Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

TERMS OF USE

Neither McGraw-Hill Education nor its licensors shall be liable to you or anyone else for any inaccuracy, error or omission, regardless of cause, in the work or for any damages resulting therefrom. McGraw-Hill Education has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill Education and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

Preface

As all the prior editions of this textbook before, the twenty-eighth edition of *Jawetz, Melnick, & Adelberg's Medical Microbiology* remains true to the goals of the first edition published in 1954, which is to “to provide a brief, accurate and up-to-date presentation of those aspects of medical microbiology that are of particular significance to the fields of clinical infections and chemotherapy.”

For the twenty-seventh edition, under the authorship of Dr. Karen Carroll, all chapters had been extensively revised, reflecting the tremendous expansion of medical knowledge afforded by molecular mechanisms and diagnostics, advances in our understanding of microbial pathogenesis, and the discovery of novel pathogens. While Dr. Carroll decided to step down as an author and contributor for this new edition, the remaining authors would like to express their gratitude for her leadership and contributions to the previous, greatly expanded edition. For the 28th edition, Chapter 47, “Principles of Diagnostic Medical Microbiology,” and Chapter 48, “Cases and Clinical Correlations,” were again updated to reflect the continued expansion in laboratory diagnostics as well as new antimicrobial therapies in the treatment of infectious diseases.

Chapter 48 was specifically updated to reflect clinically important and currently emerging infectious disease cases.

New to this edition are Peter Hotez, MD, PhD, Rojelio Mejia, MD, and Stefan Riedel, MD, PhD, D(ABMM). Dr. Hotez is the Dean of the National School of Tropical Medicine at Baylor College of Medicine in Houston, TX, and is a Professor of Pediatrics, Molecular Virology and Microbiology; he brings extensive expertise in parasitology. Dr. Mejia is an Assistant Professor in the Department of Pediatrics, Section of Tropical Medicine, at the National School of Tropical Medicine, Baylor College of Medicine in Houston, TX. Dr. Riedel is the Associate Medical Director of the Clinical Microbiology Laboratories at Beth Israel Deaconess Medical Center in Boston, MA, and holds the academic rank of Associate Professor of Pathology at Harvard Medical School. Following Dr. Carroll's departure as an author and contributor to this textbook, Dr. Riedel assumed the role as Editor-in-Chief for this revised, 28th edition of the textbook.

The authors hope that the changes to this current edition will continue to be helpful to the student of microbiology and infectious diseases.

SECTION I FUNDAMENTALS OF MICROBIOLOGY

C H A P T E R

1

The Science of Microbiology

INTRODUCTION

Microbiology is the study of microorganisms, a large and diverse group of microscopic organisms that exist as single cells or cell clusters; it also includes viruses, which are microscopic but not cellular. Microorganisms have a tremendous impact on all life and the physical and chemical makeup of our planet. They are responsible for cycling the chemical elements essential for life, including carbon, nitrogen, sulfur, hydrogen, and oxygen; more photosynthesis is carried out by microorganisms than by green plants. Furthermore, there are 100 million times as many bacteria in the oceans (13×10^{28}) as there are stars in the known universe. The rate of viral infections in the oceans is about 1×10^{23} infections per second, and these infections remove 20–40% of all bacterial cells each day. It has been estimated that 5×10^{30} microbial cells exist on earth; excluding cellulose, these cells constitute about 90% of the biomass of the entire biosphere. Humans also have an intimate relationship with microorganisms; 50–60% of the cells in our bodies are microbes (see Chapter 10). The bacteria present in the average human gut weigh about 1 kg, and a human adult will excrete his or her own weight in fecal bacteria each year. The number of genes contained within this gut flora outnumber that contained within our genome by 150-fold; even in our own genome, 8% of the DNA is derived from remnants of viral genomes.

BIOLOGIC PRINCIPLES ILLUSTRATED BY MICROBIOLOGY

Nowhere is **biologic diversity** demonstrated more dramatically than by microorganisms, cells, or viruses that are not directly visible to the unaided eye. In form and function, be

it biochemical property or genetic mechanism, analysis of microorganisms takes us to the limits of biologic understanding. Thus, the need for **originality**—one test of the merit of a scientific **hypothesis**—can be fully met in microbiology. A useful hypothesis should provide a basis for **generalization**, and microbial diversity provides an arena in which this challenge is ever present.

Prediction, the practical outgrowth of science, is a product created by a blend of technique and theory. **Biochemistry**, **molecular biology**, and **genetics** provide the tools required for analysis of microorganisms. **Microbiology**, in turn, extends the horizons of these scientific disciplines. A biologist might describe such an exchange as **mutualism**, that is, one that benefits all contributing parties. Lichens are an example of microbial mutualism. Lichens consist of a fungus and phototropic partner, either an alga (a eukaryote) or a cyanobacterium (a prokaryote) (Figure 1-1). The phototropic component is the primary producer, and the fungus provides the phototroph with an anchor and protection from the elements. In biology, mutualism is called **symbiosis**, a continuing association of different organisms. If the exchange operates primarily to the benefit of one party, the association is described as **parasitism**, a relationship in which a **host** provides the primary benefit to the parasite. Isolation and characterization of a parasite—such as a pathogenic bacterium or virus—often require effective mimicry in the laboratory of the growth environment provided by host cells. This demand sometimes represents a major challenge to investigators.

The terms *mutualism*, *symbiosis*, and *parasitism* relate to the science of **ecology**, and the principles of environmental biology are implicit in microbiology. Microorganisms are the products of **evolution**, the biologic consequence of **natural**

FIGURE 1-1 Diagram of a lichen, consisting of cells of a phototroph, either an alga or a cyanobacterium, entwined within the hyphae of the fungal partner. selection operating on a vast array of genetically diverse organisms. It is useful to keep the complexity of natural history in mind before generalizing about microorganisms, the most heterogeneous subset of all living creatures.

A major biologic division separates the eukaryotes, organisms containing a membrane-bound nucleus from prokaryotes, organisms in which DNA is not physically separated from the cytoplasm. As described in this chapter and in Chapter 2, further major distinctions can be made between eukaryotes and prokaryotes. Eukaryotes, for example, are distinguished by their relatively large size and by the presence of specialized membrane-bound organelles such as mitochondria.

As described more fully later in this chapter, eukaryotic microorganisms—or, phylogenetically speaking, the Eukarya—are unified by their distinct cell structure and phylogenetic history. Among the groups of eukaryotic microorganisms are the **algae**, the **protozoa**, the **fungi**, and the **slime molds**. A class of microorganisms that share characteristics common to both prokaryotes and eukaryotes are the archaeobacteria and are described in Chapter 3.

VIRUSES

The unique properties of viruses set them apart from living creatures. Viruses lack many of the attributes of cells, including the ability to self-replicate. Only when it infects a cell does a virus acquire the key attribute of a living system—reproduction. Viruses are known to infect a wide variety of

plant and animal hosts as well as protists, fungi, and bacteria. However, most viruses are restricted to infecting specific types of cells of only one host species, a property known as “**tropism**”. Recently, viruses called **virophages** have been discovered that infect other viruses. Host–virus interactions tend to be highly specific, and the biologic range of viruses mirrors the diversity of potential host cells. Further diversity of viruses is exhibited by their broad array of strategies for replication and survival.

Viral particles are generally small (eg, adenovirus has a diameter of 90 nm) and consist of a nucleic acid molecule, either DNA or RNA, enclosed in a protein coat, or capsid (sometimes itself surrounded by an envelope of lipids, proteins, and carbohydrates). Proteins—frequently glycoproteins—comprising the capsid and/or making up part of the lipid envelope (e.g., HIV gp120) determine the specificity of interaction of a virus with its host cell. The capsid protects the nucleic acid cargo. The surface proteins, whether they are externally exposed on the capsid or associated with the envelope facilitates attachment and penetration of the host cell by the virus. Once inside the cell, viral nucleic acid redirects the host’s enzymatic machinery to functions associated with replication and assembly of the virus. In some cases, genetic information from the virus can be incorporated as DNA into a host chromosome (a **provirus**). In other instances, the viral genetic information can serve as a basis for cellular manufacture and release of copies of the virus. This process calls for replication of the viral nucleic acid and production of specific viral proteins. **Maturation** consists of assembling newly synthesized nucleic acid and protein subunits into mature

viral particles, which are then liberated into the extracellular environment. Some very small viruses require the assistance of another virus in the host cell for their replication. The delta agent, also known as hepatitis D virus (HDV), has a RNA genome that is too small to code for even a single capsid protein (the only HDV-encoded protein is delta antigen) and needs help from hepatitis B virus for packaging and transmission.

Some viruses are large and complex. For example, Mimi-virus, a DNA virus infecting *Acanthamoeba*, a free-living soil amoeba, has a diameter of 400–500 nm and a genome that encodes 979 proteins, including the first four aminoacyl tRNA synthetases ever found outside of cellular organisms. This virus also encodes enzymes for polysaccharide biosynthesis, a process typically performed by the infected cell. An even larger marine virus has recently been discovered (*Megavirus*); its genome (1,259,197-bp) encodes 1120 putative proteins and is larger than that of some bacteria (see Table 7-1). Because of their large size, these viruses resemble bacteria when observed in stained preparations by light microscopy; however, they do not undergo cell division or contain ribosomes.

Several transmissible plant diseases are caused by **viroids**—small, single-stranded, covalently closed circular RNA molecules existing as highly base-paired rod-like structures. They range in size from 246 to 375 nucleotides in length. The extracellular form of the viroid is naked RNA—there is no capsid of any kind. The RNA molecule contains no protein-encoding genes, and the viroid is therefore totally dependent on host functions for its replication. Viroid RNA is replicated by the DNA-dependent RNA polymerase of the plant host; preemption of this enzyme may contribute to viroid pathogenicity.

The RNAs of viroids have been shown to contain inverted repeated base sequences (also known as insertion sequences) at their 3' and 5' ends, a characteristic of transposable elements (see Chapter 7) and retroviruses. Thus, it is likely that they have evolved from transposable elements or retroviruses by the deletion of internal sequences.

The general properties of animal viruses pathogenic for humans are described in Chapter 29. Bacterial viruses, known as bacterial phages, are described in Chapter 7.

PRIONS

A number of remarkable discoveries in the past three decades have led to the molecular and genetic characterization of the transmissible agent causing **scrapie**, a degenerative central nervous system disease of sheep. Studies have identified a specific protein in preparations from scrapie-infected brains of sheep that can reproduce the symptoms of scrapie in previously uninfected sheep (Figure 1-2). Attempts to identify additional components, such as nucleic acid, have been unsuccessful. To distinguish this agent from viruses and viroids, the term *prion* was introduced to emphasize its proteinaceous and infectious nature. The

FIGURE 1-2 Prion. Prions isolated from the brain of a scrapie-infected hamster. This neurodegenerative disease is caused by a prion. (Reproduced with permission from Stanley B. Prusiner.)

protein that **prions** are made of (PrP) is found throughout the body, even in healthy people and in animals, and is encoded by the host's chromosomal DNA. The normal form of the prion protein is called PrP^c. PrP^c is a sialoglycoprotein with a molecular mass of 35,000–36,000 Da and a mainly α -helical secondary structure that is sensitive to proteases and soluble in detergent. Several topological forms exist: one cell surface form anchored by a glycolipid, and two transmembrane forms. The disease scrapie manifests itself when a conformational change occurs in the prion protein, changing it from its normal or cellular form PrP^c to the infectious disease-causing isoform, PrP^{Sc} (Figure 1-3); this in turn alters the way the proteins interconnect. The exact three-dimensional structure of PrP^{Sc} is unknown; however, it has a higher proportion of β -sheet structures in place of the normal α -helix structures. Aggregations of PrP^{Sc} form highly structured **amyloid** fibers, which accumulate to form plaques. It is unclear if these aggregates are the cause of the cell damage or are simply a side effect of the underlying disease process. One model of prion replication suggests that PrP^c exists only as fibrils, and that the fibril ends bind PrP^c and convert it to PrP^{Sc}.

