogen

There is no evidence that estrogen alone is effective in the treatment of stress or urge urinary incontinence. The Women's Health Initiative, a large randomized trial evaluating a number of outcomes in postmenopausal women in the United States, demonstrated that there was a 39% increased risk of developing urinary incontinence in women after 1 year of initiating estrogen and progestin therapy and a 52% risk of developing incontinence after initiating estrogen alone. Of all types of incontinence, there was a higher risk of developing stress urinary incontinence followed by mixed urinary incontinence.

The only context in which estrogen has been shown to be effective is with vaginal preparations that improve vaginal conditioning and promote growth of normal vaginal flora to prevent recurrent urinary tract infections.

Continence Pessaries

Intravaginal devices such as pessaries are used for women with stress urinary incontinence related to pelvic floor laxity or pelvic organ prolapse (Fig. 53.5). These devices are appealing to women with stress urinary incontinence who wish to avoid surgery. Women who are not finished with childbearing, who currently are not appropriate surgical candidates, or who are waiting to have surgery can use continence pessaries as an interim management option.

Pessaries made specifically for stress urinary incontinence provide support for the bladder neck and stabilize the urethrovesical junction. The mechanism by which these devices are believed to restore continence is similar to that achieved by surgery. By stabilizing the urethrovesical junction, the pessary allows complete transmission of intra-abdominal pressure to the urethra and helps to increase the urethral closure pressure.

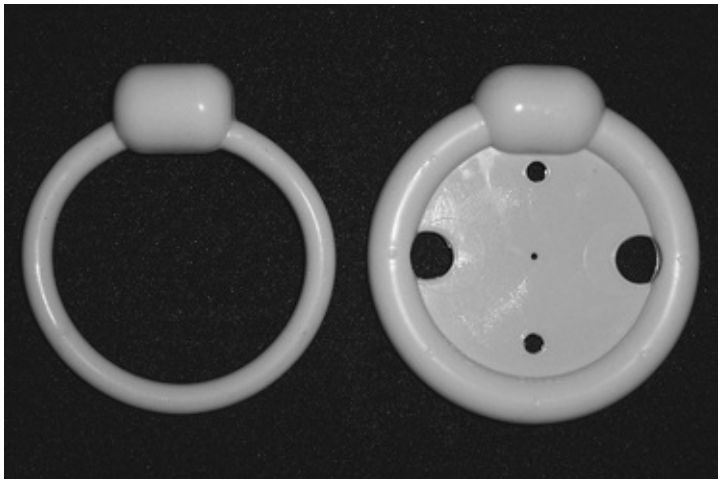

Figure 53.5 Examples of vaginal pessaries used for management of stress urinary incontinence.

The pessary is fitted by an experienced health professional, and the patient should not feel the device in the vagina when the appropriate size of pessary is used. The patient is provided with teaching regarding the removal and insertion of the device. Initial follow-up should be within 2 weeks of fitting such that the function and fit of the pessary can be assessed within a timely fashion for the patient. The size or type of the pessary may need to be changed. If the patient is unable to care for her pessary, she may need to be followed every 6 weeks to 3 months by a health professional who can remove the pessary, inspect the condition of the vagina, and clean and then reinsert the pessary for her.

There are a number of continence pessaries from which to choose, and much of the decision lies with the individual needs of the patient and the preference of the health professional. There are minimal risks associated with the use of a pessary for pelvic organ prolapse or incontinence. The risks are related to inappropriate sizing, fitting, and care, and as a result, patients may experience malodorous vaginal discharge, abrasions, or ulcerations.

The medical literature examining the use of vaginal pessaries for the treatment of urinary incontinence has a paucity of information. A Cochrane review to examine the effect of mechanical devices on urinary incontinence in women was subsequently withdrawn in 2003 because of a lack of research evidence. The National Institutes of Health (NIH) has an ongoing study to evaluate the use of continence pessaries as well as behavioral training in women with stress urinary incontinence.

Functional Electrical Stimulation

Functional electrical stimulation (FES) has been proposed as a means to reeducate and strengthen the pelvic floor muscles. Pelvic floor FES produces an electrically stimulated contraction of the smooth and striated muscles of the pelvic floor. It may be a useful adjunct in the subset of patients who find it difficult to mount a voluntary contraction of the pelvic floor muscles or who have significant weakness of these muscles. A recent randomized control trial demonstrated that training of the pelvic floor muscles via voluntary contraction of these muscles was superior to FES in patients with genuine stress incontinence. Other prospective clinical trials have also found that FES does not significantly increase the effectiveness of pelvic floor muscle exercises and other behavioral therapy. In general, FES for pelvic floor muscle strengthening has been poorly studied, but these devices have been approved for

Medicare payment in the United States after a patient has failed a first-line therapeutic trial. European use of these devices is much more common practice.

Summary Points

- The etiology of overactive bladder and urinary incontinence is

multifactorial. It is difficult to determine all of the factors contributing to a patient's symptoms of overactive bladder or incontinence. By taking a stepwise approach, starting with conservative therapy to manage these concerns, it may be possible to significantly improve a patient's quality of life.

- Conservative therapy involves management plans that are not invasive and have low risk profiles. The appropriate stepped approach should first involve lifestyle modifications, whereupon the patient is an active participant in her own therapy. There must be accurate and timely instruction of bladder training and or pelvic floor muscle exercises.
- Should the care necessitate use of medications, there are a number to choose from. The appropriate choice of pharmacotherapy will be determined by the patient's symptoms and tolerance to and the costs of the medication as well as physician preference. Presently, pharmacotherapy is advocated for patients with overactive bladder and urge and mixed urinary incontinence. These medications can be used following or in conjunction with lifestyle modifications and behavioral therapy.
- Vaginal pessaries for incontinence are a viable option to many women who may be undecided on surgical correction for their stress urinary incontinence. These devices afford a way of controlling or reducing episodes of stress incontinence and can also be used in conjunction with behavior therapy such as pelvic floor muscle exercises.
- There is need for further research in the area of nonsurgical management of urinary incontinence. Many of the management options described previously have not undergone randomized placebo-controlled trials, and efficacy for many needs to be substantiated further.

Fecal Incontinence and Defecation Disorders

Dee E. Fenner
Catherine Ann Matthews

Bowel control problems cover a broad range of symptoms and pathophysiology that encompass disorders of bowel evacuation and storage, bowel motility, anorectal pain syndromes, and anatomic abnormalities such as hemorrhoids, anal fissures, and tumors. Patients may present to the obstetrician–gynecologist with symptoms that range from excessive straining, having to support the perineum or posterior vaginal wall to defecate, or suffering from frank fecal incontinence.

Bowel and anorectal disorders are divided into two major categories: those arising from a defined structural or neuropathic defect versus a functional disorder in which no such pathology can be detected. For example, obstructed defecation may be caused by an anatomic defect of the posterior vaginal wall (rectocele or perineocele) or may result from the functional inability to voluntarily relax the muscles of the pelvic floor (pelvic floor dyssynergia). The Rome III criteria are a set of consensus agreed-on criteria that standardized definitions about functional disorders of the bowel, rectum, and anus. The broad category of functional bowel disorders includes irritable bowel syndrome (IBS), functional abdominal bloating, functional constipation, and functional diarrhea. Included in the category of functional anorectal disorders is functional fecal incontinence and functional anorectal pain syndromes including levator ani syndrome, proctalgia fugax, and pelvic floor dyssynergia. The specific diagnostic criteria for each of these functional disorders are listed in Table 54.1.

The prevalence of bowel disorders is higher in women than in men. Highly variable rates of defecatory dysfunction and fecal incontinence have been reported, which most likely reflects the heterogeneity of the populations studied, the use of nonstandardized questionnaires, a variety of definitions in terms of frequency of defecation or fecal loss, and patient reluctance to disclose these potentially embarrassing problems. Constipation, defined as less than three stools per week, affects 2% to 28% of those surveyed. Obstructed defecation occurs in approximately 7% of the adult population affected by constipation, and while many of these women demonstrate posterior vaginal wall defects radiologically, it is unclear whether this is a cause or a consequence of chronic straining.

Fecal incontinence is defined as the inability to defer the elimination of liquid or solid

stool until there is a socially acceptable time and place to do so. Anal incontinence includes the inability to defer the elimination of gas, which may be equally socially embarrassing. The community-based prevalence of fecal incontinence has been reported as 1.4% to 2.2%. Aging has been consistently identified as a major risk factor for the development of fecal incontinence, and the prevalence has been reported to approach 50% in nursing home residents. A recent study of more than 3,000 community-dwelling women found a population-adjusted prevalence of 7.7% when fecal incontinence was defined as loss of liquid or solid stool at least monthly. The prevalence of fecal incontinence increased linearly with age (Fig. 54.1). Significant independent risk factors included age, depression, vaginal parity, and a history of operative vaginal delivery. A recent study of the prevalence of anal incontinence in women seeking general gynecologic care suggested that the prevalence of symptoms when asked in this population is higher. In a group of 457 women seeking general gynecologic care, the overall rate of bothersome anal incontinence was 28.4%. The mean age of this cohort was 39.9 years and after logistic regression analysis, IBS (odds ratio [OR] 3.2; 95% confidence interval [CI] 1.75 to 5.93), constipation (OR 2.11; CI 1.22 to 3.63), age (OR 1.05; CI 1.03 to 1.07), and higher body mass index

(OR 1.04; CI 1.01 to 1.08) remained significant risk factors. It is unclear if it was the type of questionnaire or comfort of the patients in disclosing this information to their gynecologist that resulted in such a dramatically higher affirmative response. This study certainly raises the question of anal incontinence being a silent affliction for many women.

TABLE 54.1 ROME III Criteria for Functional Disorders

IBS	At least 12 weeks or more, which need not be consecutive, in the preceding 12 months of abdominal discomfort or pain that has two of three features: 1. Relief with defecation, 2. Onset associated with a change in the frequency of stool, and/or 3. Onset associated with a change in form (appearance of stool).
Functional abdominal bloating	At least 12 weeks, which need not be consecutive, in the preceding 12 months of: 1. Feeling of abdominal fullness, bloating, or visible distension; and 2. Insufficient criterion for the diagnosis of dyspepsia, IBS, or other functional disorder.

Functional constipation	At least 12 weeks, which need not be consecutive, in the preceding 12 months of two or more of the following: 1. Straining >1/4 of defecations, 2. Lumpy or hard stools >1/4 of defecations, 3. Sensation of incomplete evacuation >1/4 of defecations, 4. Sensation of anorectal obstruction/blockage >1/4 of defecations, 5. Manual maneuvers to facilitate >1/4 of defecations, and/or 6. <3 defecations per week.
Functional diarrhea	At least 12 weeks, which need not be consecutive, in the preceding 12 months of: 1. Loose (mushy) or watery stools, 2. Present >3/4 of the time, and 3. No abdominal pain.
Functional fecal incontinence	Recurrent uncontrolled passage of fecal material for >1 month, in an individual with a developmental age of at least 4 years, associated with: 1. Fecal impaction, 2. Diarrhea, or 3. Nonstructural anal sphincter dysfunction.
Levator ani syndrome	At least 12 weeks, which need not be consecutive, in the preceding 12 months of: 1. Chronic or recurrent rectal pain or aching, 2. Episodes last 20 minutes or longer, and 3. Other causes of rectal pain such as inflammatory bowel disease, cryptitis, fissure, hemorrhoids, and the like, have been excluded.
Pelvic floor	1. Patient must satisfy diagnostic criteria for functional constipation; 2. There must be manometric, EMG, or radiologic evidence for inappropriate contraction or failure to relax the pelvic floor muscles during repeated attempts to

dyssynergia	defecate; 3. There must be evidence of adequate propulsive forces during attempts to defecate; and 4. There must be evidence of incomplete evacuation.

IBS, irritable bowel syndrome; EMG, electromyography.

Fecal incontinence is also significantly more common in women with other pelvic floor disorders; 7% to 30% of women with urinary incontinence and/or pelvic organ prolapse also have fecal incontinence. The presence of both urinary and fecal incontinence is known as dual or double incontinence. In a recent case-controlled study of women with and without pelvic floor disorders, those with pelvic organ prolapse and/or urinary incontinence were five times more likely to report bothersome anal incontinence than a group of healthy control women. The presence of this "double" incontinence has been associated with a significantly higher adverse effect on quality of life. It is clear that while screening for bowel problems in the general gynecologic population is important, it is imperative that any woman with pelvic floor dysfunction is comprehensively evaluated for concomitant fecal incontinence.

Many patients are reluctant to seek medical attention for bowel disorders because of embarrassment and social stigma. Primary care providers, including obstetricians and gynecologists, are therefore integral to the successful disclosure of such problems by routinely inquiring about bowel function during periodic health care visits. Ideally, a few written questions such as "Do you have difficulty emptying your bowels" and "Do you leak gas, liquid, or solid stool" should be part of the standard office intake questionnaire. Several reports have shown that twice the number of patients complain of fecal or flatal incontinence when given written questionnaires than when answering verbal questions. If an affirmative response if obtained, then further quantification of the problem is obviously required. The Wexner fecal incontinence scale is a quick and simple questionnaire that has been validated to track changes in symptoms and is a useful tool to assess and track patient progress (Table 54.2).

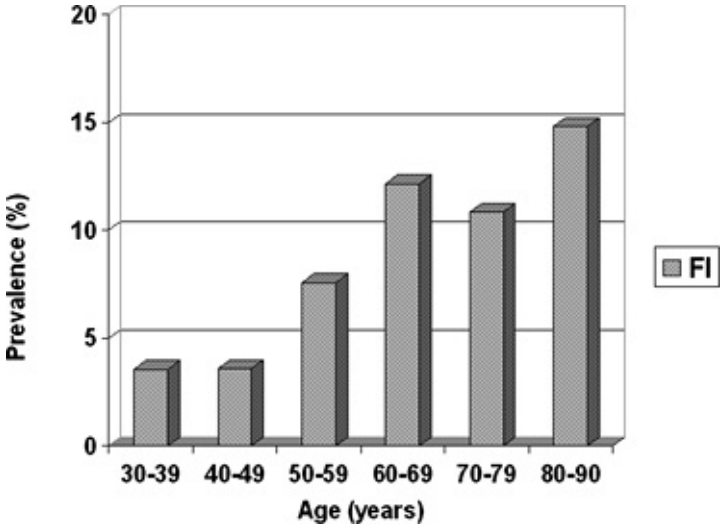

Figure 54.1 Prevalence of fecal incontinence by decade of age. (*FI*, fecal incontinence.) (From Melville JL, Fan MY, Newton K, et al. Fecal incontinence in US women: a population-based study. *Am J Obstet Gynecol* 2005;193(6):2071–2076.)

Because approximately 10% of women will experience some alteration in bowel habits after one vaginal delivery, it is especially critical to incorporate open-ended questions concerning flatal or fecal incontinence and fecal urgency at the 6-week postpartum visit. Other high-risk groups that should be targeted for additional questions regarding bowel storage and evacuation are women with other pelvic floor disorders and those over age 65.

A critical component of screening for anorectal disorders includes colon cancer screening. The recommended screening guidelines from the American Cancer Society are presented in Table 54.3. In general, screening guidelines are for “asymptomatic” patients and those not at an increased risk for colon cancer. First-degree relatives of patients with colon cancer or patients with acute changes in bowel habits, including gross or occult blood, should be referred to a gastroenterologist or surgeon for colonoscopy and other evaluation.

TABLE 54.2 Wexner Scale for Anal Incontinence, a Validat Instrument to Quantify the Type and Severity of Incontine

How often…	Never	Rarely (<1x/month)	Sometimes (1-3x/month)	Usually (1-6x/week)	A (>
Are you incontinent of:					
Solid stool	0	1	2	3	

Liquid stool	0	1	2	3
Gas/flatus	0	1	2	3
Do you wear a pad due to stool incontinence	0	1	2	3
Do you alter your lifestyle due to stool incontinence	0	1	2	3

Anatomy

The anorectum comprises the distal-most portion of the gastrointestinal tract. The rectum is a hollow muscular tube, 12 to 15 cm long, composed of a continuous layer of longitudinal smooth muscle that interlaces with the underlying circular smooth muscle. It is separated from the anus by the dentate, or pectineal line that demarcates a transition in the type of epithelium and innervation. The rectum is lined by columnar epithelium and is under autonomic control. In contrast, stratified squamous epithelium, innervated by the somatic nervous system, is found in the anal canal.

The anal sphincter complex is made up of the internal anal sphincter (IAS) and external anal sphincter (EAS), which provide both resting and increased voluntary tone to the anal canal. The IAS is a thickened expansion of the circular smooth muscle of the bowel wall, a predominantly slow-twitch, fatigue-resistant muscle that contributes approximately 70% to 75% of the resting sphincter pressure but only 40% after sudden rectal distension and 65% during constant rectal distension. The anus is therefore normally closed by the tonic activity of the IAS that is primarily responsible for maintaining anal continence at rest. This barrier is reinforced during voluntary squeeze by the EAS. The anal mucosal folds, together with the expansive anal vascular cushions, provide a tight seal. These barriers are further augmented by the puborectalis muscle, which when tonically contracted forms a flaplike valve that creates a forward pull and reinforces the anorectal angle. Figure 54.2 demonstrates a simplified drawing of the sphincter complex.

Through voluntary contraction, the EAS can contribute an additional 25% of anal squeeze pressure. Because the

EAS is made up of fast-twitch, fatigable fibers, this increased tone cannot be maintained over a prolonged period. The EAS is integral to maintaining voluntary control over the evacuation of gas and liquid stool. The pudendal nerve, which arises from the second, third, and fourth sacral nerves, innervates the EAS. A pudendal nerve block creates a loss of sensation in the perianal and genital skin and weakness of the anal sphincter muscle but does not affect rectal sensation that is most likely transmitted along the S2, S3, and S4 parasympathetic nerves. These nerve fibers traverse along the pelvic splanchnic nerves and are independent of the pudendal nerves.

TABLE 54.3 Colon and Rectal Cancer Screening Recommendations

Beginning at age 50, both men and women should follow one of these five testing schedules:

- yearly FOBT[a] or FIT
- flexible sigmoidoscopy every 5 years
- yearly FOBT[a] or FIT, plus flexible sigmoidoscopy every 5 years[b]
- double-contrast barium enema every 5 years
- colonoscopy every 10 years.

All positive tests should be followed up with colonoscopy. People should talk to their doctor about starting colorectal cancer screening earlier and/or undergoing screening more often if they have any of the following colorectal cancer risk factors:

- a personal history of colorectal cancer or adenomatous polyps
- a strong family history of colorectal cancer or polyps (cancer or polyps in a first-degree relative [parent, sibling, or child] younger than age 60 or in two first-degree relatives of any age)
- a personal history of chronic inflammatory bowel disease
- a family history of an hereditary colorectal cancer syndrome (familial adenomatous polyposis or hereditary nonpolyposis colon cancer).

FOBT, fecal occult blood test; FIT, fecal immunochemical test.
[a]For FOBT, the take-home multiple sample method should be

used.
[b]The combination of yearly FOBT or FIT flexible sigmoidoscopy every 5 years is preferred over either of these options alone.

Anorectal Physiology

The successful storage and evacuation of fecal material relies on normal stool consistency and bowel motility, rectal compliance, an intact anal sphincter complex, and the ability to voluntarily relax the puborectalis muscle and sphincters to facilitate defecation. The physiology of voluntary bowel evacuation relies on the rectoanal inhibitory reflex (RAIR). When a bolus of fecal material is delivered to the rectum, increased rectal pressure and distension causes transient relaxation of the IAS, allowing a small sample of the rectal contents to come in contact with the sensory afferent somatic nerves innervating the anoderm. The amplitude and duration of this relaxation increases with the volume of rectal distension and is mediated by the myenteric plexus. The RAIR facilitates the discrimination of gas, liquid, or solid fecal material that is present in the rectum and permits voluntary evacuation in a socially acceptable manner. Once the conscious decision has been made to permit evacuation, the puborectalis muscle relaxes, increasing the anorectal angle and allowing passage of solid fecal material. Patients who experience paradoxical contraction of the puborectalis muscle and sphincter complex with straining suffer from severe obstructed defecation and require biofeedback and physical therapy to reverse this pathology.

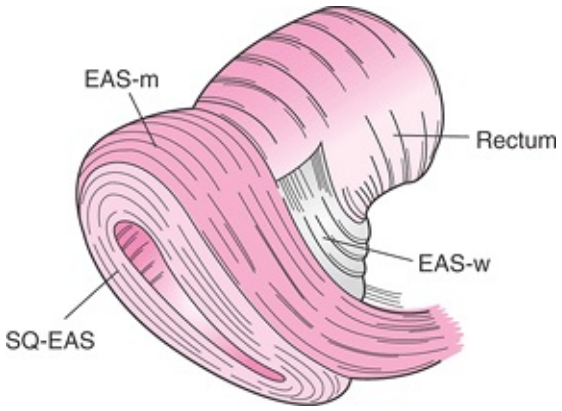

Figure 54.2 Anatomy of the external anal sphincter. (*EAS-m*, main body of the external anal sphincter; *SQ-EAS*, subcutaneous external anal sphincter; *EAS-w*, lateral wing portion of the external anal sphincter.)

Fecal Incontinence

Etiology and Pathophysiology

The etiologies of fecal incontinence are many and are listed in Table 54.4. It is helpful to divide the etiologies between those that start outside or above the pelvis versus those within the pelvis. In many cases, patients will have several abnormalities that lead to fecal incontinence, such as diarrhea-predominant IBS and a chronic third-degree laceration. The etiologies outside the pelvis include all

the pathologies that cause diarrhea or increased intestinal motility. Neurologic conditions such as multiple sclerosis, diabetic neuropathy, trauma, or neoplasms in the spinal cord or cauda equina initially begin as pathologies outside the pelvis, and the pelvic floor is presumed normal. As these neuropathies progress, the pelvic floor muscular function or rectal sensation may become impaired, resulting in fecal incontinence.

TABLE 54.4 Etiologies of Fecal Incontinence

Pathology outside the pelvis
Diarrheal states
- Infectious diarrhea
- IBS
- Inflammatory bowel disease
- Short-gut syndrome
- Bacterial overgrowth (common in cases of diabetic gastroparesis)
- Laxative abuse
- Radiation enteritis
- Carcinoid tumor
- Malabsorption

Neurologic diseases
- Congenital anomalies (e.g., myelomeningocele)
- Multiple sclerosis
- Diabetic neuropathy
- Neoplasms or injury of the brain, spinal cord, or cauda equina
- Scleroderma (reduced rectal compliance)

Pathology within the pelvis
Obstetric injury
- Disruption of IAS
- Disruption of EAS
- Pelvic floor/anal sphincter denervation

Trauma
- Pelvic fracture
- Anorectal surgery
- Anal intercourse

- Rectovaginal fistula
- Rectal neoplasia
- Rectal prolapse
- Rectocele/perineocele
- Hemorrhoids
- Overflow
  - Impaction
  - Encopresis

Fecal incontinence that arises from pathology within the pelvis is largely attributed to two broad categories: direct anatomical disruption of the sphincter complex, with or without neuropathy, usually occurring with the first delivery that results in an earlier presentation of fecal incontinence and neurogenic dysfunction of the pelvic floor and sphincter complex that appears to be cumulative and leads to a presentation of fecal incontinence in later life.

Historically, incontinence secondary to pelvic floor/anal sphincter denervation has been designated as “idiopathic” and represents as many as 80% of patients with fecal incontinence. Denervation may be secondary to pregnancy, vaginal delivery, chronic straining with constipation, rectal prolapse, or descending perineal syndrome. Histologic studies of the EAS and puborectalis in women with idiopathic fecal incontinence show fibrosis, scarring, and fiber-type grouping consistent with nerve damage and reinnervation. Electromyographic studies (EMGs) have demonstrated reinnervation of the pelvic floor with increased fiber density and prolongation of nerve conduction.

Obstetric Anal Sphincter Injury

In younger women, a common cause of fecal incontinence is anatomic damage to the anal sphincter that is sustained at the time of vaginal delivery, with or without neuronal injury. Damage to the anal sphincter can occur by mechanical disruption or separation of the IAS or EAS or by damage to the muscle innervation by stretching or crushing the pudendal and pelvic nerve. In a landmark study from England in 1993, 13% of primiparous women and 23% of multiparous women developed fecal incontinence or fecal urgency at 6 weeks postpartum. All but one of the symptomatic women had evidence of anatomic anal sphincter disruption on endoanal ultrasound. While pudendal nerve studies initially showed prolongation, the vast majority demonstrated full neuronal recovery by 6 months postpartum. This study suggested that the contribution of an anatomic sphincter injury was a greater determinant of developing symptoms than denervation injury, highlighting the need to identify obstetric risk factors that are associated with anal sphincter tears.

The prevalence of clinically recognized anal sphincter lacerations varies widely and has been reported to occur in 0.6% to 20.0% of vaginal deliveries, with higher rates documented after operative vaginal delivery. Results obtained from endoanal ultrasound studies of the anal sphincter complex after one vaginal delivery demonstrate an incidence of “occult” anal sphincter disruption in 11% to 35%. Occult sphincter lacerations are not recognized at

delivery, and in fact, the perineal skin may be intact with an underlying muscle tear not visible. Risk factors for both occult and clinically recognized anal sphincter disruption include midline episiotomy, operative vaginal delivery (both forceps and vacuum), persistent occiput posterior head position, prolonged second stage of labor (>2 hours), and delivery of macrosomic infants.

Persistent symptoms of anorectal dysfunction are reported by 20% to 50% of women who sustain an anal sphincter injury and have a primary repair. Overall, the prevalence of anal incontinence and fecal incontinence following visible sphincter lacerations has been reported at approximately 40% and 13%, respectively. Current evidence suggests that if a primiparous woman presents with symptoms of fecal incontinence, there is a 76.8% chance of an anal sphincter defect being identifiable on endoanal ultrasonography. Several studies that investigated women up to 5 years postpartum following a third-degree tear and a primary repair have shown that as many as 85% will have persistent structural defects with approximately 58% subsequently running the risk of developing fecal incontinence.

Anal Incontinence and Symptoms Distant from Delivery

Differences in rates of incontinence reported by women with and without lacerations may fade with advancing age, depending on the time since delivery. Several retrospective studies have looked at the impact of sphincter laceration on anal incontinence symptoms and report different long-term risks. A retrospective cohort study on 125 matched pairs of women with and without a history of sphincter laceration, with a median follow-up of 14 years after index delivery, found a threefold higher risk of anal incontinence in the tear group. In contrast, a 30-year retrospective cohort study reported equal rates of anal incontinence among women who delivered vaginally with an overt sphincter rupture, in those with episiotomy without sphincter rupture, and in those who only delivered by cesarean section. Another study of 4,569 women 18 years after delivery found that only 6% of the reports of fecal incontinence were attributable to a prior sphincter tear. One prospective cohort study of 242 women 5 years after vaginal delivery identified age (OR 1.1; 95% CI 1.0 to 1.2) and prior overt sphincter laceration (OR 2.3; 95% CI 1.1 to 5.0) as well as subsequent vaginal delivery (OR 2.4; 95% CI 1.1 to 5.6) as predictive of anal incontinence symptoms.

Effect of Subsequent Vaginal Delivery

Severity of anal incontinence symptoms may be affected by subsequent vaginal delivery. A study following 117 women with a history of third- or fourth-degree lacerations 1 to 10 years after primary repair found that the 43 women who underwent another vaginal delivery had an increased risk (relative risk [RR] 1.6; 95% CI 1.1 to 2.5) of anal incontinence when compared with the risk found in the 74 women without more deliveries. The chance of developing permanent anal incontinence after a subsequent delivery may also be affected by the severity of the tear in the index pregnancy. In a series of 177 women, severe anal incontinence was reported more commonly after a second delivery in those who had sustained a fourth-degree laceration in their first delivery when compared with

women who had only third-degree lacerations (P = 0.043).

The presence of transient incontinence after sphincter laceration and repair is also predictive of the likelihood of developing permanent incontinence with a subsequent delivery. In a study of 56 women with complete EAS tears, 23 (41%) had transient incontinence and 4 (7%) had permanent incontinence following their first delivery. Among the 23 with transient incontinence, 9 (39%) had recurrent symptoms with a subsequent delivery, and in 4 (17%), these symptoms became permanent. Not all studies, however, conclude that subsequent delivery negatively affects anal continence. A comparison of 125 women with third- and fourth-degree lacerations to 125 controls 14 years after their first delivery identified sphincter laceration as an independent risk factor for fecal incontinence (RR 2.54; 95% CI 1.45 to 4.45), but there was no observed increased risk with subsequent vaginal deliveries. In another retrospective analysis, 234 women who had sustained a complete third-degree laceration were contacted for phone interviews regarding continence. In this cohort, no differences were found between women with zero, one, or two subsequent deliveries, nor were there any differences between women who sustained additional third-degree laceration and those without any subsequent deliveries. These studies question whether increases in anal incontinence are due to subsequent vaginal delivery or to other influences, including age.

Anal Incontinence and Cesarean Delivery

The role of pregnancy and the protective effect of cesarean delivery on anal incontinence are unclear. A prospective cohort study of 184 primiparous women 6 weeks following delivery found that none of the sixteen women who delivered by cesarean had altered fecal incontinence, whereas 42 of 169 (25%) women undergoing vaginal delivery had impairment of fecal continence. In contrast, a European study that evaluated 46 women 3 months following delivery reported that 2 of the 6 patients having elective cesarean delivery complained of anal incontinence even though the results of endoanal ultrasounds and anal manometry were normal. An observational questionnaire study of 1,004 women also found no significant difference in fecal incontinence when comparing women who delivered via cesarean only to women who had at least one vaginal delivery. The study reported an overall prevalence of bothersome fecal incontinence of 13% and found a significant increase in prevalence when comparing multiparous with nulliparous women (OR 2.26; 95% CI 1.22 to 4.19). Similarly, another study from Australia suggested that pregnancy itself, not route of delivery, impacted the risk of fecal incontinence.

Two prospective randomized studies, in secondary analyses, have evaluated the impact of vaginal delivery versus cesarean on the development of anal incontinence. The first was a randomized trial of 949 women on the effect of perineal massage on vaginal delivery. Three months postpartum, 29 women (3.1%) reported fecal incontinence, and 242 (25.5%) had involuntary escape of flatus. Multivariate analysis of predictors of postpartum anal incontinence showed a significant independent association with forceps versus spontaneous vaginal delivery but not with vacuum extraction, episiotomy, or cesarean. When episiotomy and type of delivery were replaced by degree of perineal injury in the analysis, incontinence of flatus or stool was predicted by anal sphincter laceration but not by lesser

degrees of perineal trauma. The second study was a secondary analysis of a multicenter, international trial of 2,088 women with a

singleton breech fetus who were randomized to cesarean versus vaginal delivery. Mothers completed a structured questionnaire at 2 years postpartum to determine relationships of the index delivery to various health problems, including anal incontinence. Overall, the prevalence of fecal and anal incontinence was 2.3% and 12.1%, respectively. No differences were found between delivery groups in the incidence of fecal or flatal incontinence in an intent-to-treat analysis.

Conflicting results from these studies make it challenging to recommend the optimal mode of delivery to maximally reduce the chance of developing anorectal dysfunction, even in women with a prior history of an anal sphincter tear. What *is* known is that anal incontinence following vaginal delivery is strongly associated with both overt and occult sphincter lacerations. The use of forceps has been consistently identified as an independent risk factor for fecal incontinence, and they should be used cautiously in women with increased risk factors for sustaining an anal sphincter tear. It is important to note that cesarean deliveries, especially those performed late in labor, may not confer all the benefit to the pelvic floor than was previously expected.

Evaluation

History

Because of the complex nature of the stool continence mechanism and the myriad disorders that can affect the normal functioning of the posterior compartment, a detailed and precise history regarding the problem is imperative. The practitioner needs to understand the duration of the symptoms, what exactly was happening when the symptoms first started, the precise quality and consistency of stool that is successfully stored versus that which is leaked, the patient's bowel habit history, and normal dietary habits. Specific questions concerning diarrhea, loose or mushy stools, the presence or absence of fecal urgency (especially after eating), passage of mucus, average number and quality of stools per day, presence of pain or bloating, difficulty wiping clean, feelings of incomplete evacuation and straining to empty, splinting the vagina or perineum to empty, bowel control during sexual intercourse, practicing anal intercourse, and frequency/severity of incontinent episodes should all be determined. It is important to identify if the patient can sense when she needs to have a bowel movement and how that relates to any possible leakage versus just finding stool in her underclothes. A sensory impairment is suggested when stool leakage occurs without warning, whereas a motor impairment is likely if the patient is merely unable to get to a toilet on time. A prospective diary of food intake, bowel habits, and incontinence episodes can be useful. Several standardized questionnaires and fecal incontinence severity scoring systems are available, including the Wexner scale in Table 54.2. A complete review of systems should be obtained, including abdominal pain or cramping, lower back or pelvic pain, any changes in pelvic or lower extremity sensation, and any urinary retention or leakage. Any acute change in neurologic function should direct the practitioner to rule out central nervous system disorders such as multiple sclerosis or a

neoplasm of the brain or spinal cord.

A comprehensive obstetric history including mode of delivery, length of second stage, use of forceps/vacuum, birth weights, episiotomies or lacerations, and any wound complications should be obtained. As always, a full understanding of the patient's other medical conditions that may be impacting the continence mechanism should be sought. A review of all laxatives and other medications, both prescription and over the counter, can yield important information. Many medications including nonsteroidal anti-inflammatory drugs (NSAIDs), iron, anticholinergics, antidepressants, narcotics, and pseudoephedrine can cause chronic constipation that may contribute to overflow incontinence or pelvic floor neuropathy secondary to straining. Finally, patients should be queried about all prior investigations including flexible sigmoidoscopy, colonoscopy, and barium enemas. Any previous operative reports relating to the posterior compartment should be reviewed.

Physical Examination

Examination begins with careful inspection of the perineum and anal region. It is important to note the presence or absence of fecal material and whether or not there is discoloration and irritation of perianal skin, which is commonly seen in patients with significant incontinence. The perianal skin creases or folds should completely encircle the anus. In cases of complete anal sphincter disruption, a “dovetail” sign is usually present in which only a semicircular presence of creases or folds is present. Attention to the presence of any protruding tissue around or from the anus should be made, as in the case of external hemorrhoids or rectal mucosal prolapse (Fig. 54.3). Careful inspection for a rectovaginal fistula should be performed, and any dimpling should be probed with a silver wire or lacrimal probe. The size of the genital hiatus and perineal body should be measured, and the vagina should be examined for evidence of genital prolapse, which may be an indicator of pelvic floor neuromuscular function. Any prior episiotomies, lacerations, or surgical scars should be noted. Whether or not the anal mucosal skin is completely coapted is important to note as well.

Eliciting the clitoral-anal or bulbocavernosus reflex can grossly test the innervation of the EAS. If this is intact, the reflex implies that the pudendal nerve afferents and the rectal or external hemorrhoidal branch of the pudendal efferent nerves are functional. Sensation in the S2–4 dermatomes should be screened by dull and pinprick discrimination

when touching the perineum. Abnormalities in either the perianal reflexes or sensation should prompt further neurologic testing.

Figure 54.3 Dovetail sign and rectovaginal fistula. A silver wire probe is placed through the rectovaginal fistula. A gloved index finger palpates for rectal tone at rest and with a pelvic floor contraction. Note loss of the perianal fold from 9 o'clock to 3 o'clock.

Next, the patient should be asked to squeeze “as if trying not to pass gas.” Inspection of the perianal folds should be evaluated for a concentric contraction and some upward movement of the perineal body. Substitution with contraction of the buttocks, upper thighs, or abdomen should be noted. The patient should then be asked to bear down “as if trying to have a bowel movement.” She should be reassured that it is expected that she may pass flatus or even some fecal material during this part of the examination. The practitioner should note the degree of perineal descent and any prolapse of the vagina, pelvic viscera, or rectum. If there does appear to be any pelvic organ prolapse, the examination can then be repeated in the standing position or after straining on the commode to maximize the prolapse.

A rectal examination is then used to assess both the resting and squeeze tone of the anal canal. The resting tone of the anal canal is an indicator of IAS function. When the patient is asked to squeeze, a circumferential contraction and tightening should be felt in addition to some upward movement of the rectum and posterior compartment. On vaginal examination, the levator ani should be palpated for strength and symmetry. Any scarring or retraction of the posterior vaginal wall should be noted. In addition to assessing rectal tone, the anal canal and rectum should be palpated for masses, a dilated rectum, or the

presence of stool in the rectal vault. A chronically distended rectum with stool, a tumor, or with intussusception of the bowel will disrupt the normal RAIR. If this reflex is suppressed, the anal canal remains dilated, the EAS becomes fatigued, and incontinence will occur.

Testing

The clinical diagnosis based on physical examination and history alone will be accurate in a majority of patients. However, further evaluation, including radiologic and physiologic tests listed in Table 54.5, have been shown in a prospective study at a tertiary colorectal referral center to alter the final diagnosis of the cause of fecal incontinence in approximately one out of five cases. The specific historical and physical examination findings that are helpful in determining the sequence of tests that are ordered are any abnormalities in stool consistency and frequency and the degree of rectal tone on digital rectal examination. The algorithm presented provides a flow diagram based on these findings. The presence of normal resting and squeeze tone of the anal canal directs the clinician away from an abnormality of the sphincter complex and instead focuses on etiologies outside the pelvis. Poor resting tone or the inability to voluntarily squeeze the anal sphincter, in contrast, then focuses attention on the neuromuscular evaluation of the sphincter complex itself (Fig. 54.4).

Treatment

The treatment of fecal incontinence includes medications, biofeedback, electrical stimulation, and surgery. In every patient, regardless of the integrity of the sphincter complex, maintaining normal stool consistency and frequency is the first step in management. The goal for every patient is to have a predictable bowel movement every morning that is the size of a six-inch log and of moderately firm consistency. Soft, mushy stools can be very difficult for patients to control and evacuate completely, a problem that leads to constant seepage and the inability to ever wipe clean. If patients are having several bowel movements throughout the day, this implies rapid colonic motility or an enhanced gastrocolic reflex, both of which can create symptoms of fecal urgency and incontinence.

Dietary and Behavioral Treatments

The successful evacuation of a formed, bulked stool every morning can be achieved by taking a fiber supplement at night such as methylcellulose or psyllium. High-fiber cereals and a hot beverage for breakfast the next morning will usually prompt the gastrocolic reflex, and before leaving

---

the comfortable home environment, patients will typically experience a defecatory urge. For some patients, especially those with retained stool within a rectocele pocket (not that common if the stool is sufficiently bulked), the use of a daily cleansing enema eliminates the seepage of residual fecal material. If patients report several further bowel movements throughout the rest of the day following the complete morning evacuation, then the use of an agent to slow the intestinal transit time is indicated. Commonly used medications that

can be used to slow the gastrointestinal tract are listed in Table 54.6. Titration of the selected medication over the course of a month is frequently necessary to achieve the desired result of a single bowel movement in the morning. Patients with diarrhea dependent IBS also should be conscious of the specific foods that exacerbate their symptoms. Additional doses of antimotility drugs are frequently required before eating in restaurants.

TABLE 54.5 Commonly Used Tests to Evaluate Bowel Function

Colonoscopy: A colonoscopy is indicated for any patient with chronic diarrhea or a history of nonhealing perineal lacerations to rule out inflammatory bowel disease or malignancy.

Sphincter Ultrasound (Transanal or Transperineal): Transanal endosonography that utilizes a rotating rectal probe provides excellent visualization of all layers of the anal canal and sphincter complex. The IAS, comprised of smooth muscle, appears as a dark, hypoechoic ring. The striated EAS, which lies external to the IAS, has a brighter, hyperechoic appearance. Breaks in the EAS appear as “gaps” or dark spaces within the hyperechoic ring (Fig. 54.6). Transperineal ultrasound with a high-frequency probe can be used to visualize the sphincter complex.

Anal Manometry: Anal manometry, once a mainstay of evaluation, is rarely indicated as most experienced clinicians can estimate the pressure in the anal canal with a simple rectal examination. It is helpful for patients who have had surgery to the anorectal canal or radiation therapy to determine rectal sensation and rectal capacity.

Electromyography: EMG evaluates the bioelectrical action potentials that are generated by depolarization of skeletal striated muscle. EMG is rarely indicated outside of the research laboratory.

Pudendal Nerve Terminal Motor Latencies: Nerve conduction studies measure the time from stimulation of a nerve to a response in the muscle that it innervates. The pudendal nerve is stimulated at the ischial spine, and the latency is determined by the amount of time it takes for the external sphincter to contract, which is normally about 2 msec. Prolonged PNTMLs have been found in patients with idiopathic fecal incontinence and in patients with rectal prolapse; however, there is often poor correlation between

nerve conduction studies, patient symptoms, and surgical outcomes such that the test is rarely done.

Defecography: Defecating proctograms are very helpful in some patients with fecal incontinence because all components of the pelvic floor can be visualized during attempted storage and evacuation. Sigmoidoceles, rectal intussusception, rectal prolapse, retention of stool within a rectocele pocket, and perineal descent can be visualized. Defecography is also useful when evaluating chronic constipation and obstructed defecation. Patients should be warned that while this test is potentially embarrassing, it can yield important information.

Magnetic Resonance Imaging: Specialized dynamic MRI may replace defecography in the future, as it has the ability to also evaluate the anatomy of the anal sphincter complex and levator muscles, along with pelvic organ prolapse and perineal descent. At present, this test is not readily available and remains considerably more expensive than standard radiologic tests.

Colon Transit or Sitz Marker Study: A transit study is used to evaluate colonic motility and is used in the evaluation of constipation and obstructed defecation. It may be indicated with suspected overflow incontinence. There are numerous variations of the study. Patients ingest a capsule containing 25 to 30 radiopaque rings. Five days later, an abdominal flat plate is obtained, and normally, 80% of the markers should have passed. Global colon dysfunction is indicated if the rings are dispersed throughout the colon, whereas segmental dysfunction is suggested if rings are clustered together in one area.

IAS, internal anal sphincter; EAS external anal sphincter; EMG, electromyography; PTNMLs, pudendal nerve terminal motor latencies, MRI, magnetic resonance imaging.

Biofeedback

Biofeedback for fecal incontinence, like urinary incontinence, requires a motivated patient, a feedback device, and a planned exercise program. This typically is conducted by a trained pelvic floor physical therapist. In order for biofeedback to be successful, a patient must have an intact neurologic system, and through biofeedback, she will learn to perceive normal sensation and the ability to contract the pelvic floor muscles voluntarily.

Several studies have found biofeedback in correctly selected patients to be very successful in that 60% to 70% of patients with fecal incontinence secondary to abnormalities of the pelvic floor will have a 90% reduction in their incontinence.

A measuring device, either an electrode or pressure transducer, is used transvaginally or transanally to record and give feedback to the patient. She then uses this feedback to increase or lengthen pelvic floor contraction. If the patient has incontinence secondary to a sensory deficit in the rectum, rectal balloons can be used to “retrain” the patient to perceive rectal distention and respond by squeezing the EAS. It is important to remember that while biofeedback and physical therapy are initially labor intensive, they have no side effects or morbidity and frequently are used in conjunction with other treatment modalities, including surgery. In addition, for patients

with double incontinence, single therapy with biofeedback may well improve both conditions. As long as the patient can follow instructions, there does not appear to be an age limit on the use of biofeedback and pelvic floor training. In fact, in a randomized trial of electrical stimulation therapy, biofeedback, and nursing intervention, older women were more likely to respond to treatment, including education, fiber, and diet management for fecal incontinence when compared with response in younger women.

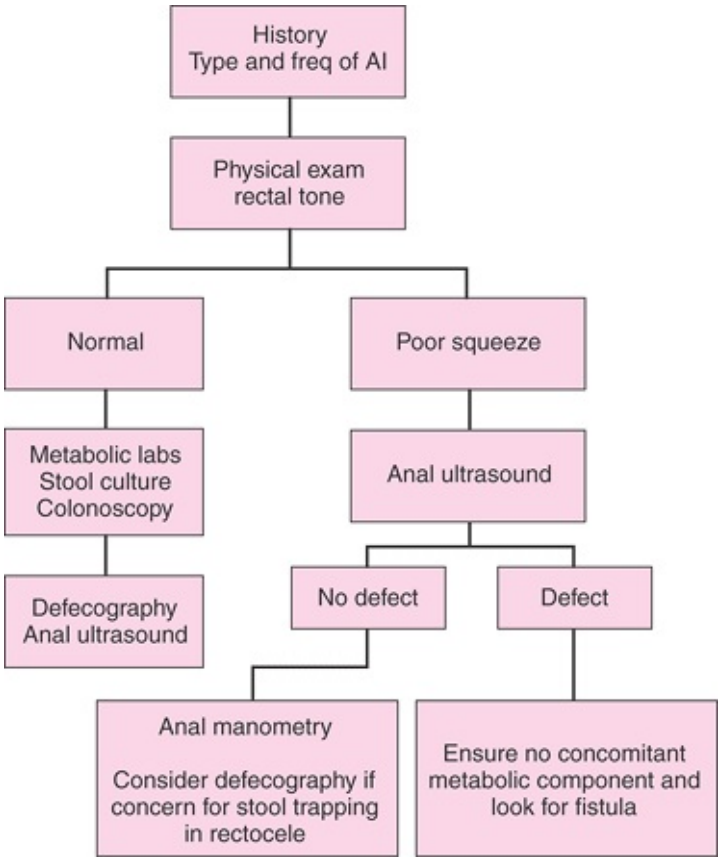

Figure 54.4 Fecal incontinence evaluation. Any diarrhea or functional bowel component should be managed prior to anal ultrasound and possible surgical therapy. (AI, anal incontinence.)

TABLE 54.6 Antidiarrheal Medications

Drug	Dosage	Mechanism of Action
Loperamide	2 mg three times/d or 4 mg followed by 2 mg after loose bowel movement	Inhibits circular and longitudinal muscle contraction
Diphenoxylate with atropine	10 mg up to four times/d	Direct action of circular smooth muscle to decrease peristalsis
Hyoscyamine sulfate	0.375 mg two times/d	Anticholinergic
Cholestyramine	4-g pack one to four times/d	Binds bile acids after cholecystectomy (helpful for patients who develop diarrhea after cholecystectomy)

Electrical Stimulation Therapy

Functional electrical stimulation therapy has been shown to reduce fecal incontinence in patients with a weakened pelvic floor who are unable to contract their EAS or puborectalis muscle on command. Because of the expense, electrical stimulation generally is reserved for patients who are unable to respond to traditional biofeedback protocols. Both transvaginal and transrectal probes are available. Most protocols recommend high-frequency stimulation at maximum tolerable stimulation of 50 MHz for 15 to 20 minutes twice a day. Response to therapy usually is seen by 6 weeks, with maximum improvement by 12 weeks.

Surgery

Surgical management of fecal incontinence includes the repair of rectal prolapse, anal sphincteroplasty, and the implantation of artificial anal sphincters. Postanal repair or posterior levatorplasty has not been shown to be effective in the treatment of fecal

incontinence in most patients and thus will not be discussed.

In women with anal sphincter defects and anal incontinence remote, the mainstay of surgical intervention is overlapping anal sphincteroplasty. Unfortunately, the reports of long-term results for a mean follow-up of 3 to 10 years are less than promising, with cure rates ranging from 0% to 28% after overlapping repair. A comparison of outcomes from five different studies is presented in the Table 54.7. A recent study of 86 women who underwent anal sphincteroplasty with a mean follow-up of 5.1 years reported that only 11% were completely continent. A remarkable 75% were incontinent of liquid and/or solid stool, and this correlated with an adverse effect on quality of life. As a retrospective study, the authors were not able to determine improvement of symptoms, and most patients subjectively said that they were better. In addition, the number of bowel movements per day and the amount of liquid stool were not determined. Therefore, it is possible that the outcomes

may be better for women with well-formed stools and no undertreated motility disorders. However, women should be counseled appropriately of the low probability of complete continence with sphincteroplasty. In addition to poor long-term outcomes, short-term complications are common, with a high rate of wound infection and superficial wound breakdown.

TABLE 54.7 Long-term Outcomes of Anal Sphincteroplasty Remote from Delivery

Author/Year	Patient with Follow-up(%)	Mean Follow-up (years)	Outcomes
Malouf 2000 (UK)	38/55 (69)	6.4	**0% continent** 10% incontinent of flatus only 63% passive soiling
Karoui 2000 (France)	74/86 (86)	3.3	**28% continent** 23% incontinent to flatus only 49% incontinent of stool

Halverson 2002 (USA)	49/71 (69)	5.8	**14% continent** 32% incontinent to flatus only 54% incontinent of stool
Bravo-Guitierrez 2004 (USA)	130/191 (71)	10.3	**6% continent** 18% incontinent to flatus only 60% incontinent of solid stool
Trowbridge 2006 (USA)	59/86 (70)	5.6	**10% continent** 15% incontinent to flatus only 75% incontinent of solid stool

Modified from Rogers RG, Abed H, Fenner DE. Current diagnosis and treatment algorithms for anal incontinence. *BJU Int* 2006;98(Suppl 1):101.

Neosphincters

There are two types of neosphincters: one using the patient's own skeletal muscle, usually the gracilis, and the other using an artificial Silastic cuff connected to a fluid reservoir to occlude the anal canal. The gracilis muscle wrap has shown inconsistent results, but improvement may be seen with the use of preoperative low-frequency electrical stimulation to produce fatigue-resistant muscle fibers. Artificial sphincters are indicated in patients with anal incontinence caused by neuromuscular disease or trauma. Complications include infection and mechanical breakdown. Success rates of 75% and complication rates of 33%, similar to muscle transposition, have been reported.

Defecation Disorders

Etiology and Pathophysiology

Normal defecation requires normal colonic motility, anorectal sensation, and a coordinated expulsive force with relaxation of the pelvic floor and anal sphincters. Constipation has many definitions and descriptions. For some women, constipation means not having a daily bowel movement, while for others having to push or having a hard stool is constipation. The Rome III criteria, as listed in Table 54.1, divides constipation into functional or slow colonic transit constipation including IBS and obstructed defecation. In reality, many women appear to have difficulty having regular bowel movements because of both slow colon transit and some component of obstructed defecation.

Functional Constipation

The pathophysiology of slow-transit constipation has been difficult to delineate in large measure because of the influence of a multitude of changing factors such as sleep, diet, physical activity, and emotional stressors. Patients with this disorder demonstrate a significant impairment in phasic colonic motor activity and also have a blunted gastrocolic reflex. In addition, a loss of ganglion cells in the myenteric plexus suggests an underlying neuropathy.

Diagnostic Studies

The acute onset of constipation should prompt the clinician to rule out an underlying metabolic (e.g., hypothyroidism) or pathologic disorder (e.g., colon cancer). Women with a long-standing history of constipation generally do not warrant an extensive laboratory workup beyond what is recommended for standard colon cancer screening. A colonic transit study can provide valuable objective information about motility throughout the colon (Table 54.5).

Management

While general measures such as increasing hydration, performing physical exercise, and dedicating time for passing

bowel movements are frequently recommended, little evidence actually exists to support their efficacy. Colonic motor activity is greatest after awakening and following a meal, and efforts to make use of this fact are encouraged.

TABLE 54.8 Medication to Facilitate Defecation

Type of Laxative	Examples	Description

Bulking agents	Psyllium Citrucel	Absorbs liquid in intestines and swells to form a soft, bulky stool
Stool softeners	Docusate	Helps liquids mix into stools (eases straining rather than causing a bowel movement)
Osmotic laxatives	PEG Saline laxatives: Magnesium hydroxide Magnesium citrate Poorly absorbed sugars: Lactulose Mannitol Sorbitol Glycerin suppositories	PEG and lactulose have been shown to increase stool frequency and improve consistency
Stimulant laxatives	Diphenylmethane derivatives: Bisacodyl Sodium picosulfate Castor oil Mineral oil Anthraquinones: Senna Cascara sagrada Aloe	Insufficient data to make a recommendation regarding use (no placebo-controlled trials)
5-HT_4 agonists	Tegaserod	Improves stool frequency, consistency, and straining

PEG, polyethylene glycol.

Before initiating a treatment for constipation, a careful review of all current medications

should be made, as many different drugs have a detrimental effect on bowel motility. Examples of such medications include NSAIDs, narcotic analgesics, calcium channel blockers, antimuscarinics, anticholinergics, antidepressants, diuretics, and antihistamines.

Several different classes of drugs exist that may effectively treat constipation and are listed in Table 54.8. Bulking agents and stool softeners are generally recommended as first-line therapy followed by the osmotic laxatives. Tegaserod has been studied in patients with constipation-dependent IBS and is not yet approved for long-term use.

Most women with constipation will have tried or used plant or herbal therapy to improve their bowel frequency or consistency. Any given fruit, vegetable, nut, spice, or stimulant such as coffee or caffeine may cause a given individual to have a loose bowel movement. The most commonly used supplements used to induce bowel movements are senna, coffee, aloe vera, plums, prunes, and flaxseed. Senna can be found in capsules, tablets, liquid extracts, and dried roots used to make teas. Many preparations are available, and the product labels for any alternative medicine advertised to induce bowel movements should be carefully read, as senna will be the most likely active ingredient. Bowel movements usually occur 6 to 12 hours after taking senna. It should not be used to induce a daily bowel movement. Senna or other anthraquinone-containing herbs should not be used by pregnant or nursing women or women with diverticular disease, ulcerative colitis, Crohn's disease, severe hemorrhoids, blood vessel disease, congestive heart failure, heart disease, severe anemia, recent colon surgery, or liver or kidney disease. Senna may interact with drugs including calcium channel blockers, such as nifedipine, and NSAIDs, such as indomethacin. Senna can cause electrolyte imbalance (loss of potassium), loss of body fluids, and dark pigmentation in the colon (called *melanosis coli*) with long-term use.

Obstructed Defecation/Outlet Constipation

Obstructed defecation occurs in up to 30% of the adult population that is affected by constipation and is significantly more common in women. Patients who present with the chief complaint of straining with the inability to evacuate stool fall under two major categories: functional obstructed defecation, also known as pelvic floor dyssynergia or anismus, and mechanical obstruction due to an anatomic defect such as posterior vaginal wall prolapse. Functional obstructed defecation is a common clinical problem that is associated with abnormal defecatory colonic motor

---

pattern, impairment in rectoanal coordination with the inability to relax the puborectalis and anal sphincters, and ineffective stool expulsion during defecation.

Pelvic Floor Dyssynergia (Anismus)

Pelvic floor dyssynergia or anismus is defined as an increase in rectal pressure during attempted evacuation in conjunction with impaired rectal emptying. However, recent evidence suggests that paradoxical contractions may be a consequence of inappropriate defecating behavior rather than a cause of constipation and that anismus should be considered as part of a more complex “brain–gut” syndrome. Patients, frequently young women with no identified pelvic floor or colonic abnormalities, have to resort to the use of

enemas or digital disimpaction to achieve relief.

Posterior Vaginal Wall Prolapse

Symptoms of disordered defecation are common in women with urogenital prolapse, especially in women with perineal descent. However, no consistent observation between the degree of posterior wall prolapse and obstructed defecation has been made. Some women with large rectoceles have no difficulty with evacuation, whereas other patients with apparently small defects report having to splint the vagina to defecate. In these patients, it is entirely possible that the anatomic defect of the posterior wall developed as a *result* of chronic straining from functional constipation rather than as a cause. A recent study from Cleveland evaluating the frequency of obstructed defecation in women with advanced prolapse actually found no association between bowel symptoms and the extent of prolapse. The true prevalence of posterior wall defects is unknown, but they are almost a ubiquitous finding on radiographic studies in vaginally parous women. Surgical correction may be warranted in women with larger anatomical defects, with evidence of contrast trapping within the rectocele pocket on defecography.

Evaluation

History

A full understanding of the patient's current and past bowel habits is imperative. The frequency and consistency of bowel movements is important, including what measures are typically employed to facilitate evacuation such as positioning on the toilet and the use of splinting techniques. Inquiries about fecal and urinary incontinence in addition to symptoms of urogenital prolapse (vaginal pressure and feeling a bulge) should be made. Patients should be asked about bowel habits as a child, as this may provide a basis for functional obstructed defecation. Any history of physical and sexual abuse should also be sought. A full review of dietary habits, exercise, and lifestyle habits is indicated.

Physical Examination

Examination in the lithotomy or left lateral Sims position is indicated in women without symptoms of prolapse. Anyone who provides a history of a vaginal bulge should be examined in the standing position with maximal Valsalva to observe the full extent of the prolapsed segment. It should always be confirmed with the patient that what is observed in the office is what she has noticed at home.

The size of the genital hiatus and perineal body is measured before assessing the vagina for evidence of pelvic floor relaxation. An abnormally long perineal body that increases in length or bulges with strain suggests the presence of a perineocele. Large external hemorrhoids may be evidence of excessive straining. With straining, an observation should be made about perineal descent that may dissipate the expulsive forces required for defecation. Any prolapse of the rectal mucosa or hemorrhoids should be noted. If the patient's history does not match what is found during the examination, she should be

placed on the toilet and instructed to strain as if trying to defecate and then examined immediately to check for vaginal or rectal prolapse. A rectal examination at rest and during straining can demonstrate defects of the rectovaginal septum, abnormal rectal tone, and the presence of any masses. Finding hard stool in the rectal vault may suggest an abnormality above the pelvic floor. In addition, if stool is palpated, the patient should be asked if she knew or felt like she needed to defecate. If she does not know that stool is in the rectum, this is a sign of pelvic floor dysfunction and loss of rectal sensation. Loss of rectal sensation is a poor prognostic sign for surgical success of symptom relief, even if the posterior wall anatomy is corrected. A screening neurologic examination including an assessment of anal reflexes and sensory discrimination then completes the examination.

Testing

There is no single gold standard investigation that provides a definitive diagnosis for defecatory dysfunction. However, the liberal use of defecography may provide the most comprehensive information about the potential etiologies that are involved (Table 54.5). The presence of anatomic defects that may be trapping stool, such as sigmoidocele, enterocele, rectocele, perineocele, and other disorders that may be interfering with stool transit, such as rectal intussusception and perineal descent, can all be visualized. In addition, the health care provider can determine if there is appropriate relaxation of the puborectalis muscle with widening of the anorectal angle during attempted defecation. If the muscle remains contracted during straining and the anorectal angle becomes more acute, then the diagnosis of anismus is reached. The other frequently useful test is a colon transit or sitz marker study (Table 54.5). This noninvasive test provides valuable information about colonic transit and the potential role that abnormal bowel motility,

a cause above the pelvic floor, may be contributing to the problem. A summary algorithm for the appropriate management strategies for women presenting with obstructed defecation is presented in Figure 54.5.

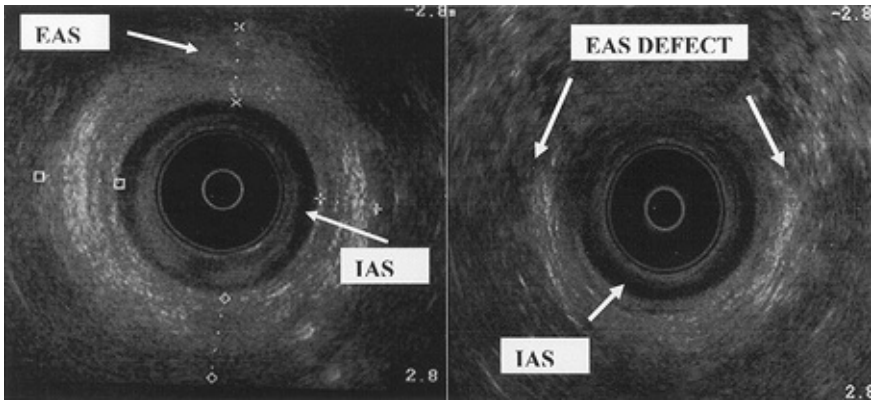

Figure 54.5 A: Transanal ultrasound. **B:** Normal EAS defect. (*EAS*, external anal sphincter.)

Treatment

Behavior Modification, Diet, and Fiber

The mainstay of treatment for functional obstructed defecation is medical therapy and dietary changes as described for functional constipation. Pharmacotherapy directed at increasing stool transit and softening the stools is prescribed. Patients with anatomic defects of the posterior vaginal wall may also benefit from fiber supplementation to bulk and stimulate stools.

Biofeedback employs the use of visual and digital feedback in order to learn techniques of pelvic floor and anal sphincter muscle relaxation when straining. A trained physical therapist is necessary to coach the patient and provide encouragement. The physical therapist must understand that unlike therapy for urinary or fecal incontinence, the patient needs to learn how to relax the pelvic floor muscles. If the patient cannot sense when she needs to have a bowel movement, rectal distention with balloon retraining may be useful. Positioning the patient with her hips flexed and feet elevated on a foot stool or book 6 or more inches off the ground can facilitate evacuation. Pelvic floor physical therapy may also teach these patients appropriate muscle coordinate to facilitate defecation. While sometimes labor intensive, this is ultimately the only measure that will result in relief of pelvic floor dyssynergia. A patient who is found to have an asymptomatic defect of the posterior wall is best managed expectantly.

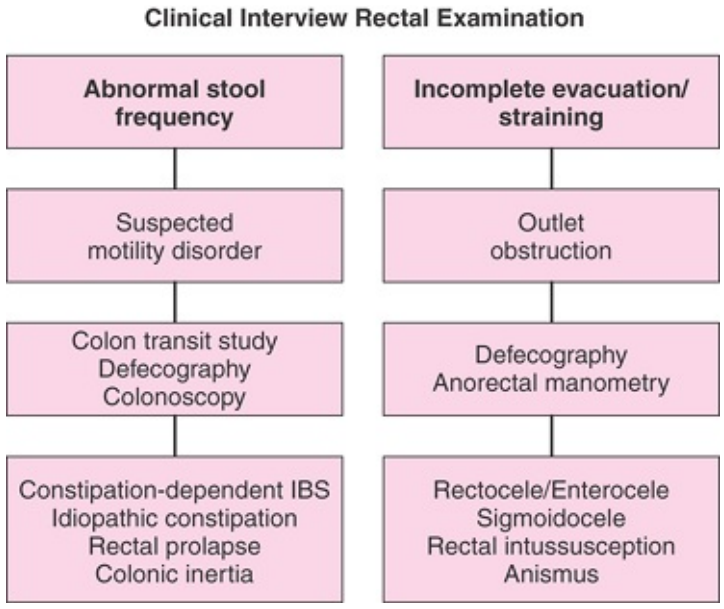

Figure 54.6 Evaluation of defecation disorder. (IBS, irritable bowel syndrome.)

Surgical Interventions

In patients with posterior vaginal wall prolapse and symptoms of obstructed defecation with trapping of stool within a rectocele pocket, surgical intervention may be indicated.

Several large series have been published regarding outcomes after posterior vaginal wall repair by using a variety of techniques. Generally, the transvaginal techniques of repair have resulted in better anatomical and functional results than via a transanal approach; however, a significant percentage of patients continue to report symptoms of disordered defecation postoperatively. A Cochrane review summarizing data from all available trials conducted on rectocele repair concluded that there is insufficient data on the effect of surgery on bowel symptoms. Table 54.9 summarizes the results from four different studies. Again, while successful anatomical correction of the deficit is achieved in the majority of patients, the functional sequelae are often less satisfactory.

Gynecologists have traditionally employed two different surgical techniques for posterior wall prolapse: plication of the rectovaginal muscularis across the midline and a site-specific repair in which discrete defects of the rectovaginal septum are sutured. A comparison study of the two techniques failed to identify any major differences in outcomes or complications. Recently, the use of graft augmentation for pelvic floor reconstruction has gained enormous popularity, including its use for the posterior compartment, despite a paucity of data regarding any improvement in efficacy. Only one randomized controlled trial has been published regarding different surgical techniques that included a graft augmentation arm for rectocele repair. This study of 106 women found that after 1 year, those subjects who received graft augmentation with porcine dermis actually had a significantly greater anatomical failure rate (46%) than those who received site-specific defect repair alone (26%) or traditional colporrhaphy (14%, P =.02). In addition to a lack of benefit regarding anatomical results, graft materials also are associated with erosion and disrupted wound healing. Until additional research has been conducted regarding the efficacy of graft augmentation for posterior vaginal wall reconstruction, their use cannot be endorsed.

TABLE 54.9 Functional Outcome of Rectocele Repairs

Author	Number of Patients	Follow-up Time (months)	Type of Repair	Symptom	Preoper
Kahn	171	42	Levator ani plication	Subjective prolapse Obstructed defecation Constipation Dyspareunia	64 — 22 18
				Subjective

Kenton	55	12	Discrete fascial repair	Subjective prolapse Obstructed defecation Constipation Dyspareunia	86 30 41 28
Porter	125	18	Discrete fascial repair	Subjective prolapse Obstructed defecation	100 30
			Discrete fascial repair	Constipation Dyspareunia	60 67

PEG, polyethylene glycol.

Conclusion

Abnormalities of the posterior vaginal compartment may present with myriad symptoms ranging from obstructed defecation to fecal incontinence. The comprehensive evaluation and management of these disorders requires a careful history, physical examination, and prudent use of diagnostic tests. A multidisciplinary approach is recommended, as global pelvic floor dysfunction, including urinary incontinence and urogenital prolapse, frequently co-exists. All women presenting for routine gynecologic care should be screened for anorectal disorders given their high prevalence and deleterious effect on quality of life. Alarming symptoms such as an acute change in bowel habits and the presence of blood in the stool should elicit a prompt referral. The majority of patients with both fecal incontinence and obstructed defecation can achieve satisfactory results with conservative interventions that include stool bulking, pelvic floor physical therapy, and good toileting habits. Surgical intervention for posterior compartment defects should only be considered once all stool motility and consistency abnormalities have been addressed.

Summary Points

- Bowel and anorectal disorders are divided into two major categories: those arising from a defined structural or neuropathic defect versus a functional disorder in which no such pathology can be detected.
- Constipation, defined as <3 stools per week, affects 2% to 28% of women surveyed.
- The mainstay of treatment for functional constipation and functional obstructed defecation is medical therapy and dietary changes.
- While successful anatomical correction of rectoceles is achieved in most patients, the functional sequelae are often less satisfactory, with approximately one third of women still needing to splint or facilitate evacuation following surgical repairs.
- Approximately 10% of women will experience some alteration in bowel habits after one vaginal delivery.
- Clinically recognized anal sphincter lacerations occur in 0.6% to 20.0% of vaginal deliveries, with higher rates documented after operative vaginal delivery. After visible sphincter lacerations, 13% and 40% of women experience fecal and anal incontinence, respectively.
- The clinical diagnosis based on physical examination and history alone accurately determines the etiology of fecal incontinence in the majority of patients.
- Fecal incontinence can be treated with dietary changes, medications, biofeedback, electrical stimulation, and surgery.
- Anal sphincteroplasties for chronic third-degree lacerations have poor long-term results, with cure rates ranging from 0% to 28% after overlapping repairs.

Leiomyomata

Arthur F. Haney

Uterine leiomyomata, commonly termed *fibroids*, are by far the most common benign tumors of the female genital tract and likely are the most common soft tissue tumors of all. Approximately 200,000 hysterectomies and 20,000 myomectomies are performed annually in the United States because of symptoms caused by leiomyomata. The symptoms are location dependent: very large leiomyomata may have few if any symptoms, and alternatively, small leiomyomata may cause life-threatening uterine bleeding and disabling dysmenorrhea. The incidence of leiomyomata far exceeds the frequency of clinical problems, with as many as 50% of women having identifiable fibroids at menopause.

Clinical Presentation

Leiomyomata come to clinical attention for a variety of symptoms (Table 55.1) depending on tumor size and location (Fig. 55.1). It is not unusual for fibroids to become symptomatic before age 30, but all occur after puberty. Excessive menstrual bleeding (menorrhagia) is the most frequent symptom. Fibroids may cause debilitating dysmenorrhea as well as compress the adjacent pelvic viscera (frequent urination, constipation, or hydronephrosis) and cause pelvic pain with physical activities or intercourse. The symptoms caused by leiomyomata vary depending on the size, number, and location of the tumors. Irregular vaginal bleeding (oligomenorrhea), regardless of the amount, or intermenstrual bleeding (metrorrhagia) does not suggest fibroids but rather an underlying endocrine abnormality (e.g., anovulation). Furthermore, the typical scenario encountered with fibroids is not a sudden heavy bleeding episode but rather gradually increasing menstrual bleeding, paralleling tumor growth. Leiomyomata may undergo rapid enlargement during pregnancy, outstripping their blood supply and resulting in central avascular necrosis, the so-called red degeneration. The pain may be severe, requiring hospitalization and narcotics, but rarely puts a pregnancy at risk. As the size and number of the leiomyomata increase, the adjacent pelvic viscera may be compressed, resulting in urinary frequency, constipation, and occasionally dyspareunia. Rarely, when the fibroids are large and fill the pelvis or grow laterally from the midportion of the uterine body, they compress the ureters, causing hydronephrosis (Fig. 55.2). Intracavitary fibroids often are on a vascular pedicle and may be even be extruded through the cervix, presenting as a necrotic mass. Rarely, large uterine leiomyomata will become incarcerated in the pelvis when rapidly expanding

tumors are entrapped by the promontory of the sacrum, causing the cervix to descend and occasionally present at the introitus. This is particularly true when a woman with large serosal leiomyomata conceives and both the tumors as well as the gravid uterus enlarge rapidly. While fibroids can cause symptoms at any age after puberty, they typically do so in the early to mid 30s. With the rising age at which women first attempt pregnancy, this increasingly represents a difficult management problem that did not exist a generation ago when simple hysterectomy was the frequent curative choice. Preserving reproductive function while relieving symptoms is the most pressing current challenge.

Anatomic Features

Leiomyomata are benign, sex steroid–responsive, smooth muscle tumors of the uterus originating as clonal expansions of individual myometrial cells. The histology is virtually indistinguishable from normal myometrium except for a discrete circular whorling pattern with the cellularity and mitotic activity being highly variable. The number of mitoses per high powered field is usually low (<5 to 8 per high-power field), with mitotic activity utilized to predict the risk of malignancy. Leiomyosarcomas do not arise from preexisting leiomyomata and present much later in life, well after menopause. There are often areas of fibrosis interspersed with the smooth muscle and occasional calcification,

especially after pregnancy-induced degeneration and in postmenopausal women. Leiomyomata typically grow in a spherical or nodular fashion with a relatively distinct demarcation from the surrounding normal myometrium, reflecting their clonal origin.

TABLE 55.1 Symptoms of Leiomyomata

- Menorrhagia
- Dysmenorrhea
- Pelvic pressure (pressure on adjacent pelvic viscera)
  - Urinary frequency
  - Constipation
  - Dyspareunia
- Infertility
- Repetitive pregnancy loss
  - First trimester
  - Second and third trimester (preterm labor)
- Abdominal Distension

Leiomyomata can arise from cells located anywhere in the myometrium (Fig. 55.1), with women often having very large numbers of fibroids. When the cell of origin is near the serosal surface, the path of least resistance to expansion is to grow outward into the

peritoneal cavity, termed a *serosal* or *subserosal fibroid*. Serosal tumors can grow very large with few or minimal symptoms, as they do not cause bleeding. Occasionally, a pedunculated fibroid will result with a pedicle narrower than the tumor diameter that contains the vascular supply. These may become detached from the uterus completely and reestablish blood supply from an adjacent organ. This is likely the result of pressure necrosis of the interface between the tumor and the adjacent viscera or torsion of the pedicle and attachment at the new site during healing. When the myometrial cell of origin is within the myometrium, this forms an intramural fibroid. These are associated with menorrhagia and dysmenorrhea, with failure to constrict the vessels supplying the endometrium during menses. If the myometrial cell of origin is near the endometrium, the tumor will find the path of least resistance to growth toward the endometrium, and a submucosal fibroid will result. These are most frequently associated with menorrhagia and dysmenorrhea, even when of relatively small size. If the fibroid originates from a cell immediately adjacent to the endometrial layer, the tumor may completely protrude into the endometrial cavity, and an intracavitary fibroid on a pedicle may develop. These intracavitary tumors can cause the most severe symptoms despite their small size. With uterine contractions increasing the intracavitary pressure, the stalk may elongate, extruding the fibroid through the cervix, typically associated with a sanguineous vaginal discharge and erosion of the surface of the fibroid. Aseptic necrosis may be present, and the degenerating tumor becomes secondarily infected, often making it difficult to distinguish from a necrotic cervical cancer. While cervical fibroids can occur, they are very infrequent, paralleling the small number of myometrial cells within the cervix. There is virtually no neovascularity within fibroids, and they derive their vascular supply from the vessels on the periphery of the tumor at the interface with the normally vascularized myometrium. While fibroids are stimulated to grow by sex steroids but the vascular supply is not, this is the limiting factor for the growth of individual tumors. Once the uterine vasculature

---

is maximally enlarged, the fibroids will cease growing and the center may even undergo necrosis, limiting their ultimate size. This is initially described as “red degeneration” and later, as the devitalized central tissue is replaced by fibrosis, described as “hyalinized degeneration” and may ultimately become calcified. It is not unusual to find marked calcium deposits in leiomyomata that have long ago undergone degeneration and were never symptomatic. Collateral vascular channels are comparably maximally engorged and may represent a surgical challenge. Not surprisingly, the blood loss with any extirpative surgery may be large, even if performed by experienced surgeons.

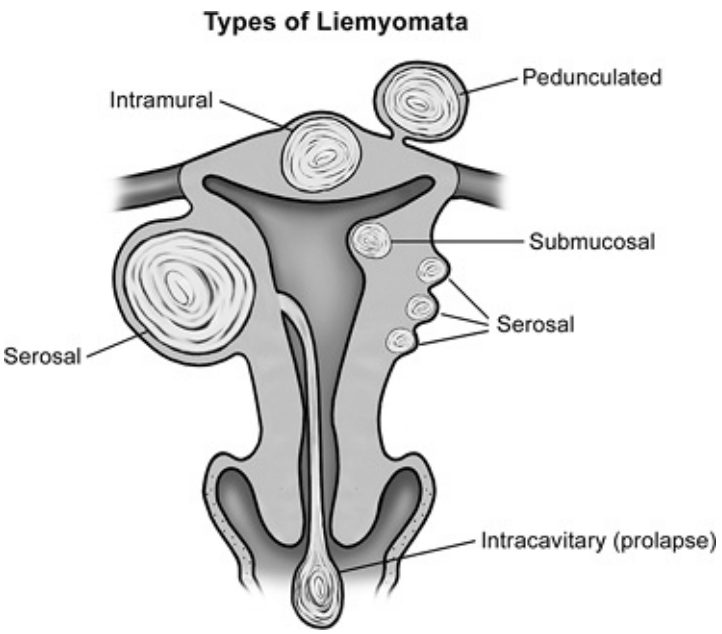

Figure 55.1 Possible locations of leiomyomata. This schematic diagram illustrates the many locations at which leiomyomata may develop. Symptoms related to heavy vaginal bleeding are generally greater when the leiomyomata are in close proximity to the endometrial cavity, with serosal tumors able to attain large size with virtually no change in menstrual bleeding. Fibroids can develop anywhere in the uterus, with the cervix having proportionally fewer because of its lower complement of myometrial cells.

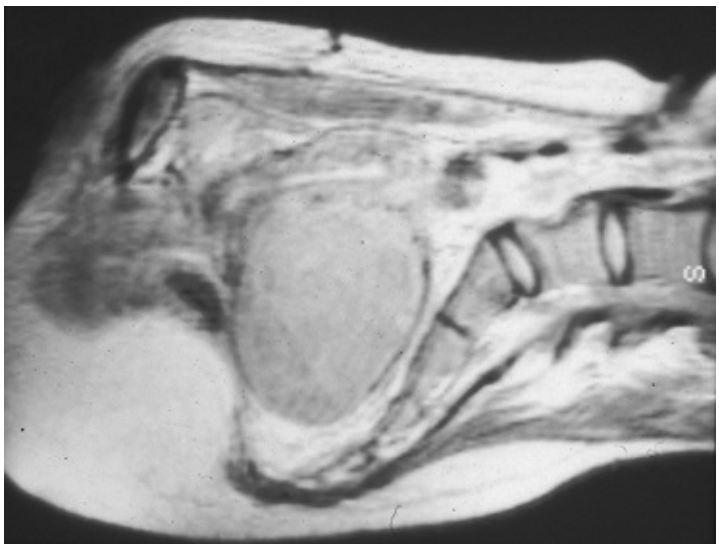

Figure 55.2 MRI of leiomyomata. This MRI demonstrates a large leiomyomata arising from the posterior aspect of the uterus and filling the entire pelvis. It directly contacts the promontory of the sacrum.

Influence of Sex Steroids

There is little doubt that the growth of leiomyomata is dependent on sex steroids as they: (a) are not noted prior to puberty, (b) typically regress after menopause, (c) possess sex steroid receptors (estrogen and progesterone), (d) often dramatically enlarge during pregnancy when estrogen and progesterone levels are very high, and (e) can be made to shrink with medically induced hypogonadism. Clearly, the uterus, like other secondary sex organs, initially develops to its adult size with exposure to the levels of ovarian steroids produced at puberty. However, this growth is programmed and should cease once reaching the appropriate development, despite continued exposure to sex steroids throughout the reproductive life span.

There is no evidence that higher or aberrant patterns of ovarian steroid secretion of estrogens, progestins, or androgens contribute to the development of leiomyomata. However, myomatous tissue has the same number of estrogen receptors but a higher number of progesterone receptors than the adjacent normal myometrium. This coupled with the observations that mitoses within myomas are more frequent in the luteal phase of the cycle and that progesterone up-regulates several growth factors suggests that progesterone is somehow causally involved in either myomatous development or continued growth. Since estrogen stimulates the synthesis of progesterone receptors in other reproductive tissues, a more complex relationship between the two dominant female sex steroids and leiomyomata is likely. Despite these observations, there is no consensus as to the specific roles of the various sex steroids aside from being necessary but not sufficient to develop leiomyomata. Situations that increase lifetime exposure to estrogen such as obesity and early menarche are associated with increased risk with the interval from the last delivery inversely related to risk.

The use of oral contraceptives has not been demonstrated to impact the likelihood of developing or enhancing the growth of fibroids. Treatment of postmenopausal women with hormonal replacement therapy may allow continued growth of previously existent but quiescent leiomyomata. There is no evidence to suggest that if leiomyomata are not present they will develop in response to hormone replacement therapy after menopause. In clinical decision making, there is no rationale for withholding hormone replacement therapy for fear of stimulating leiomyomata in otherwise appropriate candidates for postmenopausal hormonal replacement. Special note should be made of postmenopausal women with breast cancer treated with tamoxifen, as this compound has mixed estrogen agonist and antagonist properties and has the potential to influence the pattern of fibroid growth. Undoubtedly, gonadal steroids are important in the growth of leiomyomata.

Genetic Inheritance Pattern

It is estimated that more than 40% of first-degree female relatives of women with leiomyomata will develop fibroids sometime during their lifetime. These will not necessarily be symptomatic, and the number and location are not predictable. While leiomyomata are common in all races, black women appear to have a somewhat higher incidence than women of other ethnicities, despite being a common disease in all ethnicities. Black women who are undergoing hysterectomies have increased numbers of fibroids that are larger in size. Leiomyomata are by far the commonest genital tract

tumors for all women and remain the most frequent indication for gynecologic surgery. This familial pattern seems most consistent with a multifactorial genetic inheritance pattern, which is modified by confounding cofactors such as the impact of gonadal steroids. Aside from noting that the disease has apparent familial, age, and ethnic associations, there is little clinical predictability for an individual woman.

Molecular Mechanisms and Genetic Dysregulation

Leiomyomas represent monoclonal neoplasms, a situation in which etiologic genetic mutations in individual tumors are likely. Cytogenetic studies of individual leiomyomas reveal that approximately one third have some type of chromosomal aberration, but these are not consistent between individual tumors in the same woman, further supporting their clonal nature. The most common aberrant patterns are translocations between chromosomes 12 and 14, deletions of the short arm of chromosome 7, and rearrangements of the long arm of chromosome 6. It is not clear whether there is clinical relevance to these differences in terms of the rate of tumor growth, recurrence rates, and responses to the various therapies. Interestingly, when tumors have translocations between chromosomes 12 and 14, they are more likely to be larger myomas, whereas deletions of the long arm of chromosome 7 are found more often in smaller tumors. While there are no consistent alterations in gene expression noted in leiomyomata, the transcription factor high-motility group A2 is up-regulated

---

in leiomyomata with expressing the 12;14 chromosome translocation. These observations imply that despite similar histologic appearance and benign growth characteristics, there may be several molecular mechanisms by which these tumors develop.

Undoubtedly, individual myometrial cells become neoplastic as a result of a complex interaction between ethnicity, genetic mutations, endogenous sex steroids, and reproductive patterns. Molecular geneticists have noted abnormal expression of a variety of genes leading to altered growth factors and steroid receptors in individual leiomyomata, but there remains no single predominant molecular mechanism or group of mechanisms underlying their development and growth. In the coming years, this molecular puzzle will undoubtedly be better understood but will just as likely prove to be very complex without a single abnormality identified.

Impact of Leiomyomata on Reproduction

The impact of leiomyomata on pregnancy remains difficult to define for individual patients (Table 55.2). Clearly, the most logical approach to achieving pregnancy is for a woman with leiomyomata to attempt to conceive and elect treatment only if difficulty is encountered. There is general agreement that intracavitary and submucosal leiomyomata can be causally related to infertility on the basis of implantation failure. The presence of fibroids within the endometrial cavity or impinging on the cavity contour can be detected by a hysterosalpingogram, sonohysterography, or hysteroscopy, and their removal should improve fertility. With intramural leiomyomata, a relationship to infertility is less certain, and all other potential etiologies should be considered before considering leiomyomata

etiology. Intramural leiomyomata have been associated with a reduced pregnancy rate following assisted reproductive technology (ART), suggesting that they may have an impact on implantation. Given the time and expense of ART, it is prudent to remove intramural fibroids in selected infertile women prior to undergoing ART. Postoperative adhesions that may form after myomectomy are of lesser importance when undergoing ART, as they will not affect oocyte retrieval. While fibroids can be found anywhere in the myometrium, when they arise adjacent to the tubal ostia, they may occlude a tube or impede its function. For this to be seriously considered a problem related to infertility, however, both fallopian tubes would need to be affected, which is an infrequent circumstance.

TABLE 55.2 Mechanisms of Infertility with Leiomyomata

- Impaired implantation
  - Submucous
  - Intracavitary
  - Enlarged uterine cavity volume
- Impaired tubal transport
  - Obstruction
  - Distension

Whether leiomyomata are associated with a higher risk of first-trimester pregnancy loss, preterm labor, or intrauterine growth restriction is much more controversial. The impact of fibroids in individual patients is critically dependent on location, not simply size or number. Clearly, many women with large myomatous uteri deliver infants without difficulty, whereas in others, fibroids may compromise the ability of the endometrial cavity to accommodate a growing fetus or the maternal vascular adaptation necessary for normal placental function. Complicating this picture is our inability to predict which women with leiomyomata will experience rapid enlargement of their fibroids during pregnancy. An abruption can occasionally occur when the placental bed overlies an enlarging fibroid. Lower-segment fibroids have the potential to obstruct labor, and a classic cesarean delivery is occasionally required when the presenting part is unable to be directly applied to the cervix. If the leiomyomata are extremely large and intramural in location, preconception removal may be considered, but the potential benefit must be carefully weighed against the complications of the procedure. Clinical judgment will be sorely taxed to make correct decisions in the absence of a previous adverse clinical outcome. Overall, term delivery rates following myomectomy for symptomatic leiomyomata in an unselected patient population vary from 40% to 50%. The need to also perform a cesarean following myomectomy needs to be considered in any risk–benefit analysis.

Leiomyosarcoma

Rarely, a leiomyosarcoma is encountered instead of leiomyomata, but these are typically in older postmenopausal women with an average age well over 60. The diagnosis is often suggested by enlargement of the uterus after menopause in the absence of any hormone replacement therapy. Uterine fibroids known to be present prior to menopause may enlarge when the gonadal steroids are replaced, but this does not represent a frequent problem.

While leiomyomata are not thought to transform into malignant smooth muscle tumors, a small proportion of women with fibroids have the same pattern of chromosome deletions and transcriptional profiles that are observed in leiomyosarcomas. However, clinical transformation has not documented this, so it remains an interesting but not clinically relevant observation. Occasionally, lung metastasis of histologically benign-appearing smooth muscle is observed. These can be from the so-called benign metastasizing leiomyomata or another condition called *lymphangioleiomyomatosis*, characterized by the proliferation of leiomyoma-like cells in the lungs that have been observed. These are extremely rare and should not alter the recommendations to women with typical uterine leiomyomata.

Rapid growth alone is not indicative of malignancy, as this is a common occurrence in premenopausal women. No physical findings or unique imaging characteristics can reliably distinguish leiomyomata from leiomyosarcoma. Leiomyosarcoma are diagnosed by histology and not gross appearance, as degenerating leiomyomata may have unusual and varied features, including necrosis and central liquefaction. The histologic changes suggesting malignancy include increased numbers of mitoses, cellular pleomorphism, and thrombotic degeneration within the tumor. Many fibroids are very cellular but without other characteristics suggestive of malignant potential. Typically, >10 mitoses per high-power field suggests a risk that the tumor is malignant, with between 5 and 10 representing an actively growing fibroid and <5 more typical for leiomyoma. Because of the difficulty in accurately characterizing the number of mitoses by frozen section microscopy, the intraoperative diagnosis of a leiomyosarcoma is difficult to make with confidence and permanent sections are required. Leiomyosarcomas are estimated to comprise 0.1% of all uterine tumors, and 1.7% of women undergoing hysterectomy for leiomyomata are in their seventh decade of life.

Diagnostic Studies

The majority of leiomyomata are detected on pelvic examination performed because of gynecologic symptoms. The uterus is typically noted to be enlarged and irregular on bimanual examination. It is important to distinguish leiomyomata from other pelvic masses, and it may be difficult to do so in the presence of a large uterus. This is most easily done with an endovaginal or abdominal ultrasound scan, as the leiomyomata appear echogenic with similar acoustic impedance to the normal myometrium. Computerized tomography and magnetic resonance imaging (MRI) may prove useful in selected circumstances (Table 55.3, Fig. 55.2), but they are much more expensive and yield little more useful information than office sonography.

The proximity of the leiomyomata to the endometrial cavity can usually be demonstrated

by taking advantage of the acoustic differences between normal myometrium, fibroid tumors, and the endometrial cavity. The endometrial stripe is a reliable marker of the endometrial cavity, and finding a smooth, continuous endometrial stripe with normal underlying myometrium between the cavity and any fibroids suggests that they are not submucosal. Simultaneously injecting saline into the endometrial cavity while performing an endovaginal ultrasound examination (sonohysterography) improves the ability to delineate submucous and intracavitary leiomyomata. However, it is not possible to distinguish an endometrial polyp from an intracavitary myoma by virtually any imaging technique.

TABLE 55.3 Diagnostic Imaging Techniques

Endovaginal ultrasonography
Sonohysterography
Hysterosalpingography
Hysteroscopy
Computerized tomography
Magnetic resonance imaging

The closer the fibroid is to the endometrial cavity, the greater the likelihood and severity of dysmenorrhea and menorrhagia. Additionally, distortion of the endometrial cavity increases the probability that difficulty in achieving and maintaining a pregnancy will be encountered. Hysterosalpingography is often undertaken if infertility is present concurrently, as this technique can identify intracavitary tumors or a large but otherwise normal endometrial cavity caused by the stretching the normal myometrium around leiomyomata (Fig. 55.3). This radiographic technique has the added advantage of determining tubal patency as well. Increasingly, office hysteroscopy is being used when tubal patency is not an issue, as this technique allows clear differentiation between leiomyomata and other intracavitary pathology such as endometrial adhesions, uterine septae, and endometrial polyps.

Adenomyosis, which is another disease involving the myometrium, can occasionally be difficult to distinguish clinically from leiomyomata, and imaging studies may not be helpful. This is a process wherein functional endometrial glands and stroma infiltrate the myometrium. Frequently, a marked fibrotic reaction is present around the nests of endometrial cells, presumably because of irritation caused by menstrual shedding. When the process is localized, these fibrotic areas may be difficult to distinguish from leiomyomata and the true diagnosis only made at surgery. Leiomyomata typically have a clear demarcation from the underlying myometrium whereas adenomyosis has a very indistinct infiltrating border, making complete surgical excision problematic. MRI has been

reported to be useful in differentiating adenomyosis from leiomyomata, as it better delineates the borders of the intramyometrial pathology, but this is not routinely utilized preoperatively because of the expense involved. Like endometriosis, adenomyosis may be associated with an elevation in serum CA125, but this is a very nonspecific serum marker.

Preventing Development, Progression, and Recurrence

The ultimate goal of understanding the pathophysiology of leiomyomata is to prevent their occurrence in both clearly genetically susceptible women as well as women without a familial history. With further insight regarding the

molecular mechanism(s) of growth, it may be possible to identify medicinal approaches that will interfere with the molecular pathway(s) and reduce the risk of development, progression, and recurrence of leiomyomata. This will be particularly useful for women at risk for development of leiomyomata because of a strong familial history, those with previous myomectomy, and women with leiomyomata approaching menopause who can anticipate spontaneous regression once ovarian function ceases. There are few, if any, predictors of the development of leiomyomata aside from a family history. Endocrine markers such as early puberty, late menopause, parity, oral contraceptive use, and hormone replacement therapy have not been correlated with the recurrence of fibroids after myomectomy.

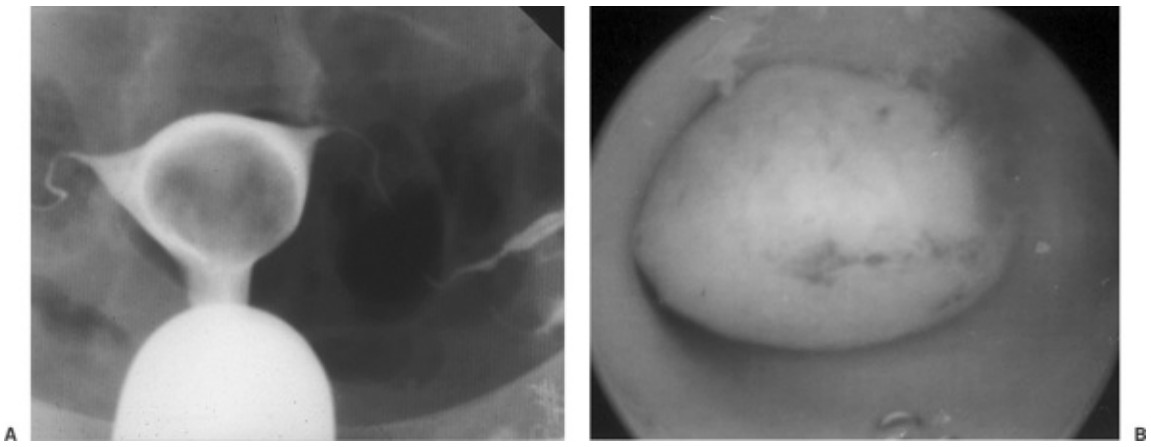

Figure 55.3 An intracavitary leiomyomata. **A:** Hysterosalpingogram using a water soluble contrast medium demonstrates a large smooth filling defect within the endometrial cavity resulting from an intracavitary fibroid. The mass effect on the study is nonspecific, and only direct visualization can confirm that it is caused by a fibroid. **B:** Hysteroscopic view of this intracavitary leiomyomata.

When to Treat

Despite the fact that fibroids are responsible for a large number of gynecologic surgeries, treating these benign tumors requires the same risk–benefit analysis as any other

therapeutic decision. Often, simply using a prostaglandin synthetase inhibitor or oral contraceptives will adequately relieve the symptoms. While an increasing variety of treatment options exist, it is important that the treatment be goal directed to alleviate the specific symptoms. Simply identifying leiomyomata does not imply that they will continue to enlarge, become symptomatic, or require treatment in the future. Occasionally, however, it may be appropriate to remove asymptomatic, extremely large leiomyomata in an effort to prevent anticipated reproductive problems. Similarly, when intracavitary or submucous myomas are present and the woman has not attempted pregnancy, it is likely that removal of the fibroids will improve her chances. Large tumors that fill the pelvis can impinge on the pelvic sidewalls, causing hydronephrosis, and their removal is critical to prevent renal impairment.

The growth characteristics of individual fibroids remain highly unpredictable, with many having limited growth potential. Some leiomyoma have already experienced rapid growth and have undergone aseptic necrosis and replacement by fibrosis, so they have no further growth potential and will not regress after menopause. While many fibroids may gradually enlarge and cause symptoms well before the anticipated regression at menopause, the growth pattern is so varied that there are simply no predictive characteristics helpful in identifying which women will need future intervention and which will not.

Gradually worsening dysmenorrhea and menorrhagia are more frequently linked than other symptoms. When these symptoms are mild, nonsteroidal anti-inflammatory agents and oral contraceptives are often useful, and the symptoms may improve sufficiently to avoid further intervention. In most cases, a therapeutic medical trial is indicated before proceeding to more aggressive medical or surgical options.

Location of the fibroids is important with regard to the development of symptoms: the closer the proximity to the endometrial cavity, the greater and earlier the symptoms are observed. Intramural, submucosal, and intracavitary fibroids are far more likely to be responsible for dysmenorrhea and menorrhagia than pedunculated or subserosal myomas. Severe symptoms may warrant intervention at a relatively small size, particularly when an intracavitary or submucosal fibroid is present. Similarly, the closer to the serosal surface the fibroids are located, the larger the size will be attained before being detected. Indeed, some extremely large leiomyomata will not be associated with any symptoms aside from increased abdominal girth. Because

---

the bladder is adjacent to the uterus, the most frequent symptom associated with a large myomatous uterus is increased urinary frequency. Rarely, compression of the colon against the sacrum may cause difficulty with defecation; however, more often than not, complaints of constipation are not completely relieved by removing or shrinking the leiomyomata.

Selecting the Appropriate Therapy

When clear indications for treatment are present, the most critical questions to ask before making a therapy decision pertain to (a) whether future reproduction is desired and (b) how soon menopause can be anticipated. As a simple hysterectomy represents a definitive cure, this is an attractive option for many symptomatic women when maintenance of

reproduction is not desired, menopause is not imminent, and more conservative measures have failed to alleviate the symptoms (Fig. 55.4). This also requires an assessment of each woman's preferences as well as her surgical and anesthetic risks. Clearly, women view extirpation of the uterus in their own social, cultural, and religious context, and removal of any genital structure cannot be viewed as inconsequential, even if there is no intention of future reproduction. Many women wish to preserve the uterus independent of reproduction, and they should be provided with the full spectrum of therapeutic options and their choices respected. When the preservation of future childbearing is desired, a myomectomy is the primary choice. However, since the recurrence risk of symptomatic leiomyomata is high, myomectomy should be viewed as being able to provide a disease-free interval and the women encouraged to attempt pregnancy as soon as it is feasible. Even in the absence of a desire to retain fertility, many women are interested in nonsurgical options to avoid the risks of surgery for benign disease.

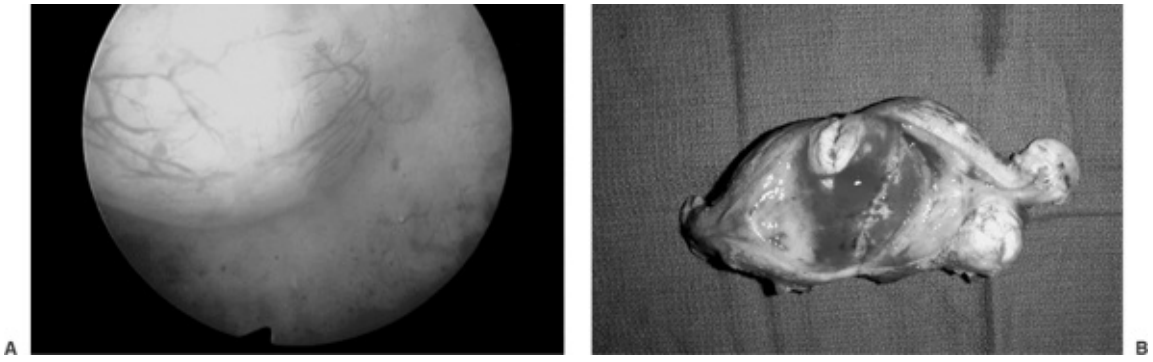

Figure 55.4 Submucous leiomyomata. **A:** Submucous fibroid is visualized at hysteroscopy from a woman with a history of menometrorrhagia unresponsive to medical management with nonsteroidal anti-inflammatory drugs and oral contraceptives. While the tumor protrudes into the endometrial cavity, the majority of it is still within the underlying myometrium. **B:** Hysterectomy specimen that demonstrates the submucous myoma responsible for the excessive vaginal bleeding.

Extirpative Surgery for Leiomyomata

The current mainstay of treatment for symptomatic leiomyomata is surgical, either hysterectomy or myomectomy, depending on the woman's desires regarding future childbearing (Table 55.4). Given the risks inherent with these surgical procedures, the decision to proceed with any surgery should be based on a personalized clinical risk–benefit assessment with the pivotal issue being future reproduction. Virtually no woman with leiomyomata needs to be faced with the painful choice of having to endure the symptoms in order to maintain reproductive potential versus relieving symptoms at the price of terminating reproduction. A myomectomy is almost always an option, even if a large number of fibroids are present and/or the tumors

are very large. The uterus functions well in pregnancy after a myomectomy, despite the impact of multiple incisions.

Hysterectomy

When future childbearing is not desired, the symptoms are severe enough to warrant treatment, and the woman has no contraindications, a simple hysterectomy is often chosen. This permanently relieves the symptoms, prevents recurrences, provides permanent contraception, and improves the self-reported quality of life. An infrequently considered and underappreciated additional benefit is making the decision whether to use hormone replacement therapy after menopause much simpler, with estrogen replacement alone the favored option. The decision to proceed with removal of the uterus should be based on an individualized risk–benefit analysis, weighing relief of symptoms against the surgical risk. The surgical approach should be individualized based on the size and location of the fibroids, the degree of uterine descensus, the woman's habitus, and whether or not an oophorectomy is being considered or other pathology is present. The available techniques are an abdominal hysterectomy, vaginal hysterectomy, or a minimal invasive hysterectomy.

Preservation of the cervix in appropriately selected women is an increasingly popular option since the myometrium is responsible for the growth of leiomyomata. The structural ligamentous support of the cervix and vaginal apex remains intact when the cervix is retained, reducing, at least theoretically, the rate of vaginal prolapse. Additionally, the major portion of the surgical morbidity of a hysterectomy relates to the surgical dissection necessary for removal of the cervix, and this is avoided when choosing a supracervical

hysterectomy without sacrificing the benefits. The risk of developing a subsequent cervical dysplasia is very low in this age group, and it is easily treated as an outpatient if it occurs, but the continued need for screening cervical cytology should be emphasized.

The risk of any complications with a hysterectomy are significant and when prospectively documented are approximately 17% with abdominal hysterectomy, 23% for vaginal hysterectomy, and 19% with a minimally invasive approach. The risk is apparently higher when the hysterectomy is done for fibroids, likely due to the increased size of the uterus. The complications include the usual problems associated with any abdominal surgery, specifically, injury to the bladder or ureters. The risk of ureteral injury is seven times greater with the vaginal approach, likely secondary to the limitations in visualization of the anatomy when operating through the vagina. Despite these concerns, hysterectomy is associated with a high level of patient satisfaction.

Hysteroscopic Myomectomy

Most intracavitary leiomyomata and a substantial number of submucous leiomyomata can be resected via surgical hysteroscopy in an ambulatory setting. If the tumor protrudes completely into the endometrial cavity via a stalk (e.g., a completely intracavitary myoma), a hysteroscopic resection is by far the most cost-effective method of removal. This requires an experienced hysteroscopic surgeon and should not be attempted unless the requisite skill is available. When a submucosal leiomyoma is predominately within the endometrial cavity, it is amenable to removal via hysteroscopic resection. However, if despite protruding into the endometrial cavity the bulk of the tumor is still contained within the underlying myometrium, a hysteroscopic approach will likely not prove to be successful and indeed can prove hazardous. In this circumstance, extreme caution should be exercised, and converting to an abdominal procedure should not be perceived as a failure but rather should be considered the safest option.

A hysteroscopic myomectomy is typically performed by using a hysteroscopic resectoscope comparable to that used for transurethral prostate resection. It is inserted through the cervix, the endometrial cavity is distended with a nonconductive media, and the myoma is resected by electrical loop excision of the fibroid. The fragments are removed with the effluent of the distending media by using the inflow/outflow channels. Careful preoperative selection of patients is required to ensure safe and effective removal in an ambulatory setting. Preoperative shrinkage of the leiomyoma by the use of a gonadotropin-releasing hormone (GnRH) agonist may often be helpful, which also affords a reduction in the height of the surrounding endometrium. Preoperative atrophy of the endometrium providing a clear operative field can be accomplished without resorting to complete pituitary down-regulation with a 10-day preoperative course of a progestin (20 mg of medroxyprogesterone acetate per day) or an androgen (danazol 800 mg per day). Care must also be taken to avoid excessive intravascular absorption of the distending medium, which can result in fluid overload, electrolyte imbalances, or a bleeding diathesis, depending on the choice of the distending medium.

Abdominal Myomectomy

When symptomatic leiomyomata are not amenable to a hysteroscopic approach, an abdominal approach usually is required. With infrequent exceptions, a low transverse incision yields adequate surgical exposure. Rarely, a vaginal myomectomy can be performed with the proper selection of patients, but this clinical situation is rare. The goal of a myomectomy is to remove all of the identifiable leiomyomata with the least possible impact on the reproductive tract. There are numerous surgical techniques, but in general, the myometrium is incised over the myoma, which is dissected from the surrounding myometrium. The incision is closed in layers with absorbable suture to ensure hemostasis and integrity of the myometrium (Fig. 55.5). Entry into the endometrial cavity is not associated with any

significant morbidity, but it is essential to not have sutures remain in the endometrial cavity in order to prevent intrauterine adhesions. Approximating the myometrium underlying the endometrium is all that is necessary. Fibroids extending to the cervix can represent a significant surgical challenge because of their proximity to the bladder and ureters as well as the difficulty attaining hemostasis. Similarly, parasitic fibroids can be difficult to remove, depending on the site of their acquired vascular supply (Fig. 55.6).

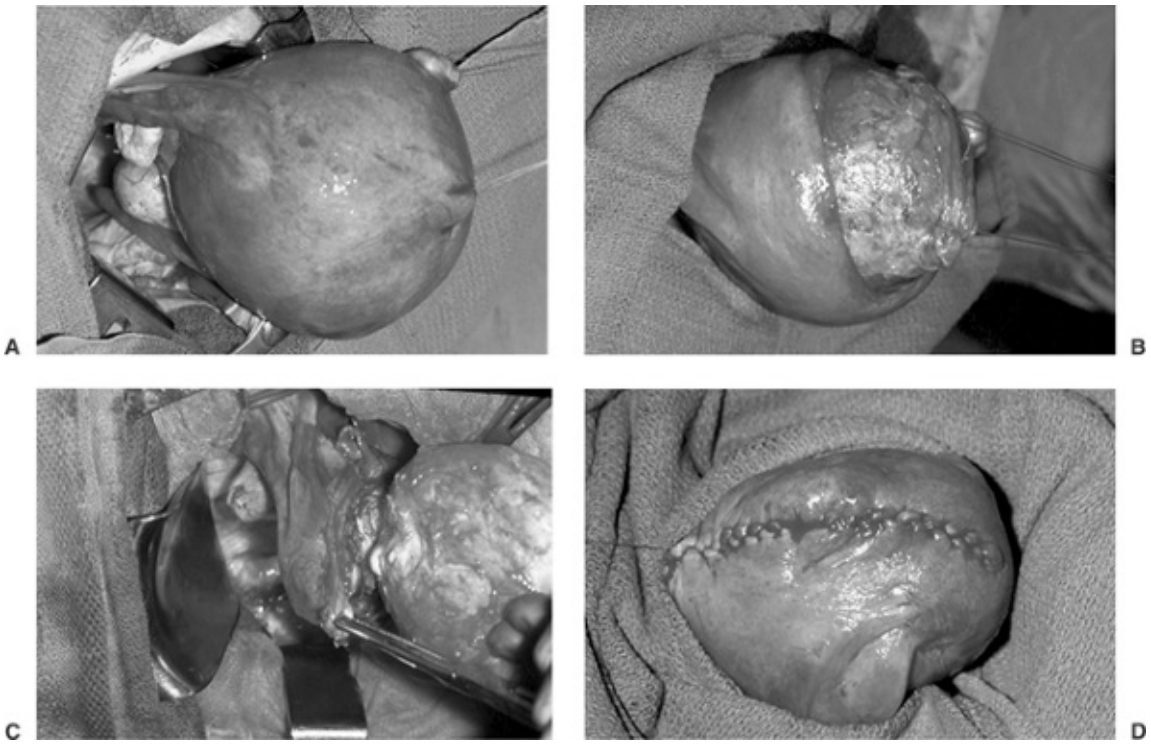

Figure 55.5 Myomectomy. **A:** Surgical exposure of a large uterus containing an intramural leiomyoma. **B:** The fibroid is dissected from the underlying myometrium. **C:** The uterine incision is extended down into the cavity, and the fibroid is removed. **D:** The myometrium is reapproximated in layers, and the uterine muscle wall closed.

As myometrium is extremely well vascularized, significant intraoperative blood loss is frequently encountered. Myomectomy at the time of cesarean section is particularly hazardous because of the increased vascularity of the myometrium associated with

pregnancy. Careful surgical technique to minimize blood loss, applying an intraoperative tourniquet around the lower uterine segment to compress the uterine arteries, intramyometrial injection of vasospastic agents such as vasopressin, and employing an intraoperative blood scavenger system can all help to reduce blood loss. These steps, coupled with the preoperative correction of anemia, storage of autologous blood, and preoperative mild overhydration to reduce the amount of red blood cell loss per unit volume of blood lost, have dramatically reduced the need for homologous transfusion. It is extremely rare that a hysterectomy becomes necessary because of intraoperative blood loss. Caution should be exercised when utilizing intramyometrial vasopressin, as bleeding may occur after the metabolism of the vasopressin, resulting in unappreciated blood loss and an increase in the risk of postoperative adhesion formation. In the immediate postoperative interval, it is common for women with multiple uterine incisions to experience febrile morbidity unrelated to any demonstrable infection. It is not clear whether this is related to a tissue reaction from the relatively large area of tissue trauma or a response to hemorrhage within the myometrium, but it is a benign finding, and antibiotic therapy should be reserved for women with clinical findings suggesting infection.

Once the myometrium has sustained a surgical incision involving a significant portion of the uterine wall, an elective cesarean section is generally recommended as the route of delivery. When the defect in the myometrium is properly repaired, the likelihood of a dehiscence during pregnancy is very remote, estimated to be approximately 0.002%. The incisions required for a myomectomy are not equivalent to that of a low transverse uterine incision utilized for cesarean sections. Rather, it is more comparable to a fundal incision used in a classical cesarean section, which is in the contractile portion of the uterus. Furthermore, the endometrial cavity does not need to be entered for there to be concern regarding the integrity of the uterine wall during labor. Following a myomectomy, couples should wait 2 to 3 months before attempting pregnancy to allow complete healing of the uterine incisions. The selection of women in whom a trial of labor could be allowed is based on the depth and number of myomectomy incisions. Only those

women with very superficial incisions should be allowed the option of a trial of labor with careful monitoring. As a result, an elective cesarean section is the preferred route of delivery for the vast majority of women with a previous abdominal myomectomy.

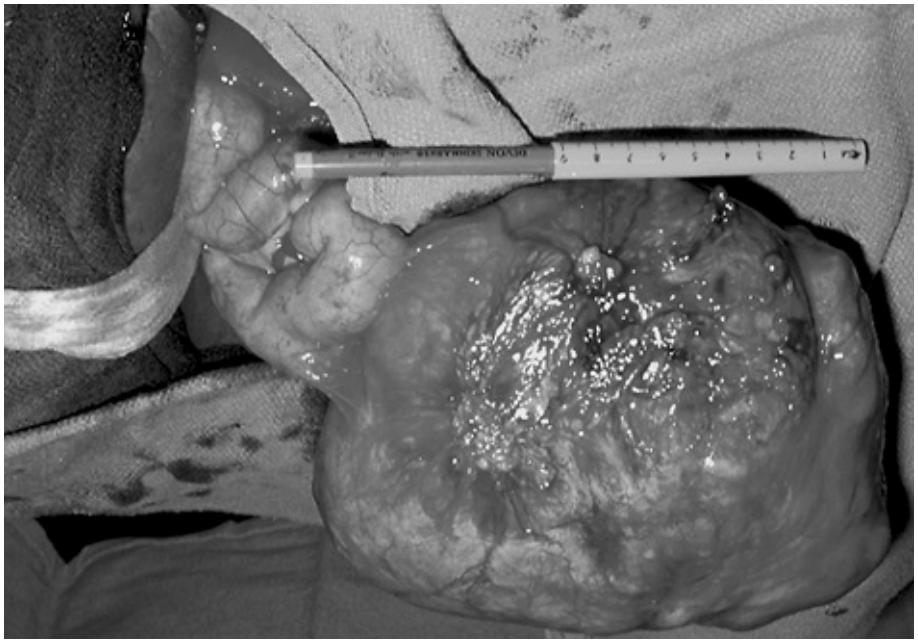

Figure 55.6 A parasitic fibroid. A large tumor has become parasitic to a loop of small bowel, deriving its blood supply from the new vascular source. This typically only happens with large posterior or fundal tumors and is more common when they are pedunculated. The mechanism is felt to be pressure necrosis and revascularization during healing of the necrosis of the bowel wall.

Minimally Invasive Myomectomy

Improvements in minimally invasive surgical techniques now allow some fibroids to be removed via endoscopy with the benefit of smaller incisions and less recovery time. Pedunculated, serosal, and selected intramural leiomyomas can be dissected free from the surrounding myometrium, morcellated, and the incision closed via laparoscopy. However, the surgery is lengthy and technically challenging and should be undertaken by only the most experienced minimally invasive surgeons. Furthermore, since only fibroids that are easily identifiable visually can be removed via laparoscopy, this therapy should be reserved for those situations when removal of a specific tumor or tumors can be anticipated to relieve the symptoms. Small intramural fibroids cannot be identified endoscopically, so a higher rate of subsequent symptomatic leiomyomata can be anticipated. Endoscopic closure of the uterine incisions is also technically difficult, and there have been several reports of spontaneous uterine rupture during pregnancy after laparoscopic myomectomy. This is additionally disconcerting, as they occurred prior to the onset of labor. This is distinctly different from the experience with abdominal myomectomy, where the risk of uterine rupture is felt to be limited to labor. This suggests that even with careful attention to incision closure by skilled minimally invasive surgeons, the incidence of uterine rupture should be judged a major risk factor to be considered when choosing the endoscopic approach. In the absence of long-term safety studies, laparoscopic myomectomy should be performed only in those women for whom future childbearing is not desired.

Recurrence of Leiomyomata

Since there is a genetic basis for the development of leiomyomata, even when all of the palpable leiomyomata have been surgically removed, the rate of recurrence and/or persistence with continued growth has been variably reported to be as high as 30% to 40%, depending on the number of tumors removed and the length of follow-up. Indeed, between 10% and 25% of women undergoing myomectomies require another surgical procedure within the next decade. The longer the interval of observation and the greater the number of myomas encountered, the greater the observed recurrence risk. Isolated large fibroids have lower recurrence rates than when multiple small tumors are present, despite an overall smaller volume of leiomyomata (Fig. 55.7). Different histologic types or cytogenetic abnormalities do not have any predictive value for recurrence.

Virtually all the data regarding recurrence—-or more properly stated, development of additional clinically apparent leiomyomata—-has been derived from women undergoing myomectomy where all of the palpable fibroids have been removed. Obviously, small tumors may remain, and this will be impossible to separate from new clonal expansions of myometrial cells from persistence of small nonpalpable tumors not identified at surgery. When a GnRH agonist is used preoperatively, the leiomyomata shrink in diameter and become softer and may not be detected at surgery, only to reemerge promptly after discontinuance. It may be more appropriate to simply consider the frequency and time to recurrence of symptoms rather than consider which fibroids are responsible for any symptoms.

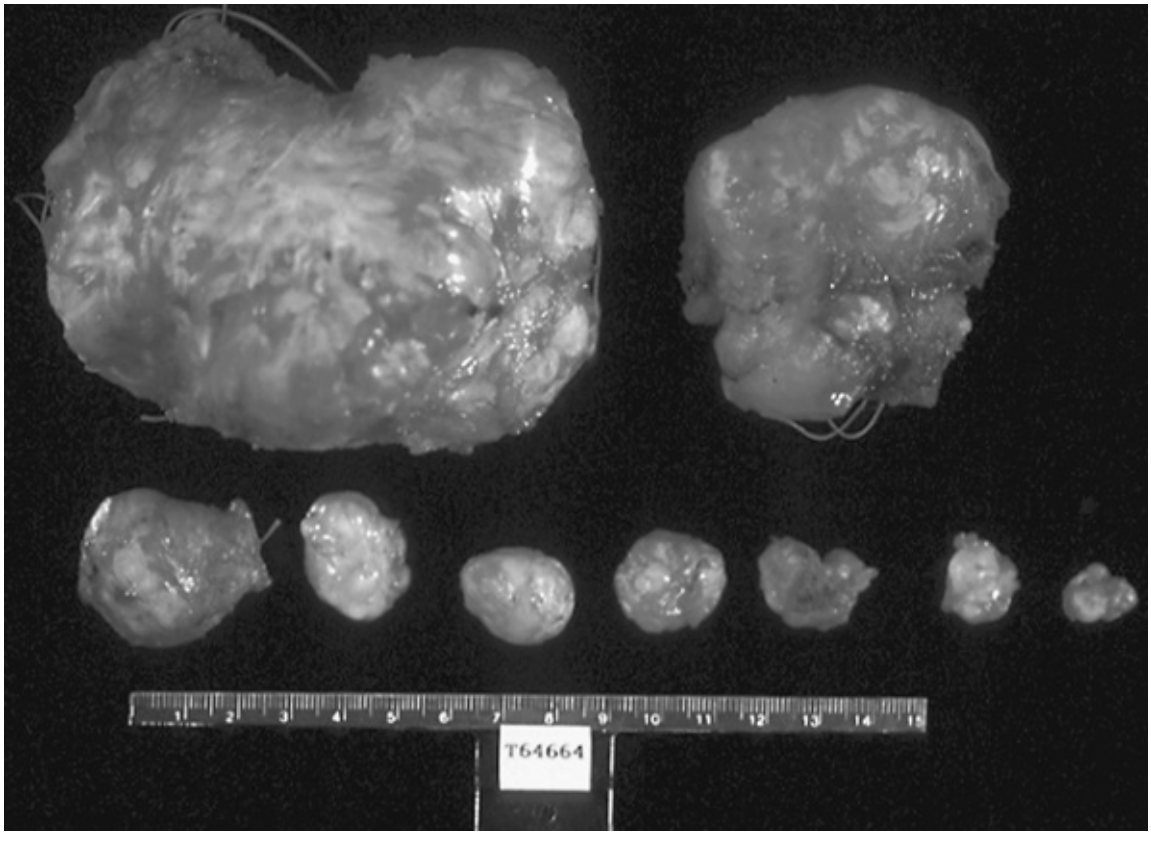

Figure 55.7 Multiple leiomyomata excised at myomectomy. Many individual fibroids of different sizes and shapes can be encountered within the same patient. Some are very large and obvious, while others may be small and difficult to palpate.

The typical time frame for the return of symptomatic fibroids after abdominal myomectomy is 3 to 5 years. Women should be counseled that when all the palpable myomas are removed, this provides an interval of time free of symptoms and the opportunity to reproduce but does not definitively "cure" an inherited predisposition to the development of fibroids. No long-term data are available for recurrence rates for non-extirpative techniques.

Postoperative Pelvic Adhesions

A major complication of any myomectomy is the development of postoperative adhesions involving viscera adherent to the uterine incision sites as well as de novo adhesions at nonsurgical sites, generally attributable to the unavoidable peritoneal trauma. The frequency of postoperative adhesions following myomectomy exceeds 50% and can result in reduced fertility, pain, or bowel obstruction. Careful surgical technique to minimize the degree of surgical trauma, confining the incisions to the anterior uterine surface so as to prevent contact with the bowel and adnexal structures, and covering the posterior uterine incisions with surgical barriers have been advocated to minimize the rate of postoperative adhesions. The materials used as adhesion prevention barriers are quite varied and include oxidized regenerated cellulose that is degraded by leukocytes; polytetrafluoroethylene, a nonreactive permanent material that is typically removed several weeks following surgery after the peritoneum has reconstituted itself (Fig. 55.8); and hydrolysable barriers, such as hyaluronic acid. All of these materials have their advantages and disadvantages, and few comparative studies are available. In the only direct comparative study, the fewer postoperative adhesions were associated with the use of the barrier composed of polytetrafluoroethylene versus oxidized regenerated cellulose. Improvements in surgical barrier technology, other systemic or intraperitoneal medicaments, and alternative surgical strategies will undoubtedly be forthcoming to help reduce the rate of postoperative adhesions.

Non-Extirpative Therapies

When removing the fibroids is not appropriate either because of patient choice or when confounding medical problems exist, a non-extirpative approach can be undertaken. A variety of options exist (Table 55.5), including medical suppression, destruction of the myomas in situ, or depriving them of their vascular supply. These approaches all suffer from the lack of long-term data regarding recurrence or the safety of subsequent pregnancy. However, with the onset of menopause, the tumors can be anticipated to spontaneously regress, so a temporizing measure may suffice to

permanently relieve symptoms. The recurrence of fibroids has not been assessed in women

treating their symptoms attributable to fibroids by one of the newer non-extirpative therapies such as uterine artery embolization (UAE) or MRI-guided high intensity focused ultrasound (HIFU). If the newer techniques are mainly applied to women close to menopause, this may be a non-issue, but if younger women elect nonextirpative therapies, only long-term comparative trials will yield useful discriminating information. Undoubtedly, the technical skill to remove or destroy all the leiomyomata by any technique is critically important to the rate of persistence and/or recurrence.

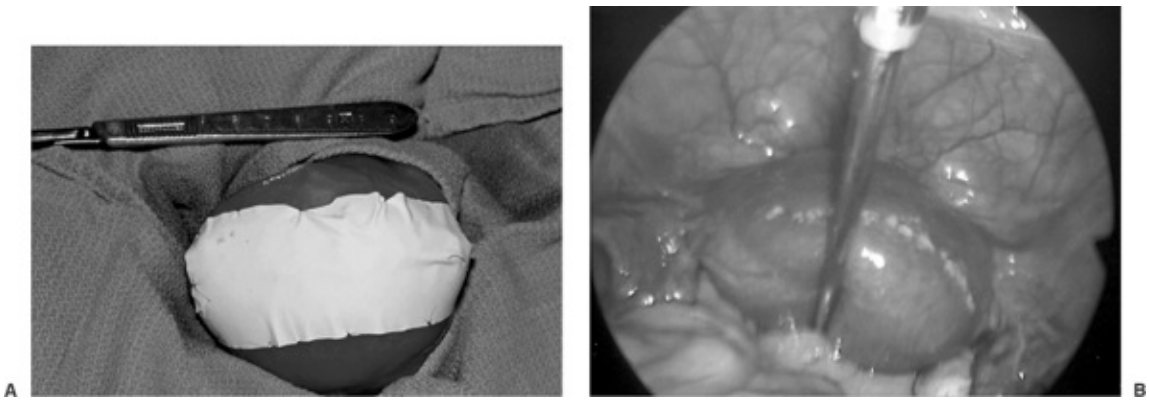

Figure 55.8 Placement of a barrier of polytetrafluoroethylene at the time of myomectomy. To reduce the risk of adhesion formation between the visceral peritoneum of the uterus and the tubes and ovaries, a permanent barrier composed of polytetrafluoroethylene is anchored over the uterine incision with permanent sutures **(A)**. The barrier is removed several weeks later via laparoscopy. **B:** The appearance of the uterine incision a year after the barrier was retrieved at a laparoscopy done for unrelated reasons. Note that the healed uterine incision does not have any adhesion and represents an optimal surgical result.

Medical Suppression

Many medicinal agents have been considered for the treatment of symptomatic leiomyomata, including estrogen antagonists, progesterone antagonists (mifepristone), androgens (danazol), and pituitary down-regulation with GnRH agonists. However, only suppressing ovarian steroid production and creating a state of hypogonadism with GnRH agonists has been demonstrated to reduce the size of leiomyomata and relieve symptoms to such a degree as to be clinically useful. While the volume of the leiomyomata typically decreases by 35% to 50%, this is somewhat misleading. Physicians consider a reduction in the size of fibroids to be the most clinically useful measure of shrinkage and the diameter decreases far less than the total volume as determined by using imaging measurements. Unfortunately, most leiomyomata rapidly return to the pretreatment size on discontinuance of GnRH-agonist therapy, and the return of symptoms parallels the enlargement.

TABLE 55.5 Non-extirpative Options

- Myolysis
  - UAE
  - MRI-guided HIFU
- Medically induced hypogonadism
  - GnRH agonist
  - GnRH agonist with “add-back” therapy

UAE, uterine artery embolization; MRI, magnetic resonance imaging; HIFU, high intensity focused ultrasound; GnRH, gonadotropin-releasing hormone.

Hypogonadism cannot be sustained for a prolonged interval because of the significant side effects such as vasomotor hot flashes, accelerated bone loss, genital tract atrophy, and loss of the cardiovascular protection. Approximately 1% of the bone mass is lost per month after the onset of hypoestrogenism, and the hot flashes and genital tract atrophy can be very debilitating. While most of the bone mass is regained if the therapy is limited to 6 months in young women, longer intervals of therapy may result in a permanent loss of age-adjusted bone mineral density. To alleviate the severity of the hypogonadal symptoms, the simultaneous administration of low doses of estrogen and progestin simultaneously with GnRH agonists, the so-called “add-back” regimens, have been utilized. These regimens relieve the hypoestrogenic symptoms, prevent bone loss, and can be used indefinitely.

The important question to ask is, “What is the goal of medical suppression?” Currently, the most relevant clinical use of GnRH agonists is to stop excessive vaginal bleeding and improve the hemogram prior to surgery or in order to delay surgery to correct other medical problems that are posing an increased surgical risk. It is important to recognize that there is an initial agonistic action of the GnRH agonist lasting 2 to 3 weeks before attaining the hypogonadal state. Hence, bleeding may transiently worsen before stopping, and GnRH agonists are of little use for acute management of bleeding. While the use of a preoperative GnRH agonist has been touted to reduce surgical blood loss and shorten operative time, there are scant data to support these contentions. Indeed, the softening of small intramural leiomyomata by hypogonadism may make it difficult to palpate them during a myomectomy and perhaps even make those identified more difficult to remove by reducing the demarcation between the normal myometrium and the fibroid. Given the variation in blood loss with surgery, it will be very difficult to demonstrate reduced surgical blood loss with GnRH agonist pretreatment. Until convincing clinical data are available, the use of GnRH agonists for other than for preoperative correction of anemia will remain controversial.

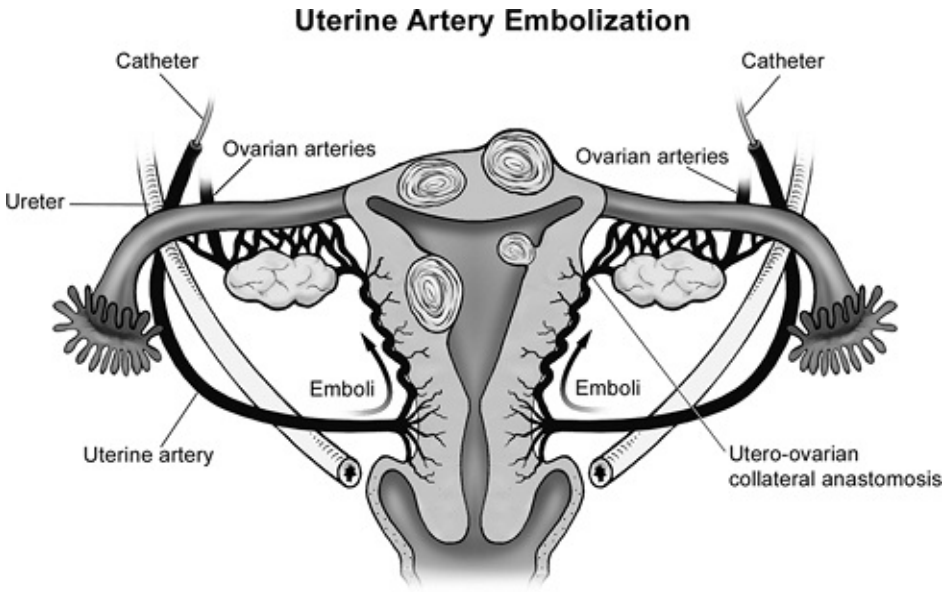

Figure 55.9 The technique of UAE. This schematic diagram demonstrates the technique used to inject emboli into the uterine arteries and deprive the normal myometrium as well as the leiomyomata of blood supply. Note that the uterine arteries have collateral connections with the ovarian arteries and provide a pathway for potential embolization to the ovarian vessels, inducing ovarian ischemia and premature oocyte depletion.

Myolysis

There have been many attempts at inducing therapeutic necrosis of cells within the center of a fibroid (e.g., myolysis), thereby shrinking the tumor size, relieving symptoms, and preventing progressive growth of the tumors. The aseptic necrosis may cause significant pain in the immediate post-treatment interval, comparable to that observed with degeneration of leiomyomata seen in pregnancy. None of the various techniques of myolysis have long-term data regarding efficacy, particularly with respect to the normalcy of subsequent pregnancy, safety, and persistence and/or recurrence rates. As a result, myolysis should be confined to those women who are not interested in subsequent pregnancy until well-designed, long-term comparative trials demonstrate safety.

Uterine Artery Embolization

When menorrhagia is the primary clinical symptom and either the surgical risk is judged unacceptable or the patient declines extirpative surgery, therapeutic embolization of the uterine arteries can be utilized to reduce symptoms. This strategy is to simultaneously deprive the uterus and the fibroids of their blood supply, induce necrosis, and reduce the symptoms (Fig. 55.9). Importantly, there is no dominant vascular pedicle to individual fibroids, and the embolization is performed on both uterine arteries to reduce the blood supply to the leiomyomata. The procedure involves cannulating a femoral artery and identifying the uterine arteries. An embolic agent is then infused to induce clotting and thus obstruct the blood flow to the uterus. This therapeutic approach has been used

previously in women with otherwise uncontrollable postpartum hemorrhage and as a palliation for women exsanguinating from locally eroding advanced cervical cancer. In those clinical situations, the uterine arteries are the primary vascular supply to the bleeding sites, and occluding them reduces this vascular supply. UAE has been successfully employed under these circumstances and compares well with the morbidity from the other available option, which is emergency surgery. Based on the success in these clinical situations, UAE has now been applied as primary therapy for symptoms attributable to fibroids.

The vascular supply to the myomatous uterus varies significantly from woman to woman, with a large aberrant blood supply developing from normally minor collateral vasculature, including the ovarian artery collaterals. For the technique to be successful, it depends on a significant differential requirement for blood supply for the fibroids compared with the surrounding normal myometrium. Several case series of selected women with leiomyomata have demonstrated a resolution of the menorrhagia ranging

---

from 65% to 90%, but virtually no data are available for the efficacy for other symptoms attributable to leiomyomata such as dysmenorrhea, pressure on adjacent viscera, and pelvic pressure. Estimates of the reduction in fibroid size after UAE ranges from 30% to 50%, which is comparable to the reduction seen with GnRH-agonist treatment. While the leiomyomata typically decrease in size, the actual reduction is clinically disappointing, as the sonographic volume measurements decrease proportionally more than the diameter of fibroids.

Since UAE has only been widely utilized for only slightly over a decade, the long-term safety and efficacy remain to be demonstrated. This is particularly true with regard to women wishing retain fertility where increased uterine blood flow during pregnancy is a normal physiologic adaptation that is critically important to the survival and normal development of the fetus. Only small numbers of spontaneous pregnancies have been reported, since the majority of women undergoing UAE are over 40 years of age and not desirous of further childbearing. Inadequate information is available regarding the incidence of intrauterine growth restriction and abnormal placentation or the value of a cesarean section to prevent uterine rupture during pregnancy or labor. As with an abdominal myomectomy, the risks involved are likely to be related to the number, size, and location of the fibroids being treated.

A major concern relates to ovarian function following UAE. As there are substantial vascular collaterals between the uterine and ovarian arteries, embolic particles have been noted to embolize the ovarian vessels, reduce ovarian blood supply, and cause premature ovarian failure. The overall rate of ovarian failure has been reported to be between 5% and 10%, with most of these women being over age 40 at the time of the UAE. However, amenorrhea and ovarian failure are insensitive markers of oocyte loss, and a large percentage of the oocytes may be lost without causing ovarian failure. Women may also experience post-procedure amenorrhea in the presence of normal ovarian function, indicating loss of the integrity of the endometrium, which is also of concern regarding future fertility.

UAE has been widely touted as avoiding the surgical risks, causing less pain, and requiring less recovery time than surgery. However, the aseptic necrosis often causes significant abdominal pain, and women undergoing UAE are routinely hospitalized for parenteral narcotic administration for 24 to 48 hours. If intracavitary or submucous myomas are present, the avascular necrosis following UAE may result in prolapse of the degenerating myoma through the cervix. There is a post-embolization syndrome that can develop similar to that observed after a myocardial infarction, manifested by a flulike syndrome with general malaise, elevated temperature, and leukocytosis. This is difficult to distinguish from an infection and is usually treated with antibiotics. Sepsis can occur, but whether it is secondary to an ascending infection or from another source is not clear. Serious acute complications necessitating hysterectomy and even including death have been reported. Until randomized comparative trials with long-term follow-up are available, UAE should be considered primarily for women with unacceptably high surgical risks or for those women without future reproductive desires who do not want surgery.

Magnetic Resonance Imaging–Guided High Intensity Focused Ultrasound

A recent development in the therapy options for fibroids is the use of ultrasound energy dissipation to thermally injure individual myomas. This technique involves coupling very precise MRI with the ability to focus high levels of ultrasound energy in a specified volume. The energy dissipation is directed toward individual fibroids, where the generated heat will cause aseptic tissue necrosis initially in the center of the individual fibroid tumor and spreading outward toward the periphery of the tumor. HIFU differs theoretically from UAE in that if the control of the thermal injury can be precisely controlled, the surrounding normal uterine smooth muscle should not sustain injury while selectively injuring the fibroid. As there are not specific vessels supplying individual fibroids, UAE achieves its therapeutic affect by depriving vascular supply to both the normal uterine smooth muscle as well as the fibroids contained within the uterine corpus with the hope that the normal uterine muscle sustains less injury than the fibroid. Obviously, multiple small leiomyomata will represent a challenge for HIFU technology, given the difficulty in generating high enough heat to confined areas with less control of the spread of the thermal injury to the adjacent normal tissue. HIFU has gained regulatory approval for use as treatment for symptoms related to fibroids in women who are not desirous of future fertility. As with UAE, it remains to be determined whether this will allow treatment of symptomatic leiomyomata in women who wish to become pregnant in the future. HFIU is a new, expensive technology available in a limited number of centers, and further experience will be required to determine the optimal clinical situation for its use.

Summary Points

- Leiomyomata are benign smooth muscle tumors responsible for approximately 200,000 hysterectomies annually because of menorrhagia, dysmenorrhea, and pelvic discomfort.
- They are gonadal steroid–responsive clonal expansions of individual

myometrial cells that can grow to impressive size despite being almost invariably benign in women in their reproductive years.

- Leiomyomata have a non-Mendelian inheritance pattern, with up to a 50% recurrence rate after myomectomy. While cytogenetic abnormalities are observed in individual fibroid tumors, no consistent molecular mechanism(s) has been identified as being responsible for the development of leiomyomata.
- Treatment should be directed toward specific clinical symptoms, with current therapeutic choices focusing on extirpation with hysterectomy most often selected for definitive treatment and myomectomy prior to the completion of childbearing, albeit with a significant recurrence risk.
- Intracavitary and selected submucous leiomyomata can be resected hysteroscopically, and while laparoscopic myomectomy is now technically feasible, the risk of uterine rupture during subsequent pregnancy limits this approach.
- While GnRH agonist–induced hypogonadism can reduce the volume of leiomyomata by up to 50%, the severe side effects and rapid return to pretreatment size after discontinuance make this approach useful only for specific short-term goals such as shrinking an intracavitary tumor prior to hysteroscopic resection, preoperative correction of anemia, or preoperative reduction in size to change the surgical approach.
- UAE and MRI-guided focused ultrasound myolysis can be selectively employed to reduce symptoms in women who do not desire further childbearing, but their safety and efficacy have not been demonstrated when future reproduction is desired.

Disorders of the Breast

Mary L. Gemignani

Breast cancer remains the most common cancer in women and is second only to lung cancer as the leading cause of cancer-related death in the United States. It is estimated that in 2006, there will be 212,920 new cases of breast cancer diagnosed in women and 40,970 cancer-related deaths. The lifetime risk among women of developing breast cancer is 12.5% (1 in 8); the lifetime risk of dying from breast cancer is 3.6% (1 in 28). Although breast cancer remains a serious health concern in the United States, as well as in other countries, breast cancer mortality is declining. This decline is thought to be secondary to increased use of mammographic screening and early detection of breast cancer.

Obstetricians and gynecologists are commonly the primary care physicians for many women. According to the American College of Obstetricians and Gynecologists (ACOG), the diagnosis of breast disease, as well as the education of women on breast self-examination and their referral for mammographic screening, is central to the obstetrician–gynecologist's role in women's health care.

This chapter presents an overview of breast cancer screening, benign and malignant conditions of the breast, and the role of the obstetrician–gynecologist in the diagnosis of and education of women about breast disease.

Anatomy of the Breast

The adult breast lies between the second and sixth ribs in the vertical plane and between the sternal edge (medially) and midaxillary line (laterally). The average breast measures 10 to 12 cm in diameter and is 5 to 7 cm in thickness. It is concentric, with a lateral projection into the axilla named the *axillary tail of Spence*.

The breast consists of three major structures: skin, subcutaneous fatty tissue, and breast tissue (parenchyma and stroma). The skin contains hair follicles, sebaceous glands, and eccrine sweat glands. The glandular breast is divided into 15 to 20 segments (lobes) that are separated by connective tissue and converge at the nipple in a radial arrangement. These lobes are made up of 20 to 40 lobules, which in turn consist of 10 to 100 alveoli (tubulosaccular secretory units). Five to ten major collecting milk ducts drain each segment and open at the nipple into subareolar lactiferous sinuses.

A superficial pectoral fascia envelops the breast; the undersurface of the breast lies on the deep pectoral fascia. Between these two fascial layers are fibrous bands known as *Cooper suspensory ligaments*, which provide support for the breast. The space between the deep layers of the superficial fascia of the breast and the deep investing fascia of the pectoralis is the retromammary bursa.

The epidermis of the nipple (mammary papilla) and areola is pigmented and wrinkled and consists of keratinized, stratified squamous epithelium that contains smooth muscle fibers in dense connective tissue. These fibers are responsible for the erection of the nipple. Two receptor-type nerve endings (Ruffini-like bodies and end bulb of Krause) are present on the nipple and are associated with the tactile reception of stretch and pressure.

The areola has no hair follicles; it has sebaceous glands (at its margin), apocrine sweat glands, and accessory areolar glands (Montgomery glands) that open on the surface of the areola as small elevations called *Morgagni tubercles*.

The blood supply of the breast is mostly from superficial vessels. The principal blood supply is derived from the internal thoracic (mammary) and lateral thoracic artery and their tributaries. The posterior intercostal arteries of the second to fourth intercostal spaces also give off tributaries known as the mammary branches.

The superficial veins follow the arteries and drain through perforating branches of the internal thoracic vein, tributaries of the axillary vein, and perforating branches of posterior intercostal veins. The veins anastomose circumferentially around the nipple, which is named the *circulus venosus*.

Epidemiology of Breast Cancer

Risk Factors and Assessment

Age

The incidence of breast cancer increases with age. Age is the most significant risk factor for breast cancer.

Family History

Hereditary breast cancers account for 5% to 10% of all breast cancers and are thought to be attributable to highly penetrant mutations in breast cancer–susceptibility genes. Two such tumor-suppressor genes, *BRCA1* and *BRCA2*, have been well characterized. Breast cancer has also been noted to occur in association with other cancers, such as in Li-Fraumeni syndrome and Cowden syndrome.

Personal History

A patient's history of prior breast biopsy is important. Although the number of breast biopsies undergone does not increase a woman's risk of breast cancer, certain pathologic entities do play a role. Atypical ductal or lobular hyperplasia and lobular carcinoma in situ

(LCIS) are considered markers of increased risk of developing invasive breast cancer. A personal history of breast cancer increases the risk for development of another breast cancer. Women treated for breast cancer are at risk for the development of a contralateral breast cancer. Various studies have shown this risk to be between 0.5% and 1.0% per year. In addition, patients treated with breast conservation (lumpectomy and radiation therapy) are at risk for an ipsilateral recurrence. In these women, this risk could be 10% or higher at 10 years post-treatment.

Reproductive History

Early menarche, late menopause, and nulliparity are thought to be risk factors for breast cancer. Age at first pregnancy is also thought to be a relative risk (RR) factor for breast cancer. Early age at first pregnancy is often associated with a lower risk for breast cancer; pregnancy by the age of 30 may reduce risk by up to 30%, and a full-term pregnancy by the age of 20 reduces risk by 50%. Breast-feeding has been reported to reduce risk of breast cancer, and the greatest effect is seen when cumulative times exceed 24 months. The effect of menopause as it relates to breast cancer risk has been examined. Late menopause poses an increase in risk of breast cancer. Bilateral oophorectomy before natural menopause has been reported to reduce risk of breast cancer.

Exogenous Hormone Use

The role of exogenous estrogens in the promotion of breast cancer is still controversial. Studies of oral contraceptive pills (OCPs) and hormone replacement therapy (HRT) have yielded conflicting results. Studies of HRT and breast cancer risk indicate that women who are currently using HRT are at increased risk for breast cancer development. A meta-analysis of the largest studies, however, suggests that the increased risk is only about 10%. Women who have taken HRT in the past but are not currently using HRT are not at increased risk. Long-term use of HRT (>10 years) has been associated with relative increase in breast cancer risk, and the highest risk was noted in those patients using HRT with progestins (RR 1.41). Of note, multiple studies have shown that patients who develop breast cancer while on HRT have smaller, less aggressive cancers and a lower risk of death from breast cancer.

Recently, results from the Women's Health Initiative (WHI) randomized controlled trial were reported. Between 1993 and 1998, 16,609 women with an intact uterus were randomized to receive combination HRT (0.625 mg per day of conjugated equine estrogens and 2.500 mg per day of medroxyprogesterone acetate) versus placebo. The planned duration of the trial was 8.5 years; however, the data and safety monitoring board of the committee recommended halting the trial because the incidence of invasive breast cancer had exceeded the stopping boundary that had been set at the initiation of the trial. This occurred after a mean of 5.2 years of follow-up. The increased risk of breast cancer-reported hazard ratio (HR) was 1.25 (95% confidence interval [CI] 1.00 to 1.59). There was also a reported increased risk of coronary heart disease (HR 1.29; 95% CI 1.02 to 1.63), and stroke (HR 1.41; 95% CI 1.39 to 3.25). Beneficial effects included decreased risk of colorectal cancer (HR 0.63; 95% CI 0.43 to 0.92) and hip fracture (HR 0.66; 95% CI 0.45 to 0.98). Based

on the data, the safety monitoring board initially did not recommend stopping the estrogen-alone arm in women who had had a hysterectomy. Results of the estrogen-only arm of the WHI study have been reported. The study included 10,739 postmenopausal women (aged 50 to 79 years) with prior hysterectomy. These women were randomized to receive 0.625mg per day of conjugated equine estrogen or placebo. In February 2004, the National Institutes of Health (NIH) decided to terminate the intervention phase of the estrogen-only study, which had been scheduled for a close-out interval of October 2004 to March 2005. With an average follow-up of 6.8 years, there was an increased risk of stroke (HR 1.39; 95% CI 1.10 to 1.77), a decreased risk of hip fracture (HR 0.61; 95% CI 0.41 to 0.91), and no effect on coronary heart disease incidence (HR 0.91; 95% CI 0.75 to 1.12). The investigators noted a possible reduction in breast cancer risk (HR 0.77; 95% CI 0.59 to 1.01) that warrants further investigation.

The annual increased risk for an individual woman is still relatively small. The increased risk for breast cancer is apparent after 4 years of HRT use. The ACOG stresses the importance of addressing the reasons for initiating or continuing on HRT. It is no longer recommended to prevent heart disease in healthy women (primary prevention) or to protect women with pre-existing heart disease

---

(secondary prevention). In addition, it is no longer recommended solely for prevention of osteoporosis.

HRT is highly effective in treating vasomotor symptoms with limited effective alternative therapies. In this setting, short-term use (<5 years) can be considered, as data on short-term use does not show an increased association with breast cancer. A recent study surveyed attitudes of obstetricians and gynecologists toward hormone therapy after the WHI results were published. Respondents to the survey remained skeptical of the results; 49.1% did not find them convincing. There was strong support for the use of HRT for vasomotor symptoms, vaginal dryness, and osteoporosis, but most of the physicians that were surveyed did not find it useful for prevention of cardiovascular disease or dementia.

In the past, most studies addressing OCP use and breast cancer risk concluded that there was a significant increase in risk associated with OCP use. However, the majority of studies regarding OCP use and breast cancer risk have demonstrated little association with breast cancer incidence rates. In women who have used OCP for extended periods of time (>10 years), a minimal, nonsignificant increase in breast cancer cases has been reported, seen most commonly in the group of women who began using OCP at a young age (<20 years). Past or present use of OCP at the time of diagnosis of breast cancer does not affect mortality from breast cancer. The presence of a family history of breast cancer does not appear to further increase the risk of breast cancer associated with either OCP or HRT use.

Prior Exposure to Radiation Therapy

Exposure to ionizing radiation, such as that which occurs in treatment with mantle radiation for Hodgkin's disease, poses a risk for breast cancer. This is noted 7 to 10 years after completion of radiation therapy. The cumulative probability of breast cancer at age 40 approaches 35% in these women. The risk of breast cancer associated with radiation

exposure decreases with increasing age at exposure.

Other Factors

Breast cancer is more frequent in Jewish women than in non-Jewish women and in black women more often than in white women. Asian women have a low incidence of breast cancer. Japanese women show lower rates of breast cancer than white women. Although postmenopausal breast cancer is less common in Japanese women who have migrated to Western countries than among the general populations of these countries, after two or three generations, the incidences of breast cancer in these women approaches that of white women. The Western diet, with its increased intake of animal fat, has been implicated in these studies.

Alcohol consumption has been reported to increase breast cancer risk in a dose-related manner. Women who drink approximately one drink per day have slightly elevated risk of breast cancer over nondrinkers. This risk is significantly higher with moderate to high alcohol consumption (two to five drinks per day).

Relative Risk

RR is a ratio that depicts the likelihood over time of an event's occurrence in a study population relative to that in a reference population. It is often used to quantify risk factors for breast cancer. Absolute risk is a percentage that depicts the likelihood over time of the occurrence of an event. For rare events, these two are the same, but for common events they are not. It is best to discuss risk with patients in terms of absolute risk rather than RR.

Several models exist to estimate a woman's risk of breast cancer. The Gail model, developed for use in the National Surgical Adjuvant Breast and Bowel Project (NSABP P-1) Breast Cancer Prevention Trial, is available from the National Cancer Institute (NCI) and provides a measurement of absolute risk over time for breast cancer. However, in familial-type hereditary cases, it underestimates the risk of breast cancer by overlooking age at onset, bilaterality of disease among affected family members, and breast cancer in non-first-degree relatives (Table 56.1).

BRCA1 and BRCA2

BRCA1 and *BRCA2* are breast cancer–susceptibility genes that have expanded our knowledge of familial breast cancer. Linkage studies done in 1990 in early-onset breast cancer families led to cloning of the *BRCA1* gene at the University of Utah in Salt Lake City in 1994. The *BRCA1* gene consists of 22 coding exons distributed over approximately 100 kb of genomic DNA on chromosome 17q21. It is thought to be responsible for approximately 45% of early-onset hereditary breast cancers and nearly 90% of hereditary ovarian cancers in families with a high incidence of breast and ovarian cancers. Two specific mutations, 185delAG and 5382insC, are present in approximately 1.00% and 0.25% of the Ashkenazi Jewish population, respectively. They are thought to be founder mutations (i.e., an altered gene or genes seen with a high frequency in a population originating from a small ancestral group, one or more

of the founders of which were carriers of the mutant gene).

BRCA2 was isolated on chromosome 13q12–13 in 1995. The *BRCA2* gene is composed of 26 coding exons distributed over approximately 70 kb of genomic DNA. This gene appears to account for 35% of families with early-onset breast cancer. It confers a lower risk of ovarian cancer compared with that found in breast cancer. A single mutation, 6174delT, is found in approximately 1.4% of the Ashkenazi Jewish population. Together, both *BRCA1* and *BRCA2* mutations are found in approximately 1 in 40 Ashkenazi Jewish individuals. For both genes, the estimated penetrance is 70% to 90% for breast cancer by age 70, but the risk of breast cancer by age 50 may be lower for *BRCA2* mutations.

TABLE 56.1 Breast Cancer Risk Factors

Personal and Family History Factors with RR >4.0

- Certain inherited genetic mutations for breast cancer
- Two or more first-degree relatives with breast cancer diagnosed at an early age
- Personal history of breast cancer
- Age (≥65 y vs. <65 y, although risk increases across all ages until age 80 y)

Personal and Family History Factors with Relative Risk 2.1 to 4.0

- One first-degree relative with breast cancer
- Nodular densities seen on mammogram (>75% of breast volume)
- Atypical hyperplasia
- High-dose ionizing radiation administered to the chest
- Ovaries not surgically removed before age 40 years

Personal and Family History Factors with RR 1.1 to 2.0

- High socioeconomic status
- Urban residence
- Northern U.S. residence

Reproductive Factors That Increase RR

- Early menarche (<12 y)
- Late menopause (≥55 y)
- No full-term pregnancies (for breast cancer diagnosed at age 40+ y)
- Late age at first full-term pregnancy (≥30 y)
- Never breast-fed a child

Other Factors That Affect Circulating Hormones or Genetic

Susceptibility
- Postmenopausal obesity
- Alcohol consumption
- Recent HRT
- Recent oral contraceptive use
- Being tall
- Personal history of cancer of endometrium, ovary, or colon
- Jewish heritage

RR, relative risk; HRT, hormone replacement therapy.
Data from Hulka BS, Stark AT. Breast cancer: cause and prevention. *Lancet* 1995;346:883–887; Kelsey JL. Breast cancer epidemiology: summary and future directions. *Epidemiol Rev* 1993;15:256–263; American Cancer Society. *Breast cancer facts and figures 2001–2002*. Atlanta, GA: Author, 2001.

The likelihood of a patient having a *BRCA1* or *BRCA2* mutation is dependent on certain factors such as age at the time of diagnosis of breast or ovarian cancer and the number and age of first- and second-degree relatives in the same parental lineage and ethnicity with breast or ovarian cancer. The parental lineage can be either maternal or paternal. The American Society of Clinical Oncology has issued guidelines for recommending genetic testing for families with high probability (>10%) of having a mutation for *BRCA1* (Table 56.2).

Identification of patients with a high-risk family history should be referred for genetic counseling and testing. The decision to undergo genetic testing is a complex one, as it can affect an individual's personal, psychologic, social, financial, and ethical well-being.

Women who have a negative genetic test should still be considered at risk on the basis of age and environment and because of the possibility of other genetic factors or unknown mutations.

TABLE 56.2 American Society of Clinical Oncology Guidelines for Recommending Genetic Testing for Families with High Probability (>10%) of Having *BRCA1* Mutation

- Three or more kindred with breast cancer before age 50
- Two or more breast cancers and one or more ovarian

- ancer diagnosed at any age
- Sister pairs with two breast cancers, two ovarian cancers, or a breast and an ovarian cancer, all diagnosed before age 50

History and Physical Examination

Obtaining a thorough history, including a family history and information on menstrual status, pregnancies and lactation, hormone use, prior breast surgeries, and trauma, is essential. In addition, ascertaining whether the patient performs breast self-examinations, as well as the presence and characterization of nipple discharge or a breast mass, is important.

Bilateral breast examination is best performed following menstruation and prior to ovulation. At this time, breast engorgement and tenderness is less likely to be present. A multipositional breast examination should be performed, including examination in the upright and supine positions (Figs. 56.1, 56.2). Breast retraction and subtle changes in the skin and nipple may be missed if the patient is examined in only one position. Examination should be performed with hands at sides; with hands elevated above the head; and finally, with the arms tensed at the waist (contracting the pectoralis muscles). Attention is directed toward the supraclavicular area and axilla. Digital palpation is performed beneath the lateral pectoralis muscles into the axilla itself.

The second phase of the breast examination is conducted with the patient in the supine position. Digital palpation is carried out by using the index and middle fingers and applying varying amounts of pressure with the flats or pads of the fingers. A thorough examination systemically covers the entire breast and chest wall. The examination can be done in a clockwise direction or by rows (stripwise). It is important to carefully examine beneath the nipple–areolar complex and within the axilla.

An inflammatory appearance of the breast should raise suspicion of an inflammatory carcinoma. The classic appearance of inflammatory breast cancer includes a red, swollen breast with skin edema (“peau d'orange”). The breast is generally not tender. If the inflammation persists

following a short course of antibiotics to rule out cellulitis, biopsy of the breast and skin is warranted. Inflammatory breast cancer is often a clinical diagnosis, and a benign skin biopsy should not dissuade the clinician from undertaking further evaluation and treatment. Any asymmetric skin changes or changes of the nipple–areolar complex should arouse suspicion. Paget disease of the nipple is the presence of intraductal or invasive cancer involving the nipple and should be excluded by a nipple biopsy of the abnormal area following a mammogram.

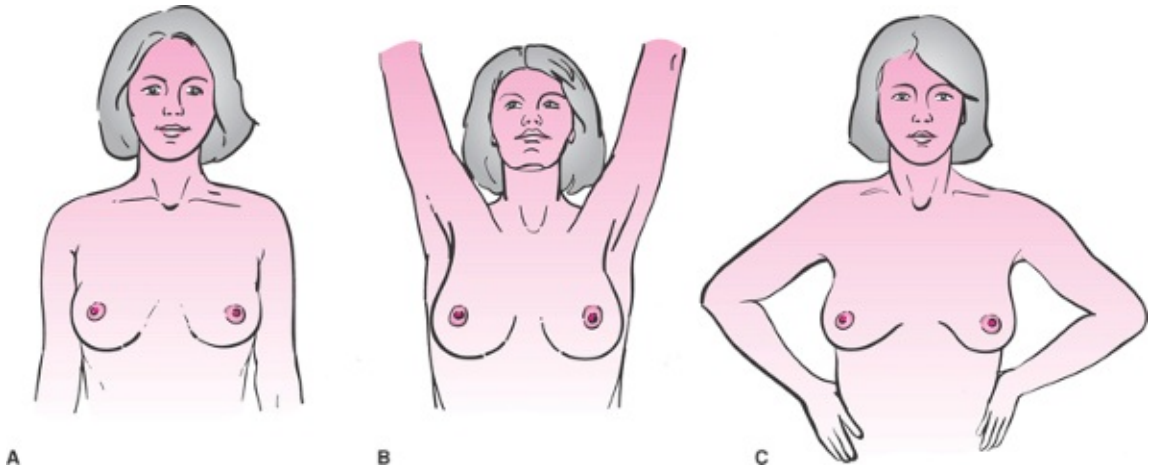

Figure 56.1 A: Inspection of patient with arms at sides. **B:** Inspection of patient with both arms raised. **C:** Inspection of patient with hands at waist, pectoral muscles contracted.

It is important to instruct patients in the technique of breast self-examination. Physician-directed discussion on breast self-examination is the most effective approach. Physicians have the opportunity to reinforce what is normal versus abnormal to patients during the examination.

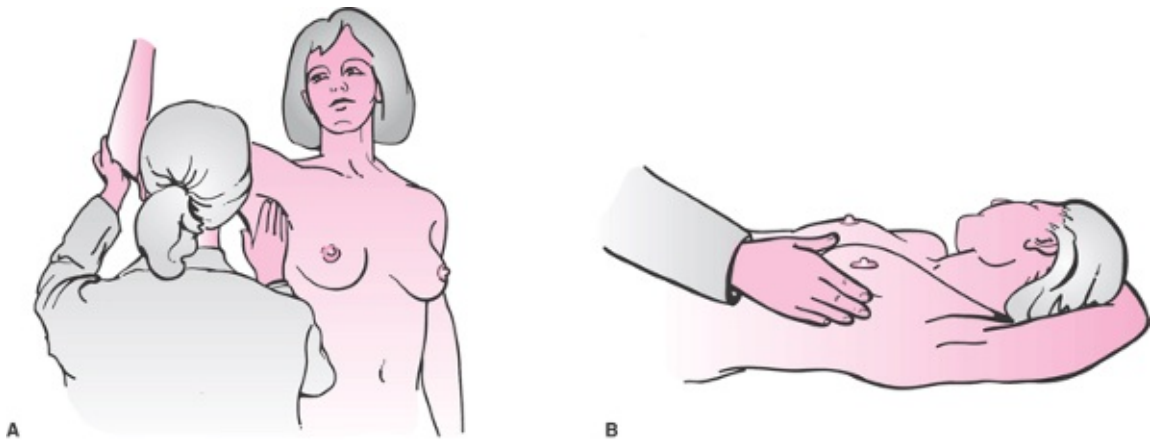

Figure 56.2 A: Palpation with patient upright, with support of ipsilateral elbow; axillary nodes and also supraclavicular nodes examined. **B:** Palpation of breast with patient in the supine position.

If no abnormal findings are noted on examination, it is critical to document negative findings. The date of the last mammogram, discussion of cancer screening, and plans for follow-up should also be recorded.

Hormones (HRT or OCPs) should not be renewed without a documented annual breast examination or mammography, if indicated. A great deal of litigation results from failure to diagnose breast cancer. The Physician Insurers Association of America's breast cancer

claims study, conducted in 1988, determined that 75% of successful malpractice lawsuits involved primary care physicians with practices in family medicine, internal medicine, or obstetrics and gynecology. It is important that the medical chart includes careful documentation, since approximately one-third of the cases reported in the Physician Insurers Association of America's study resulted from inadequate documentation.

Mammography

The primary goal of mammography is to screen asymptomatic women to help in detection of breast cancer at an early stage. In general, a routine screening mammogram consists of a mediolateral oblique (MLO) view and a craniocaudal (CC) view of each breast. With modern low-dose screening, the dose is <0.100 rad per study (for comparison, a chest x-ray delivers 0.025 rad per study). The effectiveness of screening also varies depending on the density of the breast.

Breast composition may be one of four patterns of increasing density:

. almost entirely fat
. scattered fibroglandular densities
. heterogeneously dense
. extremely dense.

The greater the breast density, the lower the sensitivity of the mammogram. Because some palpable cancers are invisible on mammography, a negative study cannot always exclude cancer. It is important to note that the false-negative rate for mammograms is 10% to 15% and that a normal mammogram does not eliminate the need for further evaluation of a dominant mass in the breast. If the clinical examination is suspicious, a negative mammogram should not delay further investigation.

Mammographic screening in women 40 years or older has reduced mortality by 20% to 30%. The efficacy of screening mammography in decreasing breast cancer mortality has been demonstrated in numerous studies. In the 1960s, the Health Insurance Plan of Greater New York performed a study of physical examination and mammography in a study group of 30,756 women and a control group of 30,239 women between the ages of 40 to 64 years. At 10-year follow-up, the study group had a 30% decrease in breast cancer mortality compared with the control group.

A total of eight large randomized trials on mammographic screening have been conducted. Six of the eight trials revealed a statistically significant reduction in mortality with mammographic screening. The reduction in mortality was not as evident among women between the ages of 40 and 49 compared with women over 50 years of age. The relative mortality reduction appears later in women between the ages of 40 and 49 at randomization compared with women 50 years of age or older. It is also likely that the small numbers of women between 40 and 49 years of age in the existing randomized trials may have contributed to this difference.

In a meta-analysis of eight randomized, controlled trials of mammographic screening, a statistically significant 18% reduction in mortality in women aged 40 to 49 was noted. Combined data from five Swedish trials yielded a statistically significant mortality decrease of 29% (Table 56.3).

TABLE 56.3 Randomized Population-based Mammography Trials

Trial	Relative Risk (95% confidence interval)
Malmö	0.96 (0.68–1.35)
Canada	1.08 (0.84–1.40)
Göteborg	0.55 (0.31–0.95)
Stockholm	0.73 (0.50–1.06)
Kopperberg	0.58 (0.45–0.76)
Östergötland	0.76 (0.61–0.95)
New York	0.79 (0.64–0.98)
Edinburgh	0.87 (0.70–1.08)

A published re-analysis excluded six of the eight studies because of issues related to randomization methods used and other factors in these trials. A re-analysis of the meta-analysis excluded six of the eight studies because of issues related to randomization methods used and other factors in these trials. This re-analysis questioned the risk reduction offered by mammography and resulted in much controversy.

Screening Interval

For several years, there has been a significant debate about the appropriate age at which to commence mammographic screening. In 1997, the American Cancer Society (ACS) and the NCI modified the guidelines for mammographic screening for women between the ages of 40 and 49, recommending regular mammograms for women in this age group. The

recommended intervals differ: the ACS recommends a yearly mammogram starting at age 40, while the NCI recommends a mammogram every 1 or 2 years. The ACOG recommendations on mammography are similar to the NCI guidelines.

Annual screening mammography may commence earlier than age 40 in a few special circumstances (Table 56.4).

BI-RADS

In the past, a lack of uniformity in mammography terminology and reporting often led to confusion as to the malignant nature of a lesion. In 1994, the Mammography Quality Standards Act was passed by Congress and is administered by the Food and Drug Administration (FDA). It requires that mammography facilities monitor the results of their breast cancer–detection programs, including the number of recommended biopsies and the size, number, and stage of cancers detected. The American College of Radiology (ACR) Breast Imaging Reporting and Data System uses a terminology and lexicon system called *BI-RADS* for reporting abnormalities seen on mammography

(Table 56.5). This standardized reporting system was developed in 1995. Each category leads to a fixed assessment and specific management recommendations.

TABLE 56.4 Screening Guidelines for Women Under Age 40

Condition	Timing of Annual Mammography
Lobular cancer in situ or breast cancer diagnosis	At time of diagnosis
First-degree relative with premenopausal breast cancer	10 y earlier than relative's age at diagnosis but not younger than 25 y
Mantle irradiation for Hodgkin's disease	8 y after completion of radiation therapy
BRCA1 or *BRCA2* mutation	Age 25–35 y; specific age chosen based on adequacy of mammography imaging in the first study and patient choice

Data from American College of Obstetricians and Gynecologists. *Primary and preventive care: periodic assessments*. ACOG Committee Opinion No. 246. Washington, DC: Author, 2000.

In addition, associated findings such as skin or nipple retraction, skin thickening, skin lesions, axillary adenopathy, and the presence of architectural distortion should also be reported.

TABLE 56.5 American College of Radiology BI-RADS Assessment Categories

BI-RADS Category	Assessment
0	Need additional imaging evaluation; assessment is incomplete
1	Negative
2	Benign finding(s)
3	Probably benign finding; initial short-interval follow-up suggested
4[a]	Suspicious abnormality; biopsy should be considered
5	Highly suggestive of malignancy; appropriate action should be taken
6	Known biopsy; proven malignancy; appropriate action should be taken

BI-RADS, Breast Imaging Reporting and Data System.
[a]By subdividing category 4 into 4a, 4b, and 4c, it is encouraged that relevant probabilities for malignancy be

> indicated within this category so that the patient and her physician can make an informed decision on the ultimate course of action.
> American College of Radiology. *Illustrated Breast Imaging Reporting and Data System (BI-RADS)*, 4th ed. Reston, VA: Author, 2003. Reprinted with permission of the American College of Radiology. No other representation of this material is authorized without expressed, written permission from the American College of Radiology.

The predictors of malignancy for the BI-RADS categories are 0% to 2% for category 3 and approximately 98% or greater for category 5.

Category 4 is less predictable. Liberman and colleagues and Orel and colleagues have placed the risk of malignancy for this category around 30%.

The ACR Task Force has published a new edition of the BI-RADS classification system that will attempt to provide data on category 4 in terms of risk of malignancy. In the new edition of BI-RADS, category 4 is divided into three parts based on the prebiopsy risk for malignancy of the lesion: 4a (small); 4b (low, medium, and high); and 4c (substantial), in an effort to better guide clinicians and to collect meaningful data about this category. By subdividing the category, the ACR hopes to provide better communication to the referring physician about the prebiopsy risk of malignancy. Additionally, the fourth edition of the lexicon also addresses the assignment of categories to ultrasound and magnetic resonance imaging (MRI) findings. One recent retrospective study evaluated interobserver variability and positive predictive value of BI-RADS categories 4a, 4b, and 4c. The risk of malignancy was found to be 6%, 15%, and 53%, respectively.

Diagnostic Mammography

Abnormalities found on mammographic screening may need further evaluation with additional mammography views or other imaging modalities, such as ultrasound or MRI. In some screening programs, the mammograms are reviewed by the radiologist as they are performed, and if additional views are needed, they are performed on the same day. In other programs, if additional studies are required, the patient is called back for them at a later date. In several studies, the frequency of “call backs” has ranged from 5% to 11%.

Mammographic Lesions

A mass is defined as a space-occupying lesion seen in two different projections. If a possible mass is seen on only one view, it is called a *density* until its three-dimensionality is confirmed. A description of the shape and the margins of the lesion are also necessary. The highest frequency of carcinoma is noted in masses that have an irregular shape or spiculated borders. These lesions are associated with pleomorphic calcifications that appear discontinuous and linear in distribution. This discontinuous linear pattern suggests irregular filling of a duct with abnormal cells.

Microcalcifications

The BI-RADS lexicon describes calcification morphology (shape) and distribution. Calcifications may be scattered or clustered, coarse or fine, old or new. Comparison with prior mammograms is often necessary (Table 56.6).

TABLE 56.6 Morphology of Microcalcifications and Associated Lesions

Morphology	Description/Associated Lesion
Typically benign	• Includes skin (lucent-centered) • Vascular (parallel tracks) • Coarse "popcornlike" (fibroadenomas) • Large rodlike (secretory disease) • Eggshell or rim (fat necrosis) • Milk of calcium (within tiny cysts) • Dystrophic (after trauma or irradiation)
Intermediate	• Amorphous/indistinct (round or "flake shaped," small or hazy in appearance)
Higher probability of malignancy	• Pleomorphic or heterogeneous (granular, varying in size and shape, <0.5 mm) • Fine/linear/branching (casting) • Linear and discontinuous

Breast Ultrasound and Magnetic Resonance Imaging

Breast ultrasonography can be used to distinguish between solid and cystic masses in the breast. It can be used to evaluate a focal mass identified on a mammogram or a palpable mass. It is also used as an adjuvant for biopsy. Because of its low specificity, it is not thought to be a good modality for screening. It cannot replace mammography, as it has no ability to detect microcalcifications. Ultrasound can complement mammography in young women with dense breasts because dense breasts limit the accuracy of the mammogram.

MRI has a high sensitivity in the diagnosis of breast cancer, ranging from 86% to 100%, but a low specificity of 37% to 97%. Because of this low specificity, it is of limited value in

screening. It is an expensive test that requires intravenous contrast, and the technology for performing biopsy under MRI guidance is not widely available. Current uses include evaluation of breast implants for rupture, evaluation of pectoralis involvement with extensive breast cancer, and evaluation of postlumpectomy bed fibrosis. Other uses include evaluation of occult breast cancers and evaluation of multifocal disease in those patients who are considering breast conservation. Studies on the use of MRI for surveillance of women at high risk for hereditary breast cancer have been published recently. Warner and colleagues compared breast MRI with mammography, screening ultrasonography, and physical examination in 196 women at high risk for developing breast cancer. These women had proven mutations in the *BRCA* genes or strong family histories of breast and/or ovarian cancer. Six invasive cancers were found, including two cancers not identified through other modalities (i.e., mammography, ultrasound, and physical examination). A study of 236 women with *BRCA* mutations and MRI in conjunction with mammographic screening and clinical breast examination detected 22 cancers. Of these, 77% were detected by MRI and 32% were detected by MRI alone.

A multi-institutional Dutch national study trial for MRI screening in women with a familial or genetic predisposition, published in 2004, included 1,909 women. Of them, 358 were *BRCA* mutation carriers; 45 cancers were diagnosed, and 22 of these (49%) were detected by MRI alone. This demonstrates the greater sensitivity of MRI over the use of mammography alone in screening for breast cancer in these high-risk women.

Overall, MRI has proven to be an extremely valuable tool in screening women at the highest risk for developing breast cancer. Determining the optimal point in time to perform the MRI in relation to the mammogram is currently under investigation.

Digital Mammography

In 1991, the NCI convened a panel of experts on breast imaging. The panel placed high priority on the development of digital mammography. Four full-field systems were developed and underwent FDA testing. The benefits of digital mammography over traditional film mammography concern image acquisition and facilitation of storage. In addition, digital-image processing allows manipulation of image contrast and may enhance subtle contrast differences. In January 2000, the General Electric Senographe 2000D was approved by the FDA.

Pilot studies and U.S. Department of Defense full-field digital mammography screening trials of digital mammography versus conventional film mammography have found that the two modalities are similar in terms of the number of cancers diagnosed. However, the researchers noted a lower recall rate with digital mammography. Since its introduction, population-based screening trials comparing screen-film and full-field digital mammography have been conducted. In the Oslo I study conducted in Norway, full-field digital and screen-film mammography was performed in 3,683 women 50 to 69 years of age. The investigators found no statistically significant difference in cancer detection rates between the two modalities. The Oslo II study yielded similar results in cancer detection rates. Full-field digital mammography did yield higher cancer detection rates, but this difference between film and digital mammography was not statistically significant. In

Canada and the United States, 49,528 women were enrolled in the Digital Mammographic Imaging Screening Trial (DMIST). All participants underwent both digital and film mammography in random order. The investigators noted that although the diagnostic accuracy of digital and film mammography was similar, the accuracy of digital mammography was better in women under age 50 years, in those with radiographically dense breasts, and in premenopausal or perimenopausal women. Thus, in women who met these

criteria, the investigators recommended digital mammography. How feasible this is remains a question, however. It is thought that fewer than 10% of facilities in the United States currently have digital mammographic systems. The cost of installing a digital mammographic system can significantly increase the cost of performing mammograms. However, when both technologies are available, the use of digital mammography can be tailored to the individual.

With ongoing research into this new technology, new adjunct technologies may be developed. For example, telemammography will make telemedicine consultations possible. Computer-aided diagnosis may facilitate second opinions for digital mammographic studies.

Diagnostic Evaluation

Palpable Mass

The workup of a patient with a dominant mass should include a bilateral mammogram. In addition to gaining valuable information about the characteristics of the mass, a secondary purpose in this setting is to screen the normal surrounding breast as well as the contralateral breast for nonpalpable mammographic abnormalities (densities or calcifications). Evaluation of a palpable mass is important to determine whether the mass is cancerous even if the mammogram is negative.

Fine-needle Aspiration or Biopsy

Fine-needle aspiration (FNA) can be extremely useful in providing a cytologic analysis of a palpable breast mass. Many palpable thickenings and all dominant masses should be considered for FNA, as it can differentiate between solid and cystic masses. In addition, FNA can diagnose and treat simple cysts and provide cellular material for cytologic analysis. The FNA should be performed after radiologic examination because the resultant hematoma could mask an underlying abnormality.

The breast is prepped with alcohol; with the physician facing the patient, the lesion is stabilized with the physician's opposite hand. Usually, a 21-gauge or 25-gauge needle on a 10-cc syringe is used. Approximately 3 cc of air is aspirated into the syringe to facilitate expulsion of the contents onto the slide following the procedure. The needle is introduced into the lesion, and suction is applied on the syringe (Fig. 56.3). If the mass is cystic, the fluid is completely evacuated and the lesion should completely disappear. The syringe is withdrawn, and the fluid is discarded if it is serous and nonbloody. The patient should return in 4 to 6 weeks for reexamination.

If the lesion encountered is not cystic or suspected to be solid, an FNA biopsy can be performed in the same manner. After insertion into the lesion, multiple passes (10 to 15) through the lesion with changes in direction allow extensive sampling and create a “feel” for the mass (carcinomas are usually hard and gritty). The goal of sampling is to obtain material in the hub of the needle, not to fill the syringe. Care should be taken to release the suction before withdrawing the needle to prevent aspiration into the syringe. The sample is then ejected onto a glass slide, gently smeared with another slide, and placed in sterile jars containing 95% ethanol for transport to the cytology lab. Alternatively, it can be placed in a specimen jar containing cytofixative. The needle should be removed from the syringe, the medium aspirated into the syringe,

the needle replaced, and the medium then ejected into the jar.

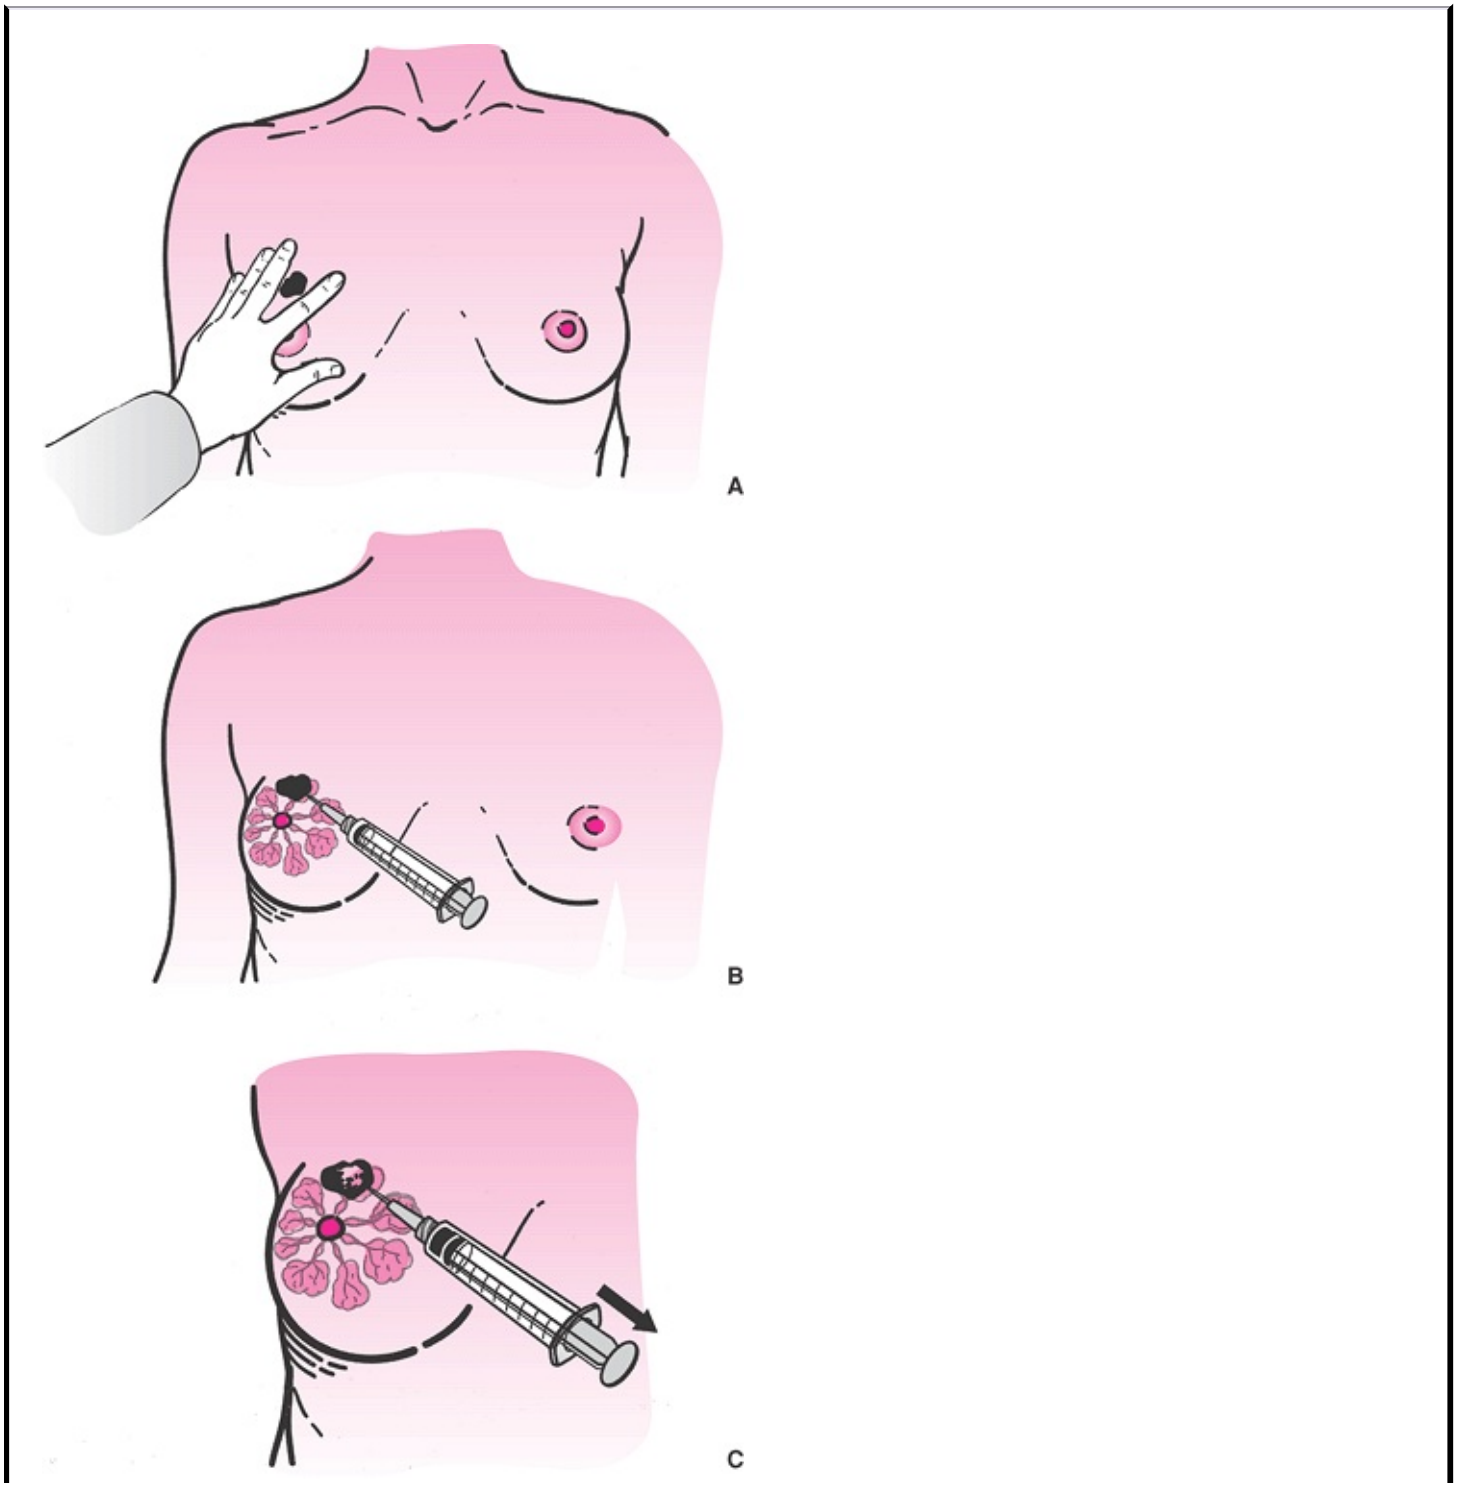

Figure 56.3 Aspiration biopsy. **A:** Mass. **B:** Stabilizing the lesion. **C:** Aspirating.

An FNA requires a cytopathologist who is experienced in breast pathology. The false-negative rate can range from 3% to 35% depending on the expertise of the aspirator and the cytopathologist, the size of the lesion, the location within the breast, and the cellular composition of the lesion. Negative findings of an FNA in the presence of a suspicious mass should not preclude further diagnostic evaluation. A diagnosis of atypical cells following an FNA warrants a surgical biopsy. Any mass remaining after aspiration of a cyst should be excised. Similarly, a cyst that recurs in the same location after one or two aspirations should be excised.

The false-positive rate of an FNA is <1%, but in the United States, most surgeons will not perform definitive surgery (i.e., a mastectomy or axillary dissection) without a prior surgical biopsy, core-needle biopsy, or frozen-section diagnosis at the time of surgery. An FNA that is positive for adenocarcinoma could, however, provide a preliminary diagnosis and guide subsequent management.

Patients with palpable solid masses can have a biopsy of the mass in the office with use of a Tru-cut 14-gauge biopsy device. The breast is prepped sterilely and a local anesthetic is used to infiltrate the skin. A small nick is made in the skin with a scalpel to accommodate the biopsy instrument. A core biopsy of the solid mass is obtained. The instrument has a "firing" range and therefore should be kept parallel to the chest wall to avoid penetrating trauma. The specimen is placed in formalin and sent to pathology. It is believed that if the specimen "floats" in the solution, it is likely nondiagnostic fat. Tumor specimens will have a grayish appearance and will typically "sink" in the solution.

Needle Localization and Excision

Needle localization is a technique that allows surgical excision of a lesion that is nonpalpable. The technique uses a hook-wire system to target the lesion, and image guidance can be provided by mammogram, ultrasound, and, in some cases, MRI. In mammography-guided needle localization, coordinates of the lesion are obtained by placing the breast in an alphanumeric grid. The needle is inserted, and when adequate placement is noted, the hook wire is deployed and the needle removed. Two mammographic views are then obtained.

The mammography films are available intraoperatively and show the relationship between the lesion and localizing hook. Excision with needle localization allows the surgeon to minimize the amount of breast tissue removed by following the needle to the targeted lesion. After removal, a specimen radiograph is obtained to ensure that successful removal of the lesion has been performed. Radiologists and surgeons who are experienced in needle localization and excisions report only 0.2% to 0.3% of lesions missed with this approach. The specimen radiograph helps to ascertain that the lesion was not missed.

Image-Guided Percutaneous Breast Biopsy

With the current advancements available in breast imaging, percutaneous image-guided breast biopsy is increasingly being used as an alternative to surgical biopsy. Percutaneous biopsy methods differ with respect to the method of imaging guidance and the tissue-acquisition device used. The use of image-guided percutaneous biopsy has advantages over surgical excision for the diagnosis of breast lesions. It is less invasive, and because less tissue is removed, it will result in less scarring on subsequent mammograms. Regardless of whether the diagnosis is benign or malignant, the patients who have percutaneous biopsies will undergo fewer operations. In addition, in cases of malignancy, the discussion and surgical treatment plan can be streamlined. The choice of which image-guided modality to use depends on the lesion. Stereotactic biopsy is best for calcifications. If a lesion is seen on ultrasound, it is best to use that modality, as it is easier to use and has been reported to be less costly.

Stereotactic Biopsy

Stereotactic biopsy uses specialized mammography equipment to calculate the location of a lesion in three dimensions. Stereotactic biopsy can be performed with the patient prone on a dedicated table or with the patient sitting in an upright unit. An automated core needle or directional vacuum-assisted biopsy probe is used to obtain the tissue specimens. Multiple tissue specimens are obtained for pathologic analysis. Many reports in the medical literature state that the procedure has a sensitivity of 70% to 100% and a specificity of 85% to 100%. The greatest success is noted in reports using 14-gauge core needles, as well as in those with increased numbers of specimens obtained. In mass lesions, it is likely that five core samples may be adequate for accurate diagnosis; however, ten or more core specimens may be required in cases of calcifications.

Ultrasound-guided Biopsy

The use of ultrasound imaging for percutaneous biopsy of lesions seen on ultrasound has certain advantages. For example, it requires no specialized equipment, no radiation exposure, and has the ability to sample areas that may be inaccessible with stereotactic biopsy (such as the axilla). A 14-gauge automated needle is used, and real-time imaging allows accurate positioning. Multiple tissue core samples are sent for pathologic analysis.

Tissue-acquisition Devices

Available tissue-acquisition devices include fine needles, automated core needles, directional vacuum-assisted probes, and biopsy cannulas. Excellent results have been obtained by using the 14-gauge automated needle for biopsy of masses under ultrasound or stereotactic guidance. Most centers use larger tissue-acquisition devices

instead of fine needles because of accuracy of tissue diagnosis when a larger volume of tissue is obtained. Compared with the automated needle, the vacuum device acquires larger samples of tissue, has a higher frequency of retrieval of calcifications, and may

provide more accurate lesion characterization. Accurate placement of a localizing clip through the biopsy probe is necessary to facilitate subsequent localization if needed.

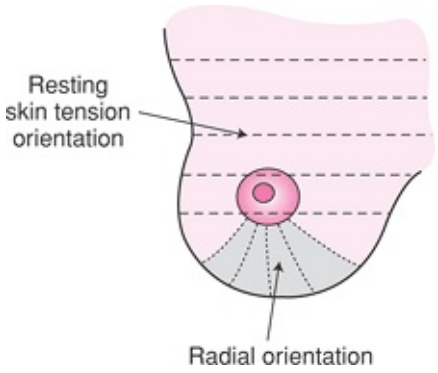

Figure 56.4 Optimal orientation of biopsy incisions.

Surgical Excision/Breast Biopsy

The ACOG has stopped short of recommending that open biopsy be performed by every obstetrician and gynecologist.

A biopsy can be performed on an outpatient basis under local anesthesia in the majority of patients. It is important to choose the appropriate incision and location (Fig. 56.4). Unless the lesion is close to the nipple or suspected to be a fibroadenoma, the incision should be made in close proximity to the mass and not circumareolar. The surgeon should keep in mind the possibility of subsequent mastectomy when placing the incision. Many times, the biopsy is part of the treatment. The specimen should be adequately oriented for margin analysis by the pathologist and also sent for the appropriate markers such as estrogen-receptor (ER) and progesterone-receptor (PR) status and *HER2/neu*. Orientation of the specimen is important, as a reexcision of a close or involved margin may need to be performed.

The incision should be closed with fine suture material, with a subcuticular closure. Hemostasis needs to be ascertained prior to closing and is usually achieved with electrocautery. Weck clips can be placed in the cavity bed if a diagnosis of breast cancer is known and breast conservation is planned. No particular immobilization is required, but a good support bra is recommended to minimize hematoma and induration.

Benign Breast Conditions

Fibrocystic Changes

Fibrocystic change is the most common benign breast condition in women. It is a result of fluctuating hormone levels and most common in premenopausal women between the ages of 20 and 56. It is often associated with pain and tenderness (mastodynia) and tends to be

bilateral. Most women will report symptoms during the premenstrual phase of the cycle.

Pain is due to breast stromal edema, ductal dilation, and associated inflammatory response. An increase in breast size is also frequently reported. The differential diagnosis for breast pain includes other conditions affecting the anterior chest wall, such as intercostal neuralgia, myalgia, and chronic costochondritis. Women with large pendulous breasts will have associated stretching of Cooper ligaments and associated breast pain.

Etiologic factors are still inconclusive. The ingestion of foods and medications containing methylxanthines has been implicated through an inhibition of 3858-cyclic adenosine monophosphate (cAMP) phosphodiesterase and 3858-cyclic guanosine monophosphate (cGMP) phosphodiesterase. This inhibition will lead to accumulation of increased amounts of cAMP and cGMP. High levels of cAMP and cGMP have been detected in patients with fibrocystic change. In some studies, reduction of dietary methylxanthines has been associated with symptomatic subjective reduction in pain, tenderness, and palpable nodularity. Other studies, however, have failed to show an effect from decreased consumption of dietary methylxanthines.

Fibrocystic change is not a risk factor for cancer in the majority of women. Histologically, there are two changes noted with fibrocystic change: nonproliferative changes and proliferative changes. The nonproliferative changes include cystic changes with formation of microcysts (2 mm or less in size), macrocysts, and fibrosis.

Proliferative Changes

Proliferative changes include hyperplasia and adenosis. Hyperplasia is proliferation of ductal epithelium, which results in layering of the cells. Atypia may be associated with this proliferation. If atypia is noted, this confers a fivefold increase in breast cancer risk for the patient. Hyperplasia with atypia is the only fibrocystic change associated with an increased risk factor for breast cancer. If atypia is noted on a core biopsy, a surgical excision of the area is recommended, as it is thought that there is a 50% chance of finding a coexistent carcinoma.

Adenosis is also a proliferative lesion, caused by changes in the acini in the distal mammary lobule. Sclerosing adenosis refers to the dense, fibrotic tissue surrounding these small ducts. These lesions may present as a palpable mass in women in their 30s and 40s.

A papilloma can result from this ductal proliferation. Papillomas are papillary lesions with a branching fibrovascular core surrounded by epithelium. These lesions are associated with serosanguineous nipple discharge in 25% to 50% of presentations. There is a small palpable mass adjacent to the areola 90% of the time. Intraductal papillomas

---

are rarely associated with carcinoma, but require surgical excision to rule out the possibility of misdiagnosis of a malignancy.

Management of fibrocystic changes includes regular physical examinations, appropriate imaging, and supportive measures. Recommendations for use of a good support bra may be helpful, especially in physically active women. Dietary restrictions of methylxanthines may produce subjective improvement in 65% of patients. The use of vitamins A and E has been

reported in some studies to be helpful. Diuretic therapy during the premenstrual period has been reported to provide temporary relief and requires cyclical use. Fluid retention is a result of cyclical hormonal stimulation.

OCPs suppress symptoms of fibrocystic changes in the majority of patients (70% to 90%). Symptoms often recur after discontinuation. Other medications, such as danazol (17α-norethisterone), in doses of 100 to 400 mg per day should be reserved for patients in whom other agents have been ineffective. Their side effect profile can lead to poor compliance. A 3- to 6-month course can provide significant reduction in symptoms, and its effect can last several months after its discontinuation.

Fibroadenoma

Fibroadenomas are benign fibroepithelial tumors and are the second most common benign lesion of the breast. They are the most common lesion found in women under the age of 25. They will persist during the menstrual years of a woman's life, but regression after menopause has been reported. Patients typically present with a mobile, smooth, painless, palpable mass. Ultrasound examination, along with physical examination, can help in making the diagnosis. Mammographically, fibroadenomas may appear as round, oval, or lobulated masses with circumscribed margins. In older women, they can have a rim of coarse calcifications. FNA will reveal benign ductal epithelial cells and elongated dense stromal cells. Microscopically fibrous tissue composes most of the fibroadenoma. Carcinoma arising in fibroadenomas is rare.

Fibroadenomas can be followed without the need for complete surgical excision. This can be achieved with physical examination or ultrasound examination if they are not palpable. However, surgical excision should be performed if:

- the mass continues to enlarge
- the results of FNA or core biopsy are inconclusive or yield atypia
- the patient desires surgical excision.

Phyllodes Tumor

Phyllodes tumors are uncommon, slow-growing fibroepithelial tumors. Previously referred to as cystosarcoma phyllodes, this name contributed to confusion in understanding this entity. Although very similar to a fibroadenoma, the stromal component is hypercellular with increased pleomorphism and mitotic activity. Phyllodes tumors can occur in women of any age, but more commonly occur in premenopausal women.

Malignant behavior in phyllodes tumors is rare in premenopausal women. Malignant phyllodes tumors are noted when there is a combination of increased mitotic activity, invasive borders, or marked pleomorphism. Incomplete excision is a major determinant for local recurrence. Treatment is total surgical excision with a wide margin of healthy tissue.

Superficial Thrombophlebitis

Superficial thrombophlebitis is also known as Mondor disease of the breast. It is an uncommon benign inflammatory process. It can occur spontaneously but usually is associated with breast trauma, breast surgery, or pregnancy. It is a thrombophlebitis of the thoracoepigastric vein, which drains the upper-outer quadrant of the breast. Patients present with acute pain and a linear, tender fibrotic band with skin retraction over the distribution of the thoracoepigastric vein.

Treatment is conservative, with analgesics and application of heat. The condition resolves in 1 to 3 weeks. Skin retraction superficial to the area of inflammation can remain if the inflammation is extensive. Biopsy is not necessary.

Mastitis

Mastitis usually occurs in relation to lactation. It can occur in nonpuerperal periods in association with galactorrhea. Skin organisms, *Staphylococcus aureus*, and *Streptococcus* spp. may cause infection of the nipple and breast ducts. Presence of milk in the ducts is an excellent medium for infection.

Women with mastitis may continue to breast-feed. Antibiotic therapy with dicloxacillin sodium (250 mg four times daily) or penicillin G is indicated. If there is no response, an abscess that may require surgical drainage must be excluded. Inflammatory carcinomas can mimic mastitis, and if no resolution of infection is noted despite continued antibiotics, a skin biopsy may be indicated.

Galactoceles are milk-filled cysts. They are usually tender and present after the abrupt termination of breast-feeding. Aspiration of the cyst is often necessary for symptomatic relief. If re-accumulation occurs, however, surgical excision may be required to avoid infection.

Duct Ectasia

Duct ectasia is a condition usually occurring in perimenopausal or postmenopausal women. Patients present with a tender, hard erythematous mass adjacent to the areola in association with burning, itching, or a sensation of

---

pulling in the nipple area. A thick greenish-black discharge may be present. Histologic evaluation of the area shows dilate, distended terminal collecting ducts obstructed with inspissated lipid-containing epithelial cells and phagocytic histiocytes. This process tends to occur in a segmental fashion extending from the involved nipple area to adjacent ducts. Occasionally, as a result of this infection, a small abscess forms at the base of the nipple. Treatment is excisional biopsy.

Younger women can present with inflammation of the ducts in the region of the nipple, which may produce fissures and fistulas with connection from the nipple ducts to the skin at the edges of the areola. Prior periductal mastitis leads to the squamous epithelium of the terminal dilated portion of the collecting ducts to undergo squamous metaplasia. Keratin is formed in the duct, accumulates, and can cause an abscess at the base of the nipple. Excision of the area is usually necessary.

Fat Necrosis

Fat necrosis is a relatively uncommon benign condition occurring as a response to breast trauma. Patients present with a hard mass that can mimic a carcinoma. The irregular mass is palpable and may involve skin retraction. Multiple calcifications can be seen on mammography.

The histology is active chronic inflammatory cells, with lymphocytes and histiocytes predominating. In the later stages, a collagenous scar is noted, with “oil cysts” or free lipid material released by lipocyte necrosis. Fat necrosis does not increase the risk of carcinoma, and its clinical importance is in the differential diagnosis of a carcinoma.

Nipple Discharge

Nipple discharge has been reported in 10% to 15% of women with benign breast disease and in 2.5% to 3.0% of those with carcinoma. The discharge is classified according to its appearance as milky, green, bloody, serous, cloudy, or purulent. The drainage should be classified according to whether it is unilateral, bilateral, or spontaneous, or recurrent. This information is obtained at the time of a thorough history and physical examination. For example, if the drainage first appeared in the patient's bra or nightgown on awakening, this finding is significant. The presence of a mass should also be investigated. The risk of cancer is increased when the discharge is unilateral from a single duct, occurs in a postmenopausal patient, or when a mass is present.

Unilateral, Spontaneous Nipple Discharge

In cases of unilateral, spontaneous nipple discharge, several causes are included in the differential. The most common cause of nipple discharge is mammary duct ectasia, which produces a multicolored (green, yellow, white, brown, gray, or reddish brown) nipple discharge. The reddish-brown discharge is often mistaken for a blood discharge. It is thought to be due to an increase in glandular secretions, with the production of an irritating lipid fluid that can produce a nipple discharge. Guaiac of the discharge can help to diagnose whether it is bloody.

The next most common cause of a multicolored, sticky nipple discharge is nonpuerperal mastitis. The persistent type involves inflammation in deeper portions of the breast; the transient types are associated with periareolar inflammation. If the inflammation develops into an inflammatory mass, surgical excision and drainage are necessary. Medical management with local care, avoidance of all nipple manipulation, and nonsteroidal anti-inflammatory agents and an antistaphylococcal antibiotic are often successful when infection is suspected.

Bloody nipple discharge warrants surgical evaluation. Intraductal papillomas are the most common cause of bloody nipple discharge. During the breast examination, physicians should look for an associated periareolar mass. The examination consists of gently and carefully palpating the subareolar region to identify the pressure point that produces the discharge. It is important to reproduce the discharge and demonstrate the breast quadrant from

which it emanates. All significant nipple discharges warrant referral for tissue biopsy. Although a mass is usually present when the discharge is due to cancer, there is no palpable mass in 13% of cancers with nipple secretions. Bloody discharge occurring in the third trimester of pregnancy, however, may be regarded as physiologic and does not require intervention unless persistent for several months after delivery. There are no contraindications to breast-feeding in these patients.

In addition, physicians should not rely solely on the cytology of the discharge because there is an 18% false-negative rate and a 2.6% false-positive rate with standard cytology alone.

Galactography (injecting radiopaque contrast into the discharging duct and then performing mammography) offers better visualization of small intraductal papillomas, but cannot differentiate between benign and malignant lesions. A surgical procedure is still necessary. Mammography has a 9.5% false-negative rate and a 1.6% false-positive rate for detecting cancer in patients with a nipple discharge.

Breast Cancer

Natural History

The most common site of origin of breast cancer is the upper-outer quadrant (38.5%), central area (29%), upper-inner quadrant (14.2%), lower-outer quadrant (8.8%), and the lower-inner quadrant (5%). These percentages correlate with the amount of tissue that is present in these quadrants. Metachronous bilateral carcinoma of the breast has been observed in 5% to 8% of patients.

Metastasis to the ipsilateral axilla is the most common route of spread. Metastasis to the internal mammary nodes is more frequent with inner-quadrant lesions and is more likely to occur when involvement of the axillary nodes is also present.

Pathology

Ductal Carcinoma In Situ

Ductal carcinoma in situ (DCIS) is an abnormal proliferation of malignant epithelial cells within the mammary ductal–lobular system without invasion into the surrounding stroma. It is classified as a heterogenous group of lesions with different growth patterns and cytologic features. Classification of DCIS has traditionally been based on architectural pattern. The most common types are comedo, cribriform, micropapillary, papillary, and solid.

Paget's Disease

Paget's disease is involvement of the nipple with intraductal carcinoma. In absence of a palpable mass, invasive carcinoma occurs in fewer than 40% of cases. The malignant cells are large and pale-staining and are seen in the basal layer and upper portions of the epidermis. Diagnosis is made through a nipple biopsy.

Lobular Carcinoma In Situ

Foote and Stewart initially described LCIS in 1941 as a noninvasive lesion arising from the lobules and terminal ducts of the breast. LCIS is characterized by a solid proliferation of small cells with round to oval nuclei that distort the involved spaces in the terminal duct-lobular units. Three important features of LCIS are:

. It is usually an incidental microscopic finding that is not detected clinically or by gross pathologic examination.

. It is multicentric, and the associated cancer may be ductal or lobular.

. The risk for subsequent cancer is the same for both breasts.

It is unfortunate that Foote and Stewart chose the name they did, as it has led to a great deal of confusion over the past several decades. LCIS is a marker for breast cancer risk and is not a malignant finding.

Invasive Duct Carcinoma

Invasive duct carcinoma is the most common group of malignant mammary tumors and comprises 65% to 80% of all mammary carcinomas. Included in this group are special subtypes: tubular, medullary, metaplastic, mucinous (colloid) papillary, and adenoid cystic carcinoma. Each subtype constitutes only 1% to 2% of all invasive breast cancers, except medullary carcinoma, which constitutes 7%, and the rare adenoid cystic carcinomas, at fewer than 0.1%.

Many of these subtypes, such as tubular and medullary carcinomas, carry an excellent prognosis. Metaplastic carcinomas, however, often have an aggressive behavior. These tumors are characterized by the presence of homologous (epithelial) or heterologous (mesenchymal) elements. Two types have been described: squamous and pseudosarcomatous metaplasia.

Invasive duct carcinoma not otherwise specified (NOS) is a generic term that includes tumors that may express more than one element of the specific forms of duct carcinoma.

Infiltrating Lobular Carcinoma

Infiltrating lobular carcinoma has been reported to constitute 10% to 14% of invasive carcinomas. These carcinomas are characterized by uniform cells with small, round nuclei and limited cytoplasm. The presence of intracytoplasmic mucin vacuoles often gives the cells the appearance of signet-ring cells. The cells tend to grow circumferentially around ducts and lobules with a linear arrangement. This pattern is referred to as “Indian-file” or targetoid growth. There is often an associated desmoplastic stromal reaction.

Inflammatory Carcinoma

Inflammatory carcinoma is characterized by cutaneous findings present with an underlying invasive carcinoma. Usually, the invasive tumor is a poorly differentiated infiltrating duct

carcinoma. On microscopic evaluation, skin involvement often reveals tumor emboli in dermal lymphatics with an associated lymphocytic reaction in the dermis.

Metastases from Extramammary Tumors

The most common primary site of an occult extramammary tumor is the lung. Other primary sites include the ovaries, uterus, kidneys, and stomach. In those previously diagnosed, melanoma, prostate, cervix, uterus, and urinary bladder are the most common sites. Metastatic ovarian cancer may simulate papillary or mucinous carcinoma of the breast. A workup and history are often helpful in difficult cases. Often, identification of an in situ component helps to provide definitive evidence of a mammary origin.

Biologic Markers/Prognostic Factors

Axillary Lymph Node Status

The most important prognostic factor is nodal status. The presence of metastasis, as well as the number of lymph nodes involved, is significant and correlates with local failure and distant metastases. It is predictive of overall survival.

Tumor Size

Tumor size correlates with the incidence of lymph node metastases. The size of the tumor is also important, even in the absence of lymph node involvement. Patients with tumors <1 cm in size or with good histologic types measuring <3 cm do very well.

Histologic Grade

Histologic grade also correlates with breast cancer outcome. Poorly differentiated tumors have been associated with more aggressive behavior.

Estrogen Receptors/Progesterone Receptors

The hormone receptors can be measured by immunohistochemical (IHC) studies using monoclonal antibodies directed against the receptors. Positivity correlates with response to antihormonal agents, as well as better prognosis.

HER2/neu

HER2/neu is an oncogene whose protein product may function as a growth factor receptor. It can be detected by IHC demonstration of the protein product or by gene amplifications. Overexpression or amplification has been shown to correlate with a poor prognosis; however, the studies differ with regard to the method of detection used, as well as the interpretation of results. *HER2/neu* has been used as a predictor of response to certain chemotherapeutic agents. Particularly, increased response to doxorubicin-based therapy has been reported in the treatment of patients with positive nodes and overexpression of

HER2/neu. Trastuzumab (Herceptin) is a humanized anti-HER2 antibody against the extracellular domain of the 2-neu oncoprotein. Its use in the metastatic setting has been reported to demonstrate an increase in response rate and prolongation of disease-free and overall survival.

Four major adjuvant trials, Herceptin Adjuvant (HERA), National Surgical Adjuvant Breast and Bowel Project (NSABP) B-31, North Central Cancer Treatment Group (NCCTG) N9831, and Breast Cancer International Research Group (BCIRG) 006, have investigated the use of trastuzumab in the adjuvant setting. These trials have shown that that trastuzumab reduces the 3-year risk of recurrence by about 50% in this population. More than 13,000 women with *HER2/neu*-positive breast cancers were enrolled and received 1 year of adjuvant treatment with trastuzumab. These trials used different chemotherapy regimens but had similar improvements in recurrence-free survival. Cardiac events were at an acceptable level; however, they did note a slightly higher incidence (0.6% to 3.3%) of congestive heart failure that was responsive to treatment. There was an overall survival benefit in the NSABP B-31 and NCCTG N9831 trials, and a trend toward an overall survival benefit in the HERA and BCIRG trials.

p53

A tumor-suppressor gene, *p53* has a protein product that is a nuclear transcription factor with many functions, including regulation of the cell cycle and apoptosis. Most clinical studies have used IHC to study protein expression. Accumulation of *p53* protein has been reported to correlate with reduced survival in some studies.

Staging of Breast Cancer

Staging of Breast Cancer using the Tumor-Node-Metastasis System

The American Joint Committee on Cancer (AJCC) determines staging of breast cancer. The AJCC staging system is a clinical and pathologic staging system based on the tumor–node–metastasis (TNM) system. The new updated AJCC staging system incorporates sentinel node staging. It distinguishes micrometastasis from isolated tumor cells on the basis of size and histologic evidence of malignant activity. In the current AJCC staging system, supraclavicular lymph node metastasis is now classified as N3 disease, rather than M1 disease as in the old system (Tables 56.7, 56.8).

Treatment of Breast Cancer

Mastectomy

William Halsted performed a radical mastectomy in 1894. The guiding principle at that time was centered on the belief that cancer originates in the breast and spreads in a stepwise fashion, first to the regional lymph nodes and then to distant sites. Removal of all the breast tissue, pectoral muscles, and axillary contents was the standard surgical

treatment. Over the next several decades, two simultaneous trends existed. One involved less radical surgery, which included removal of the breast and axillary contents but preserved the pectoral muscles and more skin. This was described by Patey and Dyson in 1948 and is the modern-day modified radical mastectomy. The other trend involved more extensive surgery, the extended radical mastectomy, which included en-bloc removal of the internal mammary chain at the time of radical mastectomy. Subsequent randomized trials failed to show a survival advantage with the extended radical mastectomy when compared with the radical mastectomy.

Breast-conservation Therapy

The shift toward less radical surgery at the time of mastectomy occurred for several reasons. As earlier diagnosis of breast cancer with smaller tumors and less involvement of pectoral muscles occurred, the need for radical procedures decreased. In addition, even with radical mastectomy, not all patients were cured, and although regional recurrences were low, patients died of distant disease. The morbidity of the radical mastectomy was well documented, including lymphedema, immobility of the shoulder, and disfigurement. A shift to breast conservation followed the same trends. The initial trials with radiation therapy using radium implants at the Princess Margaret Hospital in Toronto had promising results.

M0	No distant metastasis
M1	Distant metastasis

ITCs, isolated tumor cells; IHC, immunohistochemical; H&E, hema reverse transcriptase/polymerase chain reaction; SLN, sentinel ly

[a]Clinically apparent is defined as detected by imaging studies (ex clinical examination or grossly visible pathologically.

[b]Classification is based on axillary lymph node dissection with or v Classification based solely on SLN dissection without subsequent a designated (sn) for “sentinel node” (e.g., pN0[i +][sn]).

[c]Not clinically apparent is defined as not detected by imaging stu lymphoscintigraphy) or by clinical examination.

Based on American Joint Committee on Cancer. *AJCC cancer stagi* Springer, 2002:171–180. Available at: *http://www.cancer.gov/cancertopics/pdq/treatment/breast/Hea*

This led to randomization studies comparing breast-conservation therapy with mastectomy. Table 56.9 lists randomized trials that compared radical and modified radical mastectomy in stage I and stage II carcinoma of the breast.

In breast-conserving surgery, a wide local excision is performed with excision of the tumor and a 1- to 2-cm rim of normal tissue. This excision is referred to as lumpectomy or a tumorectomy. This differs from a quadrantectomy, in which a resection of the tumor with the overlying skin and the involved quadrant of the breast is performed. The six randomized trials differed with respect to the type of wide local excision performed as well as tumor size in the patients who were randomized. In the Milan trial, a quadrantectomy was performed. In the Insitut Gustave Roussy trial, the “tumorectomy” performed was

removal of the tumor and a 2-cm margin of normal tissue. In the United States, the NSABP B-06 trial did not specify the margins on the lumpectomy specimen, providing they were grossly free of tumor.

In all trials, the authors noted comparable disease-free survival in both arms. The only difference noted was in local recurrence. In addition to the randomized trials, there are many nonrandomized reports published with similar results in survival between breast conservation and mastectomy.

Radiation therapy is an important component of breast conservation. Adequate surgical margins are required to be negative on pathologic inspection. After healing, the radiation therapy is planned. Treatment to the entire breast should be at a dose of 1.8 to 2.0 Gy per day for a total of 45 to 50 Gy. A 10- to 15-Gy electron-therapy boost is often given to the lumpectomy bed.

Breast conservation depends on the use of radiation. The question of whether lumpectomy alone would yield similar results has been addressed through randomized trials. Local recurrence rates of 18% to 40% with lumpectomy alone have been reported, compared with 2% to 14% with lumpectomy and radiation. In these studies, a significant

reduction in relapse was noted in the lumpectomy-and-radiation arm.

TABLE 56.8 Stage by Tumor, Node, Metastasis

Stage 0	Tis, N0, M0
Stage I	T1,[a] N0, M0
Stage IIA	T0, N1, M0 T1,[a] N1, M0 T2, N0, M0
Stage IIB	T2, N1, M0 T3, N0, M0

The NSABP B-17 trial is the only randomized trial of lumpectomy alone versus lumpectomy and radiation in patients with DCIS. Ipsilateral relapse was 7% in the radiation arm versus 16.4% in the lumpectomy-alone arm. Actuarial 5-year survival showed an ipsilateral recurrence rate of 7.5% for noninvasive and 2.9% for invasive recurrence in the lumpectomy-plus-radiation arm. By comparison, the rates were 10.4% and 10.5%, respectively, in the lumpectomy-alone arm. The overall survival was excellent and comparable to that seen with mastectomy. In cases of invasive recurrence, patients in the lumpectomy-plus-radiation arm can be salvaged with mastectomy.

Interest in partial breast radiation for early-stage breast cancers has prompted single institution studies using brachytherapy catheters, the MammoSite Balloon (Proxima

Company, Alpharetta, GA), and three-dimensional external beam partial breast treatment. These approaches are being studied as an alternative to the standard 5- to 6-week whole-breast radiation treatment. To shorten the radiation course, the proportion of breast tissue to be irradiated is significantly less. Data on local recurrences after radiation show that the majority of recurrences after lumpectomy and whole-breast radiation occur in the same quadrant, thus the reason to consider partial-breast radiation. In this manner, a greater dose will be delivered to the lumpectomy site and the surrounding tissue in a shorter course of therapy. Currently, the National Surgical Adjuvant Breast and Bowel Project and Radiation

Therapy Oncology Group (RTOG) cooperative groups are opening a phase III trial comparing whole breast radiation therapy to some form of partial breast radiation. The partial breast treatment will be delivered by using brachytherapy catheters, MammoSite Balloon, or external three-dimensional conformal treatment. Randomization to either whole or partial-breast radiation will occur at entry into the trial. Patients are currently being enrolled in this study.

Patient Selection

Possible contraindications can interfere with offering a patient breast-conservation therapy. Cosmetic result should be considered when deciding whether to offer breast-conserving surgery; tumor size in relation to breast size is an important consideration. In addition, other factors that may affect the ability to receive irradiation must be considered (i.e., history of prior breast or chest irradiation, concurrent pregnancy or autoimmune connective tissue disease). Particularly with a history of systemic lupus erythematosus, radiation may not be a possibility. Women with multiple cancers in the breast are not candidates for this approach and require a mastectomy. In addition, patients with extensive calcifications on a mammogram suggesting a diffuse process may be better treated with mastectomy.

An area of controversy remains over the status of negative margins at the time of lumpectomy. Generally a reexcision should be performed. Extensive intraductal component (EIC) is a condition that exists when >25% of the tumor is associated with DCIS. In these cases, the invasive component may be outside the area of the intraductal carcinoma. This has been reported to have a higher relapse rate with breast conservation; however, it is thought to be secondary to margin status, since margin involvement may be an indication of residual intraductal carcinoma. In DCIS, Silverstein and associates developed the Van Nuys prognostic index (VNPI). The system combines the scores for histologic grade, tumor size, and margin status of a lesion in order to obtain an overall score. It considers margins of 1 cm to indicate a decreased rate of local relapse, even with no radiation.

Management of the Axilla

The axilla is a pyramidal space between the arm and thoracic wall. It contains the axillary vessels and their branches, the brachial plexus and its branches, and lymph nodes embedded in fatty tissue. The primary route of lymphatic drainage of the breast is through

the axillary lymph nodes. The lymph nodes are also divided into levels based on location relative to the pectoralis minor. Level 1 lymph nodes lie lateral to the lateral border of the pectoralis minor muscle. Level 2 nodes lie behind the pectoralis minor muscle, and level 3 nodes are medial to the medial border of this muscle.