There are several prion diseases of importance (Table 1-1 and see Chapter 42). Kuru, Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler-Scheinker disease, and fatal familial insomnia affect humans. Bovine spongiform encephalopathy (BSE), which is thought to result from the ingestion of feeds and bone meal prepared from rendered sheep offal, has been responsible for the deaths of more than 184,000 cattle in Great Britain since its discovery in 1985. A new variant

Both normal prion protein (NP) and abnormal prion protein (PP) are present.

FIGURE 1-3 Proposed mechanism by which prions replicate. The normal and abnormal prion proteins differ in their tertiary structure. (Reproduced with permission from Nester EW, Anderson DG, Roberts CE, et al: *Microbiology: A Human Perspective*, 6th ed. McGraw-Hill, 2009, p. 342. © McGraw-Hill Education.)

of CJD (vCJD) has been associated with human ingestion of prion-infected beef in the United Kingdom and in France. A common feature of all of these diseases is the conversion of a host-encoded sialoglycoprotein to a protease-resistant form as a consequence of infection. Recently, an **α -synuclein** prion was discovered that caused a neurodegenerative disease called multiple system atrophy in humans.

Human prion diseases are unique in that they manifest as sporadic, genetic, and infectious diseases. The study of prion biology is an important emerging area of biomedical investigation, and much remains to be learned.

The general features of the nonliving members of the microbial world are given in Table 1-2.

PROKARYOTES

The primary distinguishing characteristics of the prokaryotes are their relatively small size, usually on the order of 1 μm in diameter, and the absence of a nuclear membrane. The DNA of almost all bacteria is a circle which if extended linearly would be about 1 mM; this is the prokaryotic chromosome. Bacteria are **haploid** (if multiple copies of the chromosome are present they are all the same). Most prokaryotes have only a single large chromosome that is organized into a structure known as a **nucleoid**. The chromosomal DNA must be folded more than 1000-fold just to fit within the confines of a prokaryotic cell. Substantial evidence suggests that the folding may be orderly and may bring specified regions of the DNA into proximity. The **nucleoid** can be visualized by electron microscopy as well as by light microscopy after treatment of the cell to make the nucleoid visible. Thus, it would be a mistake to conclude that subcellular differentiation, clearly demarcated by membranes in eukaryotes, is lacking in prokaryotes. Indeed, some prokaryotes form membrane-bound subcellular structures with specialized function such as the chromatophores of photosynthetic bacteria (see Chapter 2).

Prokaryotic Diversity

The small size and haploid organization of the prokaryotic chromosome limits the amount of genetic information it can contain. Recent data based on genome sequencing indicate that the number of genes within a prokaryote may vary from 468 in *Mycoplasma genitalium* to 7825 in *Streptomyces coelicolor*, and many of these genes must be dedicated to essential functions such as energy generation, macromolecular synthesis, and cellular replication. Any one prokaryote carries relatively few genes that allow physiologic accommodation of the organism to its environment. The range of potential prokaryotic environments is unimaginably broad, and it follows that the prokaryotic group encompasses a heterogeneous range of specialists, each adapted to a rather narrowly circumscribed niche.

The range of prokaryotic niches is illustrated by consideration of strategies used for generation of metabolic energy. Light from the sun is the chief source of energy for life. Some prokaryotes such as the purple bacteria convert light energy to metabolic energy in the absence of oxygen production. Other prokaryotes, exemplified by the blue-green bacteria (**Cyanobacteria**), produce oxygen that can provide energy through respiration in the absence of light. **Aerobic organisms** depend on respiration with oxygen for their energy. Some **anaerobic organisms** can use electron acceptors other than oxygen in respiration. Many anaerobes carry out **fermentations** in which energy is derived by metabolic rearrangement of chemical growth substrates. The tremendous chemical range of potential growth substrates for aerobic or anaerobic growth is mirrored in the diversity of prokaryotes that have adapted to their utilization.

TABLE 1-1 Common Human and Animal Prion Diseases

Type	Name	Etiology
Human prion diseases		
Acquired	Variant Creutzfeldt-Jakob disease ^a	Associated with ingestion or inoculation of prion-infected material
	Kuru	
	Iatrogenic Creutzfeldt-Jakob disease ^b	
Sporadic	Creutzfeldt-Jakob disease	Source of infection unknown
Familial	Gerstmann-Sträussler-Scheinker	Associated with specific mutations within the gene encoding PrP
	Fatal familial insomnia	
	Creutzfeldt-Jakob disease	
Animal prion diseases		
Cattle	Bovine spongiform encephalopathy	Exposure to prion-contaminated meat and bone meal
Sheep	Scrapie	Ingestion of scrapie-contaminated material
Deer, elk	Chronic wasting disease	Ingestion of prion-contaminated material
Mink	Transmissible mink encephalopathy	Source of infection unknown
Cats	Feline spongiform encephalopathy ^a	Exposure to prion-contaminated meat and bone meal

PrP, prion protein.

^aAssociated with exposure to bovine spongiform encephalopathy-contaminated materials.

^bAssociated with prion-contaminated biologic materials, such as dura mater grafts, corneal transplants, and cadaver-derived human growth hormone, or by prion-contaminated surgical instruments.

Prokaryotic Communities

A useful survival strategy for specialists is to enter into **consortia**, arrangements in which the physiologic characteristics of different organisms contribute to survival of the group as a whole. If the organisms within a physically interconnected community are directly derived from a single cell, the community is a **clone** that may contain up to 10⁸ or greater cells. The biology of such a community differs substantially from that of a single cell. For example, the high cell number virtually ensures the presence within the clone of at least one cell carrying a variant of any gene on the chromosome. Thus, genetic variability—the wellspring of the evolutionary process called natural selection—is ensured within a clone. The high number of cells within clones is also likely to provide

physiologic protection to at least some members of the group. Extracellular polysaccharides, for example, may afford protection against potentially lethal agents such as antibiotics or heavy metal ions. Large amounts of polysaccharides produced by the high number of cells within a clone may allow cells within the interior to survive exposure to a lethal agent at a concentration that might kill single cells.

Many bacteria exploit a cell–cell communication mechanism called **quorum sensing** to regulate the transcription of genes involved in diverse physiologic processes, including bioluminescence, plasmid conjugal transfer, and the production of virulence determinants. Quorum sensing depends on the production of one or more diffusible signal molecules (eg, acetylated homoserine lactone [AHL]) termed **autoinducers** or **pheromones** that enable a bacterium to monitor its own cell population density (Figure 1-4). The cooperative activities leading to **biofilm** formation are controlled by quorum sensing. It is an example of multicellular behavior in prokaryotes.

Another distinguishing characteristic of prokaryotes is their capacity to exchange small packets of genetic information. This information may be carried on **plasmids**, small and specialized genetic elements that are capable of replication within at least one prokaryotic cell line. In some cases, plasmids may be transferred from one cell to another and thus may carry sets of specialized genetic information through a population. Some plasmids exhibit a **broad host range** that allows them to convey sets of genes to diverse organisms. Of particular concern

TABLE 1-2 Distinguishing Characteristics of Viruses, Viroids, and Prions

Viruses	Viroids	Prions
Obligate intracellular agents	Obligate intracellular agents	Abnormal form of a cellular protein
Consist of either DNA or RNA surrounded by a protein coat	Consist only of RNA; no protein coat	Consist only of protein; no DNA or RNA

Reproduced with permission from Nester EW, Anderson DG, Roberts CE, et al: *Microbiology: A Human Perspective*, 6th ed. McGraw-Hill, 2009, p. 13. © McGraw-Hill Education.

FIGURE 1-4 Quorum sensing. (Reproduced with permission from Nester EW, Anderson DG, Roberts CE, et al: *Microbiology: A Human Perspective*, 6th ed. McGraw-Hill, 2009, p. 181. © McGraw-Hill Education.)

are **drug resistance plasmids** that may render diverse bacteria resistant to antibiotic treatment (Chapter 7).

The survival strategy of a single prokaryotic cell line may lead to a range of interactions with other organisms. These may include **symbiotic** relationships illustrated by complex nutritional exchanges among organisms within the human gut. These exchanges benefit both the microorganisms and their human host. **Parasitic** interactions can be quite deleterious to the host. Advanced symbiosis or parasitism can lead to loss of functions that may not allow growth of the symbiont or parasite independent of its host.

The **mycoplasmas**, for example, are parasitic prokaryotes that have lost the ability to form a cell wall. Adaptation of these organisms to their parasitic environment has resulted in incorporation of a substantial quantity of cholesterol into their cell membranes. Cholesterol, not found in other prokaryotes, is assimilated from the metabolic environment provided by the host. Loss of function is exemplified also by obligate intracellular parasites, the **chlamydiae** and **rickettsiae**. These bacteria are extremely small (0.2–0.5 μm in diameter) and depend on the host cell for many essential metabolites and coenzymes. This loss of function is reflected by the presence of a smaller genome with fewer genes (see Table 7-1).

The most widely distributed examples of bacterial symbionts appear to be chloroplasts and mitochondria, the energy-yielding organelles of eukaryotes. Evidence points to the conclusion that ancestors of these chloroplasts and mitochondria were **endosymbionts**, essentially “domesticated bacteria” that established symbiosis within the cell membrane of the ancestral eukaryotic host. The presence of multiple copies of these organelles may have contributed to the relatively large size of eukaryotic cells and to their capacity for specialization, a trait ultimately reflected in the evolution of differentiated multicellular organisms.

Classification of the Prokaryotes

An understanding of any group of organisms requires their **classification**. An appropriate classification system

allows a scientist to choose characteristics that allow swift and accurate categorization of a newly encountered organism. This categorical organization allows prediction of many additional traits shared by other members of the category. In a hospital setting, successful classification of a pathogenic organism may provide the most direct route to its elimination. Classification may also provide a broad understanding of relationships among different organisms, and such information may have great practical value. For example, elimination of a pathogenic organism will be relatively long-lasting if its habitat is occupied by a non-pathogenic variant.

The principles of prokaryotic classification are discussed in Chapter 3. At the outset, it should be recognized that any prokaryotic characteristic might serve as a potential criterion for classification. However, not all criteria are equally effective in grouping organisms. Possession of DNA, for example, is a useless criterion for distinguishing organisms because all cells contain DNA. The presence of a broad host range plasmid is not a useful criterion because such plasmids may be found in diverse hosts and need not be present all of the time. Useful criteria may be structural, physiologic, biochemical, or genetic. **Spores**—specialized cell structures that may allow survival in extreme environments—are useful structural criteria for classification because well-characterized subsets of bacteria form spores. Some bacterial groups can be effectively subdivided based upon their ability to ferment specified carbohydrates. Such criteria may be ineffective when applied to other bacterial groups that may lack any fermentative capability. A biochemical test, the **Gram-stain**, is an effective criterion for classification because response to the stain reflects fundamental differences in the bacterial cell envelope that divide most bacteria into two major groups.

Genetic criteria are increasingly used in bacterial classification, and many of these advances are made possible by the development of DNA-based technologies. It is now possible to design DNA probe or DNA amplification assays (eg, polymerase chain reaction [PCR] assays) that swiftly identify organisms carrying specified genetic regions with

common ancestry. Comparison of DNA sequences for some genes has led to the elucidation of **phylogenetic relationships** among prokaryotes. Ancestral cell lines can be traced, and organisms can be grouped based on their evolutionary affinities. These investigations have led to some striking conclusions. For example, comparison of cytochrome c sequences suggests that all eukaryotes, including humans, arose from one of three different groups of purple photosynthetic bacteria. This conclusion in part explains the evolutionary origin of eukaryotes, but it does not fully take into account the generally accepted view that the eukaryotic cell was derived from the evolutionary merger of different prokaryotic cell lines.

Bacteria and Archaeobacteria: The Major Subdivisions Within the Prokaryotes

A major success in molecular phylogeny has been the demonstration that prokaryotes fall into two major groups. Most investigations have been directed to one group, the bacteria. The other group, the archaeobacteria, has received relatively little attention until recently, partly because many of its representatives are difficult to study in the laboratory. Some archaeobacteria, for example, are killed by contact with oxygen, and others grow at temperatures exceeding that of boiling water. Before molecular evidence became available, the major subgroupings of archaeobacteria had seemed disparate. The methanogens carry out an anaerobic respiration that gives rise to methane, the halophiles demand extremely high salt concentrations for growth, and the thermoacidophiles require high temperature and acidity for growth. It has now been established that these prokaryotes share biochemical traits such as cell wall or membrane components that set the group entirely apart from all other living organisms. An intriguing trait shared by archaeobacteria and eukaryotes is the presence of **introns** within genes. The function of introns—segments of DNA that interrupts informational DNA within genes—is not established. What is known is that introns represent a fundamental characteristic shared by the DNA of archaeobacteria and eukaryotes. This common trait has led to the suggestion that—just as mitochondria and chloroplasts appear to be evolutionary derivatives of the bacteria—the eukaryotic nucleus may have arisen from an archaeobacterial ancestor.

PROTISTS

The “true nucleus” of eukaryotes (from Gr *karyon*, “nucleus”) is only one of their distinguishing features. The membrane-bound organelles, the microtubules, and the microfilaments of eukaryotes form a complex intracellular structure unlike that found in prokaryotes. The organelles responsible for the motility of eukaryotic cells are flagella or cilia—complex multistranded structures that do not resemble the flagella of prokaryotes. Gene expression in eukaryotes takes place

through a series of events achieving physiologic integration of the nucleus with the endoplasmic reticulum, a structure that has no counterpart in prokaryotes. Eukaryotes are set apart by the organization of their cellular DNA in chromosomes separated by a distinctive mitotic apparatus during cell division.

In general, genetic transfer among eukaryotes depends on fusion of **haploid gametes** to form a **diploid** cell containing a full set of genes derived from each gamete. The life cycle of many eukaryotes is almost entirely in the diploid state, a form not encountered in prokaryotes. Fusion of gametes to form reproductive progeny is a highly specific event and establishes the basis for eukaryotic **species**. This term can be applied only metaphorically to the prokaryotes, which exchange fragments of DNA through recombination. Currently, the term *protist* is used informally as a catch-all term for unicellular eukaryotic microorganisms. Because protists as a whole are **paraphyletic**, newer classification systems often split up traditional subdivisions or groups based on morphological or biochemical characteristics.

Traditionally, microbial eukaryotes—**protists**—are placed in one of the four following major groups: algae, protozoa, fungi, and slime molds. These traditional subdivisions, largely based on superficial commonalities, have been largely replaced by classification schemes based on **phylogenetics**. Molecular methods used by modern taxonomists have been used to generate data supporting the redistribution of some members of these groups into diverse and sometimes distantly related phyla. For example, the **water molds** are now considered to be closely related to photosynthetic organisms such as brown algae and diatoms.

Algae

The term *algae* has long been used to denote all organisms that produce O_2 as a product of photosynthesis. One former subgroup of these organisms—the blue-green algae, or cyanobacteria—are prokaryotic and no longer are termed algae. This classification is reserved exclusively for a large diverse group of photosynthetic eukaryotic organisms. Formerly, all algae were thought to contain chlorophyll in the photosynthetic membrane of their chloroplast, a subcellular organelle that is similar in structure to cyanobacteria. Modern taxonomic approaches have recognized that some algae lack chlorophyll and have a free-living heterotrophic or parasitic life style. Many algal species are unicellular microorganisms. Other algae may form extremely large multicellular structures. Kelps of brown algae sometimes are several hundred meters in length. Several algae produce toxins that are poisonous to humans and other animals. Dinoflagellates, a unicellular alga, are responsible for algal blooms, or **red tides**, in the ocean (Figure 1-5). Red tides caused by the dinoflagellate *Gonyaulax* species are serious because this organism produces potent neurotoxins such as

FIGURE 1-5 The dinoflagellate *Gymnodinium* scanning electron micrograph (4000 \times). (Reproduced with permission from Dr. David Phillips/Visuals Unlimited.)

saxitoxin and **gonyautoxins**, which accumulate in shellfish (eg, clams, mussels, scallops, and oysters) that feed on this organism. Ingestion of these shellfish by humans results in symptoms of **paralytic shellfish poisoning** and can lead to death. Some algae (eg, *Prototheca* and *Helicosporidium*) are parasites of metazoans or plants. **Protothecosis** is a disease of dogs, cats, cattle, and rarely humans caused by a type of algae, *Prototheca*, that lacks chlorophyll. The two most common species are *P. wickerhamii* and *P. zopfii*; most human cases, which are associated with a defective immune system, are caused by *P. wickerhamii*.

Protozoa

Protozoa is an informal term for single-celled nonphotosynthetic eukaryotes that are either free-living or parasitic. Protozoa are abundant in aqueous environments and soil. They range in size from as little as 1 μ m to several millimeters, or more. All protozoa are **heterotrophic**, deriving nutrients from other organisms, either by ingesting them whole or by consuming their organic tissue or waste products. Some protozoans take in food by **phagocytosis**, engulfing organic particles with **pseudopodia** (eg, amoeba), or taking in food through a mouth-like aperture called a **cytostome**. Other protozoans absorb dissolved nutrients through their cell membranes, a process called **osmotrophy**.

Historically, the major groups of protozoa included: **flagellates**, motile cells possessing whip-like organelles of locomotion; **amoebae**, cells that move by extending pseudopodia; and **ciliates**, cells possessing large numbers of short hair-like organelles of motility. Intermediate forms

are known that have flagella at one stage in their life cycle and pseudopodia at another stage. A fourth major group of protozoa, the sporozoa, are strict parasites that are usually nonmotile; most of these reproduce sexually and asexually in alternate generations by means of spores. Recent taxonomic studies have shown that only the ciliates are **monophyletic**, that is, a distinct lineage of organisms sharing common ancestry. The other classes of protozoa are all **polyphyletic** groups made up of organisms that, despite similarities in appearance (eg, flagellates) or way of life (eg, endoparasitic), are not necessarily closely related to one another. Protozoan parasites of humans are discussed in Chapter 46.

Fungi

The fungi are nonphotosynthetic protists that may or may not grow as a mass of branching, interlacing filaments (“hyphae”) known as a **mycelium**. If a fungus grows simply as a single cell it is called a **yeast**. If mycelial growth occurs, it is called a **mold**. Most fungi of medical importance grow dimorphically, that is, they exist as a mold at room temperature but as a yeast at body temperature. Remarkably, the largest known contiguous fungal mycelium covered an area of 2400 acres (9.7 km²) at a site in eastern Oregon. Although the hyphae exhibit cross walls, the cross walls are perforated and allow free passage of nuclei and cytoplasm. The entire organism is thus a **coenocyte** (a multinucleated mass of continuous cytoplasm) confined within a series of branching tubes. These tubes, made of polysaccharides such as chitin, are homologous with cell walls.

The fungi probably represent an evolutionary offshoot of the protozoa; they are unrelated to the actinomycetes, mycelial bacteria that they superficially resemble. The major subdivisions (phyla) of fungi are Chytridiomycota, Zygomycota (the zygomycetes), Ascomycota (the ascomycetes), Basidiomycota (the basidiomycetes), and the “deuteromycetes” (or imperfect fungi). The evolution of the ascomycetes from the phycomycetes is seen in a transitional group, whose members form a zygote but then transform this directly into an ascus. The basidiomycetes are believed to have evolved in turn from the ascomycetes. The classification of fungi and their medical significance are discussed further in Chapter 45.

Slime Molds

These organisms are characterized by the presence, as a stage in their life cycle, of an ameboid multinucleate mass of cytoplasm called a **plasmodium**. The plasmodium of a slime mold is analogous to the mycelium of a true fungus. Both are coenocytic. Whereas in the latter, cytoplasmic flow is confined to the branching network of chitinous tubes, in the former, the cytoplasm can flow in all directions. This flow causes the plasmodium to migrate in the direction of its food source, frequently bacteria. In response to a chemical signal, 3', 5'-cyclic AMP, the plasmodium, which reaches

FIGURE 1-6 Slime molds. **A:** Life cycle of an acellular slime mold. **B:** Fruiting body of a cellular slime mold. (Reproduced with permission from Carolina Biological Supply/DIOMEDIA.)

macroscopic size, differentiates into a stalked body that can produce individual motile cells. These cells, flagellated or ameboid, initiate a new round in the life cycle of the slime mold (Figure 1-6). The cycle frequently is initiated by sexual fusion of single cells.

The growth of slime molds depends on nutrients provided by bacterial or, in some cases, plant cells. Reproduction of the slime molds via plasmodia can depend on intercellular recognition and fusion of cells from the same species. The life cycle of the slime molds illustrates a central theme of this chapter—the interdependency of living forms. Full understanding of any microorganism requires both knowledge of the other organisms with which it coevolved and an appreciation of the range of physiologic responses that may contribute to survival.

CHAPTER SUMMARY

- Microorganisms are a large and diverse group of organisms existing as single cells or clusters; they also include viruses, which are microscopic but not cellular.
- A virus consists of a nucleic acid molecule, either DNA or RNA, enclosed in a protein coat, or capsid, sometimes enclosed by an envelope composed of lipids, proteins, and carbohydrates.
- A prion is an infectious protein, which is capable of causing chronic neurologic diseases.
- Prokaryotes consist of bacteria and archaeobacteria.
- Prokaryotes are haploid.
- Microbial eukaryotes, or protists, are members of four major groups: algae, protozoa, fungi, and slime molds.
- Eukaryotes have a true nucleus and are diploid.