In an axillary dissection, nerve branches of the brachial plexus are encountered. The lateral and medial pectoral nerves supply the pectoralis muscles. The thoracodorsal nerve runs downward and innervates the latissimus dorsi. The long thoracic nerve is located on the medial wall of the axilla on the serratus anterior. It arises from the C5 to C7 roots, and injury to these nerves results in paralysis to part or all of the serratus anterior. The functional deficit is inability to raise the arm above the level of the shoulder.

At the time of Halsted's radical mastectomy procedure, a complete axillary dissection was performed. The status of the axilla is the most important prognostic factor for breast cancer. The use of axillary dissection has, in the past, been demonstrated to significantly decrease local recurrence, which may ultimately translate to a survival advantage.

Clinical examination of the axilla is inaccurate, as even in patients with a T1 lesion, there is a 10% risk of lymph node metastasis. Prior to the use of sentinel lymph node (SLN) biopsy, there was no accurate method to adequately stage the axilla without an axillary dissection. Axillary lymph node sampling (i.e., removal of only a few lymph nodes) was inadequate.

Metastatic involvement of lymph nodes usually occurs in a stepwise manner. Rosen and coworkers demonstrated the incidence of “skip metastasis” to be <2%. A complete level 1 and 2 lymph node dissection provides excellent local control, and local recurrence after this procedure has been shown to be <1%. The NSABP B-04 trial randomized patients with clinically negative nodes to one of three groups: radical mastectomy, total mastectomy with nodal irradiation, or total mastectomy alone. The patients who had no axillary nodal therapy had an overall worse survival if recurrence occurred.

The morbidity associated with axillary lymphadenectomy is not inconsequential. About 10% to 15% of patients will develop lymphedema. In addition, numbness, pain, or weakness contribute to a significant decrease in the quality of life in these patients.

Sentinel Lymph Node Biopsy

SLN biopsy in breast cancer evolved out of efforts to minimize the morbidity associated with axillary lymph node dissection while still providing important staging information. Initial studies in melanoma, by Morton and colleagues in 1992, demonstrated the feasibility of the concept. Methods employed include use of blue dye or radioisotope (Fig. 56.5).

Several studies have confirmed the accuracy of SLN biopsy. In the majority of the studies, successful identification of the SLN occurs between 92% and 98% of the time. The combination of blue dye and isotope has been reported to be better for identification of the SLN; when used in combination, the positive predictive value of the technique approaches 100%, with a negative predictive value

---

close to 95%. The false-negative rate is about 5% to 10% in most studies.

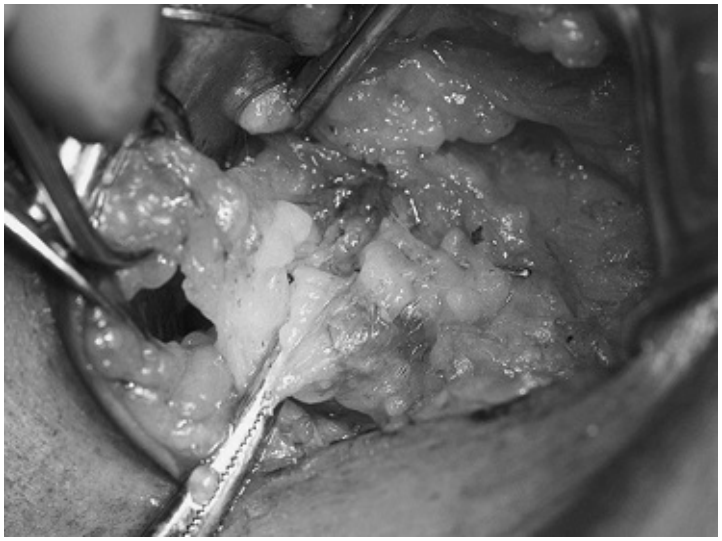

Figure 56.5 Intraoperative identification of the SLN.

The validity of the SLN concept lies in the ability of the SLN to predict the status of the regional lymphatic basin. Turner and colleagues performed IHC staining of all lymph nodes, sentinel and nonsentinel, in a series of patients undergoing standard axillary dissection with negative nodes. Of 157 SLNs, 10 (6.00%) demonstrated IHC positivity compared with 1 of 1,087 (0.09%) of the non-SLNs. This provided validity to the SLN concept.

Overall, greater scrutiny is paid to SLNs through serial sectioning and IHC stains. This is possible because only a few SLNs are obtained at the time of the procedure and would not be cost-effective in a standard axillary dissection that yields an average of 20 nodes.

The use of the SLN biopsy procedure is widely employed in invasive breast cancer. In certain situations, however, a standard axillary dissection should still be considered. These include:

- in cases of palpable suspicious nodes
- in cases of large lesions (the majority of reports indicate that the procedure is reliable if there are no suspicious nodes in the axilla)
- in cases of prior radiation, of a large excisional cavity close to the axilla, or any condition in which disruption of the lymphatics is suspected.

Systemic Treatment

Adjuvant treatment in breast cancer was first used over 100 years ago. In 1894, Beatson reported on the results of oophorectomy and response rate in the metastatic breast cancer setting. Initially, the use of systemic therapy involved the use of single-agent chemotherapy; later, multiagent chemotherapy was employed. As in most breast cancer trials, the initial reports were of patients with metastatic disease.

Multiple randomized studies have demonstrated that the addition of chemotherapy

improves overall survival in patients with breast cancer. The decision to use adjuvant chemotherapy or hormonal therapy depends on certain factors such as the size of the primary tumor, lymph node status, and the presence or absence of metastatic disease. In addition, the expression or lack of expression of ER or PR (ER/PR status) is also an important factor.

Adjuvant chemotherapy is standard treatment for patients with positive nodes or large tumors. The combination of CMF (cyclophosphamide, methotrexate, and 5-fluorouracil [5-FU]) has been used for many years in the treatment of patients with breast cancer. An anthracycline-based regimen, such as FAC (5-FU, Adriamycin, and cyclophosphamide), has been used in patients with high risk factors for recurrence. The use of paclitaxel is also considered in this setting. For patients with intermediate risk factors, such as ER-negative tumors (>1 cm in size) and negative nodes, chemotherapy is considered.

The Early Breast Cancer Trialists' Collaborative Group was formed in 1985 to analyze all available, properly conducted, randomized trials. A second overview was done in 1990 and a third in 1995. In women under the age of 50, administration of multiagent chemotherapy decreased the annual risk of relapse by 35% and mortality by 27%. With 10 years of follow-up, this translates into absolute gains of 7% in patients with node-negative tumors and 11% in those with node-positive tumors. For women over the age of 50 years, the benefits of chemotherapy were smaller but still significant. Annual risk reduction was 20% for recurrence and 11% for mortality. At 10 years of follow-up, this risk reduction translated into absolute gains of 2% in patients with node-negative tumors and 3% in patients with node-positive tumors. It is important to note that in the overview, different regimens of CMF were used, but the greatest benefit was seen in those using CMF for 6 months or longer.

The question of whether to use CMF or FAC in high-risk patients (tumors = 2 cm in size or ER/PR-negative with negative nodes) has been addressed. While the anthracycline regimen is more toxic than CMF, trials have shown superiority with this regimen. Presently, other factors are used to determine which regimen to recommend in this subgroup. The most promising candidate factor is *HER2/neu* overexpression because increased response rates with an anthracycline-based therapy have been reported in cases where there is overexpression of *HER2/neu*.

The use of taxanes, such as docetaxel and paclitaxel, as adjuvant treatment in combination with anthracycline-based chemotherapy is being investigated. Postmenopausal women with negative nodes and ER-negative tumors >1 cm in size are also considered for chemotherapy. In these patients, CMF is usually the treatment of choice.

The question of whether to use CMF or FAC in high-risk patients (tumors at least 2 cm or ER/PR-negative with negative nodes) has been addressed. Although the anthracycline regimen is more toxic than CMF, recent trials have demonstrated its superiority. Determining whether to use FAC also is based on other factors. Tumors with *HER2/neu* overexpression have an associated increased response rate with an anthracycline-based therapy.

The use of taxanes such as docetaxel and paclitaxel as adjuvant treatment, in combination with anthracycline-based chemotherapy, are currently being investigated. Several randomized trials have been conducted to test the feasibility and effectiveness of anthracycline and/or taxanes administered in a dose-dense fashion. Dose density refers to the frequency of administration of a drug or regimen compared with standard regimens. These trials have resulted in an overall modest, beneficial impact on disease recurrence in patients with early breast cancer. The most benefit was seen in patients with node-positive disease and/or hormone receptor–negative tumors and *Her-2/neu* overexpression. The Cancer and Leukemia Group B (CALGB) trial 9741 compared concurrent versus sequential regimens in patients with node-positive breast cancer. In the trial's 2 ×2 factorial design, the regimens consisted of four concurrent cycles of doxorubicin and cyclophosphamide, followed by four cycles of paclitaxel in Q2-week and Q3-week regimens. This was compared with sequential treatment consisting of four cycles of doxorubicin, followed by four cycles of paclitaxel and four cycles of cyclophosphamide in Q2-week and Q3-week regimens. The dose-dense treatment (Q2 week) significantly improved disease-free survival and overall survival compared with the Q3-week regimen. There was no difference between sequential and concurrent schedules. The use of trastuzumab in addition to combination chemotherapy has also associated with a decrease in relapse in *HER2/neu* positive breast cancers.

Metastatic Disease

The goal of therapy in metastatic disease is palliation of symptoms, as cure is unlikely. The majority of patients with metastatic disease receive antihormonal therapy. First-line agents include tamoxifen or aromatase inhibitors (AIs), such as letrozole or anastrozole. These agents offer a 20% response in ER/PR-positive tumors. Disease stabilization is the goal of therapy, and because these therapies are less toxic than chemotherapy, most patients will remain on them for prolonged periods of time. On failure of these agents, however, chemotherapy is the next step.

High-dose Chemotherapy

Five large randomized trials have been conducted addressing the use of high-dose chemotherapy with bone marrow or stem cell rescue in metastatic breast cancer. Only one trial, conducted in South Africa, showed a lower rate of relapse. The other four trials showed no increase in overall survival. The investigators of the trial conducted in South Africa subsequently admitted to fraud. Thus, it is felt that high-dose chemotherapy offers no survival advantage over conventional treatment approaches.

Neoadjuvant Chemotherapy

Preoperative or neoadjuvant chemotherapy is attractive, as it may reduce the amount of disease present and thereby facilitate in obtaining clean surgical margins when the disease is still confined to the breast. This is often the case in inflammatory breast cancer, or in N2 disease, in which neoadjuvant chemotherapy may improve surgical resectability. A significant response of 50% to 90% has been seen with this approach.

Down-staging of the tumor, as well as the axillary lymph nodes, has been reported.

Adjuvant Therapy

At the November 2000 NIH Consensus Development Conference for Adjuvant Therapy for Breast Cancer, a 14-member panel consisting of representatives from the several disciplines involved in treating breast cancer reviewed MEDLINE data for January 1995 through July 2000. There were several consensus decisions regarding the use of adjuvant therapy in breast cancer:

- The use of adjuvant hormonal therapy should be based on the presence of hormone-receptor protein in tumor tissues.
- Adjuvant polychemotherapy should be recommended to women with localized breast cancer regardless of lymph node, menopausal, or hormone-receptor status, because it improves survival.
- The inclusion of anthracycline chemotherapy in adjuvant chemotherapy has an associated small but statistically significant improvement in survival compared with regimens that do not contain anthracycline.
- Available data are inconclusive regarding the use of taxanes in node-positive disease.
- The use of adjuvant dose-intensive chemotherapy regimens in high-risk breast cancer, and of taxanes in lymph node–negative breast cancer, should be restricted to randomized studies.
- Women with a high risk of local recurrence will benefit from radiation therapy postmastectomy. This finding applies to women with four or more positive nodes or advanced primary cancer. In women with one to three positive nodes, the benefits of the use of postmastectomy irradiation are uncertain and should be tested in randomized controlled trials.

- Quality of life should be evaluated in selected randomized trials to examine the impact of the major acute and long-term adverse effects of adjuvant treatments.

Tamoxifen is used as adjuvant hormonal treatment in premenopausal women with ER/PR-positive breast cancers. AIs are used as an alternative to tamoxifen in the adjuvant setting in postmenopausal, hormone-positive patients. Three double-blind, randomized, prospective studies—the Arimidex, tamoxifen-alone, or in combination trial (ATAC); the Intergroup Exemestane Study (EIS); and the MA-17 trial—have confirmed the superiority of AI over tamoxifen in early-stage cancers in postmenopausal women. All three studies have demonstrated an increase in disease-free survival. Short-term side effects were acceptable, but all had a negative impact on bone health. Based on the results of these trials, patients who are postmenopausal have the option of starting on anastrozole as first-line therapy after initial diagnosis. Patients who have been on tamoxifen for 2 to 3 years can be switched to an AI to complete a total of 5 years of therapy. Patients who have completed 5 years of tamoxifen have the option of no further therapy versus letrozole. The optimal duration of letrozole in this setting has not been defined.

Radiation Therapy

Radiation therapy is used in conjunction with lumpectomy for patients opting for breast conservation. The dose used is 1.8 to 2.0 Gy per day for a total of 45 to 50 Gy to the entire breast. A 10- to 15-Gy electron-therapy boost is often given to the lumpectomy bed.

Postmastectomy chest wall irradiation is used with increasing frequency. Patients with large tumors (T3 lesions) and more than four positive nodes are offered chest wall radiation because they are at risk for local–regional failure. Chest wall radiation is 50 Gy over 5 weeks, with a 10-Gy boost to the mastectomy scar. For patients with a chest wall recurrence, the option of surgical debulking followed by chest wall irradiation is employed.

Radiation therapy can also be used in the palliative setting. It can be used for metastatic lesions to the bone or brain and can help to alleviate the patient's symptoms.

Stage-directed Therapy

Patients with intraductal carcinoma and stage I and stage II breast cancer have the options of breast-conservation therapy and mastectomy.

For patients with invasive breast cancer, the axillary nodes can be addressed with an SLN biopsy and, possibly, an axillary dissection.

In intraductal carcinoma, an SLN biopsy or axillary dissection is generally not indicated. There are special circumstances of intraductal carcinoma, such as high-grade DCIS or extensive DCIS, in which a microinvasive component may be associated with the intraductal carcinoma. In these circumstances, particularly if a mastectomy is being performed, an SLN biopsy may be considered.

For patients with more extensive disease, a mastectomy may be necessary. The use of postmastectomy chest wall irradiation in these patients may also be considered.

Breast Reconstruction

Breast reconstruction represents a major advance in cancer rehabilitation for patients undergoing a mastectomy. Previously, a 2-year surveillance period was recommended prior to reconstruction for detection of local disease recurrence. Immediate reconstruction has not interfered with disease detection, however, and it has the advantage of combining the two procedures into one. In addition, a greater amount of skin can be saved with planned immediate reconstruction, and the scar tissue that would be encountered with delayed procedure can be avoided.

A delayed reconstruction can be performed if the patient is ambiguous about the reconstruction or if operative risk is increased with prolonged anesthesia. It is also considered in those patients with locally advanced disease if a delay in adjuvant irradiation or chemotherapy is anticipated because of the reconstruction.

Reconstruction options include expandable breast prosthesis (implant) and autologous tissue transfer. Tissue-transfer operations may yield the greatest symmetry between

breasts, especially with larger breasts; however, they take longer, require greater surgical expertise, involve a longer recovery, and result in another scar at the donor site. The donor site may be the latissimus dorsi, transverse rectus abdominus, or gluteal muscle.

Special Issues

Chemoprevention

Chemoprevention is the principle that cancer prevention can be achieved through pharmacologic intervention. It refers to the use of a medication in a healthy patient to reduce the risk of a particular cancer. It is an option for all women with significant risk for future breast cancer development. Currently, the only FDA-approved medication for prevention of breast cancer is tamoxifen. Tamoxifen is a selective estrogen receptor modulator (SERM) that acts as an antiestrogen in breast tissue. It has been used in the adjuvant setting in breast cancer since 1972 for both metastatic and early breast cancers. A reduction of 40% to 50% in contralateral breast cancer was seen in the adjuvant setting; thus, it was thought to be an ideal agent to use in a chemopreventive setting.

The trial to determine the role of tamoxifen in chemoprevention was performed by the NSABP. In this randomized, double-blinded trial, women with a projected risk

---

of breast cancer of >1.66% over a 5-year period received either tamoxifen or a placebo for a period of 5 years. The Gail model was used to assess the risk. When an independent reviewing agency verified a 50% reduction in both invasive and noninvasive breast cancer cases in the population taking tamoxifen, the trial results were unblinded earlier than expected. Shortly thereafter, the use of tamoxifen was approved for chemoprevention.

Two other chemoprevention trials using tamoxifen have been reported: the Italian tamoxifen-prevention study and the Royal Marsden Hospital tamoxifen trial in the United Kingdom. These two trials did not reveal a statistically significant reduction in breast cancer risk in women randomized to tamoxifen. However, the studies differed in respect to subject numbers, median age, eligibility criteria, risk, and use of HRT.

Another SERM, raloxifene, is approved by the FDA for use in osteoporosis. In studies in which raloxifene was used for the treatment of osteoporosis, a secondary finding was a noted reduction in breast cancer risk of 50% to 70% in the population taking the medication. The women in the trials were at fairly low risk of breast cancer development. Results from the randomized, double-blind trial to compare raloxifene with tamoxifen in a population of postmenopausal women at increased risk for breast cancer development, the study of tamoxifen and raloxifene (STAR) trial/P-2 study, were recently reported.

The STAR trial randomized 19,747 postmenopausal women with an increased 5-year Gail risk to receive either tamoxifen or raloxifene. There were 163 and 168 invasive breast cancers in each group, respectively. The conclusion was that they were equivalent in reducing risks of breast cancer in postmenopausal women at high risk. Raloxifene had a better side effect profile, with fewer uterine cancers and thromboembolic events compared with those found with tamoxifen. The risk reduction is thought to be about 50%,

which is extrapolated from the P-1 study of tamoxifen and placebo. There was no placebo arm in this study; the conclusions were based on raloxifene having the same risk reduction as tamoxifen in the STAR trial.

In the NASBP P-1 study, there was an increased risk of developing endometrial cancer with tamoxifen use (annual risk of 2.3 in 1,000 women vs. 0.9 in 1,000 women in the placebo group). All cases of endometrial cancer in the patients taking tamoxifen were early stage. Another important side effect noted was a higher incidence of thromboembolic phenomena. Raloxifene does not increase the risk of endometrial cancer and thus may prove to be an adequate alternative to tamoxifen in a chemopreventive role. An ideal SERM would have an antiestrogenic activity on breast and uterine tissues but estrogenic effects on bone and the cardiovascular system among others. Current investigations into other SERMs are being conducted.

Hereditary Breast Cancer

One of the most characteristic features of hereditary breast cancer is its tendency to manifest at a young age. In the Breast Cancer Consortium's study of *BRCA1*-linked families that transmit *BRCA1* mutations, more than 80% of breast cancers occurred in women under 50 years of age.

Pathologic Features

Most *BRCA1*-associated breast cancers have been reported to be of an infiltrating ductal type with an overrepresentation of poorly differentiated high-grade types. The tumors tend to be ER/PR negative. Fewer than 20% of these cancers are ER/PR positive, even when age matched with non–*BRCA1*-associated controls. In *BRCA2*, there is less of this over-representation of aggressive histology. Overall, *BRCA2*-associated breast cancers tend to be ER/PR positive.

Stage

Most studies demonstrate that *BRCA*-associated breast cancers are seen at a stage comparable to non–*BRCA*-associated breast cancers. The incidence of axillary metastasis does not appear to be significantly different in patients with *BRCA*-associated breast cancers. In the literature, conflicting study data exist regarding the prognosis of patients with *BRCA*-associated breast cancer. Some studies have conferred a worse prognosis in patients with certain mutations in *BRCA1*. Some of these reports have been of highly selected groups of women, and thus further study is necessary in larger series of women with *BRCA1* and *BRCA2* mutations.

Treatment

Although some researchers have questioned the role of breast-conservation therapy in women with hereditary predisposition, there is no reason to suspect a unique survival advantage for mastectomy in these women.

Studies that have examined the outcomes of breast-conservation therapy in women with

BRCA mutations are small with variable follow-up. Local ipsilateral recurrence appears to be about 15% at 5 years. Although this is higher than would be expected for patients treated with breast-conservation therapy, it is within the range observed for treatment of young women with breast cancer. It is likely to be an influence of the age at diagnosis and not because of radiation resistance.

After breast-conservation therapy, however, the breast tissue remains at risk for developing a second primary breast cancer. Women with *BRCA* mutations may be at risk for a late ipsilateral recurrence because of the development of a second primary.

The degree of contralateral risk needs to also be addressed with patients. Some studies have reported an estimated average risk of 2.5% to 5% per year in *BRCA1* mutation carriers, and this risk may be higher with younger age at diagnosis. In patients with *BRCA2*, the risk appears lower,

---

estimated at 1.8% per year. Unlike the *BRCA1*-associated risk, the age dependence is unknown in *BRCA2*.

Surveillance versus Prophylactic Surgery in High-risk Patients

Patients with a genetic predisposition to breast cancer often ask about risk reduction. Many of these patients are young women. The diverse issues related to prophylactic mastectomy include both physical and psychologic factors. Appropriate counseling is very important, because these women often experience regret after the procedure. Prophylactic mastectomy has been reported to have a risk reduction of approximately 90% in larger studies. However, this reduction often relates to the type of mastectomy performed (e.g., subcutaneous mastectomy may not remove all breast tissue).

Women with a genetic predisposition to breast cancer are also candidates for chemoprevention with tamoxifen or, if they are postmenopausal, for consideration for the STAR trial. In the NSABP P-1 trial, women who had *BRCA* mutations were not protected by tamoxifen. However, because the number of such patients was small and confidence intervals were wide, more data are needed. In addition, it is likely that chemoprevention may have no significant impact in *BRCA1*, where the tumors are predominantly ER-negative. The data are still inconclusive regarding *BRCA*-predisposition genes and the use of tamoxifen for chemoprevention.

Participation in a screening program is another option. Many women considering prophylactic mastectomy are young and have dense breasts on mammography. The use of additional screening modalities, such as bilateral breast ultrasonography or MRI, should be considered. Breast self-examination and clinical breast examinations are other options.

These women are also at risk for developing ovarian cancer, and prophylactic oophorectomy at approximately age 40 years is an option. In addition, prophylactic oophorectomy before the age of 40 has been reported to decrease the risk of breast cancer significantly. Even prophylactic risk-reducing salpingo-oophorectomy, however, does not exclude the risk of primary peritoneal cancer, which is estimated at 2%. Ovarian cancer screening programs currently use serum CA 125 and pelvic ultrasonography. Ovarian

screening is not recommended for the general population, however, because of the low specificity of the tools currently available.

Conclusion

Screening for breast cancer is clearly indicated for all women at the appropriate age. Determining a woman's unique risk factors will help to determine both the age at which the screening should begin and also the intensity of the screening. It will also help to identify those women who need to be counseled regarding options for prevention of breast cancer. The hope is that by correctly identifying high-risk populations and then applying appropriate screening schedules and chemopreventive agents, many cases of breast cancers will be averted completely and that those that still occur will be found at the earliest stages. The role of the obstetrician and gynecologist in providing information on breast cancer diagnosis and screening is very important.

In addition, an understanding of breast disease, both benign and malignant, is crucial not only in the diagnosis of disease, but also in helping to guide women in their treatment and follow-up.

Summary Points

- Obstetricians and gynecologists are the primary care physicians for many women. According to the ACOG, the diagnosis of breast disease, as well as the education of women on breast self-examination and their referral for mammographic screening, is central to the obstetrician–gynecologist's role in women's health care.
- Breast cancer is a common cancer in women that has a lifetime risk of occurring in 1 in 8 women.
- The incidence of breast cancer increases with age and is the most significant risk factor for breast cancer. Family history is also very important, and women with a strong family history should be referred for genetic counseling and testing.
- There are two primary surgical treatments for breast cancer: mastectomy or breast-conservation therapy with lumpectomy with radiation. Sentinel node biopsy allows for accurate assessment and surgical staging for breast cancer.
- Adjuvant systemic chemotherapy encompasses combination chemotherapy regimens. Tumor factors and menopausal status play a crucial role in decision making. Hormonal therapy with tamoxifen or AIs is the mainstay of treatment in estrogen/progesterone-positive tumors.

Vulvar and Vaginal Cancer

Natalie S. Gould
Joan L. Walker

Vulvar and vaginal cancer represent uncommon gynecologic cancers that occur most often in older women. Squamous lesions are the most frequent histology, and risk factors are similar for both disease sites. This chapter describes the epidemiology, clinical presentation, patterns of spread, and treatment of squamous cell carcinomas of the vulva and vagina. Less common histologic subtypes, including Paget's disease, melanoma, adenocarcinomas, and sarcomas, are also reviewed.

Vulvar Carcinoma In Situ

Vulvar carcinoma theoretically results from malignant transformation of a vulvar carcinoma in situ as is seen with cervical squamous lesions. Unlike squamous lesions of the cervix, the natural history of vulvar intraepithelial neoplasia (VIN) is less well understood. The incidence of vulvar dysplasia has increased over the last 20 years, particularly among younger women. A report from Austria demonstrated a 307% increase in the overall incidence of high-grade VIN and a 394% increase among women younger than 50 years of age between 1985 and 1998. In a review of Surveillance, Epidemiology, and End Results (SEER) data, Judson found that the incidence of VIN III increased 411% from 1973 to 2000 from 0.56 cases per 100, 000 to 2.86 per 100, 000. This increase in incidence occurred predominantly in women younger than 65 years with a peak incidence from 40 to 49 years. Jones recently reviewed 405 cases of VIN2–3 treated between 1962 and 2003 in New Zealand. The mean age at diagnosis decreased from 50 to 39. Factors implicated in the increase in dysplasia include increased human papillomavirus (HPV) infection; tobacco use; immunosuppression either with HIV, organ transplant, or diabetes; and increased surveillance.

Patients with VIN most commonly present with pruritus and vulvar lesions. These lesions may appear scaly, white, red, or hyperpigmented (Figs. 57.1, 57.2). Careful inspection with 5% acetic acid and liberal use of punch biopsy are the cornerstones of diagnosis (Fig. 57.3). An underlying malignancy may be present in 3.2% to 22.0% of patients who undergo surgical excision for vulvar carcinoma in situ. Wide local excision with at least a 5-mm margin is the preferred management option, as it allows pathologic confirmation and is associated with less morbidity than skinning vulvectomy. Skinning vulvectomy with split-thickness skin

graft may be an option in patients with widespread disease. Small series, which are hindered by short clinical follow-up, demonstrate regression of VIN with use of 5% imiquimod cream. Carbon dioxide laser ablation or ablation with the Cavitron ultrasonic surgical aspirator (CUSA) is also an effective option for patients with multifocal or clitoral disease with a better cosmetic outcome. Recurrences are frequent (10% to 50%) despite surgical technique used or the presence of negative surgical margins. Untreated VIN3 has a risk of progression to invasive cancer of 2% to 9%. Therapy should be tailored to symptom control and ruling out underlying malignancy. Patients should be followed every few months with careful visual inspection of the vulva and be taught self-exam skills as well.

Epidemiology

Vulvar carcinoma is the fourth most common genital tract malignancy in women, representing 3% to 5% of gynecologic malignancies with an estimated 3,740 cases and 880 deaths per year in the United States in 2006. The majority of cancers are squamous in origin, with occasional cases

of basal cell carcinoma, melanoma, adenocarcinoma, and Paget's disease.

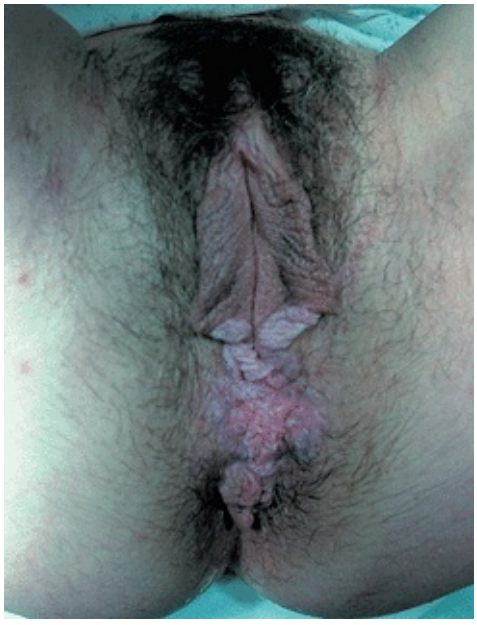

Figure 57.1 Vulvar carcinoma in situ presenting as a white or hyperpigmented lesion. (See Color Plate)

Figure 57.2 Vulvar carcinoma in situ presenting as a white or hyperpigmented lesion.

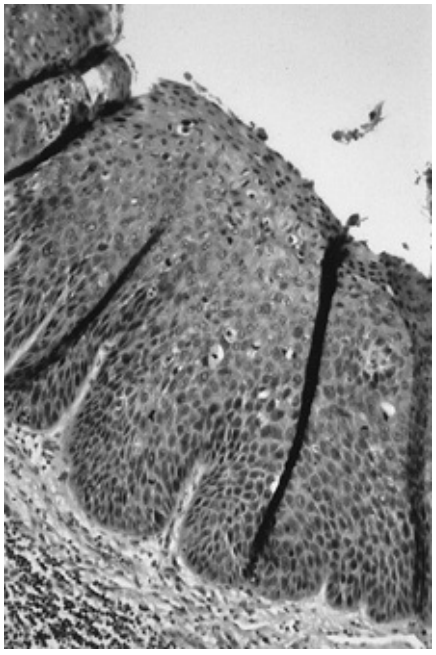

Figure 57.3 Vulvar carcinoma in situ with full-thickness involvement of dysplastic cells.

Vulvar cancer tends to be a disease of older women, with a mean age at diagnosis of approximately 65 years. As the population ages, more older women will be at risk for vulvar carcinoma. Despite a dramatic increase in the incidence of VIN3 seen from 1973 to 2000, Judson found only a 20% increase in invasive vulvar cancer over that time. Evidence exists that there are two distinct types of vulvar carcinoma with different etiologies. Tumors in older women are often unifocal and may be associated with chronic vulvar inflammation of long-standing duration such as lichen sclerosus or hyperplastic dystrophy. These keratinizing squamous cell carcinomas have associated HPV changes in only 6% of cases. While retrospective studies indicate that up to 50% of vulvar carcinomas are related to hyperplastic dystrophies and lichen sclerosus, prospective studies have demonstrated that only 5% of women with vulvar dystrophies develop invasive carcinoma. Cancers found in younger women tend to be multifocal with adjacent VIN and have a basaloid or warty histology. Nearly 90% are associated with HPV infection, particularly HPV 16. Of women with HPV-associated lesions in a series by Trimble and colleagues, 38% were under age 55 compared with only 17% of those with classic keratinizing squamous cancers. Other associated risk factors include immunosuppression from chronic steroid use, organ transplant, diabetes or HIV, smoking, and a history of other lower genital tract dysplasia or neoplasia.

Presentation

Most women present with pruritus, burning, or bleeding in the presence of an identifiable lesion (Figs. 57.4, 57.5).

Unfortunately, there is often a delay of many months or even years between onset of symptoms and diagnosis. This is in part because patients self-medicate with a variety of over-the-counter preparations rather than seek care and also because physicians may not biopsy liberally. The cornerstone for diagnosis of vulvar malignancy is a low threshold for an office biopsy, as it may be extremely difficult to distinguish clinically between dysplasia, chronic vulvar dystrophy, and carcinoma (Fig. 57.6). Any patient with symptoms lasting for longer than 2 weeks deserves a thorough exam and a biopsy. In order to adequately evaluate a patient with a vulvar lesion, 5% acetic acid is applied to the vulva for 5 minutes and then the area is examined either with the naked eye or a handheld magnifying glass. The entire vulva, including the hair-bearing, perianal, and periclitoral regions, should be examined for suspicious ulcerations and hyperpigmented, acetowhite, or gross warty lesions. Up to 5% of patients will have multifocal disease and may require multiple 5-mm punch biopsies.

Staging/Spread Patterns

The International Federation of Gynecology and Obstetrics (FIGO) surgical classification system replaced clinical staging for vulvar cancer in 1989 (Table 57.1). By relying on histopathologic classification of the lymph nodes, the new system more accurately reflects prognosis since the previous system provided an inaccurate assessment of inguinal femoral lymph node involvement in one fourth of cases.

TABLE 57.1 Vulvar Carcinoma: International Federation of Gynecology and Obstetrics Staging 1994

Stage 0	Carcinoma in situ, intraepithelial neoplasia grade III
Stage I	Lesions ≤2 cm in size (T1), confined to the vulva or perineum, no nodal metastasis
Ia	Lesions ≤2.0 cm in size, confined to the vulva or perineum and with stromal invasion ≤1.0 mm, no nodal metastasis

Ib	Lesions ≤2.0 cm in size, confined to the vulva or perineum and with stromal invasion >1.0 mm, no nodal metastasis
Stage II	Tumor confined to the vulva or perineum, >2 cm in greatest dimension (T2), no nodal metastasis
Stage III	Tumor of any size with adjacent spread to the lower urethra or vagina, the anus, or unilateral regional lymph node metastasis
Stage IVa	Tumor invades any of the following: upper urethra, bladder mucosa, rectal mucosa, pelvic bone, or bilateral regional node metastases
Stage IVb	Any distant metastasis including pelvic lymph nodes

Local spread occurs to contiguous structures such as the vagina, urethra, and rectum. Metastatic spread via lymphatics is common and has been well characterized by anatomic studies. Lateralized lesions tend to be characterized by spread to the ipsilateral inguinal nodes first, followed by contralateral inguinal nodes, and then pelvic nodes. Midline lesions, or those approaching 1 cm from the midline, may have lymphatic drainage to both inguinal regions. Metastasis to the contralateral groin or pelvic nodes is rare in the absence of ipsilateral groin node involvement. The superficial inguinal nodes above the cribriform fascia are believed to be involved prior to the deep femoral nodes below the cribriform fascia. Risk of lymphatic spread is related to tumor size, tumor thickness, older patient age, tumor grade, presence of lymphovascular space invasion, and clinically suspicious groin nodes. The Gynecologic Oncology Group (GOG) found groin node metastasis in 19% of patients with lesions ≤2 cm and in 42% of patients with lesions >2 cm. The GOG surgicopathologic staging analysis also demonstrated that lymph node dissection could be safely omitted in patients with <1 mm of stromal invasion. Hematogenous metastasis to distant organs such as bone, liver, and lungs is rare as a primary event but may be seen in patients with recurrent disease.

Treatment

Historically, vulvar cancer has been treated with en-bloc radical vulvectomy and bilateral inguinofemoral lymphadenectomy or “longhorn incision” (Figs. 57.7, 57.8). This technique resulted in significantly improved survival, but the morbidity was extensive with a median hospitalization of 30 days, 70% to 90% wound breakdown, and chronic debilitating

lymphedema in nearly 9% of women. Significant disruption in self-image and sexual function also occurred. Attempts to decrease morbidity first led to the use of separate incisions for groin node dissection while continuing to use radical vulvectomy. In 1981, Hacker and colleagues reported a series of 100 patients who underwent radical vulvectomy and lymphadenectomy through three separate incisions. The incidence of major wound breakdown was only 14%, with a mean hospitalization shortened to 19 days. This procedure lead to the shortest length of hospitalization reported at that time and produced a dramatic decrease in complications. The majority of local recurrences were salvaged with repeat excision. Overall survival was not compromised by deviating from en-bloc dissection, and the authors concluded that this technique is appropriate for patients with stages I and II vulvar carcinoma.

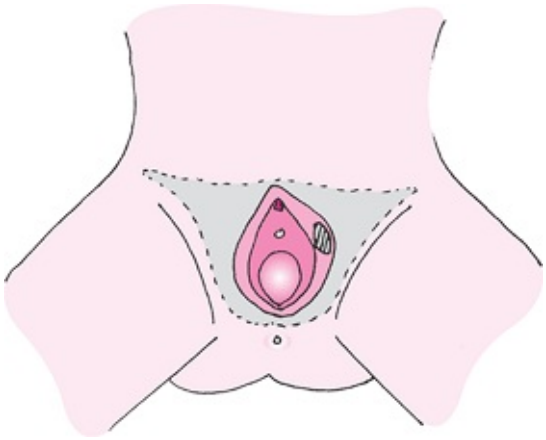

Figure 57.7 A longhorn incision. Radical excision of the vulva from genitocrural fold to genitocrural fold, deep to the inferior fascia of the urogenital diaphragm along with en-bloc lymphadenectomy.

Figure 57.8 Surgical specimen after en-bloc radical vulvectomy and inguinofemoral lymphadenectomy via longhorn incision.

DiSaia and associates first proposed conservative vulvar surgery in 1979 as a way of preserving sexual function in young patients. Requirements for conservative surgery were an invasive cancer ≤1 cm in diameter confined to the vulva with <5-mm depth of invasion. Patients were treated with radical wide excision ensuring a 3-cm margin, and lymphadenectomy was performed through separate groin incisions. There were no recurrences at a mean follow-up of 32 months, and sexual function was deemed preserved. The authors concluded that there existed a subset of patients with vulvar cancer who could be treated with less radical vulvar procedures.

Berman and coworkers expanded the experience with conservative surgery in 1989 with a report of 50 patients with T1 lesions treated with radical local excision, again providing a 3-cm margin and superficial lymphadenectomy. No patient had a resection margin positive for carcinoma. Median hospital stay was shortened to 7 days, and only 12% required wound debridement compared with 50% or more with historical controls. There were five recurrences (10%), four of them local. All local recurrences were salvaged with a second local resection.

In 1990, Burke and colleagues provided the first report of a conservative vulvar surgery in patients with both T1 and T2 lesions. Thirty-two patients (15 with T2 lesions) underwent radical wide excision, removing a 1- to 2-cm margin of normal tissue in addition to selective inguinal

---

dissection. The mean lesion diameter was 23.0 mm with a mean depth of invasion of 4.1 mm. No patients had invasive cancer at the surgical margins, but 19% were positive for VIN. The authors reported only 15.5% wound separation, with a mean hospital stay of 10 days. Three patients (10%) developed local recurrence, and two were salvaged with repeat excision. The authors concluded that radical wide excision appears to be an acceptable surgical option for patients with resectable vulvar carcinomas.

As these retrospective trials used differing criteria to identify patients suitable for less radical approaches, the GOG conducted a prospective trial beginning in 1983 that evaluated modified radical hemivulvectomy and ipsilateral superficial inguinal lymphadenectomy in 155 patients with clinical stage I vulva carcinoma limited to a depth of invasion of <5 mm. A 2-cm margin of normal skin around the lesion was excised. There were 19 recurrences and 7 deaths among 122 patients available for evaluation. Recurrences were evenly distributed between local and distant failures. Acute and long-term morbidity was decreased significantly compared with that found in historical controls but at the cost of increased risk of local recurrence. The authors concluded that although there was no consensus regarding the characteristics that would make a patient with early vulvar carcinoma a candidate for a limited surgical approach, this approach appeared to be an alternative to traditional radical surgery for a highly selected group of patients with stage I vulvar carcinoma (Figs. 57.9, 57.10).

A need for establishing a clear margin for treatment of patients with vulvar cancer may be more important than the particular treatments. Heaps and colleagues reviewed surgicopathologic factors predictive of local recurrence in 135 patients treated with radical vulvectomy or radical local excision. Twenty-one developed local recurrence after radical

resection. No patient with a surgical tumor-free margin ≥8 mm suffered from local recurrence but 48% with <8-mm margin recurred locally. As an 8-mm margin on fixed tissue corresponds to 10-mm margin with fresh tissue, the authors concluded that use of a 1-cm margin should successfully prevent local recurrence and reduce the currently used standard margin by over 50%. This would allow further modification of the procedure in order to decrease morbidity and avoid disfigurement and loss of organ function without sacrificing survival.

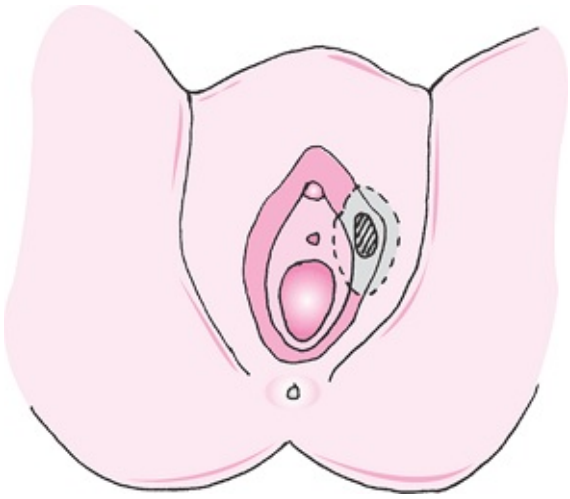

Figure 57.9 Modified radical vulvectomy. Radical excision of the vulva deep to the inferior fascia of the urogenital diaphragm with a 2-cm margin around the lesion.

Figure 57.10 Surgical specimen after modified radical vulvectomy. Lymphadenectomy is performed through separate incisions.

Other modifications in the surgical management of vulvar carcinoma over the last 30 years include the elimination of routine pelvic lymphadenectomy and elimination of contralateral groin node dissection in patients with lateral T1 lesions and negative

ipsilateral nodes.

Overall survival in vulvar carcinoma is related to groin node status and lesion diameter with nodal status being the most important factor. Five-year survival is 98% for patients with negative nodes and a T1 lesion. Patients with one to two positive ipsilateral nodes have over 70% to 80% 5-year survival, while those with three or more positive nodes or bilaterally positive nodes have survival in the range of 12% to 36% (Table 57.2). Postoperative adjuvant groin radiotherapy is indicated in patients with more than one positive node or clinically evident groin nodes.

TABLE 57.2 Survival by Groin Node Status and Lesion Size in Vulvar Carcinoma

Node Status	Lesion Size	Relative 5-year Survival (%)
Negative	≤2.0 cm	98
Negative	2.1–8.0 cm	87
One positive	≤2.0 cm	87
Negative	>8.0 cm	75
One positive	>2.0 cm	75
Two unilaterally positive	≤8.0 cm	75
Two unilaterally positive	>8.0 cm	29
Three or more positive	Any	29
Bilaterally positive	Any	29

Radiotherapy for vulvar carcinomas is indicated in patients with unresectable vulvar tumors or unresectable groin nodes. Boronow popularized treatment of locally advanced tumors with radiotherapy followed by resection of the primary tumor in order to preserve urethral, bladder, or rectal function and to avoid the morbidity of pelvic exenteration. In recent years, concurrent radiotherapy and chemotherapy has been shown to improve both local control and overall survival. The GOG has demonstrated high rates of resectability and local control of the lymph nodes in patients with clinically suspicious, fixed, or ulcerated nodes treated preoperatively with radiotherapy, concurrent cisplatin/5-fluorouracil (5-FU) chemotherapy, and followed by tailored surgery. Small series also demonstrate good results with neoadjuvant chemotherapy for unresectable vulvar cancer.

New approaches to decrease morbidity of groin node dissection include the use of lymphatic mapping and sentinel lymph node biopsy. While this technique is widely used for breast cancer and cutaneous melanoma, it is being prospectively evaluated by the GOG and other investigators. Intraoperative mapping with lymphoscintigraphy, with or without vital dye, may identify up to 100% of sentinel nodes. Theoretical advantages to this procedure include avoiding the risks and morbidity of a complete inguinal lymphadenectomy in node-negative patients as well as allowing more thorough pathologic evaluation of a smaller number of nodes that have the highest probability of containing metastatic disease. While the morbidity associated with lymph node dissection includes the risk of lymphedema, infection, and wound breakdown, it is not clear whether patients who undergo only sentinel node biopsy will have recurrence patterns and survival that differ from traditionally treated patients. Complete lymph node dissection with removal of microscopic disease confers both a therapeutic and diagnostic benefit. Until further data is available, sentinel node mapping should be utilized to identify the initial nodes of spread and ensure that these areas are excised along with remaining inguinal femoral lymph nodes. If prospective studies illustrate that sentinel node mapping can predict lymph node involvement with sufficiently high negative predictive value without compromising groin recurrence and overall survival, then less extensive lymphadenectomy may be indicated in the future.

Recurrence after definitive therapy for vulvar carcinoma may occur locally in the vulva or in the groin. Most treatment failures occur within the first 2 years after primary therapy. Local recurrence depends on prior surgical technique, with higher rates of recurrence seen with less aggressive vulvar approaches. Local relapse rates range from 10% to 23%. Vulvar recurrences may be characterized as new primaries due to field effect or recurrence at the prior site of excision. They are usually salvageable with radical excision, although patients who have had prior radiotherapy will require some type of reconstructive flap to ensure adequate vascular supply and healing. Groin recurrences are less common and more difficult to treat. If the patient has not been irradiated, surgical excision of the nodes with postoperative radiotherapy is the treatment of choice. If radiotherapy has already been administered, no satisfactory therapy exists and survival is dismal. A recent review of long-term survival after vulvar carcinoma from the Mayo Clinic found that 35% of patients who experienced disease recurrence did so more than 5 years after initial treatment. This highlights the need for continued surveillance in patients with vulvar carcinoma. Distant

recurrence after treatment for vulvar carcinoma is uncommon and associated with a very poor prognosis. Chemotherapy for recurrent or metastatic disease has not been shown to be of value.

Other Histologic Subtypes

Rare histologic types of vulvar carcinoma exist, representing about 10% of vulvar malignancies. These include melanoma, invasive Paget's disease, basal cell carcinoma, verrucous carcinoma, Merkel cell carcinoma, adenocarcinoma, adenosquamous carcinoma, transitional cell carcinoma, sarcomas, and metastatic disease from other sites. A thorough description of the clinical presentation and appearance of the gross specimen may be helpful in assisting the pathologist to differentiate these tumors.

Melanoma

Melanoma is the second most common vulvar malignancy, accounting for about 6.0% of vulvar lesions and 1.3% of all melanomas among women. It is highly aggressive and characterized by both local recurrence and distant metastasis through hematogenous spread. The median age at presentation is 66 years, several decades older than for cutaneous melanomas. It is more common in white women with a relative risk of 2.6 compared with that found in other races. Overall 5-year survival ranges from 35% to 50%.

Patients frequently present with bleeding, pruritus, and visible lesions, but many may be asymptomatic. The differential diagnosis of a pigmented lesion includes melanoma, lentigo, vulvar melanosis, squamous dysplasia, hemangioma, Paget's disease, various nevi, and acanthosis nigricans. Biopsy should be considered for any pigmented lesion, particularly if the borders are indistinct or spreading or the lesion is raised. Excisional biopsy is preferred to better delineate depth of invasion. A punch biopsy of the most nodular area is the next best option. Three histologic subtypes of vulvar melanoma have been described: superficial spreading, lentiginous, and nodular. In recent series from Sweden encompassing cases over 25 years, lentiginous melanoma was most common. Other series have found superficial spreading to be most common. Tumor thickness in millimeters and presence of ulceration are significant prognostic factors. Immunohistochemical testing may be necessary to distinguish between melanoma and Paget's disease. Primary vulvar Paget's disease is immunoreactive for cytokeratin 7 (CK 7) and carcinoembryonic antigen (CEA), whereas melanoma is positive for S-100 and HMB-45 while lacking CEA and CK 7.

TABLE 57.3 Melanoma Staging: Breslow, Clark, and Chung Microstaging Levels

Level	Breslow	Clark	Chung

I	Tumor thickness <0.75 mm	In situ, melanoma; all tumor is above epidermal basement membrane	In situ melanoma; all tumor is above epidermal basement membrane
II	Tumor thickness 0.75–1.50 mm	Tumor extends through the basement membrane into papillary dermis	Tumor invasion = 1 mm
III	Tumor thickness 1.51–2.25 mm	Tumor fills papillary dermis and extends to the reticular dermis but does not invade it	Tumor invasion 1–2 mm
IV	Tumor thickness 2.26–3.00	Tumor extends into the reticular dermis	Tumor invasion >2 mm
V	Tumor thickness >3.00 mm	Tumor extends into the subcutaneous fat	Tumor extends into the subcutaneous fat

Unlike squamous lesions, vulvar melanoma is staged by using classification systems for cutaneous melanomas. The Clark system is based on level of invasion, while the Breslow system is based on vertical thickness of the lesion from the surface of intact epithelium to the deepest point of invasion. Other staging systems include Chung's modification of the Clark system and the American Joint Committee on Cancer (AJCC) staging system (Table 57.3). While the Breslow and Chung microstaging systems are more accurate than the Clark system, prospective evaluation by the GOG found that the AJCC staging system is most predictive of survival (Table 57.4).

As with squamous lesions, more conservative vulvar surgery is now being advocated for melanoma. Excision should include a 2- to 3-cm lateral margin and at least a 1-cm deep margin. The role of lymphadenectomy in vulvar melanoma remains unresolved. Prospective evaluations have failed to show a survival benefit with lymphadenectomy. Data from cutaneous melanomas demonstrate a rate of occult lymph node metastases of <5% with tumors ≤1 mm in thickness. More than 70% of patients with tumors >4 mm thick

will have occult nodal disease. Consensus opinion suggests that elective lymph node dissection may be omitted in patients with vulvar melanomas measuring ≤1 mm in thickness who have no signs of metastatic disease, but may be performed in patients with >1 mm and <4 mm of tumor thickness for purposes of locoregional control and prognosis. Sentinel lymph node dissection appears to have a role in vulvar melanoma, although numbers of patients treated this way remain small. Adjuvant therapy for advanced disease includes the use of chemotherapy, immune modulators, and tumor vaccines. Given the small number of patients, no trials specific to vulvar melanoma have evaluated the role of adjuvant therapy.

Paget's Disease

Paget's disease accounts for 1% to 2% of vulvar malignancies. It occurs most frequently in postmenopausal white women and is characterized by red, eczematous, weeping lesions with a superficial white coating and intense pruritus (Fig. 57.11). As with other vulvar malignancies, there may be a long delay between initial symptoms and diagnosis. Histologic disease may spread well beyond the visible lesion. Biopsy reveals characteristic large eosinophilic cells in the basal layer of the epithelium (Fig. 57.12). Paget's disease of the vulva may exist as four clinical entities, the first of which is noninvasive or intraepithelial Paget's disease. This represents 60% of cases and is cured with local excision. In invasive Paget's disease, the Paget cells penetrate the basement membrane and invade the dermis. Intraepithelial Paget's disease may also be associated with an underlying adenocarcinoma of sweat gland origin or a coexistent cancer. Underlying malignancy is seen in approximately 20% to 30% of patients, a rate lower than that seen with mammary Paget's disease. Parker and coworkers reported poor survival in patients with invasive Paget's disease and in patients with underlying malignancy. Patients

with clitoral disease also had a poorer prognosis. Therapy for Paget's disease involves wide excision. A skinning vulvectomy with split-thickness skin graft is often needed to remove large areas of involved skin. Recurrences tend to be local and range from 7% to 58% with an average of about 30%. Some authors recommend sending margins for frozen section to ensure complete resection, while others have not demonstrated a benefit to this approach with respect to recurrence. Radical surgery is reserved for patients with underlying malignancy. As in other vulvar malignancies, long-term surveillance is important.

TABLE 57.4 American Joint Committee on Cancer Staging for Vulvar Melanoma

Stage	Description
IA	Primary melanoma <0.75 mm thick or Clark level II

IB	Primary melanoma 0.75–1.50 mm thick or Clark level III
IIA	Primary melanoma 1.51–4.00 mm thick or Clark level IV
IIB	Primary melanoma >4.00 mm thick or Clark level V
III	Regional lymph node or in-transit metastases
IV	Systemic metastases

Figure 57.11 Paget's disease of the vulva with characteristic red appearance.

Basal Cell Carcinoma

Basal cell carcinoma accounts for 2% to 4% of vulvar malignancies. It is typically seen in older women and tends to be well circumscribed, firm, and typically <2 cm in diameter. The differential diagnosis is both broad and may be histologically difficult, but when basal cell carcinoma is clearly identified, there is no need for radical excision or lymph node dissection. Metastasis is extremely rare, and wide local excision is the preferred therapy.

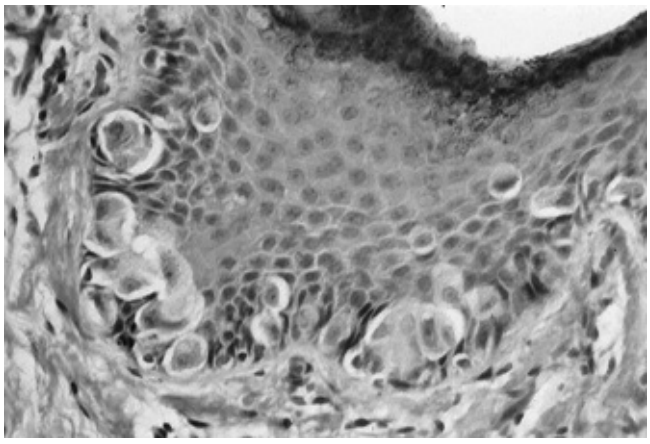

Figure 57.12 Paget's disease of the vulva. Large eosinophilic cells with large nuclei and prominent cytoplasm in basal cells represent Paget cells.

Verrucous Carcinoma

Verrucous carcinoma is a variant of squamous cell carcinoma with distinctive pathologic and clinical characteristics. It is characterized by a large condylomatous or cauliflowerlike lesion with minimal cellular atypia, a pushing border, and rare metastasis. Unless biopsies are deep enough, it may be confused with benign condyloma or papilloma. Wide local excision is the preferred therapy. Radiotherapy is contraindicated, given the potential for anaplastic transformation.

Merkel Cell Carcinoma

Merkel cell tumors are neuroendocrine tumors of the skin and resemble small cell carcinomas. They are associated with lymphatic and distant metastases and have a very poor prognosis.

Adenocarcinoma

Adenocarcinoma of the vulva tends to arise in the Bartholin gland, although it may also arise from the sweat glands or Skene glands of the vulva (Fig. 57.13). Adenoid cystic carcinoma also arises from the Bartholin gland and is characterized by slow growth and a tendency for local and perineural invasion (Fig. 57.14). Surgical resection is complicated by these invasive qualities, and obtaining adequate margins is often problematic. Distant metastasis is most commonly seen in the lung. Therapy involves radical excision, ipsilateral lymphadenectomy, and postoperative radiotherapy.

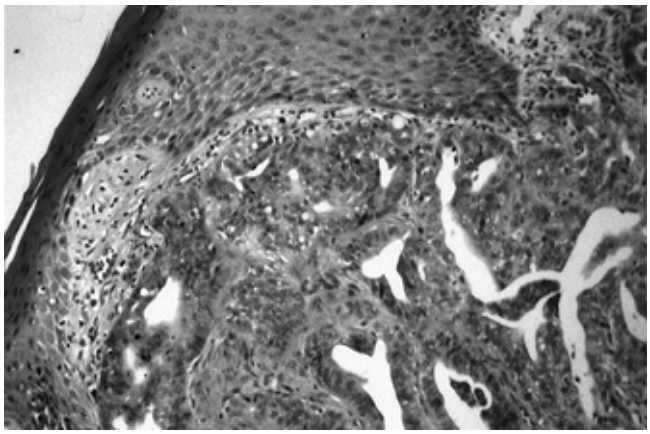

Figure 57.13 Moderately differentiated adenocarcinoma arising from vulva.

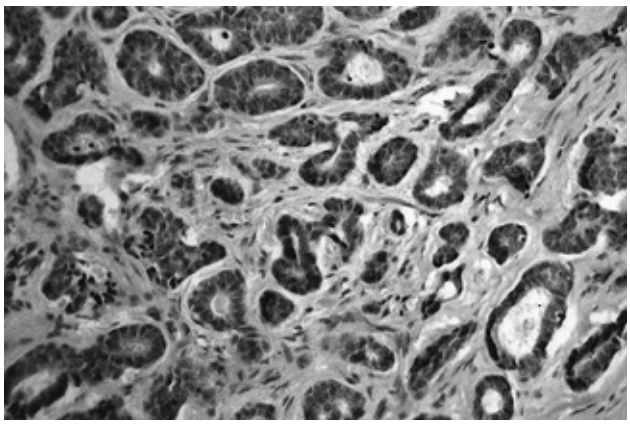

Figure 57.14 Adenoid cystic carcinoma arising from the Bartholin gland.

Adenosquamous Carcinoma

Adenosquamous carcinoma is a rare cause of Bartholin gland carcinoma and is composed of both malignant squamous and glandular components.

Transitional Cell Carcinoma

Transitional cell carcinoma may arise within the Bartholin gland but is more commonly seen as metastatic spread from a urethral or bladder carcinoma.

Sarcoma

Sarcomas of the vulva are extremely rare, representing only 1% to 3% of vulvar malignancies. While leiomyosarcoma is the most common histologic subtype, malignant fibrous histiocytoma and various other sarcomas have been reported. Radical surgery is the primary therapy, although the behavior of these neoplasms is not well understood.

Metastatic Disease

Metastatic disease to the vulva usually occurs from other lower genital tract malignancies, most commonly those of the cervix. Rare other causes include malignancies arising from the vagina, endometrium, ovary, breast, kidney, stomach, or lung.

Vaginal Carcinoma

Primary vaginal cancer is the fifth most common gynecologic malignancy, with an expected 2,420 new cases and 820 deaths per year in the United States in 2006. Only fallopian tube carcinomas are a less common gynecologic malignancy than vaginal carcinoma. The vast majority of vaginal neoplasms are metastatic from other sites, particularly direct extension from the cervix, vulva, or endometrium. Lymphatic or hematogenous spread to the vagina is also possible. Primary vaginal neoplasms are typically squamous in origin and occur in postmenopausal women. Risk factors for vaginal dysplasia or carcinoma include a history of prior lower genital tract dysplasia or carcinoma, tobacco use, low socioeconomic status, history of genital warts or HPV infection, prior abnormal Pap smear, prior radiotherapy of the genital tract, immunosuppression, vaginal discharge or irritation, and early hysterectomy. History of diethylstilbestrol (DES) exposure is associated with development of clear cell adenocarcinoma of the vagina.

Vaginal Intraepithelial Neoplasia

The vagina is the least common site for lower genital tract dysplasia, occurring 100 times less frequently than cervical dysplasia. A review by Dodge and associates of 121 patients with biopsy-proven vaginal intraepithelial neoplasia (VAIN) showed that 65% of women with a uterus in place had associated cervical intraepithelial neoplasia, and 10% had associated VIN. The upper third of the vagina is the most common site of involvement, and over 60% of these women will have multifocal disease. The mean age for patients with VAIN III is approximately 40 years.

Diagnosis is through careful colposcopic inspection after application of 5% acetic acid and directed biopsy (Figs. 57.15, 57.16). Due to the large surface area of the vagina, the presence of rugae, and posthysterectomy changes, colposcopic evaluation may be difficult and time-consuming. It is important to remember to colposcopically evaluate the vagina in patients with cytologic abnormalities, particularly those with normal-appearing cervices. Acetowhite epithelium is the most common colposcopic feature. Application of half-strength Lugol solution is frequently helpful for identification of nonstaining areas, which may represent dysplasia. Most patients with vaginal dysplasia are completely asymptomatic, and fewer than 5% will present with bleeding or abnormal vaginal discharge. Postmenopausal patients with low-grade cytologic abnormalities who have

clinical signs of atrophy may benefit from a short course of intravaginal estrogen. Recommendations by the 2001 American Society for Colposcopy and Cervical Pathology (ASCCP) Consensus Conference encourage treatment for 1 week with intravaginal estrogen before repeating cytology. If abnormal cytology persists, then colposcopy with directed

biopsy is indicated. Various treatment options have been employed for therapy of VAIN. These include laser ablation, partial or total vaginectomy, topical 5% 5-FU cream, Cavitron ultrasonic aspiration, and loop electrosurgical excision procedure (LEEP). Choice of therapy for VAIN depends on the number, severity, and location of lesions; whether the patient is sexually active; and whether she has had prior radiotherapy as well as physician and patient preference. Invasive carcinoma is found in 12% to 28% of patients undergoing upper vaginectomy for VAIN III. Overall recurrence rates after therapy range from 10% to 42%. While partial vaginectomy is well suited to unifocal lesions and those involving the upper aspect of the vagina, it may lead to vaginal shortening and sexual dysfunction as well as intraoperative complications such as cystotomy or hemorrhage. Total vaginectomy with split-thickness skin graft is reserved for patients who have failed more conservative approaches. Laser ablation to a depth of 2 to 3 mm is associated with minimal blood loss and is well suited for multifocal lesions. The challenge with laser therapy is ensuring that no lesions have been missed among the vaginal rugae or incorporated into the vaginal cuff. In addition, the vaginal epithelium is very thin, and care must be taken to prevent extension through the vagina, particularly in posthysterectomy patients. While 5-FU allows patients to treat themselves medically, it may be associated with significant skin desquamation and chronic ulceration and be poorly tolerated. Dodge and colleagues found that recurrence is highest after laser ablation (38%) and 5-FU (59%) as well among those patients with multifocal disease (45%). Recurrence is lowest after partial vaginectomy, with cure rates between 68% and 82%. Overall, 2% to 12% of patients progress to vaginal cancer after therapy for vaginal dysplasia, so careful cytologic and colposcopic surveillance is critical. Consideration should also be given as to whether a portion of the upper vagina should be resected when patients undergo hysterectomy for persistent cervical dysplasia.

TABLE 57.5 Vaginal Carcinoma: FIGO and AJCC Clinical Staging

AJC	FIGO	Description
Tis	Stage 0	Carcinoma in situ, intraepithelial neoplasia grade III
T1	Stage I	Carcinoma is limited to the vaginal wall
T2	Stage II	Carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall
T3	Stage III	Carcinoma has extended to the pelvic wall
	Stage IV	Carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum
T4	Stage	Tumor invades bladder or rectal mucosa or

IVa	direct extension beyond the true pelvis
Stage IVb	Spread to distant organs

FIGO, International Federation of Gynecology and Obstetrics; AJCC, American Joint Committee on Cancer.

Squamous Carcinoma

Squamous carcinoma accounts for 80% to 90% of vaginal carcinomas, with a mean age at presentation of 60 to 65 years. To be considered primary vaginal carcinoma, a patient must have no evidence of disease in either the vulva

or cervix. Staging of vaginal cancers is clinical and based on either the FIGO or AJCC system (Table 57.5). As with vaginal dysplasia, the most common location will be the posterior upper third of the vagina, but the entire vaginal cylinder is at risk for malignant transformation. Abnormal vaginal bleeding occurs in over half of patients. Less common symptoms include abnormal vaginal discharge, pain, and dysuria (Fig. 57.17). Vaginal carcinoma may spread by local extension, lymphatic spread to pelvic or inguinal nodes, or hematogenously. Lesions involving the upper two thirds of the vagina tend to spread to pelvic nodes, while lesions involving the lower third of the vagina tend to spread to inguinal nodes, as would be seen with vulvar malignancies. Therapy for vaginal carcinoma is generally tailored to the location, size, and stage of the tumor. It is often impossible to excise a lesion with adequate margins because of proximity to the urethra, bladder, and rectum, so surgical resection is typically reserved for small stage I tumors confined to the posterior aspect of the vaginal apex. Larger lesions and those located in the mid to lower vagina are treated with external beam radiation in combination with brachytherapy. The location of the tumor also influences which lymph nodes fields are radiated. Radiation fields may be extended to include inguinal and femoral lymph node regions for distal third lesions, whereas proximal vaginal lesions may include radiation of the pelvic and paraaortic regions. Because of the close proximity of the urethra, bladder, and rectum, these structures are predisposed to injury from either surgery or radiation. Treatment-related complications may affect 10% to 15% of patients treated for vaginal cancer and include rectovaginal and vesicovaginal fistula formation, radiation cystitis or proctitis, and stenosis.

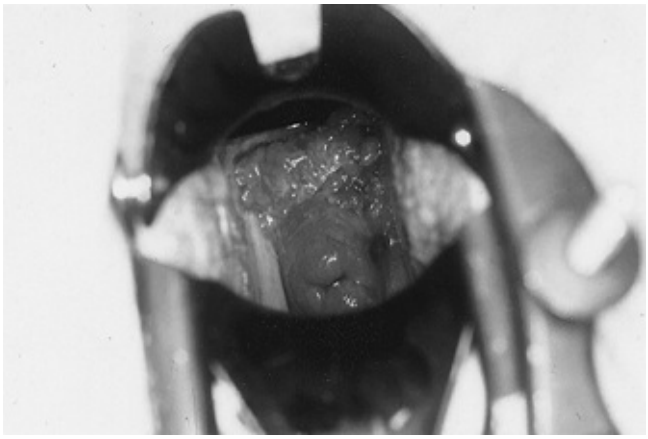

Figure 57.17 Vaginal carcinoma located in upper third of the vagina.

Historically, the prognosis for patients with vaginal cancer has been poor, with the most important predictor being the stage at time of diagnosis. A recent retrospective review by Frank and associates with 193 patients indicated that 5-year disease-specific survival in patients treated with definitive radiation therapy was 85%, 78%, and 58% for stage I, II, and III/IVa patients, respectively. The recent improvement in overall survival in patients with cervical and vulvar cancer treated with combination chemotherapy and radiation suggests a potential role in vaginal cancer; however, data specific to vaginal cancer does not exist. Recurrent disease tends to occur locally within 2 years of primary therapy. Exenterative procedures are required to adequately treat locally recurrent or persistent disease but are associated with considerable morbidity.

Clear Cell Adenocarcinoma

Clear cell adenocarcinoma of the vagina is a rare malignancy that most commonly is seen in young women whose mothers received DES during pregnancy for prevention of miscarriage (Fig. 57.18). This association was first noted in 1970, leading to removal of the drug from the U.S. market in 1971. Approximately 60% of patients with clear cell carcinoma are known to have been exposed to DES or other synthetic estrogens. The risk of developing clear cell adenocarcinoma of the cervix or vagina has been estimated at 1 in 1,000 to 1 in 1,500, with DES exposure in the first trimester conveying the greatest risk. The median age at diagnosis for DES-exposed patients is 19 years. DES-exposed daughters do not appear to have an increased risk of developing any other malignancies but do have an increased risk of cervical dysplasia. This may be due to increased surveillance or congenital abnormalities in the lower genital tract. No increased risk in squamous cancers of the cervix or vagina has been reported in DES-exposed women. Clear cell carcinoma unrelated to DES exposure is an uncommon entity seen in both premenopausal and postmenopausal women, with peaks at ages 25 and 70.

Most patients present with early-stage disease, located in the exocervix or upper third of the vagina. Therapy is typically surgical and involves radical hysterectomy with removal of the upper vagina and pelvic lymphadenectomy. While this results in sterility, it may allow ovarian preservation and improved vaginal function over treatment with radiotherapy.

is more than 90% and approximately 80% for patients with stage II disease. Favorable factors in survival include early-stage disease, older age, a tubulocystic histology, superficial invasion, small tumor diameter, and negative nodal status.

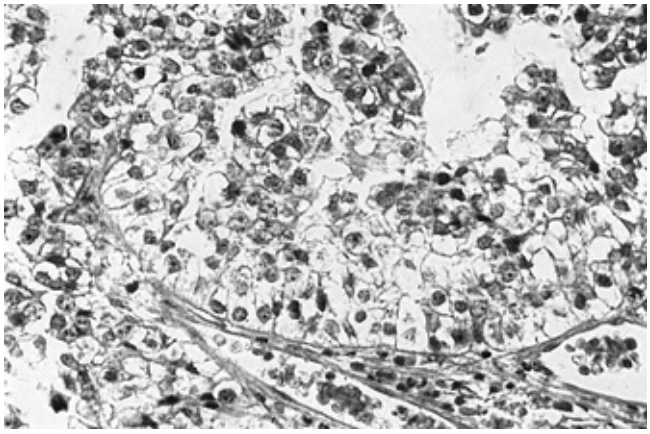

Figure 57.18 Clear cell adenocarcinoma of the vagina associated with DES exposure.

Melanoma

Melanoma is the second most common cancer of the vagina, accounting for <5% of vaginal malignancies and 0.3% of all melanomas among women. Nodular lesions are the most frequent histologic subtype. While vulvar melanoma is more common among white women, no association with race is seen for vaginal melanoma. It is a disease of older women, and overall 5-year survival is poor at only 19%.

Sarcoma Botryoides

Sarcoma botryoides, or embryonal rhabdomyosarcoma, is a rare sarcoma found in young girls. It presents with vaginal bleeding and a polypoid “grapelike” mass. Historically, this was treated with radical surgery, but now multimodality chemotherapy with VAC (vincristine, dactinomycin, and cyclophosphamide) and limited surgery can allow for a cure while preserving reproductive function. Radiotherapy may also be used in conjunction with multiagent chemotherapy.

Endodermal Sinus Tumor

Endodermal sinus tumor is an extremely rare germ cell tumor arising in the vagina. It is seen in infants and treated with combination chemotherapy, as is used for germ cell tumors of the ovary.

Lymphoma

Vaginal involvement with lymphoma may be secondary to systemic disease or may be localized to the vagina. This rare entity presents with bleeding and a vaginal mass. Primary vaginal lymphomas are typically diffuse, large B-cell type. Serum levels of lactate dehydrogenase are elevated in these patients, but preoperative diagnosis is difficult. Chloroacetate esterase or myeloperoxidase stains as well as expression of CD 20 may be useful in distinguishing these tumors.

Metastatic Disease

Although primary vaginal malignancy is quite rare, metastatic spread to the vagina is common and occurs through direct extension of vulvar, cervical, endometrial, and rectal malignancies. A thorough search for another primary site should be undertaken before concluding that a patient has a primary vaginal malignancy.

Summary Points

- The incidence of VIN is increasing, with younger patients more likely to have HPV-related lesions. The underlying risk for cancer in a field of VINIII is 3.2% to 22.0%.
- Vulvar carcinoma in older women tends to be unifocal and is associated with chronic vulvar irritation rather than HPV changes. Carcinomas in younger women tend to be multifocal, and HPV changes are seen in 90% of cases (HPV 16 is most common).
- The risk of groin node metastasis with vulvar carcinoma increases with increasing tumor size, depth of invasion, and presence of lymphovascular space involvement.
- Modifications in surgery to reduce the radical nature of vulvar and groin surgery are possible in select patients. Vulvar resection margins should be at least 1 cm. The use of sentinel node biopsy to modify groin node dissections remains investigational.
- Squamous cell carcinoma of the vagina is a rare entity that is best treated with combined external beam radiation therapy and brachytherapy.

Cervical Cancer

Robert L. Giuntoli II
Robert E. Bristow

In the 1930s, cervical cancer was the number one cause of cancer-related deaths among women in the United States. With the advent of cytologic screening, there has been a 70% reduction in deaths from cervical cancer. The American Cancer Society has estimated that in the United States in 2007 there will be 11,150 new cases of invasive carcinoma of the cervix resulting in 3,670 deaths. The average age of diagnosis for cervical cancer is 52 years, and the distribution of cases is bimodal with peaks at 35 to 39 years and 60 to 64 years. Worldwide, cervical cancer continues to be a leading cause of death due to cancer among women, with approximately 500,000 cases estimated to have occurred in 2002. Lifetime risks for cervical cancer show significant geographic variation, ranging from 0.4% in Israel to 5.3% in Cali, Colombia.

Risk Factors

Screening

Cytologic evaluation of cells obtained from the cervix and vagina was first proposed by Papanicolaou and Traut in the 1940s as a method for detecting cervical cancer and its precursors. Cervical cytology has proved to be the most efficacious and cost-effective method for cancer screening. By increasing detection of preinvasive and early invasive disease, cervical cancer screening with the Pap smear has decreased both the incidence and mortality from cervical cancer in communities with active screening programs. A single negative Pap smear may decrease the risk for cervical cancer by 45%, and nine negative smears during a lifetime decrease the risk by as much as 99%. The introduction of liquid-based cervical cytology has resulted in improved sensitivity without loss of specificity. Additionally, human papillomavirus (HPV) testing can be performed on the remaining sample in order to better triage women with early cytologic changes.

Despite the recognized benefits of cytologic screening, substantial subgroups of women in the United States do not undergo appropriate screening. One half of women with newly diagnosed invasive cervical carcinoma have never had a Pap smear, and another 10% have not had a Pap smear in the 5 years preceding diagnosis. The absence of prior regular Pap

smear screening is associated with a two- to sixfold increase in the risk of developing cervical cancer. Unscreened populations include older women, the uninsured, ethnic minorities, and women of lower socioeconomic status, particularly those in rural areas. Women over age 65 years should continue to be screened, as 25% of all cases of cervical cancer and 41% of deaths from the disease occur in women in this age group.

Race

Although the incidence of cervical cancer in the United States has declined significantly, the rates among blacks remain about twice as high as those among whites. The incidence is also approximately two times higher for Hispanic Americans and even higher for Native Americans, while most Asian American groups experience rates similar to whites. When socioeconomic differences are controlled for, the excess risk of cervical cancer among blacks is substantially reduced, from >70% to <30%. Racial differences are also apparent in survival, with 59% of blacks with cervical cancer surviving 5 years compared to 67% of whites with the disease.

Sexual and Reproductive Factors

First intercourse before 16 years of age is associated with a twofold increased risk of cervical cancer compared with that for women whose first intercourse occurred after age 20 years. Cervical cancer risk is also directly proportional to the number of lifetime sexual partners. Although difficult to separate epidemiologically, there is evidence to

indicate that both early age at first coitus and the number of lifetime sexual partners have independent effects on cervical cancer risk. Increasing parity also appears to be a separate risk factor for cervical cancer, even after controlling for socioeconomic and reproductive characteristics.

Smoking

Cigarette smoking has emerged as an important etiologic factor in squamous cell carcinoma (SCC) of the cervix. The increased risk for smokers is approximately twofold, with the highest risk observed for long-term or high-intensity smokers. Proposed mechanisms include genotoxic or immunosuppressive effects of smoke-derived nicotine and cotinine, present in high levels in the cervical mucus of smokers.

Contraceptive Use

Numerous confounding factors—time interval since last cervical smear, sexual behavior, and role of the male partner, among others—complicate the interpretation of the data on oral contraceptive use and cervical cancer. After controlling for these and other variables, it appears that long-term oral contraceptive users (≥5 years) have about a twofold increased risk of cervical cancer compared with that of nonusers. Use of barrier methods, especially those that combine both mechanical and chemical protection, have been shown to lower the risk of cervical cancer, presumably because of reduced exposure to infectious

agents.

Immunosuppression

Cell-mediated immunity appears to be a factor in the development of cervical cancer. Immunocompromised women (e.g., from renal transplantation or HIV infection) may not only be at higher risk for the disease but also demonstrate more rapid progression from preinvasive to invasive lesions and an accelerated course once invasive disease has been diagnosed. HIV-positive women with cervical cancer may have a higher recurrence risk and cancer-related death rate compared with HIV-negative control subjects.

Human Papillomavirus Infection

HPVs are members of the family Papovaviridae. They are nonenveloped virions with a double-stranded circular DNA genome of 7,800 to 7,900 base pairs contained in an icosahedral capsid. HPV infects epithelial cells of the skin and mucosal membranes. The HPV genome contains three regions. The upstream regulatory region (URR) controls production of viral proteins. The early region encodes for proteins E1, E2, E3, E4, E5, E6, and E7, which influence viral infection and replication. The late region encodes proteins L1 and L2, which are the major and minor capsid proteins, respectively. Differences in E6, E7, and L1 gene sequences of >10% constitute a distinct HPV type. Of the more than 100 types of HPV characterized, over 30 infect the anogenital tract.

Accumulated epidemiologic evidence has demonstrated HPV infection to be a necessary but insufficient factor in the development of invasive cervical cancer. Walboomers and associates found 99.7% of invasive cervical cancers to be positive by polymerase chain reaction for HPV DNA. HPV 16 and 18 account for approximately 67% of invasive cervical cancers.

Infection by HPV results in translation and transcription of the early proteins. The E6 and E7 open reading frames of the HPV genome are particularly important in the immortalization and transformation of infected cells. The protein products synthesized from the E6 and E7 open reading frames can bind to the gene products of the p53 and retinoblastoma (Rb) tumor suppressor genes, respectively. In condylomas and low-grade dysplasias, HPV DNA remains in an episomal (closed circular) form in which E6 and E7 transcription remains well regulated. Viral integration results in the overexpression of the E6 and E7 viral protein products with increased binding and inactivation of their respective tumor suppressor proteins. Removal of these inhibitory influences on cellular proliferation is thought to provide HPV-infected cells with a growth advantage, ultimately leading to neoplastic transformation. E6 and E7 are consistently expressed in HPV-associated anogenital malignancies.

HPV types are divided into three groups based on their association with neoplastic and malignant processes. Low oncogenic risk–type viruses include types 6, 11, 42, 43, and 44 and are associated with condyloma acuminatum and some cases of low-grade squamous intraepithelial lesions but rarely with invasive cancer. High oncogenic risk–type viruses include types 16, 18, 31, 45, and 56 and are commonly detected in women with high-grade

squamous intraepithelial lesions (HGSIL) and invasive cancer. HPV types 33, 35, 39, 51, and 52 can be considered as being of intermediate oncogenic risk, as they are occasionally associated with HGSIL and invasive carcinomas. The oncogenic risk of the HPV types appears to be related to the binding affinity of their E6 and E7 proteins to p53 and Rb respectively. E6 and E7 proteins from high-risk HPV bind with high affinity to p53 and Rb, respectively, whereas low-risk HPV E6 and E7 proteins bind with very low affinity.

HPV is the most common sexually transmitted disease. An estimated 75% to 80% of sexually active women will test positive at some point for HPV DNA. HPV infections are most common at the onset of sexual activity, with the majority of infections being transient. Serial testing typically demonstrates clearing of the virus. Persistent infection occurs in the minority of women, and these individuals are at highest risk for precancerous and invasive lesions. The incidence of dysplasia is approximately ten times lower than the incidence of HPV infection and reflects the transient nature of the majority of HPV infections.

Clinical Features

Presenting Symptoms

The most common symptom of cervical cancer is abnormal vaginal bleeding or discharge. Abnormal bleeding may take the form of postcoital spotting, intermenstrual bleeding, menorrhagia, or postmenopausal spotting. Chronic bleeding can be associated with fatigue or other symptoms related to anemia. Serosanguineous or yellowish vaginal discharge, frequently associated with a foul odor, may accompany an advanced or necrotic carcinoma. Pelvic pain may result from locally advanced disease or tumor necrosis. Tumor extension to the pelvic side wall may cause sciatic pain or back pain associated with urinary tract obstruction and hydronephrosis. Metastatic tumor to the iliac and paraaortic lymph nodes can extend into the lumbosacral nerve roots and present as lumbosacral back pain. Urinary or rectal symptoms (e.g., hematuria, hematochezia, fistulas) can be associated with bladder or rectal invasion by advanced-stage cervical carcinoma.

Physical Findings

Invasive carcinoma of the cervix displays a wide range of gross appearances. Early lesions may be focally indurated or ulcerated or present as a slightly elevated and granular area that bleeds readily on contact (Fig. 58.1). More advanced tumors have several types of gross appearance: exophytic, endophytic, or infiltrative. Exophytic tumors characteristically have a friable polypoid or papillary appearance. Endophytic tumors are usually ulcerated or nodular but may be clinically inapparent if located high within the endocervical canal. Such tumors frequently invade deep into the cervical stroma to produce an enlarged, hard, barrel-shaped cervix that may only be appreciated on rectovaginal pelvic examination. The infiltrative pattern of tumor growth may produce surrounding tissue necrosis and erosion of normal anatomic landmarks.

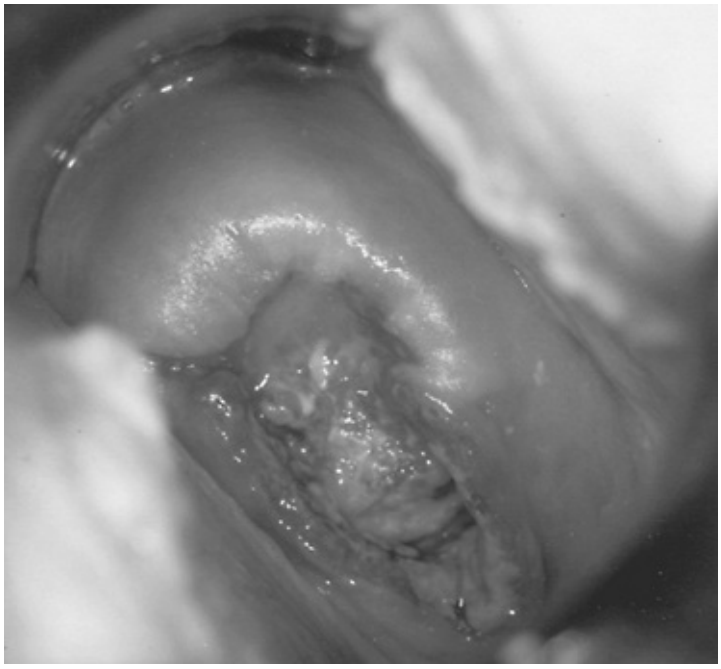

Figure 58.1 Gross appearance of SCC of the cervix. This is an ulcerative type of lesion.

Spread of Disease

Parametrial Extension

Cervical cancer generally follows an orderly pattern of disease progression. Initially, tumor cells usually spread through parametrial lymphatic vessels, expanding and replacing parametrial lymph nodes (Fig. 58.2). These individual tumor masses enlarge and become confluent, eventually replacing the normal parametrial tissue. Less commonly, the central tumor mass reaches the pelvic sidewall by direct contiguous extension through the cardinal (Mackenrodt) ligament. Significant involvement of the medial portion of this ligament may result in ureteral obstruction and hydronephrosis.

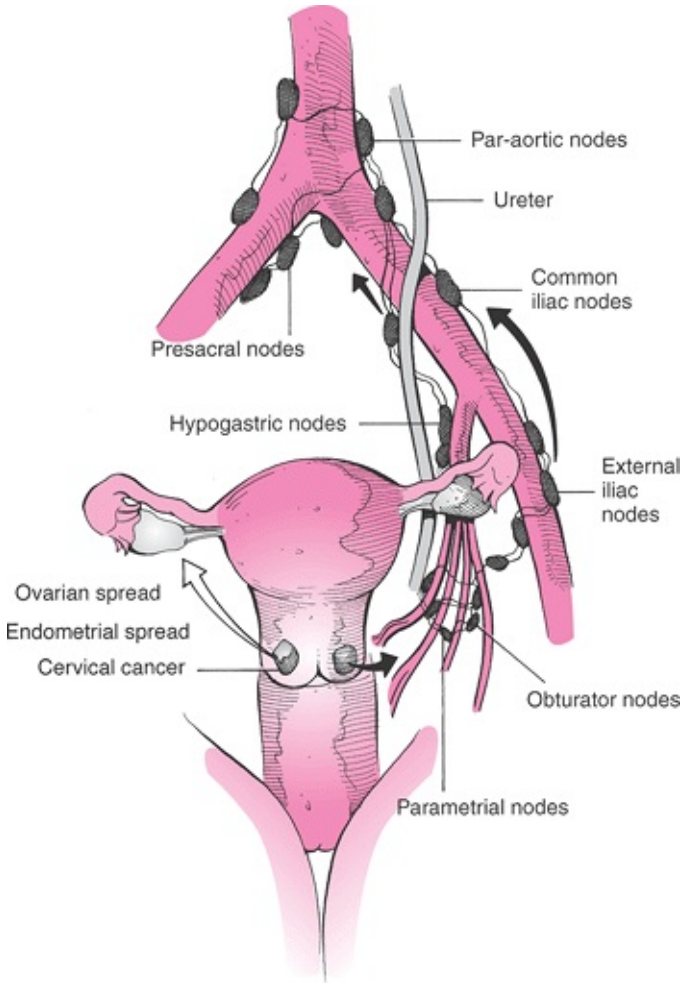

Figure 58.2 Anatomic pathways of spread in invasive cervical carcinoma.

Lymph Node Involvement

Pelvic lymph nodes are usually the first site of embolic lymphatic spread of cervical cancer. The lymph node groups most commonly involved are the obturator, external iliac, and hypogastric (Fig. 58.2). Isolated, positive common iliac nodes have been reported and these nodes should be included in a pelvic lymphadenectomy. The inferior gluteal and sacral lymph nodes are less frequently involved. Secondary nodal involvement (i.e., paraaortic) seldom occurs in the absence of pelvic nodal disease. Rarely, retrograde lymphatic embolization may occur to the inguinal lymph nodes. Patients with locally advanced pelvic disease may have detectable metastatic spread to the scalene nodes. Consequently, careful clinical assessment of the groin and supraclavicular fossa areas should be included as part of the physical examination.

Vaginal Extension

When the primary tumor has extended beyond the confines of the cervix, the upper vagina is frequently involved (50% of cases). Anterior extension through the vesicovaginal septum is most common, often obliterating the dissection plane between the bladder and

underlying cervical tumor, making surgical therapy difficult or impossible. Posteriorly, a deep peritoneal cul-de-sac (pouch of Douglas) can represent an anatomic barrier to direct tumor spread from the cervix and vagina to the rectum.

Bladder and Rectal Involvement

In the absence of lateral parametrial disease, anterior and posterior spread of cervical cancer to the bladder and rectum is uncommon. Approximately 20% of patients with tumor extending to the pelvic sidewall will have biopsy-proven bladder invasion.

Endometrial Involvement

The endometrium is involved in 2% to 10% of cervical cancer cases treated with surgery, although the overall incidence (including nonsurgical cases) is unknown. Although endometrial extension does not alter a patient's stage of disease, it has been associated with decreased survival and a higher incidence of distant metastases.

Ovarian Metastasis

Rarely, ovarian involvement with cervical cancer occurs through the lymphatic connections between the uterus and adnexal structures. In patients undergoing surgical treatment for early-stage disease, ovarian metastasis is present in <1% of SCCs and slightly >1% of adenocarcinomas. The true incidence of ovarian involvement with advanced-stage tumors is unknown, as pathologic evaluation of the adnexae is not commonly performed in such cases.

Hematogenous Spread

Hematogenous spread of cervical cancer is uncommon, particularly at the time of initial diagnosis. However, when blood-borne metastases do occur, the lung, liver, and bone are the sites most frequently involved.

Diagnosis and Staging

Diagnosis and Evaluation of Disease Extent

Pathologic documentation of invasive disease should always be obtained prior to initiating therapy for cervical cancer. Cervical cancer is one of the two gynecologic malignancies (vaginal cancer being the other) that still uses a clinically based staging system, which facilitates comparison of results between institutions irrespective of the availability of diagnostic technological resources. The International Federation of Gynecology and Obstetrics (FIGO) staging system used for cervical carcinoma is based on clinical evaluation (visual inspection, palpation, colposcopy); radiographic examination of the chest, kidneys, and skeleton; and endocervical curettage and biopsies (conization or incisional biopsies). Staging procedures allowed by FIGO convention are shown in Table 58.1. Lymphangiograms, arteriograms, computed tomography (CT) scans, magnetic resonance imaging (MRI), and laparoscopy or laparotomy should not be used for clinical staging. However, information

from such additional studies and procedures may be used to modify the treatment approach.

In 1995, FIGO revised the clinical staging system of cervical carcinoma (Table 58.2). Stage I disease includes those neoplasms that are clinically confined to the cervix. In the current staging classification, stage IA tumors are those that are diagnosed by microscopic evaluation of a conization specimen (microinvasive carcinoma). Stage IA1 is defined as a tumor with stromal invasion no >3 mm in depth

beneath the basement membrane and no >7 mm wide. Stage IA2 tumors have stromal invasion >3 mm but no >5 mm deep and are no >7 mm wide. This division in the definition of microinvasive disease reflects data indicating that patients with <3 mm of invasion are at very low risk of metastatic disease and may be treated more conservatively. All grossly visible lesions should technically be classified as stage IB. The 1995 staging system divides stage IB lesions into stage IB1 (no >4 cm in maximal diameter) and stage IB2 (>4 cm in maximal diameter), reflecting the prognostic importance of tumor volume for macroscopic lesions limited to the cervix.

TABLE 58.1 Staging Procedures for Cervical Cancer

Physical examination	Examination under anesthesia recommended
Radiologic studies	Chest x-ray Intravenous pyelogram Barium enema Skeletal x-ray
Procedures	Colposcopy Cervical biopsy Conization Endocervical curettage Cystoscopy Proctoscopy
Optional studies[a]	CT Lymphangiography Ultrasonography MRI Radionucleotide scanning Laparoscopy/Laparotomy

[a]Not allowed for staging purposes by FIGO.

TABLE 58.2 International Federation of Gynecology and Obstetrics Staging of Cervical Carcinoma

Stage	Clinical Features
0	Carcinoma in situ, intraepithelial carcinoma
I	Carcinoma is strictly confined to the cervix
IA	Invasive cancer identified only microscopically. All gross lesions even with superficial invasion are stage IB cancers. Invasion is limited to measured stromal invasion = 5 mm deep and <7 mm wide.
IA1	Measured invasion of stroma = 3 mm deep and <7 mm wide
IA2	Measured invasion of stroma >3 mm deep but = 5 mm deep and <7 mm wide
IB	Clinical lesions confined to the cervix or preclinical lesions greater than stage IA
IB1	Clinical lesions = 4 cm in size
IB2	Clinical lesions >4 cm in size
II	Carcinoma extends beyond the cervix but has not extended to the pelvic wall. Carcinoma involves the vagina but not as far as the lower third.
IIA	No obvious parametrial involvement

IIB	Obvious parametrial involvement
III	Carcinoma has extended to the pelvic wall. On rectal examination, there is no cancerfree space between the tumor and the pelvic wall. The tumor involves the lower third of the vagina. All cases of hydronephrosis or nonfunctioning kidney are included unless known to be due to another cause.
IIIA	No extension to the pelvic wall
IIIB	Extension to the pelvic wall, hydronephrosis, or nonfunctioning kidney
IV	Carcinoma has extended beyond the true pelvis or has clinically involved the mucosa of the bladder or rectum. Bullous edema does permit a case to be allocated to stage IV.
IVA	Spread of growth to adjacent organs
IVB	Spread to distant organs

Examination under anesthesia is recommended for accurate staging. It is important to palpate the entire vagina to determine whether disease is limited to the cervix (IB), extends to the upper two thirds of the vagina (IIA), or also involves the lower third of the vagina (IIIA) (Fig. 58.3). Tumor extension into the parametrial tissue (IIB) or to the pelvic sidewall (IIIB) is best appreciated on rectovaginal examination. It is impossible at clinical examination to decide whether a smooth and indurated parametrium is truly cancerous or only inflammatory, and the case should be considered stage III only if the parametrium is nodular on the pelvic wall or if the growth itself extends to the pelvic wall. Biopsy-proven invasion of bladder or rectal mucosa by cystoscopy or proctoscopy is required for a diagnosis of stage IVA disease. In the United States, the distribution of patients by clinical stage is stage I, 38%; stage II, 32%; stage III, 26%; and stage IV, 4%.

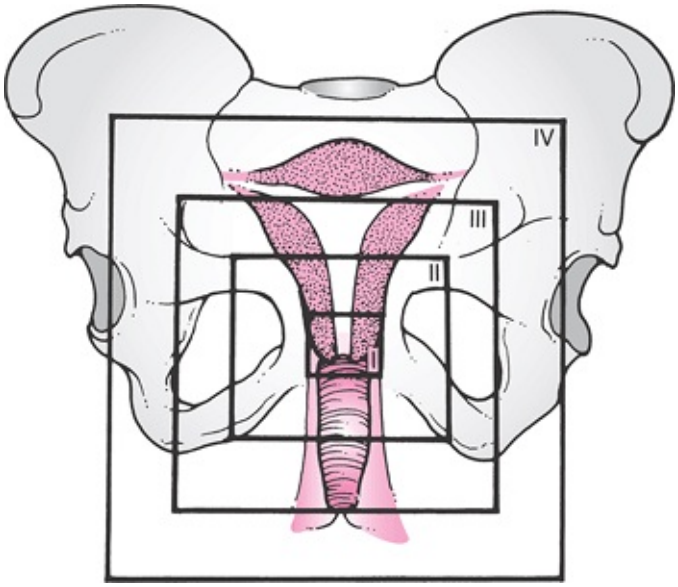

Figure 58.3 Clinical stages of carcinoma of the cervix. In stage I, only the cervix is involved. In stage II, the parametrium or upper two thirds of the vagina is involved. In stage III, the malignancy extends to the pelvic sidewall or involves the lower third of the vagina. Stage IV reflects involvement of the bladder or rectal mucosa (stage IVA) or distant metastasis (stage IVB).

When there is doubt concerning which stage a tumor should be assigned, the earlier stage is mandatory. Once a clinical stage has been determined and treatment initiated, subsequent findings on either extended clinical staging (CT, MRI, etc.) or surgical exploration should not alter the assigned stage. Assignment of a more advanced stage during treatment will result in an apparent but deceptive improvement in the results of treatment for earlier stage disease.

Surgical or Radiographic Staging

The current FIGO staging classification for cervical cancer is based on pretreatment clinical findings. Only the subclassification of stage I (IA1, IA2) requires pathologic assessment. Although nonapproved studies or procedures do not change FIGO clinical staging, the results can impact prognosis or treatment. Discrepancies between clinical staging and surgicopathologic findings range from 17.3% to 38.5% in patients with clinical stage I disease to 42.9% to 89.5% in patients with stage III disease. This has led some authors to emphasize surgical staging of cervical carcinoma to identify occult tumor spread and determine the presence

of extrapelvic disease so that adjunctive or extended-field radiation therapy may be offered. Transperitoneal surgical staging procedures (e.g., laparotomy), when followed by abdominopelvic irradiation, are associated with appreciable complications, particularly enteric morbidity. The extraperitoneal surgical approach can be performed through a paraumbilical or paramedian incision or laparoscopically and allows accurate assessment of pelvic and paraaortic nodal status. Using this approach, an incision in the peritoneum is

avoided and adhesion formation is minimized. It is associated with few complications and does not delay institution of radiation therapy. Others have advocated imaging studies to evaluate lymphatic involvement. Combined positron emission tomography–CT has been associated with a sensitivity of 73% in identifying stage I cervical cancer patients with positive lymph nodes. This combined modality may also be utilized in the restaging of patients with a suspected cervical cancer recurrence.

Prognostic Variables

Tumor Characteristics

Clinical stage of disease at the time of presentation is the most important determinant of subsequent survival, regardless of treatment modality. Five-year survival declines as FIGO stage at diagnosis increases: stage IA, 97%; stage IB, 70% to 85%; stage II, 60% to 70%; stage III, 30% to 45%; stage IV, 12% to 18%. Prognostic variables directly related to surgicopathologic tumor characteristics and their effect on survival were compiled by Kosary for the National Cancer Institutes Surveillance, Epidemiology, and End Results (SEER) program for the period of 1973 through 1987. This study included 17,119 cases of invasive cervical cancer and found that FIGO stage, tumor histology, histologic grade, and lymph node status are all independent prognostic variables relating to survival.

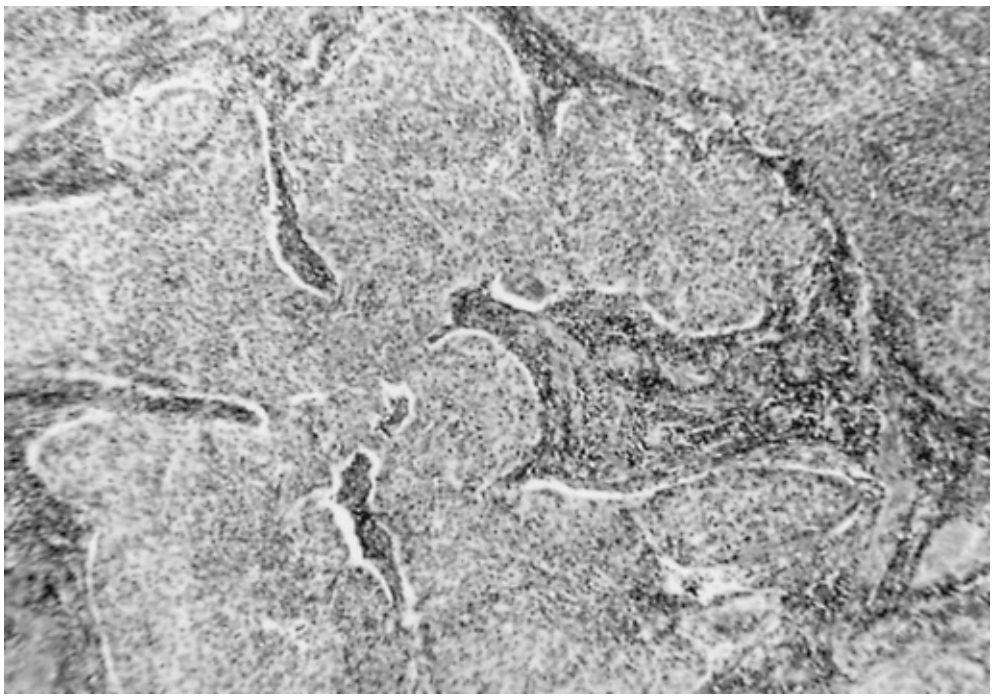

Figure 58.4 Moderately differentiated SCC of the cervix.

SCCs accounted for 74.9% of cases in the SEER database and can be categorized according to the degree of histologic tumor differentiation. Well-differentiated tumors account for about 5% of cervical SCCs and are composed of sheets and cords of cells with abundant acidophilic cytoplasm, clearly visible intercellular bridges, and production of variable

amounts of keratin. Moderately differentiated tumors are the most common variety, with 85% of SCCs falling in this category (Fig. 58.4). These tumors are characterized by masses and cords of spindle-shaped squamous cells with elongated nuclei and scant cytoplasm and more frequent mitoses. Poorly differentiated tumors constitute approximately 10% of cervical SCCs and demonstrate numerous mitoses and cells with closely crowded nuclei and scant cytoplasm. In the SEER database, 5-year survival for patients with well-differentiated tumors was 74.5%; for those with moderately differentiated tumors, it was 63.7%; and it fell to 51.4% for those patients with poorly differentiated carcinomas. Approximately 15% to 20% of cervical cancer cases are adenocarcinomas. After controlling for known prognostic variables, the SEER study found no difference in overall survival between patients with cervical SCC and adenocarcinoma. However, adenosquamous histology was associated with decreased survival. Survival is also correlated with depth of tumor invasion into the cervical stroma and overall tumor volume.

Among surgically treated patients, survival is directly related to the number and location of lymph node metastasis. The frequency of positive lymph nodes increases with the stage of disease (Table 58.3). For all stages of disease, when both pelvic and paraaortic lymph nodes are negative, the 5-year survival rate is 75.2%. Survival decreases to 45.6% with positive pelvic nodes, and the risk of recurrence is related to the number of nodes involved. The recurrence rate is 35% with one positive pelvic lymph node, 59% with two or three positive nodes, and 69% with metastases to more than three pelvic lymph nodes. When paraaortic nodes are involved, the 5-year survival rate ranges from 15% to 45%.

TABLE 58.3 Incidence of Pelvic and Paraaortic Lymph Node Metastasis by International Federation of Gynecology and Obstetrics Stage of Cervical Carcinoma

Stage	n	Positive Pelvic Nodes (%)	Positive Paraaortic Nodes (%)
IA1	179	0.5	0.0
IA2	178	6.2	<1.0
IB	1,926	15.9	2.2
IIA	110	24.5	11.0
IIB	324	31.4	19.0

III	125	44.8	30.0
IVA	23	55.0	40.0

Host Factors

Multiple patient variables have been evaluated to determine influence outcome. Several hematologic parameters have been associated with cervical cancer survival outcome. The incidence of pretreatment anemia (hemoglobin of 12 g/dL or less) increases with advancing stage of disease, occurring in 25%, 33%, and 45% of patients with stages I, II, and III disease, respectively. Anemia is associated with a higher incidence of pelvic recurrences and decreased survival, primarily due to more frequent radiation therapy failures. Tumor hypoxia is the proposed mechanism of radio resistance in the presence of anemia. Another prognostic hematologic parameter is thrombocytosis (>400,000/mm^3), which has been associated with decreased survival after controlling for cell type, stage, and age. Whether or not patient age at diagnosis of cervical cancer is a significant and independent predictor of clinical outcome remains controversial with conflicting data from epidemiologic studies. Coexistent medical conditions may affect the success of treatment. Diabetes and hypertension are frequently associated with significant vascular disease and potentially contribute to both tumor hypoxia and decreased blood supply to normal pelvic tissues. These conditions result in a higher incidence of treatment complications and pelvic tumor recurrence as well as decreased survival.

Treatment Modalities

Surgery and radiation therapy are the two primary therapeutic modalities most commonly used to treat invasive cervical carcinoma. In general, primary surgical management is limited to patients with stage I and IIA disease, while radiation therapy can be applied to patients with all stages of disease. For patients with early-stage disease, multiple factors should be considered in selecting the most appropriate treatment program. Age is not a contraindication to surgical management, provided the patient does not have significant medical comorbidity. Young patients desiring ovarian preservation and sexually active patients are preferentially managed surgically. Other reasons for the selection of radical surgery over radiation include concomitant inflammatory bowel disease, previous radiation for other disease, and the presence of a coexistent adnexal neoplasm.

Primary Surgery

Surgery provides the opportunity to perform a thorough pelvic and abdominal exploration, which can identify patients with a disparity between the clinical and surgicopathologic stages. Such patients can then be offered an individualized treatment plan based on their precise disease status. The primary surgical management of cervical cancer generally consists of hysterectomy. However, for patients with stage IA1 lesions who desire fertility

preservation, cervical conization with clear surgical margins is acceptable treatment. Yet, the safety and efficacy of surgery to preserve fertility (e.g., radical trachelectomy) for patients with larger stage I lesions has yet to be fully evaluated. There are five distinct variations or classes of hysterectomy used in the treatment of cervical cancer.

Classes of Hysterectomy

Class I

A class I hysterectomy refers to the standard extrafascial total abdominal hysterectomy. This procedure ensures complete removal of the cervix with minimal disruption to surrounding structures and is appropriate treatment for stage IA1 disease.

Class II

A class II hysterectomy is also referred to as a modified radical hysterectomy (Figs. 58.5,58.6,58.7). This procedure involves dissection of the ureters from the parametrial and paracervical tissues down to the ureterovesical junction. This permits removal of all parametrial tissue medial to the ureters as well as the medial half of the uterosacral ligament and proximal 1 to 2 cm of vagina. This operation is usually performed in conjunction with pelvic lymphadenectomy.

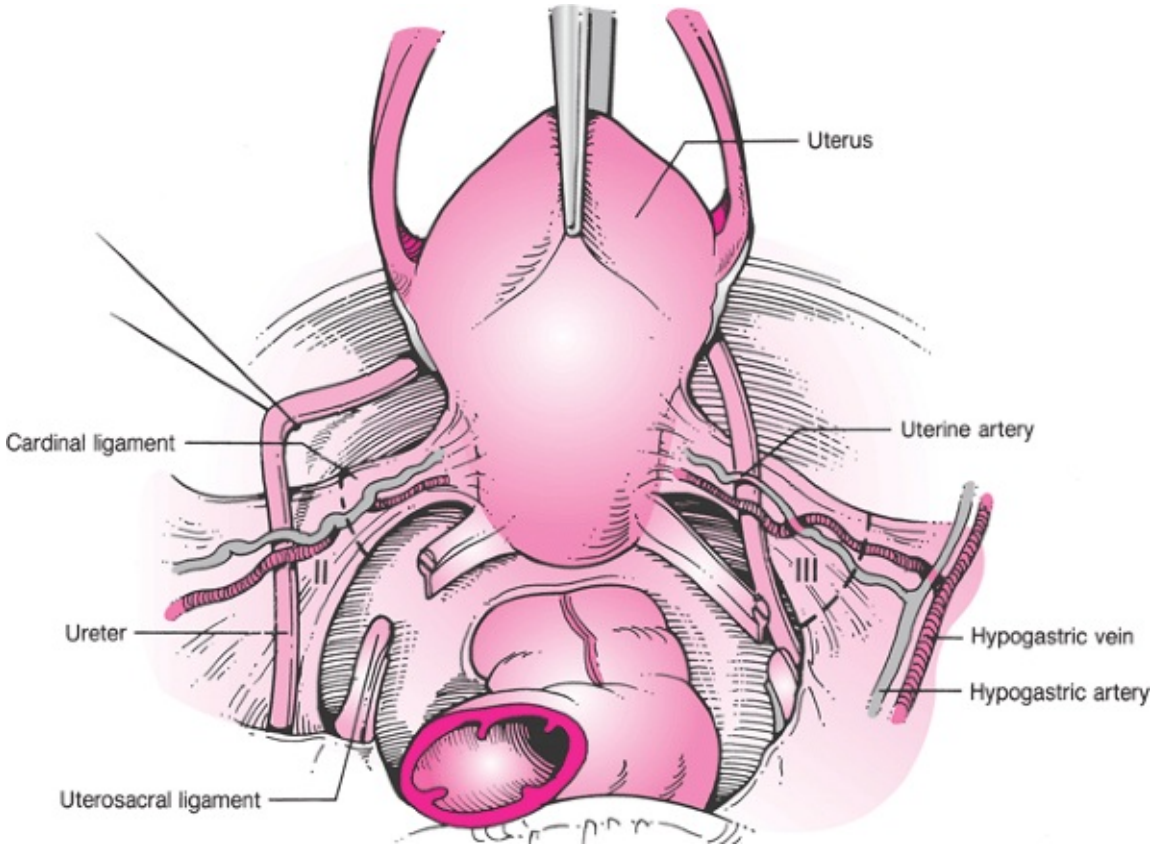

Figure 58.5 Anatomic dissection of radical hysterectomy. The cardinal ligaments are transected (*dashed line*) at the level of the ureter (class II) or at the pelvic side wall

(class III).