REVIEW QUESTIONS

1. Which one of the following terms characterizes the interaction between herpes simplex virus and a human?
 - (A) Parasitism
 - (B) Symbiosis
 - (C) Endosymbiosis
 - (D) Endoparasitism
 - (E) Consortia
2. Which one of the following agents lacks nucleic acid?
 - (A) Bacteria
 - (B) Viruses
 - (C) Viroids
 - (D) Prions
 - (E) Protozoa
3. Which one of the following is a prokaryote?
 - (A) Bacteria
 - (B) Algae
 - (C) Protozoa
 - (D) Fungi
 - (E) Slime molds
4. Which one of the following agents simultaneously contains both DNA and RNA?
 - (A) Bacteria
 - (B) Viruses
 - (C) Viroids
 - (D) Prions
 - (E) Plasmids
5. Which of the following cannot be infected by viruses?
 - (A) Bacteria
 - (B) Protozoa
 - (C) Human cells
 - (D) Viruses
 - (E) None of the above

6. Viruses, bacteria, and protists are uniquely characterized by their respective size. True or false?
(A) True
(B) False
7. Quorum sensing in prokaryotes involves
(A) Cell-cell communication
(B) Production of molecules such as AHL
(C) An example of multicellular behavior
(D) Regulation of genes involved in diverse physiologic processes
(E) All of the above
8. A 16-year-old female patient presented to her family physician with a complaint of an abnormal vaginal discharge and pruritus (itching). The patient denied having sexual activity and recently completed a course of doxycycline for the treatment of her acne. An examination of a Gram-stained vaginal smear revealed the presence of Gram-positive oval cells about 4–8 μm in diameter. Her vaginitis is caused by which of the following agents?
(A) Bacterium
(B) Virus
(C) Protozoa
(D) Fungus
(E) Prion
9. A 65-year-old man develops dementia, progressive over several months, along with ataxia and somnolence. An electroencephalographic pattern shows paroxysms with high voltages and slow waves, suggestive of CJD. By which of the following agents is this disease caused?
(A) Bacterium
(B) Virus
(C) Viroid
(D) Prion
(E) Plasmid
10. Twenty minutes after ingesting a raw clam, a 35-year-old man experiences paresthesias of the mouth and extremities, headache, and ataxia. These symptoms are the result of a neurotoxin produced by algae called
(A) Amoeba
(B) Blue-green algae
(C) Dinoflagellates
(D) Kelp
(E) None of the above

Cell Structure

This chapter discusses the basic structure and function of the components that make up eukaryotic and prokaryotic cells. It begins with a discussion of the microscope. Historically, the microscope first revealed the presence of bacteria and later the secrets of cell structure. Today, it remains a powerful tool in cell biology.

OPTICAL METHODS

The Light Microscope

The resolving power of the light microscope under ideal conditions is about half the wavelength of the light being used. (**Resolving power** is the distance that must separate two point sources of light if they are to be seen as two distinct images.) With yellow light of a wavelength of $0.4\ \mu\text{m}$, the smallest separable diameters are thus about $0.2\ \mu\text{m}$ (ie, one-third the width of a typical prokaryotic cell). The useful magnification of a microscope is the magnification that makes visible the smallest resolvable particles. Several types of light microscopes, which are commonly used in microbiology, are discussed as follows.

A. Bright-Field Microscope

The bright-field microscope is the most commonly used in microbiology courses and consists of two series of lenses (**objective** and **ocular lens**), which function together to resolve the image. These microscopes generally employ a 100-power objective lens with a 10-power ocular lens, thus magnifying the specimen 1000 times. Particles $0.2\ \mu\text{m}$ in diameter are therefore magnified to about $0.2\ \text{mm}$ and so become clearly visible. Further magnification would give no greater resolution of detail and would reduce the visible area (**field**).

With this microscope, specimens are rendered visible because of the differences in **contrast** between them and the surrounding medium. Many bacteria are difficult to see well because of their lack of contrast with the surrounding medium. Dyes (stains) can be used to stain cells or their organelles and increase their contrast so that they can be more easily seen in the bright-field microscope.

B. Phase-Contrast Microscope

The phase-contrast microscope was developed to improve contrast differences between cells and the surrounding medium, making it possible to see living cells without staining them; with bright-field microscopes, killed and stained preparations must be used. The phase-contrast microscope takes advantage of the fact that light waves passing through transparent objects, such as cells, emerge in different phases depending on the properties of the materials through which they pass. This effect is amplified by a special ring in the objective lens of a phase-contrast microscope, leading to the formation of a dark image on a light background (Figure 2-1).

C. Dark-Field Microscope

The dark-field microscope is a light microscope in which the lighting system has been modified to reach the specimen from the sides only. This is accomplished through the use of a special condenser that both blocks direct light rays and deflects light off a mirror on the side of the condenser at an oblique angle. This creates a “dark field” that contrasts against the highlighted edge of the specimens and results when the oblique rays are reflected from the edge of the specimen upward into the objective of the microscope. Resolution by dark-field microscopy is quite high. Thus, this technique has been particularly useful for observing organisms such as *Treponema pallidum*, a spirochete that is smaller than $0.2\ \mu\text{m}$ in diameter and therefore cannot be observed with a bright-field or phase-contrast microscope (Figure 2-2A).

D. Fluorescence Microscope

The fluorescence microscope is used to visualize specimens that **fluoresce**, which is the ability to absorb short wavelengths of light (ultraviolet) and give off light at a longer wavelength (visible). Some organisms fluoresce naturally because of the presence within the cells of naturally fluorescent substances such as chlorophyll. Those that do not naturally fluoresce may be stained with a group of fluorescent dyes called **fluorochromes**. Fluorescence microscopy is widely used in clinical diagnostic microbiology. For example, the fluorochrome auramine O, which glows yellow when exposed to ultraviolet light, is strongly absorbed by the cell envelope of

FIGURE 2-1 Using the phase contrast illumination technique, this photomicrograph of a wet mount of a vaginal discharge specimen revealed the presence of the flagellated protozoan, *Trichomonas vaginalis*. (Courtesy of Centers for Disease Control and Prevention, Public Health Image Library, ID# 5238.)

Mycobacterium tuberculosis, the bacterium that causes tuberculosis. When the dye is applied to a specimen suspected of containing *M. tuberculosis* and exposed to ultraviolet light, the bacterium can be detected by the appearance of bright yellow organisms against a dark background.

The principal use of fluorescence microscopy is a diagnostic technique called the **fluorescent-antibody (FA) technique** or **immunofluorescence**. In this technique, specific antibodies (eg, antibodies to *Legionella pneumophila*) are chemically labeled with a fluorochrome such as **fluorescein isothiocyanate (FITC)**. These fluorescent antibodies are then added to a microscope slide containing a clinical specimen. If the specimen contains *L. pneumophila*, the fluorescent antibodies will bind to antigens on the surface of the bacterium, causing it to fluoresce when exposed to ultraviolet light (Figure 2-2B).

E. Differential Interference Contrast Microscope

Differential interference contrast (DIC) microscopes employ a polarizer to produce polarized light. The polarized light beam passes through a prism that generates two distinct beams; these beams pass through the specimen and enter the objective lens, where they are recombined into a single beam. Because of slight differences in refractive index of the substances each beam passed through, the combined beams are not totally in phase but instead create an interference effect, which intensifies subtle differences in cell structure. Structures, such as spores, vacuoles, and granules, appear three dimensional. DIC microscopy is particularly useful for observing unstained cells because of its ability to generate images that reveal internal cell structures that are less apparent by bright-field techniques.

The Electron Microscope

The high resolving power of electron microscopes has enabled scientists to observe the detailed structures of prokaryotic

and eukaryotic cells. The superior resolution of the electron microscope is because electrons have a much shorter wavelength than the photons of white light.

There are two types of electron microscopes in general use: The **transmission electron microscope (TEM)**, which has many features in common with the light microscope; and the **scanning electron microscope (SEM)**. The TEM was the first to be developed and uses a beam of electrons projected from an electron gun and directed or focused by an electromagnetic condenser lens onto a thin specimen. As the electrons strike the specimen, they are differentially scattered by the number and mass of atoms in the specimen; some electrons pass through the specimen and are gathered and focused by an electromagnetic objective lens, which presents an image of the specimen to the projector lens system for further enlargement. The image is visualized by allowing it to impinge on a screen that fluoresces when struck with the electrons. The image can be recorded on photographic film. TEM can resolve particles 0.001 μm apart. Thus, viruses with diameters of 0.01–0.2 μm are easily resolved by TEM.

The SEM generally has a lower resolving power than the TEM; however, it is particularly useful for providing three-dimensional images of the surface of microscopic objects. Electrons are focused by means of lenses into a very fine point. The interaction of electrons with the specimen results in the release of different forms of radiation (eg, secondary electrons) from the surface of the material, which can be captured by an appropriate detector, amplified, and then imaged on a television screen (Figure 2-2C).

An important technique in electron microscopy is the use of “shadowing.” This involves depositing a thin layer of heavy metal (eg, platinum) on the specimen by placing it in the path of a beam of metal ions in a vacuum. The beam is directed at a low angle to the specimen so that it acquires a “shadow” in the form of an uncoated area on the other side. When an electron beam is then passed through the coated preparation in the electron microscope and a positive print is made from the “negative” image, a three-dimensional effect is achieved (eg, see Figure 2-24).

Other important techniques in electron microscopy include the use of ultrathin sections of embedded material, a method of freeze-drying specimens that prevents the distortion caused by conventional drying procedures, and the use of negative staining with an electron-dense material such as phosphotungstic acid or uranyl salts (eg, see Figure 42-1). Without these heavy metal salts, there would not be enough contrast to detect the details of the specimen.

Confocal Scanning Laser Microscope

The **confocal scanning laser microscope (CSLM)** couples a laser light source to a light microscope. In confocal scanning laser microscopy, a laser beam is bounced off a mirror that directs the beam through a scanning device. Then the laser beam is directed through a pinhole that precisely adjusts the plane of focus of the beam to a given vertical layer within the

FIGURE 2-3 Using laser light, CDC laboratory scientists sometimes work with a confocal microscope when studying various pathogens. (Courtesy of James Gathany, Centers for Disease Control and Prevention, Public Health Image Library, ID# 1960.)

specimen. By precisely illuminating only a single plane of the specimen, illumination intensity drops off rapidly above and below the plane of focus, and stray light from other planes of focus are minimized. Thus, in a relatively thick specimen, various layers can be observed by adjusting the plane of focus of the laser beam.

Cells are often stained with fluorescent dyes to make them more visible. Alternatively, false color images can be generated by adjusting the microscope in such a way as to make different layers take on different colors. The CSLM is equipped with computer software to assemble digital images for subsequent image processing. Thus, images obtained from different layers can be stored and then digitally overlaid to reconstruct a three-dimensional image of the entire specimen (Figure 2-3).

Scanning Probe Microscopes

A new class of microscopes, called **scanning probe microscopes**, measures surface features by moving a sharp probe over the object's surface. The **scanning tunneling microscope** and the **atomic force microscope** are the examples of this new class of microscopes, which enable scientists to view atoms or molecules on the surface of a specimen. For example, interactions between proteins of the bacterium *Escherichia coli* can be studied with the atomic force microscope (Figure 2-4).

EUKARYOTIC CELL STRUCTURE

The Nucleus

The **nucleus** contains the cell's genome. It is bounded by a membrane, which is composed of two lipid bilayer membranes: the inner and the outer membrane. The inner membrane is usually a simple sac, but the outermost membrane is, in many places, continuous with the endoplasmic

FIGURE 2-4 Atomic force microscopy. Micrograph of a fragment of DNA. The bright peaks are enzymes attached to the DNA. (Reproduced with permission from Torunn Berg, Photo Researchers, Inc.)

reticulum (ER). The **nuclear membrane** exhibits selective permeability because of pores, which consist of a complex of several proteins whose function is to import substances into and export substances out of the nucleus. The chromosomes

of eukaryotic cells contain linear DNA macromolecules arranged as a double helix. They are only visible with a light microscope when the cell is undergoing division and the DNA is in a highly condensed form; at other times, the chromosomes are not condensed and appear as in Figure 2-5. Eukaryotic DNA macromolecules are associated with basic proteins called **histones** that bind to the DNA by ionic interactions.

A structure often visible within the nucleus is the **nucleolus**, an area rich in RNA that is the site of ribosomal RNA synthesis (see Figure 2-5). Ribosomal proteins synthesized in the cytoplasm are transported into the nucleolus and combine with ribosomal RNA to form the small and large subunits of the eukaryotic ribosome. These are then exported to the cytoplasm, where they associate to form an intact ribosome that can function in protein synthesis.

Cytoplasmic Structures

The cytoplasm of eukaryotic cells is characterized by the presence of an ER, vacuoles, self-reproducing plastids, and an

FIGURE 2-5 Eukaryotic cells. **A:** Diagrammatic representation of an animal cell. **B:** Diagrammatic representation of a plant cell. **C:** Micrograph of an animal cell shows several membrane-bound structures, including mitochondria and a nucleus. Fig. 2-3(C) Reproduced with permission from Thomas Fritsche, MD, PhD.)

elaborate cytoskeleton composed of microtubules, microfilaments, and intermediate filaments.

The **endoplasmic reticulum (ER)** is a network of membrane-bound channels continuous with the nuclear membrane. Two types of ER are recognized: **rough**, to which 80S ribosomes are attached; and **smooth**, which does not have attached ribosomes (see Figure 2-5). Rough ER is a major producer of glycoproteins as well as new membrane material that is transported throughout the cell; smooth ER participates in the synthesis of lipids and in some aspects of carbohydrate metabolism. The **Golgi complex** consists of a stack of membranes that function in concert with the ER to chemically modify and sort products of the ER into those destined to be secreted and those that function in other membranous structures of the cell.

The plastids include **mitochondria** and **chloroplasts**. Several lines of evidence suggest that mitochondria and chloroplasts arose from the engulfment of a prokaryotic cell by a larger cell (**endosymbiosis**). Current hypotheses, making use of mitochondrial genome and proteome data, suggest that the mitochondrial ancestor was most closely related to Alphaproteobacteria and that chloroplasts are related to nitrogen-fixing cyanobacteria. Mitochondria are of prokaryotic size (Figure 2-5), and its membrane, which lacks sterols, is much less rigid than the eukaryotic cell's cytoplasmic membrane, which does contain sterols. Mitochondria contain two sets of membranes. The outermost membrane is rather permeable, having numerous minute channels that allow passage of ions and small molecules (eg, adenosine triphosphate [ATP]). Invagination of the outer membrane forms a system of inner folded membranes called **cristae**. The cristae are the sites of enzymes involved in respiration and ATP production. Cristae also contain specific transport proteins that regulate passage of metabolites into and out of the mitochondrial **matrix**. The matrix contains a number of enzymes, particularly those of the citric acid cycle. Chloroplasts are the photosynthetic cell organelles that can convert the energy of sunlight into chemical energy through photosynthesis. Chlorophyll and all other components needed for photosynthesis are located in a series of flattened membrane discs called **thylakoids**. The size, shape, and number of chloroplasts per cell vary markedly; in contrast to mitochondria, chloroplasts are generally much larger than prokaryotes. Mitochondria and chloroplasts contain their own DNA, which exists in a covalently closed circular form and codes for some (not all) of their constituent proteins and transfer RNAs. Mitochondria and chloroplasts also contain 70S ribosomes, the same as those of prokaryotes.

Eukaryotic microorganisms that were previously thought to lack mitochondria (**amitochondriate eukaryotes**) have been recently shown to contain some mitochondrial remnants either through the maintenance of membrane-enclosed respiratory organelles called **hydrogenosomes**, **mitosomes**, or nuclear genes of mitochondrial origin. There are two types of amitochondriate eukaryotes: type II (eg, *Trichomonas vaginalis*) harbors a hydrogenosome, while type I (eg, *Giardia lamblia*) lacks organelles involved in core energy metabolism. Some amitochondrial parasites (eg, *Entamoeba histolytica*)

are intermediate and appear to be evolving from a type II to type I. Some hydrogenosomes have been identified that contain DNA and ribosomes. The hydrogenosome, although similar in size to mitochondria, lacks cristae and the enzymes of the tricarboxylic acid cycle. Pyruvate is taken up by the hydrogenosome, and H_2 , CO_2 , acetate, and ATP are produced. The mitosome has only recently been discovered and named, and its function has not been well characterized.

Lysosomes are membrane-enclosed vesicles that contain various digestive enzymes that the cell uses to digest macromolecules such as proteins, fats, and polysaccharides. The lysosome allows these enzymes to be partitioned away from the cytoplasm proper, where they could destroy key cellular macromolecules if not contained. After the hydrolysis of macromolecules in the lysosome, the resulting monomers pass from the lysosome into the cytoplasm, where they serve as nutrients.

The **peroxisome** is a membrane-enclosed structure whose function is to produce H_2O_2 from the reduction of O_2 by various hydrogen donors. The H_2O_2 produced in the peroxisome is subsequently degraded to H_2O and O_2 by the enzyme **catalase**. Peroxisomes are believed to be of evolutionary origin unrelated to mitochondria.

The **cytoskeleton** is a three-dimensional structure that fills the cytoplasm. Eukaryotic cells contain three main kinds of cytoskeletal filaments: **microfilaments**, **intermediate filaments**, and **microtubules**. Each cytoskeletal filament type is formed by polymerization of a distinct type of protein subunit and has its own shape and intracellular distribution. Microfilaments are about 7 nm in diameter and are polymers composed of the protein **actin**. These fibers form scaffolds throughout the cell, defining and maintaining the shape of the cell. Microfilaments can also carry out intracellular transport/trafficking, and cellular movements, including gliding, contraction, and cytokinesis.

Microtubules are hollow cylinders about 23 nm in diameter (lumen is approximately 15 nm in diameter) most commonly comprising 13 protofilaments that, in turn, are polymers of alpha and beta **tubulin**. Microtubules assist microfilaments in maintaining cell structure, form the spindle fibers for separating chromosomes during mitosis, and play an important role in cell motility. Intermediate filaments are composed of various proteins (eg, **keratin**, **lamin**, and **desmin**) depending on the type of cell in which they are found. They are normally 8–12 nm in diameter and provide tensile strength for the cell. They are most commonly known as the support system or “scaffolding” for the cell and nucleus. All filaments react with **accessory proteins** (eg, Rho and dynein) that regulate and link the filaments to other cell components and each other.

Surface Layers

The cytoplasm is enclosed within a plasma membrane composed of protein and phospholipid similar to the prokaryotic cell membrane illustrated later (see Figure 2-13). Most animal cells have no other surface layers; however, plant cells have an outer cell wall composed of cellulose (Figure 2-5B). Many

20 μm

FIGURE 2-6 A paramecium moves with the aid of cilia on the cell surface. (© Manfred Kage.)

eukaryotic microorganisms also have an outer **cell wall**, which may be composed of a polysaccharide such as cellulose or chitin or may be inorganic (eg, the silica wall of diatoms).

Motility Organelles

Many eukaryotic microorganisms have organelles called **flagella** (eg, *T. vaginalis*) or **cilia** (eg, *Paramecium*) that move with a wavelike motion to propel the cell through water. Eukaryotic flagella emanate from the polar region of the cell, and cilia, which are shorter than flagella, surround the cell (Figure 2-6).

Both the flagella and the cilia of eukaryotic cells have the same basic structure and biochemical composition. Both consist of a series of microtubules, hollow protein cylinders composed of a protein called **tubulin** surrounded by a membrane. The arrangement of the microtubules is commonly referred to as the “9 + 2 arrangement” because it consists of nine doublets of microtubules surrounding two single central microtubules (Figure 2-7). Each doublet is connected to another by the protein **dynein**. The dynein arms attached to the microtubule function as the molecular motors.

PROKARYOTIC CELL STRUCTURE

The prokaryotic cell is simpler than the eukaryotic cell at every level, with one exception: The cell envelope is more complex.

The Nucleoid

Prokaryotes have no true nuclei; instead they package their DNA in a structure known as the **nucleoid**. The negatively charged DNA is at least partially neutralized by small polyamines and magnesium ions. Nucleoid-associated proteins exist in bacteria and are distinct from histones in eukaryotic chromatin.

Electron micrographs of a typical prokaryotic cell reveal the absence of a nuclear membrane and a mitotic apparatus. The exception to this rule is the planctomycetes, a divergent group of aquatic bacteria, which have a nucleoid surrounded by a nuclear envelope consisting of two membranes.

(Reproduced with permission. © Dr. Gopal Murti/SPL/Photo Researchers Inc.)

The distinction between prokaryotes and eukaryotes that still holds is that prokaryotes have no eukaryotic-type mitotic apparatus. The nuclear region is filled with DNA fibrils (Figure 2-8). The nucleoid of most bacterial cells consists of a single continuous circular molecule ranging in size from 0.58 to almost 10 million base pairs. However, a few bacteria have been shown to have two, three, or even four dissimilar chromosomes. For example, *Vibrio cholerae* and *Brucella melitensis* have two dissimilar chromosomes. There are exceptions to this rule of circularity because some prokaryotes (eg, *Borrelia burgdorferi* and *Streptomyces coelicolor*) have been shown to have a linear chromosome.

In bacteria, the number of nucleoids, and therefore the number of chromosomes, depends on the growth conditions. Rapidly growing bacteria have more nucleoids per cell than slowly growing ones; however, when multiple copies are present, they are all the same (ie, prokaryotic cells are **haploid**).

Cytoplasmic Structures

Prokaryotic cells lack autonomous plastids, such as mitochondria and chloroplasts; the electron transport enzymes are localized instead in the cytoplasmic membrane. The photosynthetic pigments (carotenoids, bacteriochlorophyll) of photosynthetic bacteria are contained in intracytoplasmic membrane systems of various morphologies. Membrane vesicles (**chromatophores**) or lamellae are commonly observed membrane types. Some photosynthetic bacteria have specialized nonunit membrane-enclosed structures called **chlorosomes**. In some cyanobacteria (formerly known as blue-green algae), the photosynthetic membranes often form multilayered structures known as **thylakoids** (Figure 2-9). The major accessory pigments used for light harvesting are the phycobilins found on the outer surface of the thylakoid membranes.

Bacteria often store reserve materials in the form of insoluble granules, which appear as refractile bodies in the cytoplasm when viewed by phase-contrast microscopy. These so-called **inclusion bodies** almost always function in the storage of energy or as a reservoir of structural building blocks. Most cellular inclusions are bounded by a thin nonunit membrane consisting of lipid, which serves to separate the inclusion from the cytoplasm proper. One of the most common inclusion bodies consists of **poly- β -hydroxybutyric acid (PHB)**, a lipid-like compound consisting of chains of

FIGURE 2-9 Thin section of *Synechocystis* during division. Many structures are visible. (Reproduced from Stanier RY: The position of cyanobacteria in the world of phototrophs. Carlsberg Res Commun 42:77-98, 1977. With kind permission of Springer + Business Media.)

β -hydroxybutyric acid units connected through ester linkages. PHB is produced when the source of nitrogen, sulfur, or phosphorous is limited and there is excess carbon in the medium (Figure 2-10A). Another storage product formed by prokaryotes when carbon is in excess is **glycogen**, which is a polymer of glucose. PHB and glycogen are used as carbon sources when protein and nucleic acid synthesis are resumed. A variety of prokaryotes are capable of oxidizing reduced sulfur compounds, such as hydrogen sulfide and thiosulfate, producing intracellular granules of elemental **sulfur** (Figure 2-10B). As the reduced sulfur source becomes

limiting, the sulfur in the granules is oxidized, usually to sulfate, and the granules slowly disappear. Many bacteria accumulate large reserves of inorganic phosphate in the form of granules of **polyphosphate**. These granules can be degraded and used as sources of phosphate for nucleic acid and phospholipid synthesis to support growth. These granules are sometimes termed **volutin granules** or **metachromatic granules** because they stain red with a blue dye. They are characteristic features of *Corynebacterium* (see Chapter 13).