Class III

In a class III or radical abdominal hysterectomy, the ureters are completely dissected from within the paracervical tunnel, and the bladder and rectum are extensively mobilized (Figs. 58.5,58.6,58.7). Establishing the paravesical and pararectal spaces facilitates removal of all the parametrial tissue out to the pelvic sidewall, complete resection of the uterosacral ligaments, and excision of the upper one third to one half of the vagina. Bilateral pelvic lymphadenectomy is performed with this procedure, removing all lymph-bearing tissue between the midcommon iliac vessels distally to the circumflex iliac vessels and from within the obturator fossa ventral to the obturator nerve.

Class IV/Class V

A class IV or extended radical hysterectomy includes removal of the superior vesical artery, periureteral tissue, and up to three fourths of the vagina. In a class V or partial exenteration operation, the distal ureters and a portion of the bladder are resected. Class IV and class V procedures are rarely performed today because most patients with disease extensive enough to require these operations can be more adequately treated with primary radiation therapy.

Complications of Radical Abdominal Hysterectomy

Modern surgical techniques and anesthesia have reduced the operative mortality associated with radical hysterectomy to 0.6%. Potentially fatal pulmonary embolism occurs in 1% to 2% of patients. Urinary and bowel fistula formation and incisional complications related to surgical treatment tend to occur early in the postoperative period and are usually amenable to surgical repair. Ureterovaginal and vesicovaginal fistulas occur in 2.0% and 0.9% of patients, respectively. The most commonly observed complication after radical hysterectomy is urinary dysfunction resulting from partial denervation of the detrusor muscle during excision of the paracervical and paravaginal tissue. Radical hysterectomy results in vaginal shortening; however, with sexual activity, gradual lengthening will occur. Pelvic lymphocyst formation occurs in 2.0% to 6.7% of patients following radical hysterectomy and pelvic lymphadenectomy. The incidence is somewhat lower when the retroperitoneal spaces are left open. Most lymphocysts are asymptomatic and do not require intervention, but lymphocysts may occasionally produce pelvic pain, ureteral obstruction, or partial venous obstruction with thrombosis.

Primary Radiation Therapy

Radiation therapy can be used for all stages of disease and for most patients regardless of age, body habitus, or coexisting medical conditions. The recommended nomenclature for measurement of absorbed radiation dose is the gray

(Gy); 1 Gy is equal to 1 joule (J) of energy absorbed per kilogram of substance. Radiation dose is also commonly expressed as centigray (cGy), with 100 cGy equal to 1Gy. By convention, the irradiation dose used in the treatment of cervical cancer is described relative to two anatomic landmarks within the pelvis. Point A is defined as a point 2 cm above the lateral vaginal fornix and 2 cm lateral to the uterine canal corresponding to the paracervical triangle. Point B reflects the dose delivered to the pelvic sidewall and is located 3 cm lateral to point A.

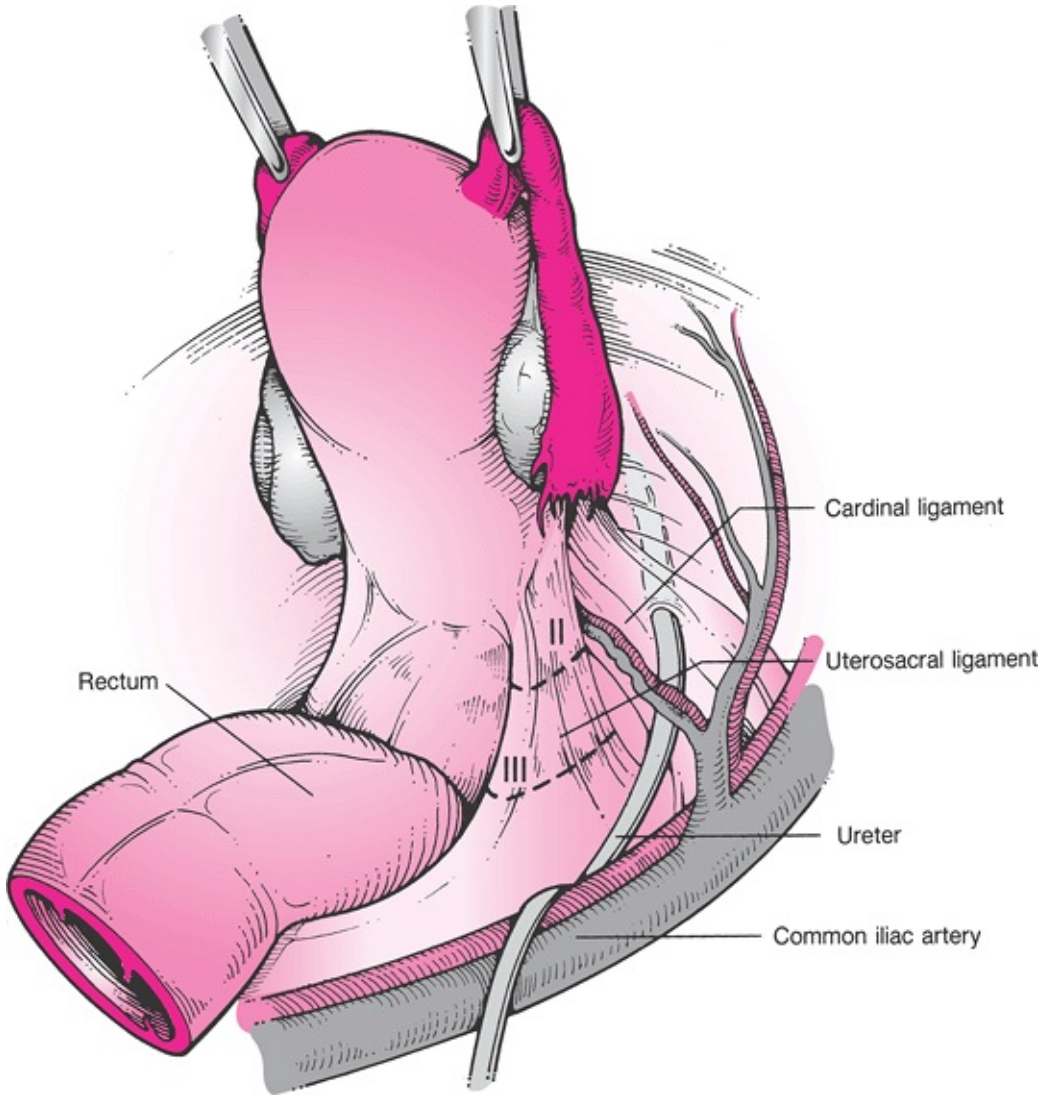

Figure 58.6 Anatomic dissection of radical hysterectomy. The uterosacral ligaments are divided at the sacrum (class III) or midway between the sacrum and the uterus (class II).

The technical treatment modalities used in modern radiation therapy for cervical cancer consist of a combination of external irradiation and local irradiation. External irradiation is delivered from a source remote from the body (e.g., linear accelerator, cobalt-60) and is used to treat the regional lymph nodes, decrease tumor volume, and reduce the anatomic distortion produced by larger tumor masses. External beam irradiation treatment for cervical cancer is usually delivered by using a four-field technique (anterior, posterior, and

lateral fields). The precise treatment volume is determined according to individual patient anatomy but usually measures 15 cm × 15 cm to 18 cm × 18 cm. The pelvic radiation field extends 1 to 2 cm beyond the lateral borders of the bony pelvis and inferiorly beyond the border of the obturator foramen. The cephalad margin may be extended to 18 cm in length to treat the common iliac lymph nodes or even higher if paraaortic lymph node coverage is necessary. A typical external beam radiation treatment portal for cervical cancer is shown in Figure 58.8.

Brachytherapy refers to a radiation source in direct proximity to the target tissue and may be delivered by using a variety of intracavitary applicator devices, but the intrauterine tandem and vaginal colpostats are used most frequently for primary treatment (Fig. 58.9). Once adequate placement is assured, the device is after-loaded with radioactive isotope (e.g., radium-226, cesium-137, iridium-192). Alternatively, vaginal cylinders or interstitial needle implants may be used to deliver local radiation therapy, depending on patient anatomy and tumor distribution. While cesium-137 is typically utilized for low dose rate (LDR) brachytherapy, iridium-192 is normally used for high dose rate (HDR) brachytherapy. Several advantages are associated with HDR brachytherapy. Treatment time is decreased, radiation exposure to personnel is minimized, and therapy can be given as an outpatient. Outcomes associated with HDR and LDR appear to be equivalent.

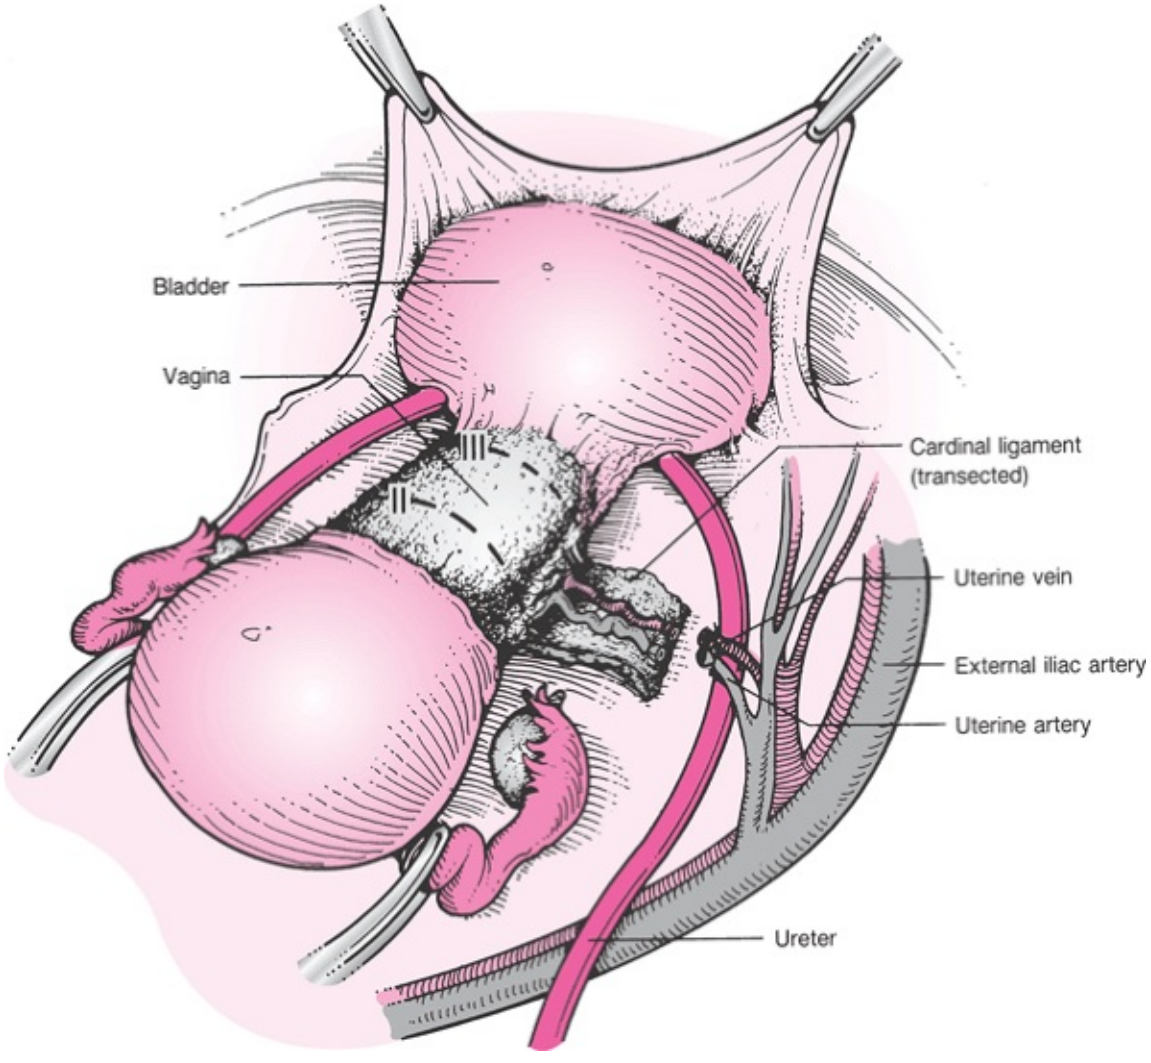

Figure 58.7 Anatomic dissection of radical hysterectomy. In a class II radical hysterectomy, the upper 1 to 2 cm of vagina is excised. In class III radical hysterectomy, the proximal one third to one half of the vagina is removed.

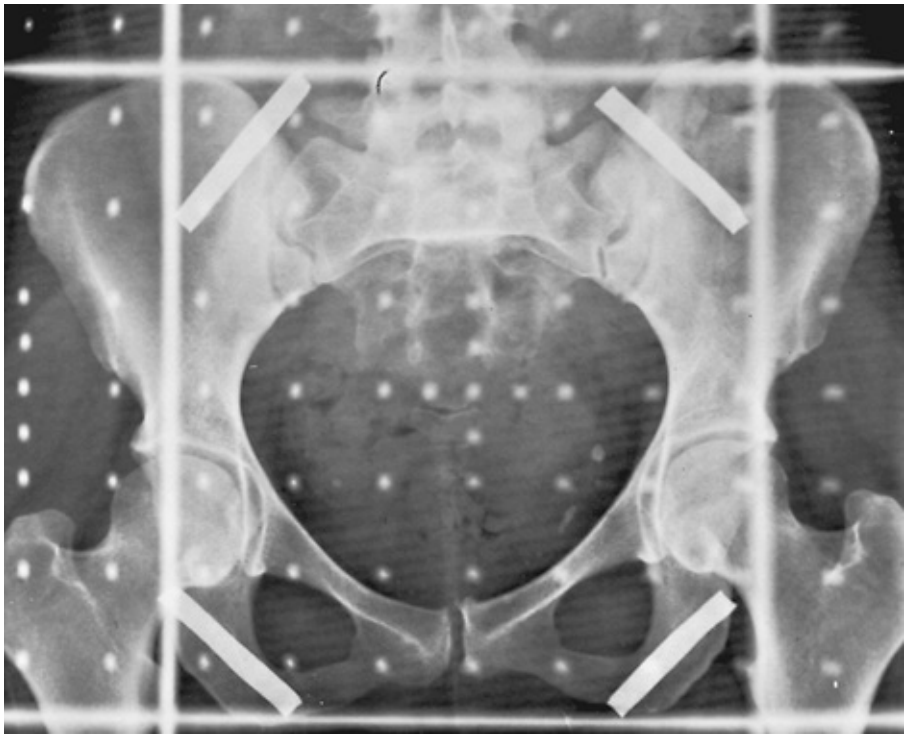

Figure 58.8 Whole pelvis radiation treatment field for cervical cancer. In this case, the lower margin of the treatment field extends below the pubic symphysis to provide coverage of the proximal vagina. Lead tapes (*white stripes*) are used for excluding the corners of a square field, reducing the total irradiated volume by approximately 10%.

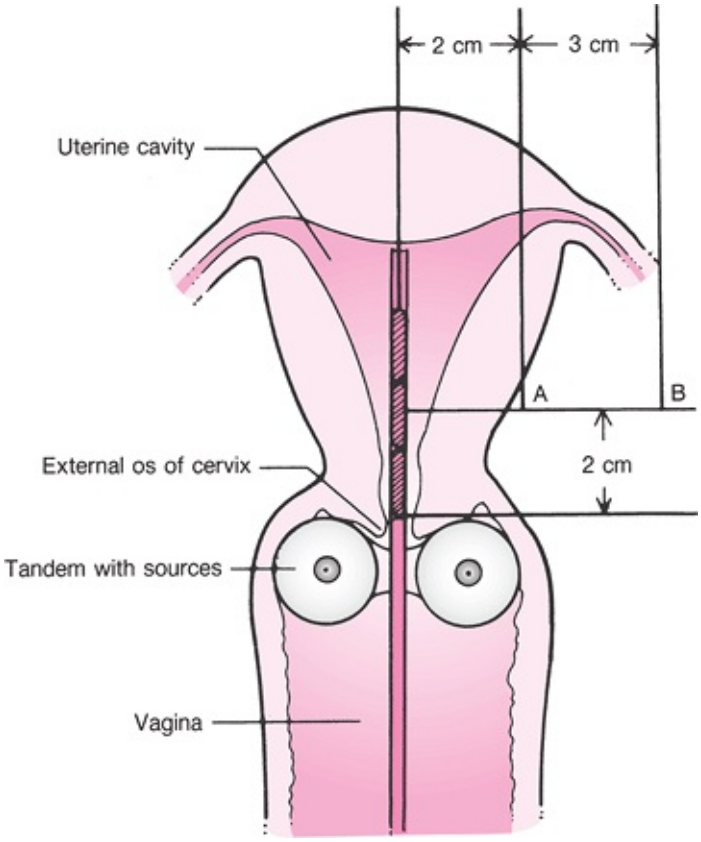

Figure 58.9 Diagram of a typical intrauterine tandem and vaginal colpostat brachytherapy placement for cervical cancer showing the anatomic landmarks point A and point B.

The total dose delivered to point A is determined by the volume of disease to be treated and ranges from 6,500 to 7,000 cGy for small stage IB lesions to 8,500 to 9,000 cGy for bulky stage IIB and stage III lesions. For patients with documented paraaortic node metastasis, or those at high risk, 4,500 cGy of extended field irradiation is delivered to the paraaortic region. Cure rates with irradiation therapy are stage dependent, with 5-year survival rates averaging 70% to 85% for stage I, 60% for stage II, 45% for stage III, and 18% to 20% for stage IV disease.

Concurrent Chemotherapy and Radiation Therapy

In 1999, five multi-institutional, randomized controlled trials reported a survival advantage associated with the concurrent administration of chemotherapy and radiation therapy in the management of cervical cancer. Although these trials differed in their inclusion criteria, chemotherapy schedules, and prescribed radiation treatment, all demonstrated a similar improvement in progressionfree survival (10% to 27%) and overall survival (10% to 17%). Many centers now administer concurrent treatment with chemotherapy and radiation therapy as standard practice for patients with locally advanced cervical cancer. Cisplatin (Platinol), 5-fluorouracil (Adrucil), and hydroxyurea (Hydrea) have been the chemotherapeutic agents most extensively studied as part of a combined modality treatment program. A commonly used contemporary regimen is cisplatin 40 mg/m^2 administered intravenously on a weekly basis during the radiation treatment interval.

Complications of Radiation Therapy

Radiation therapy is associated with both acute and chronic complications. Perforation of the uterus may occur at the time of intracavitary insertion and, if unrecognized, may result in significant blood loss, radiation damage, and peritonitis. Appropriate management consists of removal of the implant and broad-spectrum antibiotic coverage if signs of infection are present. Vaginal fibrosis and stenosis is the most common chronic complication of radiation therapy for cervical cancer and is seen in up to 70% of cases. Ovarian function is lost in virtually all patients undergoing radiation therapy to the pelvis. Proctosigmoiditis occurs in up to 8% of patients undergoing radiation therapy for cervical cancer. Symptoms include abdominal pain, diarrhea, and nausea. An antispasmodic agent, a low-gluten and low-lactose diet, and steroid enemas may be useful; however, severe cases may require hyperalimentation and a diverting colostomy. Hemorrhagic cystitis is seen in approximately 3% of patients undergoing radiation therapy for cervical cancer. In contrast to surgical therapy, fistulous complications associated with radiation therapy tend to occur late and are more difficult to repair secondary to poorly vascularized tissues from radiation fibrosis and vasculitis. Rectovaginal and vesicovaginal fistulas each occur in approximately 1% of cervical cancer patients treated with irradiation. In such cases, biopsy specimens should be obtained from the edge of the fistula to rule out recurrent cancer. Diversion of the fecal (colostomy) or urinary (percutaneous nephrostomy) stream is usually required to allow adequate healing (3 to 6 months) prior to surgical repair. Two percent of patients experience small bowel obstruction as a consequence of radiation therapy; it is more common in those patients with vascular disease or in those with a history of previous abdominal surgery. The most common site of small bowel obstruction is the terminal ileum, which is relatively fixed within the radiation field by the cecum. Complete small bowel obstruction or cases recalcitrant to conservative management require surgical intervention.

Chemotherapy

Chemotherapy as the sole mode of treating cervical cancer is indicated for patients with extrapelvic metastases (stage IVB) or those with recurrent disease who are not candidates for radiation therapy or exenterative surgery. Cisplatin has been the most extensively studied agent and has demonstrated the most consistent clinical response rates. Complete clinical responses have been observed in 24% of patients, with an additional 16% demonstrating a partial response. Unfortunately, in most series, responses to cisplatin are short lived (3 to 6 months). Other agents demonstrating at least partial activity against cervical cancer include

---

carboplatin (Paraplatin), topotecan (Hycamtin), ifosfamide (Ifex), doxorubicin hydrochloride (Adriamycin), paclitaxel (Taxol), vinblastine sulfate (Velban), vincristine sulfate (Oncovin), 5-fluorouracil, methotrexate, and altretamine (Hexalen). Several multiagent chemotherapeutic regimens have been compared with single-agent cisplatin. Only the combination of topotecan and cisplatin has demonstrated a significant improvement in overall survival compared with that found with single-agent cisplatin

(9.4vs. 6.5 months).

General Management by Stage

Stage IA1

The 5-year survival rate of stage IA1 patients approaches 100% with primary surgical therapy (Fig. 58.10). Extrafascial hysterectomy is adequate treatment for this group of patients. Conization may be used selectively if preservation of fertility is desired, provided the surgical margins are free of disease. In the absence of lymph-vascular invasion, the incidence of pelvic lymph node metastasis is 0.3%, and lymphadenectomy is not indicated. In the presence of lymph-vascular involvement, the risk of pelvic node metastasis increases to 2.6%. Pelvic lymphadenectomy and extrafascial hysterectomy should be performed in these cases. In patients who are medically inoperable, stage IA1 carcinoma can be effectively treated with intracavitary radiation.

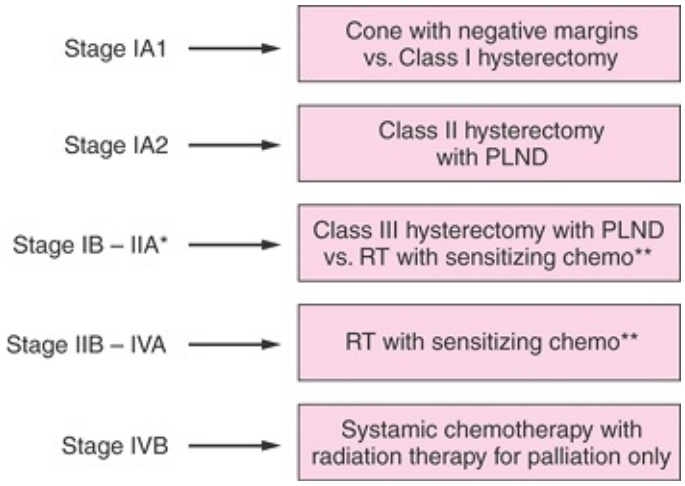

Figure 58.10 Management algorithm for carcinoma of the cervix. (PLND, pelvic lymph node dissection; RT, radiation therapy; Chemo, chemotherapy.) (*For bulky tumors >4 cm, treatment can include radiation therapy with sensitizing chemotherapy, class III hysterectomy with consideration of postoperative radiation therapy with sensitizing chemotherapy, and neoadjuvant chemotherapy with subsequent class III hysterectomy followed by possible postoperative radiation therapy with sensitizing chemotherapy. **Radiation therapy should be administered with sensitizing chemotherapy. Prior to proceeding with radiation therapy, consider surgical staging or CT scan with resection of enlarged lymph nodes [>1.5 cm].)

Stage IA2

Microinvasive carcinoma with stromal invasion of 3.1 to 5.0 mm is associated with positive pelvic lymph nodes in 6.2% of patients. The preferred treatment for these lesions is modified radical (class II) hysterectomy with pelvic lymphadenectomy. Radiation therapy is

equally effective from a survival standpoint but may carry a greater risk of posttreatment morbidity compared with risk from modified radical hysterectomy.

Stages IB1, IB2, and IIA

Both radical surgery and radiation therapy are equally effective in treating stages IB and IIA carcinoma of the cervix. Numerous uncontrolled studies support the merits of each modality, with no significant differences in pelvic tumor control or overall survival. Zander and colleagues reported on 1,092 patients with stages IB and II cervical cancer treated with radical (class III) hysterectomy and pelvic lymphadenectomy. Five-year survival rates were 84.5% for stage IB and 71.1% for stage II disease. Similar survival rates are obtained with primary radiation therapy. In one series, Perez and associates reported 5-year survival rates of 85% for 312 patients with stage IB disease and 70% for 98 patients with stage IIA disease treated with primary radiation therapy.

Therapy should be individualized for patients with bulky stage I (IB2) tumors. Treatment options include (a) radiation therapy with sensitizing chemotherapy, (b)·· radical hysterectomy with consideration of postoperative radiation therapy with sensitizing chemotherapy, and (c) neoadjuvant chemotherapy with subsequent radical hysterectomy followed by possible postoperative radiation therapy with sensitizing chemotherapy. Often, the development of a treatment plan is significantly influenced by patient and physician preference.

Primary chemoradiation is often advocated for the treatment of stage IB2 cervical cancer. Successful delivery of radiation, however, becomes more challenging as tumor size increases. This is reflected in a central failure rate as high as 17.5% in patients with cervical lesions >6 cm treated with radiation alone and in lower survival rates for larger stage IB2 tumors. For situation involving larger stage IB2 tumors, a “completion” extrafascial hysterectomy is frequently performed following radiation therapy.

While many clinicians limit the use of radical hysterectomy to patients with small stage IB (<3 to 4 cm) or stage IIA lesions, there is evidence that acceptable survival rates can be obtained with primary surgical treatment in patients with bulky disease confined to the cervix. Five-year survival rates range from 73.6% to 82.0% after radical hysterectomy and pelvic lymphadenectomy for cervical lesions >4 cm. Survival decreases to 66% at 5 years for lesions >6 cm.

An alternative management plan for patients with bulky local disease is to administer chemotherapy in order to

---

reduce the primary tumor volume prior to attempting radical hysterectomy. This approach has been termed *neoadjuvant chemotherapy*. Cisplatin, bleomycin sulfate (Blenoxane), and vinblastine has been the most extensively used drug combination. When chemotherapy is administered prior to surgery, complete clinical response rates range from 17% to 44%, with overall response rates of 80% to 90%. In addition to increasing surgical resectability, preoperative chemotherapy also decreases the number of positive pelvic lymph nodes and, in some studies, has seemingly improved 2- and 3-year survival rates.

Adjuvant Therapy following Surgery

Data are limited concerning the efficacy of postoperative pelvic irradiation in patients at high risk of recurrence after radical hysterectomy and pelvic lymphadenectomy. High-risk prognostic factors include positive pelvic lymph nodes, microscopic parametrial invasion, pelvic lymph node metastases, deep cervical invasion, and positive or close surgical margins. Sedlis and coworkers report results of a randomized, prospective trial of the Gynecologic Oncology Group comparing postoperative pelvic radiation therapy versus no further therapy for patients with high-risk stage IB cervical cancer following radical hysterectomy and pelvic lymphadenectomy. High risk factors included large tumor diameter, deep stromal invasion, and the presence of tumor in capillary lymphatic spaces. For patients with these risk factors and negative pelvic lymph nodes, adjuvant pelvic radiation was associated with a statistically significant 47% reduction in the risk of disease recurrence. Even after extensive follow-up, however, the addition of radiation therapy was not associated with a statistically significant improvement in overall survival.

Grossly Positive Lymph Nodes Encountered at Radical Hysterectomy

The management of patients with grossly positive lymph nodes encountered at the time of radical hysterectomy has been controversial. Although there are no controlled studies, radiation therapy is commonly administered in such circumstances. In order to minimize postoperative radiation-related complications and preserve cervical anatomy for brachytherapy radiation placement, some clinicians advocate abandoning the surgical procedure once metastatic disease is confirmed by intraoperative histologic frozen section. Conversely, retrospective data suggest that postoperative irradiation after resection of all gross nodal disease and radical hysterectomy is associated with a lower rate of local recurrence and may provide a modest gain in survival, particularly for patients with three or more positive pelvic lymph nodes. Significant lower-extremity lymphedema is more likely to occur in patients receiving combined modality therapy.

Stages IIB, III, IVA, and IVB

Radiation therapy is the treatment of choice for patients with stage IIB and more advanced disease. Radiation therapy for invasive cervical cancer is given as a combination of external and intracavitary treatments as described previously. Long-term survival rates are approximately 60% for stage II, 45% for stage III, and 18% for stage IV disease. Patients with stage IVB disease are usually treated with chemotherapy alone or chemotherapy in combination with local irradiation for palliation of symptoms. These patients have a uniformly poor prognosis regardless of treatment modality.

Posttreatment Surveillance

Among patients with recurrent cervical cancer, recurrence is detected within 1 year in 50% of patients and within 2 years in more than 80%. Pelvic examination and lymph node evaluation, including supraclavicular nodes, should be performed every 3 months for 2

years and then every 6 months for an additional 3 years. As many as 70% of patients with recurrent cervical cancer in the pelvis will have abnormal cervical or vaginal cytology; therefore, appropriate cytologic smears should be obtained at the time of each routine examination. Any palpable pelvic mass should be evaluated by CT with fine-needle aspiration cytology if possible. A chest x-ray should be obtained annually to detect pulmonary metastases.

Treatment of Recurrent Cervical Cancer

General Considerations

Cervical cancer detected within the first 6 months after primary therapy is often termed *persistent cancer*, while that diagnosed later is referred to as *recurrent disease*. Appropriate treatment of recurrent cervical cancer is dictated by both the site of recurrence and the modality of primary therapy. In general, patients in whom locally recurrent disease develops following primary surgery should be considered for salvage radiation therapy. Conversely, surgical treatment should be considered for those patients with recurrent central disease who initially received irradiation. Distantly metastatic recurrent tumor is not amenable to either modality alone and is an indication for palliative chemotherapy and possibly radiation therapy for local control.

Surgical Treatment of Recurrent Cervical Cancer

Only patients with recurrent tumor confined to the central pelvis are candidates for surgical intervention. Total

---

hysterectomy is inadequate treatment for centrally recurrent cervical cancer. Additionally, when radical hysterectomy is performed following maximum-dose radiation therapy, 20% to 50% of patients will experience ureteral strictures, urinary fistulas, or other serious complications. Therefore, pelvic exenteration is usually the procedure of choice for centrally recurrent cervical cancer.

Prior to exenterative surgery, a thorough investigation should be undertaken to rule out extrapelvic metastases. The clinical triad of unilateral leg edema, sciatic pain, and ureteral obstruction heralds tumor extension to the pelvic sidewall and is a contraindication to surgery. In most series, approximately 25% of patients with recurrent cervical cancer are deemed satisfactory candidates for exenterative surgery.

Anterior exenteration is indicated for treatment of recurrent cervical cancer limited to the cervix, anterior vagina, or bladder. The procedure combines radical cystectomy with radical hysterectomy and vaginectomy. Posterior exenteration combines abdominal perineal resection of the rectum with radical hysterectomy and vaginectomy and is indicated for lesions confined to the posterior fornix and rectovaginal septum. Total pelvic exenteration is most often required for recurrent cervical cancer. The procedure involves the en-bloc excision of the bladder, uterus, rectum, and vagina (Fig. 58.11).

Using current surgical stapling devices, low rectal reanastomosis can be performed in

approximately 70% of cases. Reconstruction of the urinary system is accomplished by using either an intestinal urinary conduit or one of the many techniques of continent urinary diversion (Miami pouch, Indiana pouch). A neovagina can be created by a variety of techniques using myocutaneous flaps (e.g., bulbocavernosus, gracilis, transverse rectus abdominus) or an omental flap with split-thickness skin graft. Modern surgical techniques and intensive care unit support have reduced the perioperative mortality to <7% in recent series. With proper patient selection and sound surgical judgment, 5-year survival rates after pelvic exenteration range from 45% to 61%.

Glandular Lesions of the Cervix

Adenocarcinoma In Situ

Adenocarcinoma in situ (AIS) is characterized by replacement of the endocervical glandular cells by tall columnar cells with nuclear stratification, hyperchromatism, irregularity, and increased mitotic activity (Fig. 58.12). About 50% of women with AIS also have coexistent squamous cervical intraepithelial neoplasia (CIN). Historically, AIS has been felt to be multifocal, so conization margins were thought to be unreliable in predicting the presence of residual disease. Poyner and associates reported on 28 patients with AIS in which 4 of 10 patients with negative conization margins had residual AIS in hysterectomy or repeat conization specimens. In contrast, studies using careful histologic sectioning indicated that cervical AIS lesions are usually located within the transformation zone and that true multifocality occurs in fewer than 15% of cases. A retrospective study from Shin and coworkers found only one case of residual or recurrent AIS among 98 patients undergoing conization with negative surgical margins and followed with conservative surveillance. Negative conization margins appear to be a more reliable indicator of disease clearance than previously thought. For young patients desiring to maintain reproductive capacity, AIS appears to be safely managed by cold knife conization and diligent surveillance. Clear surgical margins, however, are an absolute prerequisite to conservative management. For patients who have completed their childbearing, a simple hysterectomy should be performed because of the risk of recurrence. Patients with unreliable follow-up and those with persistently positive conization margins should not be offered surveillance.

Figure 58.11 Total pelvic exenteration performed for recurrent cervical cancer involves en-bloc resection of the bladder, vagina, uterus, and rectum. In this specimen, recurrent cervical cancer has replaced the cervix (uterine leiomyomata occupy the uterine fundus).

Cervical Adenocarcinoma

Adenocarcinoma of the cervix accounts for approximately 10% to 15% of all invasive cervical neoplasms. As with SCC of the cervix, tumor size, depth of invasion, and histologic tumor grade have been identified as predictors of pelvic lymph node metastasis and overall survival. Although cervical adenocarcinoma has been reported to have a worse prognosis than similar stage SCC, this difference is due, at least in part, to the tendency of adenocarcinoma to grow endophytically and establish a large tumor volume prior to clinical detection. When cervical adenocarcinoma and SCC are comparatively matched by patient age, clinical stage, tumor volume, and treatment method, survival outcomes are not significantly different. In general, the same treatment algorithms can be applied to patients with adenocarcinoma of the cervix as to those with cervical SCC. Some authors have advocated performing a “completion” simple hysterectomy for patients with bulky, barrel-shaped adenocarcinomas of the cervix following primary radiation therapy. While this approach may decrease the risk of local recurrence, an associated survival benefit has

yet to be conclusively demonstrated. Conservative management has been suggested for young women with microinvasive adenocarcinoma of the cervix who have obtained negative margins and desire future fertility.

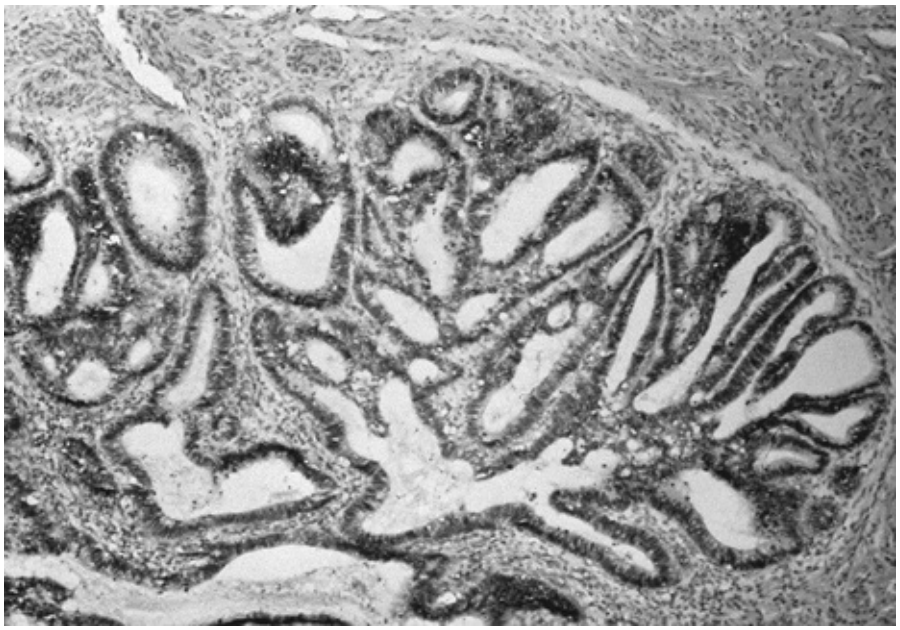

Figure 58.12 Cervical AIS showing tall columnar cells with nuclear stratification, hyperchromatism, and irregularity.

Small Cell Carcinoma

Small cell carcinoma of the uterine cervix is similar to small cell “neuroendocrine” tumor of the lung and other anatomic locations. These tumors are clinically aggressive. At presentation, disease is often widely disseminated, with the bone, brain, and liver being the most common sites. Because of the high metastatic potential of small cell carcinoma, local therapy alone (surgery or radiation) rarely results in long-term survival. Multiagent chemotherapy in combination with external-beam and intracavitary radiation therapy is a therapeutic approach currently under study. The two most commonly used chemotherapeutic regimens are vincristine, doxorubicin, and cyclophosphamide (VAC) and etoposide and platinum (i.e., cisplatin) (EP).

Carcinoma of the Cervical Stump

The natural history and patterns of spread of carcinoma of the cervical stump are similar to those of carcinoma of the intact uterus. The diagnostic evaluation, clinical staging, and principles of staging are also unchanged. In appropriate surgical candidates, early-stage disease can be treated with simple or radical trachelectomy with or without lymphadenectomy, depending on the volume of disease. Advanced-stage disease is treated with radiation therapy. However, the lack of a uterine cavity can make placement of intracavitary radiation sources difficult or impossible. In this case, vaginal colpostats alone

or an interstitial needle implant technique can be used in combination with external-beam therapy.

Incidental Cervical Cancer Found at Simple Hysterectomy

Invasive cervical cancer may be incidentally discovered in the surgical specimen after hysterectomy has been

performed. For disease more advanced than stage IA1 (without lymph-vascular involvement), simple hysterectomy is inadequate treatment, as the parametria, vaginal cuff, and pelvic lymph nodes may harbor residual tumor. Additional treatment is dictated by the volume of disease and the status of the surgical margins of resection.

Radical surgery following simple hysterectomy for invasive cervical cancer generally includes radical parametrectomy, resection of the cardinal ligaments, excision of the vaginal stump, and pelvic lymphadenectomy. Although it may be technically difficult to perform an adequate radical resection, reoperation should be considered in selected clinical situations, particularly for young patients in whom ovarian preservation is desired. Use of postoperative adjuvant radiation therapy is dictated by surgical and pathologic findings.

Cervical carcinoma at the margins of resection after simple hysterectomy or the presence of gross residual tumor are both absolute indications for radiation therapy. Patients with such findings have a much less favorable prognosis than those without residual tumor and those with comparable disease who have been appropriately staged and treated with radiation alone. Radiation therapy is also well suited for older patients or those who are poor surgical candidates. Five-year survival is 95% to 100% for patients with microscopic disease, while 82% to 84% of those with macroscopic disease and negative surgical margins survive 5 years. If the surgical margins of resection are microscopically involved with carcinoma, 5-year survival ranges from 38% to 87%; survival drops to 20% to 47% for patients with gross residual tumor.

Cervical Cancer in Pregnancy

Cervical cancer is one of the most common malignancies in pregnancy, with an estimated incidence ranging from 1 in 1,200 to 1 in 2,200 pregnancies. Conversely, 1 of 34 women diagnosed with cervical cancer is pregnant at the time of diagnosis. The most common complaint of pregnant patients with cervical cancer is abnormal bleeding. However, confusion between the symptoms of early cervical cancer and those of normal pregnancy frequently leads to a delay in diagnosis. Pathologic confirmation of the presence of invasive cervical cancer should be obtained by directed biopsy in the presence of a grossly visible lesion. Conization is indicated only for those patients with apparent microinvasive disease on directed biopsy or for patients with persistent cytologic evidence of invasive cancer in the absence of a colposcopically visible lesion. Diagnostic conization should be considered only when a diagnosis of invasive cancer will result in a modification of treatment recommendations, timing, or mode of delivery. From an obstetric standpoint, the optimal time to perform conization is between 14 and 20 weeks gestational age or after

the time of fetal viability has been reached.

The same clinical staging system of cervical cancer is employed for both nonpregnant and pregnant patients alike (Table 58.2). For pregnant patients with cervical cancer, MRI can provide imaging while minimizing fetal exposure to ionizing radiation. Treatment recommendations are individualized and are dependent on the stage of disease, gestational age at the time of diagnosis, and the desires of the patient regarding continuation of the pregnancy. Patients with well-documented stage IA1 disease (conization with negative surgical margins) may be managed with vaginal delivery and reevaluation postpartum. If the patient has completed childbearing, a simple extrafascial hysterectomy would be appropriate; otherwise, close clinical follow-up is required. For patients with stage IA2 disease, a modified radical cesarean hysterectomy with pelvic lymph node dissection is the preferred treatment. Patients with stage IB or IIA disease may be treated with surgery in the form of radical hysterectomy and pelvic lymph node dissection, either in conjunction with cesarean section or with the fetus in situ, depending on the gestational age. Radiation therapy is the treatment of choice for patients with stage IIB to IVA disease or those with stage IB and IIA disease who are not favorable candidates for radical hysterectomy. Radiation therapy may be initiated with the fetus in situ for nonviable pregnancies, with spontaneous abortion occurring 4 to 5 weeks after starting treatment. For more advanced gestations, classic cesarean delivery is performed initially, with radiation therapy commencing 2 to 3 weeks following delivery. The issue of delaying treatment in order to reach a gestational age consistent with fetal viability has been controversial. Although the data are limited and retrospective in nature, it appears that a treatment delay of 6 to 12 weeks is not detrimental for patients with localized (stage I) disease. Treatment delays are not recommended for patients with more advanced disease.

Vaccines

As cervical cancer requires infection with a foreign virus, this malignancy presents a unique opportunity for the development of vaccines for prevention and treatment. L1, the major capsid protein, is the target of prophylactic vaccines. Both a quadrivalent HPV 6/11/16/18 L1 viruslike particle vaccine (Gardasil) and a bivalent HPV 16/18 L1 viruslike particle vaccine (Cervarix) have been extensively studied. In a type-specific manner, both vaccines significantly reduce rates of persistent HPV infection, resulting in significant reductions in HPV-related disease. Lastly, as E6 and E7 proteins are consistently expressed in cervical cancers, investigators are utilizing these targets as the basis for therapeutic vaccines.

Summary Points

- Regular cervical cytologic screening with the Pap smear is the single most effective means of reducing the incidence and mortality of invasive cervical cancer.
- By convention, cervical cancer is a clinically staged disease; however, ancillary tests and surgical staging may provide useful

information and facilitate a treatment approach tailored to the true extent of disease.
- Surgery (radical hysterectomy with pelvic lymphadenectomy) and radiation therapy are associated with equivalent survival outcomes for patients with early-stage (I–IIA) cervical cancer.
- Patients with advanced-stage disease (IIB–IVA) should receive radiation therapy with curative intent, preferably in combination with concurrent chemotherapy.

Human Papillomavirus and the Management of the Abnormal Pap Test

Christine H. Holschneider

Since the advent of widespread Papanicolaou (Pap) smear screening in the United States during the 1950s, the incidence of invasive cervical cancer and mortality from this disease has fallen more than 70%. The Pap test collects exfoliated cells from the surface of the cervix. Exfoliation occurs from most normal, precancerous, and cancerous cervical epithelium. It is the detection of precancerous cells, which predate invasive disease by years, that allows for the prevention of cancer.

The management of the abnormal Pap test has undergone numerous updates, which are reflected in the consensus guidelines from the American Society for Colposcopy and Cervical Pathology (ASCCP). The current guidelines were the result of a widely inclusive consensus conference convened in 2001 and reflect the new terminology for Pap test classification, known as the Bethesda system, which also underwent consensus review in 2001. In the fall of 2006, a follow-up consensus conference was convened in Bethesda. The 2006 revised guidelines are available at *http://www.asccp.org*. An abnormal Pap test triggers follow-up evaluation, typically colposcopy with biopsies. Treatment should be based on such biopsy diagnosis. Screening and subsequent treatment are aimed at the detection and elimination of preinvasive cervical disease, thus eliminating subsequent invasive disease.

The majority of cervical lesions, approximately 70% of squamous cell carcinomas, and more than 80% of adenocarcinomas are attributable to human papillomavirus (HPV) types 16 and 18. Two vaccines, a Food and Drug Administration (FDA)-approved quadrivalent vaccine and a bivalent vaccine in phase 3 trials, protect against these HPV types. Once widely implemented, these vaccines should reduce the incidence of preinvasive cervical disease. Currently, the quadrivalent vaccine is indicated for use in girls and women 9 to 26 years of age. The Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP) recommends that all girls 11 to 12 years of age receive the quadrivalent vaccine as well as girls and women age 13 to 26 who have not yet been vaccinated and girls as young as 9 years, if indicated. These recommendations are not altered if a girl or woman in the qualifying age group is found to have an abnormal Pap or a positive HPV test. By their mid 20s, approximately 25% of women test positive for one of

the four HPV types in the quadrivalent vaccine (HPV 16, 18, 6, or 11), but only 1% test positive for HPV 16 and 18, and only 0.1% test positive for all four HPV types. Thus, the quadrivalent vaccine should offer benefit to almost all women in the indicated age range. It is critical that women, whether vaccinated or not, follow current cervical cancer screening guidelines.

Evolution of Screening Cervical Cytology and the Bethesda System

The evolution of the Pap test is instructive in many aspects. First devised as a simple method to determine the reproductive cycle of laboratory animals by George Papanicolaou, it has evolved into a source of cellular material

for sophisticated molecular and diagnostic techniques. Although apparently ever changing, the one consistent aspect of its past and future is the success that Pap screening has had in the prevention of invasive cervical cancer.

Papanicolaou performed collection of cervical cells from the posterior vaginal fornix as a method of finding early invasive cervical cancer. Ayers introduced direct sampling of the cervix with the spatula that still bears his name. Such direct sampling significantly increased the cellular yield.

The next major advance was the support that the beginnings of the American Cancer Society (ACS) provided for increasing the visibility of the Pap test. Such exposure led to increasing adoption of the technique, and this coincided with the realization that Pap smears could detect preinvasive disease as well. Richart and colleagues identified the preinvasive component to squamous cell cancer of the cervix. This was achieved, in part, by use of the colposcope in defining the cervical transformation zone.

Terminology was developed for squamous preinvasive disease and reflected its origin in the cervical epithelium. The term *cervical intraepithelial neoplasia* (CIN) was developed and began to replace the term *cervical dysplasia*. Increasing involvement in the epithelial layer was reflected by CIN grades. CIN 1 is used when only the lower third of cells of the squamous cervical epithelium are abnormal. CIN 2 represents approximately two thirds involvement, and CIN 3 represents involvement into the outer third. Full-thickness involvement is also referred to as *carcinoma in situ*. These terms still are used today to describe the histology of squamous cervical lesions (Fig. 59.1).

Technology also has led to changes in the way that cervical cytologic specimens are obtained. The first advance was the Ayers spatula, as noted previously. Next, cotton swabs, often moistened with saline, were used to obtain cells directly from the cervical transformation zone. Although an improvement, a major advance in obtaining endocervical cells occurred when the endocervical brush was introduced in the 1980s. In the late 1980s, increased attention was paid to the potential false-negative result rate of the Pap smear, widely quoted to be as high as 50%. A false-negative Pap smear result does not reflect the current condition of the cervical epithelium and can arise from errors in screening, interpretation, or sampling. Several studies have shown that the inability of a

Pap smear to render the true cervical diagnosis is more likely due to the smeared cellular sample not representing the state of the epithelium rather than the technical interpretation being misleading. Given these data, several efforts were made to reduce the false-negative rate and resulted in technology that allows for the cervical cellular sample to be rinsed into a preservative solution. Data have shown that up to 80% of the cells collected are thrown away after a conventional smear is made. Less than 10% are left on the collection device when the device is rinsed rather than smeared onto glass. From the concept of improving the cellular sample came the basis for liquid-based Pap tests, thus attempting to decrease the false-negative rate.

Figure 59.1 Correlating cytologic and histologic terminologies for neoplastic squamous epithelial changes in the cervix. (LSIL, lowgrade squamous intraepithelial lesion; HSIL, high-grade squamous intraepithelial lesion; CIN, cervical intraepithelial neoplasia.) (Images courtesy of Chisa Aoyama, M.D., David Geffen School of Medicine at UCLA.) (See Color Plate)

Since then, the FDA has approved several liquid-based cervical cytology systems. These allow for the cellular material to be deposited in a liquid preservative that rinses the collection device and fixes the cells. Liquid-based collection and processing provide more representative cervical sampling than conventional smearing of the specimen on a glass slide. In multiple studies during the last decade, liquid-based cytology for cervical cancer screening has been shown to increase the detection rate for preneoplastic squamous intraepithelial lesions compared with that found with the conventional Pap smear method.

Given the significant concern regarding the quality of Pap tests, the U.S. Government developed the Clinical Laboratories Improvement Amendment released in 1988. This guideline addressed the number of Pap tests that could be screened by cytotechnicians and the need for quality assurance review. Additionally, this amendment directed the National Institutes of Health to establish guidelines on

Pap test terminology in order for the cytology results to be more consistent. Until then, frequently some iteration of the histologic CIN categories was also used to describe cervical cytology results. As a result of this direction, the first Bethesda conference was held in 1990, leading to the development of the Bethesda system for Pap cytology reports. The most recent update of the Bethesda system terminology for reporting results of cervical cytology was in 2001 at the Third Consensus Conference.

The 2001 Bethesda system is summarized in Table 59.1. It requires evaluation of specimen adequacy, which is one of the key quality assurance elements of the Bethesda system. Although earlier thinking was that squamous metaplastic cells or endocervical cells were important in determining the adequacy of cervical screening, this concept has not been supported by the data. It has since become evident that a certain amount of squamous cellularity is more reflective of adequate sampling. Minimum squamous cellularity requirements are 8,000 squamous cells for a conventional preparation and 5,000 squamous cells for one that is liquid based. A notation is made regarding the presence or absence of an endocervical or transformation zone component.

TABLE 59.1 The 2001 Bethesda System

SPECIMEN ADEQUACY

- Satisfactory for evaluation (*notation made of presence/absence of endocervical/transformation zone component*)
- Unsatisfactory for evaluation (*because of* …)
- Specimen rejected/not processed (*because of* …)
- Specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality (*because of* …)

GENERAL CATEGORIZATION

- Negative for intraepithelial lesion or malignancy
- Epithelial cell abnormality
- Other

INTERPRETATION/RESULT

Negative for Intraepithelial Lesion of Malignancy

- Organisms (such as *Trichomonas vaginalis*, fungal organisms, shift in flora suggestive of bacterial vaginosis, *Actinomyces* spp., cellular changes consistent with herpes simplex virus)
- Other non-neoplastic findings (such as reactive cellular changes associated with inflammation, radiation, intrauterine contraceptive device, glandular cells status posthysterectomy, atrophy)

Epithelial Cell Abnormalities

Squamous

- Atypical squamous cells (ASC) of undetermined significance (ASC-US) cannot exclude HSIL (ASC-H)
- LSIL (encompassing HPV/mild dysplasia/CIN; CIN 1)
- HSIL (encompassing moderate and severe dysplasia, carcinoma in situ; CIN 2 and CIN 3)
- Squamous cell carcinoma

Glandular

- Atypical glandular cells (AGCs) (indicate endocervical, endometrial, or NOS)
- AGCs, favor neoplastic (indicate endocervical or NOS)
- Endocervical adenocarcinoma *in situ* (AIS)
- Adenocarcinoma

Other

- Endometrial cells in a woman ≥40 years of age

AUTOMATED REVIEW AND ANCILLARY TESTING EDUCATIONAL NOTES AND SUGGESTIONS

LSIL, low-grade squamous intraepithelial lesion; HPV, human papillomavirus; CIN, cervical intraepithelial neoplasia; HSIL, high-grade squamous intraepithelial lesion; AGCs, atypical glandular cells; NOS, not otherwise specified; ACIS, adenocarcinoma in situ.
Modified from Solomon D, Davey D, Kurman R, et al. The 2001 Bethesda system. Terminology for reporting results of cervical cytology. *JAMA* 2002;287:214–219.

The report then gives a general categorization of the findings followed by the interpretation of the results. One of the main changes for reporting epithelial cell abnormalities in 2001 was to the category of atypical squamous cells of undetermined significance (ASCUS). ASCUS describes cellular abnormalities that are more marked than those attributable to reactive changes but that fall short of meeting the diagnosis of squamous intraepithelial lesion. The intent in 2001 was to remove from the ASCUS category those Pap tests that contained cells suspicious but not diagnostic of high-grade squamous intraepithelial lesion (HSIL). Therefore, the category of atypical squamous cells suspicious for high-grade squamous intraepithelial lesion (ASC-H) was developed. The remaining atypical Pap test results would be designated atypical squamous cells of undetermined significance (ASC-US). Low-grade squamous intraepithelial lesion (LSIL) is being used for cells with findings consistent with either HPV effects or consistent with CIN 1–type changes since there is little ability to discern cytologically koilocytic effect from CIN 1 changes. HSIL denotes cells with findings consistent with CIN 2, 3, or carcinoma in situ. The ability to discern among these categories is limited, but they are cytologically distinct from CIN 1–HPV effect. The 2001 Bethesda system designated a specific cytology category for

adenocarcinoma in situ (AIS). Atypical glandular cells (AGC) now also have a “not otherwise specified” (AGC-NOS) and a suggested neoplasia category. Within the glandular neoplasia section, the cytopathologist is asked to designate further whether the cells are from the endocervix or endometrium, if possible.

The 2001 Bethesda system requests reporting of benign endometrial cells, when seen in the cytology specimen, for women age 40 and older. As a women nears and goes beyond the menopausal years, the presence of benign endometrial cells can be indicative of more significant endometrial cavity pathology, such as polyps, hyperplasia (both simple and atypical), and endometrial cancer.

Educational notes are recommended at the end of the Bethesda system report and now should reflect the recommendations of the ASCCP consensus conference guidelines. Many of the recommendations made at the 2001 and 2006 Bethesda conferences are based among other studies on data from the ASCUS/LSIL triage study (ALTS trial). The ALTS trial is a large, multicenter, randomized clinical trial

---

of the management of women with ASCUS and LSIL screening cytology sponsored by the U.S. National Cancer Institute. The study was primarily designed to compare the sensitivity and specificity for the detection of CIN 3 of immediate colposcopy, HPV testing, or serial accelerated cytology. Data from the initial publications have been strengthened over the past 5 years by additional clinical studies from other groups and by additional analyses of the ALTS data. A number of ALTS publications are suggested at the end of this chapter for the interested reader.

Epidemiology, Molecular Biology, and Natural History of Human Papillomavirus Infection

Since the early 1990s, HPV has been accepted as a necessary but not sufficient cause in the development of invasive cervical cancer, both squamous cell cancer and adenocarcinoma. HPV is accepted as a necessary cause because 99.7% of all cervical cancers test positive for HPV based on data by the International Agency for Research on Cancer (IARC). It is the natural history of an HPV infection that has given rise to the not-sufficient portion. Excellent data support the concept that the majority of HPV infections, particularly the initial exposure in a woman's teens and early 20s, regress spontaneously.

Although HPV-related diseases have been noted in the medical literature since the Roman-Hellenic era, it was not until researchers using electron microscopy identified mature viral particles in condylomata during the 1950s that a viral cause for these diseases was entertained strongly. The next breakthrough came with the isolation of HPV type 6 DNA from condylomata by zur Hausen and colleagues during the early 1980s. Since that time, more than 100 HPV types have been identified. A new type is designated when there are sufficient differences in the DNA sequences but still enough homology such that it is consistent with the overall family of papovaviruses.

Interestingly, HPV types have specific preferences for the type of epithelium that they infect. Our interest is in those more than 40 HPV types that infect the lower genital tract

epithelium. These HPV types have been categorized further according to their ability to cause cervical neoplasia. HPV types that rarely, if ever, are found in preinvasive or invasive cervical cancer are put in the category of low-risk human papillomavirus (LR HPV). During an active infection with LR HPV, expression of the viral proteins may lead to a proliferative epithelial response and the formation of condylomata or, in some cases, low-grade CIN. The prototypes of LR HPV are HPV 6 and 11. Conversely, those types found at least occasionally in high-grade CIN or cancer are categorized as high-risk human papillomavirus (HR HPV) (Table 59.2). Prototypes of HR HPV are HPV 16 and 18. Combined, HPV 16 and 18 are present in close to 90% of CIN 2/3 and over 70% of invasive cervical cancers. Epidemiologic evidence also indicates a significant role for HPV in cancers of the vagina, vulva, and anus. Between 64% and 91% of vaginal cancers are HPV positive. In anal cancers, HPV is detected in 88% to 94%. Of the basaloid or warty types of vulvar cancers, typically occurring in young women who frequently smoke, 60% to 90% are HPV positive. HPV has also been strongly linked to nonanogenital tract cancers, such as cancers of the oral cavity, pharynx, and larynx.

TABLE 59.2 Epidemiologic Classification of Human Papillomavirus Types

Low-risk HPV types	6, 11
Probably high-risk HPV types	26, 53, 66, 68, 73, 82
High-risk HPV types	16, 18, 31, 33, 35, 39, 45, 51,52, 56, 58, 59

HPV, human papillomavirus.

When infection occurs, replication of the viral particle requires mature squamous keratinocytes. An active HPV infection is initiated when the infectious particles reach the basal layer of the epithelium, where they bind to and enter into cells. It has been suggested that for the maintenance of infection, the virus has to infect an epithelial stem cell. The HPV DNA sequence consists of early (E) and late (L) open reading frames. The critical molecules in the process of viral replication and cellular transformation are the E6 and E7. The E6 and E7 protein products bind tumor suppressor genes p53 and pRB, respectively. Cell transformation with oncogenic HPV subtypes, such as HPV 16 or 18, may be accompanied by the fact that HPV is no longer in an episomal state but rather is integrated into the host genome. Opening of the virus for genomic integration usually

occurs in the E1/E2 region. Disruption of E2, which acts as a repressor of E6/E7, may result in unregulated expression of the transforming E6/E7 proteins and inactivation of p53 and pRB. Variations in the oncogenicity of different HPV subtypes may be due to differences in the binding efficacy of E6 and E7 to p53 and pRB or differences in their ability to inactivate these tumor suppressor genes. Low-risk types do not give rise to such changes.

As a consequence of disruption of these tumor suppressor genes, the dependence on cell cycle control is abolished and normal keratinocyte differentiation is retarded. With HPV integration into the human genome, there is constant activity of viral proteins E6 and E7, leading to increasing genomic instability, accumulation of oncogenic mutations, future loss of cell cycle control, and ultimately cancer. The viral capsule is quite uniform among the HPV types and is formed from the L1 and L2 reading frames, encoding the structural proteins. These capsule proteins are utilized in prophylactic vaccine therapy, whereas various manipulations of either the protein or HPV DNA from E6 and E7 are

---

used in therapeutic immunologic approaches. An in-depth discussion of these events can be found in reviews of HPV molecular biology.

Exposure to HPV appears to occur primarily by intimate sexual contact but does not require intercourse. Other avenues of exposure have been discussed but not verified, such as common pools, hot tubs, and bathrooms. Use of condoms reduces HPV infection but is not fully protective, which is not surprising given that HPV is transmissible through nonpenetrative sexual contact with both male and female partners. Women who practice a homosexual lifestyle are also at risk for HPV exposure. They, like their heterosexual counterparts, require Pap test screening and develop evidence of HPV exposure with positive cervical cytology findings. An abnormal Pap test result in a homosexual woman is no different in its etiology than in a result from a heterosexual woman.

Epidemiologic case studies, often using HPV DNA detection techniques, demonstrate that widespread exposure of the female and male sexually active population has occurred. Data from the CDC National Prevention Information Network indicate that by age 50, at least 80% of women will have acquired genital HPV infection. The majority (74%) of new HPV infections occur among those 15 to 24 years old. In women younger than 25 years, the prevalence of HPV infection ranges between 28% and 46%. The majority of these HPV infections are transient and appear to regress spontaneously. For college-age women, it can be expected that in 70%, the virus will no longer be detectable after 1 year. HPV clearance will increase to approximately 90% by 2 years. The reason for eradication of this viral infection is not known, but the gradual development of an effective cell-mediated immune response to the infection is a leading theory.

Reasons for suspecting that an immune response to HPV infection is the source of regression of disease are well founded but have not yet been proven definitively. Since HPV particles are freed through normal desquamation, there is no cytopathic death involved. Thus, little inflammation occurs to trigger the innate immune system. Women with transient HPV infection are less likely to develop antibody or cell-mediated responses to HPV than women with persistent HPV infections. The humoral response to naturally occurring HPV infections appears to exert little protective effect against HPV persistence or disease. Cell-mediated

immune responses are critical to viral clearance once infection is established. Women whose immune systems are compromised, such as organ transplant recipients and HIV-infected individuals, have significantly reduced ability to clear their HPV infections. Data from recently HIV-infected adolescents show that even in women with normal CD4 counts, HPV persistence may be prolonged. Women with low CD4+ cell counts (CD4 count <200/mcL) have the highest prevalence of HPV infection, most commonly harbor HR HPV types, and are at highest risk for persistence of cervical HPV infection. The incidence of CIN is four to five times higher in HIV-positive women. Given these data, the CDC designated CIN 2/3 as conditions defining a stage of early symptomatic HIV infection (category B) and invasive cervical cancer as an AIDS-defining condition (category C).

Interestingly, young women first exposed to HPV will be most likely to manifest their infections by developing CIN 1, which is detected by Pap test and can be confirmed by biopsy. However, the HPV types involved in these lesions are predominately in the high-risk category. Although this finding has not led to a change in the definition of low-risk versus high-risk types, it indicates that clinically detectable cervical cytologic abnormalities most likely represent HR HPV no matter what the degree of morphologic abnormality.

Women with persistent oncogenic HPV infections are at greatest risk of developing cervical precancer or cancer. The longer an HPV infection exists, the less likely the patient will clear it. Other associated factors are age (>30 years), infection with multiple HPV types, immunosuppression, cigarette smoking, and possibly other sexually transmitted diseases (in particular *Chlamydia trachomatis*).

HPV 16 and 18 have a unique carcinogenic potential. In the ALTS trial, the 2-year cumulative risk for developing CIN 3 or worse for HPV 16–positive women was 30% to 40%. The progression from HPV infection to HPV persistence to CIN 2/3 and ultimately cancer is estimated on average to take about 15 years, although cases of rapid-onset disease exist. This gives ample opportunity for the prevention of cervical cancer in a screened population.

Human Papillomavirus Testing Methods

Because HPV cannot be cultured, its detection depends on the identification of its DNA. Since the advent of polymerase chain reaction (PCR) and other sensitive DNA detection methods, very minute amounts of viral DNA can be detected from infected cells. Generally, these methods require the extraction of the cells' DNA and then the aggregate DNA is probed specifically for the presence of viral DNA. Using such techniques, although very sensitive, does not allow for identification of what cell in the sample carried the viral DNA. Therefore, contamination from sperm, white cells, or mucus of male origin may lead to false-positive HPV DNA test results. The most common methods for HPV DNA detection are PCR and RNA-DNA hybrid detection, which is the method used in Hybrid Capture II (HC II) (Digene, Gaithersburg, MD). General or consensus primer-mediated PCR assays have enabled screening for a broad spectrum of HPV types in clinical specimens using a single PCR reaction. Following amplification using consensus primers, individual HPV genotypes are identified by using a variety of methods. Using consensus primers in a test format known as real-time quantitative PCR, it is possible to generate viral load (concentration)

from reaction curves generated by monitoring PCR reaction kinetics in real time.

HC II is the only currently well-validated, FDA-approved test available. It uses a relatively simple and inexpensive method of detecting and amplifying a specific DNA signal. Cells are disrupted with a base solution that liberates the aggregate sample's DNA. RNA probes specific for HPV types are then added to the solution and allowed to adhere to target DNA to form DNA-RNA hybrids. This sample is then exposed to antibodies to DNA-RNA hybrids. These antibodies are already adherent to the walls of a well, and thus the DNA-RNA hybrids are fixed to the walls. Multiple antibodies that have alkaline phosphatase attached to them, thus amplifying the signal, then further detect these hybrids. The signal amplification can be up to 3,000-fold. A chemiluminescent dioxetane substrate is then added to the sample, and it is cleaved by the alkaline phosphatase. The subsequent substrate produces a type of light that can be measured in a luminometer. Such light is reported as relative light units (RLUs). The RLU of an unknown is compared with that produced from a control sample containing 10 pg/mL of relevant HPV DNA. Final data is reported as an RLU-to-PC (positive control) ratio, and a positive sample must have a value of 1.0 or greater.

The beauty of Hybrid Capture is that little additional equipment is necessary for the assay. Also, multiple HPV DNA probe types can be placed into the sample at one time, allowing for detection of multiple different HPV DNA sequences. The HC II assay for HR HPV contains RNA probes for types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68.

The general consensus is that HC II is as sensitive and specific as PCR-based HPV detection methods. However, HC II does not allow for quantification of virus and does not identify specific HPV types, whereas PCR can be used for genotyping and viral load determination. HC II's relatively simple and inexpensive method makes it superior for commercial clinical use, whereas the less standardized PCR techniques are mainly used in research settings.

Alternative HPV tests are in development and are expected to become increasingly available for clinical use, including type-specific HR HPV testing or biomarker-based assays. For clinical use outside of research protocols, only fully clinically validated, FDA-approved tests should be used.

Guidelines for Cervical Cancer Screening

The most recent guidelines for cervical cancer screening were issued by the ACS in 2002 and by the American College of Obstetricians and Gynecologists (ACOG) in 2003. Women should start their cervical cancer screening 3 years after the beginning of sexual intercourse but no later than age 21. Based on ACOG recommendations, cytology screening should be annual until age 30. For women age 30 or older who have had three consecutive negative tests, screening intervals may be increased to 2 to 3 years. Alternatively, women age 30 or older may undergo testing for HR HPV types as an adjunct to cervical cytology. If both tests are negative, rescreening should be no more frequent than every 3 years. Women who have had a total hysterectomy (includes removal of the cervix) who have no history of cervical cancer or precancer may stop screening Pap tests. According to the ACS,

women age 70 or older with three or more negative Pap tests and no abnormal cervical cancer screening test in the preceding 10 years may stop screening. Based on ACOG guidelines, even past age 30, more frequent cytologic screening may need to be continued for HIV-positive or other immunosuppressed patients, for those with prior CIN 2/3, or for those with a history of diethylstilbestrol (DES) exposure in utero. These latter groups of patients may also benefit from continued screening after hysterectomy or beyond age 70 as long as they are in reasonably good health.

Guidelines for the Management of the Abnormal Pap Test

Approximately 5.0% of all Pap tests in the United States reveal atypical squamous cells (ASC); another 2.0% LSIL; and 0.5% HSIL, AGC, and other significant cytologic abnormalities. Following the 2001 Bethesda conference, the ASCCP held a consensus conference to discuss the changes in the Bethesda system and to utilize data from the ALTS and other clinical trials to develop guidelines for the clinician in the management of abnormal Pap test results. These guidelines have been further updated in 2006. The management recommendations in this chapter (Table 59.3) also take into account the 2005 ACOG Practice Bulletin *Management of Abnormal Cervical Cytology and Histology*. Generally, the management recommendations are based on the likelihood of finding CIN 2/3 with any given cytologic abnormality (Table 59.4).

If a HR HPV test performed as an adjunct to screening cervical cytology in women age 30 years and older is positive and cervical cytology is negative, follow-up with a repeat cytology and HPV test in 12 months is recommended. If the HPV test remains positive or the cytology shows ASC or greater, colposcopy is indicated.

In the category of ASC, the ALTS data were utilized for ASC-US. Interestingly, little mention is made of ALTS use of the ASCUS category without further subcategories, and the ASCCP guidelines use the 2001 Bethesda system category of ASC-US. Essentially, ASCCP guidelines indicate that the preferred method of evaluation of the ASC-US Pap test is twofold. If it comes from a liquid-based sample, reflex testing for HR HPV DNA is preferred, and if it comes from a conventional Pap smear, secondary HPV testing is performed by using a second co-collected sample. Those patients with ASC-US who are positive for HR HPV should have immediate colposcopy, whereas those who are negative for HR HPV can revert to yearly screening. Reflex

---

HPV testing is preferred for patient convenience and cost-effectiveness, as 44% to 69% of patients can be reassured without colposcopy that their risk of CIN 2/3 or worse is very low. If no co-collection was performed, then for the ASC-US category, Pap tests should be repeated at 6 and 12 months and the patient is referred for colposcopy if results are ASC or greater. A third acceptable alternative for the management of a first ASC-US test would be immediate colposcopy. This is the least preferred, as it is generally more expense and more unpleasant for the patient.

TABLE 59.3 Management of the Abnormal Pap Test

Bethesda 2001	Next Step	Management	
Negative for intraepithelial lesions or malignancy	Routine screening	—	—
Cytology (–), HR HPV (+) in combined screening	Repeat cytology and HR HPV at 12 mo	If (+) HR HPV or repeat cytology ASC or worse:	Colposcopy
ASC-US[b]	Reflex HR HPV *or* Repeat cytology at 6 and 12 mo *or* Colposcopy	If positive HR HPV or repeat cytology ASC or worse: If negative HR HPV or no CIN on colposcopy: If CIN on biopsy:	Colposcopy F/U cytology in 1 y Treatment based on histology
ASC-H LSIL[a,c]	Colposcopy	If no CIN or if CIN 1: If ≥CIN 2:	Repeat cytology at 6 and 12 mo or HR HPV at 12 mo Treatment based on colposcopy, histology, and patient age
		Treatment based on	

HSIL[d]	Colposcopy	colposcopy, histology, and patient age	—
AGC-NOS	Colposcopy ± EMB[e] and HR HPV	If workup negative: If repeat cytology ASC or worse: If repeat AGC-NOS and negative workup: Treatment based on histology	Repeat cytology every 6 mo until negative × 4 or repeat cytology plus HR HPV at 12 mo (if HPV-), at 6 mo (if HPV+) Repeat colposcopy and EMB CKC ± Fractional D&C
AGC favor neoplasia AIS	Colposcopy ± EMB[e]	If workup negative:	Excisional procedure, preferably CKC ± Fractional D&C Refer to gynecologic oncologist
Carcinoma	Biopsy and colposcopy (if no grossly visible lesion)	If cancer or if no cancer on histology but suspicious cervical lesion: If no cancer and grossly normal cervix:	CKC

HR HPV, high-risk human papillomavirus; ASC, atypical squamous cell; ASC-US, atypical squamous cells of undetermined significance; CIN, cervical intraepithelial neoplasia; F/U, follow-up; ASC-H, atypical squamous cells suspicious for high-grade squamous intraepithelial lesion; LSIL, low-grade squamous intraepithelial lesion; HSIL, high-grade squamous intraepithelial lesion; AGC-NOS, atypical glandular cells not otherwise specified; EMB, endometrial biopsy; CKC, cold knife conization; D&C, dilation and curettage; AGC, atypical glandular cell; AIS, adenocarcinoma in situ; ECC, endocervical curettage.

[a]Adolescents (≤ 20 yr) with ASC-US or LSIL should undergo annual cytology (with colposcopy for HSIL or abnormal cytology <HSIL that persists >24 mo. HPV testing and immediate colposcopy are not recommended for adolescents.

[b]Pregnant women with ASC-US may defer colposcopy to 6 weeks postpartum.

[c]Postmenopausal women with LSIL may be managed with reflex HPV testing or repeat cytology at 6 and 12 mo or immediate colposcopy with further management as outlined for ASC-US.

[d]Immediate “see and treat” Loop electrosurgical excision acceptable except in adolescents, young women, and pregnant women.

[e]EMB recommended in all patients >35 years of age and at younger age if history of anovulatory bleeding, if any abnormal vaginal bleeding, atypical endometrial cells reported, or if colposcopy and ECC are negative for disease.

For those patients with HR HPV–positive ASC-US who do not have documented CIN at the time of colposcopy,

repeat cytology testing at 6 and 12 months or HPV DNA testing at 12 months are appropriate follow-up, with repeat colposcopy for any cytology of ASC or worse or a positive HPV test.

TABLE 59.4 Screening Cytology and Human Papillomavirus Testing Results with Associated Risk for CIN 2/3 and Invasive Cancer

Squamous Epithelial Cell Abnormality		
Pap/HPV Finding	**Risk of CIN 2/3 (%)**	**Risk of CA (%)**
Pap (–), HR HPV (+)	4	
ASCUS	6–12	0.1–0.2
ASC-US, HR HPV (–)	<2	
ASC-US, HR HPV (+)	15–27	
ASC-H	27–51	
LSIL	15–30	<1.0
HSIL	>70	1.0–2.0

Glandular Epithelial Cell Abnormality		
Pap/HPV Finding	**Risk of CIN 2/3, ACIS, or CA (%)**	
AGC-NOS	9–41	
AGC favor neoplasia	27–96	
Pap/HPV Finding	**Risk of ACIS (%)**	**Risk of CA (%)**
AIS	48–69	38

CIN, cervical intraepithelial neoplasia; HPV, human papillomavirus; CA, carcinoma; HR HPV, high-risk human papillomavirus; ASCUS, atypical squamous cells with undetermined significance; ASC-US, atypical squamous cells of undetermined significance; ASC-H, atypical squamous cells suspicious for high-grade squamous intraepithelial lesion; LSIL, low-grade squamous intraepithelial lesion; HSIL, high-grade squamous intraepithelial lesion; AIS, adenocarcinoma in

situ; AGC-NOS, atypical glandular cells not otherwise specified; AGC, atypical glandular cell.

Patients with ASC-H Pap test results should be referred for immediate colposcopy. When negative colposcopy results are noted for ASC-H, the recommendation is to review the cytology and histology for correlation and confirmation. If again supportive of the respective diagnoses, then repeat cytology at 6 and 12 months or retesting for HR HPV DNA at 12 months is acceptable, with repeat colposcopy for positive findings.

For LSIL, HR HPV DNA testing is not useful for triaging patients regarding colposcopy, as 83% of LSIL are positive for high-risk types. Given these data, colposcopy is the preferred method of evaluation for LSIL. If colposcopy reveals CIN, management is based on the degree of histologic abnormality (see below). If colposcopy does not reveal any CIN, the patient has an approximate 15% risk of CIN 2/3 being diagnosed in the subsequent 2 years. Therefore, surveillance with repeat cytology at 6 and 12 months or HPV testing at 12 months is recommended. If those are negative, annual screening may be resumed. Colposcopy should be repeated if cytology shows ASC or greater or HR HPV DNA testing is positive.

There is no question that an HSIL detected with cytology most likely will reveal CIN 2/3 on colposcopically directed biopsies, and therefore, colposcopy is the preferred method of evaluation. Management thereafter will be based on patient age and colposcopic and histologic findings (see below). As an alternative to the two-step approach of colposcopy followed by treatment based on biopsy results, a “see and treat” approach may be appropriate for these patients, with adolescents, young women, and pregnant women being exceptions.

Many clinicians are concerned when HSIL cytology is followed by a diagnosis of CIN 1 or less at colposcopy and biopsy. Up to 35% of these women will have CIN 2/3 diagnosed during an excisional procedure. Thus, the first step in managing these patients is a careful review of index cytology, colposcopy, and histology results. Such review may resolve the discrepancy and then management should follow the revised interpretation. If the discrepancy persists, a diagnostic excisional procedure is recommended, except for adolescents, young women, and pregnant women. Observation with colposcopy and cytology at 6 months intervals for 1 year (2 yrs in adolescents) is an acceptable alternative provided the endocervical sampling is negative and the colposcopy satisfactory.

In glandular lesions, the ASCCP guidelines are explicit that the Pap test showing AGC, whether further qualified or not, must be evaluated with colposcopy and endocervical sampling. For those Pap tests showing AIS or AGC that are further qualified as suggestive of neoplasia, a negative colposcopy with negative histologic assessment does not end the evaluation. In that setting, further tissue sampling is required, and the preferred method is by cold knife conization (CKC). Patients with AGC-NOS and a negative initial evaluation continue to be at increased risk. It is recommended that these women be followed by a program of repeat cervical cytology tests every 4 to 6 months until four consecutive negative tests. If a second AGC-NOS again results in a negative workup, a diagnostic

conization is indicated. Of note, approximately half of women with biopsy-confirmed ACIS have coexisting CIN; therefore, the presence of CIN on a colposcopic biopsy does not change the management of a patient with an AGC or ACIS.

When the atypical glandular cytology is suspected to be endometrial in origin, endometrial sampling should be performed as the initial evaluation. Also, when the glandular cytology is not further qualified and the woman is 35 years of age or older, has abnormal vaginal bleeding, or a history of chronic anovulation, endometrial sampling is recommended.

The finding of benign endometrial cells on a Pap test in a woman over age 40 should trigger the consideration of endometrial sampling. A careful history of the woman's menstrual pattern or evidence of any recent changes should be sought in addition to questioning, when appropriate, about postmenopausal bleeding.

For those whose cytology is consistent with AIS, colposcopy should be performed to identify any obvious areas of malignancy, but unless a definitive diagnosis is made on biopsy, a diagnostic excisional procedure is indicated, preferably a CKC. This tissue should be evaluated for the presence of AIS and the possibility of early invasive adenocarcinoma. Management of patients with glandular lesions of the cervix can be quite challenging, and these patients should be cared for by a clinician who is experienced in the management of complex cytologic and early neoplastic processes of the cervix.

Cytologic findings consistent with squamous cell cancer should always trigger a further examination, either visual if the lesion is obvious or by colposcopy if not clinically apparent. If such biopsies fail to confirm invasive carcinoma, a diagnostic excisional procedure is indicated. If cancer is confirmed, the patient should be referred to a gynecologic oncologist.

Special Circumstances

Adolescents

The likelihood of HPV clearance is very high in the adolescent, and the risk of invasive cancer extremely small. Thus, adolescents with ASC-US or LSIL may forego immediate colposcopy and be monitored with repeat cytology at 12 and 24 months instead. Referral to colposcopy should be made for any HSIL or persistent (× 24 mo) abnormal cytology less than HSIL. For adolescent or young women with HSIL for whom biopsy confirmed CIN 2/3 is not found at colposcopy, expectant management with follow-up at 6-month intervals is recommended for up to 2 years, provided colposcopy is satisfactory and endocervical sampling is negative. If cytology results are still positive without lesions noted at that time or if there is colposcopic progression to a high-grade lesion, then a loop electrosurgical excision procedure (LEEP) should be performed.

Pregnant Women

Pregnant women are generally recommended to undergo colposcopy with the same indications as nonpregnant women. Colposcopy during pregnancy is preferably performed

by clinicians who are experienced in the colposcopic changes induced by pregnancy itself. Vascular changes are more marked during pregnancy, thus making simple interpretation of the lesion colposcopically without biopsy confirmation more difficult. Therefore, it is recommended that biopsy be performed on any lesions suspicious for CIN 2/3 or worse. Follow-up with either colposcopy, cytology, or HPV DNA testing is warranted depending on the index Pap and findings at initial evaluation. A diagnostic excisional procedure during pregnancy is only recommended if invasion is suspected and if knowledge thereof will alter management. For all patients, re-evaluation with cytology and colposcopy no sooner than 6 weeks postpartum is recommended.

TABLE 59.5 Natural History of Cervical Dysplasia: Rates of Regression, Persistence, and Progression

	Regression to No CIN (%)	Persistence (%)	Progression	
			To CIN 3 (%)	To Invasive Cancer (%)
CIN 1	60[a]	30	10	<1
CIN 2	40[b]	35	20	5
CIN 3	30	48	NA	22

CIN, cervical intraepithelial neoplasia.
[a]Spontaneous regression of CIN 1 is >90% in adolescent and young women.
[b]Spontaneous regression of CIN 2 is 60% in adolescents and young women.

Management of Cervical Intraepithelial Lesions

The histologic diagnosis, patient age, desire for future childbearing, and prior Pap and treatment history direct whether expectant management or treatment is the preferred approach for the patient with CIN. Management is further based on the natural history of CIN, which is summarized in Table 59.5.

Biopsy-proven CIN 1 has the same approximate 15% risk of CIN 2/3 being diagnosed in the subsequent 2 years for HR HPV–positive ASC and LSIL with negative colposcopy. Therefore, expectant management is the preferred approach for these patients. Effective surveillance strategies recommended by the ASCCP consensus guidelines are follow-up with repeat cytology at 6 and 12 months or HPV testing at 12 months. If those are negative, annual screening may be resumed. Colposcopy should be repeated if cytology shows ASC or greater or HR HPV DNA testing is positive.

With few exceptions, which will be discussed below, treatment is generally indicated for CIN 2/3. Once it is determined that the disease should be treated, the procedure can be either ablative or excisional (Table 59.6). Three principal factors need to be considered when comparing ablative and excisional therapy: (a) completeness of the diagnostic process, (b) therapeutic efficacy, and (c) impact on future pregnancies in women who wish to preserve fertility and that endocervical sampling is negative for neoplasia. Ablative techniques do not generate any further tissue specimens and include laser vaporization and cryosurgery. Such treatment requires a satisfactory colposcopic examination that identifies the entire transformation zone and the full extent of the lesion area. Ablative therapy also requires that the colposcopic biopsies fully explain the Pap test abnormality and that endocervical sampling is negative for neoplasia. Ablative therapies are not indicated for cytologically suspected or histologically confirmed glandular

lesions or microinvasive carcinoma. Excisional techniques will generate further tissue for histologic review and include conization by cold knife (scalpel), LEEP, or laser conization. Excisional therapy is the treatment modality of choice for all cases where the lesion extends into the endocervical canal or where the endocervical sampling is positive for dysplasia, where there is a significant discrepancy between cervical cytology and colposcopic biopsies, and in cases of suspected microinvasive carcinoma or glandular lesions. A large body of evidence including randomized trials and a meta-analysis demonstrates that CKC, LEEP, cryotherapy, and laser all yield comparable success rates in treating CIN. Overall, the rate of recurrent or persistent disease is 5% to 27% after treatment with any of the excisional or ablative treatment techniques. Larger lesions size, endocervical gland involvement, positive margins status, and HPV persistence beyond 6 months posttherapy are all associated with an increased risk of persistent disease. Risk of disease recurrence is higher among women age 30 years or older and in those who have had prior treatment. Positive margins on an excisional treatment specimen revealing CIN 2/3 do not necessitate re-excision in the reliable patient, as the majority of these patients still will be without residual disease. It is also important to recognize that in up to 15% of cases, the final pathology after these excisional techniques will reveal apparently normal epithelium. The most likely reason for this is that the area of morphologic change was removed by a prior colposcopically directed biopsy. Recurrence or persistence of CIN in such cases is similar to that after an excisional specimen showing CIN. In the long term, the risk of invasive carcinoma of the cervix remains 10 to 15 times greater after treatment for CIN compared with the risk shown for the general population.

TABLE 59.6 Techniques for Treatment of Squamous Intraepithelial Lesions

Ablative
- Cryosurgery
- Laser vaporization

Excisional
- Laser excisional conization
- LEEP
- CKC (scalpel)
- Hysterectomy

LEEP, loop electrosurgical excision procedure; CKC, cold knife conization.

Since CIN typically occurs in women of childbearing age, the impact of the disease and its treatments on future fertility and pregnancy outcomes is an important consideration. Excisional therapy of CIN has been linked to preterm delivery. The best available data stem from a systematic review of 27 cohort studies, which found CKC to be associated with preterm delivery in 14%, LEEP in 11%—both significantly higher than the 5% to 7% preterm delivery rate in controls. These data indicate that excisional procedures, especially when excising to depths >10 mm, increase the risk of preterm delivery and suggest that ablative procedures may not. Thus, careful consideration should be given to the management approach of CIN in women of reproductive age.

Special Circumstances

Adolescents

In adolescents, the rate of regression of CIN 2 approaches 60% at 1 year, and the risk of progression to cancer is extremely small. Thus, observation with colposcopy and cytology at 6 month intervals for up to 2 years is a reasonable management option for adolescents and young women with biopsy-proven CIN 2/3 and satisfactory colposcopy.

Adenocarcinoma In Situ

AIS is a precursor lesion of adenocarcinoma of the cervix and is difficult to manage due to frequent endocervical location, presence of skip lesions, lack of clearly distinguishable colposcopic features, and a high incidence of residual AIS or invasive adenocarcinoma following conization. It is also a sufficiently rare diagnosis, so management at an expert center is preferable for pathologic diagnosis, treatment, and follow-up. A patient with AIS

on biopsy should undergo a CKC to rule out invasive carcinoma. CKC is preferable over laser or LEEP conization techniques to prevent thermal artifact potentially compromising histologic interpretation of diagnosis and margin status. An endocervical curettage (ECC) should be performed after the conization, as ECC status provides valuable information in addition to cone margins regarding the risk of residual disease. With positive margins, the risk of residual disease is close to 60%. Thus, repeat CKC should be performed prior to hysterectomy to rule out invasive disease. Even with negative margins, as many as 20% of patients may have residual ACIS. The risk of unsuspected invasive cancer after conization with negative margins and ECC is estimated at about 2%. Subsequent development of adenocarcinoma in conservatively managed patients has been described in multiple reports, but actual incidence estimates are difficult due to the rarity of the disease. A patient diagnosed with ACIS who has completed childbearing should be treated by hysterectomy. The incidence of ACIS is increasing in women of childbearing age, and sparing of fertility is an important concern. If a patient wishes to preserve fertility after appropriate counseling, conservative follow-up may be undertaken, provided the conization margins and ECC are negative. Pap testing, colposcopy, and endocervical sampling every 6 months is recommended. It appears reasonable to also include HPV testing in the follow-up of these patients, given the limited sensitivity of cervical cytology for glandular lesions and the fact that most ACIS and adenocarcinomas of the cervix are HPV positive.

Techniques for Treatment

Cryosurgery

The technique of cryosurgery initially was reported for treatment of CIN in the early 1970s. Using either carbon dioxide or nitrous oxide under pressure as the coolant, the cervical epithelium is frozen to a depth of 6 to 10 mm. The length of time for the freeze and the absolute temperature of the probe will determine the depth of penetration and subsequent tissue loss. Tissue is sloughed off slowly, over a period of 10 to 14 days, as a watery discharge. The most widely accepted technique for cryosurgery is to freeze the cervix for 3 minutes after formation of an ice ball on the cervix, followed by a 5-minute thaw and a repeated 3-minute freeze. Although not as widely used as it was prior to LEEP, cryosurgery is less expensive and therapeutically will have results similar to LEEP when candidates who are appropriate for ablative therapy are carefully selected and adequate caution is used with its application.

Laser Vaporization

Initially discussed in the gynecology literature in the late 1970s, laser (light amplification by stimulated emission of radiation) became the mainstay of therapy at many centers in the United States throughout the 1980s and into the 1990s. Its use does require a learning curve, and the length of time for vaporization of cervical lesions should not exceed that taken by cryosurgery. Laser is light generated in the infrared spectrum by running

electricity through a gas. For lower genital tract use, the gas used is carbon dioxide. The wavelength of such a laser is absorbed primarily by water. Thus, individual cells are heated instantaneously when the light contacts them, leading to their immediate vaporization by boiling the cellular water content. The depth of laser penetration into the cervical epithelium can be controlled quite closely by altering the spot size, the power, and the dwell time. Settings used lead to a lower power density that creates a larger area of vaporization and is achieved by a beam spot size of 2.0 to 2.5 mm. Generally, laser vaporization is done to a depth of 7 to 10 mm.

The procedure can be done safely in the office under local anesthesia, using nonsteroidal anti-inflammatory drugs to reduce postprocedure discomfort. It is not uncommon to perform laser procedures in the operating room when the area to be treated is extensive.

Laser has been widely replaced by LEEP. Tissue generation and ease of use have made LEEP attractive. However, treatment of extensive, preinvasive disease involving multiple lower genital tract structures, such as the cervix and vagina, often are performed in one sitting using laser.

Laser Excisional Conization

Rather than using laser for vaporization leading to ablation, it can be used to excise a conization specimen. The settings for the latter create a significantly greater power density, allowing the laser beam to act in an excisional rather than ablative manner. This is achieved by decreasing the spot size of the beam. Difficulty interpreting cone margins due to “char” artifact caused by laser excision and the ease of LEEP conization have significantly reduced the indications of laser conization.

Loop Electrosurgical Excision Procedure

LEEP, variably known as simply loop excision or LLETZ (large loop excision of the transformation zone), uses low-voltage, high-frequency, thin wire loop electrodes to perform a targeted removal of a cervical lesion, an excision of the transformation zone, or a cervical conization. This technique can be used in the outpatient setting and, if used appropriately, allows for excision with minimal bleeding and minimal coagulative artifact of the excisional margin.

Most LEEPs can be performed in the office under local anesthesia using a paracervical or intracervical block. Many practitioners add a vasoconstrictive agent such as epinephrine or vasopressin to the local anesthetic for the intracervical block, which is given in an intrastromal technique, circumferentially over the cervical face and avoiding the lesion area. Such treatment maximizes vasoconstriction in addition to providing local anesthesia. The transformation zone and lesion tissue can be identified by staining the cervix with modified Schiller iodine solution prior to excision. The procedure is best performed by using one or two ectocervical passes encompassing the transformation zone and lesion. If indicated by a lesion extending into the canal, by a positive endocervical sampling or by an unsatisfactory colposcopy in an older/multiparous patient, an additional endocervical “top hat” specimen can typically be removed by using a smaller-diameter electrode. The true

endocervical margin should be marked for the pathologist. Postexcision hemostasis of the surgical bed is then achieved by using the coagulation mode to achieve fulguration of the tissue with short bursts of high peak voltage current with a roller-ball electrode. Monsel solution commonly is placed in the surgical bed for further hemostasis, thus avoiding sutures.

Cold Knife Conization

The role of CKC has become increasingly limited due to the widespread use of LEEP. CKC is typically performed in the operating room under general or regional anesthesia. It is superior to LEEP or laser conization in cases where thermal artifact should be avoided on the pathologic specimen, such as in suspected microinvasion or ACIS. Patients whose cervical anatomy is significantly altered may also be best served by CKC, such as in the setting of a severely foreshortened cervix with recurrent CIN after prior excisional procedures or in a postmenopausal patient with a cervix flush with the vagina. The cervical conization

---

specimen size and shape can be adjusted to the patient's age, cervical anatomy, transformation zone, and disease distribution. CKC is performed typically after the intracervical injection of a vasoconstrictive agent. Many surgeons recommend placing absorbable sutures into the cervical stroma just caudad to the cervicovaginal junction at the 3 o'clock and 9 o'clock positions. The ability of these sutures to reduce blood flow to the cervix is unpredictable at best, but they are helpful for manipulating the cervix during the procedure and may be used to secure hemostatic material in the conization bed after completion of the procedure. A uterine sound is used to carefully determine the exact location of the endocervical canal, and a cone-shaped specimen is then excised circumferentially by using a scalpel. Hemostasis is achieved with a roller-ball electrode by using the coagulation mode, via the application of Monsel solution or other hemostatic materials and occasionally by using hemostatic sutures.

Hysterectomy

Although not commonly used at this time, there still is a limited role for hysterectomy in the treatment of cervical neoplasia. Such a need does arise in the scenario of repetitive CIN 2/3 that recurs despite less invasive treatments. It is not uncommon in this situation to end up with cervical scarring that makes a Pap test and colposcopy virtually impossible to perform. The patient, who is postchildbearing, may opt for more definitive management with hysterectomy. Prior to hysterectomy, invasive disease must be excluded by histologic evaluation of the transformation zone. In this setting, conization with frozen section evaluation at the time of hysterectomy may be helpful. The choice of vaginal versus abdominal hysterectomy is dictated by patient characteristics and other indications. The patient should be counseled that her abnormal cytology result rate posthysterectomy will not be zero. HPV-related preinvasive or invasive disease can occur in the vagina, on the vulva, or in the perianal region, thus leading to the recommendation for continued surveillance of these patients.

Posttreatment Surveillance

Treatment failures after excisional or ablative treatment methods occur in 5% to 27% of cases, underscoring the importance of effective posttreatment surveillance. Follow-up with cervical cytology screening at 6 months intervals for three to four tests prior to returning to annual screening is generally recommended. Multiple recent studies have demonstrated that HPV testing performed at least 6 months posttreatment is a powerful predictor of persistent CIN 2/3. These data make a single HPV plus Pap test at 6 months posttreatment a reasonable alternative. If negative, the patient may resume annual screening Pap tests. The routine addition of colposcopy to follow-up cytology or HPV test has not been shown to add to the detection of recurrent or persistent disease and is thus not recommended.

Summary Points

- The Pap test has a proven track record for success. Since its widespread inception in the 1950s, the incidence of invasive cervical cancer and related death has dropped more than 70%. Since then, the technique surrounding how cervical cytology is obtained and processed has changed, with increases in transformation zone sampling and decreases in apparent false-negative test result rates.
- The 2001 Bethesda system reports cytologic abnormalities as ASC-US, ASC-H, LSIL, HSIL, AGC, and ACIS to complement the invasive squamous cell cancer and adenocarcinoma categories. The corresponding histologic changes are mild, moderate, and severe CIN (CIN 1, CIN 2, and CIN 3, respectively).
- HPV is a necessary but not sufficient cause for the development of cervical precancerous and cancerous lesions. Testing for the presence of HPV DNA can improve screening for women age 30 and older and enhances the triage pattern of women whose Pap tests fall within the category of ASC-US. Posttreatment HPV testing is helpful in distinguishing patients at low versus high risk for persistent or recurrent disease.
- Treatment advances stem from the understanding that preinvasive and invasive cervical disease arises at the transformation zone. Treating this zone of change will completely eliminate preinvasive disease approximately 80% of the time. Therapies range from simple excisions of the abnormal cervical epithelium to laser or cryosurgical ablations, to surgical excisional biopsies of the cervix to hysterectomy.
- HPV vaccination is FDA approved for use in girls and women 9 to 26 years of age. It is critical that women, whether vaccinated or not, follow current cervical cancer screening guidelines.

Uterine Cancer

David G. Mutch

The uterus and endometrium are unique organs. Almost any type of tissue histology can and does arise from these pluripotent tissues. This chapter will present premalignant and malignant conditions of the uterus. This includes the premalignant condition of endometrial hyperplasia as well as the frankly malignant conditions of the uterus that comprise the following two broad categories: (a) epithelial cancer and (b) mesenchymal tumors. Both of these types of malignancies develop within the lining or the body of the uterus, and this chapter will describe the epidemiology, staging, and treatment of these cancers. The epithelial cancers are primarily comprised of endometrioid, clear cell, and papillary serous tumors. The mesenchymal tumors are less common and are comprised of three broad categories: (a) mixed Müllerian tumors, (b) stromal tumors, and (c) leiomyosarcomas.

Endometrial Hyperplasia

Classification

Endometrial hyperplasia is an abnormal condition that usually represents an overgrowth of the endometrium. This terminology encompasses a wide variety of conditions. Some of these are clearly benign and some potentially malignant. Unfortunately, there have been so many different classifications over the years that there is significant confusion about the meaning of the term *endometrial hyperplasia*. For many years, it has been suggested that endometrial hyperplasia reflects the histologic representation of the continuum between normal proliferating endometrium and adenocarcinoma in situ. This theory was based on studies first reported by Gusberg and Kaplan in 1963. In that study, the authors reported that 20% of patients who had a hysterectomy were found to have a coexisting adenocarcinoma and that endometrial cancer developed in almost 12% of the remaining patients, with an average follow-up of 5.3 years. They concluded that the risk of cancer was significantly higher in women with endometrial hyperplasia than those without and that after 10 years the cumulative risk for cancer was approximately 30%.

During the ensuing years, several different classification schemes were developed, which resulted in increased confusion regarding both diagnostic criteria and prognosis of the various subtypes of hyperplasia. In the early 1990s, the International Society of

Gynecological Pathologists endorsed a classification that used both architectural features (the degree of glandular crowding and complexity) and cytologic features, especially cellular atypia. In this classification system, simple hyperplasia is defined as abnormally thickened endometrium with histologic evidence of an increased ratio of glands to stroma; the glands are cystically dilated and somewhat irregular with some infolding and budding. Complex hyperplasia represents glandular crowding with even less intervening stroma, and the glands show significant infolding and budding (Fig. 60.1). Atypical hyperplasia refers to either simple or complex architectural patterns, in which the cells lining the glands show loss of polarity, nuclear enlargement with increased nucleus-to-cytoplasm ratio and prominent nucleoli, and irregularly condensed chromatin (Fig. 60.2). Cystic hyperplasia is a benign condition arising from inactive endometrium and is not premalignant. It is the atypical changes that portend a worse prognosis in terms of development of malignancy in these premalignant conditions.

Since the study by Gusberg and Kaplan, additional studies have clarified some of the questions regarding this disorder. Using the new criteria, Kurman and colleagues reported that the risk of progression of endometrial hyperplasia to cancer varied according to the subtype. In this study of 170 patients, untreated endometrial hyperplasia regressed spontaneously in 74% and remained stable for more than 10 years in 18%. The risk of progression to cancer was 1% for patients with simple hyperplasia without atypia, 3% for those with complex hyperplasia without atypia,

8% for those with atypical simple hyperplasia, and 29% for patients with complex atypical adenomatous hyperplasia (Table 60.1). Finally, in 2005, data from the Gynecologic Oncology Group (GOG) was reported. GOG 167 was a protocol designed to follow the natural history of this disease and to assess malignant potential in a prospectively acquired cohort of patients with complex atypical hyperplasia. Several interesting findings were published from this data: (a) the risk of concomitant cancer was approximately 40%, (b) there was little difference in the accuracy of the pathology reading between community pathologist review and that of an academic pathologist, and (c) more extensive sampling by using dilation and curettage (D&C) in addition to an endometrial biopsy did not change the accuracy of the diagnosis. Therefore, once childbearing is complete, definitive surgery is probably the best option for treatment of women with complex atypical hyperplasia, and a simple endometrial biopsy appears to adequately make the diagnosis.

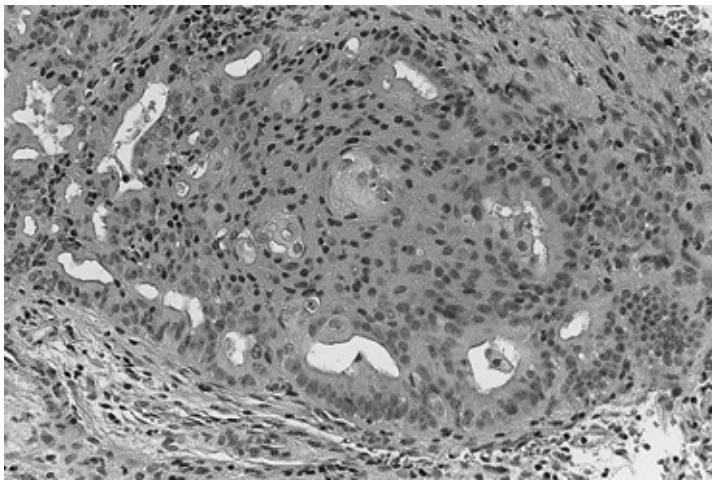

Figure 60.1 Complex hyperplasia without atypia. Closely packed glands are connected by morular squamous metaplasia. No cytologic atypia is present.

Clinical Picture and Diagnosis

Endometrial hyperplasia often becomes apparent with irregular vaginal bleeding. For this reason, this symptom should be evaluated with liberal use of the endometrial biopsy. Endometrial hyperplasia is commonly associated with a history of unopposed estrogen exposure, either exogenous or endogenous. In premenopausal women, it is associated with obesity and anovulation. Therefore, women with known polycystic ovary syndrome or known anovulation are at increased risk for developing this disease, as are obese women. Any abnormal bleeding should be investigated in the postmenopausal woman, but conditions that would increase the suspicion of an abnormal endometrium in the premenopausal woman are unopposed estrogen exposure from obesity or oral intake. Irregular bleeding in this setting should be evaluated with an endometrial biopsy.

TABLE 60.1 Natural History of Premalignant Endometrial Conditions

Type of Hyperplasia	Number of Patients	Number Persistent (%)	Number Regressed (%)	Number Cancer (%)
Simple without atypia	93	18 (19)	74 (80)	1 (1)
Complex				

without atypia	29	5 (17)	23 (79)	1 (3)
Simple with atypia	13	3 (23)	9 (69)	1 (8)
Complex with atypia	35	5 (14)	20 (57)	10 (29)

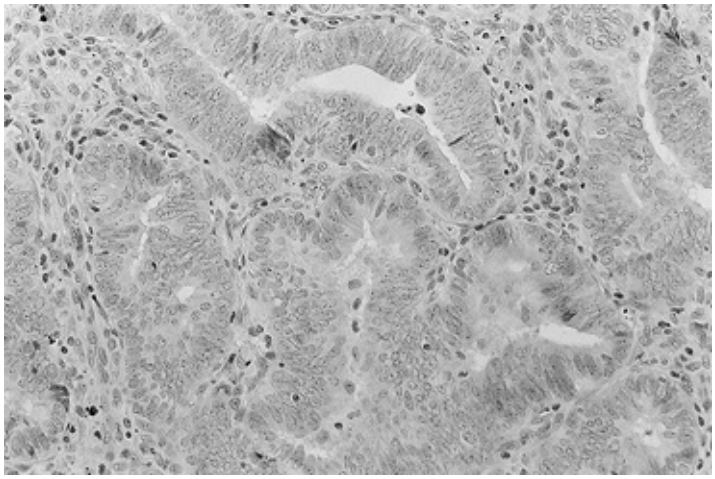

Figure 60.2 Complex hyperplasia with atypia. Closely packed, irregular glands demonstrate cytologic atypia in the form of loss of polarity and rounding up of the nuclei and nucleoli.

Cervical cytologic screening techniques are not a reliable means to diagnose endometrial abnormalities and should not be used to screen for endometrial abnormalities. Nonetheless, the Pap smear can reveal endometrial abnormalities. Atypical glandular cells of undetermined significance (AGUS) should be evaluated aggressively, because the risk of having underlying endometrial pathology is high. Endometrial biopsy clearly should be included in the evaluation of this abnormal cytology, especially in women over the age of 35. An endometrial biopsy is reported to be 97% as sensitive as a formal D&C. Therefore, a D&C to evaluate these abnormalities is usually not necessary and should be used only when an endometrial biopsy

cannot be performed; when persistent bleeding is unexplained by the biopsy; or when there is some uterine structural abnormality suspected, such as a polyp.