Certain groups of autotrophic bacteria that fix carbon dioxide to make their biochemical building blocks contain polyhedral bodies surrounded by a protein shell (**carboxysomes**) containing the key enzyme of CO_2 fixation, **ribulosebisphosphate carboxylase** (see Figure 2-9). **Magnetosomes** are intracellular crystal particles of the iron mineral magnetite (Fe_3O_4) that allow certain aquatic bacteria to exhibit **magnetotaxis** (ie, migration or orientation of the cell with respect to the earth's magnetic field). Magnetosomes are surrounded by a nonunit membrane containing phospholipids, proteins, and glycoproteins. **Gas vesicles** are found almost exclusively in microorganisms from aquatic habitats, where they provide buoyancy. The gas vesicle membrane is a 2-nm-thick layer of protein, impermeable to water and solutes but permeable to gases; thus, gas vesicles exist as gas-filled structures surrounded by the constituents of the cytoplasm (Figure 2-11).

The most numerous intracellular structure in most bacteria is the **ribosome**, the site of protein synthesis in all

living organisms. All prokaryotes have 70S ribosomes, while eukaryotes contain larger 80S ribosomes in their cytoplasm. The 70S ribosome is made up of 50S and 30S subunits. The 50S subunit contains the 23S and 5S ribosomal RNA (rRNA), while the 30S subunit contains the 16S rRNA. These rRNA molecules are complexed with a large number of ribosomal proteins. The bacterial cytoplasm also contains homologs of all the major cytoskeletal proteins of eukaryotic cells as well as additional proteins that play cytoskeletal roles (Figure 2-12).

Actin homologs (eg, MreB and Mbl) perform a variety of functions, helping to determine cell shape, segregate chromosomes, and localize proteins within the cell. Nonactin homologs (eg, FtsZ) and unique bacterial cytoskeletal proteins (eg, SecY and MinD) are involved in determining cell shape and in regulation of cell division and chromosome segregation.

The Cell Envelope

Prokaryotic cells are surrounded by complex envelope layers that differ in composition among the major groups. These structures protect the organisms from hostile environments, such as extreme osmolarity, harsh chemicals, and even antibiotics.

The Plasma Membrane

A. Structure

The plasma membrane, also called the **bacterial cytoplasmic membrane**, is visible in electron micrographs of thin sections (see Figure 2-9). It is a typical “unit membrane” composed of phospholipids and upward of 200 different proteins. Proteins account for approximately 70% of the mass of the membrane, which is a considerably higher proportion than that of mammalian cell membranes. Figure 2-13 illustrates a model of membrane organization. The membranes of prokaryotes are distinguished from those of eukaryotic cells by the absence of sterols (with some exceptions, eg, mycoplasmas, which also lack a cell wall, incorporate sterols, such as cholesterol, into their membranes when growing in sterol-containing media). However, many bacteria contain structurally related compounds called **hopanoids**, which

FIGURE 2-13 Bacterial plasma membrane structure. This diagram of the fluid mosaic model of bacterial membrane structure shown the integral proteins (green and red) floating in a lipid bilayer. Peripheral proteins (yellow) are associated loosely with the inner membrane surface. Small spheres represent the hydrophilic ends of membrane phospholipids and wiggly tails, the hydrophobic fatty acid chains. Other membrane lipids such as hopanoids (purple) may be present. For the sake of clarity, phospholipids are shown proportionately much larger size than in real membranes. (Reproduced with permission from Willey JM, Sherwood LM, Woolverton CJ: *Prescott, Harley, and Klein’s Microbiology*, 7th ed. McGraw-Hill; 2008. © McGraw-Hill Education.)

likely fulfill the same function. Unlike eukaryotes, bacteria can have a wide variety of fatty acids within their membranes. Along with the typical saturated and unsaturated fatty acids, bacterial membranes can contain fatty acids with additional methyl, hydroxy, or cyclic groups. The relative proportions of these fatty acids can be modulated by the bacterium to maintain the optimum fluidity of the membrane. For example, at least 50% of the cytoplasmic membrane must be in the semifluid state for cell growth to occur. At low temperatures, this is achieved by greatly increased synthesis and incorporation of unsaturated fatty acids into the phospholipids of the cell membrane.

The cell membranes of the *Archaea* (see Chapter 1) differ from those of the *Bacteria*. Some Archaeal cell membranes contain unique lipids, **isoprenoids**, rather than fatty acids, linked to glycerol by ether rather than an ester linkage. Some of these lipids have no phosphate groups, and therefore, they are not phospholipids. In other species, the cell membrane is made up of a lipid monolayer consisting of long lipids (about twice as long as a phospholipid) with glycerol ethers at both ends (diglycerol tetraethers). The molecules orient themselves with the polar glycerol groups on the surfaces and the non-polar hydrocarbon chain in the interior. These unusual lipids contribute to the ability of many *Archaea* to grow under environmental conditions such as high salt, low pH, or very high temperature.

B. Function

The major functions of the cytoplasmic membrane are (1) selective permeability and transport of solutes; (2) electron transport and oxidative phosphorylation in aerobic species; (3) excretion of hydrolytic exoenzymes; (4) contain the enzymes and carrier molecules that function in the biosynthesis of DNA, cell wall polymers, and membrane lipids; and (5) bear the receptors and other proteins of the chemotactic and other sensory transduction systems.

1. Permeability and transport—The cytoplasmic membrane forms a hydrophobic barrier impermeable to most hydrophilic molecules. However, several mechanisms (**transport systems**) exist that enable the cell to transport nutrients into and waste products out of the cell. These transport systems work against a concentration gradient to increase the nutrient concentrations inside the cell, a function that requires energy in some form. There are three general transport mechanisms involved in membrane transport: **passive transport**, **active transport**, and **group translocation**.

a. Passive transport—This mechanism relies on diffusion, uses no energy, and operates only when the solute is at higher concentration outside than inside the cell. **Simple diffusion** accounts for the entry of very few nutrients, including dissolved oxygen, carbon dioxide, and water itself. Simple diffusion provides neither speed nor selectivity. **Facilitated diffusion** also uses no energy, so the solute never achieves an internal concentration greater than what exists outside

the cell. However, facilitated diffusion is selective. **Channel proteins** form selective channels that facilitate the passage of specific molecules. Facilitated diffusion is common in eukaryotic microorganisms (eg, yeast) but is rare in prokaryotes. Glycerol is one of the few compounds that enters prokaryotic cells by facilitated diffusion.

b. Active transport—Many nutrients are concentrated more than a thousandfold as a result of active transport. There are two types of active transport mechanisms depending on the source of energy used: **ion-coupled transport** and **ATP-binding cassette (ABC) transport**.

1) Ion-coupled transport—These systems move a molecule across the cell membrane at the expense of a previously established ion gradient such as **proton-** or **sodium-motive force**. There are three basic types: **uniport**, **symport**, and **antiport** (Figure 2-14). Ion-coupled transport is particularly common in aerobic organisms, which have an easier time generating an ion-motive force than do anaerobes. Uniporters catalyze the transport of a substrate independent of any coupled ion. Symporters catalyze the simultaneous transport of two substrates in the same direction by a single carrier; for example, an H^+ gradient can permit symport of an oppositely charged ion (eg, glycine) or a neutral molecule (eg, galactose). Antiporters catalyze the simultaneous transport of two like-charged compounds in opposite directions by a common carrier (eg, H^+Na^+). Approximately, 40% of the substrates transported by *E. coli* use this mechanism.

2) ABC transport—This mechanism uses ATP directly to transport solutes into the cell. In Gram-negative bacteria, the transport of many nutrients is facilitated by specific **binding proteins** located in the periplasmic space; in Gram-positive cells, the binding proteins are attached to the outer surface of the cell membrane. These proteins function by transferring the bound substrate to a membrane-bound protein complex. Hydrolysis of ATP is then triggered, and the energy is used to open the membrane pore and allow the unidirectional movement of the substrate into the cell. Approximately 40% of the substrates transported by *E. coli* use this mechanism.

c. Group translocation—In addition to true transport, in which a solute is moved across the membrane without change in structure, bacteria use a process called group translocation (**vectorial metabolism**) to effect the net uptake of certain sugars (eg, glucose and mannose), the substrate becoming phosphorylated during the transport process. In a strict sense, group translocation is not active transport because no concentration gradient is involved. This process allows bacteria to use their energy resources efficiently by coupling transport with metabolism. In this process, a membrane carrier protein is first phosphorylated in the cytoplasm at the expense of **phosphoenolpyruvate**; the phosphorylated carrier protein then binds the free sugar at the exterior membrane face and transports it into the cytoplasm, releasing it as a sugar phosphate. Such systems of sugar transport are called

FIGURE 2-14 Three types of porters: **A:** uniporters, **B:** symporters, and **C:** antiporters. Uniporters catalyze the transport of a single species independently of any other, symporters catalyze the cotransport of two dissimilar species (usually a solute and a positively charged ion, H^+) in the same direction, and antiporters catalyze the exchange transport of two similar solutes in opposite directions. A single transport protein may catalyze just one of these processes, two of these processes, or even all three of these processes, depending on conditions. Uniporters, symporters, and antiporters have been found to be structurally similar and evolutionarily related, and they function by similar mechanisms. (Reproduced with permission from Saier MH Jr: Peter Mitchell and his chemiosmotic theories. *ASM News* 1997;63:13.)

phosphotransferase systems. Phosphotransferase systems are also involved in movement toward these carbon sources (**chemotaxis**) and in the regulation of several other metabolic pathways (**catabolite repression**).

d. Special transport processes—Iron (Fe) is an essential nutrient for the growth of almost all bacteria. Under anaerobic conditions, Fe is generally in the +2 oxidation state and soluble. However, under aerobic conditions, Fe is generally in the

+3 oxidation state and insoluble. The internal compartments of animals contain virtually no free Fe; it is sequestered in complexes with such proteins as **transferrin** and **lactoferrin**. Some bacteria solve this problem by secreting **siderophores**—compounds that chelate Fe and promote its transport as a soluble complex. One major group of siderophores consists of derivatives of hydroxamic acid ($-CONH_2OH$), which chelate Fe^{3+} very strongly. The iron–hydroxamate complex is actively transported into the cell by the cooperative action of a group of proteins that span the outer membrane, periplasm, and inner membrane. The iron is released, and the hydroxamate can exit the cell and be used again for iron transport.

Some pathogenic bacteria use a fundamentally different mechanism involving specific receptors that bind host transferrin and lactoferrin (as well as other iron-containing host proteins). The Fe is removed and transported into the cell using an ABC transporter.

2. Electron transport and oxidative phosphorylation

The cytochromes and other enzymes and components of the respiratory chain, including certain dehydrogenases, are located in the cytoplasmic membrane. The bacterial cytoplasmic membrane is thus a functional analog of the mitochondrial membrane—a relationship which has been taken by many biologists to support the theory that mitochondria have evolved from symbiotic bacteria. The mechanism by which ATP generation is coupled to electron transport is discussed in Chapter 6.

3. Excretion of hydrolytic exoenzymes and pathogenicity proteins

All organisms that rely on macromolecular organic polymers as a source of nutrients (eg, proteins, polysaccharides, and lipids) excrete hydrolytic enzymes that degrade these polymers to subunits small enough to penetrate the cell membrane. Higher animals secrete such enzymes into the lumen of the digestive tract; bacteria (both Gram-positive and Gram-negative) secrete them directly into the external medium or into the periplasmic space between the peptidoglycan layer and the outer membrane of the cell wall in the case of Gram-negative bacteria (see The Cell Wall).

In Gram-positive bacteria, proteins are secreted directly across the cytoplasmic membrane, but in Gram-negative bacteria, secreted proteins must traverse the outer membrane as well. At least six pathways of protein secretion have been described in bacteria: the type I, type II, type III, type IV, type V, and type VI secretion systems. A schematic overview of the type I to V systems is presented in Figure 2-15. The type I and IV secretion systems have been described in both Gram-negative and Gram-positive bacteria, but the type II, III, V, and VI secretion systems have been found only in Gram-negative bacteria. Proteins secreted by the type I and III pathways traverse the inner (cytoplasmic) membrane (IM) and outer membrane (OM) in one step, but proteins secreted by the type II and V pathways cross the IM and OM in separate steps. Proteins secreted by the type II and V pathways are

FIGURE 2-15 The protein secretion systems of Gram-negative bacteria. Five secretion systems of Gram-negative bacteria are shown. The Sec-dependent and Tat pathways deliver proteins from the cytoplasm to the periplasmic space. The type II, type V, and sometimes type IV systems complete the secretion process begun by the Sec-dependent pathway. The Tat system appears to deliver proteins only to the type II pathway. The type I and III systems bypass the Sec-dependent and Tat pathways, moving proteins directly from the cytoplasm, through the outer membrane, to the extracellular space. The type IV system can work either with the Sec-dependent pathway or can work alone to transport proteins to the extracellular space. Proteins translocated by the Sec-dependent pathway and the type III pathway are delivered to those systems by chaperone proteins. ADP, adenosine diphosphate; ATP, adenosine triphosphate; EFGY, PulS; SecD; TolC; Yop. (Reproduced with permission from Willey JM, Sherwood LM, Woolverton CJ: *Prescott, Harley, and Klein's Microbiology*, 7th ed. McGraw-Hill; 2008. © McGraw-Hill Education.)

synthesized on cytoplasmic ribosomes as preproteins containing an extra **leader** or **signal sequence** of 15–40 amino acids—most commonly about 30 amino acids—at the amino terminal and require the *sec* system for transport across the IM. In *E. coli*, the *sec* pathway comprises a number of IM proteins (SecD to SecF, SecY), a cell membrane-associated ATPase (SecA) that provides energy for export, a **chaperone** (SecB) that binds to the preprotein, and the periplasmic **signal peptidase**. After translocation, the leader sequence is cleaved off by the membrane-bound signal peptidase, and the mature protein is released into the periplasmic space. In contrast, proteins secreted by the type I and III systems do not have a leader sequence and are exported intact.

In Gram-negative and Gram-positive bacteria, another cytoplasmic membrane system that uses the twin-arginine

targeting translocase (**tat pathway**) can move proteins across the IM. In Gram-negative bacteria, these proteins are then delivered to the type II system (Figure 2-15). The *tat* pathway is distinct from the *sec* system in that it translocates already folded proteins.

Although proteins secreted by the type II and V systems are similar in the mechanism by which they cross the IM, differences exist in how they traverse the OM. Proteins secreted by the type II system are transported across the OM by a multiprotein complex (see Figure 2-15). This is the primary pathway for the secretion of extracellular degradative enzymes by Gram-negative bacteria. Elastase, phospholipase C, and exotoxin A are secreted by this system in *Pseudomonas aeruginosa*. However, proteins secreted by the type V system autotransport across the outer membrane by virtue of a

carboxyl terminal sequence, which is enzymatically removed upon release of the protein from the OM. Some extracellular proteins—eg, the IgA protease of *Neisseria gonorrhoeae* and the vacuolating cytotoxin of *Helicobacter pylori*—are secreted by this system.

The type I and III secretion pathways are *sec* independent and thus do not involve amino terminal processing of the secreted proteins. Protein secretion by these pathways occurs in a continuous process without the presence of a cytoplasmic intermediate. Type I secretion is exemplified by the α -hemolysin of *E. coli* and the adenyl cyclase of *Bordetella pertussis*. Type I secretion requires three secretory proteins: an IM ATP-binding cassette (ABC transporter), which provides energy for protein secretion; an OM protein; and a membrane fusion protein, which is anchored in the inner membrane and spans the periplasmic space (see Figure 2-15). Instead of a signal peptide, the information is located within the carboxyl terminal 60 amino acids of the secreted protein.

The type III secretion pathway is a **contact-dependent** system. It is activated by contact with a host cell, and then injects a toxin protein into the host cell directly. The type III secretion apparatus is composed of approximately 20 proteins, most of which are located in the IM. Many of these IM components are homologous to the flagellar biosynthesis apparatus of both Gram-negative and Gram-positive bacteria. As in type I secretion, the proteins secreted via the type III pathway are not subject to amino terminal processing during secretion.

Type IV pathways secrete either polypeptide toxins (directed against eukaryotic cells) or protein–DNA complexes either between two bacterial cells or between a bacterial and a eukaryotic cell. Type IV secretion is exemplified by the protein–DNA complex delivered by *Agrobacterium tumefaciens* into a plant cell. Additionally, *B. pertussis* and *H. pylori* possess type IV secretion systems that mediate secretion of pertussis toxin and interleukin-8-inducing factor, respectively. The *sec*-independent type VI secretion was recently described in *P. aeruginosa*, where it contributes to pathogenicity in patients with cystic fibrosis. This secretion system is composed of 15–20 proteins whose biochemical functions are not well understood. However, recent studies suggest that some of these proteins share homology with bacteriophage tail proteins.

The characteristics of the protein secretion systems of bacteria are summarized in Table 9-5.

4. Biosynthetic functions—The cell membrane is the site of the carrier lipids on which the subunits of the cell wall are assembled (see the discussion of synthesis of cell wall substances in Chapter 6) as well as of the enzymes of cell wall biosynthesis. The enzymes of phospholipid synthesis are also localized in the cell membrane.

5. Chemotactic systems—Attractants and repellents bind to specific receptors in the bacterial membrane (see Flagella). There are at least 20 different chemoreceptors in the membrane of *E. coli*, some of which also function as a first step in the transport process.

FIGURE 2-16 The rigid cell wall determines the shape of the bacterium. Even though the cell has split apart, the cell wall maintains its original shape. (Courtesy of Dale C. Birdsell.)

The Cell Wall

The internal osmotic pressure of most bacteria ranges from 5 to 20 atm as a result of solute concentration via active transport. In most environments, this pressure would be sufficient to burst the cell were it not for the presence of a high-tensile-strength cell wall (Figure 2-16). The bacterial cell wall owes its strength to a layer composed of a substance variously referred to as **murein**, **mucopolysaccharide**, or **peptidoglycan** (all, including “cell wall,” are synonyms). The structure of peptidoglycan is discussed as follows.

Most bacteria are classified as Gram-positive or Gram-negative according to their response to the Gram-staining procedure. This procedure was named for the histologist Hans Christian Gram, who developed this differential staining procedure in an attempt to identify bacteria in infected tissues. The Gram-stain depends on the ability of certain bacteria (the Gram-positive bacteria) to retain a complex of crystal violet (a purple dye) and iodine after a brief wash with alcohol or acetone. Gram-negative bacteria do not retain the dye–iodine complex and become translucent, but they can then be counterstained with safranin (a red dye). Thus, Gram-positive bacteria look purple under the microscope, and Gram-negative bacteria look red. The distinction between these two groups turns out to reflect fundamental differences in their cell envelopes (Table 2-1).

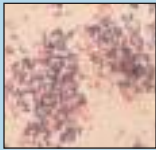

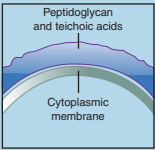

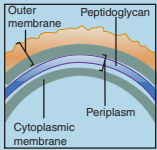

In addition to providing osmotic protection, the cell wall plays an essential role in cell division as well as serving as a primer for its own biosynthesis. The cell wall is, in general, nonselectively permeable; one layer of the Gram-negative wall, however—the outer membrane—hinders the passage of relatively large molecules (see next).

The biosynthesis of the cell wall and the antibiotics that interfere with this process are discussed in Chapter 6.

A. The Peptidoglycan Layer

Peptidoglycan is a complex polymer consisting, for the purposes of description, of three parts: a backbone, composed of alternating *N*-acetylglucosamine and *N*-acetylmuramic acid

TABLE 2-1 Comparison of Features of Gram-Positive and Gram-Negative Bacteria

		
	Gram-Positive	Gram-Negative
Color of Gram-Stained Cell	Purple	Reddish-pink
Representative Genera	<i>Bacillus</i> , <i>Staphylococcus</i> , <i>Streptococcus</i>	<i>Escherichia</i> , <i>Neisseria</i> , <i>Pseudomonas</i>
Distinguishing Structures/Components		
Peptidoglycan	Thick layer	Thin layer
Teichoic acids	Present	Absent
Outer membrane	Absent	Present
Lipopolysaccharide (endotoxin)	Absent	Present
Porin proteins	Absent (unnecessary because there is no outer membrane)	Present; allow passage of molecules through outer membrane
Periplasm	Absent	Present
General Characteristics		
Sensitivity to penicillin	Generally more susceptible (with notable exceptions)	Generally less susceptible (with notable exceptions)
Sensitivity to lysozyme	Yes	No

connected by $\beta 1\rightarrow 4$ linkages; a set of identical tetrapeptide side chains attached to *N*-acetylmuramic acid; and a set of identical peptide cross-bridges (Figure 2-17). The backbone is the same in all bacterial species; the tetrapeptide side chains and the peptide cross-bridges vary from species to species. In many Gram-negative cell walls, the cross-bridge consists of a direct peptide linkage between the diaminopimelic acid (DAP) amino group of one side chain and the carboxyl group of the terminal *D*-alanine of a second side chain.

The tetrapeptide side chains of all species, however, have certain notable features in common. Most have *L*-alanine at position 1 (attached to *N*-acetylmuramic acid), *D*-glutamate or substituted *D*-glutamate at position 2, and *D*-alanine at position 4. Position 3 is the most variable one: Most Gram-negative bacteria have diaminopimelic acid at this position, to which is linked the lipoprotein cell wall component discussed as follows. Gram-positive bacteria usually have *L*-lysine at position 3; however, some may have diaminopimelic acid or another amino acid at this position.

Diaminopimelic acid is a unique element of bacterial cell walls. It is never found in the cell walls of *Archaea* or eukaryotes. Diaminopimelic acid is the immediate precursor of lysine in the bacterial biosynthesis of that amino acid (see Figure 6-19). Bacterial mutants that are blocked before diaminopimelic acid in the biosynthetic pathway grow normally when provided with diaminopimelic acid in the medium;

when given *L*-lysine alone, however, they lyse, because they continue to grow but are specifically unable to make new cell wall peptidoglycan.

The fact that all peptidoglycan chains are cross-linked means that each peptidoglycan layer is a single giant molecule. In Gram-positive bacteria, there are as many as 40 sheets of peptidoglycan, comprising up to 50% of the cell wall material; in Gram-negative bacteria, there appears to be only one or two sheets, comprising 5–10% of the wall material. Bacteria owe their shapes, which are characteristic of particular species, to their cell wall structure.

B. Special Components of Gram-Positive Cell Walls

Most Gram-positive cell walls contain considerable amounts of **teichoic** and **teichuronic acids**, which may account for up to 50% of the dry weight of the wall and 10% of the dry weight of the total cell. In addition, some Gram-positive walls may contain polysaccharide molecules.

1. Teichoic and teichuronic acids—The term *teichoic acids* encompass all wall, membrane, or capsular polymers containing glycerophosphate or ribitol phosphate residues. These polyalcohols are connected by phosphodiester linkages and usually have other sugars and *D*-alanine attached (Figure 2-18A). Because they are negatively charged, teichoic acids are partially responsible for the net negative

FIGURE 2-17 Components and structure of peptidoglycan.

A: Chemical structure of *N*-acetylglucosamine (NAG) and *N*-acetylmuramic acid (NAM); the ring structures of the two molecules are glucose. Glycan chains are composed of alternating subunits of NAG and NAM joined by covalent bonds. Adjacent glycan chains are cross-linked via their tetrapeptide chains to create peptidoglycan.