Management

Therapy for endometrial hyperplasia must be individualized and depends on histologic

criteria, predisposing factors, patient age, and desire to maintain fertility. In addition to differences in overall prognosis, the various subtypes of endometrial hyperplasia also respond differently to progestin therapy. Ferenczy and Gelfand reported on the results of progestin therapy in 85 postmenopausal women with endometrial hyperplasia. Patients who had hyperplasia without atypia enjoyed complete reversal of the abnormality following treatment with medroxyprogesterone acetate, 10 to 20 mg daily. Patients with cellular atypia noted only a 50% response rate to the same treatment regimen. In patients with atypical hyperplasia, there was also an increased risk of recurrent hyperplasia or cancer after completion of the progestin therapy when compared with those who had hyperplasia without atypia (50% vs. 6%). Premenopausal women can also be treated with oral contraceptives for 3 months if they have no significant contraindications to their use.

Most studies suggest that cancer will develop eventually in about 20% to 30% of patients with complex atypical adenomatous hyperplasia, but some have suggested a risk as high as 82% for those with untreated atypical hyperplasia. The risk of progression appears to be higher for postmenopausal than premenopausal women. The mean duration of progression from endometrial hyperplasia to carcinoma is about 10 years for lesions without atypia and 4 years for atypical lesions. In patients with atypical hyperplasia diagnosed by an endometrial biopsy specimen, a formal D&C should be considered to rule out a coexisting adenocarcinoma. It has been suggested that if gland epithelium is found within the stroma (i.e., stromal invasion) of the curettage specimen, even if the diagnosis is hyperplasia, there is a significant chance that the uterus still contains an endometrial cancer. If a diagnosis of carcinoma in situ is made by endometrial biopsy or D&C, in almost all circumstances a hysterectomy should be performed, because this is not a clearly reproducible diagnosis and actually may represent early invasive cancer or sampling error.

Progestational therapy is very effective in reversing endometrial hyperplasia without atypia. For these patients, either cyclic or continuous therapy is appropriate, using medroxyprogesterone acetate, 10 to 20 mg per day, or megestrol acetate (Megace), 20 to 40 mg per day, for either 14 days each month or daily. Therapy should be continued for 3 months and then the endometrium should again be sampled to document response. The hyperplasia will revert to normal in 75% to 90% of patients treated with progestins. In patients who desire pregnancy, ovulation induction can be considered by using either clomiphene or menotropins (Pergonal). If a patient does not desire pregnancy, long-term oral contraceptive therapy should be considered. In those patients with persistent hyperplasia, definitive surgery should strongly be considered.

Patients with atypical hyperplasia often will opt for a hysterectomy and bilateral salpingo-oophorectomy when made aware of the risk of coexisting adenocarcinoma (approximately 40%) and the malignant potential of these lesions. A truly postmenopausal woman (last menses 2 or more years ago) should be encouraged to undergo hysterectomy, with progestin therapy reserved for patients with severe medical problems that would make them very poor surgical candidates or patients who desire preservation of childbearing potential. If the decision is made to treat a patient medically, daily progestin therapy for 3 months is recommended, followed by repeat endometrial sampling. If hyperplasia persists in these patients, a D&C should be performed to rule out a coexisting malignancy or a hysterectomy should be performed. At the time of hysterectomy, the uterus should be opened

intraoperatively, with frozen section if indicated to document the presence and extent of any malignancy so that surgical staging can be performed at the same time, if appropriate.

An interesting, but still experimental, approach is insertion of an intrauterine contraceptive progesterone system (ICPS), which releases continuous therapeutic doses of progesterone or levonorgestrel. Until more experience is gained with the ICPS, it should not be employed outside a research setting. Two preliminary studies reported on the use of danazol (Danocrine) to treat women with adenomatous hyperplasia, and in both studies, all women treated were noted to have reversal of the hyperplasia on repeat endometrial sampling. In the premenopausal women, menses resumed within 1 to 2 months following therapy. In the first study, atrophic changes were noted on repeat endometrial sampling even though the patients had normal serum estradiol levels, suggesting a direct effect on the endometrium.

A relatively recently described risk factor for endometrial hyperplasia and carcinoma is the use of tamoxifen citrate (Nolvadex) as an adjuvant treatment for breast cancer. Tamoxifen has been associated with a six- to sevenfold risk of developing endometrial cancer and an increased risk of endometrial hyperplasia, polyps, and growth of fibroids. The best method for monitoring women taking tamoxifen is unknown. Obviously, patients should have an annual pelvic examination and Pap smear. Endometrial sampling should be performed in all patients with abnormal uterine bleeding. Because tamoxifen acts as a weak estrogen, it is not unreasonable to consider annual endometrial biopsy or sonographic evaluation of endometrial stripe thickness. This recommendation, however, is not based on prospective studies but rather on an intuitive approach. According to current information, women taking tamoxifen have >84% chance of developing a thickened endometrium, making this technique relatively nonspecific in evaluating the endometrium for pathology. Based on published studies, sonography is useful only for ruling out

---

significant pathology if the endometrial stripe is <5 mm in thickness. Therefore, this may not be useful in screening women on tamoxifen.

In summary, the management of endometrial hyperplasia should be individualized, depending on the histologic findings and the patient's age health and reproductive desires. Treatment options include hormone therapy and surgery. However, if the patient has completed childbearing and the diagnosis of complex hyperplasia with atypia has been made, the data acquired from GOG 167 would encourage the recommendation of total abdominal hysterectomy and bilateral salpingo-oophorectomy. Furthermore, the increasing use of tamoxifen should alert gynecologists to expect more cases of both benign and malignant changes within the endometrium, and they should be prepared to evaluate them for these abnormalities.

Endometrial Carcinoma

Incidence and Epidemiology

The American Cancer Society estimated that there were approximately 39,079 cases of epithelial endometrial carcinoma in the United States during 2007, accounting for about 7%

of all malignancies in women. It ranks seventh in the cause of death from cancer in women and accounts for about 7,000 to 7,500 deaths each year. At this time, endometrial cancer is the fourth most common cancer in women and is the most common gynecologic cancer. Occurring more frequently than endometrial cancer are lung, breast, and colon cancers. Endometrial cancer generally is thought to be a disease of postmenopausal women. However, one fourth of the cases may occur in women who are premenopausal, and about 5% occur in women under the age of 40. Generally, the prognosis is good, with an overall survival rate for all cases of about 75%. Management of this disease has evolved significantly over the past half-century. Preoperative radiation therapy followed by hysterectomy was the standard before the early 1980s, but now almost all patients are staged surgically, and postoperative management is tailored to the risk factors identified at the time of surgical staging. In 1988, this primary operative approach was formalized by the International Federation of Gynecology and Obstetrics (FIGO) and now requires surgical staging to accurately assign stages and determine appropriate treatment and progress of this disease (Table 60.2).

TABLE 60.2 International Federation of Obstetrics and Gynecology Staging for Carcinoma of the Corpus Uteri

Stage IA G1, 2, 3	Tumor limited to endometrium
Stage IB G1, 2, 3	Invasion to less than one half the myometrium
Stage IC G1, 2, 3	Invasion to more than one half the myometrium
Stage IIA G1, 2, 3	Endocervical glandular involvement only
Stage IIB G1, 2, 3	Cervical stromal invasion
Stage IIIA G1, 2, 3	Tumor invades serosa or adnexa, or positive peritoneal cytologic findings
Stage IIIB G1, 2, 3	Vaginal metastasis

Stage IIIC G1, 2, 3	Metastasis to pelvis, paraaortic lymph nodes, or both
Stage IVA G1, 2, 3	Tumor invasion of bladder or bowel mucosa
Stage IVB	Distant metastasis including intra-abdominal or inguinal lymph nodes

Histopathology-Degree of Differentiation

Cases of carcinoma of the corpus should be classified (or graded) according to the degree of histologic differentiation, as follows:

GI, ≤5% of a nonsquamous or nonmorular solid growth pattern

G2, 6%-50% of a nonsquamous or nonmorular solid growth pattern

G3, >50% of a nonsquamous or nonmorular solid growth pattern

Notes on Pathologic Grading

1. Notable nuclear atypia, inappropriate for the architectural grade, raises the grade of a grade 1 or grade 2 tumor by 1.
2. In serous adenocarcinoma, clear cell adenocarcinoma, and squamous cell carcinoma, nuclear grading takes precedence.
3. Adenocarcinoma with squamous differentiation is graded according to the nuclear grade of the glandular component.

Rules Related to Staging

1. Because corpus cancer now is staged surgically, procedures previously used for determination of stages are no longer applicable, such as the findings from fractional D&C to differentiate between stage I and stage II.
2. There may be a small number of patients with corpus cancer who will be treated primarily with radiation therapy. If that is the case, the clinical staging adopted by FIGO in 1971 would still apply, but designation of that staging system would be noted.
3. Ideally, width of the myometrium should be measured, along with the width of tumor invasion.

Annual report on the results of treatment in gynecologic cancer. *Int J Gynecol Obstet* 1989;28:189–190, with permission.

According to data from the American Cancer Society, the number of deaths from endometrial cancer was about 4,000 in 1990. In 2007, the mortality from endometrial cancer increased to 7,400. The exact reason for this is increase is unclear. Many suggest that this increased incidence is caused by the increased use of estrogen replacement therapy (ERT). Several known pieces of information can be used to argue against this. First, death from estrogen-induced endometrial cancer is rare. These cancers usually are well differentiated and carry a low mortality rate. Also, the rate of endometrial cancer is increasing in countries such as Norway and Czechoslovakia, yet estrogens rarely are prescribed in these countries. The incidence of endometrial carcinoma has increased over the last 50 years, most likely because of the aging population, the increased frequency of certain predisposing conditions such as obesity, and improved methods of diagnosis.

Adenocarcinoma of the endometrium is mainly a malignancy of postmenopausal women and is increasingly virulent with advancing age. Peak age at diagnosis is between 50 and 65 years, and approximately 25% of all cases of endometrial carcinoma are diagnosed in premenopausal women and 5% in women younger than 40 years. Usually, but not always, these young women are either obese, chronically anovulatory, or both. Women with endometrial cancer diagnosed at an early age should be queried about family history because endometrial cancer is the most commonly inherited gynecologic malignancy. It is the second most common cancer described in hereditary nonpolyposis colon cancer (HNPCC), or Lynch syndrome.

Bohkman proposed that there are two types of endometrial cancers, designated type I and type II. Type I endometrial cancer is estrogen dependent and is thought to progress typically from hyperplasia to frank cancer in a stepwise fashion. This type of malignancy typically occurs in younger, perimenopausal women with a history of exposure to unopposed estrogen, either exogenous or endogenous. These tumors tend to arise in regions of hyperplasia, tend to be well differentiated, and tend to be associated with a more favorable prognosis. The latter type of cancer (type II) tends to occur in older women without estrogen stimulation of the endometrium, is not often associated with endometrial hyperplasia, and is more commonly associated with poorly differentiated cancer or those of unusual histologic types. It generally carries a worse prognosis. Because cancer is a genetic disease and it is now realized that it develops as the result of an accumulation of mutations in genes necessary for normal cellular function, the pathways necessary for the development of these two types of cancers may be different and is an area of intense investigation by many researchers.

The main risk factor for endometrial adenocarcinoma is long-term unopposed estrogen exposure of either endogenous or exogenous origin. Obesity, nulliparity, and late menopause appear to be associated with high endogenous levels of unopposed estrogen. In

obese women, there is an increased peripheral conversion of androstenedione to estrone by fat cells. Nulliparity seems to be associated with endometrial cancer because ovarian dysfunction (chronic anovulatory cycles and polycystic ovaries) contributes to both the infertility and the unopposed estrogen levels. Estrogen-secreting tumors, such as granulosa cell tumors, are associated with endometrial cancer up to 25% of the time. Other risk factors include a history of pelvic irradiation, a history of breast or ovarian cancer, and use of tamoxifen (Table 60.3).

TABLE 60.3 Factors Associated with an Increased Incidence of Endometrial Cancer

Obesity
Diabetes (not an independent risk factor)
Hypertension
Menopause after the age of 55
High socioeconomic status
Positive family history (60% by age 70 if Lynch [HNPCC] family)
Polycystic ovary syndrome
Unopposed estrogen exposure in postmenopause
Estrogen-secreting tumor
Urban residence
Pelvic irradiation
History of another adenocarcinoma
Tamoxifen use
Lynch syndrome (HNPCC)

HNPCC, hereditary nonpolyposis colorectal cancer.

Oral contraceptives appear to provide protection from endometrial cancer. At least eight population-based studies suggest that this is so. The use of oral contraceptives appears to decrease the risk of developing endometrial cancer in women 20 to 54 years of age by 50% over those women who never have used oral contraceptives. This protective effect appears to last for at least 10 years in women who used oral contraceptives for at least 1 year. Cigarette smoking also decreases the risk of endometrial cancer. There appears to be a dosage relationship to this benefit, such that the greater the number of cigarettes smoked the less the risk of developing cancer. In one study, this decrease was quite profound: 30% when one pack was smoked and another 30% if more than one pack was smoked. Furthermore, the greatest risk reduction was in the heaviest women. This is not too surprising, because it is these women who are at the highest risk of developing endometrial cancer, so they might be expected to enjoy the greatest benefit from a factor which

decreased their risk. This benefit of risk reduction is strongly outweighed by the increased risk of other health problems of smoking such as heart and lung disease and, therefore, appears to be small consolation.

The relationship between unopposed estrogen exposure and endometrial cancer is well described. Although the risk of endometrial cancer is increased in these women, their prognosis tends to be better. Women with unopposed estrogen use tend to have lower stage, lower grade lesions with better prognosis.

Race is another predictor of survival and type of endometrial cancer. White women have a higher incidence

---

but also have a higher survival rate than black women. This originally was thought to be secondary to socioeconomic status, in that the diagnosis was made later because of less access to health care, and therefore, the cancer was of a higher stage. However, when these variables are controlled for, the survival appears to be less in black women than white. The exact reason for this is unclear. Black women have similar survival to white women when matched for poor prognostic factors. It appears that black women tend to have more poor prognostic variables, especially histologic type. With the advent of the Human Genome Project, a better understanding of the genetic differences among cancers can be more thoroughly evaluated and better understood. This may give us some insight into how different genetic changes occur or are differentially expressed in different patient populations.

Breast cancer is the most common cancer diagnosed in women in the United States, thereby making tamoxifen a widely used drug in this country. It is estimated that about 80,000 women will start taking tamoxifen each year. Tamoxifen is a selective estrogen receptor modulator, and it has varying effects on estrogen-responsive tissue. The endometrium responds to tamoxifen stimulation much like it does to estrogen. Therefore, the effects of tamoxifen on the endometrium are like those of unopposed estrogen, so the risk of endometrial cancer in women on tamoxifen therapy is increased. In 1985, Killackey reported on three patients with breast cancer who were receiving tamoxifen and then developed endometrial cancer. This and many other reports suggest that there is a significant increase in the risk of developing endometrial cancer while on tamoxifen. The National Surgical Adjuvant Breast and Bowel Project (NSABP) is one of the best studies published on this subject. This study analyzed 2,843 patients with node-negative estrogen receptor–positive breast cancer who were randomized to placebo or 20 mg of tamoxifen a day. There was a significant increase in the risk of endometrial cancer in the tamoxifen arm such that the relative risk was almost three times that of the control arm. These data combined with others suggest that the increased risk of endometrial cancer in women taking tamoxifen is between two and three times that of the population not taking tamoxifen. Women who have breast cancer are also at increased risk to develop endometrial cancer. These studies often do not take this increased susceptibility into account and therefore may overstate the risk of endometrial cancer in women taking tamoxifen. The benefits of tamoxifen use for prevention of breast cancer recurrence, more than 120 per 1,000 women, far outweigh the risks of 6 endometrial cancers per 1,000 women.

Genetics

Cancer is the result of accumulation of mutations within the human genome. These mutations can be either acquired or inherited. As more becomes understood through the Human Genome Project and other research focused on more subtle DNA differences, there will be even better understanding of the mechanism by which these cancers develop. It is therefore essential that clinicians be aware of the information provided by the Human Genome Project as well as other genetic research and use it to better help their patients.

Endometrial cancer is the most commonly inherited gynecologic cancer. The clearest hereditary link to this disease is seen in HNPCC, also known as the Lynch syndrome after Henry Lynch, who helped to define this familial cancer syndrome. Clinical features of HNPCC were described first in the medical literature in 1913 by Aldred Warthin, who identified a clustering of predominantly stomach and endometrial cancers in the family of his seamstress. This inherited pattern of cancers gained little attention over the subsequent 50 years or more until characterized by Henry Lynch as a cancer family syndrome. Subsequently, the pattern of autosomal dominantly inherited risk of gastrointestinal cancers and gynecologic cancers became known as HNPCC, although some experts prefer to use Lynch syndrome because they think that it more accurately describes the disease that encompasses both the colorectal tumors and extracolonic cancers.

HNPCC is a clinically defined disease in which the primary genetic defect has been identified as a mutation in the mismatch repair genes. It is an autosomal dominant disease with a varying risk of penetrance. This is usually around 80% for the commonly mutated mismatch repair genes MLH1 and MSH2. The less commonly inherited mutations may have a penetrance that is somewhat less. That means that about 80% of the patients who inherit one of these mutations will develop a cancer. During the 1990s, specific genes responsible for HNPCC were identified and are known as the mismatch repair genes. Assigning an individual the diagnosis of Lynch syndrome prior to the discovery of these genes was based only on family history, and presently, the diagnosis can be assigned to those who meet diagnostic criteria (Amsterdam or Bethesda) as well as if an inherited genetic mutation in one of the mismatch repair genes is identified. The clinical criteria for defining this disease can be seen in Tables 60.4 and 60.5. These criteria have evolved gradually from those factors focused on colorectal cancers to those that may encompass other cancers associated with the syndrome. Not all patients who fit the criteria of having clinical HNPCC have a mutation in any of these mismatch repair genes, indicating that there is still more to learn about the development of this disease. It is believed that as many as 10% to 30% of cancers ultimately may be categorized as familial. Most of the inherited abnormalities in this group of patients are unknown. Only about 5% of all endometrial cancers can be characterized as HNPCC or Lynch. Thus, the disease of interest, HNPCC, accounts for an important, but minor, percentage of all colorectal or endometrial cancers. It is now becoming understood that women with relatives with this disease can be at increased

---

risk for other malignancies. This brings home the point that all women with cancers should have a detailed family history taken, which will assess their risk of developing cancers and

determine any relative risk for their family members. For instance, the normal population has about a 2% chance of developing a colon cancer versus 80% cumulative risk in a patient with clear HNPCC. When counseling patients, the cumulative risk of developing a cancer over the course of one's life is the most informative means of conveying this information. An example of cumulative risk assessment for various HNPCC cancers in a patient with HNPCC can be seen in Table 60.6.

TABLE 60.4 Amsterdam Criteria

1. Patient must meet ALL of the following:
   1. Three or more relatives with a histologically verified colorectal cancer, one of whom is a first-degree relative of the other two (FAP should be excluded), AND
   2. Colorectal cancer involving at least two generations, AND
   3. One or more colorectal cancers diagnosed before the age of 50.
2. Patient must meet ALL of the following:
   1. Three or more relatives with a histologically verified HNPCC-associated cancer (colorectal cancer, cancer of the endometrium, small bowel, ureter, or kidney), one of whom is a first-degree relative of the other two, AND
   2. Colorectal cancer involving at least two generations, AND
   3. One or more colorectal cancer cases diagnosed before the age of 50.

FAP, familial adenomatous polyposis; HNPCC, hereditary nonpolyposis colorectal cancer.

TABLE 60.5 Bethesda Criteria

Patient may meet ANY ONE of the following criteria:

1. Individual with cancer in families who meet the Amsterdam criteria.
2. Individual with two HNPCC-related cancers, including synchronous and metachronous colorectal cancers or associated extracolonic cancers: endometrial, ovarian,

gastric, hepatobiliary, small bowel, or transitional cell carcinoma of the renal pelvis or ureter.
3. Individual with colorectal cancer and a first-degree relative with colorectal cancer or HNPCC-related extracolonic cancer or a colorectal adenoma; one of the cancers diagnosed at an age <45 years, and the adenoma diagnosed at age <40 years.
4. Individual with colorectal cancer or endometrial cancer diagnosed at age <45 years.
5. Individual with right-sided colon cancer with an undifferentiated pattern (solid or cribriform) on histology, diagnosed at <45 years; solid or cribriform pattern defined as poorly differentiated or undifferentiated carcinoma composed of irregular, solid sheets of large eosinophilic cells and containing small glandlike spaces.
6. Individual with signet-ring cell-type colorectal cancer diagnosed at age <45 years (signet-ring cell type defined as tumor composed of >50% signet-ring cells).
7. Individual with colorectal adenoma diagnosed at age <40 years.

HNPCC, hereditary nonpolyposis colorectal cancer.

Interestingly, the risk of a woman with HNPCC developing colorectal cancer may be less than that of a male with HNPCC (60% vs. 80%). Estrogen may play a protective role in this decreased risk. As stated previously, endometrial cancer is the second most common disease in women with HNPCC. An HNPCC mutation confers a significant cumulative risk of developing an endometrial cancer. In the normal population, a lifetime risk is about 1.5% versus 60% if one has inherited a mismatch repair defect or has clinically defined HNPCC.

Genes responsible for the development of a cancer are of two types: (a) oncogenes, which are dominantly expressed cellular control genes, and (b) tumor suppressor genes, which are nondominant cellular control genes. A more recently described set of genes is called *mismatch repair genes* and can be classified as tumor suppressor genes. These genes are responsible for ensuring fidelity in the DNA replicative process. The job of these genes is to search for and identify mismatches that occur during replication and to excise and repair the errors. In humans, they consist of the genes MLH1, MSH2, MSH6, PMS1, and PMS2. It is these genes that are responsible for the development of HNPCC cancers. When they are mutated and do not repair mismatches in the DNA, errors accumulate through normal division, and eventually enough errors occur in a gene(s) responsible for control of cell growth resulting in the development of a cancer. The importance of these mismatch repair genes is made clear when we see how highly conserved they are across species. The mismatch repair genes of *Escherichia coli* are not that different from the mismatch repair genes that are found in humans. It is now possible to test for mutations in these genes,

therefore, allowing assessment of the risk of an individual getting a cancer and understanding the risk of that individual passing that risk on to offspring. Any patient with endometrial cancer should have a thorough family history taken to detect the possibility of an inherited problem. If genetic testing is deemed appropriate, this may be offered to the patient and family. However, before genetic testing is recommended, the patient should undergo counseling by a trained genetic counselor.

In summary, HNPCC is a clinically defined disease described by the Amsterdam and Bethesda criteria that has a genetic basis. The genes responsible for this syndrome can be sequenced and mutations detected. Risk of developing an inherited cancer can then be assigned to these patients. Over time, the focus on these syndromes has shifted to include extracolonic cancers such as endometrial cancer. The Amsterdam Criteria II begin to take this into account, and the Bethesda criteria continued to expand on this

concept. Importantly, gynecologists see a fair number of synchronous or metachronous ovarian and endometrial cancers. These often occur in younger women and should raise the suspicion of an HNPCC association. Any patient with cancer should have a detailed family history taken to assess her risk of developing another cancer and to help assess her family members' risk of developing a cancer. If appropriate, family members should be offered genetic counseling and possible testing for mutation in the mismatch repair system.

Diagnosis

There are no accepted routine screening methods for detecting endometrial cancer in asymptomatic women or in women who are perceived to be at increased risk of developing the disease. Given the low incidence of endometrial cancer, this would be prohibitive from a cost standpoint. Furthermore, the complications of screening may be higher than the benefits. Clinical studies have evaluated routine endometrial biopsy, transvaginal ultrasonography, and Pap smears, but none of these techniques is sensitive or specific enough to be applied to the general population. Even though a routine Pap smear cannot be relied on as a screen for endometrial cancer, this malignancy should be suspected in any nonpregnant woman with atypical endometrial cells or in any postmenopausal woman with normal endometrial cells on a Pap smear. A Pap smear that reveals AGUS in a woman over the age of 35 should be evaluated by colposcopy, endocervical curettage (ECC), and endometrial biopsy to rule out endometrial cancer in addition to a possible cervical lesion.

Abnormal uterine bleeding is the most common initial symptom of endometrial cancer. Any bleeding in a postmenopausal woman must be evaluated promptly, although overall, only about 20% of these patients have a genital malignancy. The likelihood that postmenopausal bleeding is indicative of a uterine cancer clearly increases with increasing age. Perimenopausal women with abnormal bleeding must also undergo thorough investigation, with the most suspicious patterns being increased menstrual flow, a decreased menstrual interval, and intermenstrual bleeding. Whenever possible, the diagnostic procedure for evaluating the endometrium should be an office endometrial biopsy, which, under optimal conditions, approaches the accuracy of a formal D&C (>90%). An ECC usually should be performed in the evaluation of postmenopausal bleeding to rule out an endocervical carcinoma as the etiology. If the endometrial biopsy and ECC are satisfactory (with adequate tissue for a diagnosis) and demonstrate no significant abnormality, no further evaluation is necessary. If postmenopausal bleeding is persistent or recurrent or other high-risk factors exist, a fractional D&C should be considered. High-risk factors include atypical hyperplasia or endometrial polyps. Hysteroscopy should be considered if bleeding is recurrent or if either polyps or submucous fibroids are suspected. Many clinical studies now support the usefulness of transvaginal ultrasonography for evaluating the thickness of the endometrium in patients with postmenopausal bleeding. Various investigators have suggested that when the endometrial stripe is thinner than 5 mm, the cause of bleeding usually is related to atrophy, but there have been occasional reports of biopsy-proven malignancy even in patients with thin endometrial stripes. Additionally, almost all women

on tamoxifen will have a thickened endometrium, making this test less useful in this patient population. Ultrasound should never substitute for endometrial biopsy if there is an indication that there may be some underlying endometrial pathology.

If endometrial adenocarcinoma is diagnosed, further evaluation of the patient is necessary prior to deciding on the therapeutic approach. A careful physical examination should be performed, with particular attention to supraclavicular and inguinal lymph nodes. A thorough evaluation of the abdomen should be performed, and a bimanual rectovaginal examination to evaluate the size and

---

mobility of the uterus is important. The size and consistency of the cervix; the adnexal structures and parametrium; and the entire vagina, vulva, and rectum are important. These structures should be evaluated for nodules, masses, induration, and plaquelike lesions that might signify metastatic disease. Any suspicious genital lesions should be sampled for biopsy, and the stool should be tested for occult blood. The histologic subtype and grade of tumor can be determined from the endometrial biopsy or D&C specimen, but it is important to remember that approximately one third of the time, the final grade of tumor as determined on the hysterectomy specimen will differ from the original. Additionally, a chest radiograph and routine laboratory studies should be obtained. Based on other risk factors and symptoms, consideration should be given to performing a barium enema examination or a colonoscopy as well as preoperative computed tomography or magnetic resonance imaging to evaluate the uterus for depth of invasion and to document occult metastatic disease. An additional test that successfully predicts either deep myometrial invasion or distant disease is the serum tumor marker CA-125. Several studies have documented that 53% to 87% of patients with clinical stage I disease who later were found to have had extrauterine disease at the time of surgery had elevated CA-125, compared with only 2% to 12% of patients with surgically validated stage I disease. These studies may not be routinely necessary if the decision for full surgical staging can be made intraoperatively (i.e., if the necessary surgical expertise is available to perform pelvic and paraaortic lymphadenectomy).

Because endometrial cancer is now staged surgically instead of using the old clinical schema, several practical considerations should be noted. In the past, preoperative irradiation was used in many patients, especially those with grade 2 or 3 lesions, positive ECC findings, or a large uterus. Depending on where the patient was treated, preoperative irradiation could consist of intracavitary radium or cesium for approximately 72 hours or external beam irradiation of 4,000 to 4,500 cGy to the pelvis. Using these types of treatment plans, many patients received either unnecessary radiation or radiation that did not encompass all of their disease (e.g., paraaortic node metastasis). A second consideration is that all patients should at least be evaluated for full surgical staging, including selective pelvic and paraaortic node dissection to determine the extent of the disease. With the adoption of the new surgical staging scheme (Table 60.2), most patients should undergo primary surgical therapy, including a hysterectomy, bilateral salpingo-oophorectomy, peritoneal cytologic analysis, and selective pelvic and paraaortic node dissection, as indicated. Because endometrial cancer can spread via both the lymphatics and the bloodstream, as well as transmurally or transtubally into the peritoneal cavity, a

thorough exploration of the entire abdominal cavity is necessary to document any extrauterine metastasis. Only patients with technically inoperable tumors or medical conditions that make them poor operative candidates should be considered for primary radiation therapy. In these cases, patients should be staged by using the older clinical staging schema.

TABLE 60.7 Prognostic Factors

Stage of disease

Prognostic Factors

Several well-recognized factors can be used to predict the prognosis of a patient with adenocarcinoma of the endometrium. Preoperative evaluation, coupled with the findings at the time of surgical staging and final pathology, allows individualization of postoperative therapy. These factors are exceedingly important in selecting appropriate postoperative therapy for patients (Table 60.7).

Staging

Until the late 1980s, endometrial cancer was clinically staged by using clinical information obtained from examination of the patient and the fractional D&C (Table 60.8). This staging system, however, failed to recognize important prognostic factors such as deep myometrial invasion and clinically occult extrauterine disease and often underestimated the extent of disease. Because of these inadequacies, FIGO modified this staging schema in 1988 to reflect the information obtained from surgical exploration and pathologic evaluation of removed tissue. Endometrial cancer is now staged according to the FIGO staging system (Table 60.2). The recommendation is for all medically operable patients with clinical stage I disease, regardless of tumor grade, to undergo an extrafascial total abdominal hysterectomy and bilateral salpingo-oophorectomy for both staging and therapeutic purposes. A radical hysterectomy may be appropriate in certain circumstances in which the disease is known to involve the cervix or parametrium. There is one

study that suggests that a radical hysterectomy performed for cervical involvement of endometrial cancer offers a survival advantage over those patients with cervical

involvement who had a less radical procedure. The abdominal wall incision should be adequate to perform both pelvic and paraaortic lymph node sampling, if indicated by tumor grade and depth of invasion into the myometrium. Immediately after the peritoneal cavity is entered, fluid (either ascites or washing) is obtained for cytologic analysis.

TABLE 60.8 Clinical Staging

Stage I	Disease confined to uterus
Stage II	Disease extends to cervix
Stage III	Disease extends to pelvis
Stage IV	Distant metastasis

Although the FIGO surgical staging schema has been in effect for more than 15 years, there is still considerable controversy as to which patients should undergo the pelvic and paraaortic lymph node sampling as required by this schema. It is also unclear how to select these patients and which preoperative and intraoperative findings can be used to define the patient population most likely to benefit from this procedure. Many institutions send the uterus for frozen section analysis intraoperatively and use the pathologic determination of tumor grade and depth of invasion to determine the need for full surgical staging. Others use preoperative information obtained from the endometrial biopsy specimen and radiographic information, especially when patients need to be referred to another center for surgical staging. Because the error rate for poor prognostic features is high with intraoperative evaluation, more gynecologic oncologists are recommending that all patients undergo staging so that all necessary information is available for postoperative treatment planning.

In a large study by the GOG of 621 women with clinical stage I disease, 22% of patients were found to have disease outside the uterus. The sites of distant disease were evenly divided between paraaortic and pelvic lymph nodes and positive peritoneal cytology. Adnexal involvement was less likely than nodal involvement or positive peritoneal cytologic findings. Equally important, an additional study documented that only 24% of patients with clinical stage II disease actually had pathologic confirmation of cervical involvement at the time of hysterectomy. On occasion, patients are found to have simultaneous endometrial and ovarian cancers, with a reported incidence rate of 1.4% to 3.8%. Although the difference between metastatic and synchronous primary tumors usually can be determined by routine pathologic examination, this determination occasionally cannot be made with any degree of certainty. The survival of patients with endometrial

cancer by stage can be seen in Table 60.9.

Tumor Grade

Grading provides a measure of tumor aggressiveness, and it is now an essential part of the FIGO staging for endometrial cancer. Tumor grade is one of the most important prognostic factors for predicting overall survival. Assignment of tumor grade is based on both architectural patterns such as gland formation and nuclear atypia and is affected significantly by interobserver reproducibility. It is also not unusual for the tumor grade from the endometrial biopsy to vary from the final tumor grade from the hysterectomy specimen. The higher the tumor grade, the more likely the patient will have deep myometrial invasion as well as lymph node and other metastases. Grade is clearly an independent predictor of long-term survival as well as a predictor of other poor prognostic features. Survival based on grade of the tumor alone can be seen in Table 60.10, and the relationship between grade and the depth of myometrial invasion can be seen in Table 60.11. Examples of the various degrees of differentiation can be seen in Figures 60.3,60.4,60.5.

Depth of Myometrial Invasion

Depth of myometrial invasion is another important prognostic factor that directly correlates with the likelihood of extrauterine disease and disease recurrence. In the new surgical staging criteria, maximum depth of myometrial invasion determines the subcategories within stage I disease. It is believed that increasing depth of invasion is associated with a higher likelihood of access to the lymphatic system, thereby increasing the incidence of both pelvic and paraaortic lymph node metastasis. In a study by Boronow and others, only 1% of patients without myometrial invasion had pelvic lymph node involvement, compared with

25% having positive pelvic lymph nodes with outer-third involvement. Survival was also shown to correlate with depth of invasion, with an 80% to 90% 5-year survival with minimal invasion compared with 60% survival with deep invasion. For early-grade lesions, gross evaluation of depth of invasion is quite accurate at about 85% to 90%. As the cancer becomes less well differentiated, the gross evaluation is less accurate because the margins of the cancer are more infiltrative and less clearly demarcated. Furthermore, as the cancer becomes less well differentiated, there is a greater likelihood of deep myometrial invasion and an associated decrease in survival (Table 60.11).

Lymph Node Metastasis

For patients with clinical stage I endometrial cancer, lymph node involvement is the most important independent prognostic factor, being associated with a sixfold increase in the risk of recurrent disease. In all patients with endometrial cancer, approximately 10% will have positive pelvic lymph nodes, and 6% will have positive paraaortic lymph nodes, with paraaortic node involvement being the most important predictor of survival. The incidence of lymph node involvement correlates with stage and grade of tumor, depth of myometrial involvement, and location of the cancer in the uterus (i.e., fundal versus lower uterine segment). In patients with clinical stage II disease (i.e., cervical involvement), lymph node metastasis occurs in approximately 35%.

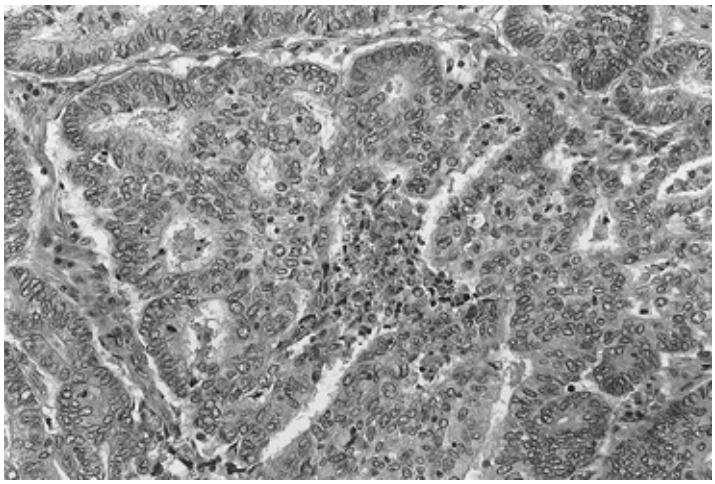

Figure 60.3 Well-differentiated adenocarcinoma. Back-to-back glands with no intervening stroma.

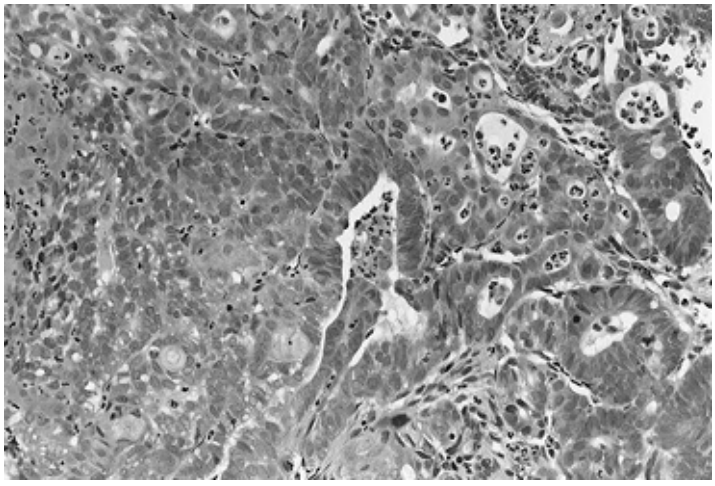

Figure 60.4 Moderately differentiated adenocarcinoma. The left half of this photograph shows back-to-back glands, while the central portion shows solid carcinoma.

Adnexal and Intraperitoneal Involvement

Clinically occult adnexal metastasis occurs in approximately 10% of patients with clinical stage I disease, with most having other high-risk factors such as deep myometrial invasion or lymph node involvement. In patients with adnexal metastasis as their only high-risk factor, overall survival seems to be minimally affected. Other extrauterine intraperitoneal disease is associated with a significant decrease in survival.

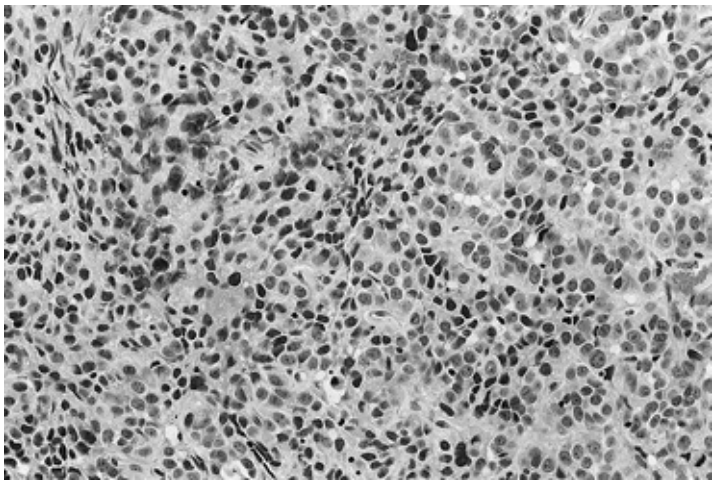

Figure 60.5 Poorly differentiated adenocarcinoma. Predominantly solid carcinoma with very focal glandular differentiated.

Tumor Size

Schink and colleagues reported that the size of the endometrial tumor was of prognostic significance. They reviewed tumor size in 91 patients with disease apparently confined to the uterus and found that if the tumor was smaller than 2 cm, the chance of nodal metastasis was about 6%. However, if the tumor was larger than 2 cm, the chance of nodal metastasis was over 20%. In this study, tumor size was an independent prognostic variable.

Histologic Subtype

The histologic subtype of adenocarcinoma may have an independent impact on patient outcome. Approximately 80% of endometrial cancers are of endometrioid histology. These cancers can be of varying degrees of differentiation. There are thought to be of two subtypes as follows: (a) type 1 arises from endometrial hyperplasia, is estrogen dependent, and usually confers a better prognosis, and (b) type 2 endometrial cancer tends to be more poorly differentiated, is not dependent on estrogen stimulation, and generally carries a worse prognosis. Squamous differentiation is seen in 15% to 25% of endometrioid tumors. The significance of squamous differentiation is unclear, and its impact has been debated for many years. In the past, the terms *adenoacanthoma* and *adenosquamous carcinoma* were used to identify adenocarcinomas with either benign or malignant squamous differentiation. More recently, Zaino and colleagues recommended that these terms be replaced with the more descriptive term *adenocarcinoma with squamous differentiation*. Although the squamous elements can have varying degrees of differentiation, they usually correlate with the glandular components. Furthermore, the differentiation of the glandular component appears to be the important prognostic feature.

Papillary serous and clear cell cancers of the endometrium are both quite rare (approximately 5% each) but have a significantly worse prognosis compared with that of endometrioid adenocarcinoma. Both of these histologic types are more common in older

women, who tend to have distant disease, even when clinically it appears to be stage I (Figs. 60.6, 60.7). These two histologic types account for a disproportionate number of deaths from this disease. Most people feel that these histologic types and the carcinosarcomas (malignant mixed müllerian tumors [MMMTs]) almost always require adjuvant therapy.

Age

Although it is recognized clearly that advancing patient age at diagnosis is associated with a poorer outcome, there is no agreement as to why this is true. In a study by Lurain and colleagues, increasing patient age was an independent prognostic factor associated with recurrent disease. No patient under age 50 years developed recurrent cancer, compared with 12% of women between 50 and 75 years and 33% of women older than 75 years. For every 1-year increase in age over 50 years, there was a 7% increase in the rate of recurrence. Younger patients tend to have early, well-differentiated lesions with no or minimal myometrial invasion. Younger patients also tend to be in better general health, thereby allowing more aggressive definitive surgery. It has been suggested that older women are more likely to ignore signs of vaginal bleeding, thereby delaying diagnosis until the stage is more advanced. Interestingly, however, the length of time between onset of bleeding and presentation to a clinician does not correlate with tumor stage, and patients with advanced stage disease have not necessarily delayed seeking medical care.

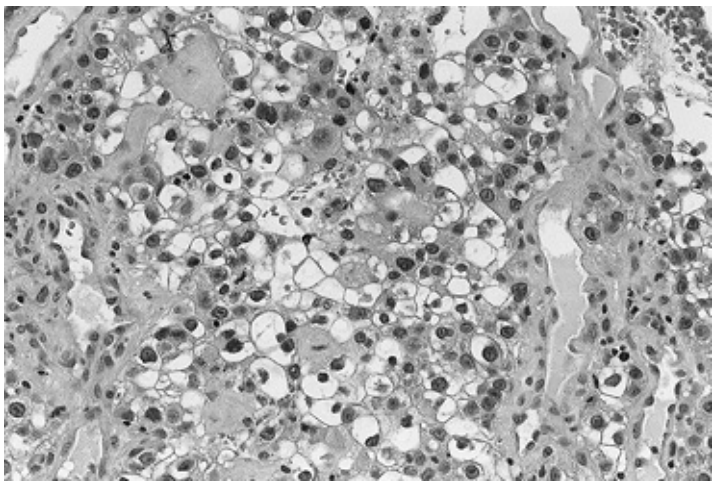

Figure 60.6 Clear cell carcinoma. The tumor forms sheets of cells with cleared cytoplasm and pleomorphic nuclei.

Peritoneal Cytology

The significance of malignant peritoneal cytologic findings obtained during surgical staging for endometrial cancer is controversial. In essentially all published studies, a positive peritoneal cytology result is associated with other high-risk

features such as deep myometrial invasion, adnexal spread, positive lymph node

metastasis, and cervical involvement. Several studies showed a two- to threefold increase in the risk of recurrent disease in patients with positive peritoneal cytology, but usually these patients have one or more other high-risk factors, and many times the recurrent disease is outside the peritoneal cavity. In patients found to have positive cytologic findings, it is unclear whether any currently available therapy would have any impact on eventual outcome.

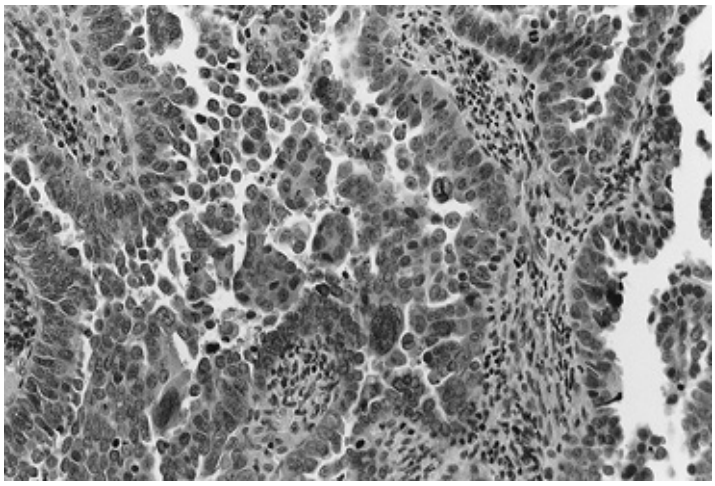

Figure 60.7 Serous carcinoma. The tumor shows marked intraluminal complexity and high-grade nuclear atypia.

Race

Even with correction for age and tumor stage, black women with endometrial cancer have a much poorer prognosis than white women. For all stages of endometrial cancer, white women have an 86% 5-year survival compared with a 55% 5-year survival for black women, and within each stage the relative survival is worse for blacks.

Other Factors

Many other factors have been shown to affect prognosis, including hormone receptor status of the tumor, DNA content or ploidy, proliferative index, and oncogene expression. Both estrogen receptor and progesterone receptor levels have been shown to be prognostic factors independent of tumor grade, with the progesterone receptor level being the more important for predicting overall survival. Progesterone receptor levels also can be used to predict which patients with advanced or recurrent disease are more likely to respond to hormone therapy. Recently, many papers have emerged suggesting that p53 overexpression is an important prognostic indicator, and some are using it to help guide adjuvant therapy, as it may suggest a more aggressive histologic type.

Management

The primary management of endometrial cancer is surgery (Table 60.12), consisting of

removal of the uterus, cervix, and adnexal structures. Surgical staging procedures, including careful exploration of the abdomen and pelvis and lymphadenectomy, often are done at the same time, as described previously. As soon as the uterus has been removed, it should be sent to the pathology laboratory for evaluation. For patients in whom lymph node sampling is indicated (Table 60.12), representative samples of lymph node–bearing tissue from the lower aorta and vena cava are removed. Pelvic lymph node sampling should remove nodes from common and external iliac and obturator regions. An omental biopsy may be performed and is indicated for patients with papillary serous and clear cell cancers. In patients who are very poor candidates for exploratory laparotomy (e.g., morbidly obese), vaginal hysterectomy or laparoscopically assisted vaginal hysterectomy should be considered. Every effort should be made to remove the adnexal structures; therefore, laparoscopically assisted vaginal hysterectomy may be preferable. If appropriate surgical expertise is available, the full surgical staging, including pelvic and paraaortic lymphadenectomy, can be performed through the laparoscope. Until additional information is obtained, vaginal hysterectomy should be limited to very select patients who otherwise might be given radiation therapy only. In patients with clinically apparent cervical involvement, radical hysterectomy with bilateral salpingo-oophorectomy and lymph node dissection may be considered. Data is being accumulated in a prospective manner by the GOG comparing the efficacy and safety of laparoscopic surgery compared with that of conventional laparotomy. This data should be forthcoming and will help to guide future therapy.

TABLE 60.12 Surgical Therapy of Endometrial Cancer

Risk Group (incidence)	Positive Pelvic Nodes (%)	Surgery
Low risk (30%) Stage IA, IB Grade 1	3	TAH-BSO, peritoneal cytology
Moderate risk (50%) Stage IB Grades 2, 3	9	TAH-BSO, LND, peritoneal cytology
High risk (20%) Stage ICperitoneal Grades 1, 2, 3 cytology	18	TAH-BSO, LND, peritoneal cytology

TAH-BSO, total abdominal hysterectomy–bilateral salpingo-oophorectomy; LND, lymph node dissection.
From Creasman WT, Morrow CP, Bundy BN, et al. Surgical pathologic spread patterns of endometrial cancer. A gynecologic oncology group study. *Cancer* 1987; 60(Suppl): 2035–2041.

Following surgery and review of the final pathology report, patients may be divided into risk groups based on the many prognostic factors discussed previously. This classification can then be used to individualize the recommended postoperative therapy, if needed. Because formal surgical staging has been utilized widely for <10 years, most of the information on recommendations for postoperative radiation therapy is based on clinically staged patients. The risk of pelvic recurrence in patients with high-risk factors but negative surgical staging is largely unknown. The GOG study based on surgicopathologic correlation found that even when sampled lymph nodes were negative, patients with deep myometrial invasion and poorly differentiated cancers were still at a higher risk of recurrence. Even though the surgical staging procedures failed to document extrauterine pelvic disease, postoperative pelvic irradiation was associated with a decreased risk of local recurrence. It is not yet clear whether surgical staging can define a

subgroup of stage I patients other than the already identified low-risk patients, who can be treated without adjuvant radiation therapy.

Treatment for patients with stage II disease remains somewhat controversial. Most studies suggest that patients with cervical involvement are at a higher risk for vaginal vault recurrence and often recommend adjuvant vaginal cuff irradiation. Whether or not those patients with otherwise negative surgical staging also need pelvic irradiation remains to be confirmed. With clinically apparent cervical involvement, treatment recommendations include either radical hysterectomy or preoperative irradiation followed by extrafascial hysterectomy.

Treatment for patients with documented extrauterine disease (stages III and IV) or patients with high-risk stage I disease should be individualized to encompass the true extent of the disease. Therapeutic options include pelvic irradiation, extended-field irradiation to cover the paraaortic lymph nodes, whole-abdomen irradiation, and systemic hormone therapy or chemotherapy. In most cases, management of distant metastasis with either high-dose progestins or chemotherapy is palliative only, with little expectation for long-term control of disease. The most widely used chemotherapy agents include doxorubicin hydrochloride (Adriamycin) and cisplatin (Platinol) or carboplatin (Paraplatin).

Data is emerging suggesting that chemotherapy may be more effective than radiation in locally advanced endometrial cancer. GOG 122 randomized patients with locally advanced extrauterine disease after comprehensive staging to radiation therapy compared with cisplatin and doxorubicin. The results of this study found a survival advantage for those patients treated with chemotherapy. This was the first report indicating that chemotherapy

is active enough in this disease to compete with radiation therapy. This study was ongoing, while another study (GOG 177) was open to the evaluation of advanced stage and recurrent endometrial cancer, randomizing these patients to cisplatin and doxorubicin plus or minus paclitaxel with cytokine support. GOG 177 showed that the triple-agent therapy utilizing paclitaxel, doxorubicin, and cisplatin (TAP) was the superior combination. Based on this data, the most active combination of agents must be considered. However, TAP is quite toxic and therefore should be used carefully. There is an ongoing trial randomizing TAP with platin-based therapy and paclitaxel (PT) to determine if the less toxic combination of PT is comparable to the more toxic TAP. At present, most postoperative regimens for locally advanced disease include a combination of radiation with chemotherapy. Those patients with distant disease are usually treated with a platin-taxane–based combination.

Progestins have been used for many years in the management of recurrent endometrial carcinoma, with approximately one third of patients having a favorable response. Patients with well-differentiated tumors have a higher response rate than those with moderately or poorly differentiated cancers. Although the role of estrogen and progesterone receptors in endometrial cancer therapy has not yet been accepted widely, it does appear that the responsiveness of recurrent tumor to progestin therapy is related to the content of both estrogen and progesterone receptors. If both receptors are present, the likelihood of a favorable response is good, regardless of tumor grade or other high-risk factors. If the concentration of receptors is low, it is unlikely that the recurrent tumor will respond to progestins, and other chemotherapy should be considered. A recent GOG trial demonstrated that cycling tamoxifen with progestational agents might afford an increased response over either agent alone.

Approximately 10% to 15% of patients with endometrial cancer are inoperable, usually because of morbid obesity or severe intercurrent disease. In these patients, primary radiation therapy should be considered. In most cases, a combination of external beam and intracavitary irradiation should be used, and with definitive therapy approximately 85% to 90% of patients with early-stage disease will have control of uterine disease. The overall risk of recurrence in these patients with stage I disease correlates with tumor grade, with a 5-year survival of 94% for grade 1, 92% for grade 2, and 78% for grade 3 tumors.

Posttreatment Surveillance

Many studies have confirmed that after treatment of endometrial cancer, most recurrences will occur within 3 years. Approximately one half of these recurrences will be asymptomatic, and many will be at the vaginal apex. Thus, the traditional recommendation has been to follow patients with physical examination and vaginal cytology every 3 to 4 months for the first 2 to 3 years and then at 6-month intervals for at least 5 years. Serial serum CA-125 measurements also have been suggested for surveillance of patients who have been treated for endometrial cancer, although the level may be normal in patients with early recurrent disease. However, because treated endometrial cancer will not recur in the great majority of patients, several studies have addressed the cost-effectiveness of this traditional recommendation. In a study from the M. D. Anderson Cancer Center, 59% of patients with recurrence were asymptomatic, with over one half

being picked up on physical examination, 26% by an elevated CA-125, and only 4% by vaginal cytologic examination. Because of these findings, these authors recommended that physical examination, serum CA-125 assay, and vaginal cytology be performed only every 6 to 12 months on asymptomatic patients. A Canadian study reported that only one recurrence was documented during more than 200 routine follow-up visits after treatment for endometrial cancer, using a schedule of examinations of every 3 months for the first year, every 4 months for the second year, and every 6 months thereafter. There was no difference in the salvage rates of recurrent disease picked up during routine surveillance

compared with recurrent disease documented in symptomatic patients. In this study, no recurrence was picked up by vaginal cytology alone. In a third study from Duke University, an analysis of various follow-up techniques demonstrated that routine vaginal cytology and chest radiograph were not cost-effective. The recommendation of these investigators is to follow patients every 6 months with examination alone, using additional testing to evaluate any symptoms. Most authorities still recommend periodic vaginal cytology in patients undergoing surveillance for endometrial cancer.

Estrogen Replacement Therapy after Treatment

For many years, it has been thought that a history of endometrial cancer, even successfully treated, was an absolute contraindication to ERT, as adenocarcinoma of the endometrium is considered an estrogen-dependent neoplasm. Because no scientific data support the contention that ERT is dangerous for patients who have had a hysterectomy for endometrial cancer and because the body of evidence is increasing in supporting the value of ERT in decreasing morbidity and mortality from heart disease, stroke, and osteoporosis, many physicians and patients are questioning the earlier proscription. During the last decade, there have been several small retrospective studies of patients given ERT following treatment for early-stage endometrial cancer (Table 60.13). In 1986, Creasman and coworkers reported on 221 patients with stage I endometrial cancer, of whom 47 (21%) were given postoperative estrogen replacement for a median of 26 months. Statistical analysis revealed no increased risk of recurrence or death between those who received ERT and those who did not when adjustments were made for tumor grade, myometrial invasion, nodal metastasis, peritoneal cytology, and age. In fact, the risk of recurrence was significantly higher in the untreated group (15% vs. 2%), as was the risk of dying of intercurrent disease. Lee and others reported similar study design and conclusions 3 years later. In both of these studies, selection bias may have contributed to the results, but it does appear that a low-risk group of patients can be selected who can safely take estrogen replacement. Chapman and colleagues retrospectively reviewed information on 123 patients with stages I and II endometrial cancer, of whom 62 received ERT, and again documented no increase in recurrences or deaths from this malignancy. In a committee opinion in August 1993, the American College of Obstetricians and Gynecologists concluded that there are no definitive data to support specific recommendations regarding ERT for women previously treated for endometrial cancer. The opinion states that estrogens could be used for the same indications as for any other woman, except that the selection of appropriate candidates should be based on prognostic indicators and the risk that a patient

is willing to assume. The gynecologic practice committee, due to the paucity of data, could not evaluate the need for progestational agents in addition to estrogens. A large GOG trial was under way to assess the risk of hormonal replacement in these patients but was closed due to poor accrual in the wake of the Women's Health Initiative (WHI) trial. This question may never be answered in a prospective manner.

ERT, estrogen replacement therapy.

Uterine Sarcomas

Sarcomas of the uterus carry a poor prognosis, but fortunately, they are rare and represent <5% of all uterine tumors. The incidence of these tumors is about 1.7 in 100,000 women per year in the United States. The classification of the various histologic types, in order of frequency, can be seen in Table 60.14. There is some retrospective evidence that sarcomas tend to arise more commonly in patients who have undergone pelvic irradiation in the past. A clear cause-and-effect relationship between irradiation and sarcomas has not been established, and new data have failed to corroborate the older literature.

TABLE 60.14 Classification of Uterine Sarcomas by Frequency

Mixed homologous müllerian sarcoma (carcinosarcoma)
Mixed heterologous müllerian sarcomas (carcinosarcoma)
Leiomyosarcomas
Endometrial stromal sarcomas
Other sarcomas

These lesions arise primarily from two tissues: endometrial sarcomas arise from endometrial glands and stroma, and leiomyosarcomas arise from the myometrium itself. The MMMTs arise from the pluripotent endometrial stroma. Other sarcomas, such as angiosarcoma and fibrosarcoma, arise in supporting tissues. In general, uterine sarcomas are the most malignant type of uterine tumor and tend to differ significantly from endometrial adenocarcinomas with regard to patterns of spread and prognosis.

The relative incidence of the various subtypes of uterine sarcomas differs significantly in the literature, with mixed mesodermal sarcomas being the most common in recent studies. The staging criteria for uterine sarcomas are based on the FIGO classification for endometrial cancers (Table 60.2).

Classification

Numerous classification schemes for uterine sarcomas have been proposed, depending on both cell type and site of origin. In 1959, Ober suggested a classification of the endometrial sarcomas. This does not include the pure sarcomas, which are self-explanatory. This classification can be seen in Table 60.15. It should be further noted that many pathologists are now considering MMMTs of the endometrium to be poorly differentiate endometrial cancer and not a sarcoma. Generally, homologous tumors are comprised of tumors that should belong in the normal uterus, such as smooth muscle or endometrial stroma. Heterologous elements are those tissues that normally would not be found in the uterus,

such as bone (osteosarcoma) or cartilage (chondrosarcoma). Most pathologists have adopted this classification, which has the advantage of being able to classify these malignancies for study, because most tumors fall into four major groups. Pure tumors are composed of only one cell type, whereas mixed tumors have more than one cell type. Homologous tumors contain tissue elements that are indigenous to the uterus, whereas heterologous tumors are defined as those that contain tissue elements foreign to the uterus (Table 60.15). Because the great majority of uterine sarcomas fall into one of four categories, the GOG has accepted a more simplified classification:

- Leiomyosarcoma
- Endometrial stromal sarcoma
- Mixed homologous Müllerian sarcoma (carcinosarcoma)
- Mixed heterologous Müllerian sarcoma (mixed mesodermal sarcoma)

TABLE 60.15 Classifications of Uterine Sarcomas

Homologous	Heterologous
Ober Classification	
Pure	
Stromal sarcoma (endolymphatic stromal myosis)	Rhabdomyosarcoma
Leiomyosarcoma	Chondrosarcoma
Angiosarcoma	Osteosarcoma
Fibrosarcoma	Liposarcoma
Mixed	MMMT
GOG Classification	
Leiomyosarcomas	

Endometrial stromal sarcomas

Mixed homologous müllerian sarcomas (carcinosarcoma)

Mixed heterologous müllerian sarcomas (mixed mesodermal sarcoma)

Other uterine sarcomas

MMMT, malignant mixed Müllerian tumor.

Leiomyosarcoma

Leiomyosarcoma is a malignancy of smooth muscle. This sarcoma was thought to be the most common of the malignant mesenchymal tumors, a concept that is supported by literature before the 1970s. However, more recent data from the GOG and other sources suggest that leiomyosarcoma is the second most common sarcoma of the uterus and accounts for about one out of seven of all uterine sarcomas, or about 16%. This information is detailed in GOG data published on 447 uterine sarcomas. This malignancy is found in younger women, with a median age at diagnosis between 43 and 53 years. Leiomyosarcoma is more common in black women and is associated with a poorer prognosis in these patients. The patterns of spread for leiomyosarcoma appears to be via both lymphatics and the vasculature, because distant metastases will develop in many patients even if lymph node biopsy results are negative at the time of surgery.

Although there is some disagreement about the exact histologic criteria required for a diagnosis of leiomyosarcoma, the most important factor appears to be the mitotic count of the tumor. Cellular myomas and bizarre leiomyomas may appear to be malignant, but if there are fewer than 5 mitoses per 10 high-power fields (HPF), the lesion is considered benign. Tumors with more than 10 mitoses per 10 HPF are malignant, and those with 5 to 10 mitoses per 10 HPF are thought to have an uncertain potential for malignancy. Many investigators agree that 5-year survival is

related to the number of mitoses per 10 HPF, with a 95% to 98% survival with fewer than 5 mitoses per 10 HPF, approximately 40% survival with 5 to 10 mitoses per 10 HPF, and very poor survival (15% to 20%) with more than 10 mitoses per 10 HPF. An example of a leiomyosarcoma can be seen in Figure 60.8. The etiology of leiomyosarcoma is unclear. As its name suggests, this tumor was thought to arise within benign leiomyoma. However, in most cases, it appears to arise independently of these tumors. Hysterectomy was felt to be indicated for a rapidly enlarging uterus or rapidly growing fibroid tumors for fear that this represented degeneration of leiomyomas into a sarcoma. Investigators from the University of Southern California addressed this question best. These authors retrospectively reviewed

a large series of patients with “rapidly enlarging” leiomyomas and found the incidence of sarcoma to be very low. They recommended that surgery for a concern of leiomyosarcoma was not warranted for fibroid tumors that were enlarging rapidly, and reasons for surgery should focus on other issues such as symptoms of pressure, pain, or bleeding.

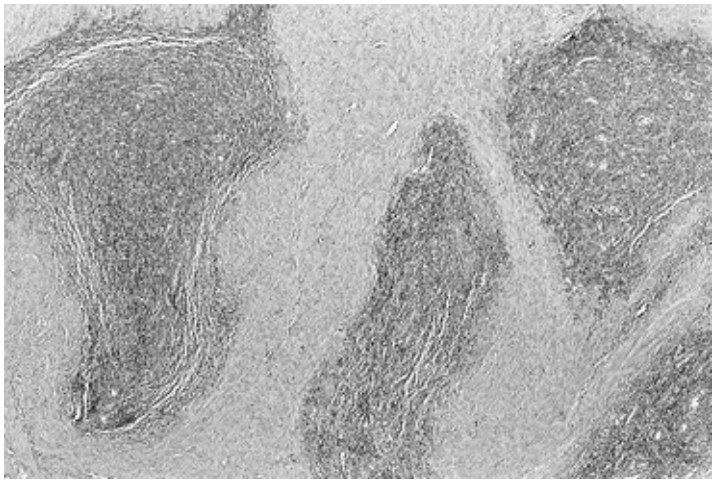

Figure 60.8 Leiomyosarcoma. Interlacing fascicles of smooth muscle cells exhibit high-grade cytologic atypia and increased mitotic activity. Other areas of this tumor showed coagulative necrosis.

This sarcoma should be treated as any other uterine malignancy and should include comprehensive staging with total abdominal hysterectomy, bilateral salpingo-oophorectomy, and pelvic and paraaortic lymph node dissection. The staging system for leiomyosarcomas is the same as for an endometrial cancer (Table 60.2). Postoperative therapy is controversial, and recent data from Hensley at the Memorial Sloan-Kettering Cancer Center described a very high response rate in metastatic leiomyosarcoma utilizing a 4-week regimen of gemcitabine and docetaxel. This regimen should probably be considered the standard treatment for metastatic or recurrent disease.

Endometrial Stromal Sarcomas

Endometrial stromal sarcomas are the least common of the three most common uterine sarcomas. The most often seen initial symptom of an endometrial stromal sarcoma is vaginal bleeding. These sarcomas are generally yellow in color, fleshy in texture, and often are polypoid. At the time of diagnosis and treatment, usually by hysterectomy, 40% of patients have disease outside of the uterus. Endometrial stromal sarcomas are just as aggressive as the other uterine sarcomas, and the prognosis is very similar.

Endometrial stromal tumors usually are divided into three groups: benign stromal nodules, endolymphatic stromal myosis, and endometrial stromal sarcoma. Benign stromal nodules usually are well-circumscribed tumors with clearly defined pushing margins. These tumors may grow to many centimeters but are always benign. No cases of metastasis or recurrence have been reported. The second histologic type, endolymphatic stromal myosis, is an

infiltrative tumor that generally has an indolent course. Endolymphatic stromal myosis is also known as low-grade stromal sarcoma. Gross inspection of the surgical specimen often reveals an infiltrative growth pattern, and it can project from the cut surface in a wormlike manner that may also extend into blood vessels in the broad ligament. Microscopically, there are little cellular atypia and few, if any, mitoses. The clinical course is slowly progressive, and management is usually by surgery alone. However, the tumor can recur many years after initial incidence. It is a hormonally responsive tumor and often grows in the presence of estrogen and can regress or stabilize when exposed to progestational agents. There are reports of low-grade endometrial stromal sarcomas being stabilized for many years with progestational therapy. Chronic progestational therapy should be considered in these patients.

Endometrial stromal sarcoma, on the other hand, has a much more aggressive course, with frequent and widespread metastases and a very poor prognosis. As with leiomyosarcoma, the diagnosis of stromal sarcoma versus low-grade stromal sarcoma depends on the number of mitoses per 10 HPF, with 10 mitoses being the cutoff to categorize the tumor as an endometrial stromal sarcoma (Fig. 60.9). Despite this distinction, controversy still exists as to the prognostic significance of the number of mitoses seen. A study from the Mayo Clinic failed to identify this feature as an independent prognostic variable. As with most sarcomas, irradiation may control local disease but has little effect on overall survival. These tumors often exhibit high concentrations of both estrogen and progesterone receptors, and occasional responses have been seen when high-dose progesterone therapy is administered.

Mixed Müllerian Tumor

MMMT is the most common uterine sarcoma, accounting for more than 50% of all cases in recent series. It should be noted that many pathologists now consider this malignancy to be a poorly differentiated endometrial cancer rather than a variant of a uterine sarcoma. This malignancy is aggressive, and more than 60% of patients will have

disease outside of the uterus at the time of diagnosis. It tends to metastasize early via lymphatic vessels, blood vessels, and local spread. It is more common in blacks than whites and is associated with prior pelvic irradiation in up to one third of patients. The main initial symptom is vaginal bleeding, and on examination, most patients are found to have an enlarged uterus, often with a polypoid mass protruding through the cervix. This tumor tends to be aggressive, with early metastasis to pelvic and paraaortic lymph nodes and adjacent tissue. Hematogenous spread, especially to the liver and lungs, is common.

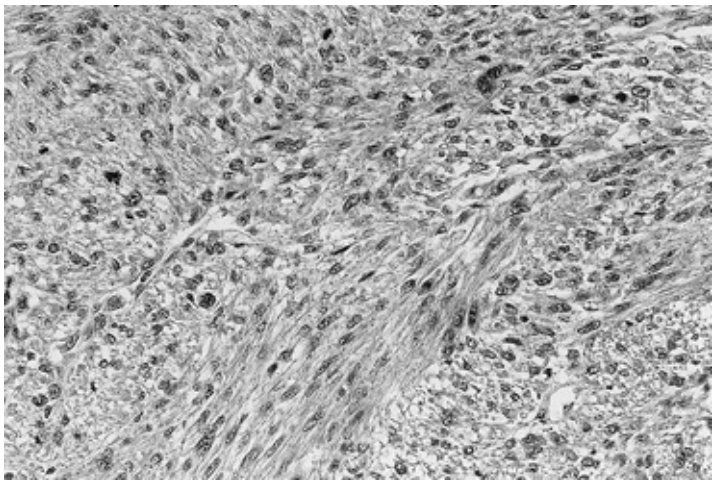

Figure 60.9 Endometrial stromal sarcoma. Nests of bland endometrial stromal cells diffusely infiltrate the myometrium.

Histologically, it is composed of both sarcomatous and carcinomatous elements, with the sarcomatous element being divided into homologous types (tissue normally found in the uterus) (Fig. 60.10) and heterologous types (tissue such as cartilage or bone not usually found in the uterus) (Fig. 60.11). In some series, heterologous elements were associated with a worse prognosis. Rhabdomyosarcoma was the most common heterologous element in these cancers. In the most recent GOG series, the median progressionfree interval of homologous tumors was 22.7 months, with a median progressionfree interval of 62.6 months in the homologous tumors. Staging is very important in this tumor, because extrauterine disease correlates very strongly with survival. Almost no one with disease outside the uterus is cured of her disease. The single most important factor correlating with survival other than extrauterine disease is depth of myometrial invasion. Recurrences usually occur within the first 2 years and often are comprised of only the carcinomatous elements. Some centers feel that this tumor is so aggressive that they recommend adjuvant therapy even when there is no apparent disease outside of the uterus.

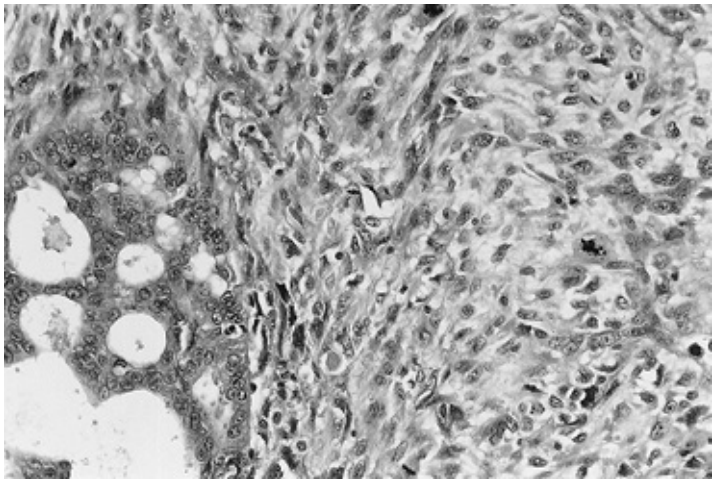

Figure 60.10 Malignant mixed Müllerian tumor, homologous type. Well differentiated.

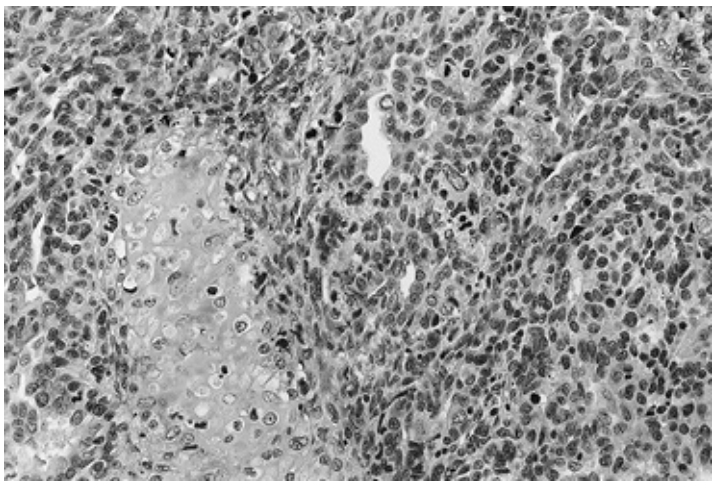

Figure 60.11 MMMT, heterologous type.

Other Sarcomas

Pure heterologous uterine sarcomas are rare. Rhabdomyosarcoma is the most common and usually occurs in children. This used to be called *sarcoma botryoides* in children. Management of this rare group of tumors has changed over the last 50 years from primary surgery to chemotherapy. Müllerian adenosarcoma is a rare sarcoma originally described by Skull. This tumor usually causes vaginal bleeding and is of low malignant potential. Its course is indolent and prolonged, with an overall long-term survival rate of about 90%.

Treatment

Total abdominal hysterectomy with bilateral salpingo-oophorectomy is the treatment of choice for almost all uterine sarcomas. Because there is no formal staging system for sarcomas, most authorities feel that the endometrial staging system should be used. Local spread of a sarcoma can be treated with radiation therapy. This may not improve overall survival but will control local disease and diminish the likelihood of the morbidity of a pelvic recurrence. Unfortunately, there are no good prospective randomized trials evaluating the efficacy of postoperative radiation therapy

on overall survival. The retrospective studies that do exist show only a benefit for local control. The largest study to address this issue by Salzer comprised more than 900 patients and failed to show a statistically significant survival benefit with postoperative radiation therapy, only a benefit of local control. It can be argued that control of microscopic local disease must be obtained before the cancer can be cured. Typically, 5,000 to 6,000 cGy is given with or without adjuvant brachytherapy. Investigators from the Mallinckrodt Institute of Radiology noted fewer pelvic recurrences when more than 5,000 cGy were used.

TABLE 60.16 Most Active Agents in Uterine Sarcomas in Order of Response Rate

Cisplatin, doxorubicin, paclitaxel
Cisplatin, paclitaxel
Cisplatin, doxorubicin
Docetaxel, gemcitibine
Doxorubicin
Ifosfamide
Cisplatin
Etoposide
Mitoxantrone
Paclitaxel

Some patients with leiomyosarcoma may experience an isolated pulmonary metastasis. These sometimes can be resected for cure. Significant 5-year survivals have been recorded in these rare situations. Recurrences of low-grade tumors should be considered for resection no matter where they are.

Recurrences also can be treated with chemotherapy. Many agents have shown activity (Table 60.16). Unfortunately, no therapy has shown a significant increase in overall survival.

Summary Points

- Uterine cancers comprise a wide variety of histologic types that carry a wide range of metastatic potential and survival.
- Endometrial hyperplasia is a premalignant precursor to endometrioid adenocarcinoma. Simple hyperplasia has a low propensity to progress to a cancer (<1%), whereas complex hyperplasia with atypia has a 30% chance of developing into a cancer.
- Endometrial cancer is the most common gynecologic cancer. Type I endometrial cancers are associated with relative estrogen excess. This can be endogenous, as in obese women who have significant conversion of steroids to estrone, or it can be exogenous, as in women who take unopposed ERT.
- Type II endometrial cancers are not associated with estrogen and are comprised of more aggressive histologic types, such as poorly differentiated endometrioid, papillary serous, and clear cell cancers. These latter types have a survival rate as poor as 60%, compared with a >80% survival in the other histologic types.
- Management of endometrial cancers consists of comprehensive

staging, including a total hysterectomy, bilateral salpingo-oophorectomy, pelvic washings, pelvic and paraaortic lymph node dissection, and careful abdominal exploration. Management may also include combination chemotherapy with postoperative radiation therapy or chemotherapy alone.

- Postoperative surveillance should include regular examination with Pap smear. The most common site of recurrence is at the vaginal cuff. Radiation treatment of an isolated cuff recurrence has a cure rate of 50% with external radiation therapy.
- Endometrial cancer is the most common inherited form of gynecologic cancer and is associated with HNPCC or Lynch II syndrome. It is important to take a careful family history to assess if the risk is high, and formal genetic counseling and genetic testing may be appropriate.
- Sarcomas are the most lethal of the uterine malignancies, with an overall survival of around 50%. There are several histologic types of sarcomas. The most common is the MMMT, followed by the leiomyosarcoma, and finally by the endometrial stromal sarcomas. Therapy consists of exploratory laparotomy and staging procedure as outlined for endometrial cancers. Postoperative radiation therapy may be recommended, but this is associated only with decreased pelvic recurrence and not improved survival.

Ovarian and Tubal Cancers

Ilana Cass
Beth Y. Karlan

Abnormalities of the ovary or fallopian tube may result from physiologic changes, infectious processes, or benign or malignant neoplasms. Patients may exhibit a pelvic mass with or without other signs or symptoms. These disorders may occur at any age from childhood to senescence. Depending on patient age, physiologic and pathologic manifestations and implications may vary. For example, teenage patients with a pelvic mass most likely will have a benign germ cell or epithelial ovarian tumor, whereas postmenopausal women have a significantly greater risk of epithelial ovarian carcinoma. The differential diagnosis and the radiologic and tumor marker workup will vary, depending on patient age and initial complaints. The clinician must be vigilant and willing to evaluate the vague symptoms that are frequently the hallmark of many ovarian and tubal pathologies, especially in women over the age of 40.

In recent years, we have gained an increased understanding of ovarian and tubal tumor biology and the underlying molecular genetics, but these advances can be translated only slowly to the clinic. This chapter will outline ovarian and fallopian tube neoplasms, including the common epithelial histologies as well as rarer germ cell and stromal tumors. Epidemiology and risk factors for these cancers, including inherited cancer susceptibility due to mutations in *BRCA1*, *BRCA2*, and hereditary nonpolyposis colorectal cancer (HNPCC) will be discussed as well as preventative and screening strategies.

Germ Cell Tumors

Germ cell tumors occur most frequently in young women and girls and account for 90% of prepubertal tumors and 60% of tumors in women younger than 20 years. These tumors arise from the germ cells originating in the embryonic yolk sac. Patients usually present with complaints of abdominal pain and have an associated pelvic or abdominal mass. Others might present with acute abdominal pain as a result of ovarian rupture, hemorrhage, or torsion. A misdiagnosis of acute appendicitis has been made in these circumstances.

Mature Cystic Teratoma

Mature cystic teratomas, also known as dermoid cysts, are the most common benign

ovarian neoplasm, with a peak incidence from ages 20 to 40 years. However, they can also be seen in infancy as well as in menopausal woman. Mature cystic teratomas originate from primordial germ cells and are composed of well-differentiated derivatives of any combination of the three germ layers: ectoderm, mesoderm, and endoderm. Ectodermal elements usually predominate. Although they are in general benign, on rare occasion they may undergo malignant transformation in one of the elements, with squamous cell carcinoma being the most frequent malignant histology.

Grossly, the tumors are round or oval with a smooth, glistening, gray-white surface. The majority of tumors measure 5 to 10 cm in diameter, with 8% to 15% of cases being bilateral. The tumors are usually unilocular but occasionally multilocular and are filled with hair and a fatty material similar to sebum. A solid portion located at one pole of the cyst and projecting into the cavity is known as a Rokitansky protuberance, where all three germ cell layers are found. (Fig. 61.1). Tissues also can be found at the protuberance, such as hair, teeth, bone, glia, neural tissue, cartilage, retina, smooth muscle, fibrous and fatty tissue, gastrointestinal and bronchial mucosa, and thyroid and salivary gland

tissue. Microscopically, ovarian stroma is noted on the outside wall, with the cyst being lined by mostly squamous cell epithelium with underlying sebaceous and sweat glands (Fig. 61.2).

Figure 61.1 Mature cystic teratoma. This mature cystic teratoma contains hair and teeth.

In the past, a diagnosis of benign cystic teratoma was usually made on an abdominal radiograph in a young woman with acute abdominal pain, because osseous differentiation or teeth could be seen in the pelvis. Transvaginal sonography, however, has become the diagnostic test of choice in most centers, although pelvic magnetic resonance imaging (MRI) can be helpful when the diagnosis is uncertain and may be especially useful when the mass is detected during pregnancy. Torsion is a frequent complication, because these tumors are relatively buoyant and mobile. Treatment usually involves ovarian cystectomy, with preservation of normal ovarian tissue and close inspection of the contralateral ovary.

This often can be accomplished laparoscopically, when the dermoid cyst can be shelled out from the remaining normal ovary. Although concern for chemical peritonitis resulting from cyst rupture exists, with copious irrigation of the peritoneal cavity, this complication can be avoided.

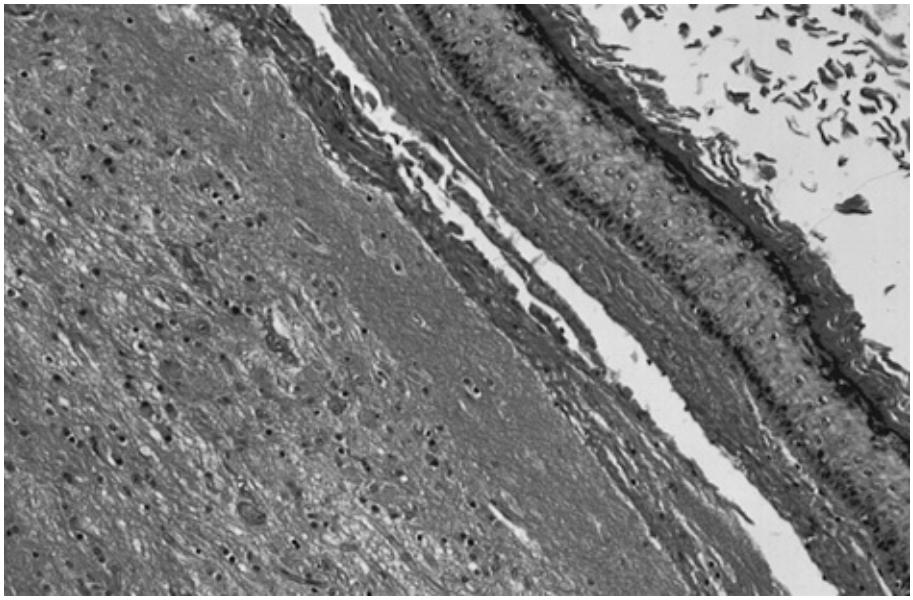

Figure 61.2 Mature cystic teratoma. Microscopically, there is a keratinizing squamous epithelium on the right and mature glial tissue on the left.

Struma Ovarii and Strumal Carcinoid

Rarely, ovarian teratomas will contain a single specialized tissue type. Struma ovarii is a subset of mature cystic teratomas in which the tumor is composed entirely or predominantly of thyroid tissue. Grossly, the cut surface shows gelatinous red to green-brown colloid, and microscopically mature thyroid tissue is seen (Fig. 61.3). Struma ovarii accounts for <3% of mature teratomas, with similar age distribution and similar clinical findings. However, thyroid gland enlargement is occasionally seen, and about 5% of patients with struma ovarii will experience signs and symptoms of thyrotoxicosis. Malignant changes in a struma ovarii are rare but can occur and are most frequently of a follicular histology (unlike primary thyroid carcinomas). Approximately 30% of reported cases of malignant struma ovarii are associated with metastasic disease. Evaluation with iodine-131 scanning may be helpful, and treatment is often similar to that given for thyroid carcinoma counterparts.

Strumal carcinoids are rare teratomas characterized by a mixture of thyroid and trabecular carcinoid tissues. Primary carcinoid tumors of the ovary account for <5% of ovarian teratomas and most likely arise from argentaffin cells found in the gastrointestinal or bronchial tissues that make up the teratoma. These tumors often are hormonally active due to the secretion of serotonin, bradykinin, and other peptide hormones that are secreted directly into the systemic circulation and are not inactivated by “first pass”

through the liver. Approximately 50% of ovarian carcinonoids >4 cm in diameter will be associated with carcinoid syndrome, including episodic cutaneous flushing, diarrhea, and bronchospasm.

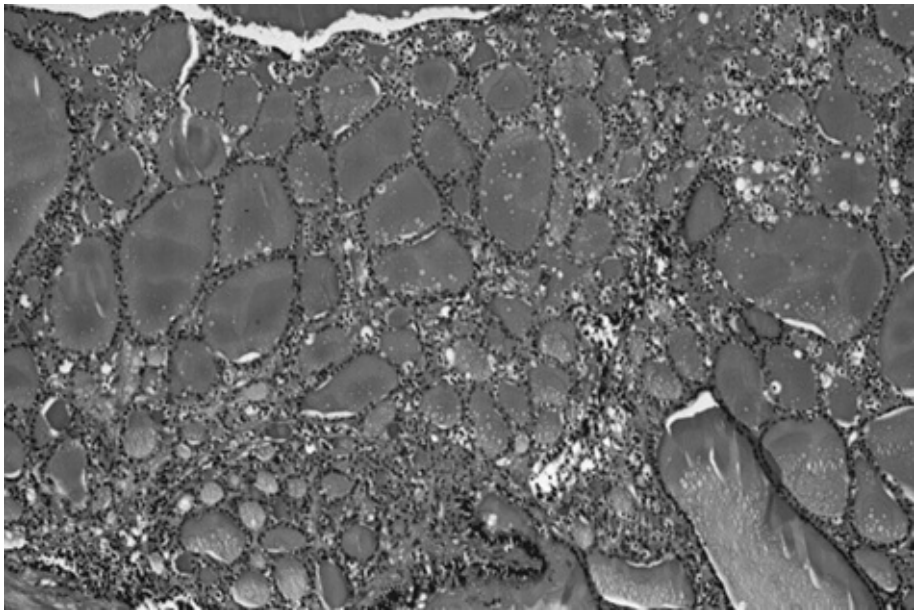

Figure 61.3 Struma ovarii. Microscopically, the tumor is composed of normal thyroid tissue.

Malignant Germ Cell Neoplasms

Malignant ovarian germ cell tumors account for <5% of all ovarian cancers. Table 61.1 provides a listing of the World Health Organization classification of germ cell tumors of the ovary. Their male counterpart, testicular cancer, is approximately ten times more common than ovarian germ cell tumors, and many of the chemotherapy regimens that are used have been adapted from clinical trials in patients with the corresponding type of testicular cancer.

These interesting tumors tend to be diagnosed at an earlier stage than the common epithelial ovarian carcinomas, and they are very sensitive to chemotherapy and, in the case of dysgerminoma, to radiotherapy as well. Germ cell tumors have distinct histopathologic features and tumor markers that are useful in diagnosis and follow-up. Table 61.2 outlines the serum markers typically associated with germ cell tumors.

Dysgerminoma

Dysgerminoma accounts for 33% of all malignant germ cell tumors, with a trend toward a decreasing incidence according to large population-based registries. Approximately 50% of the patients with this tumor are younger than 20 years and 80% are younger than 30 years, with a peak incidence among 15 to 19 year olds. Children with dysgerminoma may present with precocious puberty or primary amenorrhea. The serum lactate dehydrogenase level is almost always elevated and serves as a tumor marker during treatment and follow-up.

Although dysgerminoma tends to be unilateral, approximately 10% to 15% of tumors are bilateral. They usually are gray-white, smooth, and fleshy in appearance and on cut surface usually are solid. Hemorrhage and necrosis may be seen. Cystic areas suggest the presence of mixed germ cell elements that would require further careful sampling of the specimen. The microscopic appearance of an ovarian dysgerminoma is similar in histology to its male counterpart, testicular seminoma, with aggregates of tumor cells surrounded by connective tissue stroma containing many lymphocytes and foreign body giant cells. (Fig. 61.4). Mitotic activity is almost always present. In fewer than 10% of patients, syncytiotrophoblastic giant cells may be detected, producing human chorionic gonadotropin (hCG) that may be demonstrated in tissue section by immunohistochemical techniques and in the serum by an elevated hCG level. Syncytiotrophoblastic cells in a dysgerminoma do not have prognostic significance; however, serum ß-hCG levels can be used to monitor patient response to treatment and in follow-up.

TABLE 61.2 Tumor Markers Associated with Germ Cell Neopl

Likelihood of Elevation

Neoplasm	AFP (Normal, <10 ngmL)	CA-125 (Normal, <35 UmL)	CEA (Normal, <5 ngmL)	hCG (Normal, <5 mlUmL)	L (N < IU
Endodermal sinus tumor	Always	Usually	Maybe	Maybe	U
Immature teratoma	Maybe	Maybe	Maybe	Maybe	M
Dysgerminoma	Not elevated	Rarely	Not elevated	Rarely	U
Choriocarcinoma	Not elevated	Not elevated	Not elevated	Always	N e

AFP, α-fetoprotein; CEA, carcinoembryonic antigen; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase.

Treatment is determined by patient age. Because most patients are of reproductive age, unilateral salpingo-oophorectomy and a full staging procedure with preservation of the contralateral ovary and the uterus are recommended as long as there is no evidence of disease in the contralateral ovary. Table 61.3 is a listing of procedures required when a full staging procedure is performed. Table 61.4 illustrates the widely used International Federation of Gynecology and Obstetrics (FIGO) staging system for all ovarian cancers. Observational studies have revealed identical remission rates for conservative treatment (e.g., unilateral salpingo-oophorectomy and staging) and complete extirpative therapy (e.g., bilateral salpingo-oophorectomy with a hysterectomy) in early-stage disease. Routine biopsy of the contralateral ovary should be avoided if it appears normal. If gross tumor is noted in both ovaries, a unilateral salpingo-oophorectomy of the larger ovary, a unilateral cystectomy, and a full staging procedure followed by chemotherapy may be appropriate in those patients who desire to retain fertility. Patients with advanced disease may require complete removal of the reproductive organs, which should be performed in consultation with a gynecologic oncologist.

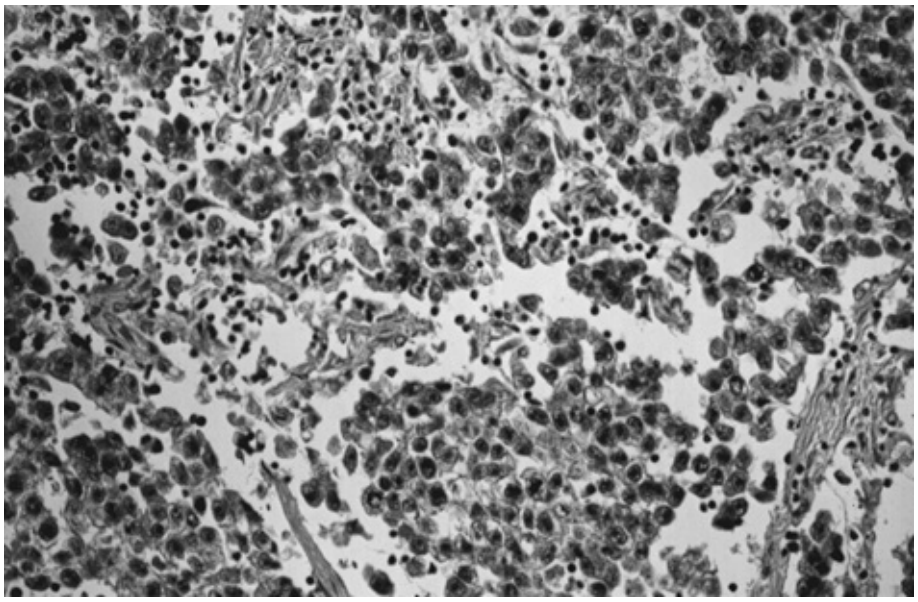

Figure 61.4 Dysgerminoma. Loose aggregates of tumor cells are separated by connective tissue that contains abundant lymphocytes.

Dysgerminoma is very sensitive to both radiation and chemotherapy. Since it is a disease of young women, chemotherapy is the most appropriate postoperative treatment in these patients and should be offered to those with disease more advanced than stage Ia. Combination therapy with (a) vincristine sulfate (Oncovin), dactinomycin (Cosmegen), and cyclophosphamide (Cytoxan) (VAC) or (b) vinblastine sulfate (Velban), bleomycin sulfate (Blenoxane), and cisplatin (Platinol) (VBP) has been used with excellent results, especially in stage I patients. The combination of bleomycin, etoposide (VP-16), and cisplatin (BEP) has been found to be even more effective in treating all stages of disease, with a sustained remission in essentially 100% of patients. The M. D. Anderson Cancer Center and the Gynecologic Oncology Group (GOG) have used BEP in their treatment of dysgerminoma in all stages of disease and have reported prolonged diseasefree interval with three to six cycles of therapy, depending on disease status, residual disease, and tumor markers. In an effort to explore

regimens with lower toxicity, the GOG reported a regimen of carboplatin and etoposide for completely staged and resected stage Ib-III patients with dysgerminomas. Despite favorable results, BEP remains the recommended first-line therapy based on descriptive studies (type III evidence). In patients with pure dysgerminoma seemingly confined to the ovary who were inadequately staged, administration of three cycles of adjuvant BEP is recommended due to a recurrence rate of 20%. However, the scientific merit of this treatment plan requires further investigation. Another option is to offer a repeat surgery to fully stage the disease. There have been several reports of secondary neoplasm, especially hematologic malignancies, after the use of BEP and other etoposide-based regimens. Although these are rare occurrences, careful long-term follow-up and evaluation of the risk–benefit ratio may be warranted to assess the efficacy of this regimen with and without etoposide.

TABLE 61.3 Complete Staging Procedure for Ovarian Malignancy

- Removal of ascites for cytologic evaluation. If there is no ascites, do peritoneal washing with 50–100 mL of normal saline in the pelvis, the paracolic spaces, and infradiaphragmatic area.
- Thorough examination of all peritoneal surfaces, intestine, and other viscera.
- BSO ± TAH or USO if tumor is limited to one ovary and future fertility desired.
- Cytoreductive surgery, reducing tumor size, including lymph nodes, to ≤1 cm residual size whenever possible.
- If tumor appears to be confined to the pelvis, the following procedures should be carried out:
  Infracolic omentectomy
  Biopsy of all suspicious areas or adhesions
  Evaluation and sampling of paraaortic and pelvic lymph nodes
  Routine biopsies from the cul-de-sac, right and left pelvic side walls, and the right and left paracolic spaces
  Right diaphragmatic scraping or biopsy
  Appendectomy, especially for mucinous tumors.

BSO, bilateral salpingo-oophorectomy; TAH, total abdominal hysterectomy; USO, unilateral salpingo-oophorectomy.

TABLE 61.4 International Federation of Gynecology and Obstetrics Staging for Ovarian Cancer.

Stage I.	Growth limited to the ovaries
Stage Ia	Growth limited to one ovary, no ascites, no tumor on the external surface, capsule intact

Stage Ib	Growth limited to both ovaries, no ascites, no tumor on the external surfaces, capsules intact
Stage Ic	Tumor either stage Ia or Ib but with tumor on the surface of one or both ovaries
Stage II	Growth involving one or both ovaries with pelvic extension
Stage IIa	Extension or metastasis to the uterus or tubes
Stage IIb	Extension to other pelvic tissues
Stage IIc	Tumor either stage IIa or IIb but with tumor on the surface of one or both ovaries, or with capsule(s) ruptured, or with ascites containing malignant cells, or with positive peritoneal washings
Stage III	Tumor involving one or both ovaries with peritoneal implants outside the pelvis or positive retroperitoneal or inguinal nodes Superficial liver metastasis equals stage III Tumor is limited to the true pelvis but with histologically verified malignant extension to small bowel or omentum
Stage IIIa	Tumor grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces
Stage IIIb	Tumor of one or both ovaries with histologically confirmed implants of abdominal peritoneal surfaces equal to 2 cm in diameter Nodes negative
Stage IIIc	Abdominal implants >2 cm in diameter or positive retroperitoneal or inguinal nodes

Stage IV	Growth involving one or both ovaries with distant metastasis If pleural effusion is present, there must be positive cytologic test results to allot a case to stage IV Parenchymal liver metastasis equals stage IV

Immature Cystic Teratoma

Like mature cystic teratoma, immature cystic teratoma is composed of tissues derived from all three germinal layers, except that they also contain embryonic tissue. This group of tumors is the most common malignant germ cell tumor, representing about 36% of all such tumors. Unlike mature cystic teratoma, which occurs in all ages but more frequently in the reproductive years, immature cystic teratoma is essentially found in the first 3 decades of life. It usually grows rapidly through its capsule, forming adhesions to the surrounding structures, and implants in the peritoneal cavity.

Tumors are usually smooth and unilateral, ranging from 9 to 28 cm. A mature cystic teratoma may be present in the other ovary. Tumors are predominantly solid, with some cystic areas filled with serous or mucinous fluid or fatty material (Fig. 61.5). The cut surface is soft and usually gray to pink to brown. Microscopically, the most common immature tissue present is neural, derived from the ectoderm (Fig. 61.6). A histologic grading system was therefore proposed, based on the relative amount of mature and immature neuroepithelial tissues, mitotic activity, and degree of differentiation.

Grade 0: Mature tissue only

Grade 1: Limited immature neuroepithelial tissue and mitotic activity

Grade 2: Moderate amount of immature tissue and mitotic activity

Grade 3: Large quantities of immature tissue and mitotic activity.

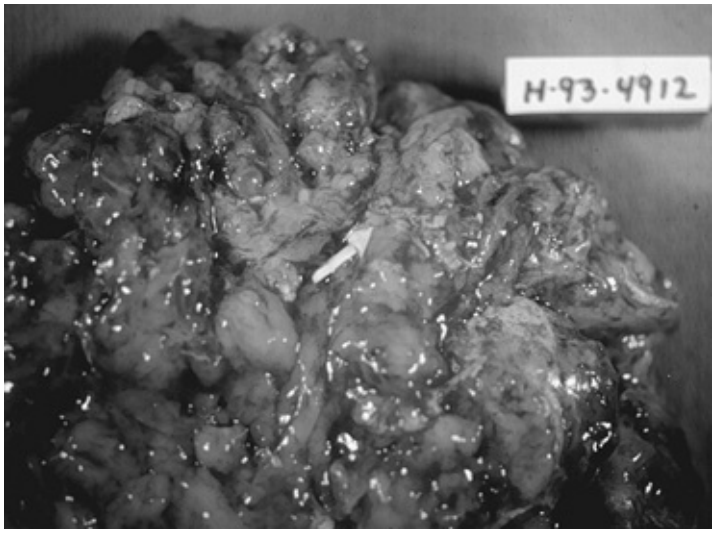

Figure 61.5 Immature teratoma. This bulky neoplasm, removed from a 20-year-old woman, weighed 1,800 g. The neuroectodermal elements appeared opaque and friable (*arrow*).

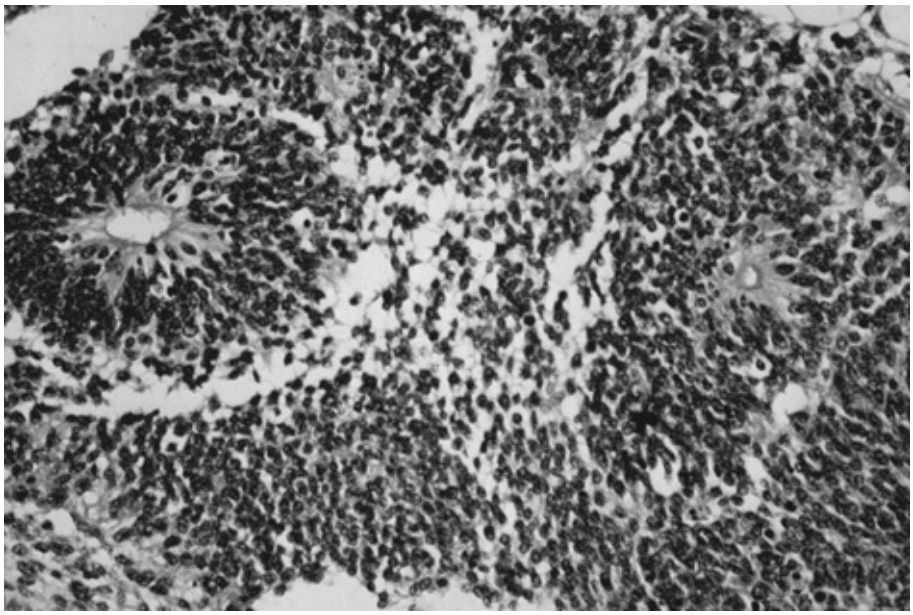

Figure 61.6 Immature teratoma. These tumors are graded based on the presence and extent of neuroepithelial elements. Note the rosettes.

Prognosis correlates with histologic grade of tumors, as the presence of immature elements worsens the prognosis. In patients with stage Ia/grade 1 disease, surgery alone, consisting of an exploratory laparotomy, unilateral salpingo-oophorectomy, and a complete staging procedure (Table 61.3), is sufficient. For more advanced disease, adjuvant chemotherapy after surgery is necessary. Depending on disease extent, preservation of the contralateral ovary and the uterus usually is feasible. Serum α-fetoprotein (AFP) levels may be elevated (Table 61.2). Chemotherapy is discussed in detail above.

Endodermal Sinus Tumor

Endodermal sinus tumor, or yolk sac tumor, is the second most common germ cell tumor, representing 1% of all ovarian malignancies. It may be pure or part of a malignant mixed germ cell tumor. The reported age distribution ranges from 16 months to 46 years, but most patients are younger than 30 years. The serum AFP level is frequently elevated in these tumors (Table 61.2), making it a useful diagnostic test in the initial workup, in the assessment of response to therapy, and in follow-up for recurrence. Symptoms are typical of those observed with other germ cell tumors. Several cases have presented in pregnancy. No endocrine manifestations have been seen with the pure form of endodermal sinus tumor. More than 70% of endodermal sinus tumors present in stage I, although they are biologically virulent.

Grossly, tumors are usually gray-yellow, large, and solid, ranging from 3 to 30 cm in diameter. Bilateral involvement has been noted only in patients with metastatic spread to other organs. Foci of hemorrhage, necrosis, and gelatinous changes are present. Microscopically, endodermal sinus tumors display a wide range of histologic patterns. The microcystic pattern is characterized by a loose network of channels and spaces forming a honeycomb lined by flat

pleomorphic mesothelial-like cells with large hyperchromatic or vesicular nuclei. Hyaline globules or droplets, which are positive with periodic acid–Schiff stain, are found commonly. The endodermal sinus pattern is characterized by perivascular formations called *Schiller-Duval bodies* (Fig. 61.7). Other patterns include the alveolar-glandular pattern, composed of alveolar, glandlike, or cystic spaces lined by flat or cuboidal epithelium; the polyvesicular vitelline pattern, in which numerous small vesicles are surrounded by connective tissue; and the solid pattern, consisting of aggregates of small pleomorphic undifferentiated cells. These histologic patterns do not have prognostic significance.

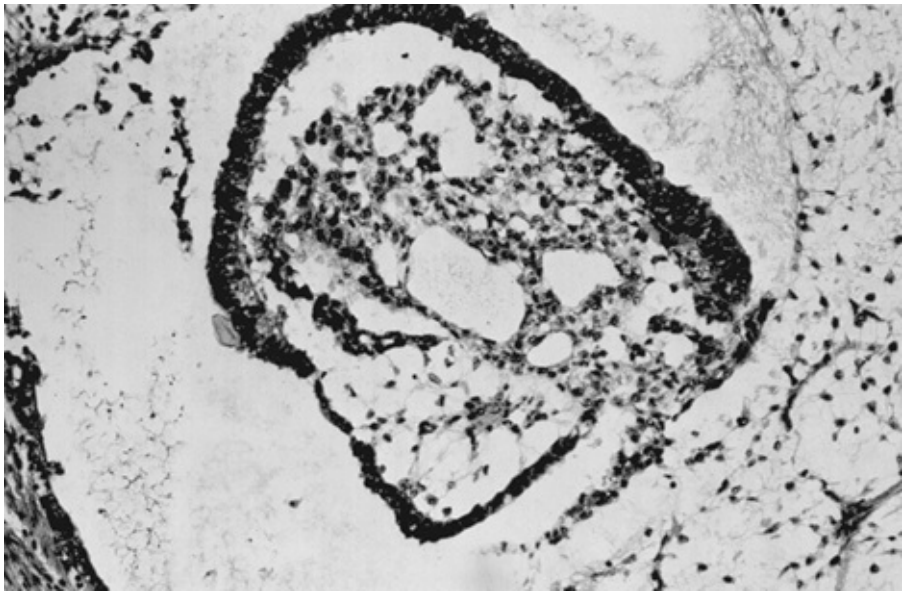

Figure 61.7 Yolk sac tumor. A characteristic finding in the endodermal sinus pattern is

the Schiller-Duval body.

In the past, patients with endodermal sinus tumors, even those with early-stage tumors, did poorly despite aggressive surgical and radiation treatments. With adjuvant chemotherapy after conservative pelvic surgery and staging laparotomy (Table 61.3), there has been a marked improvement in the prognosis of patients with this malignancy. Adjuvant chemotherapeutic regimens for all nondysgerminomatous germ cell tumors (including endodermal sinus tumors, immature cystic teratoma, embryonal cell tumors, and others) are similar, as they are grouped together in treatment protocols in several major studies. The VAC regimen, first introduced in the 1970s, resulted in a successful cure rate of >80% in stage I disease but <50% in patients with more advanced stage, as reported by a GOG study and the M. D. Anderson experience. The VBP regimen has shown superior results compared with VAC, but toxicity is increased. However, no randomized clinical trials have been performed to compare the two regimens due to the rarity of these malignancies. More recently, the BEP regimen has shown an excellent response rate of >95% in patients with local or advanced disease and has become the primary therapeutic regimen. Further studies, however, are needed to explore alternative regimens to reduce the rate of toxicity while maintaining the same efficacy. Second-look laparotomy should not be a part of posttherapy surveillance for this tumor or any other germ cell tumors. Salvage therapies, such as surgery followed by chemotherapy, in patients who have failed primary chemotherapy have shown some success; however, they are anecdotal at best due to the limited number of cases.

Embryonal Carcinoma

Embryonal carcinoma is rare, accounting for <5% of all germ cell tumors. It usually occurs in children, with a median age of 15 years. Like its testicular counterpart, embryonal carcinoma is a highly malignant neoplasm. Because it is often seen as part of mixed germ cell tumors, serum AFP and hCG levels are often elevated. Clinically, it may be associated with precocious puberty as well as abnormal vaginal bleeding in adults.

The gross pathologic picture is variable, but the tumor is usually large and soft, with a cut surface that is solid and gray-white with areas of hemorrhage and necrosis. Microscopically, embryonal carcinoma consists of primitive, undifferentiated sheets of variably sized epithelial cells (Fig. 61.8). Nuclei are vesicular, and mitoses are frequent. Syncytiotrophoblastic giant cells are frequently seen in the stroma or directly adjacent to clusters of embryonal carcinoma cells.

Polyembryoma

Polyembryoma is a rare germ cell tumor, characterized by numerous embryoid bodies that morphologically resemble normal presomite embryos. It is usually part of a mixed germ cell neoplasm and has similar symptoms. The median age of patients with polyembryoma is 15 years. The tumor is usually unilateral, ranging from 10 cm to a mass that fills the entire abdominal cavity; cut section reveals mostly solid areas with hemorrhage and necrosis.

Microscopically, embryonic bodies including an embryonic disk, amniotic cavity, yolk sac, and extraembryonic mesenchyme of

varying degrees of differentiation are noted (Fig. 61.9). Syncytiotrophoblastic cells have also been detected. AFP, hCG, and sometimes human placental lactogen can be demonstrated in the serum and in cells by immunohistochemical staining.

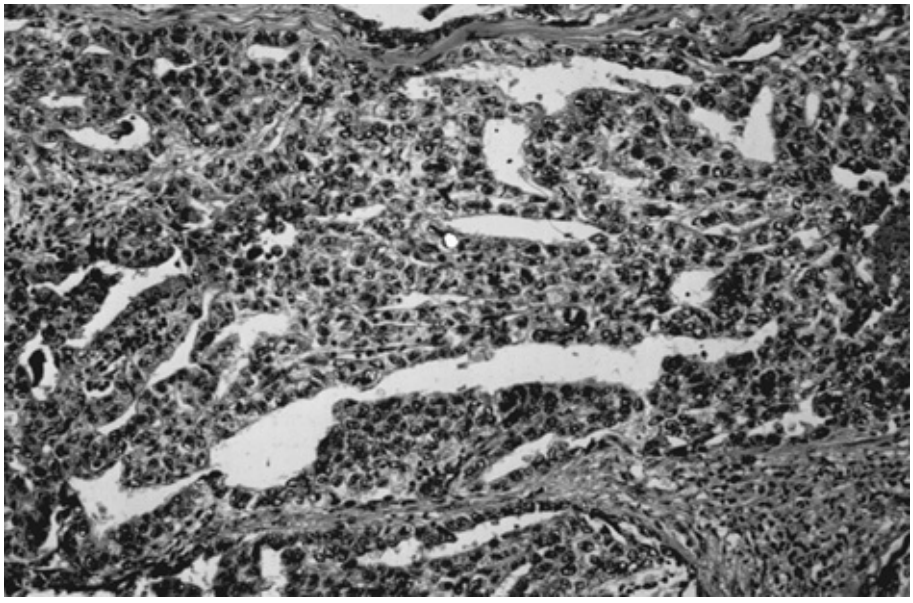

Figure 61.8 Embryonal carcinoma. Tumor cells form syncytial aggregates that surround cleftlike spaces.

Choriocarcinoma

Choriocarcinoma is a rare germ cell tumor that may be present in either pure or mixed form. Pure choriocarcinoma is usually found in prepubertal children. Isosexual precocious puberty is a common clinical finding in premenarcheal patients. In postmenarcheal patients, the presence of other germ cell components is helpful in distinguishing ovarian germ cell tumors from a gestation choriocarcinoma. A diagnosis of ectopic pregnancy is often entertained in postmenarcheal patients due to the shared signs and symptoms. The gross appearance of choriocarcinoma depends on the composition of the germ cell elements. The tumor is usually large, unilateral, and solid with areas of necrosis and hemorrhage. Microscopically, both cytotrophoblasts and syncytiotrophoblasts are present (Fig. 61.10). Treatment is as described previously for the other germ cell tumors.

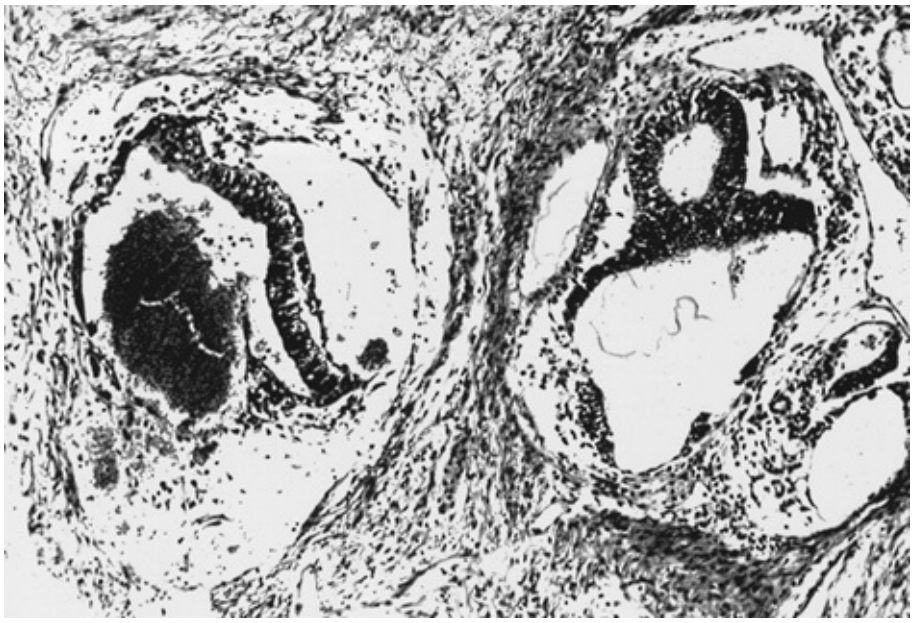

Figure 61.9 Polyembryoma. In less differentiated forms, embryoid bodies may have a bizarre appearance.

Gonadoblastoma

Gonadoblastoma almost always arises in a congenitally abnormal gonad with associated sexual maldevelopment. Patients with gonadoblastoma most often have pure or mixed gonadal dysgenesis or are male pseudohermaphrodites. Predominantly, karyotypes 46,XY, 45X/46,XY mosaicism, and rarely 46,XX or 45,X have been associated with this tumor. Gonadoblastoma is much more common in phenotypic females than in phenotypic males, with a ratio of 4:1. It is frequently associated with dysgerminoma and occasionally with other germ cell neoplasms, including yolk sac tumor, embryonal carcinoma, and choriocarcinoma.

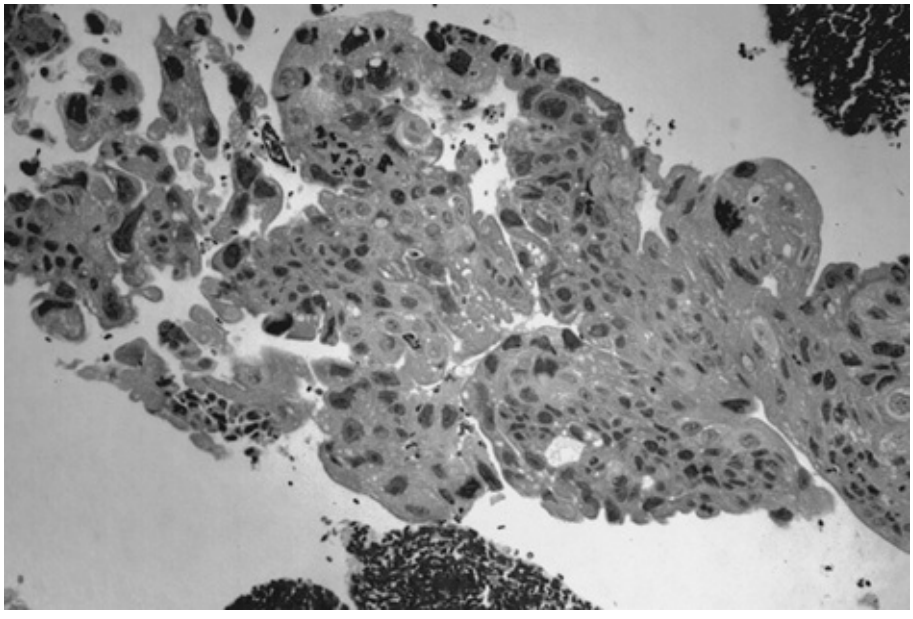

Figure 61.10 Choriocarcinoma. There is a dimorphic population of malignant cytotrophoblasts and syncytiotrophoblasts. Associated hemorrhage is a common finding.

Patients with gonadoblastoma usually complain of primary amenorrhea, virilization, or developmental abnormalities of the genitalia. A karyotype should be included in the evaluation of the young woman with a pelvic mass and any symptoms of abnormal sexual development. It is during the workup of these conditions that gonadoblastoma usually is diagnosed. It is most frequently detected in the second decade. Hot flushes and other menopausal symptoms have been noted after tumor excision, suggesting the presence of estrogen-secreting cells in these tumors. However, the exact source of the androgen or estrogen production is unknown, as the steroid production has been noted in the absence of Leydig or lutein cells.

Gonadoblastoma is more common in the right gonad than in the left and is bilateral in 38% of patients. The tumor can range from a microscopic lesion to a mass measuring up to 8 cm in diameter that is soft and fleshy to firm and hard, depending on the degree of calcification. When mixed with other malignant germ cell elements, it can grow to even larger sizes. Microscopically, gonadoblastoma is composed of cellular nests containing a mixture of germ cells and immature sex cord–stromal cells, such as Sertoli and granulosa cells (Fig. 61.11). Hyaline bodies and calcification are often present in the nests. In 50% of patients, a supervening dysgerminoma displaces most of the gonadoblastoma, pushing the cell nests to the periphery.

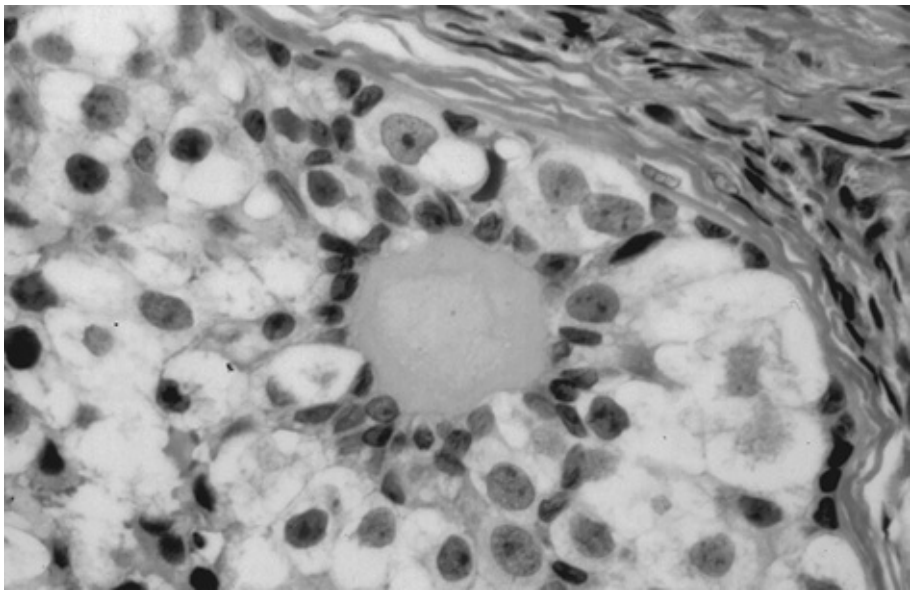

Figure 61.11 Gonadoblastoma. Large germ cells are admixed with smaller sex cord derivatives that surround rounded hyaline material resembling a Call-Exner body.

Treatment for patients with gonadal dysgenesis is a bilateral gonadectomy, because they

have an increased risk for a germ cell tumor, especially gonadoblastoma. If the gonads are not removed and tumors develop, the prognosis of patients with pure gonadoblastoma is excellent as long as the tumor and the other ovary are both removed. The prognosis in patients with gonadoblastoma associated with dysgerminomatous elements remains very good, even with metastasis. If the gonadoblastoma is associated with other germ cell tumors, such as endodermal sinus tumor,

embryonal carcinoma, or choriocarcinoma, the prognosis is poor if untreated. However, combination chemotherapy (BEP) results in significant improvement, as described previously.

Sex Cord-stromal Tumors of the Ovary

Sex cord–stromal tumor accounts for approximately 5% of all ovarian tumors. The origin of tumor cells may be the coelomic and mesonephric epithelium or the mesenchymal stroma of the genital ridge. This category includes an array of tumors derived from the sex cords (granulosa and Sertoli cells) and from the gonadal stroma (theca and Leydig cells). The most common types of sex cord–stromal tumor are granulosa cell tumors and fibrothecomas, with peak age incidence at approximately 50 years. These tumors have the potential for steroid hormone secretion, with estrogen being the predominant hormone. They are usually not seen in women younger than 20 years, except for juvenile granulosa cell tumors. (The classification of sex cord–stromal cell tumors is outlined in Table 61.5.)

Thecoma

Thecoma is a benign tumor affecting all ages, with a predominance in the postmenopausal group; it is rare in patients younger than 35 years. It accounts for 2% of all ovarian tumors. Many women with a thecoma present with abnormal or postmenopausal uterine bleeding; some present with an endometrial adenocarcinoma as a result of unopposed estrogen production by the tumor. Thecoma is composed of lipid-laden stromal cells resembling theca cells. Rather than arising as a de novo neoplasm, it may represent changes occurring in background cortical stromal hyperplasia.

Gynandroblastoma
Unclassified

Source: Serov SF, Scully RE, Robin IH. *Histological typing of ovarian tumors: international histological classification of tumors*, No. 9. Geneva: World Health Organization, 1973, with permission.

Tumor size ranges from a nonpalpable incidental finding to a large solid mass with a diameter of 15 to 20 cm. It is usually unilateral and almost never malignant. Its outer surface is smooth, and its cut surface is typically solid, lobulated, and yellow. Cystic change may be seen. Microscopic evaluation reveals masses of oval or round cells with abundant, pale, lipid-containing cytoplasm. Hyaline plaques are often noted. A luteinized thecoma sometimes occurs, usually in younger women.

Treatment for thecoma is tailored to patient age and ranges from a total abdominal hysterectomy and bilateral salpingo-oophorectomy for menopausal or postmenopausal women to a salpingo-oophorectomy or ovarian cystectomy, if possible, in patients who desire future fertility.

Fibroma

Like thecoma, fibroma is also a benign tumor affecting all ages, although most occur in women 40 to 60 years of age; fewer than 10% of patients are 30 years of age or younger. Fibroma is not associated with hormone production. In some cases, hydrothorax and ascites are found in association with a pelvic mass—a constellation of findings known as Meigs syndrome. In other cases, fibroma is seen in patients with a hereditary basal cell nevus syndrome, characterized by early-appearing basal cell carcinomas, keratocysts of the jaw, calcification of the dura, and mesenteric cysts.

Fibroma, like thecoma, ranges in size from a nonpalpable incidental finding to larger than 20 cm; it is usually unilateral but multinodular. Cut surface is firm and hard and has a whorled appearance. Microscopically, fibroma is composed of bundles of collagen-producing spindle cells arranged in a storiform pattern (Fig. 61.12). Hyalinization and intercellular edema are characteristic. The cytoplasm of tumor cells may contain small quantities of lipid, making distinction from thecoma difficult.

Treatment is similar to that for thecoma. In patients with Meigs syndrome, the hydrothorax

and ascites usually resolve after resection of the pelvic tumor.

Juvenile Granulosa Cell Tumor

Approximately 44% of all juvenile granulosa cell tumors occur in the first decade of life and 97% in the first 3 decades. Isosexual pseudoprecocious puberty is commonly associated with this tumor, along with Ollier disease (enchondromatosis), Maffucci syndrome (enchondromatosis and hemangiomatosis), and abnormal karyotypes with ambiguous genitalia. Symptoms usually include abdominal pain, increasing abdominal girth, and hemoperitoneum due to rupture. Occasionally, it may be associated with pregnancy.

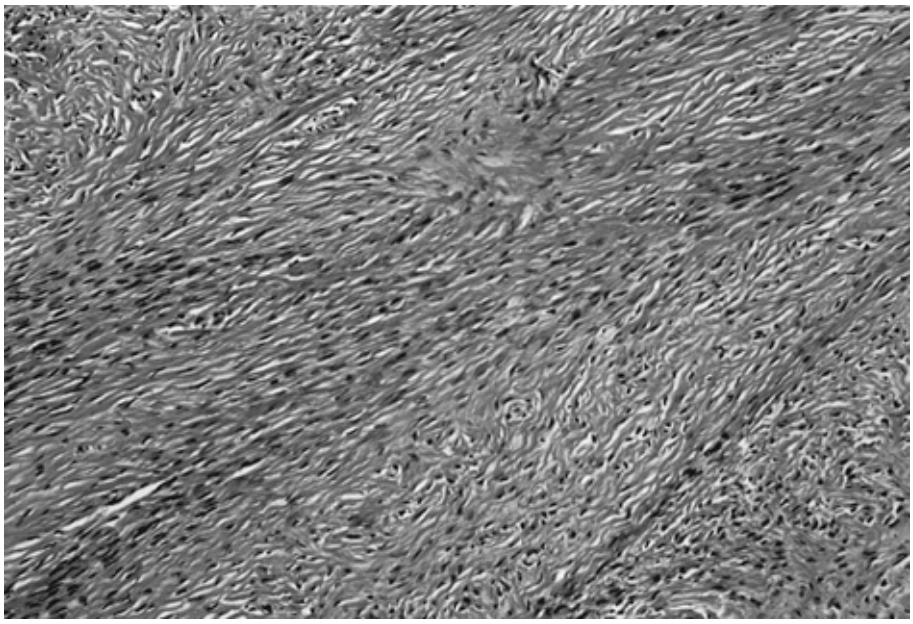

Figure 61.12 Fibroma. The tumor is composed of intersecting bundles of spindled cells.

The gross appearance of juvenile granulosa cell tumor is commonly a large yellow-to-gray, solid and cystic mass, similar to the adult form. A mixture of granulosa and theca cells may be present. Microscopic features that distinguish juvenile granulosa cell tumor from the adult form are hyperchromatism of the tumor cells, which generally lack grooves, and the frequent luteinization of both the granulosa and theca cells (Fig. 61.13). The follicles are usually immature (Fig. 61.14). Call-Exner bodies, which are pathognomonic of adult granulosa cell tumor, are rarely present in the juvenile form.

Treatment in young women usually consists of a unilateral salpingo-oophorectomy with a complete staging (Table 61.3), especially if preservation of reproductive function is desired and the tumor appears to be grossly confined to one ovary. Although the survival rate for stage I disease is >90%, juvenile granulosa cell tumor appears to behave more aggressively in advanced disease, with a survival rate of <50%. Isolated reports of successful treatment with various combination chemotherapies have been recorded. Due to the rarity of these

tumors, a standard chemotherapeutic regimen has not emerged.

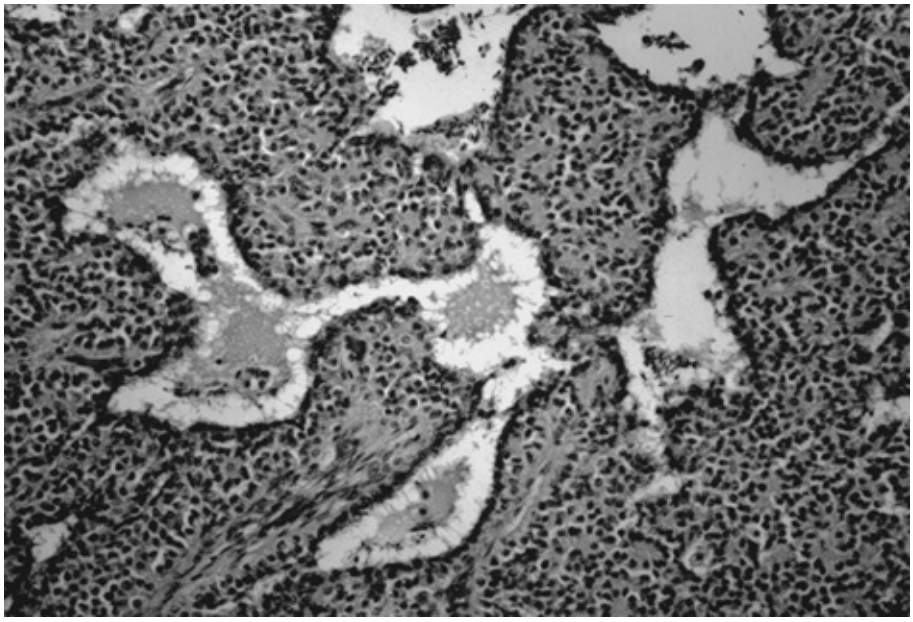

Figure 61.13 Juvenile granulosa cell tumor. Tumor cells from follicles of varying sizes and shapes contain weakly basophilic secretions.

Adult Granulosa Cell Tumor

The adult form of granulosa cell tumor accounts for 1% to 2% of all ovarian tumors and 95% of all granulosa cell tumors. Although these tumors average 10 to 12 cm in diameter, a pelvic mass is not always detectable. Peak age of occurrence is 50 to 55 years, and most granulosa cell tumors produce estrogen, which in premenopausal women is manifested by menstrual irregularities such as menorrhagia,

amenorrhea due to anovulation, or metrorrhagia. In postmenopausal women, vaginal bleeding results from endometrial stimulation. Endometrial hyperplasia or carcinoma is a common occurrence, approximately twice that seen in premenopausal women. The best estimate for the frequency of associated endometrial carcinoma is 5%.

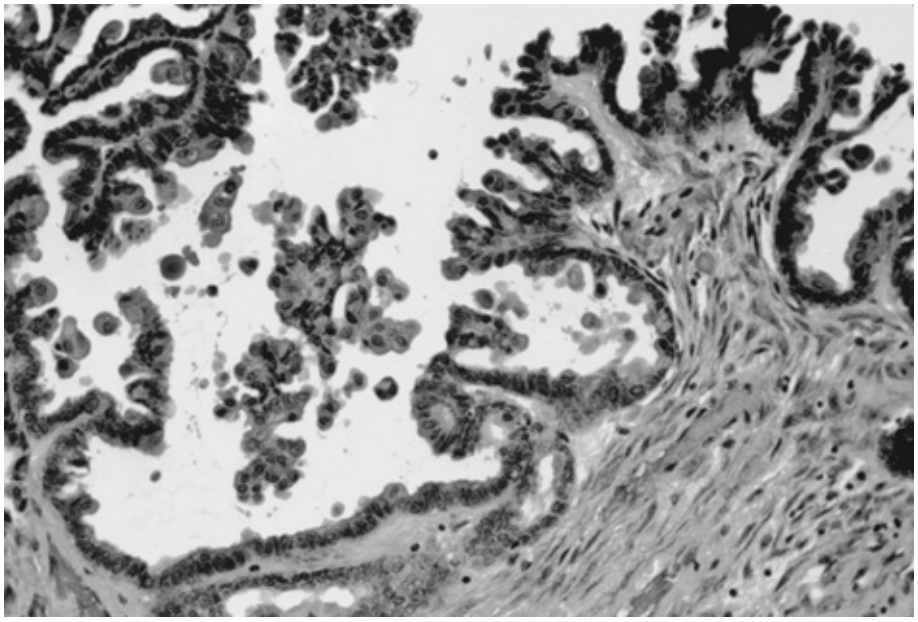

Figure 61.14 Serous tumor of low malignant potential (LMP) (atypical proliferating tumor). Ramifying papillae are lined by a relatively bland serous epithelium that forms tufts and seemingly free-floating clusters.

Grossly, the tumors are solid and gray-white or yellow, with cystic areas and hemorrhage. Microscopically, they are composed of granulosa cells and theca cells or fibroblasts, or both. Theca cells and fibroblasts are most likely a response of the ovarian stroma to granulosa cell proliferation, because only granulosa cells are found in metastatic sites. Granulosa cells may be round, polygonal, or spindle shaped, with scant cytoplasm and round or ovoid nuclei. Many different histologic patterns may be seen separately or together; these include the microfollicular pattern with its distinctive Call-Exner bodies (Fig. 61.15), macrofollicular, insular, trabecular, solid-tubular, and rarely hollow-tubular patterns. Less differentiated forms include the watered-silk or diffuse pattern. Rarely, a granulosa cell tumor undergoes sarcomatous transformation, producing the most aggressive form of the disease. Inhibin may be a useful immunohistochemical marker, and serum inhibin levels can be used to monitor the clinical course.

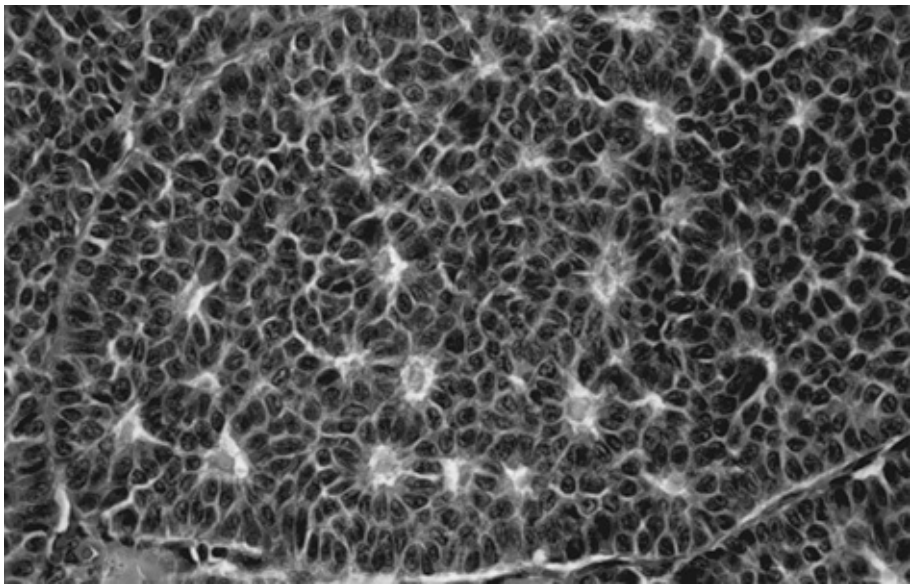

Figure 61.15 Granulosa cell tumor. The microfollicular pattern is characterized by granulosa cells with angulated nuclei surrounding small cavities that simulate the Call-Exner bodies of the developing follicle.

Although most granulosa cell tumors have a very low potential for malignant behavior, with 90% of tumors being stage Ia, they do have a propensity for late recurrence up to 10 to 20 years or more after initial diagnosis. In addition to full surgical staging (Table 61.3), surgery should include a total abdominal hysterectomy and bilateral salpingo-oophorectomy in postmenopausal patients. Conservative surgery is indicated in younger patients who wish to maintain fertility if the tumor is confined to one ovary. One of the largest series compared the impact of uterine-sparing surgery on survival in young women with stage I disease and found no difference in the 5-year disease-specific

survival between those women who had conservative versus standard surgical staging, 98% versus 97% respectively. Patient age and stage appear to be the most important prognostic factors. Although other prognostic factors include capsular rupture, tumor size, nuclear atypia, mitotic activity, and histologic pattern, studies of these factors have not been conclusive. It is difficult to evaluate the efficacy of chemotherapy in this group of tumors. Most retrospective series have been limited by their small sample size and short follow-up. Platinum-based therapy, including the VBP and BEP regimens, has been reported to be the most successful, with a 5-year survival of 50% for patients with advanced-stage disease. Taxane-based regimens have been proposed given the lack of durable remissions and significant toxicity of the BEP regimen. Investigators at M. D. Anderson reported a retrospective study of patients with predominantly granulosa cell tumors who received either BEP or a taxane-based regimen. While there were no statistical differences in clinical outcome, the BEP regimen was associated with higher toxicity. The authors suggest that taxane-platinum–based therapy merits consideration in future prospective trials for sexcord–stromal tumors. Radiotherapy has also been used with varying success in studies limited by small numbers. In recurrent disease, surgery followed by chemotherapy may offer the best mode of therapy.

Androblastoma and Sertoli-Leydig Cell Tumor

Hilus Cell Tumor

Hilus cell tumor is a subtype of Leydig cell tumor, originating from the ovarian hilus. The other subtype, which is very rare, is a nonhilar-type Leydig cell tumor derived from ovarian stromal cells and having similar clinical and pathologic features. The average age of patients with a hilus cell tumor is 58 years, and many present with symptoms of abnormal menstruation, hirsutism, and virilization. Some may present with estrogenic manifestations. Hilus cell tumors are almost always benign.

Grossly, this tumor is circumscribed, lobulated, solid, soft, and red to yellow. Tumor enlargement is usually minimal, and the tumor is often physically undetectable. Sometimes, it is incidentally discovered when the ovaries are pathologically sectioned for another purpose. Microscopic evaluation reveals circumscribed masses of steroid cells with abundant eosinophilic cytoplasm. Lipochrome pigment may also be present. The diagnostic elongate eosinophilic crystalloids of Reinke must be found for the tumor to be definitively classified as a Leydig cell neoplasm. Treatment of this benign tumor is unilateral salpingo-oophorectomy or ovarian cystectomy if future fertility is desired.

Sertoli-Leydig Cell Tumors

Sertoli-Leydig cell tumors are also termed *Sertoli-stromal cell tumors* and can be further divided into several subtypes (Table 61.5). Stage and tumor differentiation seem to be important prognostic factors. Despite the name of these tumors, hormone production is not always associated with them. Tumors that produce hormones may result in masculine or feminine phenotypes, as few of the tumors actually produce estrogen or progesterone.

Sertoli Cell Tumor

Sertoli cell tumor is very rare. Patients, ranging in age from 7 to 79 years (median, 33 years), usually present with a pelvic and/or abdominal mass. If the mass is functional, patients may present with some form of estrogenic effect, such as endometrial hyperplasia or isosexual precocious pseudopuberty. Androgenic and progestogenic effects may also occur. Most tumors are stage I unilateral masses that are well circumscribed, averaging about 9 cm in diameter. Cut surface reveals solid, yellow-to-brown, lobulated masses. Microscopic evaluation discloses closely packed hollow or solid tubules lined by Sertoli cells that can also contain abundant cytoplasmic lipid. An association between Sertoli cell tumors and Peutz-Jeghers syndrome has been reported in the literature.

Most Sertoli cell tumors are benign or early-stage malignant neoplasms that are cured with surgery. Conservative surgery with a unilateral salpingo-oophorectomy is indicated in many of these patients who are young and desire preservation of ovarian function. Only rarely are these tumors poorly differentiated and aggressive. Experience with chemotherapy in these tumors is limited due to their rarity.

Sertoli-Leydig Cell Tumor

Sertoli-Leydig cell tumor accounts for <0.5% of all ovarian tumors. It is most often seen in young women, with a mean age of occurrence of 25 years. Fewer than 10% of these tumors occur in women older than age 50 years, and fewer than 5% occur in prepubertal girls. Sertoli-Leydig cell tumor is often associated with androgen production; however, virilization develops in only 50% patients. This may be due to a lack of hormone production or insufficient androgen production. Typically, patients complain of oligomenorrhea followed by amenorrhea, breast atrophy, acne, hirsutism, temporal balding, deepening of the voice, and enlargement of the clitoris. The latter two symptoms may not resolve after tumor removal. Patients without endocrine manifestations may present with complaints of abdominal swelling or pain. Occasionally, symptoms of estrogen production, due to the Sertoli cell component of the tumor or peripheral androgenic conversion, may be seen such as menorrhagia or menometrorrhagia. Sertoli-Leydig cell tumor must be distinguished from other virilizing tumors, such as adrenal tumors, which are often associated with an elevated urinary level of 17-ketosteroids; the urinary level of 17-ketosteroids in Sertoli-Leydig cell tumor is usually normal or only slightly elevated. The serum AFP level may be increased and may be useful as a tumor marker.

The gross appearance of Sertoli-Leydig cell tumor is highly variable. Overall, it has an average diameter of 12 to 15 cm, and its cut surface is usually tan or yellow and may be cystic. Hemorrhage and necrosis are frequently seen in the poorly differentiated tumors. On microscopic examination, the tumor is composed of a mixture of Sertoli, Leydig, and undifferentiated gonadal stromal cells, with or without heterologous components, in varying proportions and degrees of differentiation. In well-differentiated lesions, Sertoli cells from tubules and Leydig cells are found in the intervening stroma (Fig. 61.16). Sertoli cells are cytologically bland, and mitotic figures are rare. Leydig cells may contain abundant lipochrome pigment or crystalloids of Reinke. Intermediate and poorly differentiated tumors are characterized by more immature components of the Sertoli and Leydig cells. Cartilage, mucinous epithelium, skeletal muscle, and other heterologous elements are found in 20% to 25% of these tumors, most of which are of intermediate differentiation. When heterologous elements have been found in poorly differentiated neoplasms, the tumors are clinically malignant. Sertoli-Leydig cell tumor with a retiform pattern may be seen with prominent hyalinized cores and papillae lined by stratified epithelial cells.

The treatment for Sertoli-Leydig cell tumor usually depends on patient age and tumor stage, degree of differentiation, and presence of heterologous elements in the tumor. The most important prognostic factor is stage. In young women with a stage Ia well-differentiated tumor who desire future pregnancy, a unilateral salpingo-oophorectomy and a staging procedure are adequate treatment (Table 61.3). However, more aggressive cytoreductive surgery (including a hysterectomy and bilateral salpingo-oophorectomy), tumor resection, and staging procedure may be indicated in postmenopausal patients or in those with more advanced disease.

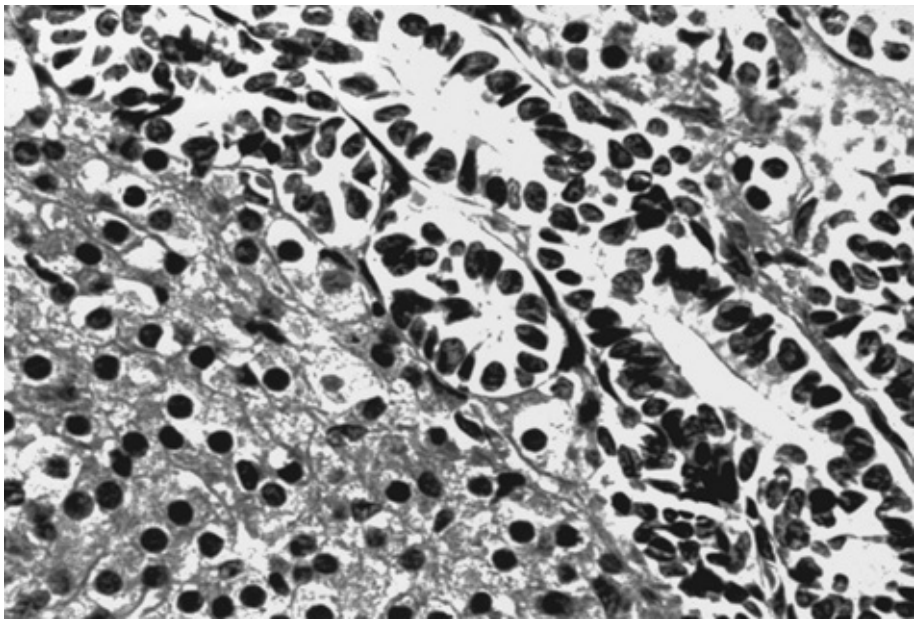

Figure 61.16 Sertoli-Leydig cell tumor. This well-differentiated tumor is composed of hollow tubules lined by Sertoli cells and adjacent sheets of Leydig cells.

Adjuvant therapy is recommended for patients who have stage Ia lesions with poorly differentiated elements or heterologous components or for those who have heterologous elements or metastatic disease. However, due to the limited number of cases, no standard adjuvant therapy has been accepted for these patients. Most of the information available comes from small series and case reports. Treatment of advanced sex cord–stromal cell tumors, unlike germ cell tumors, has not met with much success. Platinum-based therapies have yielded the best results, with an overall survival of approximately 50%. These include the VAC, VBP, and BEP regimens. As with chemotherapy, radiotherapy has been used successfully in limited cases.

Steroid Cell Tumors Not Otherwise Specified

Termed *lipid cell* or *lipoid tumors* in the past, *steroid cell tumors not otherwise specified* (NOS) are tumors composed entirely of cells resembling typical steroid hormone–secreting cells (e.g., lutein cells, Leydig cells, and adrenal cortical cells), except that specific features such as location of origin in the hilus or crystalloids of Reinke are not identified. These tumors account for approximately 0.1% of all ovarian tumors, with a mean age of occurrence of 43 to 60 years. Androgenic changes, occurring in 75% to 90% of patients, may be of many years duration. Estrogenic and progestogenic changes are occasionally noted. Although the estrogenic manifestations may be a result of estrogen production by the tumors, the aromatization of androgen to estradiol in adipose tissue may be more plausible. Cushing syndrome may also be found in some patients, accompanied by elevated serum cortisol levels. Diagnosis is often dependent on the clinical manifestation of virilization or the rare occasion of isosexual pseudoprecocity. Tumor removal results in rapid resolution of most of the hormonal effects, except for deepening of the voice and

clitoromegaly.

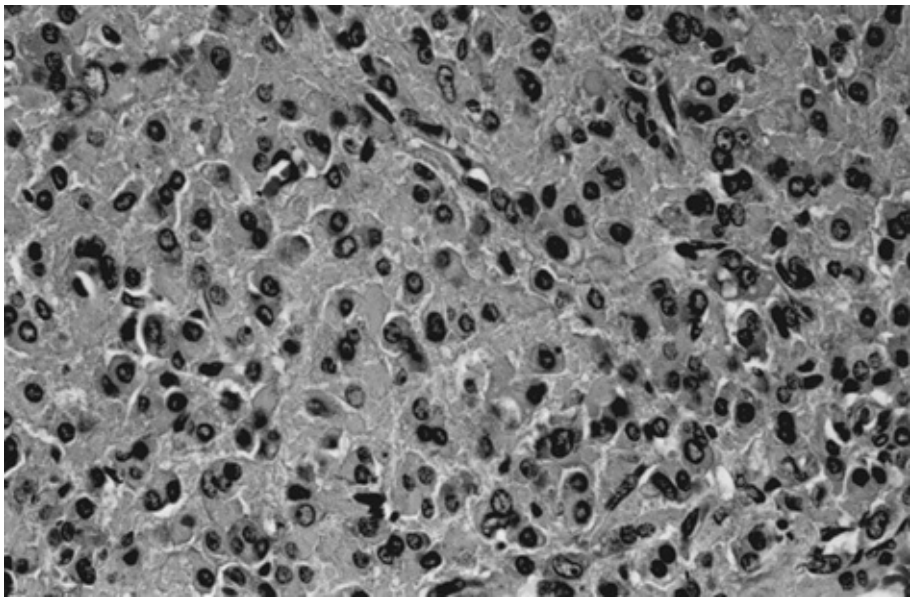

Figure 61.17 Steroid cell tumor NOS. If crystalloids of Reinke were identified in these cells, the tumor would be classified a Leydig cell tumor or possibly a hilus cell tumor, depending on the its location. The granular appearance of the cytoplasm in these polygonal-to-rounded tumor cells suggests that they contain little lipid.

Grossly, steroid cell tumors NOS are solid, well circumscribed, and yellow to orange-tan, measuring 5 to 8 cm in diameter. Hemorrhage, necrosis, and cystic degeneration are occasionally observed. The cut surface of the tumor is soft and lobulated. Microscopically, tumor cells may resemble Leydig or hilar cells (Fig. 61.17). In other instances, cells have abundant pale cytoplasm, resembling adrenocortical cells. These cells are polygonal to round and larger than Leydig cells, with central nuclei and lipid-rich cytoplasm. The striking resemblance of many of these tumors to adrenocortical tumors has led some to speculate that they may arise from the adrenocortical rests. The association with manifestations of Cushing syndrome would seem to support this theory, and detailed examination has revealed the presence of these nests in the broad ligament and the ovarian hilus. Alternatively, given the fact that steroid cell tumors NOS are often confined to the ovary may simply mean that adrenocortical hormones are being produced by cells of ovarian origin rather than by an ectopic adrenal tumor. Steroid cell tumors NOS are rarely malignant; approximately 10% to 15% of them recur or metastasize.

A unilateral salpingo-oophorectomy is adequate for stage Ia disease in young, reproductive-age women. An abdominal hysterectomy and bilateral salpingo-oophorectomy with staging and resection of all extraovarian disease are indicated in women with advanced disease or in those beyond reproductive age.

Epithelial Ovarian Tumors

Benign Neoplasms

Serous Cystadenoma

Serous and mucinous cystadenomas are the most common benign epithelial ovarian neoplasms. Serous tumors account for approximately 25% of all benign ovarian neoplasms, with an age range of 20 to 50 years; they are bilateral in 12% to 20% of patients. Symptoms are variable. For many patients, the diagnosis is made during routine pelvic examination.

Grossly, serous cystadenoma is a cystic, usually unilocular lesion, ranging from 5 to 15 cm in diameter. The inner lining of the cyst wall may be flat or partially covered by papillary projections. Microscopically, the epithelial lining can range from simple cuboidal cells, resembling the ovarian surface epithelium, to tall columnar cells, resembling the fallopian tube (Fig. 61.18). Ciliated and secretory cells may be present. Mitoses are rare, and nuclear atypia is absent. Psammoma bodies, which are concentric calcifications, are seen in 15% of tumors. Multiple, large, calcified deposits may be visible on radiologic examination of the abdomen. The stroma may vary from fibrous to cellular to hyalinized with marked stromal edema. The papillary processes are fibrous and lined by a single layer of epithelial cells.

The preoperative workup depends on patient age and the degree of suspicion of malignancy. A unilateral salpingo-oophorectomy is usually performed in patients who have completed childbearing. In those desiring future reproduction, an ovarian cystectomy is usually performed. A bilateral salpingo-oophorectomy may be performed in selected individuals, particularly in those with bilateral tumors. In such cases, discussion of a hysterectomy is reasonable but not necessary. The risk for a serous cystadenoma to undergo malignant transformation is unknown; however, molecular genetics analysis suggests that these tumors have a distinct pattern of genetic alterations compared with that found in serous cystadenocarcinomas.

Mucinous Cystadenoma

Mucinous cystadenoma accounts for approximately 25% of all benign ovarian neoplasms, with an age range of 20 to 50 years; in 2% to 3% of patients, it is bilateral. The tumor

arises from the surface epithelium of the ovary, resembling müllerian-type epithelium of the endocervix, intestinal-type epithelium, or both these types. Because of the large size that this tumor attains, patients usually present with a palpable pelvic/abdominal mass and may have associated pain.

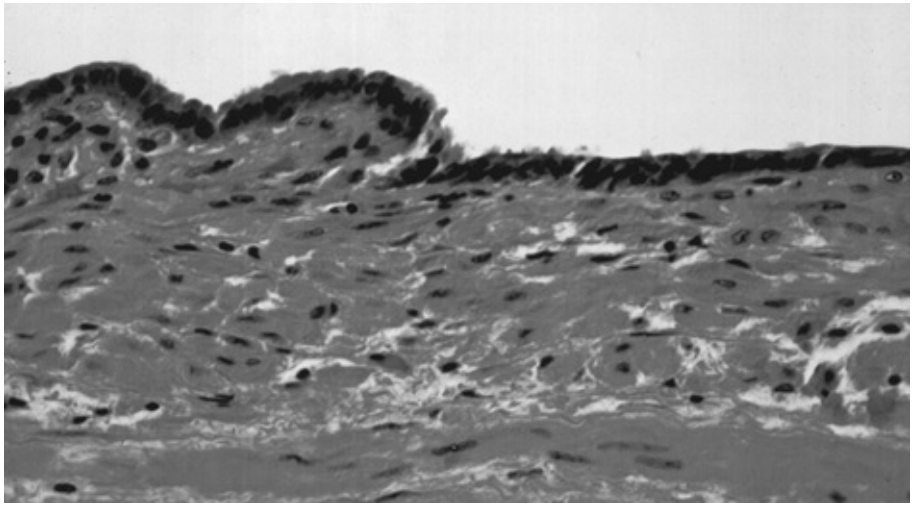

Figure 61.18 Serous cystadenoma. The lining epithelium commonly appears tubal.

Gross evaluation of a mucinous cystadenoma reveals that it is usually multilocular and larger than its serous counterpart, ranging up to 50 cm or more in diameter. The external surface is usually smooth, pinkish gray, and sometimes lobulated. Inside, locules tend to be small and contain thick, sticky, tenacious mucinous material (Fig. 61.19). Microscopically, the epithelium consists of a single layer of uniform tall columnar cells that resemble a picket fence in the endocervical type or may contain goblet, argentaffin, and Paneth cells in the gastrointestinal type (Fig. 61.20). Treatment is similar to that for serous cystadenoma. The appendix should be removed in any suspected ovarian mucinous tumor because of frequent synchronous appendiceal mucinous tumors (mucocele), even in a clinically normal-appearing appendix.

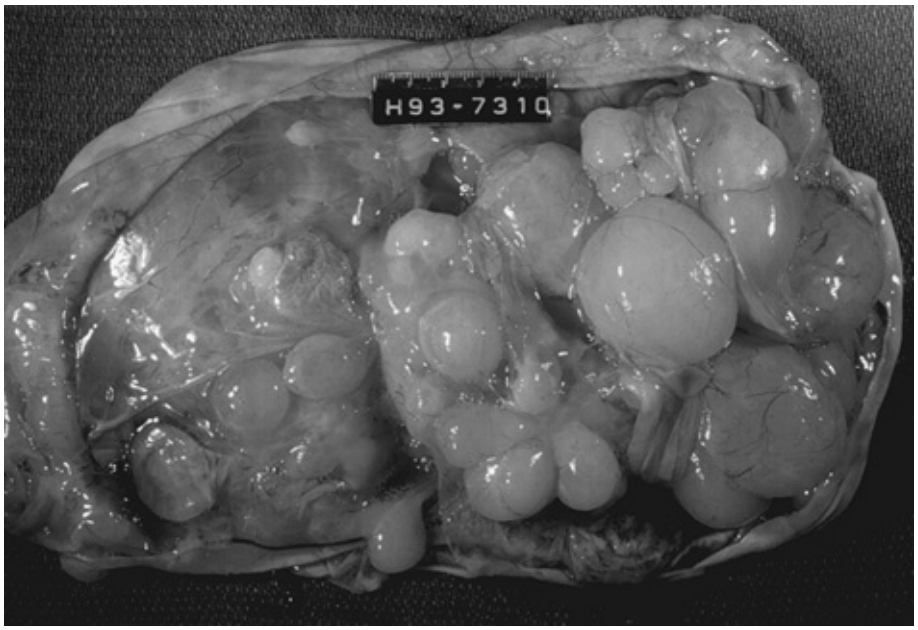

Figure 61.19 Mucinous cystadenoma. The tumor is multilocular.

Cystadenofibroma

As the name suggests, cystadenofibroma is a variant of serous cystadenoma, containing both cystic and solid components. This benign tumor is usually unilateral and has a similar age distribution to that of serous cystadenoma. It is variably papillary to solid. Papillae are broad, firm, and nonfriable. Microscopically, solid areas are found to contain small cystic structures that are histologically identical to serous cysts. As with other benign epithelial ovarian tumors, treatment is individualized based on patient age and reproductive desire.

Brenner Tumor

Also known as transitional cell tumor, Brenner tumor constitutes 2% of all primary ovarian tumors. Patients with this tumor range in age from 30 to 70 years, with a mean age of

50 years. Brenner tumor is thought to be derived from ovarian surface epithelium that undergoes a metaplastic transformation to cells resembling urothelium. It may occur synchronously with mucinous cystadenoma. Most transitional cell tumors are benign, but transformation to a malignant form has been observed. Presentation may be variable, as the tumor may be asymptomatic or may present with a palpable mass or pain. Occasionally, patients may present with vaginal bleeding, probably due to hormonal activity in the stroma.

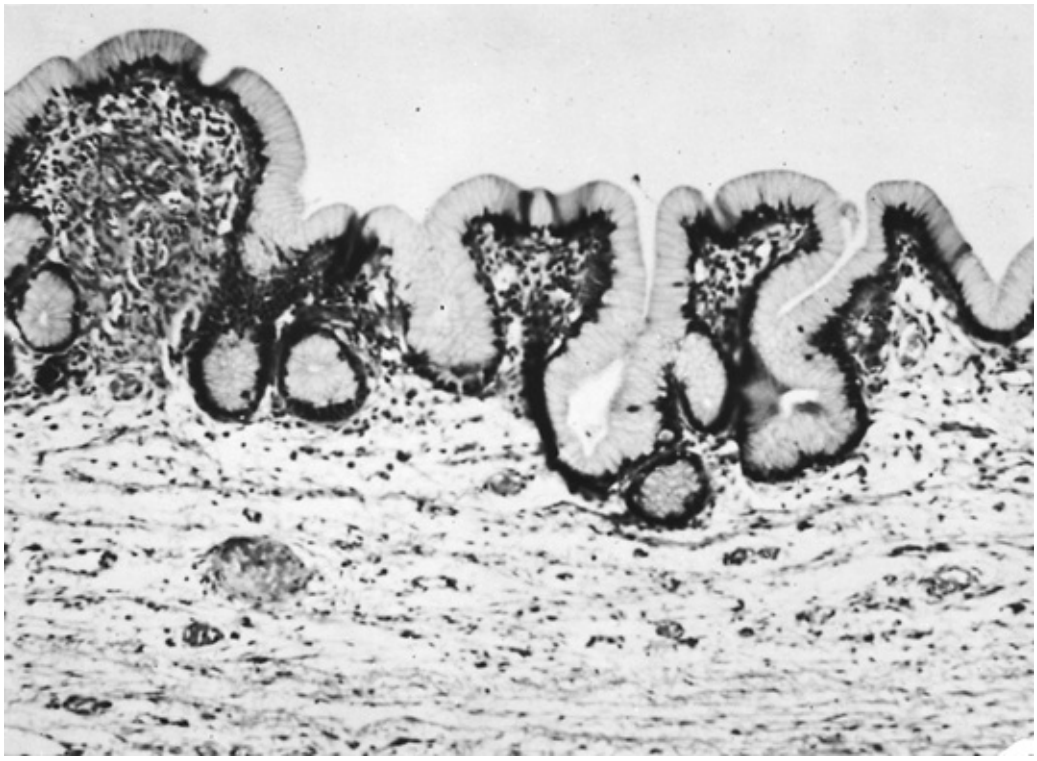

Figure 61.20 Microscopic appearance of the lining of a mucinous cystadenoma. The picket-fence epithelium is characteristic of this tumor.

Grossly, the tumor is solid—less commonly cystic—and usually unilateral, although 6% to 7%

of tumors are bilateral. Ranging in size from microscopic to as large as 30 cm in diameter, it is usually gray, white, or yellow, with a faintly lobulated cut surface. Microscopic review depicts a characteristic pattern of circumscribed epithelial nests of cells embedded in an abundant fibromatous stroma (Fig. 61.21). Epithelial cells may be round to polygonal, with eosinophilic or clear cytoplasm. When longitudinal grooves of the nuclei are present, the cells are described as having a “coffee-bean” appearance. Often, these nests of epithelial cells undergo benign cystic changes lined by either transitional cells or mucinous cells. Treatment usually is resection of the tumor, and this may involve a cystectomy or salpingo-oophorectomy with or without a hysterectomy, depending on patient age and reproductive desires.

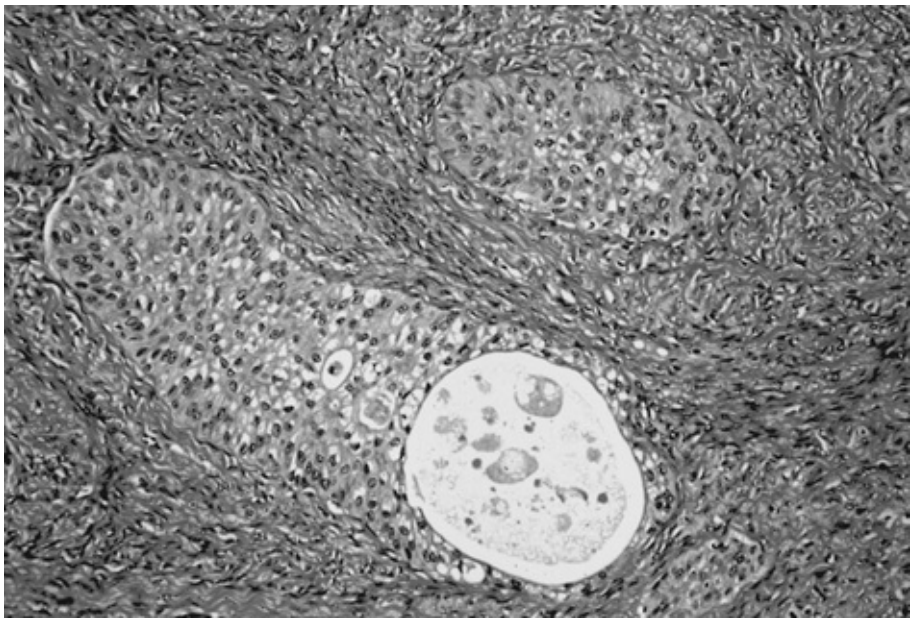

Figure 61.21 Brenner tumor. Epithelial nests embedded in a fibromatous stroma may show cystic change. Longitudinal grooves in the cells can impart a coffee-bean appearance.

Tumors of Low Malignant Potential (Atypical Proliferating Tumors)

Epidemiology

Ovarian tumors of low malignant potential (LMP), also known as atypical proliferating tumors, comprise a group of tumors showing greater epithelial proliferation than that seen in benign serous cystadenoma, although they are by definition noninvasive. Recognized by FIGO in 1971, LMP ovarian tumors account for approximately 15% of all epithelial ovarian cancers; mean age of occurrence is 40 years. A meta-analysis performed by the Collaborative Ovarian Cancer Group found that as with malignant epithelial ovarian cancer, parity, multiple births, history of breast-feeding, and oral contraceptive use are

protective against LMP tumors. A history of infertility and use of infertility drugs may increase the risk of developing an LMP tumor, although the data are weak and controversial. Prospective trials are needed to resolve the controversy surrounding the use of infertility drugs and these tumors.

Clinical Features

Patients may be asymptomatic, but usually they come to medical attention with a pelvic mass and complaints of abdominal and pelvic pain, increasing abdominal girth, or abnormal bleeding. Ultrasonography or computed tomography (CT) scan may be helpful in making the diagnosis of an ovarian mass. Serum CA-125 levels are not always elevated. When they are, the tumor is usually of serous histology. LMP tumors usually have an indolent course. Many biomarkers, such as DNA ploidy, tumor markers, oncogenes, and tumor suppressor genes, have been studied in an attempt to define a high-risk group or predict aggressive tumor behavior and thus indicate which patients might benefit from adjuvant treatment. To date, no such marker has been identified.

Pathologic Classification

LMP ovarian tumors have been described for all epithelial ovarian subtypes; the most common types are serous and mucinous tumors. The absence of stromal invasion is an absolute criterion for making the diagnosis. Careful examination of the tissue blocks is necessary to minimize the potential for sampling error or omitting an area of invasive carcinoma in LMP tumors. Approximately 20% to 30% of ovarian tumors diagnosed as borderline at frozen section prove to be carcinomas on review of the permanent section. The mean diameter of serous LMP tumors is 12 cm, and bilateral tumors are reported in 33% to 75% of patients. These tumors are usually cystic with mural clusters of papillary projections (Figs. 61.14, 61.22).

Mucinous LMP tumors are larger than their serous counterparts, with an average diameter of 17 to 20 cm; they are infrequently bilateral. They are characterized by multiloculated cystic masses, with smooth outer surfaces and areas of papillations and solid thickening on the inner surface. Microscopically, the epithelial lining of the cysts consists of tall, columnar, mucin-secreting cells, resembling the epithelium of the endocervix or intestine. Stratified epithelial cells may be atypical with hyperchromatic nuclei and mitotic figures but without stromal invasion (Fig. 61.23).

Figure 61.22 Serous tumor of LMP (atypical proliferating tumor). On the **left** is the cut surface of the ovary; on the **right** is the external surface of the ovary. The tumor is multicystic, and within some cysts are complex papillary projections.

Stage for stage, the 5-year survival rate for patients with LMP epithelial ovarian tumors is far better than that for patients with malignant epithelial ovarian cancer. A review of the literature by several investigators revealed a survival rate >95% in patients with stage I LMP ovarian tumors. Furthermore, Kurman and Trimble found that a majority of patients with LMP tumors actually died with the disease, not from it, as invasive carcinoma developed in only 8 (0.8%) of 953 patients with a mean follow-up of 7 years. The other patients died from radiation- or chemotherapy-associated complications. Recognizing that a minority of LMP tumors behave aggressively like an ovarian carcinoma, Seidman and Kurman have challenged the current classification of LMP tumors in an attempt to develop a classification system that better reflects their natural history. These investigators believe that LMP tumors are actually a heterogeneous group of tumors that can be divided into malignant or benign phenotypes based on certain pathologic features.

For serous tumors, Seidman and Kurman propose that patient outcome depends on the presence or absence of micropapillary features within the ovarian tumor and invasive versus noninvasive implants. In a large meta-analysis of serous LMP tumors, they report that patients with micropapillary serous carcinoma have 5- and 10-year survival rates of 81% and 71%, respectively. Patients with a serous borderline tumor without invasive implants (atypical proliferative serous tumor) have 5- and 10-year survival rates

>98%. However, in serous borderline tumor with invasive implants, survival rates drop to 60% to 70% at 5 and 10 years. The vast majority of patients with invasive implants, or those who progressed to invasive carcinoma, were found to have micropapillary features within the primary ovarian tumor on careful sectioning. Thus, the authors conclude that atypical proliferative serous tumors and serous borderline tumor without invasive implants follow in a very benign clinical course, while micropapillary serous LMP tumors behave much like

invasive ovarian carcinomas.

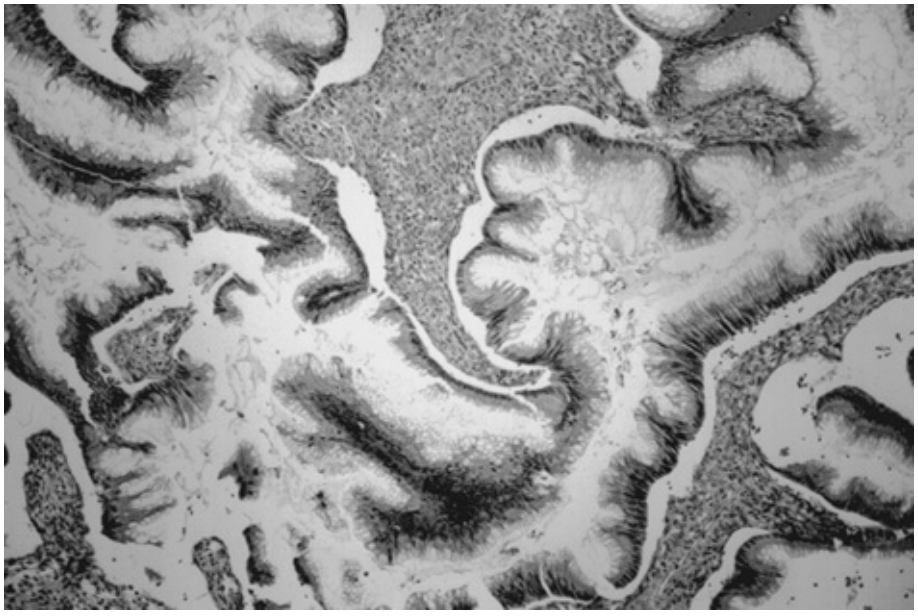

Figure 61.23 Mucinous tumor of LMP (atypical proliferating tumor). Epithelial proliferation results in pseudostratification and tufting. Mild cytologic atypia is present.

Longacre and colleagues argue that Seidman and Kurman's classification system oversimplifies the prognostic significance of pathologic features of LMP tumors based on their long-term follow-up of 276 serous LMP tumors. The Longacre group found that 6% to 7% of patients develop morphologic transformation to a low-grade serous carcinoma at intervals of 7 to 288 months, with 58% of cases occurring at >60 months from primary diagnosis. The risk of disease progression was better predicted by a combination of clinical and pathologic features including stage of disease, extraovarian implant status, stromal invasion in the primary tumor, and micropapillary architecture. They conclude that prolonged follow-up is necessary for patients with serous LMP tumors given that no single clinical or pathologic feature or combination of features could identify all adverse outcomes in their series.

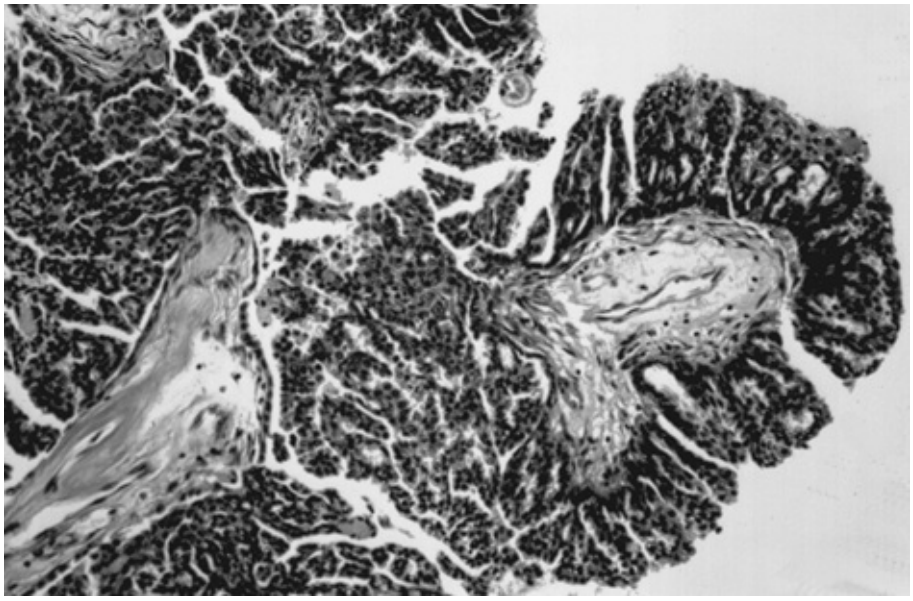

Figure 61.24 Micropapillary serous carcinoma. In this fully malignant serous carcinoma, strands of neoplastic cells stream from thick, fibrous cores, stimulating a Medusa head.

Micropapillary serous carcinoma is characterized by thin, elongated micropapillae with minimal or no fibrovascular support arising directly from thick, more centrally located papillary structures (Fig. 61.24). Mitotic activity may be seen in some of the cases, ranging from one to three figures per 10 high-power fields. The distinction between invasive and noninvasive implants may be difficult. Noninvasive implants usually have a scant epithelial component surrounded by reactive spindle cells with imperceptibly meshed epithelial and stromal cells (Fig. 61.25). On

the other hand, invasive implants usually have a more cellular epithelial component, with complex epithelial proliferation composed of multiple micropapillae and small round nests that display a destructive infiltrative growth (Fig. 61.26).

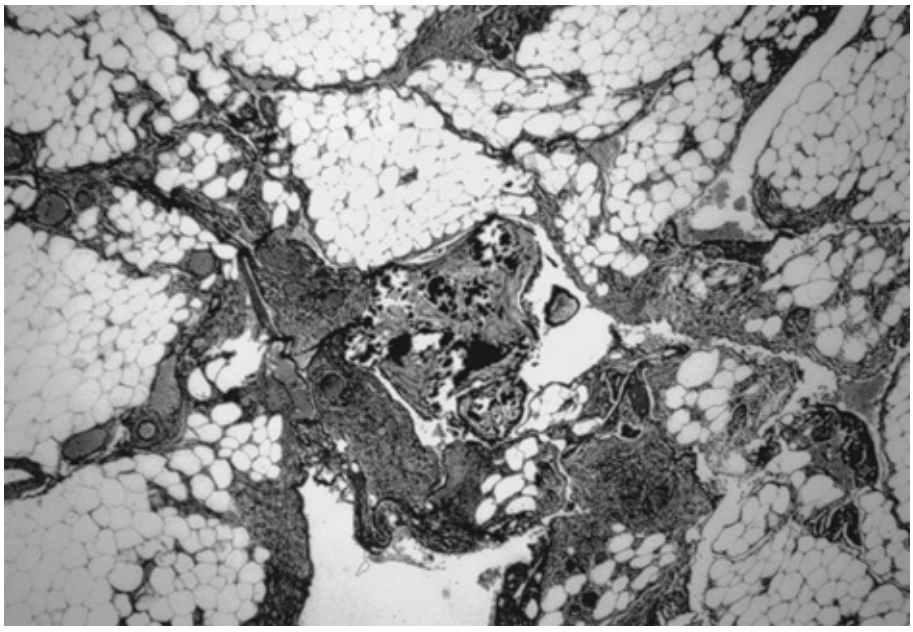

Figure 61.25 Noninvasive implant in a serous borderline tumor. A circumscribed focus of tumor is surrounded by fibroadipose tissue that shows no stromal reaction. Cell nests are heavily calcified.

Mucinous LMP tumors tend to be confined to the ovary. Advanced-stage tumors are typically associated with pseudomyxoma peritonei and frequently represent metastatic disease from the gastrointestinal tract. In such cases, careful histologic examination of the appendix is necessary to rule out an occult appendiceal primary. Primary mucinous carcinomas of the upper gastrointestinal tract and appendix can present with small primary lesions and large bilateral ovarian masses that simulate primary ovarian carcinoma. Mucinous ovarian LMP confined to the ovary have an excellent prognosis, while the survival of patients with advanced-stage disease is approximately 50%. A gastrointestinal evaluation of the stomach, pancreas, and bowel is advised in patients with advanced-stage mucinous LMP to eliminate an occult primary gastrointestinal cancer.

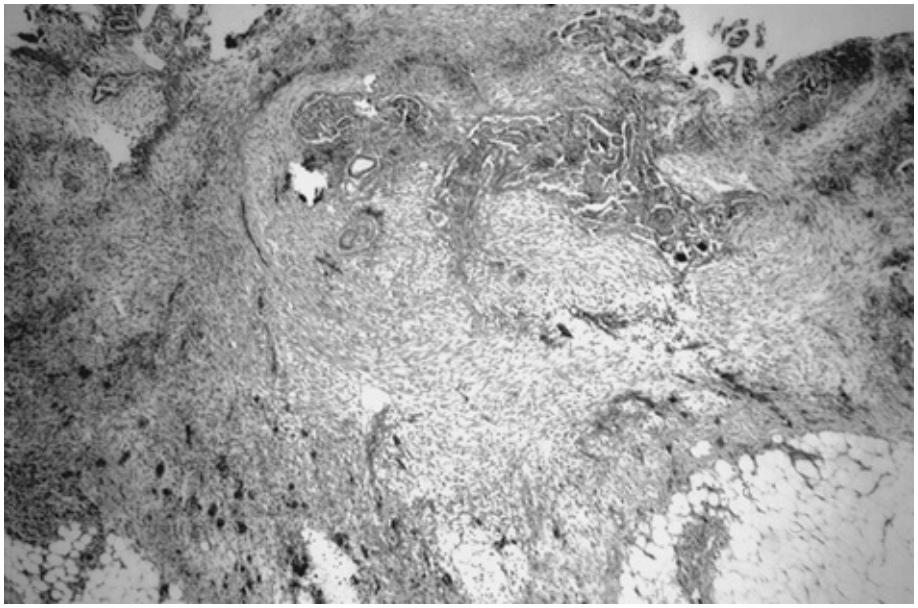

Figure 61.26 Invasive implant in a serous borderline tumor. The tumor here is more cellular. The invasive implant extends below the peritoneal surface and is associated with reactive desmoplasia.

Pseudomyxoma Peritonei

Pseudomyxoma peritonei may accompany mucinous neoplasms of the ovary and is characterized by extracellular gelatinous material in the pelvic and abdominal cavity. The primary site of origin of pseudomyxoma peritonei is debatable. Some series cite that the majority begin in the appendix, while others have described a synchronous origin in the ovary and appendix. It is suggested that perforation of the primary site leads to the dissemination of neoplastic mucus-secreting cells on the surfaces of the abdominal cavity. Pseudomyxoma is most frequently associated with an appendiceal cyst, benign adenoma or low-grade appendiceal adenocarcinoma, and/or borderline or

well-differentiated ovarian mucinous tumors. Pseudomyxoma peritonei is rarely seen in mucinous cystadenomas. The mainstay of treatment is cytoreductive surgery. Multiple adjuvant treatment modalities with systemic and intraperitoneal chemotherapy have been proposed with some survival benefit. Sugarbaker and associates have described a combined modality approach of aggressive surgical cytoreduction followed by inatroperative hyperthermic intraperitoneal chemotherapy. Patients with complete cytoreduction treated according to this protocol have shown an 86% 5-year survival, although surgical morbidity and mortality rates are significant. Patients have a high recurrence rate, with variable times to recurrence. Most series agree that when patients have recurrent disease, repeat laparotomy is required to relieve symptoms. The overall 5-year survival rate is 50%, and most patients die from bowel obstruction.

Treatment

The primary surgical treatment for patients with LMP tumors who have completed childbearing is identical to the recommendation for invasive ovarian disease, including a total abdominal hysterectomy, bilateral salpingo-oophorectomy, tumor debulking, and full staging (Table 61.3). An appendectomy should be performed in patients with a mucinous LMP tumor because of the association with a synchronous primary appendiceal tumor.

In younger patients with early-stage diagnosis and a desire for future childbearing, conservative surgery with preservation of the uterus, the contralateral ovary, and in some cases the ipsilateral ovary (i.e., cystectomy) may be the appropriate treatment. Consultation with a gynecologic oncologist and pathologist can identify those patients who are candidates for conservative management. Several studies, both cohort and observational, have reported excellent outcome with conservative management of such patients. One of the largest studies reports a 12.0% recurrence rate for patients treated conservatively with either unilateral salpingo-oophorectomy (n = 110) or ovarian cystectomy (n = 74) versus 2.5% for patients treated with definitive hysterectomy and

bilateral salpingo-oophorectomy. Recurrences or progression to carcinoma (1.5%) were more common among patients with invasive implants or advanced-stage disease. The feasibility of doing a cystectomy for an LMP ovarian tumor and conserving the rest of the ovarian tissue in early-stage disease has been described but requires further study.

LMP ovarian tumors have also been diagnosed during pregnancy. Conservative surgery is usually performed, and pregnancy does not appear to be deleterious in regard to the prognosis for these patients. Most patients deliver at full term without any complications.

Postoperative Therapy

Presently, there is no evidence to suggest that adjuvant chemotherapy in early-stage disease or in patients with optimal cytoreduction of advanced disease improves survival in patients with LMP tumors. In fact, patients may be more likely to die from the side effects of adjuvant therapy than from the disease itself. Platinum-based therapy may be appropriate for a select group of patients with micropapillary serous tumors and invasive serous implants, based on the high rates of recurrence in these patients. However, patients must be counseled that available literature does not demonstrate improved survival with chemotherapy. An ongoing prospective GOG trial will address these issues. Second-look reassessment should not be a part of the standard therapy in monitoring these patients.

Malignant Neoplasms

Epidemiology

Epithelial ovarian carcinomas account for 80% to 90% of all ovarian malignancies. Incidence rates in the United States are about 12 to 15 per 100,000 for white women compared with about 8 to 10 per 100,000 for U.S. residents of non-European heritage. The incidence rate continues to increase to about 40 cases per 100,000 women by age 50 and then continues to slowly increase to about 50 cases per 100,000 by age 65. Although the incidence rates in Asian nations are lower, studies have indicated increasing incidence rates in these countries. Other than race, risk factors for ovarian cancer identified by epidemiologic studies include age over 60; early menarche; late menopause; nulliparity; infertility; personal history of breast or colon cancer; and family history of ovarian, breast, or colon cancer. In some inherited cases, the increased risk of ovarian cancer may be >50%, depending on the type and number of family members affected and age of onset. Other factors that have been implicated but lack adequate epidemiologic evidence include high-fat diets, talcum powder, and use of infertility drugs and hormone replacement therapy. Use of an oral contraceptive, bilateral tubal ligation, and hysterectomy are protective. Epithelial tumors are derived from the ovarian surface epithelium, which is the site of ovulation. One hypothesis suggests that incessant ovulation contributes to ovarian carcinogenesis because of the repeated injury and repair of the ovarian epithelium secondary to monthly ovulation. Repair of the ovarian surface promotes proliferation-associated DNA damage. Data from the United States Collaborative Analysis support the suppression of ovarian activity as a means of preventing ovarian cancer. A study found that a high number of ovulatory cycles was associated with more genetic alterations in ovarian

cancer patients. Oral contraceptives appear to protect against ovarian cancer through suppression of ovulation and a direct antiproliferative effect of the progestins on ovarian epithelium.

Clinical Presentation

Many patients with epithelial ovarian cancer come to medical attention with advanced-stage disease, with symptoms of abdominal fullness, pain, distention, early satiety, and weight loss. Other gastrointestinal symptoms include nausea, dyspepsia, constipation, or diarrhea. Abdominal distention can be due to ascites or a large abdominopelvic mass. Abnormal vaginal bleeding is seen in 30% of the cases. The most common physical signs are ascites, manifested by a fluid wave and the absence of shifting dullness, and the presence of a pelvic mass. The mass is frequently firm, hard, and fixed with multiple nodularities. Small tumors may not be easily palpated in the presence of ascites. Possible sites of spread within the abdomen are multiple (Fig. 61.27).

Preoperative Evaluation

All patients should have a complete blood cell count and serum chemistries including liver function tests performed. These tests, though routinely done preoperatively, will select out patients who may be at higher anesthetic risk. For example, any liver or kidney dysfunction may require further investigation, or the presence of anemia may justify a workup and transfusion prior to surgery. Serum tumor markers should be assayed. Although CA-125 is the best tumor marker for women with epithelial ovarian carcinoma, it can be elevated in a variety of benign conditions and other nongynecologic malignancies. CA-125 will be elevated in 80% of serous epithelial ovarian cancers. Although it is not useful for screening, CA-125 has higher sensitivity and specificity for detecting ovarian cancer in the postmenopausal patient. Preoperatively, CA-125 may be useful in helping to predict the potential for malignancy, and if elevated, it can be used to follow response to therapy and detect an early recurrence.

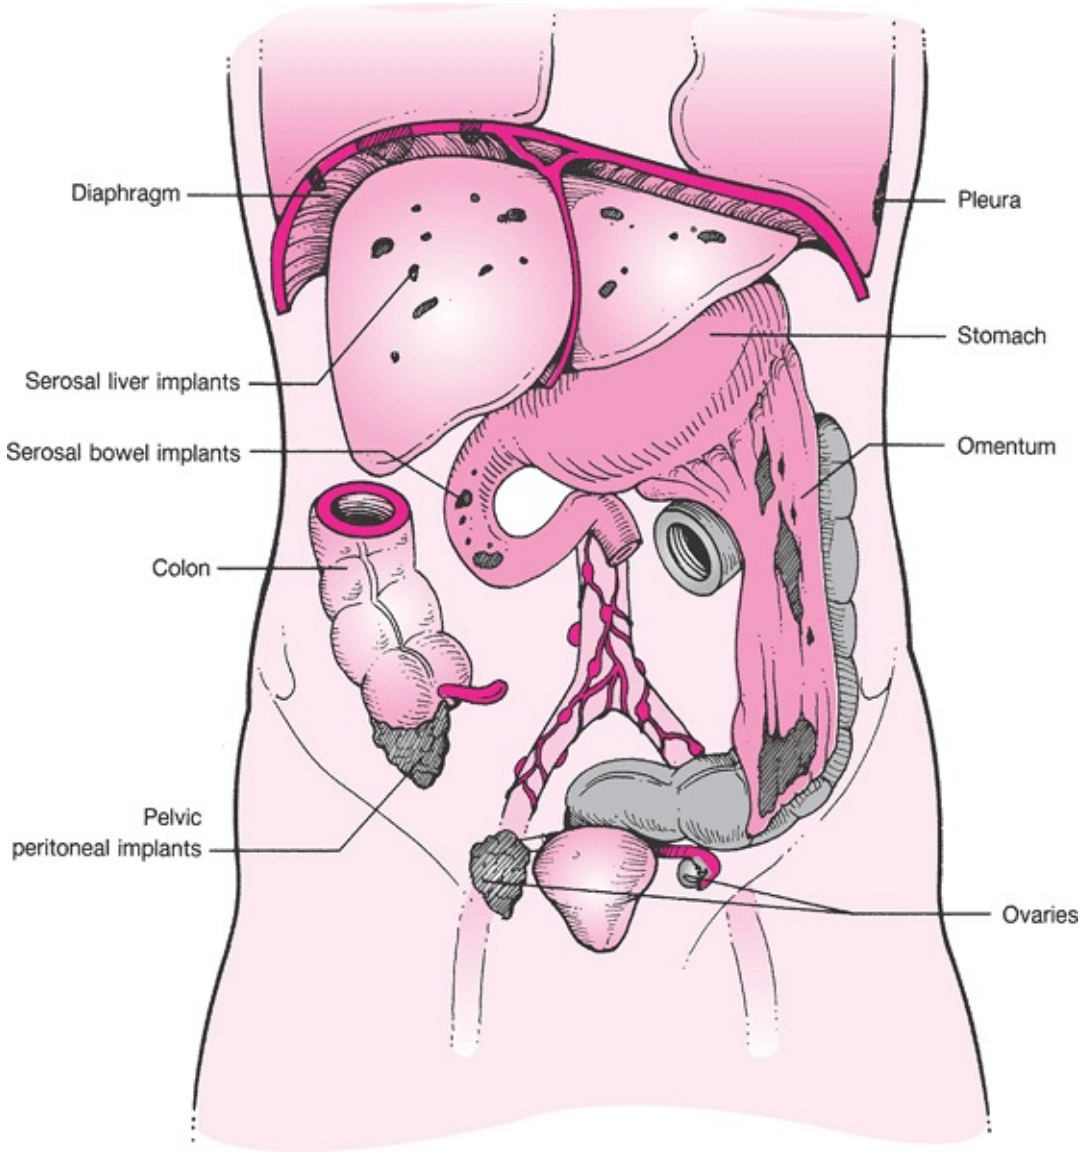

Figure 61.27 Possible sites of spread of epithelial ovarian cancer.

Chest radiographs are routinely performed to look for malignant pleural effusions, which occur in 10% of patients, and metastatic pulmonary disease, which is very rare. Barium enema examination is not routinely performed but may be helpful in patients with a left lower quadrant mass, blood in the stool, obstipation, or anemia or in patients with carcinomatosis in whom a primary gastrointestinal tract malignancy must be ruled out. Barium enema examination is not very useful in predicting the need for colon resection. Mammography is necessary to rule out a possible metastatic or synchronous breast carcinoma.

Sonography is the most useful diagnostic examination in the evaluation of a pelvic mass. It is an easily accessible and inexpensive imaging modality that provides an accurate description of ovarian pathology. Some characteristics associated with ovarian cancer include irregular ovarian cyst borders, solid elements, papillary projections, bilateral ovarian pathology, and ascites. Color Doppler imaging evaluates blood flow to an ovarian mass and can suggest a malignant process based on abnormal neovascularization. Several

studies suggest that color Doppler improves detection of ovarian cancers, although it lacks the ability to definitively identify malignancy. Three-dimensional ultrasound has the potential benefit of enhanced imaging of the ovarian architecture and measuring ovarian cyst volume; however, its application in evaluation of an adnexal mass has not been fully studied.

CT scan may be helpful in characterizing the liver, lymphatic spread, the omentum, and the mesentery. As well, it may be helpful in distinguishing a gynecologic malignancy from a metastatic pancreatic neoplasm for which surgery may not be warranted. In patients with an ovarian mass, MRI has not been shown to have any clear advantage over CT scanning, except for the evaluation of pregnant patients whose ultrasound examination was inconclusive and CT scan would result in undesirable ionizing irradiation.

Other studies such as bone and liver scintigraphy do not add any useful information. Intravenous pyelograms or renal scans may be helpful in patients with abnormal renal function or abnormal findings on ultrasonography, but they are rarely used. Immunoscintigraphy using CYT-103 or OC-125 that detects occult extra-abdominal or miliary metastasis is experimental but may be helpful in patients prior to second-look laparotomy or with recurrent disease. Positron emission tomography (PET) is a form of computer-assisted imaging that uses radionuclide-labeled analogues of glucose labeled with positron-emitting isotopes. Cancer cells are detected by their increased glucose metabolism compared with noncancer cells. PET has been examined in several preliminary studies involving the preoperative evaluation for suspected recurrent or metastatic ovarian tumors. Although the results are promising, the role of PET in the preoperative evaluation of such patients awaits further study.

Figure 61.28 Serous carcinoma. The tumor forms large, bilateral, solid, and cystic masses that have grown through the capsule. Tumor also involves the uterine serosa.

Staging

Staging is a critical step in the treatment of ovarian cancer. It is done at the time of surgical exploration in accordance with the FIGO system revised in 1987 (Table 61.4). Proper staging is absolutely necessary, because it impacts on both prognosis and subsequent treatment methods (Table 61.3). Observational studies have shown that 30% of patients who were thought to have stage I or stage II disease at initial surgery had more advanced disease with more comprehensive restaging laparotomy. A midline vertical incision is generally recommended, and it should be extended to above the umbilicus, if necessary, to allow proper exposure of the upper abdominal cavity. If an ovarian malignancy is discovered unexpectedly through a low transverse incision, the rectus muscle can be either severed or detached from the pubic symphysis to enhance surgical exposure.

Pathology

Serous Carcinoma

Serous tumor is the most common epithelial ovarian carcinoma, accounting for 40% to 50% of all such tumors. In most patients, serous tumors are bilateral and are disseminated at the time of diagnosis. They are soft, friable, mostly cystic, containing turbid or bloody fluid and having extensive papillary projections. Papillary excrescences may also be seen on the external surface or attached to adjacent structures (Fig. 61.28).

Microscopic evaluation in well-differentiated serous carcinoma reveals well-formed papillary structures that grow into cystic spaces or on the peritoneal surface of the tumor. Psammoma bodies are present in the most cases

(Fig. 61.29). With less differentiated tumors, the papillary pattern becomes less visible and the mitotic activity more brisk, and tumors become solid sheets of uniform, dark cells that are often slightly spindled and have a high nucleus-to-cytoplasm ratio.

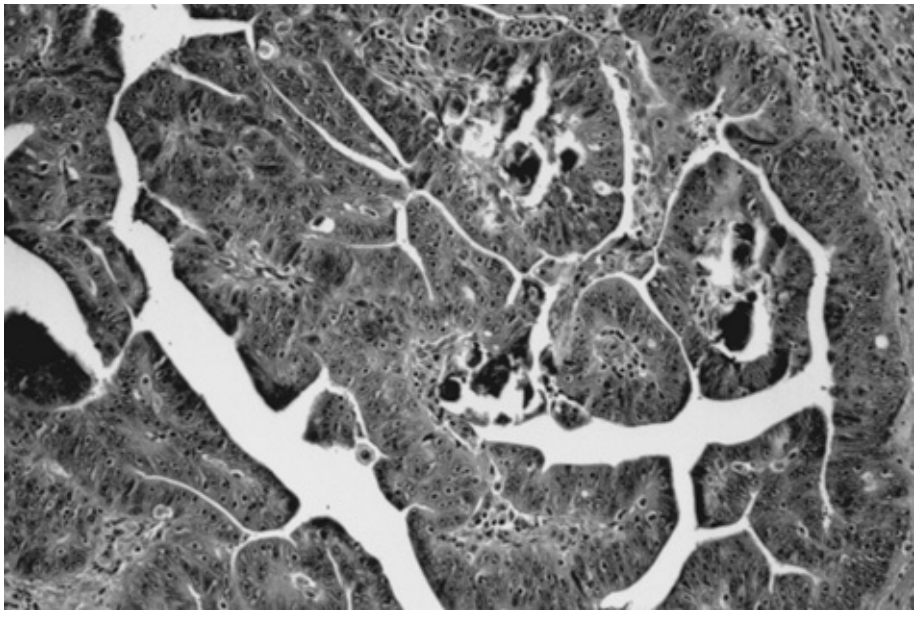

Figure 61.29 Serous carcinoma. In this tumor, papillae are lined by high-grade tumor

cells with prominent nucleoli. Psammoma bodies are present.

Mucinous Tumor

Mucinous carcinoma represents approximately 10% of all epithelial ovarian malignancies. Bilaterality is less common, present in <15% of cases. Disseminated spread is seen much less frequently than in patients with serous carcinoma. Mucinous carcinoma is usually larger than its serous counterpart, measuring approximately 15 to 30 cm in diameter. The tumor is multiloculated; solid and cystic; and filled with thick, viscous mucin.

Microscopically, invasive well-differentiated mucinous carcinoma is typically composed of more than three layers of epithelium, with prominent mucin production (Fig. 61.30). It may show only subtle irregularities in gland contour and irregular budding, with no other stromal signs of invasion. In moderately differentiated carcinoma, the glands are more back-to-back, with obvious stromal invasion, cellular stratification, and nuclear atypia. In poorly differentiated mucinous carcinoma, cells are disorganized, embedded in a dense reactive ovarian stroma. Signet-ring cells may be present, as in a Krukenberg tumor. Mucinous tumor often contains a wide range of histologic differentiation; therefore, extensive sampling must be performed to obtain the correct diagnosis.

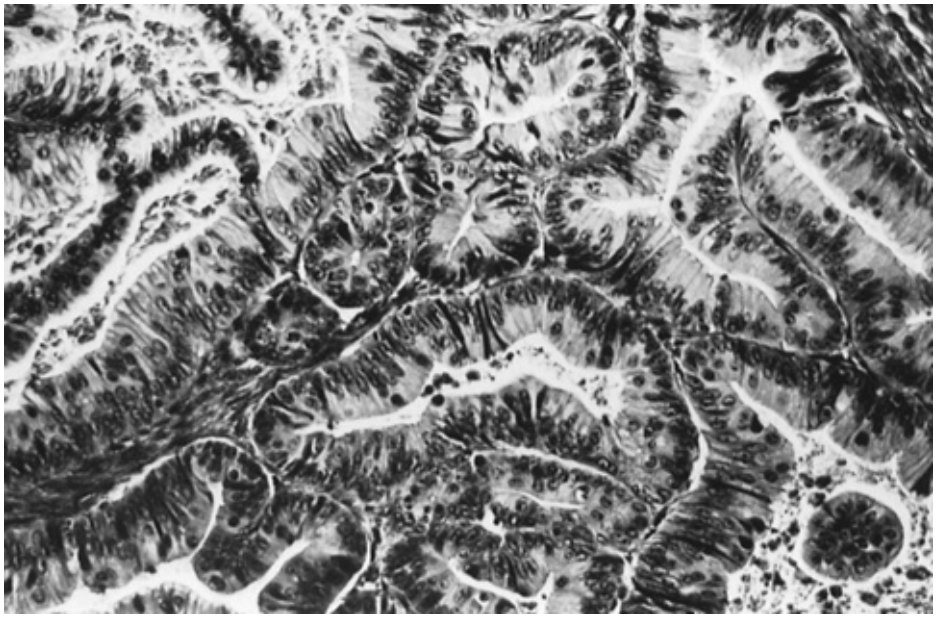

Figure 61.30 Mucinous carcinoma. Infiltrating, crowded glands are lined by tall columnar cells with pale cytoplasm. Note the atypical, stratified nuclei (original magnification 160×).

Endometrioid Tumor

Endometrioid carcinoma accounts for 13% of all epithelial ovarian malignancies. It is bilateral in 30% of cases. In up to one third of patients, endometriosis has been noted in

the same ovary or elsewhere in the pelvis. In addition, a synchronous endometrial adenocarcinoma has been seen in 20% of patients; these tumors are superficial and are associated with endometrial hyperplasia. Well-differentiated ovarian endometrioid adenocarcinoma is characterized by well-developed glands lined by tall, columnar, pseudostratified or multilayered epithelium like its uterine counterpart (Fig. 61.31). Squamous differentiation may be seen in about 30% of tumors and is usually benign. As tumors become less differentiated, the glandular pattern becomes less organized, and a solid growth pattern becomes predominant. Mitoses are more frequent, and nuclei are more high grade.

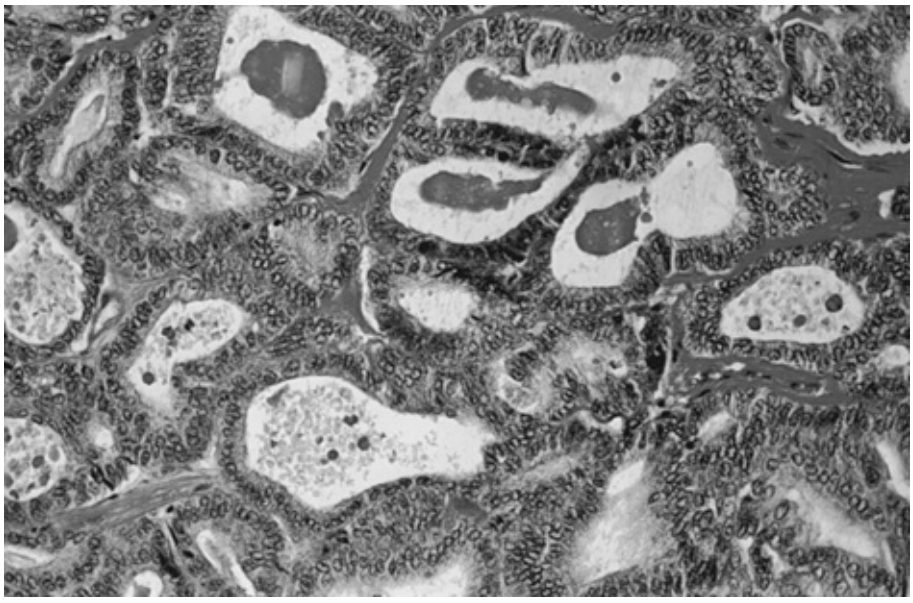

Figure 61.31 Endometrioid carcinoma. In a well-differentiated endometrioid carcinoma, the glands are smoothly rounded, closely packed, and lined by an endometrioid type of columnar epithelium.

Clear Cell Tumor

Clear cell carcinoma constitutes 5% of malignant epithelial ovarian tumors. It is bilateral in 15% to 20% of patients and confined to the ovary in 60%. Despite the limited spread of disease at the time of presentation, clear cell carcinoma is a notoriously virulent tumor. It frequently is associated with endometriosis, with 25% of tumors arising from the lining of the endometriotic cysts. A mixed form of epithelial ovarian carcinoma with clear cell tumor and endometrioid or serous carcinoma can occur, suggesting a similar histogenesis.

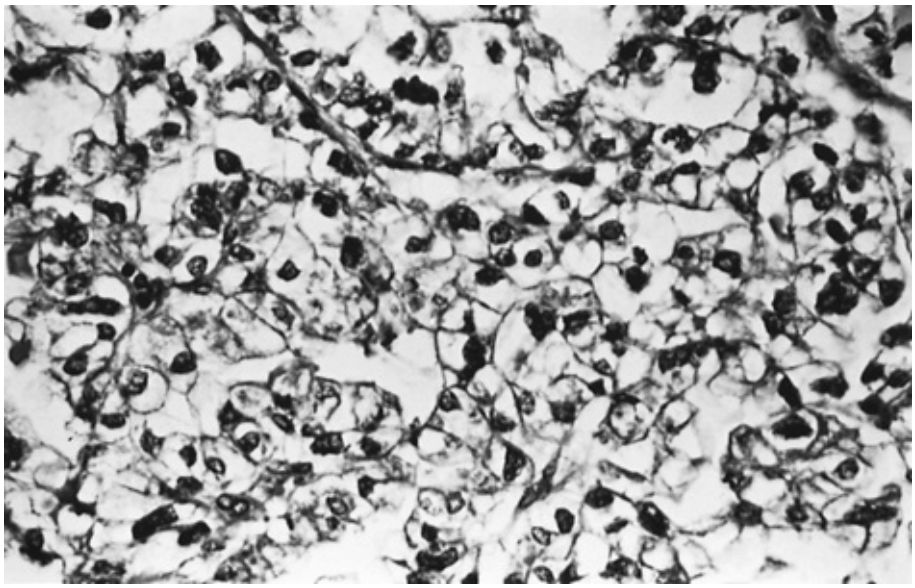

Figure 61.32 Clear cell carcinoma. In clear cell carcinoma, tumor cells are polygonal, with central nuclei and abundant clear cytoplasm (original magnification 250×).

Microscopically, clear cell tumor may be characterized by sheets of polyhedral clear cells divided by fine connective tissue septa. Cells usually have abundant glycogen in the cytoplasm that is responsible for the clear appearance of the cells. The other characteristic feature is the tubulopapillary pattern formed by the columnar secretory cells with nuclei that bulge into the lumina of the glands, giving a hobnail appearance (Fig. 61.32). Eosinophilic cells instead of secretory columnar cells may surround tubules or papillae, or a mixture of these cells may be present.

Undifferentiated Tumor

Accounting for 5% to 10% of all ovarian malignancies, undifferentiated tumor exhibits such poor differentiation that it cannot be classified into any of the categories previously described. There is a variable histologic pattern, ranging from sheets of large anaplastic cells to undifferentiated small cells to large pleomorphic giant cells with eosinophilic cytoplasm. The prognosis is usually very poor, as patients often present in advanced stage with large tumor burdens.

Brenner Tumor

Malignant Brenner tumor is very rare. It ranges from 10 to 30 cm in diameter and is usually unilateral. Microscopically, malignant Brenner tumor exhibits solid sheets of heterogeneous epithelial cells with minimal stroma. Nuclear grade and mitotic activity are high. Histologically, these cells resemble transitional cells, like those in the urologic tract. Differentiation from a carcinoma of urinary origin is based on clinical picture and surgical findings. Origin in the ovary is supported by finding a transition from a benign or proliferating Brenner tumor.

Müllerian Mesenchymal and Mixed Tumors

Müllerian mesenchymal and mixed tumors are rare ovarian tumors that are divided into subtypes, including adenosarcoma and malignant mixed mesodermal tumor; they are associated with a poor prognosis. Histologically, they resemble their uterine counterparts. Adenosarcoma contains a benign epithelial component and a sarcomatous mesenchymal component. Malignant mixed mesodermal tumor has both malignant epithelial and malignant mesenchymal components (i.e., carcinosarcoma).

Similar to epithelial ovarian tumors, these tumors are usually surgically staged. However, optimal cytoreduction and adjuvant chemotherapies for these patients may not be as effective as they are for patients with the other types of epithelial tumors. The chemotherapeutic regimens are also different, but studies are limited by the rarity of these tumors. Agents that have been tried include doxorubicin (Adriamycin), cisplatin, ifosfamide (Ifex), and paclitaxel (Taxol).

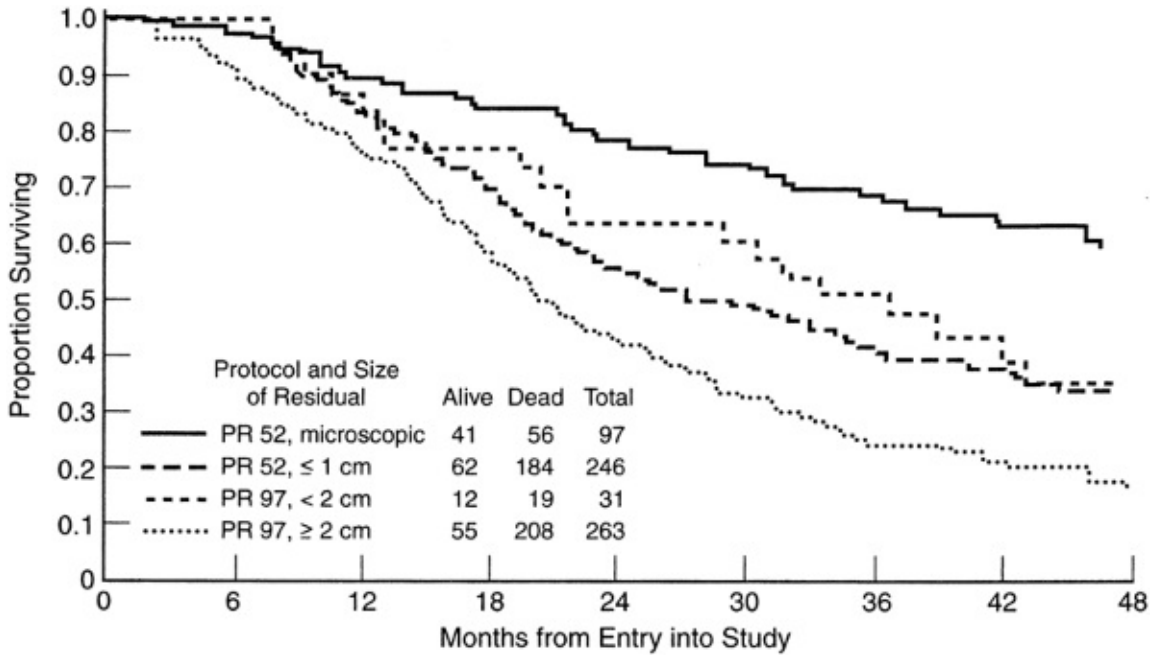

Figure 61.33 Survival by residual disease: GOG protocols 52 and 97. (From Hoskins WJ, McGuire WP, Brady MF, et al. The effect of diameter of largest residual disease on survival after primary cytoreductive surgery in patients with suboptimal residual epithelial ovarian carcinoma. *Am J Obstet Gynecol* 1994;170:974–980, with permission.)

Treatment

Surgery

Surgery is the most important aspect in the initial care of patients with epithelial ovarian cancer. Surgery alone is curative for many patients with early-stage ovarian carcinoma. For more advanced disease, surgery establishes the diagnosis and allows appropriate staging

and cytoreduction, optimally to <1 cm residual disease. Conservative surgical management of young women with stage Ia/grade 1 or 2 who desire future fertility with a unilateral salpingo-oophorectomy with a full staging procedure may be appropriate. The contralateral ovary should be carefully evaluated, as there is a 5% chance of occult metastasis or a separate primary carcinoma. Biopsy of the contralateral ovary is no longer recommended, unless there are grossly apparent abnormalities. Such patients must also have strict subsequent follow-up. Although a hysterectomy and removal of remaining adnexae is recommended for women who have completed childbearing, this recommendation is not based on randomized clinical trials.

Primary cytoreduction of ovarian carcinoma has been recommended for more than 30 years. The theory is that removal of large hypoxic tumors allows better penetration of chemotherapeutic agents and removes potential foci of chemoresistance. Optimal cytoreduction is defined as residual disease <1 cm. Several reports over the last 25 years have shown that the diameter of the largest residual disease correlates with response rate, progressionfree interval, and overall survival. The GOG evaluated survival by maximum diameter of residual disease (combined protocols 52 and 97) and found that the survival rate for patients with residual disease of ≥2 cm is about 20% at 4 years as compared with a 60% survival rate at 4 years in those with only microscopic residual disease. For patients with residual disease <2 cm, the survival rate is 40% at 4 years (Fig. 61.33). Median survival of optimally cytoreduced patients was approximately twice that of patients with suboptimal cytoreduction.

There has been great debate in the literature regarding the relative importance surgical cytoreduction as compared with inherent tumor biology of the cancer as determinants of patient survival. Patient age, the number and size of tumor nodules at the time of diagnosis, and tumor grade have been cited as significant predictors of patient outcome. Large series have found that initial optimal surgical cytoreduction could not equate the survival benefit experienced by patients who initially had small-volume disease. Some investigators have suggested that platinum-based therapy has had a larger impact on survival than surgical debulking. Data, including a large meta-analysis, have demonstrated that maximal initial surgical cytoreduction is the most powerful predictor of patient survival. Patients with ovarian cancer are more likely to have optimal cytoreduction under the care of a gynecologic oncologist as compared with general surgeons or general gynecologists. Surgical outcome data in women with ovarian cancer suggest that specialized care is associated with superior outcome. Women cared for by specialists have higher rates of optimal surgical cytoreduction, higher compliance with published guidelines regarding appropriate surgical staging and use of adjuvant chemotherapy, and a reduction in the risk of death. Despite benefit of improved survival, the majority of ovarian cancer patients in the United States never see a gynecologic oncologist. Ongoing efforts to educate physicians and patients regarding appropriate referral of ovarian cancer patients to specialized centers are needed.

At the end of chemotherapy, patients who are clinically in complete remission may be offered second-look evaluation to determine the success of therapy, as measured by the presence of any residual tumor. The reasons for second-look evaluation are (a) to

determine disease presence, thus allowing continued therapy in an attempt to improve survival; (b) to debulk any residual carcinoma; and (c) a prognostic tool for patient survival. The majority of second-look evaluations can be successfully completed via the laparoscope among surgeons with adequate expertise, with equivalent rates of detection of residual disease. A laparoscopic approach reduces the length of hospital stay (frequently done as outpatient surgery) and patient recovery time. Older studies have shown that survival rates for those who underwent second-look surgery as compared with those who did not were essentially the same, suggesting no benefit for the procedure. However, these studies have not evaluated the effect of newer chemotherapy and more effective salvage therapies. Although second-look surgery should not be considered standard of care, it should be performed in patients enrolled in clinical trials to evaluate the efficacy of newer first-line therapies and the efficacy of better salvage therapies in improving survival.

Secondary cytoreduction at the time of second-look laparotomy has also been examined in several studies that revealed a benefit in a select group of patients with gross disease that is successfully cytoreduced to microscopic disease. However, only a small number of patients will have gross residual disease after clinical response to platinum-based chemotherapy. More recent data suggest that the presence or absence of residual disease at second-look surgery is one of the most significant prognostic factors for patient survival. Therefore, until more accurate diagnostic tests can be identified to determine residual disease after standard treatment, second-look surgery could be offered to patients with advanced-stage disease in clinical remission, with the caveat that to date, the procedure has prognostic value but no impact on survival.

Interval surgical cytoreduction following a short course of chemotherapy, typically two to three cycles, for women left with residual disease after primary surgical exploration has been proposed to improve the chemosensitivity of residual disease and improve patient outcome. Patients with disease progression (5% to 15%) on chemotherapy are not good candidates for interval cytoreduction, as further surgical effort has shown minimal survival benefit. Optimal cytoreduction following the interval cytoreduction has been reported in 63% to 80% of patients. Two large prospective, randomized trials on interval cytoreduction, Gynecologic Cancer Cooperative Group of the European Organization for Research and Treatment (CGC-EORTC) 55865 and GOG 152 found conflicting results on the impact of further surgery on patient survival. Both studies involved patients with advanced-stage disease of similar ages. Overall and progressionfree survival was significantly improved in patients randomized to interval cytoreduction in the EORTC study, with a calculated reduction in risk of death of 33% compared with that found in patients who had no surgery. Further analysis revealed that this survival advantage was seen only in patients who achieved optimal residual disease (<1cm) following induction chemotherapy and interval surgery.

Interval cytoreductive surgery did not improve overall or progressionfree survival for patents in the GOG trial. The dissimilar results of these two trials may reflect different degrees of initial surgical effort. The GOG trial required maximal surgical effort with a laparotomy and removal of as much tumor as possible in which 95% of primary surgery was performed by a gynecologic oncologist, whereas the type of surgeon and extent of surgery was not described in the EORTC trial. This presumed maximal surgical effort made at

primary surgery in the GOG trial resulted in a study population of women with unresectable tumors in contrast to the EORTC study in which less primary surgical effort resulted in a study population of patients with unresected tumors. Additionally, the more effective cisplatin and paclitaxel chemotherapy used in the GOG study may have minimized the benefit of secondary surgery compared with the earlier regimen of chemotherapy in the EORTC trial (Table 61.6). Both studies confirmed the poor prognosis for women whose tumors could not be resected after maximal primary and interval surgical effort with intervening platinum-based chemotherapy.

TABLE 61.6 Comparison of the Gynecologic Oncology Group 152 and European Organization for Research and treatment of cancer studies of interval surgical debulking after induction chemotherapy

Feature	Current Study	EORTC Study[a]
No. of eligible patients	424	319
Eligible patients included in analysis (%)	100	87
Age (yr)		
Median	57	59
Range	25–81	32–74
Papillary serous carcinoma (%)	76	57
Stage IV disease (%)	6	22
Primary surgery performed by gynecologic oncologist (%)	95	Not indicated

Ascites at primary surgery (%)	79	75
Median size of residual tumor after primary surgery (%)		
≤2.0 cm	12	2
2.1–5.0 cm	43	23
>5.0 cm	44	72
Chemotherapy regimen	Paclitaxel and cisplatin	Cyclophosphamide and cisplatin
Secondary surgery performed by gynecologic oncologist (%)	44	72
Patients completing 6 cycles of chemotherapy (%)	95	84
Median progression-free survival from study entry (mo)[b]		
Secondary surgery	12.5	18
Chemotherapy alone	12.7	13
Median survival from study entry (mo)[b]	12.7	13
Secondary surgery	36.2	26
Chemotherapy alone	35.7	20

[a] Data are from van der Burg ME, van Lent M, Buyse M, et al. The effect of debulking surgery after induction chemotherapy on the prognosis in advanced epithelial ovarian cancer. *N Engl*

J Med 1995;332(10):629–634.

[b]To facilitate comparisions between trials, survival was assessed from the time of entry into the study.

The natural history of advanced-stage ovarian cancer is that disease will recur in the majority of cases. The rationale behind cytoreductive surgery followed by chemotherapy in these circumstances remains more controversial. Theoretically, secondary cytoreductive surgery can enhance the response to chemotherapy in appropriate patients by reducing tumor volume and improve chemotherapy pharmacokinetics, as is proposed in the newly diagnosed patient. The limited success of chemotherapy in the setting of recurrent disease has contributed to the controversy regarding the benefit of secondary cytoreductive surgery. Secondary cytoreductive surgery in patients with recurrent epithelial ovarian carcinoma has also been evaluated in several studies. Aggregate data suggests that secondary cytoreduction is feasible in 37% to 87% of patients who underwent the procedure with acceptable morbidity and median overall survival after secondary cytoreduction of 16.3 to 35.9 months. For those patients who achieved macroscopic resection of all residual disease at secondary cytoreduction, median survival was reported from 29 to 100 months. Although consensus is lacking, studies have found that predictors of successful secondary cytoreduction include prolonged diseasefree interval, ideally >12 months; good performance status; *primary* optimal cytoreductive surgery; absence of large-volume ascites; and a limited number of sites of recurrence.

Chemotherapy

Following surgery, most patients will require chemotherapy. However, for patients with completely staged Ia or Ib/grade 1 or 2 ovarian cancers, no survival benefit has been demonstrated with adjuvant chemotherapy. The studies have shown clear benefit to adjuvant chemotherapy in patients with Ia or Ib/grade 3, and Ic disease compared with observation. The GOG and the Gruppo Italiano Collaborativo in Oncologia Ginecologica (GICOG) studies found that patients with stage Ia or b/grade 1 or 2 had comparable survival with observation and melphalan. In contrast, select patients with stages Ia, Ib, Ic, and II had improved diseasefree intervals with cisplatin-containing regimens compared with observation, intraperitoneal phosphorus 32, or melphalan (Alkeran). Prospective trials have confirmed that adjuvant cisplatin-based chemotherapy delays disease recurrence in patients with early-stage disease and improves overall survival in patients who have not had comprehensive surgical staging. The optimal number of cycles of chemotherapy for early-stage disease remains controversial. A current prospective trial compared the efficacy of three versus six cycles of paclitaxel and cisplatin in early-stage patients and found that the three additional cycles of chemotherapy did not significantly reduce cancer recurrence rates but did significantly increase toxicity. Some authorities have questioned the validity of

this conclusion, given the small number of events in the trial (disease recurrence) and the nonconventional dose of carboplatin used, and they continue to advocate six cycles of

adjuvant therapy for early-stage ovarian carcinoma.

Various chemotherapeutic agents are active against ovarian cancer. Platinum-based therapy has been the mainstay of treatment for ovarian cancer for over 30 years. Combination platinum-based regimens have demonstrated superior response rates to single-agent platinum, although there is insufficient evidence to suggest longer overall survival in these patients. The lack of survival benefit in some trials may relate to the high crossover treatment of patients who failed on one treatment arm and received other study treatments and the varied length of patient follow-up.

Paclitaxel, a microtubule stabilizer, was found to have significant activity in many cancers, including epithelial ovarian carcinoma. In 1996, the GOG published a study comparing the efficacy of paclitaxel and cisplatin with cyclophosphamide and cisplatin as first-line adjuvant therapy in patients with suboptimally debulked epithelial ovarian carcinoma (stages III or IV). Diseasefree survival and overall survival for the paclitaxel/cisplatin group was statistically higher than for the cyclophosphamide/cisplatin group (median survival 38 to 24 months). Paclitaxel/cisplatin was also more effective in patients with advanced-stage ovarian cancer after optimal cytoreduction.

Substitution of the less toxic carboplatin for cisplatin and decreased paclitaxel infusion times have reduced cost and patient side effects compared with the paclitaxel/cisplatin regimen.

A subsequent prospective randomized trial replaced paclitaxel with docetaxel (Taxotere), another microtubule stabilizing agent, and found comparable response rates with less peripheral neuropathy. During the last 5 years, many new drugs have been found to be active second-line regimens in ovarian cancer, including topotecan, etoposide, altretamine (Hexalen), docetaxel (Taxotere), gemcitabine hydrochloride (Gemzar), vinorelbine tartrate (Navelbine), and liposome doxorubicin hydrochloride (Doxil). Both topotecan, a topoisomerase inhibitor, and liposomal doxorubicin have shown promising activity in patients with recurrent, platinum-resistant disease, with response rates of 20% to 30%. A large, prospective trial is currently randomizing patients to one of several combination multiagent chemotherapy regimens using gemcitabine, liposomal doxorubicin, or topotecan with paclitaxel/carboplatin as the control arm, to better elucidate the superior first-line regimen in advanced stage ovarian cancer patients.

The search for better chemotherapy has led to clinical trials using agents that exploit the specific tumor biology of ovarian cancer by preferentially acting on tumor cells with less damage to normal cells. Some examples of targeted therapies that have shown promising early results in recurrent ovarian cancer include thalidomide, which targets the epidermal growth factors receptor, bevacizumab (Avastin), which targets the vascular endothelial growth receptor, and trastuzumab (Herceptin), which targets the HER2/neu growth factor receptor. Oregovomab (OvaRex) is an antibody directed against the CA-125 antigen that has shown promising early results as a potential consolidation given to women who had optimal surgical cytoreduction followed by standard taxane-platinum chemotherapy to sustain clinical remission. These agents add to the list of potential treatment options for patients with ovarian cancer that can allow patients to live longer with fewer side effects.

Intraperitoneal administration of chemotherapy has long been advocated as a treatment for ovarian cancer based on the distribution of disease within the abdominopelvic cavity and the high local concentrations of chemotherapy that can be delivered via the intraperitoneal route. The pharmacologic advantage of intraperitoneal route is considerable with concentrations that are 20- to >100-fold higher for drugs such as cisplatin and paclitaxel when given via intraperitoneal catheter compared with standard intravenous therapy. The ideal drugs must have minimal local peritoneal toxicity, a steep dose–response curve, low peritoneal permeability, rapid clearance from the plasma, and immediate activity without the need for conversion to an active form. At the same time, patients should have limited peritoneal adhesions to ensure adequate drug distribution and small-volume disease, preferably microscopic or ≤5 mm in diameter.

Three large, randomized, multicenter trials comparing cisplatin-combination intraperitoneal chemotherapy with standard intravenous therapy for patients with optimally cytoreduced advanced-stage patients found an 8- to 16-month survival advantage for patients treated with intraperitoneal chemotherapy and a 21% reduction in the risk of death. A recent study randomized 415 newly diagnosed optimally cytoreduced stage III ovarian cancer patients to control intravenous cisplatin/paclitaxel versus experimental intravenous paclitaxel on day 1, intraperitoneal cisplatin on day 2, and intraperitoneal paclitaxel on day 8. At a median follow-up of 50 months, the intravenous/intraperitoneal patients had a median improved overall survival of 15.9 months (Fig. 61.34). The intravenous/intraperitoneal regimen was, however, significantly less tolerable than standard intravenous therapy. Significant abdominal pain, hematologic, metabolic, and neurologic toxic effects were seen more commonly in the experimental arm as well as catheter-related problems. Of the 205 eligible women randomized to intravenous/intraperitoneal therapy, only 42% of patients completed all six cycles. Extensive adhesions, gross contamination of bowel contents from a left-sided bowel resection, and significant obesity may also limit successful intraperitoneal access and distribution of drug delivery. Given the significant survival advantage seen among patients treated with intraperitoneal therapy, efforts should be made to optimize intraperitoneal drug selection, dosing, and delivery strategies to improve its tolerability for ovarian cancer patients.

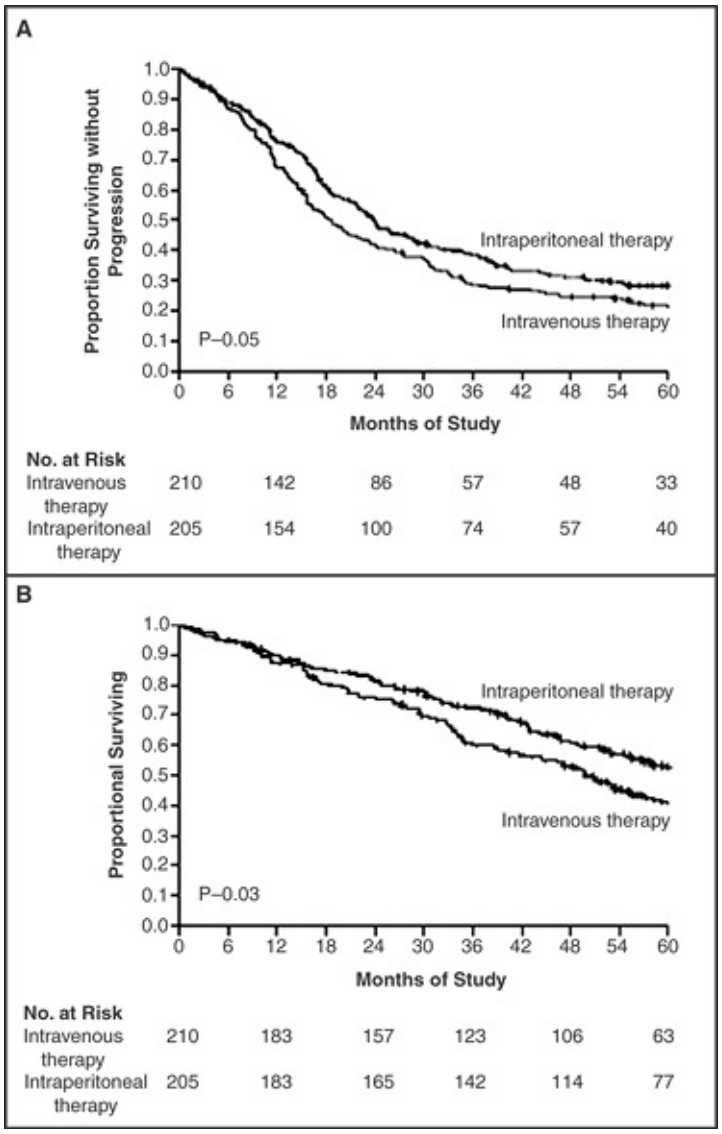

Figure 61.34 Progression free and overall survival. **A:** Progression free survival. **B:** Overall survival among 415 eligible patients with stage III ovarian cancer treated with intravenous paclitaxel and cisplatin or with intravenous paclitaxel, intraperitoneal cisplatin, and intraperitoneal paclitaxel. The median progressionfree survival in the intravenous-therapy group was 18.2 months and 23.8 months in the intraperitoneal-therapy group. The median overall survival was 49.7 months and 65.6 months, respectively. (From Armstrong DK, Bundy B, Wenzel L, et al. Intraperitoneal cisplatin and paclitaxel in ovarian cancer. *N Engl J Med* 2006;354(1):34–43, with permission.)

Neoadjuvant Chemotherapy

Neoadjuvant chemotherapy in lieu of primary surgery has been proposed as an alternative to avoid the morbidity of an unsuccessful surgical procedure for patients considered at the highest risk of having primarily unresectable tumor. Pathologic confirmation of the diagnosis by biopsy is mandatory before offering patients neoadjuvant chemotherapy. Cytologic diagnosis from ascites or a pleural effusion may be used as a surrogate for biopsy in suspected cases of advanced ovarian cancer when combined with appropriately elevated tumor markers and clinical disease distribution.

Based on available noninvasive testing, it is difficult to accurately predict which patients will not be candidates for a successful cytoreduction. The predictive ability of radiologic criteria, preoperative CA-125, volume of ascites, and distribution of abdominal/peritoneal tumor have all been proposed to distinguish between optimal and suboptimal surgical candidates with disappointing results. The identification of patient factors that predict suboptimal surgical cytoreduction is also difficult. While data suggest that older patients are less likely to undergo maximal cytoreductive surgery, chronologic age itself should not be a contraindication to cytoreductive surgery. Performance status correlates more accurately with surgical outcome.

Neoadjuvant chemotherapy has shown benefit in women with severe systemic disorders by reducing the extent of disease and improving patient performance status before undertaking surgical cytoreduction. Advocates of neoadjuvant chemotherapy have reported additional benefits, including an increased rate of optimal cytoreduction, less extensive surgery with reduced blood loss, lower morbidity, and reduced hospital stay in patients treated with chemotherapy first followed by surgery without compromising patient prognosis.

A meta-analyses reviewed available studies to better address the survival outcome of patients treated with neoadjuvant chemotherapy and to try to identify prognostic variables within this patient population. Twenty-one studies comprising 835 patients were included. The median overall survival for the cohort ranged from 10.0 to 42.0 months, with a weighted median survival of 24.5 months. A significant detrimental impact on survival was noted when patients received more cycles of chemotherapy before attempted cytoreductive surgery. The authors concluded that neoadjuvant chemotherapy in lieu of primary cytoreduction is associated with inferior survival. Although reported optimal surgical cytoreduction rates for patients with advanced-stage ovarian cancer range from 30% to 90%, most high-volume centers describe that optimal cytoreductive surgery is possible in 75% of patients. Given the significant survival benefit of optimal surgical cytoreduction, which is unparalleled by neoadjuvant chemotherapy and interval cytoreduction, it is advised that surgical exploration should be offered to all patients who are medically fit for surgery. Multi-institutional prospective trials comparing neoadjuvant with conventional therapy are under way and hope to address whether preoperative models exist that can predict surgical outcome and the impact on patient survival. In the interim, neoadjuvant chemotherapy should be reserved for the patient whose medical comorbidities severely limit the patient's ability to tolerate surgical cytoreduction.

Radiation Therapy

Abdominopelvic radiation therapy has been used postoperatively in selected patients who have microscopic or small-volume residual disease; however, with more

effective chemotherapy, radiation therapy is infrequently used adjuvant therapy in ovarian cancer. One of the largest series, compiled by investigators in Toronto in treated patients with stage II and III disease with abdominopelvic radiation, showed a 10-year diseasefree survival of 38% (n = 91) for patients with residual <2 cm and 6% (n = 91) for patients with

residual >2 cm. Further studies on the usefulness of radiation therapy for ovarian cancer are warranted.

Prognosis

With the addition of several innovative therapeutic regimens and aggressive surgical cytoreduction, survival has improved in patients with advanced-stage ovarian cancer. The overall 5-year survival for ovarian cancer patients is approximately 50% to 60%. Further strides in the management of ovarian cancer will require more knowledge of the molecular alterations that cause it. Advances in molecular biology indicate that ovarian tumorigenesis result from an accumulation of sequential genetic mutinous. With a better understanding of the neoplastic transformation of ovarian epithelium, targeted therapies may be directed against the specific genetic aberrations in an individual cancer to improve patient outcome. Several innovative trials have combined gene therapy or immunotherapy and standard chemotherapy with promising early results. Ongoing efforts in both basic and clinical research are critical for the development of prevention strategies, screening for early detection, and better therapies.

Fallopian Tube Cancers

Fallopian Tube Epithelial Carcinoma

Fallopian tube carcinoma accounts for approximately 0.1% to 0.5% of all gynecologic malignancies. Peak incidence occurs at 60 to 64 years of age. Epidemiologic observational data suggest that age and nulliparity are associated with fallopian tube carcinoma, similar to endometrial and ovarian carcinoma. The constellation of symptoms including pelvic pain, a pelvic mass, and serosanguineous vaginal discharge (Latzko's triad) occur in the minority of cases. The most common symptom is vaginal staining or bleeding. Hydrops tubae profluens is characterized by colicky lower abdominal pain relieved by a profuse, serous, watery, yellow intermittent vaginal discharge. The most common physical sign is a pelvic or abdominal mass. This mass is often thought to be an ovarian mass, with the correct diagnosis made at surgery. Occasionally, a Pap smear revealing abnormal glandular cells with negative cervical or endometrial findings may lead the clinician to the diagnosis. Serum CA-125 levels are often elevated in advanced disease, as is noted in ovarian carcinoma patients. Fallopian tube carcinoma is staged according to FIGO. In contrast to ovarian cancer, the majority of patients are diagnosed with early-stage disease: stage I, 37%; stage II, 21%; stage III, 31%; and stage IV, 10% (Table 61.7).

Fallopian tube carcinoma is usually characterized by swollen tubes secondary to intraluminal growth. Most fallopian tube adenocarcinomas are serous, histologically identical to ovarian serous carcinoma (Fig. 61.35). Other types of epithelial fallopian tube carcinoma have been reported but are very rare. Several diagnostic criteria have been established to differentiate fallopian tube malignancy from ovarian and other primary tumors. Microscopically, the tumor must arise from the endosalpinx, with a histologic pattern consistent with tubal mucosal epithelium. The transition from benign to malignant epithelium is helpful for diagnosis. The ovaries and endometrium are either normal or have

tumor smaller than that in the tube. As in epithelial ovarian carcinoma, fallopian tube epithelial tumors commonly spread by exfoliation and implantation throughout the peritoneal cavity. The extensive lymphatic channels within the fallopian tube facilitate lymphatic dissemination of tumor, and paraaortic lymph node metastases are common.

Surgery remains the principal treatment, including a total abdominal hysterectomy, bilateral salpingo-oophorectomy, tumor debulking, and a full staging, as with ovarian cancer (Table 61.3). Treatment of primary fallopian tube epithelial tumors is based on the standard management for ovarian carcinoma, due to the lack of any large-scale studies for this rare tumor. Platinum-based therapies are recommended following surgery, based on several series showing superior response rates and survival compared with other agents.

Due to the rarity of fallopian tube cancer, paclitaxel has not yet been widely studied in this disease. However, available data from a matched, case-control study of fallopian tube and ovarian carcinoma suggests that paclitaxel/platinum combination chemotherapy is equally effective in both disease sites. As in ovarian carcinoma, the prognosis is dependent on the extent of disease and the amount of residual tumor at the end of surgery. Second-look surgery may be helpful in determining treatment efficacy and persistent disease, but as in ovarian carcinoma, it is not considered standard therapy at this time.

Fallopian Tube Sarcoma

Sarcomas of the fallopian tubes may be classified as pure or mixed. They are exceedingly rare—fewer than 50 cases have been reported—and are usually found in postmenopausal women. Abdominal pain and watery or bloody vaginal discharge with signs of peritoneal spread are common findings. An ovarian origin must be ruled out by clearly identifying residual normal ovarian structure. The life expectancy of patients with these sarcomas is usually measured in months. As described in case reports, radiation and chemotherapy have not been effective.

TABLE 61.7 International Federation of Gynecology and Obstetrics Staging for Fallopian Tube Cancer

Stage 0	Carcinoma in situ (limited to tubal mucosa)
Stage I	Growth limited to the fallopian tubes
Stage Ia	Growth limited to one tube with extension into the submucosa or muscularis but not penetrating the serosal surface No ascites

Stage Ib	Growth limited to both tubes with extension into the submucosa or muscularis but not penetrating the serosal surface No ascites
Stage Ic	Tumor either stage Ia or Ib with tumor extension through or onto the tubal serosa, or with ascites containing malignant cells, or with peritoneal washings containing malignant cells
Stage II	Growth involving one or both fallopian tubes with pelvic extension
Stage IIa	Extension or metastasis to the uterus or ovaries
Stage IIb	Extension to other pelvic tissues
Stage IIc	Tumor either stage IIa or IIb and with ascites containing malignant cells or with peritoneal washings positive for malignant cells
Stage III	Tumor involving one or both fallopian tubes with peritoneal implants outside of the pelvis and or positive retroperitoneal or inguinal nodes Superficial liver metastasis equals stage III Tumor seems limited to the true pelvis but with histologically proven malignant extension to the small bowel or omentum
Stage IIIa	Tumor grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces
Stage IIIb	Tumor involving one or both tubes with histologicatly confirmed implants of abdominal peritoneal surfaces = 2 cm in diameter Lymph nodes are negative

Stage IIIc	Abdominal implants >2 cm in diameter or positive retroperitoneal or inguinal nodes
Stage IV	Growth invading one or both fallopian tubes with distant metastasis If pleural effusion is present, there must be positive cytology to be stage IV Parenchymal liver metastasis equals stage IV

Note: Staging for fallopian tube cancer is by the surgical pathological system. Operative findings designating stage are determined prior to tumor debulking. FIGO, International Federation of Gynecology and Obstetrics. *Source:* International Federation of Gynecology and Obstetrics (FIGO). *Annual report on the results of treatment in gynecological cancer*, vol 21. Stockholm: FIGO, 1991, with permission,

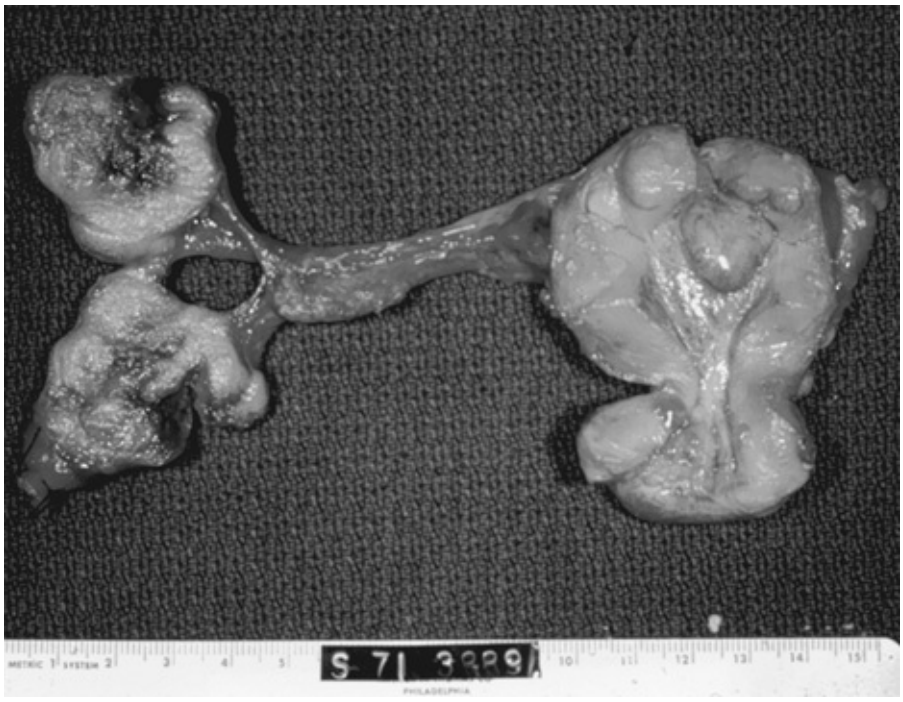

Figure 61.35 Fallopian tube carcinoma. The fallopian tube lumen and its wall have been replaced by tumor.

Metastatic Disease

Metastatic fallopian tube disease is more common than primary tumors of the fallopian

tubes. It commonly originates from a primary tumor of the ovary or endometrium and rarely from a primary of the breast, gastrointestinal tract, or uterine cervix. Lymphatic involvement and an intact tubal epithelium distinguish a metastatic tumor from a primary fallopian tube tumor. The diagnostic criteria outlined previously assist in differentiating between primary versus metastatic fallopian tube tumors.

Primary Peritoneal Carcinoma

Carcinoma may arise from the nonovarian epithelium of the peritoneal cavity, which diffusely involves peritoneal surfaces with minimal or absent involvement of the ovaries. These tumors share many of the clinical and histologic features of ovarian carcinoma. Most of these tumors are of serous histology. Clinical criteria have been established to distinguish peritoneal serous papillary carcinoma (PSPC) from its ovarian papillary serous counterpart, and molecular analyses of PSPC confirm that it is a distinct entity from ovarian carcinoma. Based on these criteria, an estimated 7% to 15% of all cases of papillary serous ovarian cancer could be reclassified as PSPC.

The etiology of PSPC remains unknown. Considering the common embryologic origin of ovarian and peritoneal epithelium, a “field effect” of malignant epithelial transformation could involve multiple sites in the müllerian tract. In rare circumstances, cases of PSPC have been described following prophylactic oophorectomy in patients with strong family histories of ovarian cancer or with documented *BRCA* mutations. PSPC appears to be another phenotypic variant of the *BRCA*-associated cancer syndromes. PSPC is staged and treated like ovarian carcinoma, with comparable response rates and survival.

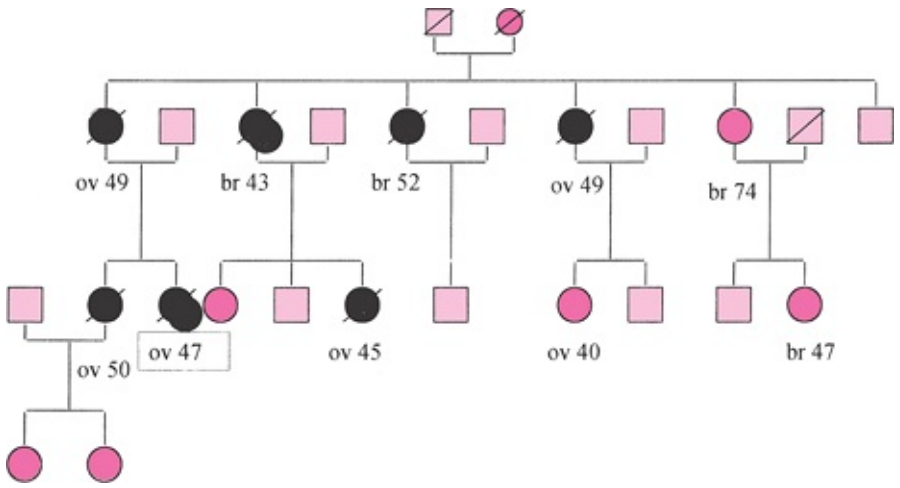

Figure 61.36 Sample family pedigree.

Hereditary Ovarian Cancer

Hereditary Forms

Approximately 7% to 15% of patients with ovarian cancer are thought to have an inherited

genetic predisposition. Although this represents a small percentage of patients with ovarian cancer, great emphasis has been placed on these genetic mutations, given their clinical, social, and ethical implications.

Hereditary ovarian cancer syndromes are linked to dominantly inherited genetic mutations. A detailed family history from both maternal and paternal sides of the family must be obtained to determine the genetic susceptibility for the woman at risk. Average age at diagnosis for this group of patients is often younger than for the general population, and most tumors are of serous histology.

The breast–ovarian cancer syndrome accounts for up to 85% of all hereditary ovarian cancer cases and is most frequently associated with mutations in the *BRCA1* or *BRCA2* genes. The *BRCA1* and *BRCA2* genes were identified and linked to hereditary breast and ovarian cancer in the 1990s. *BRCA1* is located on chromosome 17q12–21, and *BRCA2* is located on chromosome 13q12–13. Although the precise function of the *BRCA* genes is unknown, they appear to be involved in the recognition and repair of DNA damage. A sample pedigree of a breast–ovarian cancer syndrome family is illustrated in Figure 61.36. The presence of a *BRCA*-associated syndrome is suspected whenever a pedigree reveals three or more affected relatives in two generations, bilateral or premenopausal breast cancer, a relative with breast and ovarian cancer, or male breast cancer (Table 61.8).

Many mutations have been described, located throughout the entire *BRCA1* and *BRCA2* genes, with nonsense mutations or frameshift mutations being predominant. Nonsense mutations occur when a single nucleotide substitution results in a stop codon, and frameshift mutation occurs when one or more nucleotides are deleted

to produce a downstream stop codon. Certain ethnic groups have higher carrier frequencies of germline *BRCA* mutations. Three specific alterations, 185del AG and 5382insC on *BRCA1* and 6174delT on *BRCA2*, have been associated with founder mutations in approximately 2.0% to 2.4% of the Ashkenazi Jewish population. Studies have found that 40% to 60% of Jewish patients with ovarian cancer have a mutation in *BRCA1* or *BRCA2* in contrast to 5% of non-Jewish women with ovarian cancer.

TABLE 61.8 Pertinent Family History—Risk Factors for Genetic

CA, cancer; HNPCC, hereditary nonpolyposis colorectal cancer.

The lifetime risk of ovarian cancer for patients with *BRCA1* mutations is 39% to 46%, and the risk for a *BRCA2* mutation carrier is 10% to 22%. Patients with *BRCA1*-associated ovarian cancer appear to be diagnosed at a younger age than patients with sporadic ovarian cancer

or *BRCA2*-associated ovarian cancer. Studies show that *BRCA* mutations are also associated with other malignancies, including cancers of the fallopian tube, pancreas, biliary tract, and prostate and melanoma (Table 61.9).

Data have demonstrated that fallopian tube carcinoma can occur in patients with an inherited genetic predisposition to ovarian cancer by virtue of germline mutations in the *BRCA* genes. A large population-based series of patients with fallopian tube cancer found that 16% of patients had inherited mutations in *BRCA1* or *BRCA2*. Based on these data, fallopian tube carcinoma is a clinical component of the *BRCA*-associated breast–ovarian syndrome. Patients with germline *BRCA* mutations who elect to have prophylactic surgery should have both ovaries and fallopian tube removed, with careful histologic evaluation to eliminate occult fallopian tube carcinoma. It is unknown whether hysterectomy is necessary, in addition to salpingo-oophorectomy, as surgical prophylaxis for these patients in order to remove the cornual portion of the fallopian tube. To date, there has been no reported case of an isolated cornual fallopian tube carcinoma, and immunohistologic evidence suggests that the tubal fimbria are the likely site of origin for fallopian tube carcinoma. Available data suggest that uterine carcinoma is not part of the *BRCA*-associated phenotype of disease.

HNPCC syndrome accounts for approximately 10% of all hereditary ovarian cancer cases. It is an autosomal-dominant genetic syndrome characterized by three or more first-degree relatives with colon cancer (over 70% in the proximal colon) or endometrial cancer, where one is a first-degree relative of the other two, and two of them must be diagnosed with cancer before age 50. Four genes that are part of the DNA mismatch repair (MMR) pathway have been identified as being responsible for the HNPCC

phenotype: *hMSH2* or *MSH6* (chromosome 2p), *hMLH1* (chromosome 3p), *hPMS1* (chromosome 2q), or *hPMS2* (chromosome 7p). Most affected patients are found to have defects in either *hMSH2* or *hMLH1*. An inherited defect in any one of these genes increases an individual's risk of developing cancer because of an impaired ability to repair somatic genetic mutations. HNPCC syndrome family members are at risk for cancer of other gastrointestinal sites, the urologic tract, and the ovary. The risk of endometrial cancer among women with HNPCC syndrome is estimated to be 40% to 60% by age 70 compared with 1.5% in the general population. Limited studies have reported a 3.5-fold increase in the risk of ovarian cancer in members of these families (Table 61.9).

TABLE 61.9 Cancer Risks by Site for Gene Mutation Carriers

Cancer Site	Gene Mutations	Cancer Risk with Mutation (by age 70)	Population Cancer Risk
	BRCA1	87%	11%

Breast	*BRCA2*	87%	
	BRCA1	20%–60%	1.0%–1.5%
Ovary	*BRCA2*	10%–35%	
	MMR	9%–12%	
Fallopian tube	*BRCA1*	Increased	3.6/1,000,000
	BRCA2	Increased	
Endometrium	*MMR*	42%-60%	1.5
Colon	*MMR*	54%-82%	2%

MMR, mismatch repair.

Clinical Implications

Genetic Testing

Although hereditary cancers account for only 10% of epithelial ovarian malignancies, individual risk assessment and appropriate genetic testing can identify those individuals with significant lifetime risk.

The first concern in genetic testing is the scientific and technical utility of the test: the reliability of tests, their predictive value, their interpretation, and ultimately their ability to prevent cancer in patients who test positive. The second major concern relates to the ethical, legal, and social implications of gene testing. The proper selection of patients for testing is very important. Genetic counseling is imperative. As testing for these genes becomes more available to the public in both commercial and academic settings, clinicians and patients must work together to ensure that the results are used in a fashion that will carefully consider the ethical, legal, and psychosocial issues that may arise from genetic testing. Multidisciplinary services that include pre- and posttest counseling, screening, treatment, and psychosocial sessions should be established in the major referral centers. Patients must be counseled regarding the potential advantages and disadvantages of genetic testing as well as the utility of screening and prophylactic measures that are available.

American Society of Clinical Oncology (ASCO) guidelines currently recommend offering testing to anyone with personal or family history features suggestive of a genetic cancer susceptibility condition if the test result can be interpreted and will influence medical management. First- and second-degree relatives of an affected individual from a breast–ovarian cancer syndrome family carrying a mutation of the *BRCA1* or *BRCA2* gene should be offered genetic testing. Certain ethnic groups are at increased risk for carrying a *BRCA* mutation, such as Ashkenazi Jews, and a lower threshold for screening may be appropriate in these individuals. Genetic testing for the MMR genes should be considered when there is a first-degree relative with a known mutation and when the patient meets the Amsterdam or the Bethesda criteria for HNPCC syndrome (Table 61.8).

A comprehensive family history can provide an estimate of an individual's risk of carrying a genetic mutation; however, genetic testing provides more accurate information regarding the chance that a patient will develop cancer. The best way to determine if a cancer-associated mutation is present in a family is to test an affected family member, as the family member is most likely to carry a deleterious mutation. The first family member will often need comprehensive gene sequencing, and subsequent individuals can then be tested for the identified mutation, which may be unique to this particular family. In the Ashkenazi Jewish population, genetic testing for the three founder mutations is required because of the high carrier frequency in this population and occasional reports of individuals with both *BRCA1* and *BRCA2* mutations.

When assessing familial risk, remember that small families may not manifest low-penetrance genes and that families with few female relatives may underrepresent female cancers despite the presence of a predisposing family mutation. Similarly, hysterectomy and/or oophorectomy at a young age in multiple family members can mask a hereditary gynecologic cancer predisposition. When evaluating a family history, it is also important to remember that males can transmit gynecologic cancer–predisposing genes and that adoption can limit interpretation of a pedigree.

Test results may come back positive or negative for an identifiable mutation or may report a mutation of indeterminate clinical significance. When a test returns negative, interpretation will depend on the patient's family history. If an affected family member has tested positive for a mutation, then the patient has likely not inherited the deleterious mutation and her cancer risk approximates that of the general population. If there is no documented positive mutation in the family, it is still possible that the patient has a cancer-associated mutation that is not detectable with current testing. Approximately 12% of current testing results are genetic variants or polymorphisms, reported as indeterminate clinical significance. Further study of these genetic variants and associated cancer risks in large populations will help to reduce the number of indeterminate reports.

Follow-Up and Management

Screening

Follow-up and management of patients with an inherited genetic predisposition to ovarian cancer is complex due to the variable penetrance of genetic alterations and the lack of

effective early detection methods. Serum CA-125 levels and transvaginal ultrasound with color Doppler flow are the two modalities that have shown potential usefulness in surveying these patients. CA-125 levels may be elevated in other benign diseases and may not be elevated in early-stage ovarian cancer; thus, it lacks sufficient sensitivity. Transvaginal ultrasound is very sensitive in detecting adnexal masses; however, it cannot differentiate between

malignant and benign masses, resulting in a high false-positive rate and unnecessary surgery, especially in premenopausal women. Consequently, screening of the general population is not warranted with the currently available technology.

There is no conclusive evidence to support screening patients with higher risk of ovarian cancer. Ovarian surveillance modalities have not significantly improved the detection of early-stage invasive epithelial ovarian cancers, with minimal impact on the survival among the screened patients. One recent prospective study of high-risk women demonstrated enhanced survival among the screened population versus historic controls; however, conclusions are limited by small patient numbers. Despite the available data, the National Institutes of Health (NIH) *Consensus Statement on Ovarian Cancer* and the Cancer Genetic Studies Consortium (CGSC) recommend screening starting at ages 25 to 35 years as part of the annual or semiannual routine examination for women with germline *BRCA1* or *BRCA2* mutations. Yet, the benefit is not absolutely proven, as the evidence is based on expert opinion only. Table 61.10 lists the provisional recommendations for cancer surveillance and treatment for the carriers of *BRCA1* and *BRCA2* mutations. Screening and prophylactic surgery for patients with HNPCC-associated mutations is also based on expert opinion, although colonoscopy and stool occult blood testing have been shown in randomized clinical trials to reduce the incidence of and mortality from colon cancer.

Chemoprophylaxis

Recent evidence has shown that chemoprophylaxis with oral contraceptive pills for 5 years decreases ovarian cancer risk by 50% in the both general population and in high-risk women. A case-controlled study of 207 known *BRCA* mutation carriers and their sister controls found a 60% reduction of ovarian cancer risk with oral contraceptive use. Other risk-reducing strategies such as tubal ligation and hysterectomy have also demonstrated reduced incidence of ovarian cancer among many high-risk women.

TABLE 61.10 Recommendations for Treatment of Women at Hi for Gynecologic Malignancies

Method	Breast Cancer	Ovarian Cancer	HNPCC Syndrome Endometrial Cancer

Screening	Monthly self-examination Semi-annual or annual clinical examination Annual mammography (beginning age 25–35)	Semi-annual or annual rectovaginal pelvic examination Annual or semi-annual CA-125 and TVS screening (beginning age 25–35)	Annual pelvic examination TVS q1–2yr or endometrial biopsy (beginning age 30–35)
Chemoprevention Prophylactic surgery	Consider tamoxifen Counsel regarding mastectomy ± PBSO	Consider OCP Offer PBSO	Consider OCP Counsel regarding prophylactic hysterectomy or BSO or both

HNPCC, hereditary nonpolyposis colorectal cancer; TVS, transvagi
OCP, oral contraceptive pill, PBSO, prophylactic bilateral salpingo
BSO, bilateral salpingo-oophorectomy.

Prophylactic Salpingo-Oophorectomy

For women with *BRCA1* mutations, the risk of ovarian cancer markedly increases during the 40s, with 10% to 21% of *BRCA1* mutation carriers developing ovarian cancer by age 50. The risk of premenopausal ovarian cancer is much lower in *BRCA2* mutation carriers, with no more than 3% of *BRCA2* mutation carriers developing ovarian cancer by age 50. Counseling patients regarding the optimal timing of prophylactic surgery may vary depending on their specific *BRCA* mutation.

Patients need to individualize the decision for salpingo-oophorectomy based on their life factors, desire for fertility, or natural hormones, as the risk of ovarian cancer increases with age.

Prophylactic bilateral salpingo-oophorectomy (PBSO) is most commonly performed laparoscopically. While there may be a small increased risk of endometrial cancer and a theoretical increased risk of cancer in the cornual fallopian tube for the *BRCA* mutation carrier, salpingo-oophorectomy alone confers a significant cancer risk reduction with less surgical risk and postoperative recovery. There is limited information on hormonal

replacement in *BRCA1* and *BRCA2* mutation carriers, but unaffected women may have their future hormone therapy regimens simplified if hysterectomy is performed at the time of PBSO. Hysterectomy may be considered when there are other medical

indications for removal of the uterus and cervix. For women taking tamoxifen, hysterectomy may be considered to reduce their endometrial cancer risk.

The surgical pathologist must be alerted to perform a careful examination of the patient's ovaries and fallopian tubes, given the frequent reports of occult ovarian and tubal carcinoma from series of PBSO specimens among high-risk patients (2% to 15%). Rather than taking only one or two representative sections from each ovary, the complete ovaries and tubes should be serially sectioned and evaluated, as this procedure been demonstrated to improve detection of occult disease.

The efficacy of PBSO in hereditary breast–ovarian cancer syndrome has been evaluated in several studies. Recent prospective studies have documented a significant reduction with PBSO in both ovarian/peritoneal and breast carcinoma among *BRCA* mutation carriers. One study of 248 BPSO patients found a decrease of ovarian and primary peritoneal cancers by 98% and a 50% reduction in subsequent breast cancer compared with that found in age-matched controls. This supports the findings of another prospective study that documented a 50% reduction of breast cancer with PBSO among pre- and postmenopausal *BRCA* mutation carriers that persisted irrespective of the use of hormone replacement therapy. Despite oophorectomies, primary peritoneal cancer has been reported in 0.4% to 10.7% of high-risk patients, with a rate of 4.0% with 20-year follow-up, and patients must be counseled regarding this disease. It is believed that that all coelomic epithelium, including the peritoneal covering of the entire abdominopelvic cavity, is prone to malignant transformation in *BRCA* mutation carriers.

For women with HNPCC, prophylactic surgery has been shown to prevent endometrial carcinoma. However, because most HNPCC-associated endometrial cancers are diagnosed at an early stage and cured with surgery, it is feasible that risk-reducing surgery will not have any impact on patient mortality.

Recommendations from other agencies or groups are as follows:

- ACOG (2001). Women with familial ovarian or hereditary breast–ovarian cancer syndromes who do not wish to maintain their reproductive capacity may be offered PBSO. Such women should have a documented familial syndrome, preferably established via a full pedigree analysis by a geneticist. These women should be informed that removal of the tubes and ovaries does not provide 100% protection; primary peritoneal carcinoma has been reported after bilateral salpingo-oophorectomy in some cases.
- NIH *Consensus Statement on Ovarian Cancer* (1997). The probability of a hereditary ovarian cancer syndrome in a family pedigree increases with the number of affected relatives, with the number of affected generations, and with young age of onset of disease. Therefore, prophylactic oophorectomy should be considered in these settings, with careful weighing of the risks and potential benefits. The risk of ovarian cancer in women from families with hereditary ovarian cancer syndrome is sufficiently high to

recommend prophylactic oophorectomy at age 35 years or after completion of childbearing.

- CGSC. There is fair-quality evidence to recommend for prophylactic oophorectomy as a measure for reducing ovarian cancer risk, although the number of cases is small. This procedure reduces the risk of ovarian and fallopian tube and peritoneal carcinoma by approximately 85% to 90% in women with known mutations in *BRCA1* or *BRCA2*. Those considering prophylactic oophorectomy should be counseled that cancer has been documented to occur after the procedure.
- ASCO (2006). Surgical prophylaxis with PBSO represents the best known approach for decreasing ovarian and fallopian tube cancer mortality in *BRCA* carriers. Although prevention by using oral contraceptives or other modalities and/or early detection may prove useful in the future, PBSO remains the standard of care and should be discussed with all women who carry *BRCA1* or *BRCA2* mutations.

Prevention

Clearly established protective factors, as mentioned previously, include more than one full-term pregnancy, oral contraceptive use, breast-feeding, tubal ligation, and hysterectomy. However, the role of these protective factors in the management of women with known genetic risks for ovarian cancer has not been thoroughly examined. Therefore, further epidemiologic studies are required to determine their efficacy as preventive means in the care of these high-risk patients before they can be accepted as effective strategies in this subgroup of patients.

Summary Points

- Germ cell tumors are the most common gynecologic malignancy in young women. The overall cure rate is 90%. Following oophorectomy and surgical staging, the most commonly used adjuvant chemotherapy regimen is BEP.
- Sex cord–stromal tumors, such as granulosa cell and Sertoli-Leydig cell tumors, have the potential for steroid hormone production, with estrogen being the most frequently produced hormone. Primary treatment usually entails tumor resection and staging. The need for chemotherapy must be individualized, because no standard treatment has been established.
- Tumors of LMP account for approximately 15% of epithelial ovarian cancers and present at an earlier age, around 40 years. All epithelial histologic subtypes of LMP tumors exist, with serous being the most common. Therapy for LMP tumors is surgical excision, with tumor staging and debulking, if necessary. Adjuvant chemotherapy does not improve the clinical outcome for patients with LMP tumors.
- For epithelial ovarian cancer, the 5-year survival rate remains at

50% to 60%. There is no effective screening test for early detection at this time. For advanced-stage disease, optimal cytoreductive surgery followed by taxane-platinum combination therapy is the current standard of care. In selected cases, treatment is most effective when delivered intraperitoneally.

- Women with *BRCA1* or *BRCA2* mutations should be offered risk-reducing salpingo-oophorectomy around 35 to 40 years of age or when childbearing is complete. At surgery, all ovarian and tubal tissue should be removed. Complete, serial sectioning of the ovaries and fallopian tubes is necessary, with microscopic examination for occult cancers.

Management of the Adnexal Mass

Susan A. Davidson

The finding of an adnexal mass is a common gynecologic problem. As long as women have been offered medical care, the adnexal mass has presented a diagnostic as well as therapeutic challenge. Up to 300,000 women are hospitalized each year for evaluation of an adnexal mass, and the majority of these patients undergo surgery. Put another way, 5% to 10% of all women in the United States will undergo surgical evaluation for an adnexal mass, and of these, up to one fifth will have ovarian cancer. It is the identification of this subset of women that has driven much of the work advancing understanding of the development, complications of, and malignant potential of the adnexal mass as well as advancement of diagnostic tests of and surgical approaches to the adnexal mass.

In this chapter, general background information, modes of diagnosis, ancillary studies, and surgical management of the adnexal mass will be discussed, with the goal of identifying patients who should be surgically managed and those who can be expectantly followed. If surgery appears indicated, the appropriate surgical approach and surgical team will be discussed. Hopefully, with the tools that are currently available, a triage scheme can be developed for every woman with a mass in order to minimize risk in the event of a malignancy and minimize morbidity if the patient should ever need surgical intervention.

Overview

The management of an adnexal mass starts with knowledge of the differential diagnosis (Table 62.1). Adnexal mass refers not only to ovarian abnormalities but to masses originating in the fallopian tube, uterus, broad ligament, bowel, urinary system, and retroperitoneum. Taking a thorough history is, therefore, critical to management decisions. Clues may be obtained from all aspects of the patient history but should certainly include all characteristics of any abdominopelvic, gastrointestinal, and genitourinary symptoms as well as a thorough gynecologic history. If age appropriate, the results and dates of any breast and colorectal cancer screening procedures should be obtained.

During the physical examination, a full female-oriented examination should be performed, including evaluation of the lymphatics in the neck, axilla, and groin, along with breast, abdominal, and rectovaginal pelvic examination. The presence of ascites and/or an abdominal mass is highly suggestive of ovarian cancer; however, in the absence of these

findings, a fixed pelvic mass or nodularity in the cul-de-sac can be suggestive of adnexal malignancies or endometriosis. The pelvic examination is the most subjective part of the evaluation of an adnexal mass. It is particularly uninformative in women who are obese or who have an enlarged uterus. Therefore, if the patient's symptoms are concerning and no abnormalities are appreciated, further evaluation with radiologic imaging should be carried out.

Distribution of Adnexal Masses Based on Age

The thought process for triage initially starts with patient age, menopausal status, and symptoms, reflecting sequelae of sexual activity and ovarian function as well as the risk of malignancy. In the premenopausal woman, the risk of a neoplasm being malignant is 7% to 13%, while it is 30% to 45% in the postmenopausal woman.

For the young woman in her teens and up to mid 20s, the majority of ovarian cysts are benign. Hemorrhagic corpora

lutea and follicular cysts are common. In this age range, however, tubal abnormalities should be strongly considered. They include ectopic pregnancies and sequelae from tubal infections. Endometriomas and myomas (Fig. 62.1) will also start to appear, and most of the neoplasms are benign dermoid cysts. The solid mass is of concern in this age group. The germ cell tumors, which for the most part are solid and unilateral, occur rarely but almost exclusively in this population.

TABLE 62.1 Masses Occurring in the Adnexal Region

- Ovarian
  - Ovarian neoplasms
  - Ovarian cyst
  - Tuboovarian abscesses
- Tubal
  - Ectopic pregnancy
  - Hydrosalpinx
  - Tubal neoplasms
  - Paratubal cyst
  - Tuberculosis salpingitis
- Uterine myoma
- Gastrointestinal
  - Appendiceal abscess
  - Appendiceal tumor
  - Diverticular abscess
  - Colonic tumor
- Genitourinary

Pelvic kidney
Retroperitoneal
Hematoma
Lymphocyst
Lymphoma
Sarcoma

In the older yet still reproductive age group, benign masses still prevail. Again, the functional ovarian cysts are still common, and endometriomas and myomas remain high in the differential. Most neoplasms are still benign, with dermoid cysts and serous cystadenomas topping the list. Lastly, there is most concern for the postmenopausal group. While most masses are still benign, there is a big jump in the risk of malignant neoplasms with epithelial ovarian cancers prevailing.

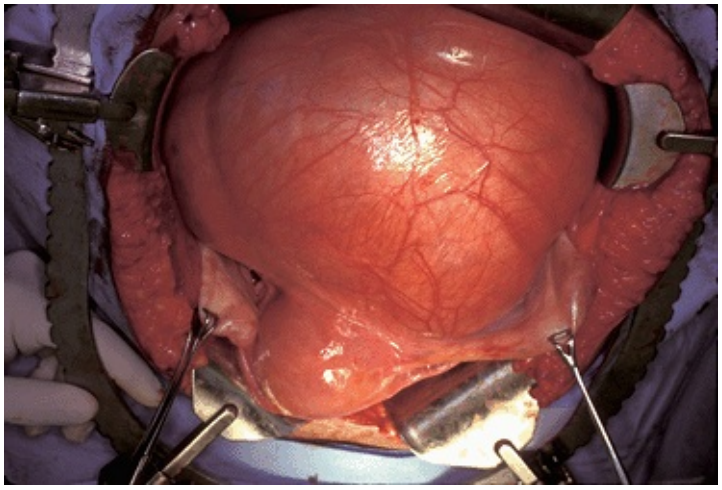

Figure 62.1 Large subserosal uterine leiomyoma. (See Color Plate)

Review of Adnexal Pathology

Non-neoplastic Cysts

Physiologic cysts can appear as adnexal masses. These include follicular cysts and corpus luteal cysts. Follicular cysts are the most common. They are usually multiple, thin-walled, and <6 to 8 cm in size. Most resolve spontaneously. Corpus luteum cysts range from 3 to 10 cm in size. Hemorrhage into the cyst and subsequent retraction of the clot can sometimes give a complex appearance. If they persist and require surgical intervention, a laparoscopic approach should be considered.

Endometriotic cysts involve both ovaries in up to 50% of cases. These cysts often are associated with dense adhesions to the broad ligament or cul-de-sac and are difficult to excise. The contents are usually chocolate colored and thick. The spectrum of

abnormalities associated with these cysts (complex appearance on sonography, bilaterality, fixation and nodularity on exam, elevated CA-125) frequently make these concerning for malignancy, although a detailed gynecologic history often offers helpful clues. Cystectomy can be performed successfully in many cases. The presence of endometriomas indicates advanced endometriosis, and usually other pelvic sites are involved. Bilateral salpingo-oophorectomy is curative, if clinically appropriate, in that estrogen drives the growth of these cysts. Ovarian endometrioid and clear cell carcinomas can be associated with benign endometriotic cysts.

Ovarian Neoplasms

The ovary is a complex structure, and as a result, a variety of neoplasms can develop. They can be divided into four main categories: epithelial, germ cell, stromal, and tumors metastatic to the ovary. The first three have numerous subtypes, and all have benign and malignant components. It is therefore beyond the scope of this chapter to review them in detail. What follows is a review of the more common clinical scenarios.

Common Epithelial Masses

The majority of ovarian masses are benign, and of these, the most common histologic type is epithelial, whether benign or malignant. The epithelial tumors are, for the most part,

of the following types: serous, mucinous, endometrioid, clear cell, and transitional cell.

Serous Tumors, Benign and Malignant

Serous tumors are the most common histologic type, and the benign counterpart accounts for 50% to 70% of all benign ovarian neoplasms. Although a patient of any age can manifest a benign serous tumor, the average age is 40 years. On ultrasonographic evaluation, these cysts range from simple cysts to cysts with some complexity characterized by the presence of internal echos and septations. They can be large and are bilateral in 20% of cases.

The invasive serous ovarian carcinoma is the prototype for invasive ovarian cancers and accounts for approximately 50% of all ovarian cancers. It usually occurs in the menopause and frequently is bilateral. As with most epithelial ovarian cancers, the tumors are typically widely disseminated at the time of diagnosis.

Mucinous Tumors, Benign and Malignant

Benign mucinous tumors, or mucinous cystadenomas, account for 25% of all benign ovarian neoplasms. They occur at a slightly younger age than serous benign tumors and can occur in young women as well. They are rarely bilateral, with both ovaries involved in only 3% of cases. Mucinous tumors tend to be very large and can be multiloculated. These are the tumors that have been reported to weigh up to 100 kg. Histologically, the cells are mucin filled and show endocervical or intestinal differentiation. These are the second most common type of ovarian neoplasm. Their invasive counterpart, the mucinous cystadenocarcinoma (Fig. 62.2), represents 15% of invasive ovarian epithelial cancers.

Endometrioid Tumors, Benign and Malignant

The third epithelial type is the endometrioid neoplasm. These tumors recapitulate the endometrium, and thus the epithelial component resembles the endometrial glandular cell. Benign tumors of this histologic type are less common and are associated histologically with changes of adenofibroma or cystadenofibroma. The endometrioid malignant ovarian neopolasm represents up to 25% of ovarian epithelial cancers and usually is moderate in size, ranging up to 20 cm. Most ovarian endometrioid neoplasms are malignant. The malignant form tends to be bilateral in 30% of cases. When an endometrioid ovarian invasive cancer is found, up to 25% of patients will have concomitant uterine endometrial cancer or hyperplasia. Pelvic endometriosis may also be found, and one hypothesis is that these lesions arise from preexisting endometriosis. When an endometrioid invasive cancer is found in the ovary, the pathologist should indicate if it is primary to the ovary or a metastasis from a primary uterine cancer.

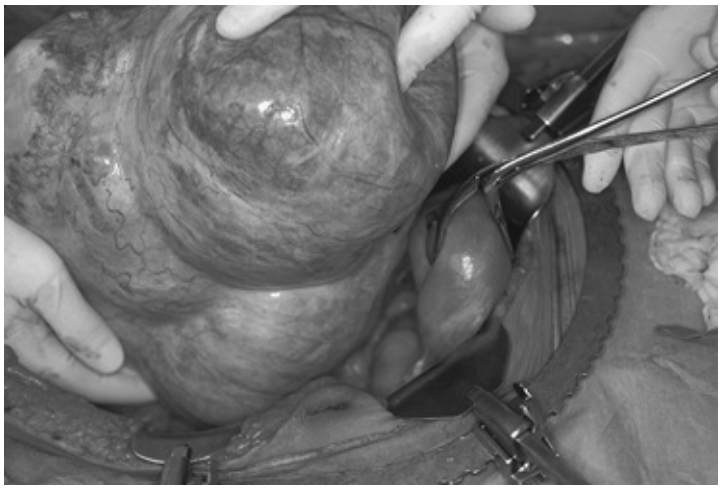

Figure 62.2 Ovarian mucinous cystadenocarcinoma.

Clear Cell Tumors

The fourth general category of epithelial ovarian neoplasms is the clear cell tumor. Benign clear cell tumors are rarely diagnosed. However, the invasive clear cell carcinoma represents 10% of all ovarian cancers. The clear cell component usually coexists with another epithelial type. The clear cell histology also is associated with endometriosis elsewhere in the pelvis in up to 25% of cases.

Transitional Cell Tumors

Lastly, transitional cell tumors, which mimic the epithelium found in the bladder, are rare. The Brenner tumor is a well-known transitional cell tumor and accounts for 2% of all ovarian epithelial tumors. Brenner tumors are usually benign, although a malignant variant does exist.

Germ Cell Tumors, Benign and Malignant

The dermoid cyst is a common benign tumor found in all ages. This tumor, also known as a teratoma, is comprised of three germ cell layers: the ectoderm, mesoderm, and endoderm. It accounts for 25% of all ovarian neoplasms, is bilateral in up to 15% of cases, and is most commonly found in the reproductive age group. The mature teratoma can grow to quite a large size before a patient has pain or notices abdominal swelling. These tumors are well known for their smooth, glistening, pearly white surface. Either cystectomy, preferable in the reproductive-age woman, or adnexectomy can be performed to treat this neoplasm effectively. These tumors are interesting because of a radiologic finding of teeth or bone on plain film. Additionally, they have a characteristic findings on ultrasonography and magnetic resonance imaging (MRI) scan. Within the cyst wall is a prominence called *Rokitansky protuberance*. These neoplasms are well known for the greasy sebaceous material associated with hair, bone, or teeth found within the cyst. Thyroid tissue, salivary gland tissue, and gastrointestinal and bronchial epithelium can be found. Other ectodermal tissues, including brain, neural, retina, and choroids plexus, are also found. Clinical complications associated with the

---

presence of these neopolasms include torsion, rupture, and infection. More uncommonly, hemolytic anemia and malignant transformation (especially of the squamous components) may also occur.

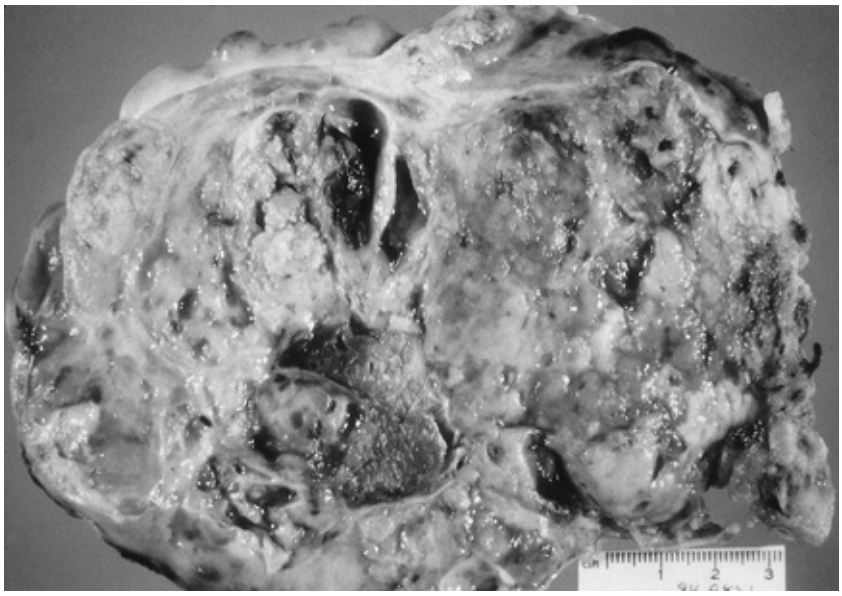

Figure 62.3 Dysgerminoma in a 17-year-old girl.

Malignant germ cell tumors account for approximately 6% of all ovarian malignancies. The most common is a dysgerminoma (Fig. 62.3). This is also the most common ovarian malignancy for young and pregnant women. This germ cell tumor is unusual in that it has a high incidence of bilaterality. If a solid tumor is found and a germ cell tumor is suspected, appropriate tumor markers as noted below may be obtained. However, none of these

markers is necessarily predictive of finding a germ cell tumor. Less common germ cell tumors are the endodermal sinus tumor, classically associated with elevated α-fetoprotein (AFP), and, carrying a worse prognosis, the malignant or immature teratoma and mixed germ cell tumors, among others.

Stromal Tumors, Benign and Malignant

The sex cord–stromal tumors (SCST) account for approximately 10% of all ovarian tumors and 5% of malignant ovarian tumors. As a category, these tumors can occur at any age, from prepubertal to postmenopausal. Most of the hormonally active tumors fall in this category. Because of this, with the exception of the inert fibroma, they are frequently associated with endometrial pathology or other evidence of estrogen or androgen excess. The prototype benign tumors are in the thecoma–fibroma group (Fig. 62.4). Ascites and pleural effusion, or Meigs syndrome, can be found with very large fibromas due to transudation of fluid from the surface of these edematous ovaries. The most common malignant tumor is the granulosa cell tumor. This tumor classically is large and hemorrhagic and as a result can cause pain. Long-term outcome is good for those with stage I disease, but unfortunately, survival is poor with advanced disease or recurrence. Another notable malignancy is the rare Sertoli-Leydig cell tumor, classically associated with androgen excess. Similar to the granulosa cell tumor, long-term outcome is linked to stage and tumor grade.

Metastatic Tumors

Approximately 3% to 5% of ovarian malignancies are metastatic from another organ. The majority are from the reproductive organs, including direct extension from tubal and endometrial cancers and rarely from cervical cancers. The most common nongynecologic sites of origin are from breast or gastrointestinal cancers. They commonly present as bilateral pelvic masses and may be associated with other stigmata of metastatic disease.

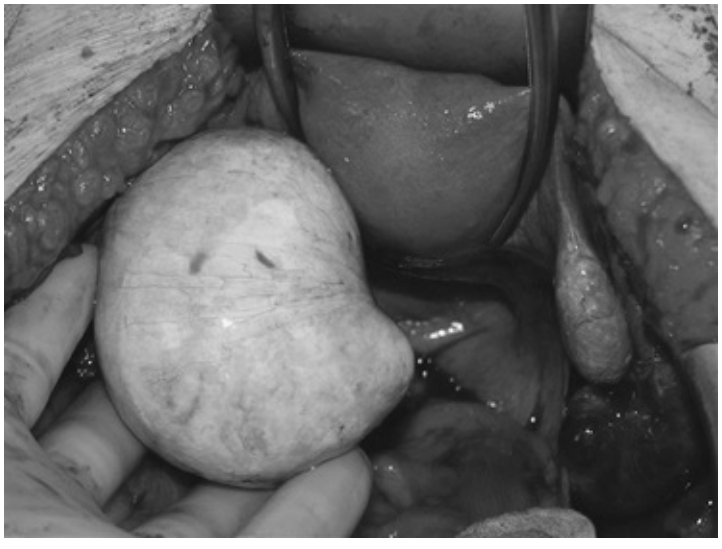

Figure 62.4 Left ovarian fibrothecoma.

Radiologic Evaluation of the Adnexal Mass

Whether suspicion of an adnexal mass arises as a result of a patient's symptoms or suspicious findings during a pelvic examination, radiologic imaging is usually the next step in the diagnostic evaluation. For gynecologic problems, transvaginal ultrasonography gives the best visualization of the adnexal region by virtue of the proximity of the adnexa to the probe. Size, location (unilateral vs. bilateral), internal characteristics, and the presence or absence of free fluid in the cul-de-sac should be noted. Particularly concerning are masses with one or more of the following characteristics: predominantly solid, >10 cm in size, thick and numerous septae, or internal papillations or nodular structures. Masses with any of these characteristics should not be observed further, and surgical evaluation would be in order (Fig. 62.5). The presence of a small volume of free fluid can be physiologic, but large volumes are ominous and suggest either a malignancy or serious medical condition. Other important features found on ultrasonography actually can be reassuring, such as calcium found next to fat, as noted in dermoid tumors. Morphology indexing has been developed to assess the malignant potential of pelvic masses by taking into consideration tumor volume and structural characteristics of the mass. On these scales, a low score is highly predictive of a benign process, while an elevated score is suggestive of a malignancy.

An ultrasonographic evaluation can help to clarify the etiology of the mass. Although not definitive, suggestions that the mass may arise from the tube, as in the case of a hydrosalpinx or tuboovarian abscess, can be helpful. Particularly troublesome are endometriomas and hemorrhagic ovarian cysts, as these can have characteristics that mimic ovarian malignancies. These are operator dependent, and as such, it is helpful to have a skilled ultrasonographer in these settings.

Simple cysts, regardless of size and patient age, are almost always benign. Data from screening studies and autopsy series suggests that the incidence of ovarian cysts in postmenopausal women is between 3% and 18%. If unilocular and <10 cm in size, the risk of malignancy is 0.1%. If these cysts are followed, 50% to 70% will resolve while one third will persist or become complex. In addition to the abnormal findings noted previously for which surgery is recommended, growth of a mass, development of complex characteristics in any age group, or development of concerning symptoms is most likely an indication for surgical evaluation. Otherwise, the stable, asymptomatic simple cyst can be followed. In addition to ultrasonographic morphology findings, Doppler sonography may add some information. Doppler ultrasonography allows an evaluation of ovarian blood flow. With emission of a sound wave from a stationary source, reflection of the sound wave from a moving target is relative to its velocity. Thus, several indices have been developed for standardization of the study of ovarian blood flow. These include the systolic-to-diastolic ratio, resistance index, and pulsatility index. Doppler analysis of flow is performed at multiple points and then color coded according to the direction of blood flow and superimposed on the anatomic location. The strategy of using Doppler ultrasonography in ovarian masses would be to detect abnormal blood flow associated with neoangiogenesis often associated with ovarian malignancy. These new, aberrant vessels lack smooth muscle, leading to low

resistance and arteriovenous shunting. Unfortunately, some benign lesions seen in premenopausal women may have similar waveforms, so it is less useful in this population. However, in the postmenopausal woman with a mass, low resistance is highly suggestive of a malignancy.

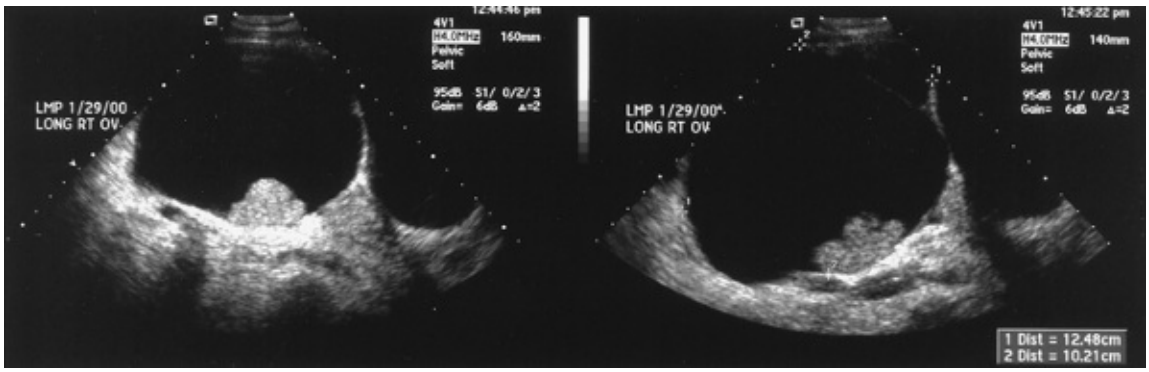

Figure 62.5 Ultrasonographic image of an ovary with internal wall papillations. The final pathology of this ovarian cyst was clear cell adenocarcinoma.

Newer ultrasound modalities have been introduced to try and improve on the discrimination between benign and malignant masses: contrast-enhanced sonography and three-dimensional sonography. In the former, intravenous contrast is given to enhance the vascular Doppler signal; one study has shown that this may help to distinguish benign from malignant tumors. In the latter, several studies have as yet failed to demonstrate on improvement in

prediction of malignancy using three-dimensional Doppler ultrasound over conventional two-dimensional Doppler.

In the event that ultrasonographic findings are uncertain or more information is needed before surgical evaluation is undertaken, computed tomography (CT) can be helpful. The conventional CT scan obtains images with a slice thickness of 7 to 8 mm. Usually, radiopaque oral agents are used to opacify the gastrointestinal tract, and intravenous contrast is used to visualize vascular and genitourinary structures. Ovarian nodularity and septations can be characterized by CT scan. Additionally, if there is a concern that ultrasonographic findings may be reflecting a loop of bowel, CT can clarify this by using oral and sometimes added rectal contrast. CT scans can clearly delineate an appropriated anatomic cause of hydronephrosis and identify any enlarged retroperitoneal lymph nodes. Lastly, if abdominal and pelvic CT scans are ordered, information regarding the upper abdomen, omentum, and liver can be obtained.

MRI uses magnetic fields and radio waves. As compared with CT scan, which uses x-ray attenuation (Fig. 62.6), multiple tissue characteristics are analyzed by MRI. One of the advantages is that no ionizing radiation is used for MRI. Patients with electrical pumps or implants such as pacemakers cannot undergo MRI evaluation. Gadolinium is used as

intravenous contrast to better visualize organs and associated abnormalities. Dermoid cysts can be accurately identified by MRI, since fat, a common component of the neoplasm, has a characteristic signal. Some recent studies suggest that MRI may be preferable to CT scanning as a complement to ultrasonography in cases where the ultrasound findings are indeterminant.

Positron emission tomography (PET) imaging is becoming increasingly important in the management of gynecologic malignancies, especially when fused with CT imaging. This radiologic test is based on the uptake of 18F-fluoro-2-deoxyglucose (FDG), as malignant cells tend to have a higher uptake of FDG compared with normal tissue due to higher glycolytic turnover. With combined PET/CT, the patient undergoes both studies in one session, and the functional (PET) and anatomical (CT) images are fused. For the CT portion, both standard oral and intravenous contrast media are used. The combined procedure localizes any FDG uptake to specific anatomical locations. PET imaging alone is felt to have limited utility in the evaluation of adnexal masses due to physiologic uptake of FDG in normal ovaries and in a variety of benign lesions, both cystic and neoplastic. However, a recently published prospective study of fused PET/CT demonstrated a high degree of accuracy in distinguishing benign from malignant adnexal masses. As with all new modalities, PET imaging, even when fused with CT, remains investigational.

Figure 62.6 CT image of dermoid cysts. Internal calcification and fat.

Tumor Markers

The purpose for using tumor markers is twofold: (a) to try to predict the benign or malignant nature of the mass and (b) to follow disease once established. Traditionally, the most important tumor marker for epithelial ovarian cancers is CA-125. This antigen is an epithelial glycoprotein measured by antibody assay using the monoclonal antibody OC-125. CA-125 is relevant in particular to epithelial ovarian cancers, for which a cutoff of 35 U/mL has been determined to divide normal from abnormal levels. This threshold has been accepted as standard by most laboratories in the United States. CA-125 is elevated in 90%

of patients with advanced-stage ovarian cancer but in only 50% of patients with stage I disease, and as such, CA125 is not an effective screening test for ovarian cancer in asymptomatic women. Additionally, many other adnexal masses and gynecologic and nongynecologic disease processes may elevate levels of CA-125 (Table 62.2, 62.3). As a result, numerous studies have shown CA-125 to be unreliable as a definite predictor of the malignant nature of a mass, especially in the premenopausal patient, in whom many of these

conditions occur. In the setting of an adnexal mass and CA-125 >65 U/mL, the likelihood of malignancy was 49% in premenopausal women and 98% in postmenopausal women. Thus, it can be highly predictive of ovarian cancer in the postmenopausal patient with a mass.

TABLE 62.2 Benign Conditions Associated with Elevated CA-125

Gynecologic
- Endometriosis
- Leiomyomata
- Adenomyosis
- Pelvic inflammatory disease
- Luteal phase menstruation
- Ovarian hyperstimulation
- Pregnancy (normal or ectopic)
- Ovarian cystadenoma

Nongynecologic
- Congestive heart failure
- Chronic renal disease
- Chronic liver disease
- Colitis, appendicitis, diverticulitis
- Pneumonia
- Systemic lupus erythematosus
- Peritonitis of any etiology
- Poorly controlled diabetes
- Pancreatitis

In the event of an epithelial ovarian cancer, preoperative CA-125 levels are not able to predict optimal surgical cytoreduction. For following disease status, however, CA-125 levels are invaluable in the management of women with ovarian cancer. Changes in CA-125 accurately reflect progression or regression of disease in over 95% of patients. Thus, CA-125 should be obtained preoperatively to establish a baseline for these patients.

CA-125 levels can be elevated postoperatively because of surgical manipulations of the abdominal organs. If a preoperative CA-125 level was not drawn and a diagnosis of cancer is made intraoperatively, either an intraoperative or postoperative CA-125 level should be measured, taking into consideration that elevated levels may be seen due to surgery. The elevation may not be so important, however, because it will be the rate of decline and actual resolution of elevated levels that will be most predicative of disease prognosis. Of note, the half-life of CA-125 is 20 days.

TABLE 62.3 Other Malignancies Associated with Elevated CA-125

Colon cancer
Lung cancer
Breast cancer
Pancreatic cancer
Endometrial cancer
Fallopian tube cancer
Primary peritoneal cancer
Vaginal cancer

Numerous other markers have been studied to attempt to predict ovarian malignancy preoperatively and to follow cancer if it is diagnosed. Other tumor antigens include CEA, CA 15-3, CA 72-4 (TAG-72), CA-130, and CA 19-9. However, only CA-125 is in common use, and clinical protocols include this tumor marker for following disease response. The other tumor markers have not been as successful, in that their accuracy is less than that of CA-125 and many assays may not be readily available. New tumor markers are currently being studied and are promising for early detection of ovarian cancer in the future.

Other tumor markers should be utilized in the setting of known or suspected nonepithelial tumors. In the young woman suspected of having a germ cell tumor, AFP, ß human chorionic gonadotropin (bHCG), and lactate dehydrogenase (LDH) should be obtained, as these are frequently elevated in endodermal sinus tumor, choriocarcinoma, and dysgerminoma, respectively. For the rare stromal malignancies, inhibin or müllerian-inhibiting substance (MIS) can sometimes be elevated in granulosa cell tumors and testosterone in Sertoli-Leydig cell tumors. With an unexpected gastrointestinal metastatic-to-the-ovary (Krukenberg) malignancy, carcinoembryonic antigen (CEA) may be elevated, and similar markers for breast and pancreatic cancers may reflect metastatic disease from those sites. If elevated, these markers can be invaluable in monitoring response to treatment and assessing for recurrence.

Surgical Evaluation

Once a decision has been made that surgical evaluation is required, a second decision must be made about choice of surgeon. Numerous studies have shown that survival is improved for women with all stages of ovarian cancer if surgical management is carried out by a gynecologic oncologist. As a result, the American College of Obstetricians and Gynecologists (ACOG) and the Society of Gynecologic Oncology (SGO) have issued joint guidelines for specialty referral for women with adnexal masses (Table 62.4). These guidelines have been evaluated and have been shown to identify 70% of the cancers in premenopausal women and 94% of the cancers in postmenopausal women. While these guidelines may lead to over-referral, that outcome appears to be preferable given the differences in ovarian cancer survival attributed to surgeon specialty.

Once the patient is scheduled for surgery, the surgeon must decide which approach to attempt: laparotomy or laparoscopy. Gynecologists have been trained to make essentially two kinds of incisions when using an open approach. The most common transverse incision is the Pfannenstiel

incision, also known as the “bikini” incision. Usually performed at the superior aspect of the pubic hair region for cosmetic reasons, its exposure is limited. When space is not a consideration for node dissection or removal of a large mass, the Pfannenstiel is useful in that it heals well, is reportedly less painful, and is associated with a lower incidence of wound dehiscence and postoperative pulmonary complications as compared with those related to vertical incisions. Other transverse approaches include the Cherney and Maylard incisions. To perform a Cherney, a low transverse skin incision is made, and the rectus muscles are identified at the insertion into the pubic symphysis and divided, commonly by using electrocautery. With the rectus muscle out of the way, pelvic exposure is greatly enhanced, and thus this incision is very useful when additional pelvic exposure is needed without compromising the cosmetic aspects of a transverse incision. Closure of the incision is straightforward. The rectus tendons should be reapproximated to the inferior tendon of the rectus sheath by using permanent sutures. In this incision, the rectus muscles are preserved. Alternatively, another space-endowing incision is the Maylard. Again, using the low transverse skin incision, once the rectus muscles are identified, the inferior epigastric vessels that reside in the lateral aspect of the rectus muscles are identified and ligated. The rectus muscles are divided by using electrocautery. If approached cautiously and slowly, division of the rectus muscles is not complicated by bleeding. As with the Cherney, the Maylard incision affords greater exposure to the pelvic region than does a Pfannenstiel.

TABLE 62.4 ACOG and SGO Guidelines for Referral or Consultation with a Gynecologic Oncologist

Premenopausal or <50 years old with one or more of the following:

- Very elevated CA-125 (>200 U/mL)

- Ascites
- Evidence of abdominal or distant metastases
- Family history of breast or ovarian cancer in a first-degree relative

Postmenopausal or >50 years old with one or more of the following:

- Elevated CA-125 (>35 U/mL)
- Ascites
- Nodular or fixed pelvic mass
- Evidence of abdominal or distant metastases
- Family history of breast or ovarian cancer in a first-degree relative

ACOG, American College of Obstetricians and Gynecologists; SGO, Society of Gynecologic Oncology.

Alternatively, when a malignancy is suspected and surgical staging may be required, a vertical incision is used because of accessibility to the upper abdomen, if this is needed; clearly, transverse skin incisions are limiting for exploration and management of disease found in the upper abdomen. There are two major vertical incisions: the paramedian and midline vertical incisions. In performing a paramedian, the skin incision is just lateral to midline. Some consider these incisions stronger because of the displacement of the skin defect over the rectus muscle defect. The incidence of incisional hernia formation is decreased. However, the midline is used most commonly. With the need for upper abdominal exposure, the midline incision is ideal because of the ability to extend the incision superiorly.

Exposure is usually ideal with the midline incision, although in many cases, the Cherney and Maylard incisions offer better exposure of the pelvis. Because the midline fascial area is less vascular, the entry in the midline can be performed quickly, with minimal damage to rectus muscles and nerves. Also, blood loss is decreased with a midline incision. However, this is considered one of the weaker incisions, and hernias, dehiscence, and eviscerations occur more readily with this incision than with others.

In summary, several incisions are available to gynecologists. Choice of incision is critical to successful evaluation of the gynecologic problem at hand. If malignancy is suspected, then the midline incision is recommended. However, suspicion of malignancy is based on a thorough knowledge of the risks, taking into consideration the radiologic characteristics of the mass and the patient's age. Thus, the incision is should be chosen by a “best educated guess” scenario of the malignant potential of the adnexal mass.

Once the abdomen is open, it is recommended that washings be obtained before manipulation of the pelvic organs so that a true assessment of cytologic spread can be obtained. This can be performed in many ways, such as with a large syringe, with or without catheter tubing attached, or with various suction devices used in a typical surgical

procedure. The solution should be isotonic so that cell lysis does not occur. Either Plasmalyte (Baxter Healthcare, Deerfield, Illinois) or normal saline, warmed to body temperature, can be used. Samples should be obtained from the pelvis, paracolic gutters, and diaphragm regions, as these would be part of the surgical staging if the mass turns out to be a malignancy. When obtaining washings, it is helpful to cup a hand in the abdomen while aspirating to minimize risk of trapping bowel epiploica or omentum in the suction device. A small amount of heparin may be added to the collection prior to submitting to cytology.

After washings are obtained, a thorough exploration of the upper and lower abdomen is in order. Access to the upper abdomen is limited in a Pfannenstiel incision but can usually be accomplished via the Cherney and Maylard incisions and always via the paramedian and midline incisions. In the upper abdomen, systematic exploration should be carried out. The entire surface of the diaphragm, liver surface and parenchyma, porta hepatis region, gallbladder fossa, kidneys and peritoneum overlying them, stomach, spleen tip, and pancreas should be manually assessed. The abdominal retroperitoneum can be evaluated by placing a

---

hand medial to the descending colon and approaching the root of the small bowel mesentery until the aortic pulse is appreciated. The lymphatics can then be evaluated to either side of the abdominal aorta. If there are no adhesions to the abdominal wall, a retractor should be placed at this time. Care should be taken in thin patients not to compress the psoas muscle and cause femoral nerve damage. Because the intent is to pack away bowel so that pelvic visualization is optimized, lysis of adhesions may be necessary at this time to release small bowel loops that may be adherent in the pelvis. However, before packing the bowel, the exploration should be completed by thoroughly inspecting the omentum, appendix, and entire lengths of the large and small bowel including their mesenteries. Finally, the adnexal mass of interest is examined. If the pelvic mass is an ovarian cyst, either a cystectomy or an oophorectomy can be performed, depending on the preoperative discussion with the patient and the index of suspicion for malignancy. For most postmenopausal women, an oophorectomy is planned. If there is any question as to whether the mass is truly malignant and the patient desires preservation of her ovaries, a cystectomy can be performed; if malignancy is suggested by frozen section, completion of the oophorectomy can be performed later during the surgery. In most medical centers, frozen section analysis should have high correlation, upward of 90%, with the final pathology findings.

Classically, when an epithelial ovarian malignancy is found in a postmenopausal woman, complete surgical staging, including total hysterectomy and bilateral salpingo-oophorectomy, is performed. Washings, as noted previously, should be obtained. Peritoneal biopsies from the bilateral pelvic sidewalls, paracolic gutters, cul-de-sac, and anterior vesical surface should be obtained. If the exploration reveals any suspicious areas, these areas should be biopsied as well. These biopsies can be obtained by lifting a small portion of peritoneum and excising sharply. Any bleeding can be cauterized for hemostasis. In lieu of obtaining a diaphragm biopsy, which can be performed by using a cervical biopsy forceps, a scraping of this area can be performed. The right side of the diaphragm is

scraped with a Pap smear spatula or tongue blade. The dominant hand is extended into the right upper quadrant and the diaphragm scraped. Cells are smeared from the spatula onto a slide and fixed with traditional preservative or submerged in liquid cytology media. To complete the staging, pelvic and paraaortic lymph node dissection and omentectomy should be performed. Lymph node dissection is not commonly performed by the general gynecologist, so this procedure will not be described here; however, several excellent references describe the technique. Possible resources for the gynecologist faced with an unexpected malignancy include consultation with a gynecologic oncologist, or if one is not available, a surgical or urologic oncologist should be called.

After ascertaining that all sites are hemostatic and sponge and instrument counts are correct, the abdomen is closed. For vertical incisions, two running sutures utilizing the mass closure technique and meeting in the midline should be sufficient for fascial closure. If there is any concern that this closure will not be durable, as in patients who are malnourished or who are on steroids or other immunosuppressive agents, interrupted closure with a permanent suture may be undertaken. Successful closure of the abdomen often is taken for granted but is a very important part of any surgical procedure. Wound infection and skin separations are unpleasant for the patient, and serious complications can result from a fascial dehiscence. Although the Smead-Jones closure traditionally has been felt to be the most secure, it is very time-consuming and may not afford any extra advantage for the patient when compared with mass abdominal wall closure. When using the mass closure, looped monofilament delayed-absorbable suture is often used. Using two sutures in this way and “running” the fascia from the opposite poles to the midline is effective. This frequently shortens operating time and the amount of time the patient is under anesthesia, especially after a prolonged tumor debulking surgery.

There are many compelling reasons to stage an ovarian cancer. First of all, the extent of tumor is clearly described within the available staging system, thus making communication among physicians and the clinical implications quite clear. Given a defined stage of disease, the patient may be prescribed the appropriate therapeutic or adjuvant therapy. Staging in ovarian cancer is particularly important, because microscopic metastases have significant implications for postoperative treatment. In a classic study, up to 30% of patients thought to have stage I ovarian cancer based on incomplete surgical staging were upgraded to a more advanced stage when microscopic metastases were discovered during a later surgery. Therefore, if full staging, which includes pelvic and paraaortic lymph node dissection, had not been included, these patients would have been treated incorrectly. Unfortunately, despite the availability of gynecologic oncologists in this country, full staging still is not offered to all patients. Not only are node dissections omitted, full palpation of the upper abdomen and omentectomy are omitted. Although the missing staging procedures sometimes can be attributed to a skill issue such as lymph node dissection, failure to evaluate the diaphragm or perform straightforward peritoneal biopsies usually reflects the surgeon's lack of understanding of the necessity of full staging for ovarian malignancies. Complete staging is described in Table 62.5.

Laparoscopic Approach to the Adnexal Mass

The role of laparoscopy in the management of the adnexal mass has advanced tremendously in recent years. Laparoscopic techniques have been developed and equipment is available such that laparoscopic surgery has never been

more versatile and safe. The advantages include less pain, shorter recovery time, the potential to minimize adhesion formation, and shorter hospital stays with associated cost savings. Minimal requirements for a laparoscopic approach to the adnexal mass include adequate surgical skill to perform competently either a cystectomy or adnexectomy, accurate and prompt frozen section services, and the availability of staging in a timely fashion in the event that rupture of a malignancy or advanced cancer is diagnosed (Table 62.6). With the laparoscopic approach, once the mass is removed, frozen section is completed as usual. If the mass is malignant, complete surgical staging should be undertaken as usual, either laparoscopically if the surgeon is skilled or by proceeding to laparotomy. If rupture of the mass occurs and the frozen section confirms malignancy, it generally is recommended that staging be performed promptly. However, if there is spill of ovarian contents inadvertently or in the process of performing cystectomy, although the stage is upgraded to stage IC, it is unclear that the prognosis is much worse; however, in many cases, the patient would be committed to adjuvant chemotherapy. Thus, this situation needs to be avoided. If a malignancy is suspected and the surgeon thinks that there is a significant likelihood of cyst rupture, then the laparoscopy should be aborted and the abdomen opened.

TABLE 62.5 Complete Staging for Ovarian Cancer

Abdominopelvic exploration
Peritoneal washings from pelvis, bilateral paracolic gutters, and
  infradiaphragmatic areas
If desirous of fertility:
  Unilateral salpingo-oophorectomy
  Biopsy of the contralateral ovary if it appears suspicious
If postmenopausal or does not desire fertility:
  Bilateral salpingo-oophorectomy
  Total hysterectomy
Pelvic node dissection
Paraaortic node dissection
Omentectomy
Peritoneal biopsies (cul-de-sac, vesical peritoneum, bilateral pelvic
  sidewalls, bilateral paracolic gutters, biopsy or scraping of right diaphragm)
Biopsy of any additional suspicious findings

TABLE 62.6 Criteria for Laparoscopic Removal of the Adnexal Mass

Surgical expertise skills appropriate for performing cystectomy or adnexectomy
Prompt and accurate frozen section services
Personnel and facilities available for timely surgical staging

A unique complication associated with the laparoscopic approach to the mass that turns out to be malignant is the occurrence of port site tumor implants. Initially, the risk of this was thought to be as high as 11%; however, this risk appears to be limited to patients found to have metastatic disease. In this setting, consideration should be given to resecting the port site at the time of laparotomy and tumor debulking to avoid subcutaneous metastasis. A recent large series found that the risk of port site implants was <1% and was limited to patients with advanced stage disease. Proper port site management may decrease this risk, and suggested techniques include rinsing instruments in povidone-iodine, use of endobags for specimen retrieval, removal of intra-abdominal fluid and gas before removal of the ports, port site irrigation, and peritoneal closure.

The key to successful laparoscopic management of an adnexal mass then returns to the main issue: selection of the appropriate patient given a best guess scenario of whether a mass is benign or malignant. A postmenopausal woman with a complex mass has a higher chance of malignancy; therefore, the surgeon planning a laparoscopic approach should absolutely have a contingency plan if malignancy is discovered. Alternatively, because the chance of malignancy is less frequent in the premenopausal group, laparoscopic approach usually is appropriate in this age group. Until it can be better predicted as to which masses are malignant, a combination of age, menopausal status, tumor marker status, and radiologic appearance (in particular, ultrasonographic findings) should be integrated to determine the best approach for each patient.

Special Clinical Situations

Ovarian cancer usually is a disease of postmenopausal women. Thus, when faced with surgical evaluation of an adnexal mass, in this population, the implications of a total hysterectomy and bilateral salpingo-oophorectomy are not striking. Premenopausal women, however, often face two other concerns: reproductive and potential ovarian function. Even

though in the premenopausal woman most masses are benign, it is clearly best to have discussed all possible options, and the outcome of those options, with the patient preoperatively. While this discussion is sometimes distressing to both the patient and her physician, care should be taken to understand the patient's wishes for reproduction and/or ovarian hormonal function as well as to explain the risks and management of occult bilateral ovarian malignancies. If the outcome of this discussion is to proceed with conservative surgery, she should be advised that if more advanced disease is diagnosed after pathologic evaluation of resected specimens, a second operation may be indicated.

For young patients who wish for preservation of fertility options, the ovary should be inspected with an eye

---

toward feasibility of cystectomy as the first procedure. The specimen can then be sent for frozen section to determine if the ovarian mass is benign or malignant. If clearly malignant, the ovary should be completely removed. If there is a question of malignancy, staging procedures should be performed. If the contralateral ovary appears normal, it can be left in situ; however, any abnormality should be biopsied. If a malignancy is confirmed, the contralateral ovary should be removed as well. If the uterus is uninvolved, it does not need to be removed. Given the advances in assisted reproductive technology, egg donation for in vitro fertilization may be available to this patient after removal of both ovaries.

Another special scenario is management of the mass with borderline histology, also known as tumors of low malignant potential (LMP). Ovarian LMP tumors have been described for all corresponding invasive epithelial ovarian neoplasms. Serous and mucinous histologies make up the largest proportion of these tumors. Histologically, LMP tumors differ from truly invasive lesions in that invasion into ovarian stroma is not detected; the epithelial lining is multilayered, there is no stromal invasion, and only mild nuclear atypia is present. These tumors account for up to 16% of ovarian malignancies. As compared with truly invasive ovarian cancers, the majority of LMP tumors are early stage and confined to one ovary, although up to one third of serous LMP tumors can be bilateral. Once resected, regardless of stage, the role of adjuvant or therapeutic chemotherapy is unclear. Unlike invasive epithelial ovarian cancers, this disease is rarely thought to benefit from adjuvant chemotherapy and remains a surgically treated disease. CA-125 levels are elevated in some of these patients and in this setting can be useful in monitoring for disease recurrence.

In the postmenopausal population, management usually is hysterectomy and bilateral salpingo-oophorectomy. Surgical staging of these tumors is controversial. At a minimum, washings should be obtained. However, consideration should be given to full surgical staging of LMP tumors, as occasionally, the final pathologic diagnosis will reveal an invasive component. In that setting, if the patient has not been staged, the oncologist is faced with the predicament of either recommending a second surgical procedure for staging or observation versus potentially unnecessary chemotherapy of an incompletely staged malignancy. If incompletely staged and the final pathologic diagnosis reveals only an LMP tumor, repeat surgical intervention for staging is not indicated, as it will not impact on clinical management.

In the premenopausal woman desirous of fertility, ovarian cystectomy is a possibility,

whether the tumor is unilateral or bilateral. Although recurrence in the involved LMP ovary treated by cystectomy is reported as high as 30%, mortality rates from recurrent disease appear to be unchanged. When cystectomies are performed in these cases, women desiring children may be able to gain a few years and complete a family before undergoing or requiring more definitive surgery.

Adnexal masses in young women may also be of germ cell origin. This is a special clinical scenario in that these neoplasms occur almost exclusively in young women. The main complaints include abdominal pain, with a pelvic mass found during examination. Some patients have acute abdominal pain resulting from torsion or rupture and hemorrhage of these masses. When evaluating a patient whose condition is not acute, the radiologic image usually reflects a solid mass with some cystic changes. During surgery, given that most of these patients have not completed childbearing and that most are confined to the ovary, a conservative approach with unilateral adnexectomy and staging can be performed. Routine biopsy of the contralateral ovary in the case of a dysgerminoma is not recommended, even though the bilaterality rate is higher with this tumor than with other germ cell tumors. Most require chemotherapy even at stage I, but the cure rate is quite high with modern chemotherapy. Hence, conservative surgical management, as outlined previously, is indicated.

Adnexal Masses in Pregnancy

Most adnexal masses diagnosed during pregnancy are simple cystic masses, and most will resolve by the second trimester. However, if the mass has not resolved by this time, most may require surgical intervention: the ovary is at risk from torsion or rupture, the pregnancy may be compromised by delay if surgery subsequently becomes necessary in the third trimester, and delivery may be changed from a vaginal to an abdominal approach due to outlet obstruction from the mass. For all of these reasons, surgery is usually indicated for a complex mass (8 cm) that persists into the second trimester. The ideal time is around 16 to 18 weeks gestation and has been shown to be relatively safe for both mother and fetus. A midline incision or one positioned over the mass should be made for adequate exposure and to minimize uterine manipulation. Fortunately, the risk of malignancy is only around 5%. In most cases, a therapeutic hysterectomy is not required. However, if a malignancy is found, surgical staging should be carried out. In cases where surgery is required in the first trimester, exogenous progesterone should be given to support the pregnancy in the event that the corpus luteum needs to be removed.

Summary Points

- Advances have been made into the diagnosis and management of the adnexal mass. These include conservative management of the simple cyst in the postmenopausal woman and the offering of a laparoscopic approach to adnexal masses in carefully selected cases.
- An ideal method for determining preoperatively whether a mass is benign or malignant has not been discovered. However, ACOG and

SGO guidelines exist to assist gynecologists in the triage of patients with an adnexal mass.

- All surgeons managing the adnexal mass should know the appropriate cancer staging procedures for the postmenopausal woman and for the young woman desiring fertility preservation. Even if the surgeon is not technically equipped to perform the lymph node dissection and debulking surgery, surgical assistance from a gynecologic oncologist can frequently be arranged. Appropriate staging is imperative to save the patient another surgical procedure and to determine the extent of the disease so that appropriate adjuvant therapy can be prescribed.
- New tumor markers and radiologic approaches are being pursued such that soon it may be possible to more accurately distinguish malignant from benign adnexal masses. In the meantime, appropriate medical and surgical management of the adnexal mass is the responsibility of all gynecologic surgeons.

Gestational Trophoblastic Neoplasms

Andrew John Li

Gestational trophoblastic neoplasia (GTN) encompasses a broad spectrum of benign and malignant tumors derived from the trophoblast of the human placenta. While they are rare in incidence, they have the potential to become rapidly fatal diseases that afflict young women in their peak reproductive years.

Traditionally, GTN is divided into three histologic categories: hydatidiform mole, invasive mole (chorioadenoma destruens), and choriocarcinoma. Partial hydatidiform moles and placental site trophoblastic tumors (PSTTs) are further recognized as histologically and clinically separate entities under the broad classification of GTN.

Despite the apparent diversity of GTN, these diseases are all derived from the human placental trophoblast and the paternal genome, with an occasional maternal contribution. Human chorionic gonadotropin (hCG) is secreted by these neoplasms and serves as a sensitive tumor marker that correlates well with the clinical course for all but PSTT.

In 1956, metastatic gestational choriocarcinoma, the most malignant form of these diseases, was shown to be curable by chemotherapy. Now, studies demonstrate the curability of most of these patients, although individualization of therapy remains fundamentally important.

This chapter will review this unusual spectrum of human neoplasms and discuss important concepts regarding diagnosis, management, and surveillance for women with GTN.

Histology

Patients may be treated for malignant GTN on the basis of clinical, radiographic, and hCG level determinations without a definitive histologic diagnosis. For this reason, the generic term of *gestational trophoblastic neoplasia* is useful, especially when treating patients with metastatic disease that is not readily accessible for pathologic evaluation. Except for PSTT, the initial histologic features of any lesion identified as GTN are less important than the clinical data and hCG level.

Hydatidiform Mole

Two distinct types of molar gestations are recognized: partial and complete hydatidiform

moles, both of which have distinct cytogenetic origins, pathologic features, and clinical behavior. While it is not as clear whether partial hydatidiform mole represents a form of GTN or an extreme form of hydropic degeneration of the placenta in a chromosomally abnormal pregnancy, it should be considered as a variant of the complete hydatidiform mole with risk of malignant sequelae. Most patients with primary molar gestations do not require adjuvant chemotherapy and may be monitored after therapeutic evacuation with serial hCG level determinations until either spontaneous regression occurs or the patient develops criteria of malignant sequelae.

Partial Hydatidiform Mole

Approximately 1% of pregnancies have a triploid karyotype and resolve in spontaneous abortion; partial hydatidiform moles represent a subset of these pregnancies with histologic features similar to the complete hydatidiform mole. A comparison of karyotypic, pathologic, and clinical

features of partial and complete hydatidiform moles is shown in Table 63.1. Partial moles are often associated with identifiable fetal parts or amniotic membranes. Grossly, the placenta demonstrates a mixture of normal and hydropic villi. Microscopic features include normal and hydropic chorionic villi with focal mild hyperplasia of trophoblastic elements. Scalloping of the hydropic villi is common, with trophoblastic inclusions in the stroma. Fetal vessels are frequently observed with nucleated fetal erythrocytes within the vessels. Normal amniotic membranes are often identified, even if a fetus is not found.

TABLE 63.1 Complete and Partial Hydatidiform Moles

Feature	Partial Hydatidiform Mole	Complete Hydatidiform Mole
Karyotype	Triploid paternal and maternal origin	Most 46XX paternal origin
Pathology		
Fetus or amnion, fetal vessels	Present	Absent
Hydropic villi	Variable, often focal	Pronounced, generalized

Trophoblastic proliferation	Focal	Variable, often marked
Clinical		
Mole clinical diagnosis	Rare	Common
Uterus large for dates	Rare	30%–50%
Malignant sequelae	<5%	6%–36%

Partial moles are almost always associated with one haploid maternal and two haploid paternal sets of chromosomes. Presumably, this results from dispermic fertilization of a haploid ovum or fertilization of a haploid ovum with a diploid sperm.

Women with partial hydatidiform mole usually have a clinical diagnosis of spontaneous abortion or missed abortion. Often, hydropic villi are not identified on ultrasound, and the diagnosis is not suspected until after evacuation of the pregnancy. Initial hCG levels are lower than those seen in patients with complete hydatidiform mole, and prompt postevacuation regression of hCG levels usually occurs. Unlike patients with complete moles, who have a 10% to 30% incidence of malignant sequelae, fewer than 5% of the patients with partial moles develop criteria requiring chemotherapy. Regardless of this low risk of malignant sequelae, all women with partial hydatidiform moles should undergo hCG surveillance after evacuation, similar to that recommended for patients with complete hydatidiform mole. If there is any doubt that the products of a conception are molar, hCG monitoring should be done.

Complete Hydatidiform Mole

Complete hydatidiform mole is identified macroscopically by edema and swelling of virtually all chorionic villi without identifiable fetal parts or amniotic membranes. Hydropic villi are usually 1 to 3 cm in diameter, giving the gross appearance of grapelike vesicles. Microscopically, the chorionic villi are hydropic with marked interstitial edema. Fetal vessels are absent in the stroma of the villi. Proliferation of cytotrophoblast and syncytiotrophoblast is observed. Regardless of the degree of trophoblastic proliferation, all patients should be followed in similar fashion. All hydatidiform moles secrete hCG, and this marker is used to monitor regression after evacuation.

Complete moles are almost uniformly diploid with paternal chromosomal markers. Most are 46XX, although a minority will demonstrate a 46XY karyotype. The most common origin of

complete hydatidiform mole is fertilization of an empty egg by a haploid sperm followed by reduplication, although some may result from dispermic fertilization of an empty egg.

Unlike women with partial hydatidiform moles, approximately one third to one half of these patients have uterine enlargement greater than expected for gestational dates. Fetal heart tones are absent. Patients often present with vaginal bleeding and spontaneous abortion of the atypical hydropic vesicles. Theca lutein cysts are detected clinically in approximately 20% of patients with complete moles. Pulmonary decompensation, pregnancy-induced hypertension, and hyperthyroidism are occasionally observed. The clinical diagnosis of molar gestation is supported by a characteristic mixed echogenic "snowstorm" image filling the uterus on an ultrasound scan (Fig. 63.1).

Invasive Mole

Invasive moles are histologically identical to complete moles but with invasion into the myometrium without intervening endometrial stroma. Invasive moles usually are diagnosed within 6 months of molar evacuation. Untreated invasive moles tend to invade the uterine wall locally, which can result in uterine perforation and hemorrhage. Direct vascular invasion and metastasis may also occur. Rarely, biopsies of distant metastases reveal the hydropic villi of invasive mole instead of solid sheets of anaplastic cells consistent with choriocarcinoma.

The identification of an invasive mole from uterine curettings may be difficult unless there is sufficient myometrium to document direct myometrial invasion.

Choriocarcinoma

Choriocarcinoma is a highly anaplastic malignancy derived from trophoblastic elements. No chorionic villi are identified. Grossly, the tumor has a red, granular appearance on cut section with focal, often extensive, central necrosis

and hemorrhage. Histologically, the lesion consists of mixed syncytioblastic and cytotrophoblastic elements with numerous abnormal mitoses, multinucleated giant cells, and extensive areas of necrosis and hemorrhage. Choriocarcinoma rapidly invades the myometrium and uterine vessels, and systemic metastasis results from hematogenous embolization. The lung and vagina are the most common sites of metastases, with secondary dissemination to the central nervous system (CNS), kidney, liver, and gastrointestinal tract.

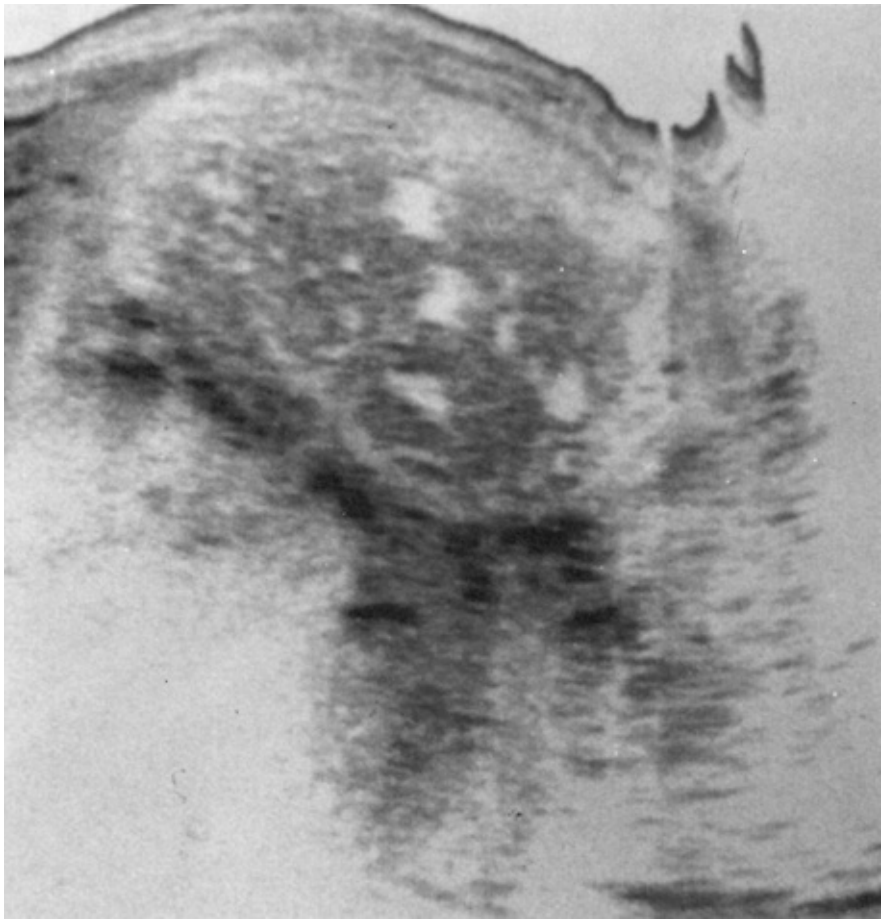

Figure 63.1 A longitudinal ultrasound reveals a hydatidiform mole. The mixed echoic pattern is caused by hydropic villi and focal intrauterine hemorrhage.

Choriocarcinomas may develop after any type of pregnancy. Approximately 50% of cases are preceded by hydatidiform mole, and the remaining are equally distributed between a normal antecedent term gestation and abortion or ectopic pregnancy. Gestational choriocarcinoma has been observed several years after the last known pregnancy. Spontaneous regression of the primary uterine site has been well documented from autopsy series of patients before the development of effective chemotherapy.

Placental Site Trophoblastic Tumor

PSTTs are locally invasive neoplasms derived from intermediate cells of the placenta. These rare neoplasms are composed of a monomorphic population of intermediate cytotrophoblast cells that secrete human placental lactogen (hPL) and relatively small amounts of hCG. There is typically local myometrial invasion with rare systemic metastases. Diagnosis is typically made by exclusion, and PSTTs should be considered with disease refractory to standard chemotherapy. Hysterectomy is the therapy of choice.

Incidence and Epidemiology

Approximately 3,000 cases of hydatidiform mole and 500 to 750 cases of malignant GTN are diagnosed in the United States each year. Hydatidiform mole is identified in approximately

1 in 1,500 to 2,000 pregnancies in the United States. There is a marked geographical variation in the incidence of this disease, with rates 5- to 15-fold higher in the Far East and Southeast Asia than in the Western industrialized nations. Some of this variation may be accounted for by the methodology of studies reporting the incidence of molar gestation, as many data were reported from the experience at referral centers and may overestimate the true incidence of molar pregnancies in the general population. Racial differences may also account for some of the geographic variations; Japanese immigrants to Hawaii have an incidence of molar gestation intermediate between that of native Hawaiians and native Japanese. Nutritional factors may also be important in the development of hydatidiform mole, including deficiencies of protein or animal fat and fat-soluble carotene.

Known risk factors for hydatidiform mole include previous molar pregnancies and maternal age. Women with

---

a history of hydatidiform mole have a four to five times higher risk of developing a subsequent molar gestation. Women at the extremes of reproductive age are also at increased risk of developing a hydatidiform mole. Several studies have confirmed that risk increases with advanced maternal age, and others have suggested an increased risk for younger women or adolescents. The impact of paternal age on the incidence of hydatidiform mole is difficult to separate from the effect of maternal age.

The incidence of partial hydatidiform mole is unknown. Presumably, many are undiagnosed because of insufficient histologic analysis of tissue from spontaneous and induced abortions. Some pathologists are not familiar with the diagnosis of partial hydatidiform mole, and karyotyping is seldom performed on material obtained from spontaneous abortions. One report reclassified approximately 10% of all moles in their studies as partial hydatidiform moles on the basis of histologic analysis.

Invasive mole follows approximately 10% to 15% of complete hydatidiform moles. In the United States, choriocarcinoma will follow in approximately 1 in 40 moles, 1 in 5,000 ectopic pregnancies, 1 in 15,000 abortions, and 1 in 150,000 normal pregnancies.

Albeit rare, GTN may also present in ectopic pregnancies and in twin gestations. The incidence of molar disease following an ectopic pregnancy is reported as 1.5 per 1,000,000 pregnancies, and only case reports and small case series have been reported. Twin pregnancy, consisting of a complete hydatidiform mole and coexistent normal fetus, is even more rare, with 30 cases identified during an 18-year period where 7,200 cases of GTN were registered at the Sheffield Trophoblast Centre. Diagnosis is difficult, and ultrasound findings in early pregnancy may be misleading. In an analysis of the major series reporting experience with twin mole/viable fetal pregnancies, successful pregnancy resulted in only 29% of cases; furthermore, an increased risk of complications, such as preeclampsia and hemorrhage, was identified.

Management

The basic principles in management of the patient with hydatidiform mole include establishment of the diagnosis, evacuation of the molar gestation, and close surveillance of hCG level after evacuation. Patients with complete hydatidiform moles frequently present

with spontaneous abortion of hydropic villi, which are pathognomonic for molar pregnancy. Absent fetal heart tones, uterine enlargement different from that expected for the gestational age, and a markedly elevated hCG level are all clinical indications that may suggest a diagnosis of hydatidiform mole. Ultrasound is now the diagnostic method of choice for evaluating patients with suspected hydatidiform mole. Ultrasound demonstrates a characteristic image of multiple echogenic regions within the uterus corresponding to hydropic villi and focal intrauterine hemorrhage.

Evaluation of the patient before evacuation of the hydatidiform mole is directed toward preparing the patient for evacuation, obtaining baseline hCG level information, and screening for associated hyperthyroidism. The following studies are recommended:

- Complete physical and pelvic examinations
- Complete blood count
- Blood chemistries, including renal, hepatic, and thyroid function tests
- Baseline serum hCG level
- Type and screen
- Chest radiograph
- Pelvic ultrasound.

Suction dilation and curettage (D&C) offers a safe, rapid, and effective method of evacuation of hydatidiform mole in most patients. Some patients who do not desire preservation of reproductive function may benefit from primary hysterectomy for evacuation of hydatidiform mole and concurrent sterilization. However, these patients must be closely followed after hysterectomy, as malignant sequelae may still develop. Hysterotomy or induction of labor for molar evacuation is not recommended.

Suction D&C for evacuation of hydatidiform mole has a low complication rate in patients with uterine sizes corresponding to <16 weeks gestation. Oxytocic agents are administered after cervical dilation and partial evacuation to aid in postoperative hemostasis. Patients with excessive uterine enlargement have a higher risk of pulmonary complications associated with D&C, which may be related to trophoblastic deportation, preeclampsia, fluid overload, anemia, and hyperthyroidism. In patients with hydatidiform mole complicated by uterine enlargement >16 weeks of gestation, baseline arterial blood gases should be obtained preoperatively with an electrocardiogram, radionucleotide-gated heart pool scan for ejection fraction, and a valvular function assessment by cardiac ultrasound. Evacuation should be performed with a laparotomy set and facilities for central hemodynamic monitoring. Patients who are Rh negative should receive the Rh immune globulin vaccine to protect future pregnancies against Rh sensitization.

Primary hysterectomy is a reasonable alternative for termination of molar gestation in patients with hydatidiform mole who have completed childbearing and desire sterilization. Hysterectomy reduces the incidence of malignant sequelae after evacuation of hydatidiform mole from approximately 20% after suction D&C to <5% after hysterectomy. However, this does not eliminate the need for careful follow-up or complete hCG

surveillance after termination of hydatidiform mole, as malignant GTN may develop even after hysterectomy. Concurrent surgical extirpation of the adnexa should be considered as with hysterectomy for benign indications.

Theca lutein cysts are clinically detected in approximately 20% of patients with molar gestations. These cysts are thin-walled and highly vascular and develop as a response to ovarian hyperstimulation from the high hCG levels produced by hydatidiform moles. They typically regress spontaneously over several weeks following molar evacuation. It is preferable to avoid operation or ovarian manipulation in patients with uncomplicated theca lutein cysts. Rarely, because of abdominal distension and respiratory compromise, they may require aspiration by ultrasonic guidance. Enlarged cysts may undergo torsion, infarction, or rupture, and oophorectomy should be considered in these circumstances.

Prophylactic short courses of methotrexate or dactinomycin chemotherapy have been considered at the time of molar evacuation in the past, as they may decrease the incidence of malignant sequelae in patients with high-risk features. However, prophylactic chemotherapy does not eliminate the chance of subsequent malignancy or the need for hCG surveillance. Routine prophylactic chemotherapy at the time of molar evacuation for patients with uncomplicated hydatidiform mole is not recommended if reliable hCG surveillance is available.

Surveillance following Molar Evacuation

Following the wide availability of sensitive hCG assays, histologic grading of molar tissue after evacuation of hydatidiform mole has assumed less importance in predicting the potential for malignant postmolar sequelae. Several sensitive hCG assays are available, measuring the ß subunit of hCG by radioimmunoassay or by radioimmunometric assay. These assays are able to detect hCG levels elevated above the baseline variations of pituitary gonadotropins. These sensitive hCG assays should be used to monitor patients with GTN after evacuation of hydatidiform mole and during therapy of patients with malignant GTN. Urinary or serum pregnancy screening tests should not be used to follow patients with GTN, because the assays do not have sufficient sensitivity to permit detection of minimal elevations of hCG levels.

The recommendations for postmolar follow-up include determination of serum ß-hCG levels every 1 to 2 weeks after evacuation until the hCG level is normal; determination of the hCG level 2 to 4 weeks after first normal level to confirm spontaneous hCG regression; and hCG surveillance every 1 to 2 months for 6 months after the first normal hCG level.

Most women with molar pregnancies undergo hCG level regression after evacuation to normal limits and require no further therapy. Strict contraception is recommended during hCG surveillance to avoid an intercurrent pregnancy that would interfere with monitoring. hCG elevation of an early normal pregnancy may potentially mask the hCG rise associated with postmolar malignant GTN.

Although an early report implicated oral contraceptives as increasing the risk for the development of postmolar malignant GTN, subsequent investigators found no significant

increase in the risk of malignant GTN associated with the use of oral contraceptives after molar evacuation. Furthermore, oral contraceptives are considered the contraception agent of choice by most experts. After completion of 6 months of hCG level surveillance with normal results, patients may attempt pregnancy if desired. Because patients are at a four- to fivefold increased risk of recurrent molar pregnancy, they should undergo early screening of future pregnancies with ultrasound to exclude recurrent molar gestations. Figure 63.2 illustrates an algorithm for diagnosis and follow-up of patients with hydatidiform mole.

False-Positive Human Chorionic Gonadotropin Tests

The sensitivity and specificity of the serum hCG level makes it an ideal tumor maker in both diagnosis and surveillance of GTN. However, hCG, a glycoprotein comprised of an α and ß subunit, is linked to eight oligosaccharides,

which promotes significant heterogeneity in its structure. Free subunits, degraded molecules, molecules with irregular side chains, and fragments of hCG are present in sera of women in pregnancy, with trophoblastic disease, and with nontrophoblastic neoplasms. Furthermore, hCG variants that include hyperglycosylated hCG (hCG-H), nicked hCG, hCG missing the ß subunit C-terminal peptide, free ß subunit, and nicked free ß subunit may also be present. While all professional laboratory hCG assays utilize antibodies to different sites on the ß subunit, variations in antibody use may lead to measurements of different hCG-related molecules.

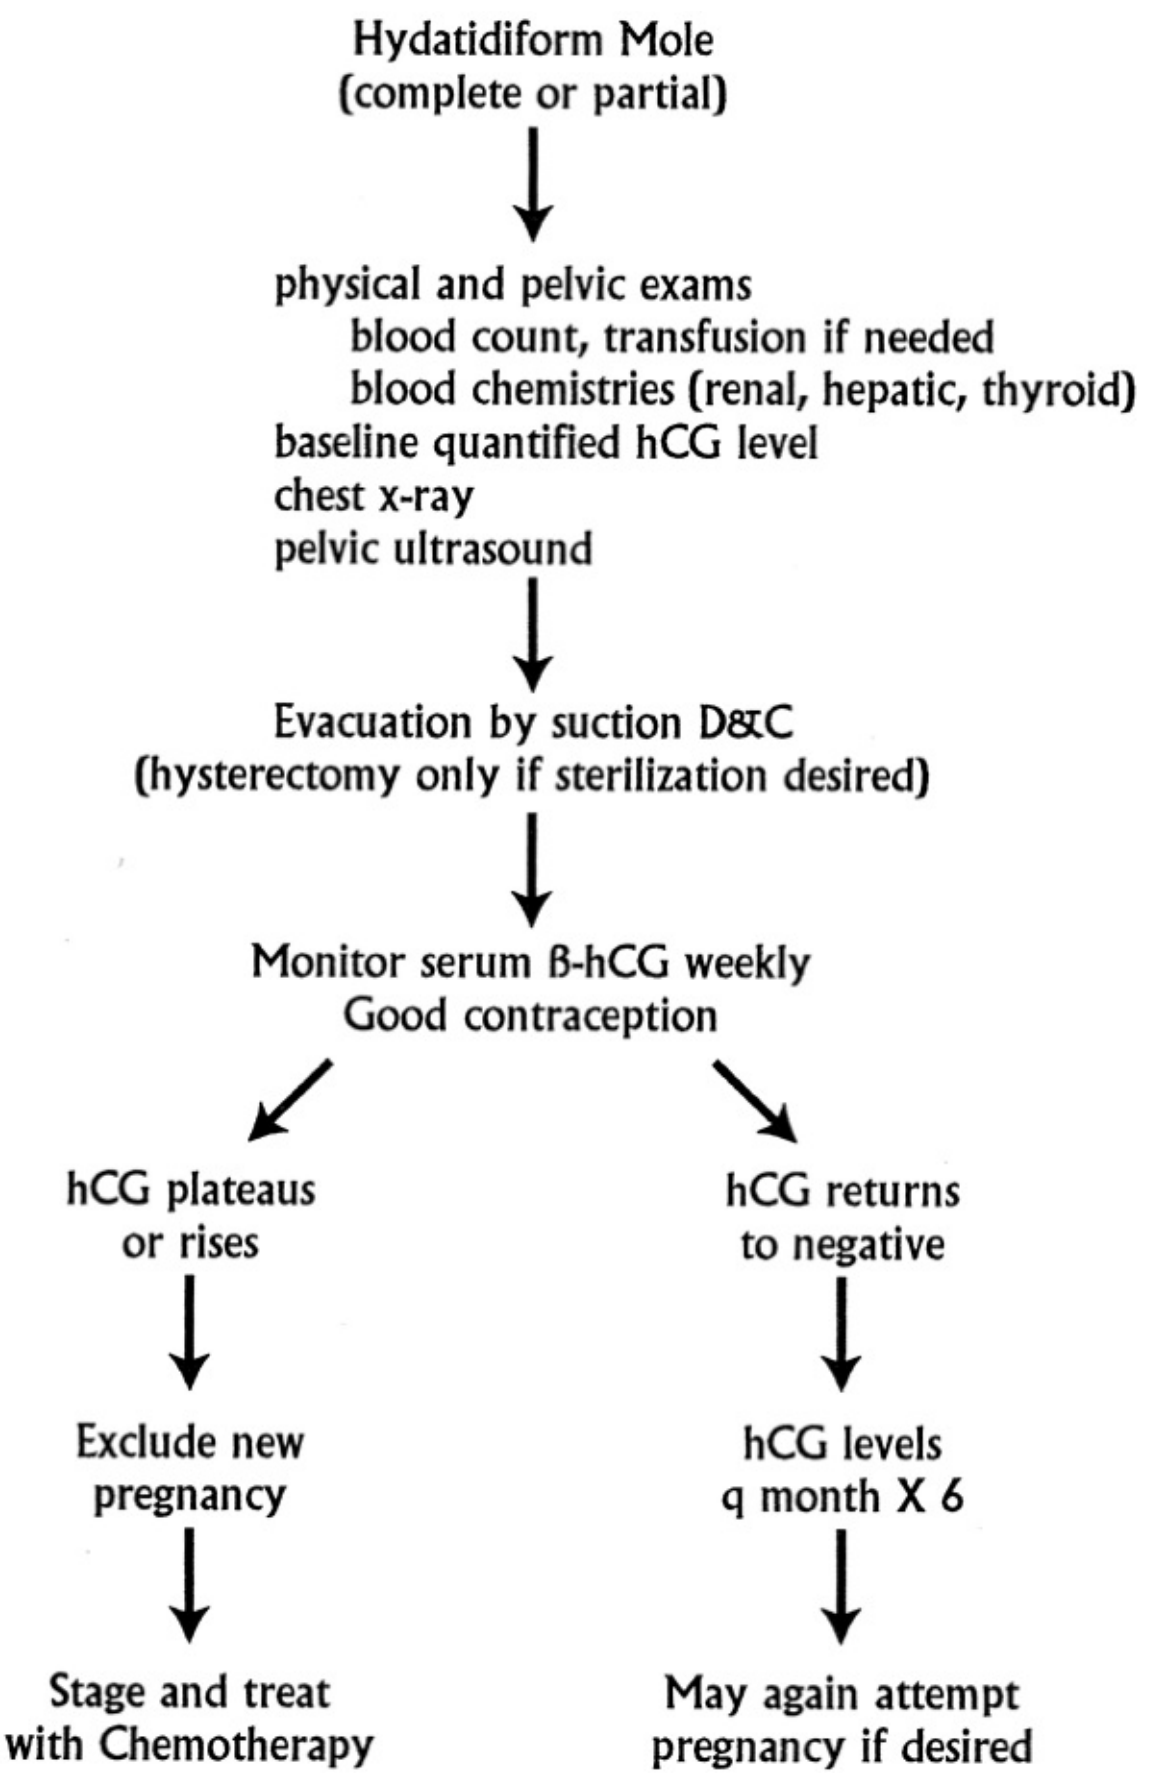

Figure 63.2 Algorithm for diagnosis and management of a patient with hydatidiform mole. (hCG, human chorionic gonadotropin; D&C, dilation and curettage.)

The heterogeneity of hCG and the variability in different hCG tests has led to a recently

recognized issue regarding false-positive assay results. This phenomenon of "phantom hCG" and "phantom choriocarcinoma" has resulted in erroneous diagnoses of invasive GTN and choriocarcinoma with unnecessary subsequent treatment. The USA hCG Reference Service recommends that in cases where false-positive hCG results are suspected, urine hCG testing for detection of ß-core fragment, the terminal degradation product of hCG and its variants, should be performed. Testing should include serum testing by a laboratory utilizing a different hCG assay. In cases with absence of urine hCG and failure to detect hCG in an alternative laboratory hCG test, the initial suspected test is likely a false positive.

False-positive results may also be due to the presence of heterophilic antibodies. These antibodies are able to complete with hCG in antibody binding utilized in commercial hCG assays and may result in persistent positive results. Treatment with a heterophilic antibody blocking reagent has been shown to reduce the incidence of false-positive results, and this test has been added to the protocol utilized by the USA hCG Reference Service.

Quiescent Gestational Trophoblastic Neoplasia

Quiescent GTN is a benign or inactive form of GTN, marked by persistently low hCG levels that may persist from months to years. Histologically, intermediate and highly differentiated syncytiotrophoblasts are observed, with the absence of cytotrophoblasts characteristic of most cases of choriocarcinoma. As approximately 1 in 5 cases of quiescent GTN will transform into true disease or choriocarcinoma, this entity is considered a premalignant condition. In a review of 69 cases with persistent low hCG levels evaluated by the USA hCG Reference Service that were considered as "true positives," all persisted for 3 months or more with minimal fluctuation. In these cases, hCG-H may be examined to discriminate between active and quiescent disease. hCG-H is independently secreted by stem cytotrophoblast cells and is the direct promoter of trophoblast invasion and malignancy. While most present assays test poorly for hCG-H, it is a more precise tumor marker for malignant or invasive GTN.

Malignant Gestational Trophoblastic Neoplasms

Malignant Sequelae following Molar Evacuation

The spectrum of malignant sequelae after evacuation of hydatidiform mole includes intrauterine molar proliferation without invasion (i.e., retained mole), invasive mole, choriocarcinoma, and the clinical identification of metastatic GTN without a histologic diagnosis. The purpose of hCG level surveillance is early detection of trophoblastic neoplasia before the development of complications related to local proliferation, uterine invasion, or distant metastases.

Before the development of effective chemotherapy for GTN, approximately 9% of women required hysterectomy for malignant sequelae after evacuation of hydatidiform mole. Many series of patients have been reported since the development of chemotherapy, with a wide range in the rate (9% to 36%) of patients requiring therapy after evacuation of hydatidiform mole. These observed differences in the frequency of malignant GTN may

reflect inclusion of partial moles in some studies, a different incidence of metastatic disease in patient populations, or different hCG level regression criteria used to define malignant GTN and assign therapy in the various studies.

Histologic and clinical features can be used to define high- and low-risk groups of patients after molar evacuation but are of little value in determining the need for therapy in individual patients. Trophoblastic proliferation, uterine enlargement, theca lutein cysts, respiratory distress syndrome after molar evacuation, and postevacuation uterine hemorrhage are all associated with a higher frequency of postmolar malignant GTN. Prompt uterine involution and regression of theca lutein cysts are favorable prognostic signs. However, the definitive method for predicting development of postmolar malignant GTN is observation of the pattern of hCG regression.

Surveillance after evacuation of a molar pregnancy should include serial hCG levels at 1-week intervals. Patients are treated with chemotherapy according to several criteria: hCG level rise, hCG level plateau for three or more consecutive weekly levels, appearance of metastases, or histologic evidence of invasive mole or choriocarcinoma.

Diagnosis

Malignant GTN is diagnosed in women with a rising or plateauing hCG level or identification of metastases after evacuation of a hydatidiform mole. Histologic diagnosis of invasive mole or choriocarcinoma is a criterion for malignant GTN. Patients who develop malignant GTN after nonmolar gestations often present with atypical symptoms attributable to distant metastases. Gastrointestinal or urologic hemorrhage, hemoptysis, or cerebral hemorrhage may be the presenting symptoms. Irregular uterine

bleeding or amenorrhea may be observed. Rarely, patients present with clinical hyperthyroidism. Under these circumstances, the diagnosis of malignant GTN is facilitated with serum hCG testing and the exclusion of normal pregnancy. The possibility of metastatic GTN should be considered in any woman of the reproductive age group presenting with metastatic disease involving the lungs or distant sites from an unknown primary site of malignancy.

After the diagnosis has been made, the following clinical, laboratory, and radiographic evaluations are recommended for a patient with malignant GTN:

- Physical and pelvic examinations
- Baseline hCG level
- Complete blood count and baseline chemistries
- Chest radiograph
- Pelvic ultrasound
- Computed tomography (CT) of brain, chest, and abdomen–pelvis.

Before a woman is treated for malignant GTN with chemotherapy, it is essential to exclude an intrauterine pregnancy with a pelvic ultrasound scan. Approximately 50% of patients

with malignant GTN have pulmonary metastases detected by routine chest radiographs. The clinical significance of small pulmonary metastases detected only by whole-lung CT scans is unknown. As CNS and hepatic metastases may develop without clinical or radiographic evidence of pulmonary or vaginal metastases, the remainder of the radiologic studies are strongly recommended regardless of whether abnormalities are detected by physical examination or chest radiograph. The role of magnetic resonance imaging studies or positron emission tomography in the evaluation of women with GTN is not yet defined.

Occult CNS metastases may be detected by using lumbar puncture with simultaneous serum and cerebrospinal fluid (CSF) hCG determinations. The plasma–CSF hCG level ratio is normally >60: 1 in the absence of CNS metastases and is usually <60: 1 in patients with CNS metastases. Some investigators have reported falsely lowered plasma–CSF hCG ratios for patients without GTN undergoing first-trimester abortions and for patients with nonmetastatic GTN. CSF hCG determinations are most frequently utilized in evaluation of patients who have developed resistance to chemotherapy with residual disease documented by elevated serum hCG levels when the site of disease is obscure.

Surgery may be useful for patients with malignant GTN, but it is rarely indicated for staging or diagnosis alone. Histologic evaluation of tissue obtained by D&C may yield prognostic information related to the response to first-line chemotherapy, but the procedure carries the risk of uterine perforation and hemorrhage. Laparoscopy, craniotomy, and thoracotomy are rarely justified to establish the primary diagnosis of malignant GTN, as this diagnosis can be made on the basis of an elevated hCG levels with radiographic evidence of metastases after excluding pregnancy.

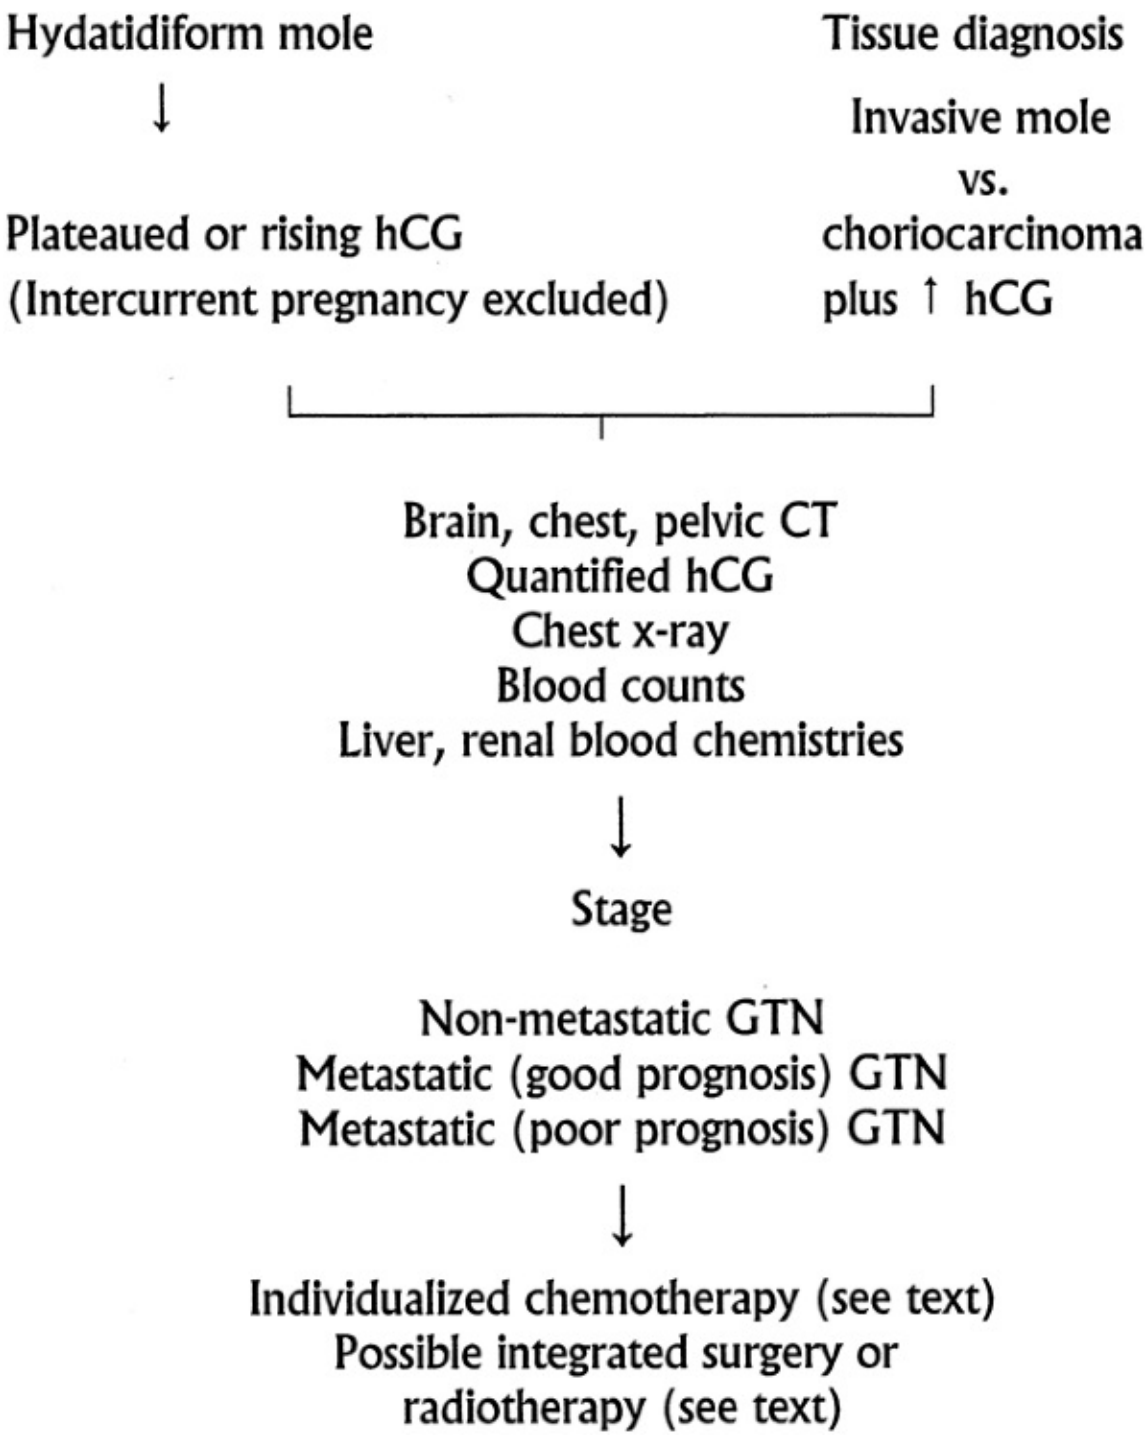

Figure 63.3 Algorithm for management of a patient with malignant gestational trophoblastic disease. (hCG, human chorionic gonadotropin; CT, computed tomography; GTN, gestational trophoblastic neoplasia.)

All patients with malignant GTN must be thoroughly evaluated for metastatic disease. Selection of the initial therapy and subsequent survival largely depend on identification of poor prognostic factors in patients with metastatic disease. Figure 63.3 demonstrates an algorithm of management of malignant GTN.

Staging and Classification

Due to considerable overlap in the clinical course of the histologic entities that comprise

malignant GTN and because a complete histologic evaluation of an individual patient with GTN is rarely possible, a variety of classification and staging systems have been used to assess risk and assign initial therapy and prognosis for these patients. Several clinical findings are important in categorizing patients for treatment, and any classification system must take these factors into consideration to be clinically useful.

A simple clinical classification system based on risk factors for malignant sequelae may be used to assign initial therapy for patients with malignant GTN. This system takes into account the factors that predict failure of the initial single-agent chemotherapy and allows identification of patients who would benefit from initial aggressive multidrug chemotherapy (Table 63.2). After radiographic studies have been completed, the patient is considered to have nonmetastatic GTN if there is no evidence of extrauterine metastases. This category is not subdivided into good-prognosis and poor-prognosis categories, because these patients can achieve approximately 100% remission rates by using current chemotherapeutic regimens. The histologic diagnosis of choriocarcinoma, although mandating treatment, does not change the initial choice of therapy. If there is any clinical or radiographic evidence of extrauterine metastases, the patient is classified as having metastatic GTN. These patients are further divided into good-prognosis and poor-prognosis categories on the basis of factors that predict the failure of primary single-agent chemotherapy with methotrexate or dactinomycin.

TABLE 63.3 World Health Organization Prognostic Scoring Syst Gestational Trophoblastic Neoplasia

Score[a]				
Prognostic factor	0	1	2	4
Age (y)	≥39	>39	—	—
Antecedent pregnancy	Hydatidiform	Abortion; ectopic	Term pregnancy	—
Interval (mo)[b]	<4	4–6	7–12	>
hCG level (IU/L)	$<10^3$	10^3–10^4	10^4–10^5	>

ABO blood groups (female/male)	O/A	B	A/O	A
Largest tumor (cm)	<3	3–5	>5	—
Site of metastasis	—	Spleen, kidney	Gastrointestinal tract, liver	B
Number of metastases	—	1–3	4–8	>8
Prior chemotherapy	—	—	Single drug	M d

[a]Low risk, ≤4; intermediate risk, 5–7; high risk, ≥8.
[b] Time between antecedent pregnancy and start of chemotherapy

The International Federation of Gynecology and Obstetrics (FIGO) developed a staging system for GTN that is based on the anatomic site of disease, conforming to the FIGO staging systems for other gynecologic malignancies:

Stage I: Disease confined to the uterine corpus

Stage II: Metastases to the vagina or pelvis

Stage III: Metastases to the lung

Stage IV: Other extrapelvic metastases.

TABLE 63.2 Clinical Classification of Malignant Gestational Trophoblastic Neoplasia

1. Nonmetastatic GTN[a]
   1. Not defined in terms of good versus poor prognosis
2. Metastatic GTN
   1. Good prognosis (i.e., absence of high-risk factors)

1. Pretreatment hCG level <40,000 mIU/mL serum β-hCG
2. <4-Month duration of symptoms attributable to disease
3. No evidence of brain or liver metastasis
4. No significant prior chemotherapy
5. No antecedent term pregnancy

2. Poor prognosis (i.e., any single high-risk factor)
1. Pretreatment hCG level >40,000 IU/mL serum β-hCG
2. >4-Month duration of symptoms attributable to disease
3. Brain and/or liver metastasis
4. Failed prior chemotherapy
5. Antecedent term pregnancy

[a]GTN, gestational trophoblastic neoplasia; hCG, human chorionic gonadotropin.

Although essentially all patients with stage IV disease are at high risk, this system does not recognize the prognostic importance of other factors such as the initial hCG level, other direct and indirect measurements of tumor burden, or duration of disease.

The World Health Organization (WHO) devised a prognostic index scoring system (Table 63.3) based on Bagshawe's analysis of the prognostic factors of his patient population; this system parallels the Charing Cross classification scheme utilized at the Trophoblastic Tumour Screening and Treatment Centre in London. In addition to using a weighted scale for risk factors analyzed by the clinical classification, such as hCG level and duration of disease, the system identifies a graded range of additional risk factors. Ectopic pregnancies and abortions are considered to have an intermediate risk between molar and term pregnancies. Blood types and age contribute to the score. The size of the largest tumor, the number of metastatic sites, and the site of metastases are considered as indirect approximations of tumor burden. After computation of each risk factor, the patient is considered to be at low risk if the score is 4 or less, at intermediate risk with a score of 5 to 7, and at high risk with a score of 8 or more. The WHO prognostic index scoring system has been found to correlate well with survival after conventional approaches to chemotherapy. However, not all of the factors have been critically evaluated to determine whether the graded scoring system is valid (Fig. 63.3).

Therapy

Before the development of effective chemotherapy against malignant GTN, surgical therapy was unsatisfactory for most patients, even for women with nonmetastatic disease confined to the uterus. Since the introduction of methotrexate in the 1950s, malignant GTN has become the most curable of human solid tumors. Therapy should be conducted by physicians who have considerable experience in the management of these diseases, and a

reliable hCG assay should be available so that therapeutic changes can be instituted when necessary. Although chemotherapy has largely supplanted surgery and radiation therapy as the first-line management of malignant GTN, these modalities continue to play an important role in the management of patients with malignant GTN.

Chemotherapy

The initial chemotherapy for malignant GTN should be selected on the basis of one of the systems of classification of malignant GTN (Table 63.4). Patients with nonmetastatic and good-prognosis GTN are initially treated with single-agent chemotherapy regimens using less vigorous therapy with methotrexate or dactinomycin. Patients with poor-prognosis metastatic GTN require initial chemotherapy using combinations of active agents. The most frequently used combination is the EMA-CO (etoposide, methotrexate, actinomycin-D, cyclophosphamide, and vincristine (Oncovin) with folinic acid rescue, dactinomycin alternating with vincristine [Oncovin], and cyclophosphamide) regimen.

Chemotherapy for Nonmetastatic Disease

A commonly used initial chemotherapy regimen for patients with nonmetastatic GTN includes cyclical courses or alternating doses of methotrexate at a dose of 1 mg/kg (maximum 50 mg) on days 1, 3, 5, and 7 with folinic acid rescue administered intramuscularly at a dose of 0.1 mg/kg on days 2, 4, 6, and 8. A variety of other agents and schedules, including daily and “pulsed” weekly dactinomycin, have also been used to treat nonmetastatic GTN with essentially equivalent remission rates. Recent reports indicate that weekly courses of methotrexate administered as a single dose of 30 mg/m^2 have an advantage over other schedules of methotrexate in reducing cost and toxicity and are equally effective. Hematologic and liver chemistry monitoring must be done. Multiple studies show remission rates in this stage of disease to be 98% to 100% when patients are appropriately treated.

TABLE 63.4 Chemotherapy for Malignant Gestational Trophoblastic Neoplasms

Type of Disease	Initial Treatment[a]	Salvage Treatment
Nonmetastatic GTN	MTX/FA or weekly MTX	Single agent, dactinomycin
Combination chemotherapy		

Good-prognosis metastatic GTN	Single agent, methotrexate in 5-d courses	Single agent, dactinomycin
Combination chemotherapy		
Poor-prognosis metastatic GTN	EMA-CO	Other combination chemotherapy

GTN, gestational trophoblastic neoplasia; MTX/FA, methotrexate–folinic acid; EMA-CO, etoposide, methotrexate with folinic acid rescue, dactinomycin alternating with vincristine (Oncovin), and cyclophosphamide.

While methotrexate and dactinomycin continue to be the mainstays of treatment for low-risk disease, there is no consensus on a single superior regimen. The Gynecologic Oncology Group, a multi-institutional collaborative association, is presently accruing patients into a randomized, phase III trial of weekly intravenous methotrexate versus pulsed dactinomycin as primary management for low-risk GTN. Until the results of this trial are realized, many clinicians prefer to utilize methotrexate as their initial chemotherapy, given its relatively lower side effect profile. For those who fail methotrexate chemotherapy, salvage rates with single-agent dactinomycin remain as high as 74%.

The major goals of therapy for patients with nonmetastatic GTN include administration of active, relatively nontoxic regimens of chemotherapy with close hCG level monitoring. For most of these patients, chemotherapy alone is adequate treatment and surgery is unnecessary. However, primary hysterectomy may be used for patients who desire sterilization, because this may reduce the amount of chemotherapy necessary to achieve remission.

Chemotherapy for Good-Prognosis Metastatic Disease

Initial therapy with single-agent methotrexate or dactinomycin is also preferred for patients with good-prognosis metastatic GTN. For these patients without high-risk factors, the ultimate sustained remission rate approaches 100%. Patients may be treated with weekly intramuscular methotrexate at 30.0 mg/m^2 or with repetitive 5-day cycles of methotrexate administered intravenously at a dose of 0.4 mg/kg per day. Similarly, dactinomycin may be administered intravenously daily at a dose of 500 μg or a weekly

“pulsed” dose. Chemotherapy is repeated every 14 days or as soon as permitted by the toxic effects. Again, hematologic and liver chemistry monitoring must be done. Remission rates with either agent are approximately 60%, and most drug-resistant patients are

salvaged with the alternative single agent. Occasionally, patients may require hysterectomy or other surgical procedures to extirpate loci of disease or a change in therapy to multidrug chemotherapy.

Chemotherapy for Poor-Prognosis Disease

Multidrug chemotherapy is selected as the initial therapy for patients with poor-prognosis metastatic GTN. Survival is poor for this group if the initial therapy is with only a single agent, and it is important to diagnose poor-prognosis, high-risk features in these patients so that appropriate initial therapy may be selected.

The most successful and least toxic multiagent regimen is EMA-CO. Other salvage regimens include MAC (methotrexate, actinomycin D, and cytoxan) and the modified Bagshawe regimen of hydroxyurea, methotrexate, vincristine, cyclophosphamide, dactinomycin, and doxorubicin (Adriamycin). Because VP-16, cisplatin, 5-FU, vinca alkaloids, and bleomycin all demonstrate activity against GTN, other salvage regimens are based on combinations employing some of these agents. Regardless of regimen, another cycle of chemotherapy is administered as soon as toxicity from the previous cycle has cleared. Although toxicity may be marked with these combinations, aggressive initial multiagent chemotherapy is usually necessary to ensure optimal survival for patients in this category. Patients with poor-prognosis metastatic GTN should be treated at centers that specialize in the therapy of patients with GTN, as physician experience with the therapy of this disease appears to improve the outcome for these patients. At the John I. Brewer Trophoblastic Disease Center, over 93% of 30 patients with metastatic high-risk GTD were cured after treatment with EMA-CO, often in conjunction with brain radiation and surgical resection of sites of persistent tumor and salvage platinum-based chemotherapy.

Patients with poor-prognosis metastatic GTN who have failed standard chemotherapy regimens are extremely challenging in terms of designing appropriate coordinations of chemotherapy and other therapeutic modalities to produce salvage. Frequently, patients must be treated without regard for toxicity and must be supported through episodes of profound marrow suppression, sepsis, and nutritional deprivation to have a chance at salvage.

Surgical and Radiation Therapy

Hysterectomy

Because of improvements in chemotherapy, hysterectomy is rarely indicated as the initial therapy for women with malignant GTN. However, for patients with nonmetastatic or good-prognosis metastatic GTN with uterine disease, hysterectomy appears to decrease the duration of hospital stay and number of courses of chemotherapy required to achieve remission. Delayed or secondary hysterectomy is required for approximately 10% of patients as salvage therapy in these categories, but chemotherapy alone is successful in curing approximately 85% of patients with nonmetastatic and good-prognosis metastatic GTN. Among women with poor-prognosis metastatic GTN, preservation of childbearing capacity must be of secondary importance, but primary or delayed hysterectomy does not appear to

offer as many benefits as in the therapy of patients with low-risk disease.

Surgical procedures for the purpose of removing sites of GTN are performed during a cycle of chemotherapy. Theoretically, this prevents dissemination of disease caused by embolization of GTN during the surgical manipulation of tissues. The complications of surgery and wound healing do not appear to be increased by using this approach.

The use of selective uterine artery embolization (UAE) with polyvinyl alcohol particles has become an accepted alternative treatment modality for control of uterine bleeding resulting from leiomyomata or peripartum hemorrhage. A single case report has identified use of UAE in a patient with vaginal bleeding after a diagnosis of low-risk persistent trophoblastic disease following a spontaneous abortion. Spontaneous resolution of elevated hCG was observed, suggesting that UAE may be considered as a potential alternative to chemotherapy. Until further studies are performed, however, embolization remains experimental.

Thoracotomy

Thoracotomy with pulmonary segmental resection has been the most frequently performed procedure other than hysterectomy to remove drug-resistant disease. The radiographic regression of pulmonary nodules may lag far behind the response measured by hCG levels, and the persistence of a lung nodule after hCG normalization should not necessarily be interpreted as indicating persistent disease.

There have been reports of success with resection of solitary pulmonary nodules in highly selected women with drug-resistant disease. Before considering pulmonary resection, it is important to exclude the possibility of disease elsewhere. If the patient has not had a hysterectomy, occult pelvic GTN should be evaluated with arteriography or other imaging techniques, such as magnetic resonance imaging. Prompt hCG remission after pulmonary resection predicts a favorable outcome.

Brain and Liver Metastases

Whole-brain and whole-liver irradiation are often used as adjuncts to chemotherapy in the treatment of patients with metastases to these sites. Whole-brain irradiation of 3,000 cGy over 10 days should be instituted immediately in conjunction with chemotherapy after brain metastases are diagnosed. The rationale for this treatment is to prevent hemorrhage from these highly vascular metastases. With this

---

approach, survival rates of approximately 85% are achieved for patients receiving primary therapy for brain metastases; survival rates of approximately 50% are achieved for all patients with brain metastases, including those developing metastases during chemotherapy or at the time of recurrence. An alternate approach includes the combined use of high-dose systemic methotrexate with intermittent intrathecal methotrexate.

Craniotomy is not often required for the primary therapy or diagnosis of brain metastases from GTN and usually is not successful when used alone. However, neurosurgical consultation should be obtained early in the course of therapy in the event that

hemorrhage into brain lesions occurs and craniotomy is required for stabilization of the patient.

Whole-organ irradiation of approximately 2,000 cGy delivered over 10 days may be used to treat liver metastases and prevent hepatic hemorrhage. Some investigators have not used hepatic irradiation to avoid exacerbation of the toxic hepatic effects of chemotherapy. Others have advocated selective occlusion of the hepatic artery by means of ligation or embolization when bleeding has occurred. Patients with hepatic metastases have a poor prognosis and require aggressive chemotherapy with careful monitoring during therapy to maximize the chances for survival. Whole-organ irradiation does not appear to compromise tolerance of aggressive chemotherapy.

Placental Site Trophoblastic Tumors

PSTT is a rare placental neoplasm that is histologically and clinically distinct from other forms of GTN. As PSTTs lack significant volume of syncytiotrophoblast elements and do not secrete high levels of hCG, serum hCG levels are not as reliable a tumor marker as seen in other forms of GTN. However, PSTTs are characteristically comprised of a proliferation of intermediate trophoblastic cells and secrete hPL. Serum hPL levels correlate with tumor volume and are a more consistent marker for this disease.

PSTTs usually are locally aggressive, with invasion into the myometrium. They are typically resistant to traditional chemotherapeutic agents. Most women with PSTT require hysterectomy, although anecdotal reports suggest that a minority may be cured by D&C alone. Rarely, PSTT may pursue a more aggressive course, characterized by distant metastases and rapidly progressive disease.

Monitoring Therapy

Laboratory Evaluations

During chemotherapy, hematologic, renal, and hepatic indices should be monitored carefully. Toxicity from methotrexate- and dactinomycin-based chemotherapy is relatively predictable. Unless a patient is receiving salvage chemotherapy for drug-resistant or recurrent GTN, new cycles of therapy should be withheld unless the total leukocyte count is >3,000 cells/mm^3, the platelet count is >100,000/mm^3, and the renal and hepatic indices are normal. Radiographic studies of metastatic lesions and pelvic examination should be repeated frequently to monitor response to therapy.

More important than radiographic surveillance is closely following the hCG level response during therapy. Sensitive assays of the hCG levels should be performed at 1-week intervals during therapy. Chemotherapy should be changed if the hCG titer has not dropped at least 25% after a treatment cycle or if toxicity does not permit adequate dosage or frequency of administration.

Human Chorionic Gonadotropin Level Remission and

Surveillance

Complete remission is defined as three consecutive weekly hCG levels in the normal range. After remission has been achieved, hCG levels should be followed every 1 to 2 weeks for the first 3 months after completion of therapy, every 2 to 4 weeks for the next 3 months, and every 1 to 2 months for the completion of the first year of surveillance. Recurrent episodes of GTN usually develop within a few months after completion of therapy, but late recurrences develop in a few cases.

Prevention of Recurrent Disease

Despite the accuracy of hCG assays, a tumor burden of 10^4 cells may exist despite normal serum hCG levels. Recurrence rates after therapy for GTN have been 3% to 26%, depending on the patient population being studied. Patients with poor-prognosis metastatic GTN usually have a much higher recurrence rate than patients with low-risk disease. Most investigators agree that maintenance chemotherapy beyond the first normal hCG level should be administered. Typically, patients undergo one additional cycle of chemotherapy beyond the first normal hCG level for patients with nonmetastatic disease, two cycles of maintenance chemotherapy for patients with good-prognosis metastatic GTN, and three to four cycles of maintenance chemotherapy for patients with poor-prognosis metastatic GTN. Toxicity must be considered in continuing therapy for these patients.

Reproduction after Therapy

Most women treated for GTN are successfully cured by chemotherapy without resorting to hysterectomy. Several reports have documented that there is little or no increased risk of congenital malformation of infants from subsequent pregnancies. There may be a slight increase in the incidence of spontaneous abortions in this population, but this increase may be an artifact of increased hCG level surveillance and identification of preclinical pregnancies in women who have previously received treatment for GTN. There also is an increased incidence of repeat molar gestation in patients who have had a prior hydatidiform mole. Patients who have received intensive therapy for poor-prognosis metastatic GTN often undergo hysterectomy during therapy or may develop ovarian failure as a result of prolonged multidrug chemotherapy. Only a few patients in this category with uterine conservation are able to conceive or desire to attempt pregnancy after therapy.

Although the risk of congenital anomalies is not significantly increased after chemotherapy for malignant GTN, obstetric complications may be increased. Major obstetric complications can be observed in as many as 9% of these pregnancies. The incidence of placenta accreta in particular appears to be increased.

Women treated for malignant GTN are typically counseled to delay pregnancy through the first year of hCG surveillance in order to prevent diagnostic confusion of elevations in serum hCG with persistent or recurrent GTN and to avoid complications of such disease during a new pregnancy. However, modern imaging modalities allow feasible identification of a normal intrauterine pregnancy, and studies suggest that those who conceive within 12

months of completing chemotherapy are not at increased risk of relapse. In a review of 230 women who became pregnant during the first year after therapy at the Charing Cross Hospital in London, 71% delivered at full term, and an increased rate of spontaneous abortion, stillbirth, and congenital anomalies was not observed. While most clinicians continue to recommend contraception during the first year of surveillance, women who do conceive may be counseled of a likely favorable outcome. Due to the increased risk of subsequent molar disease, hCG testing 6 weeks postpartum in these women should be considered.

Summary Points

- GTN represents a spectrum of human tumors, ranging from benign with potential malignant sequelae to highly malignant.
- Primary hydatidiform mole (complete) usually presents as a pregnancy with threatened first-trimester vaginal bleeding. Other frequent findings include discordant uterine size, ovarian cystic enlargement, and hyperemesis but may also include hyperthyroidism and preeclampsia.
- Evacuation of hydatidiform mole is best done by suction D&C, with caution used regarding trophoblastic deportation and pulmonary embolization.
- Individualization of therapy is critical for successful treatment of patients with GTN. Although chemotherapy is the primary modality for therapy, surgery and radiotherapy may also have a role.
- hCG is a sensitive and reliable marker for GTN and can be effectively used to aid in diagnosis, monitor therapy, and maintain follow-up evaluation.

The Special Approach to Solving the Profession's Liability Crisis, Improving Patient Safety, and Preventing Medical Errors

Louis Weinstein
Jason K. Baxter

> *Something deeply hidden had to be behind things.*
>
> —Albert Einstein, 1879–1955

Issues surrounding professional liability in medicine have been present for many years, but only recently has medical malpractice, because of the high cost of liability insurance, become a major focus for health care providers. During this time interval, there have been three periods labeled as “malpractice crises.” The first crisis appeared in the early to mid 1970s. During this time, the frequency and severity of claims rose dramatically while the coffers of the insurance companies were depleted by the recession following the Arab oil embargo. Many insurance companies stopped writing policies, leaving many physicians without coverage. Tort reform started to occur with MICRA (California's Medical Injury Compensation Reform Act), becoming the poster child and the sole single success continuously cited by those pushing tort reform. Medical societies started their own insurance carriers, and many states established joint underwriting associations and various funds to soften the financial blow to physicians. During that time and up to the current situation, minimal effort was made to address the underlying problems of preventable medical errors and an unsafe health care system.

The second crisis occurred in the mid 1980s. The key issue that time was the marked increase in liability insurance cost, not its availability. The rate of return for the insurance companies plummeted secondary to the marked decrease in interest rates. Occurrence policies transitioned to claims-made policies, with the physician responsible for large tails. This helped to keep physicians practicing in the same location, as it became prohibitively expensive to move to a different state. Other states adopted various tort reform measures, and eventually, the crisis abated. Unfortunately,

the issue of preventable medical errors and an unsafe health care system again was not addressed.

The current crisis is different because of the inability of the physician or institution to pass on the increased costs of liability insurance and the major emphasis of the public, industry, and government on improving patient safety and preventing medical errors. The crisis is most felt by specialties such as obstetrics, orthopedics, neurosurgery, and radiology. Liability insurance is available, but it is primarily an economic issue, as most physicians can obtain coverage but at a premium that makes it less likely that they can continue their current practice.

During the last 20 years, health care spending has increased dramatically as technology has improved and patient expectations have risen. This has resulted in a proliferation of avoidable errors with increased costs to care for those who suffer harm. The end result is a linear increase in the cost of professional liability insurance and the costs associated with litigation.

This problem is especially evident in the practice of obstetrics because of the large number of patient interactions that occur over a short time period, resulting in an increase in the number of adverse events or potential adverse events. It is important to understand that the definition of an adverse event is one that results in unintended harm to the patient that is not related to the underlying disease or clinical condition and is secondary to an act of commission or omission. Although serious adverse events are infrequent in a busy obstetric service, they do occur, are often preventable, may result in an injury, and have the potential to become a legal action. A recent publication revealed that 5% of obstetric patients experienced an adverse or potentially adverse event and that 87% of the problems were due to errors. The most common were system errors such as inadequate staff, physician, or operating room availability and lack of uniformity of care.

There is abundant misinformation cited by physicians about the malpractice arena such as number of frivolous claims, financial outcome of claims, and the rarity of medical errors. The physician is most happy if there are very few claims and all are dropped or won in court. The physician, the insurer, and the defense attorney desire secrecy, deny fault, try to place blame on someone else, and prolong the process, thus making it expensive for the plaintiff to continue.

Most physicians believe that frivolous litigation (claims with no scientific basis) are common and costly. In a review of 1,452 closed malpractice claims, 3% of the claims had no verifiable medical injury and 37% did not involve errors. The vast majority of these claims did not result in any compensation, while the majority that did involve error resulted in compensation. The obstetrician–gynecologist was most frequently sued followed by the general surgeon. Eighty percent of the claims involved injuries that caused significant disability or death. Payment occurred in the absence of injury in 0.4% of claims, payment in the absence of error in 10.0%, and no payment in the presence of error in 16.0%. The authors concluded that eliminating all claims that did not involve errors would decrease the direct costs by 13% to 16% and that most of these claims resulted in no payment. The malpractice system did well in compensating those patients who had legitimate claims, but

17% of claims in which an error occurred received no compensation. The overhead costs of the total system were extraordinary, with the plaintiffs only receiving 54% of total compensation paid. Other than preventing medical errors, the efforts of reform should be placed in improving the efficiency of the system in order to decrease the exorbitant overhead costs.

The current professional liability crisis has reawakened the interest in tort reform, a concept that has been discussed for over 30 years. At a conference on medical malpractice policy, it was observed that the political stakeholders on one side lobbied for adoption of a California MICRA-style tort reform to discourage lawsuits and limit recoveries, while the academic community was unanimous that traditional tort reform is an incomplete solution to a critical problem. The emphasis of most medical professional societies has been on seeking tort reform with the imposition of noneconomic damage caps and contingency fee limits. The purpose of tort reform has been on reducing liability for medical errors and not on error prevention. Both Studdert and colleagues and Kessler and associates have demonstrated that the pursuit of tort reform over the last 30 years has had minimal results, with little attention paid to improving the quality of medical care and the safety of the health care system. Also, the tort reform currently being pursued has not been linked to newer developments in evidence-based medicine or the increasing number of preventable medical errors. These contrary positions cannot be reconciled.

An attempt at federal tort reform, the HEALTH Act of 2003 (Help Efficient Accessible Low-cost Timely Health Care) has stalled in Congress several times and is unlikely to pass in the future. The name of the act is ironic, as health care is often not timely, clearly not efficient, and certainly not low cost. Nothing in the act addresses the issues of patient safety and preventable medical errors. If the federal government is truly committed to improving patient safety, it should mandate and assist in the funding of a national electronic health record. Patient safety and quality of care are adversely affected on a daily basis by the common occurrence of missing clinical information. A national electronic health record will immediately improve patient safety, dramatically increase efficiency, and decrease costs with the likelihood of a decrease in liability actions.

Tort reform supporters cite the passage in 1976 of MICRA in California with the resultant effect being that liability insurance rates have risen at a slower pace than those in other states. The noneconomic damage cap of $250,000 is important for tort reform but is unfair to injured patients, as it has not been adjusted for inflation since its passage.

The tort reform represented by MICRA is in reality an *insurance reform act*. Caps will have little effect on frivolous lawsuits, as the amount of money involved in these types of suits is usually below the cap. While the limits on attorney contingency fees may be the most important part of MICRA, this is one of the major blocks to passage of tort reform, as the majority of politicians who would vote at the national level are attorneys. The problem with any type of tort reform is that it is a *back end approach*. No evidence exists that it addresses the real issues: preventable medical errors, improved patient safety, full disclosure of all adverse events, and poor practitioners. These same issues have been present during all of the professional liability crises. The only rational solution to solving the professional liability crisis is to deal directly with the issues of patient safety and

medical errors.

Patient safety must be the predominant theme in any discussion of liability issues. A recent study analyzed 4 months of medical care in a 40-bed medical unit of a major teaching hospital. Adverse events were experienced by 8% of patients, and 4% experienced near misses. Only 55% of adverse events, 34% of medical errors, and 31% of near misses were documented in the medical record. No hospital incident reports were filed in any of the events.

A university analysis of 90 closed claims in obstetrics–gynecology identified specific factors that may have contributed to adverse events in 78% of cases, with most having more than one factor. Communication problems existed in 31% of cases, clinical performance in 31%, diagnostic issues in 18%, and patient behavior in 14%. It is these types of issues that must be dealt with before any professional society or group of physicians can expect to see tort reform.

Five years after the Institute of Medicine report *To Err Is Human*, progress in the prevention of medical errors and improvements in patient safety has been slow to nonexistent. The rapid advances in medical technology and the increasing workload secondary to staff reductions have markedly elevated the number of preventable medical errors. An attempt by the Agency for Healthcare Research and Quality to determine a national estimate for the improvement in patient safety by using existing measures has demonstrated little to no improvement since 1999. The number of deaths that occur yearly in U.S. hospitals appears to have doubled since the 1999 Institute of Medicine report. While the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has attempted to improve patient safety, medical errors and deaths have continued to increase. The JCAHO review of hospitals with the threat of loss of accreditation produces transient compliance in addressing patient safety issues. Historically, after the review, the majority of hospitals return to “business as usual.”

It is difficult to evaluate any improvements in patient safety, as data are not available to yield a credible result. One reason that data are difficult to obtain is that the vast majority of incidents occurring in a hospital are actually not reported to any oversight body. Pronovost and coworkers have proposed two measures that can be captured with minimal bias: (a) how often are patients harmed, and (b) how often do clinicians provide appropriate interventions? Two other measures that are elusive to track are (a) have clinicians learned from their mistakes, and (b) how successful are clinicians and hospitals in creating a culture of safety?

A major change in the culture of medicine is required in order to improve patient safety and prevent medical errors. The assumptions that must be addressed to change the culture are that medicine is extremely complex but can be mastered by one person, perfection is an obtainable goal for the individual, physicians are fierce supporters of autonomy, the leadership of the physician cannot be questioned, and that full open disclosure of all medical errors will increase liability actions. Lessons learned from the aviation industry are that a complex system like medicine requires teamwork, the captain cannot be the master of all systems, any member of the team can challenge another when safety is involved, information obtained about adverse events or near misses can be used to improve the

system to prevent future occurrences, and full open disclosure increases public trust. These lessons are directly applicable to medicine and must be used in order to improve patient safety and prevent medical errors.

The traditional way that most hospitals respond to patient safety issues is to develop a hospital policy to deal with a previous adverse event or system failure. It is rare that members of the medical staff are familiar with all the hospital policies that are in place. It is unusual for any type of system to be in place for implementation or follow-up of results of the policy. Hospitals continue to be reactive to patient safety issues and avoidable medical errors. It is obvious that only a proactive approach will ever change the current dangerous nature of the U.S. health care system.

The Institute for Healthcare Improvement (IHI) has recently announced its 5 Million Lives campaign, an attempt to protect patients from 5 million incidents of medical errors over a period of 24 months, ending December 9, 2008. This campaign follows the success of the 100,000 Lives campaign. In that campaign, there were 3,100 participating hospitals, and an estimated 122,000 inpatient deaths were prevented over 18 months following the six interventions recommended by the IHI. The six interventions implemented that had been proven to prevent avoidable deaths were (a) availability of rapid response teams, (b) evidence-based care for acute myocardial infarction, (c) prevention of adverse drug events, (d) prevention of central line infections, (e) prevention of surgical site infections, and (f) prevention of ventilator-associated pneumonia (Table 64.1). Currently, the IHI estimates that there are 40 to 50 incidents of harm that occur for every 100 hospital admissions. With 37 million hospital admissions each year in the United States, this results in approximately 40,000 injuries in hospitals daily for a yearly amount of

15 million injured patients. Along with the previous six interventions, six new ones that have been added are (a) prevention of methicillin-resistant *Staphylococcus aureus* (MRSA) infection, (b) reduce harm from high-alert medications (heparin/insulin), (c) reduce surgical complications, (d) prevent pressure ulcers, (e) deliver reliable evidence-based care for congestive heart failure, and (f) get “boards on board.” In addition to the lives saved, a marked decrease in economic expenditures and liability actions should also result from these initiatives.

TABLE 64.1 Institute for Healthcare Improvement 12 Interventions that will protect patients from 5 million incidents of medical harm

1. Availability of rapid response teams
2. Evidence based care for acute myocardial infarction
3. Prevention of adverse drug events
4. Prevention of central line infections

5. Prevention of surgical site infections
6. Prevention of ventilator associated pneumonia
7. Prevention of MRSA infection
8. Reduce harm from high-alert medication (heparin/insulin)
9. Reduce surgical complications
10. Prevent pressure ulcers
11. Deliver reliable, evidence-based care for congestive heart failure
12. Get Boards on board

http://www.ihi.org/IHI/Programs/Campaign

The concept of getting the boards on board is very interesting, as traditionally, hospital boards of directors have been very passive in initiating change and accelerating the improvement of care. This concept was discussed in an article by George Annas on the patient's right to safety. Annas presents the treatise of the judicial recognition that hospitalized patients have an explicit right to safety and that hospitals have a duty to implement patient safety measures. He further opines that hospitals that do little to improve patient safety should be viewed as negligent and be sued for negligence when a violation of the right to safety results in a patient injury. He believes that physicians and lawyers should be allies in the patient safety movement and that the patient's right to safe medical care can only be pursued by a legal claim against the hospital and its board. His argument is strengthened by the example of the adoption by anesthesiologists of pulse oximetry, which markedly improved patient safety but only occurred when judges and juries declared it the standard of care.

The majority of the medical errors that occur are system errors, although individual nurses or physicians are often in place to prevent the problem. It has been documented that the office setting has a 10-fold increase in adverse events compared with that found in the hospital (which already has 40 to 50 errors per 100 hospital admissions), but no system exists to address these errors. When one considers the number of patients that this represents and the effects on individuals and their families, it becomes obvious why the public is so enraged over the patient safety issue.

TABLE 64.2 JCAHO's Strategies for Improving the Medical Liability System and Preventing Patient Injury—Major Recommendations

1. Pursue patient safety initiatives that prevent medical injury
2. Promote open communication between patients and

practitioners
3. Create an injury compensation system that is patient-centered and serves the common good.

In 2005, the JCAHO released a white paper report that is a product of its Public Policy Initiative. Entitled “Health Care at the Crossroads—Strategies for Improving the Medical Liability System and Preventing Patient Injury,” the document makes three major recommendations with numerous subrecommendations. The major recommendations include the following: I—pursue patient safety initiatives that prevent medical injury, II—promote open communication between patients and practitioners, and III—create an injury compensation system that is patient centered and serves the common good (Table 64.2). It is critical that the energy, effort, and money spent by practitioners and professional organizations on pursuing tort reform be redirected to devise strategies of change consistent with these recommendations. This will start the process of resolving the professional liability crisis.

Risk Management

The current system of risk management that has been in place for many decades has no proven track record in improving patient safety or decreasing preventable medical errors. Risk managers commonly are senior nurses who are often supervised by semiretired physicians or administrators with minimal expertise in new medical technologies. Those who do have medical experience have been away from clinical practice for a long period of time. Uniformly, they are institutionally supported and have little or no formal training in communication skills or behavior modification. The risk management office typically has three roles to play. The first is loss prevention with resolution of claims at minimal cost to the institution. The second is management of the unresolved claim with assignment to a defense attorney whose prime directive is to protect the institution or insurance company. The third role is risk financing, which is to transfer away as much of the financial risk as possible to protect the institution or insurance carrier. Nowhere is the injured patient considered

or a support system established for the involved health care providers.

An important function of the risk management office is collecting information about the adverse event. The information collected during the investigation is considered secret, with no sharing or discussion with the injured party/family and minimal sharing with the involved physician(s). Usually, the only way for the patient to receive any information about the injury is through legal action. Compensation, even if appropriate, is commonly delayed when it is most needed by the patient or family. Feedback to the health care providers is often absent or markedly delayed. Any education performed uses closed claims data, which takes a long time to become available and has much of the information sealed by the settlement. To prevent repetitive errors or fix system problems, information must be available on a real-time basis and open to all involved in clinical care. The vast

majority of patient errors are from system breakdowns, and the only way to devise systems to prevent these errors is total transparency.

Liability Insurance

Common sources of professional liability insurance are policies purchased from commercial carriers, physician-owned companies, self-insured trusts, or risk retention groups (RRGs). Most insurance carriers base rates on geographic location, with consideration of the frequency and severity of paid claims associated with the specialty in the region. The experience record of the individual physician is rarely considered in establishing the premium. Insurers use class rating, which diminishes the ability of physicians to decrease their individual costs. The level set is different for a physician with a similar practice in another county or state. The justification for this rate structure is based on retrospective data of physicians in that geographic area, as insurers believe that it is too imprecise to base premiums on the experience rating of the individual physician. No meaningful incentives are given to physician groups to improve patient safety or prevent medical errors. This system of rate setting has been in place for many years, and it is time that other approaches are tried. This is unlikely to happen without federal legislation.

Solutions

The proposed solution of tort reform to solve the present professional liability crisis is unlikely to occur at either the federal or state level. Tort reform does not address preventable medical errors (often misconstrued as negligence) or patient safety. This is a back end approach that has been tried numerous times without success. It benefits mostly the insurance industry and does little to assist the injured patient. Three areas that must be dealt with directly in order to eliminate medical errors and improve patient safety are risk management, professional liability insurance, and the tort system.

Risk Management

The name *risk management* is archaic and should be changed to *patient safety and risk prevention*. Risk managers are employed by either the institution or insurance company and are not working for the best interests of the patient or the provider. Risk managers are a major impediment to full disclosure of important information to the patient, family, or health care team. The patient should be the prime focus of the risk prevention team, and the office must act in a proactive manner. A separate office of litigation management should be established to deal with the legal issues involved when a lawsuit has been filed and settlement is considered.

There is a great variation in communications skills among physicians, with few having any formal training in this area. Patient satisfaction has been directly linked to physician communications skills, and communication failures have been associated with an increase in medical errors. Patients who were dissatisfied with their medical care and initiated legal action cite communication issues approximately 70% of time. Physicians with a history of patient complaints are at increased risk of lawsuit. A Veterans Health Administration report documented an underreporting of adverse events within the hospital, but if a patient

incident report had been generated, the tort claim was more likely to end in payment, and the payment was likely to be higher. One study revealed that physicians with a midrange of patient complaints had a 26% increase in malpractice lawsuits, while those with the most complaints had a 110% increase. It must become routine that physician communication skills be assessed and those who are poor communicators be made aware of their deficiencies and corrective action taken.

When a physician is being considered for employment, his or her total work record and litigation history (regardless of outcome) should be reviewed. All past patient complaints should be evaluated to determine if a pattern exists. The methods used to resolve the complaints should be addressed, and evidence should be presented as to what corrective actions or education the physician took to prevent recurrences.

Hospital practitioners are the best observers of the quality of the health care system. The Institute of Medicine's National Roundtable on Health Care Quality stated that the threats to quality are overuse, underuse, and misuse of treatments. Physicians must be willing to report any of these perceived threats or potential system errors noted. Every report must be carefully evaluated, action must be initiated to resolve the issue, and expeditious follow-up must be given to the reporting physician. The hospital staff frequently knows which systems or physicians are putting

---

patients at unnecessary risk. The hospital staff (physicians, nurses, technicians, etc.) working as a team is the *key* to improving patient safety and preventing medical errors. Everyone must be equally empowered to improve patient safety and prevent medical errors. The reporting system must be user-friendly and nonpunitive in nature.

The total medical enterprise must protect the patient from avoidable medical injury and improve patient safety. Preventable medical errors must be identified early, acknowledged completely to the patient and family, and proper compensation provided expeditiously when appropriate.

The cloak of privileged communication and protected peer review should be removed if the public is to regain trust in the health care system. This is clearly evidenced by the book entitled *Wall of Silence*, in which patients and families detail their outrage over the current lack of disclosure of medical mistakes. Florida is taking an early lead in opening peer review by its amendment to its state constitution that peer review meeting minutes be made public.

A new movement exists to support the importance and positive impact of early full disclosure of any adverse outcome to the patient. Patients want full disclosure of all medical errors. They want to know that an error occurred, what specifically happened, why it happened, how the error will be corrected, how the error will be prevented from happening again, and an apology. The actual practice of full disclosure is uncommon, but it is the only approach to dealing with a medical error. The major barrier to full disclosure has been the risk manager's fear of malpractice litigation. Despite this fear, full disclosure has not been demonstrated to increase the risk of legal action to either to the physician or institution.

A relatively new approach to full disclosure is the issuance of an “I'm sorry” letter. More states are adopting laws that exempt expressions of regret or apology from being considered an admission of liability. Regardless of state laws, full disclosure is the right thing to do and unequivocally what patients want and deserve. Although physicians often disclose an adverse event, they “choose their words carefully,” often not directly stating that an error occurred.

There is a major difference between an apology and “I'm sorry.” An apology acknowledges responsibility for an adverse action that is associated with an expression of remorse. An adverse action is an injury to the patient that should have been avoided if the physician or system had performed in a proper manner. An unfortunate outcome that was not related to a physician or system error is best dealt with by “I'm sorry,” as there is no acknowledgment of an error. Physicians have to learn and understand the apology process. The four parts of an apology are (a) acknowledgment of the offense; (b) explanation for committing the offense; (c) expression of remorse, shame, forbearance, and humility; and (d) some form of reparation. Other considerations need to be given to who offers the apology, to whom it is given, and the timing of the apology. An effective apology is a profound healing event, and healing is what the injured patient and family truly desire.

An excellent example of full disclosure and its benefits is the 3R's (Recognize, Respond, Resolve) program of the Colorado Physicians Insurance Company (COPIC). The program assists the physician in responding quickly to a patient with an unanticipated medical outcome, communicating with the patient in an empathetic manner, and arranging for additional care or services that the patient might need as a result of the outcome. The program began October 2000 and through December 2006; there were 3,248 qualifying incidents from 2,835 enrolled physicians. During this time, there were 731 patient reimbursements for a total of $3.9 million, or an average of $5,400 per paid incident. Reimbursement is capped at $5,000 for loss of time and $25,000 for medical expenses. Of the 731 patients receiving compensation, 7 proceeded to legal action. Physicians in the 3R's program must agree to prompt reporting of adverse events, full disclosure of all patient injuries, participation in education programs on effective physician patient communication, and making changes to prevent future medical errors. Resolution of the event with financial compensation is not reported to the state or National Practitioner Data Bank. By this process, physicians accrue points used to obtain preferred premium rate status. This type of program could easily be initiated on a national level, and professional medical organizations should spearhead this approach.

Insurance

As professional liability insurance becomes extremely expensive or unavailable, the use of RRGs or insurance captives has increased. The advantages of each are that they better align the risk management program with the discrete provider institution, and risk experience data are much easier to obtain with a known medical staff. Weaknesses of the RRG or captive are that they are poorly diversified, suboptimally capitalized, and solely beholden to the sponsoring institution or physician group. The RRG and captive that have been successful have an aggressive system of claims management in place and educational

efforts for the physicians that focus on patient safety, communication skills, and complete elimination of preventable medical errors. Organizations such as the COPIC identify patient injuries quickly and focus on the needs of the patient or family with early intervention.

The beneficial role of excess insurance coverage has not been well evaluated, and most state patient compensation funds are coming to a close. Having excess coverage has become a self-fulfilling prophecy for large awards. Rarely has a physician or institution become responsible for paying an award that exceeds the current limits of insurance. As the cost of excess coverage has become prohibitive, most hospitals and providers have eliminated or lowered the limits of the excess coverage.

Insurance actuaries are responsible for setting premiums based on frequency and severity of paid claims linked to specialty and practice location. Comparison rates for commercial providers who are in the business of generating a profit are used for a base. Actuaries are extremely conservative, and their approach focuses on protection of the assets of the insurance company or institution. The setting of rates should be based on the individual physician's experience, accounting for claims made, accumulated settlement history, record of any medical staff issues, number of patient complaints, and some analysis of mode of practice. Board certification and maintenance of certification should be required for the insured physicians.

Consideration must be given to a new paradigm for 21st century insurance coverage called *enterprise liability*. In this model, the enterprise (health care system) becomes responsible for the safety and quality of all health care practiced within the institution. All parties, including the board of directors of the institution, must have a common organizational goal—that being the elimination of all preventable medical injuries. Institutions are able to develop databases of risk experience that are more reliable than that done for the individual physician, allowing actuaries to better determine liability exposure. Because the institution has more financial reserves and is involved in many more cases than the individual physician, the motivation for the elimination of preventable medical errors should be paramount. The shift of liability coverage from individual to institution is more likely to stabilize rates, as only the entity becomes responsible. An increasing trend for enterprise liability has been the number of physicians becoming employed by the institution as hospitalists or in obstetrics, the rapid rise in the Laborist movement—becoming full-time, hospital-employed obstetric providers.

Assisting the Tort System

While the health care system works to eliminate all preventable medical errors, the legal system needs to eliminate false or misleading expert witness testimony for either the plaintiff or defendant. One approach to this would be for medical schools and professional medical organizations in various regions of the country to establish a clearinghouse for evaluation of medical injuries or adverse outcomes. Any board-certified practitioner in the region with documented expertise as established by preset criteria (e.g., peer-reviewed publications, master clinician) could be listed with the clearinghouse. The list of physicians with their documented expertise would be available for public scrutiny. An attorney,

patient, or judicial court could contact the clearinghouse and request an expert review of the medical care rendered. The organization would identify the physician with documented expertise to review the pertinent materials and render a concise report about the medical care. This report would be available for public review and could be used as determined by the requesting party. The fee charged for the expert physician's time would be paid according to an established schedule. In another approach, the same organizations could convene panels of expert physicians to establish clear, concise definitions of standards of care for the majority of common medical issues encountered, removing the legal system from the determination of what constitutes standard of care. The solutions offered by these approaches could return credibility to expert witness testimony.

Hospitals must be required to inform patients about any real or potential medical errors that occur during their medical care. These discussions must be carefully constructed and linked to a process that leads to early dispute resolution and correction of system errors. Patients should receive answers about their treatment and prognosis and about how the costs will be covered for further medical care and loss of earning power.

Both the medical and legal professions need to consider new alternatives to the current litigation process. A legislation entitled the Fair and Reliable Medical Justice Act (S. 1337), which authorized the secretary of Health and Human Services (HHS) to fund ten demonstration project grants to test three alternative dispute resolutions processes, was introduced in 2005 and discussed in committee June 2006 but has not yet been implemented. Included were early disclosure and compensation, special health care courts, and administrative determination of compensation.

The Early Offers pilot program currently being used by the Indian Health Service under HHS is an example of an alternative dispute resolution process. Using this program, HHS reviews a claim within 90 days of it being filed and assesses its value. The patient has the same 90 days to submit an amount for which the claim can be settled. Both the HHS assessment and the patient's amount are submitted independently to a settlement depository. If the patient's amount is at or below the HHS amount, the case is settled immediately. If the numbers are not close, legal action may ensue, with both offers remaining confidential.

The Kaiser Permanente Institute for Health Policy has suggested new alternatives to litigation that have the potential to promote a more fair and predictable compensation to the injured patient while removing the secrecy surrounding the legal process. The first is “early offer reform,” which offers to the patient payment for all future out-of-pocket medical expenses related to the injury. The second is to develop a list of “avoidable classes of events” that encompass adverse medical outcomes that should not have occurred in a safe medical care system. When one of these events occurs, the provider must make an early offer of an amount that has already been established. An event that occurs outside the established list is then subject to adjudication. The third is the establishment of “medical courts” staffed by full-time expert judges. This type of court would be better positioned to determine

---

if an error was due to negligent medical care versus an adverse outcome beyond the control of the health care system.

Conclusion

The current professional liability system has not been demonstrated to be successful in deterring patient injuries or improving patient safety. Although most physicians and professional organizations believe tort reform to be the answer, it is unlikely to occur and does not solve the problems of preventable medical errors, an unsafe health care system, or negligent medical practice. Therefore, consideration should be given to the 12 interventions shown earlier in the chapter. To solve the professional liability crisis, we need to take a *SPECIAL* approach (*S*afety, *P*revention of error, *E*lectronic health record, *C*ommunication, *I*nsurance reform, *A*lternative dispute process, *L*ives 5 million campaign). Taking this approach will result in improved patient safety, elimination of preventable medical errors, and establishment of an equitable judicial process that will fairly and promptly compensate the injured patient.

Summary Points

- Create a culture that focuses on patient safety and risk prevention.
- Eliminate all preventable medical errors.
- Provide full disclosure of medical errors, adverse events, and near misses.
- Instruct physicians in communication skills and teamwork.
- Develop a national electronic medical record.
- Adopt the 5 Million Lives campaign of the IHI.
- Dissolve the cloak of secrecy regarding peer review and litigation outcome.
- Establish a claims management team to proactively respond to any injured patient.
- Identify neutral experts to review adverse medical outcomes.
- Establish evidence-based standards of care for common events.
- Increase the use of alternative forms of dispute resolution.
- Remove subquality physicians from practice.

Appendix: Evidence-Based Approach to Obstetrics and Gynecology

Ronald S. Gibbs

In this appendix, a number of tools are provided that are necessary for interpreting scientific literature.

What Are α, ß, and Power?

In the methods section of many articles, the authors give an alpha and a beta. *Alpha* (α) equals the probability that the different results found in an experiment occurred by chance. This is commonly set at <5%. In some situations, α is set at 1% (α <0.01). A type I error occurs when the null hypothesis is true but is incorrectly rejected, leading one to conclude that two factors are associated.

Beta (ß) is the probability of failing to find a specified difference to be statistically significant. 1-ß is defined as the *power* of a test, that is, the ability to be able to say that enough subjects in both groups have been sampled so that a very small difference between the two groups will not have been missed. Power is usually set at 0.8. A type II error occurs if the null hypothesis is not rejected when it should be, leading one to conclude incorrectly that two factors are not associated.

What are Sensitivity, Specificity, and Positive and Negative Predictive Values?

Sensitivity, *specificity*, and *positive and negative predictive values* are terms that have made their way into daily clinical conversations. Here is the best way to explain them.

Test	Gold Standard; Diseased	Gold Standard; Diseasefree
Positive	a = Number of individuals diseased and positive	b = Number of individuals diseasefree and positive
	c = Number of individuals diseased and negative	d = Number of individuals diseasefree and negative
Negative	a + c = Total number of diseased	b + d = Total number of diseasefree

individuals individuals

$$\text{Sensitivity} = \frac{a}{a+c} = \text{The proportion of the diseased labeled positive by the test.}$$

$$\text{Specificity} = \frac{d}{b+d} = \text{The proportion of the diseasefree labeled negative by the test.}$$

$$PV+ = \frac{a}{a+b} = \text{Positive predictive value.}$$

$$PV- = \frac{d}{c+d} = \text{Negative predictive value.}$$

How Is Sample Size Determined?

The sample size is determined by setting the α and power (1-ß) and estimating the differences in rates for the primary outcome. Then, the sample size (i.e., the number of subjects in each arm of the study) may be obtained from standard tables or computer programs. For a given α and

ß, the sample size increases with decreasing differences in rates of the outcome.

Approximate Sample Size When α = 0.05 (one tailed) and Power = 0.8 (i.e., ß = 0.2) versus Difference in Rates of Primary Outcome

Differences in Rates of Outcomes between Groups (%)	Approximate Sample Size (Number of Subjects Per Study Arm)[a]
60	10
50	15
40	25
30	30
20	75
10	250
5	335

[a]Actual sample size depends on the specific rates. For example, the sample size differs whether the difference in rates is 50% versus 30% compared with 40% versus 20% even though the differences in proportion is 20% in both examples.

For example, you desire to do a study of prophylactic antibiotics after radical hysterectomy. You estimate that the rate of infection without prophylaxis in 40%, whereas the rate with prophylaxis will be 10% (i.e., a 30% absolute difference in rates of the primary outcome).

If α = 0.05 and power = 0.80, you will find that the sample size will be 30 subjects per arm.

Now, if you decide to study prophylaxis for dermoid cystectomy and estimate that the rates with and without prophylactic antibiotics are 10% and 5%, respectively (i.e., a 5% absolute difference in outcomes), then with α = 0.05 and power = 0.8, here the sample size increases dramatically to 335 subjects per arm.

What are Relative Risk and Odds Ratio, and How Do They Differ?

		Exposed: Yes	Exposed: No
Diseased	Yes	A	b
	No	C	d
		N_1	N_0

$$\text{Relative risk (RR)} = \frac{\text{Risk for the exposed}}{\text{Risk for the unexposed}} = \frac{a/N_1}{b/N_0} = \frac{a \times N_0}{b \times N_1}$$

		Exposed: Yes	Exposed: No
Diseased	Yes	a	b
	No	c	d

$$\text{Odds ratio (OR)} = \frac{\text{Exposure odds among cases (diseased)}}{\text{Exposure odds among controls (not diseased)}}$$

$$= \frac{\frac{a}{a+c}}{\frac{b}{b+d}} = \frac{\frac{a}{c}}{\frac{b}{d}}$$

$$= \frac{ad}{bc}$$

For rare diseases, a + c is approximately equal to c, and b + d is approximately equal to d.

In case-control and follow-up studies, the magnitude of an association is measured between the exposure and the disease.

In follow-up studies, the strength of an association is estimated by calculating the positive relative risk.

In case-control studies, the odds ratio is typically used. When rare diseases are studied, the OR from a case-control study with appropriate controls is very similar to the RR from a follow-up study.

In the figure below, the effect of antibiotics for preterm premature rupture of membranes (PROM) are shown. The vertical hatch mark shows the RR, and the horizontal line shows the 95% confidence interval (95% CI). If the 95% CI excludes 1.0, then the RR is statistically significant.

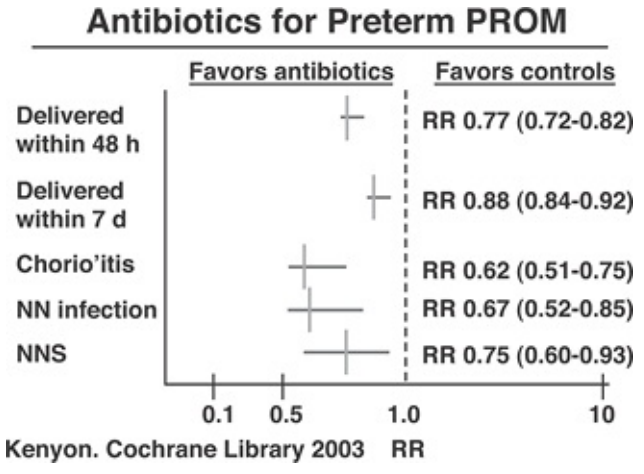

Figure App.1 Antibiotics for preterm premature rupture of the membranes. (*NN*, ???;

NNS, ???; *RR*, relative risk.) (From Kenyon. Cochrane Library, 2003.)

TABLE 1. Two-by-two Matrix of Possible Test Results for a 1-Hour Glucose Tolerance Test

	Gestational Diabetes Present	Gestational Diabetes Absent
Glucose tolerance test		
Positive	True positive (case detected)	False positive (false alarm)
Negative	False negative (case missed)	True negative (true normal)

From Richardson DK, Schwartz JS, Weinbaum PJ, et al. Diagnostic tests in obstetrics: a method for improved evaluation. *Am J Obstet Gynecol* 1985;152:613–618.

What Is a Receiver Operator Characteristic Curve?

Receiver operator characteristic curves are commonly used to show the relationship between sensitivity and false-positive rates for a diagnostic test.

Here one sees the relationship between the 1-hour plasma glucose and the diagnosis of gestational diabetes. With Carpenter's cutoff (= 130 mg/dL), the sensitivity is high but at a cost of more false positives. With O'Sullivan's cutoff (= 143 mg/dL), there are fewer false positives but at the cost of a lower sensitivity.

How Is the Level of Evidence Graded?

There are several similar systems for evidence grading. Shown below is the method outlined by the U.S. Preventative Services Task Force. It is used in this text as well as in American College of Obstetrics and Gynecology (ACOG) publications.

I: Evidence obtained from at least one properly designed randomized controlled trial.

II-1: Evidence obtained from well-designed controlled trials without randomization.

II-2: Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group.

II-3: Evidence obtained from multiple time series with or without the intervention. Dramatic results in uncontrolled experiments also could be regarded as this type of evidence.

III: Opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.

Based on the highest level of evidence found in the data, recommendations are provided and graded according to the following categories:

Level A: Recommendations are based on good and consistent scientific evidence.

Level B: Recommendations are based on limited or inconsistent scientific evidence.

Level C: Recommendations are based primarily on consensus and expert opinion.

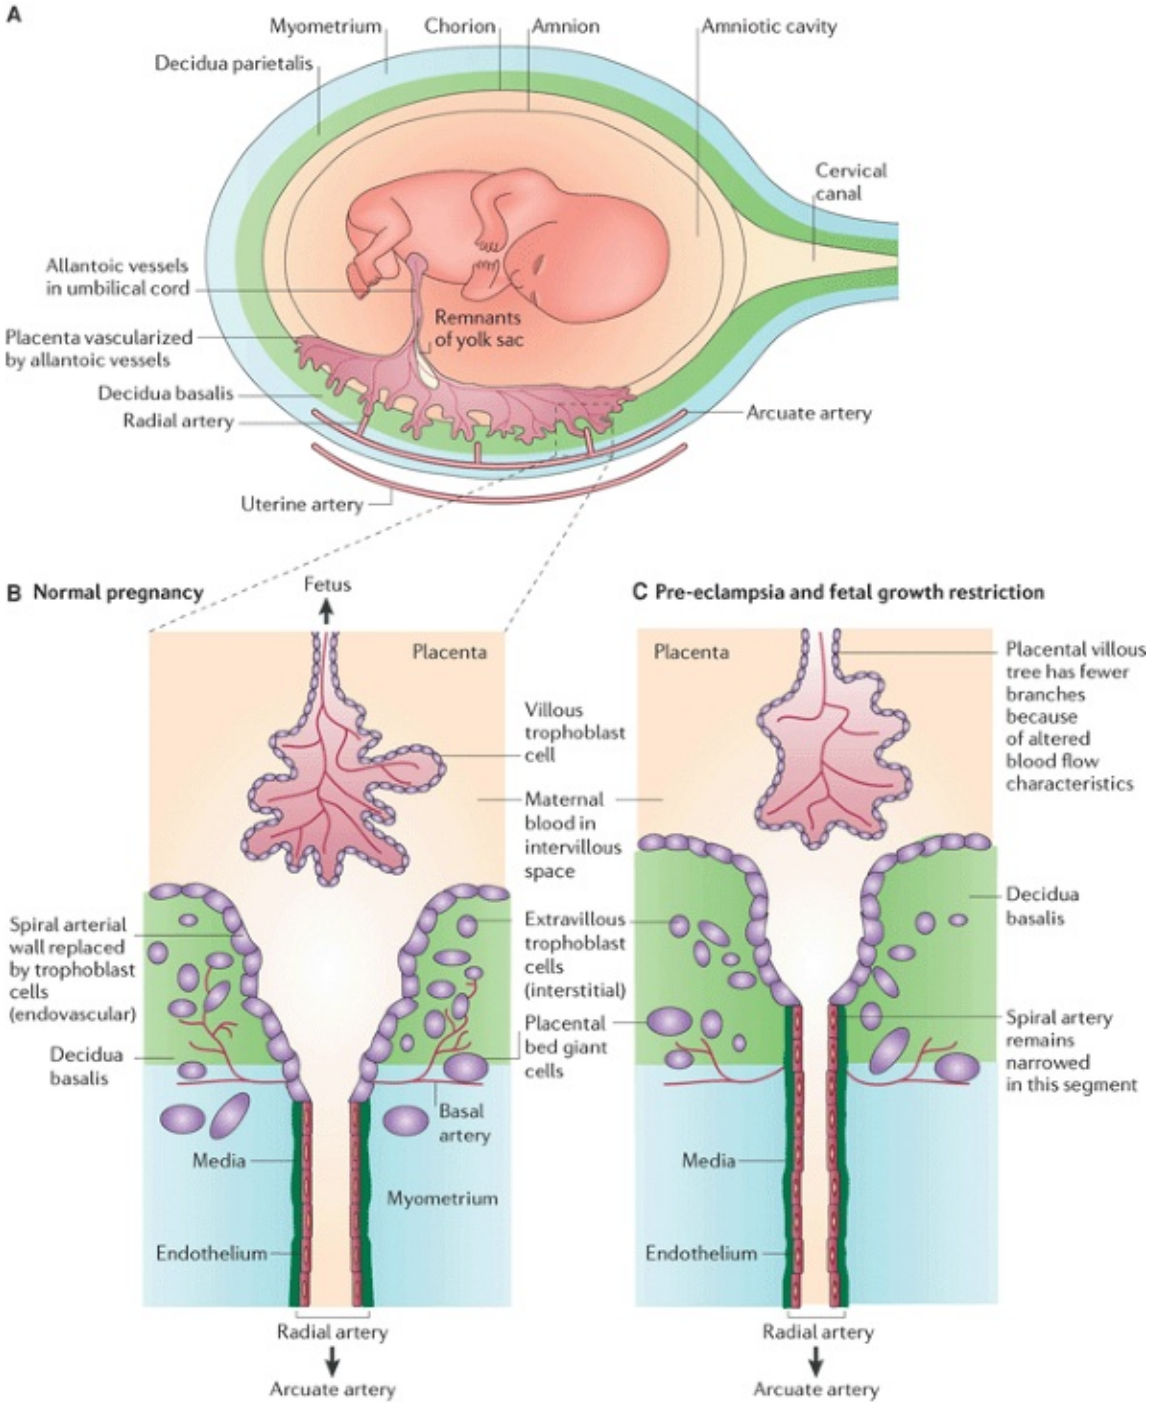
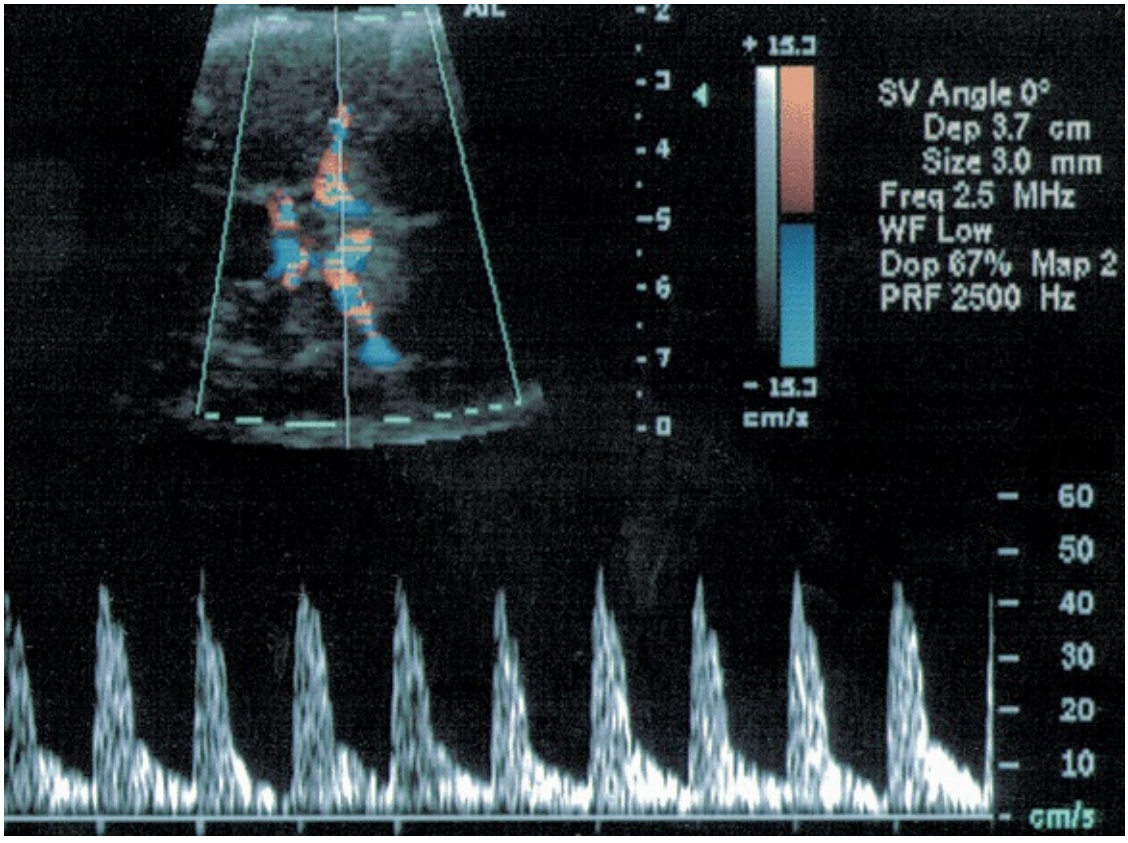
Color Plates



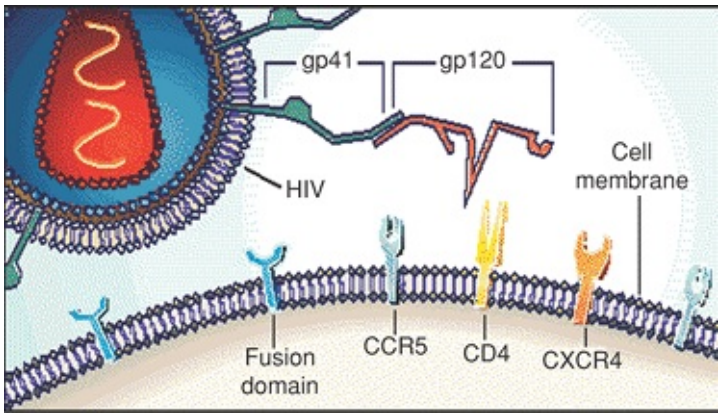
Color Plate 13.1 (A) Gross anatomy of uterus with placental implantation and blood supply. Remodeling of the spiral arteries in normal pregnancy **(B)**, demonstrating the

normal dilation of the artery by means of loss of elastic vascular media and preeclampsia or fetal growth restriction **(C)** with abnormal invasion and remodeling that impedes the development of low-resistance flow. (Reprinted from Moffett A, Loke C. Immunology of placentation in eutherian mammals. Nat Rev Immunol 2006; 6(8):584-594. Copyright © Nature Publishing Group, with permission.) (see black and white image)

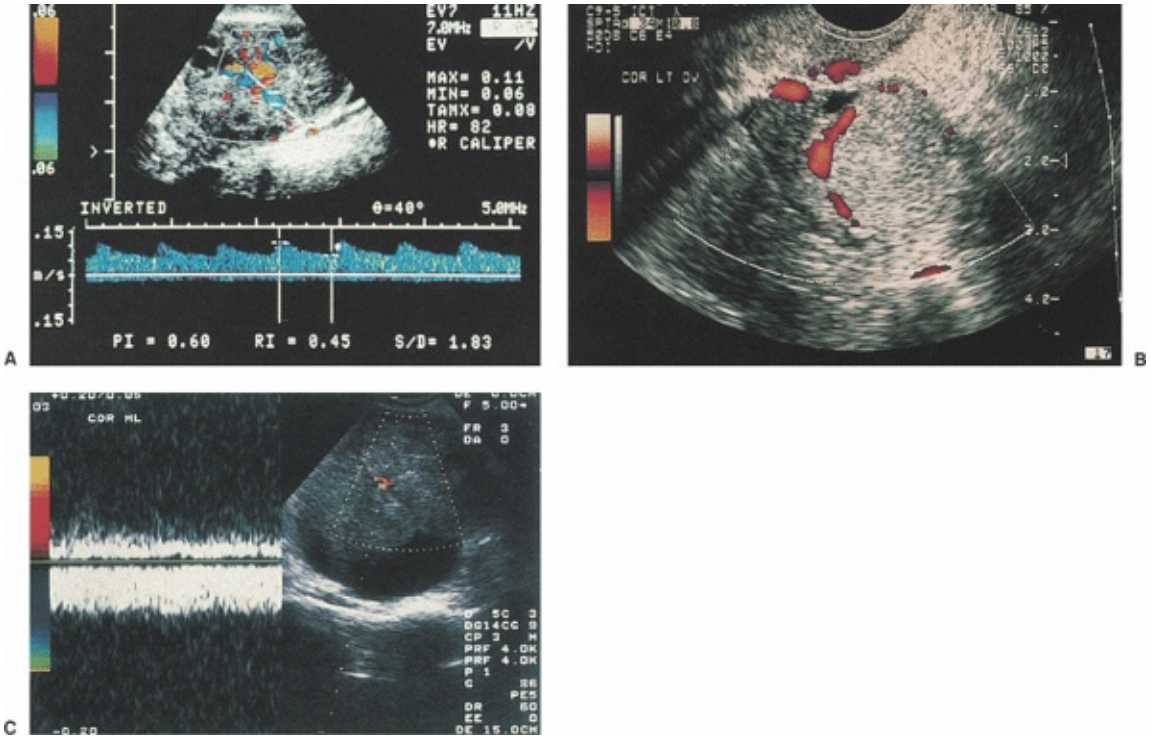


Color Plate 13.6 The ultrasound color Doppler image shows the circle of Willis and the MCA branches. Also shown is the near 0-degree angle of insonation and a normal MCA FVW. (see black and white image)

Color Plate 14.5 Placenta **(A)** and infants **(B)** delivery from a monochorionic, diamniotic twin gestation complicated by TTTS. Note the larger placental area associated with the recipient twin and the palor and impaired growth of the donor twin. (see black and white image)



Color Plate 20.1 Early in the course of HIV infection, the R5 strain viruses predominate, but eventually both X4 and R5 strains are recovered. (From Levy JA. Infection by human immunodeficiency virus—CD4 is not enough. *N Engl J Med* 1996;335:1525–1527, Figure 1A. Illustrations © Massachusetts Medical Society, with permission.) (see black and white image)

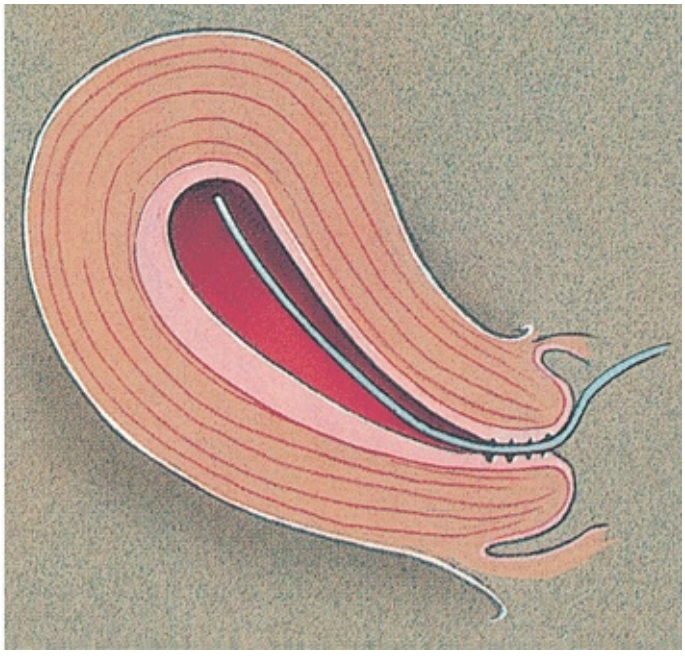


Color Plate 30.2 Transvaginal color Doppler sonography. **A:** TV-CDS showing low-

impedance flow (resistive index ? 0.45; pulsatile index ? 0.60) within the wall of a corpus luteum. **B:** Amplitude color Doppler image of hemorrhagic corpus luteum showing no flow within the center of the mass, which contained an organized clot. **C:** Complex mass with low-impedance arterial and increased venous flow within an irregular solid area, which is highly indicative of ovarian cancer. (see black and white image)

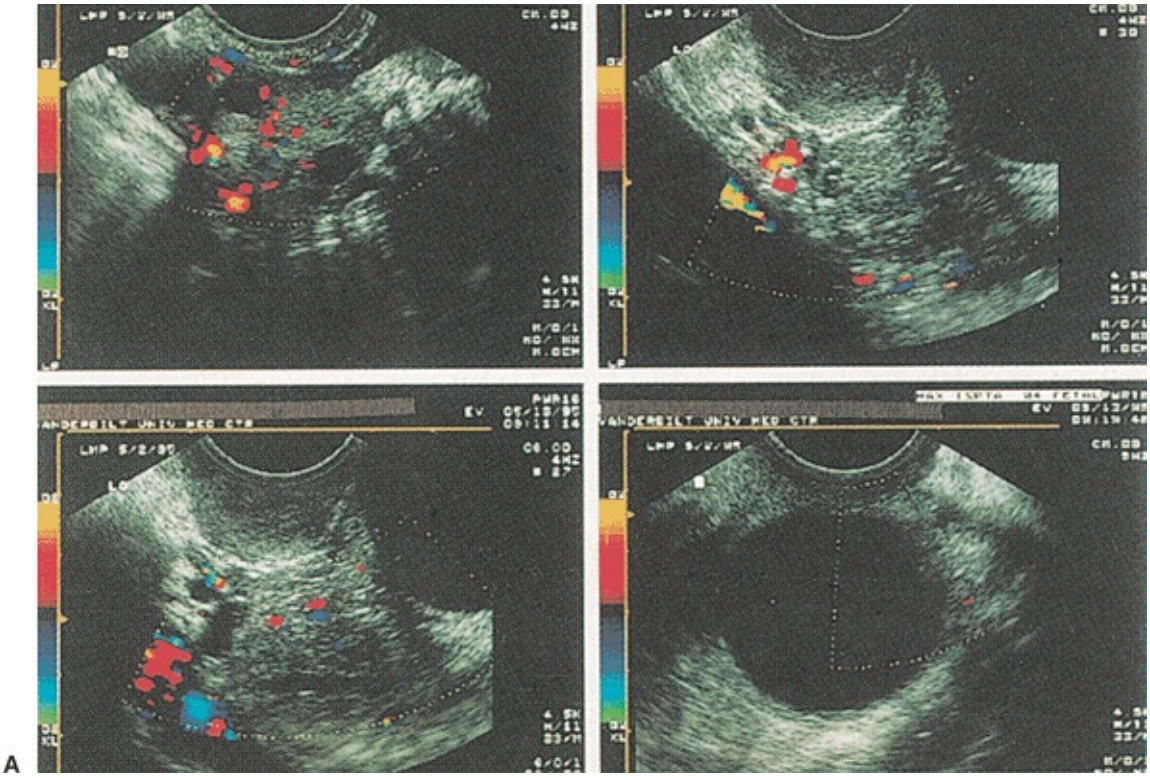
A

Color Plate 30.3 Endometrial disorders. **A:** Diagram showing proximity of the endometrium of an anteflexed uterus to the transvaginal probe. The field of view depicting the long axis of the uterus and endometrium is shown. (Drawing by Paul Gross, MS.) (see black and white image)



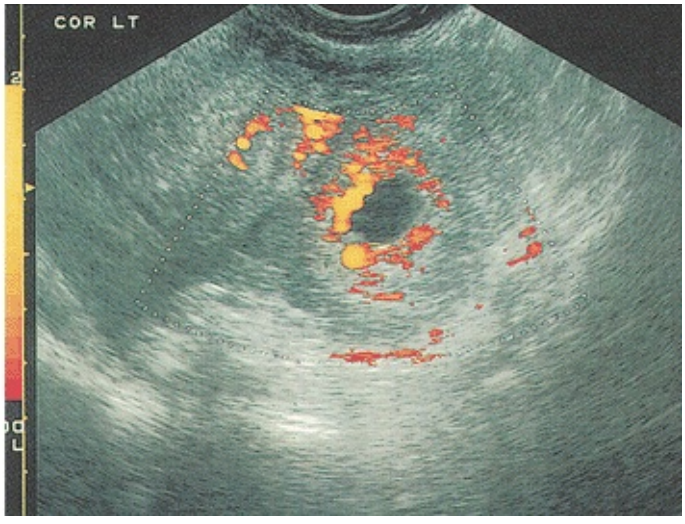
A

Color Plate 30.4 Saline infusion SIS. **A:** Diagram showing an intrauterine catheter used for distension of lumen with saline for detailed evaluation of the endometrium from the inside. (Diagram by Paul Gross, MS.) (see black and white image)



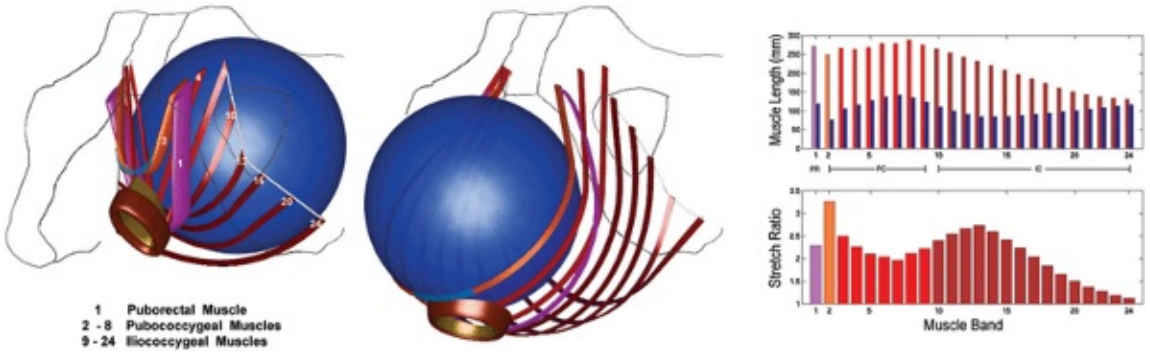
A

Color Plate 30.6 Pelvic pain. **A:** Composite TVUS showing an enlarged left ovary **(top right and bottom left)** without flow and associated with a paraovarian cyst in the left adnexa **(lower right)**. The right ovary **(top left)** was normal, showing intraparenchymal flow. The left adnexa was found to be twisted three times and was surgically untwisted with a good result. (see black and white image)



B

Color Plate 30.7 Ectopic pregnancy. **B:** TV-CDS showing vascularity of the tubal ring of an unruptured ectopic pregnancy. (see black and white image)



Color Plate 48.17 Bowling-ball model. **Left:** Computer model of selected levator ani muscle bands before birth, with muscle fibers numbered and the muscle groups identified. **Middle:** Muscle band lengthening present at the end of the second stage of labor. **Right:** Graphic representation of the original and final muscle **(top)** and the stretch ratio **(bottom)**, indicating the degree to which each muscle band must lengthen to accommodate a normal sized fetal head. Note that the pubococcygeal muscle fascicles labeled *PC2* undergo the greatest degree of stretch and would be the most vulnerable to stretch-induced injury. (From Lien KC, Mooney B, DeLancey JO, et al. Levator ani muscle stretch induced by simulated vaginal birth. *Obstet Gynecol* 2004;103:31–40. Copyright © Biomechanics Research Laboratory 2005.) (see black and white image)