B: Interconnected glycan chains form a very large three-dimensional molecule of peptidoglycan. The $\beta 1 \rightarrow 4$ linkages in the backbone are cleaved by lysozyme. (Reproduced with permission from Nester EW, Anderson DG, Roberts CE, et al: *Microbiology: A Human Perspective*, 6th ed. McGraw-Hill, 2009. © McGraw-Hill Education.)

charge of the cell surface. There are two types of teichoic acids: **wall teichoic acid (WTA)**, covalently linked to peptidoglycan; and **membrane teichoic acid**, covalently linked to membrane glycolipid. Because the latter are intimately associated with lipids, they have been called **lipoteichoic acids (LTA)**. Together with peptidoglycan, WTA and LTA make up a polyanionic network or matrix that provides functions relating to the elasticity, porosity, tensile strength, and electrostatic properties of the envelope. Although not all Gram-positive bacteria have conventional LTA and WTA, those that lack these polymers generally have functionally similar ones.

Most teichoic acids contain substantial amounts of *D*-alanine, usually attached to position 2 or 3 of glycerol or

position 3 or 4 of ribitol. In some of the more complex teichoic acids, however, *D*-alanine is attached to one of the sugar residues. In addition to *D*-alanine, other substituents may be attached to the free hydroxyl groups of glycerol and ribitol (eg, glucose, galactose, *N*-acetylglucosamine, *N*-acetylgalactosamine, or succinate). A given species may have more than one type of sugar substituent in addition to *D*-alanine; in such cases, it is not certain whether the different sugars occur on the same or on separate teichoic acid molecules. The composition of the teichoic acid formed by a given bacterial species can vary with the composition of the growth medium.

The teichoic acids constitute major surface antigens of those Gram-positive species that possess them, and their

FIGURE 2-18 **A:** Teichoic acid structure. The segment of a teichoic acid made of phosphate, glycerol, and a side chain, R. R may represent D-alanine, glucose, or other molecules. **B:** Teichoic and lipoteichoic acids of the Gram-positive envelope. accessibility to antibodies has been taken as evidence that they lie on the outside surface of the peptidoglycan. Their activity is often increased, however, by partial digestion of the peptidoglycan; thus, much of the teichoic acid may lie between the cytoplasmic membrane and the peptidoglycan layer, possibly extending upward through pores in the latter (Figure 2-18B). In the pneumococcus (*Streptococcus pneumoniae*), the teichoic acids bear the antigenic determinants called **Forssman antigen**. In *Streptococcus pyogenes*, LTA is associated with the M protein that protrudes from the cell membrane through the peptidoglycan layer. The long M protein molecules together with the LTA form microfibrils that facilitate the attachment of *S. pyogenes* to animal cells (see Chapter 14).

The **teichuronic acids** are similar polymers, but the repeat units include sugar acids (eg, *N*-acetylmannosuronic or D-glucosuronic acid) instead of phosphoric acids. They are synthesized in place of teichoic acids when phosphate is limiting.

2. Polysaccharides—The hydrolysis of Gram-positive walls has yielded, from certain species, neutral sugars, such as mannose, arabinose, rhamnose, and glucosamine, and acidic sugars, such as glucuronic acid and mannuronic acid. It has been proposed that these sugars exist as subunits of polysaccharides in the cell wall; the discovery, however, that teichoic and teichuronic acids may contain a variety of sugars (see Figure 2-18A) leaves the true origin of these sugars uncertain.

C. Special Components of Gram-Negative Cell Walls

Gram-negative cell walls contain three components that lie outside of the peptidoglycan layer: outer membrane, lipopolysaccharide, and lipoprotein (Figure 2-19).

1. Outer membrane—The outer membrane is chemically distinct from all other biological membranes. It is a bilayered structure; its inner leaflet resembles in composition that of the cytoplasmic membrane, and its outer leaflet contains a distinctive component, a **lipopolysaccharide (LPS)** (see next). As a result, this is an asymmetrical membrane, and the properties of this bilayer differ considerably from those of a symmetrical biologic membrane such as the cell membrane.

The ability of the outer membrane to exclude hydrophobic molecules is an unusual feature among biologic membranes and serves to protect the cell (in the case of enteric bacteria) from deleterious substances such as bile salts. Because of its lipid nature, the outer membrane would be expected to exclude hydrophilic molecules as well. However, the outer membrane has special channels, consisting of protein molecules called **porins** that permit the passive diffusion of low-molecular-weight hydrophilic compounds, such as sugars, amino acids, and certain ions. Large antibiotic molecules penetrate the outer membrane relatively slowly, which accounts for the relatively high resistance of Gram-negative bacteria to some antibiotics. The permeability of the outer membrane varies widely from one Gram-negative species to another; in *P. aeruginosa*, for example, which is extremely

FIGURE 2-19 Molecular representation of the envelope of a Gram-negative bacterium. Ovals and rectangles represent sugar residues, and circles depict the polar head groups of the glycerophospholipids (phosphatidylethanolamine and phosphatidylglycerol). The core region shown is that of *E. coli* K-12, a strain that does not normally contain an O-antigen repeat unless transformed with an appropriate plasmid. MDO, membrane-derived oligosaccharides. (Reproduced with permission from Raetz CRH: Bacterial endotoxins: Extraordinary lipids that activate eucaryotic signal transduction. *J Bacteriol* 1993;175:5745.)

resistant to antibacterial agents, the outer membrane is 100 times less permeable than that of *E. coli*.

The major proteins of the outer membrane, named according to the genes that code for them, have been placed into several functional categories on the basis of mutants in which they are lacking and on the basis of experiments in which purified proteins have been reconstituted into artificial membranes. Porins, exemplified by OmpC, D, and F and PhoE of *E. coli* and *Salmonella typhimurium*, are trimeric proteins that penetrate both the inner and outer leaflets of the outer membrane (Figure 2-20). They form relatively nonspecific pores that permit the free diffusion of small hydrophilic solutes across the outer membrane. The porins of different species have different exclusion limits, ranging from molecular weights of about 600 in *E. coli* and *S. typhimurium* to more than 3000 in *P. aeruginosa*.

Members of a second group of outer membrane proteins, which resemble porins in many ways, are exemplified by LamB and Tsx. LamB, an inducible porin that is also the

receptor for lambda bacteriophage, is responsible for most of the transmembrane diffusion of maltose and maltodextrins; Tsx, the receptor for T6 bacteriophage, is responsible for the transmembrane diffusion of nucleosides and some amino acids. LamB allows some passage of other solutes; however, its relative specificity may reflect weak interactions of solutes with configuration-specific sites within the channel.

The OmpA protein is an abundant protein in the outer membrane. The OmpA protein participates in the anchoring of the outer membrane to the peptidoglycan layer; it is also the sex pilus receptor in F-mediated bacterial conjugation (see Chapter 7).

The outer membrane also contains a set of less abundant proteins that are involved in the transport of specific molecules, such as vitamin B₁₂ and iron-siderophore complexes. They show high affinity for their substrates and probably function like the classic carrier transport systems of the cytoplasmic membrane. The proper function of these proteins requires energy coupled through a protein called **TonB**.

FIGURE 2-20 **A:** General fold of a porin monomer (OmpF porin from *Escherichia coli*). The large hollow β -barrel structure is formed by antiparallel arrangement of 16 β -strands. The strands are connected by short loops or regular turns on the periplasmic rim (*bottom*), and long irregular loops face the cell exterior (*top*). The internal loop, which connects β -strands 5 and 6 and extends inside the barrel, is highlighted in *dark*. The chain terminals are marked. The surface closest to the viewer is involved in subunit contacts. **B:** Schematic representation of the OmpF trimer. The view is from the extracellular space along the molecular threefold symmetry axis. (Reproduced with permission from Schirmer T: General and specific porins from bacterial outer membranes. *J Struct Biol* 1998;121:101.)

Additional minor proteins include a limited number of enzymes, among them phospholipases and proteases.

The topology of the major proteins of the outer membrane, based on cross-linking studies and analyses of functional relationships, is shown in Figure 2-19. The outer membrane is connected to both the peptidoglycan layer and the cytoplasmic membrane. The connection with the peptidoglycan layer is primarily mediated by the outer membrane lipoprotein (see next). About one-third of the lipoprotein molecules are covalently linked to peptidoglycan and help hold the two structures together. A noncovalent association of some of the porins with the peptidoglycan layer plays a lesser role in connecting the outer membrane with this structure. Outer membrane proteins are synthesized on ribosomes bound to the cytoplasmic surface of the cell membrane. They are translocated into the periplasm via the Sec translocase. They then fold in the periplasm before being inserted into the outer membrane. In *E. coli*, YaeT appears to function primarily in outer membrane protein insertion.

2. Lipopolysaccharide (LPS)—The LPS of Gram-negative cell walls consists of a complex glycolipid, called lipid A, to which is attached a polysaccharide made up of a core and a terminal series of repeat units (Figure 2-21A). The lipid A component is embedded in the outer leaflet of the membrane anchoring the LPS. LPS is synthesized on the cytoplasmic membrane and transported to its final exterior position. In *E. coli*, LPS insertion is mediated by OstA. The

presence of LPS is required for the function of many outer membrane proteins.

Lipid A consists of phosphorylated glucosamine disaccharide units to which are attached several long-chain fatty acids (Figure 2-21). β -Hydroxymyristic acid, a C14 fatty acid, is always present and is unique to this lipid; the other fatty acids, along with substituent groups on the phosphates, vary according to the bacterial species.

The polysaccharide **core**, shown in Figure 2-21A and B, is similar in all Gram-negative species that have LPS and includes two characteristic sugars, **ketodeoxyoctanoic acid (KDO)** and a heptose. Each species, however, contains a unique repeat unit, that of *Salmonella* being shown in Figure 2-21A. The repeat units are usually linear trisaccharides or branched tetra- or pentasaccharides. The repeat unit is referred to as the **O antigen**. The hydrophilic carbohydrate chains of the O antigen cover the bacterial surface and exclude hydrophobic compounds.

The negatively charged LPS molecules are noncovalently cross-bridged by divalent cations (ie, Ca^{2+} and Mg^{2+}); this stabilizes the membrane and provides a barrier to hydrophobic molecules. Removal of the divalent cations with chelating agents or their displacement by polycationic antibiotics, such as polymyxins and aminoglycosides, renders the outer membrane permeable to large hydrophobic molecules.

LPS, which is extremely toxic to animals, has been called the **endotoxin** of Gram-negative bacteria because it is firmly bound to the cell surface and is released only when the cells

FIGURE 2-21 Lipopolysaccharide structure. **A:** The lipopolysaccharide from *Salmonella*. This slightly simplified diagram illustrates one form of the LPS. Abe, abequose; Gal, galactose; GlcN, glucosamine; Hep, heptulose; KDO, 2-keto-3-deoxyoctonate; Man, mannose; NAG, *N*-acetylglucosamine; P, phosphate; Rha, L-rhamnose. Lipid A is buried in the outer membrane. **B:** Molecular model of an *E. coli* lipopolysaccharide. The lipid A and core polysaccharide are straight; the O side chain is bent at an angle in this model. are lysed. When LPS is split into lipid A and polysaccharide, all the toxicity is associated with the former. The O antigen is highly immunogenic in a vertebrate animal. Antigenic specificity is conferred by the O antigen because this antigen is highly variable among species and even in strains within a species. The number of possible antigenic types is very great: Over 1000 have been recognized in *Salmonella* alone. Not all Gram-negative bacteria have outer membrane LPS composed of a variable number of repeated oligosaccharide units (see Figure 2-21); the outer membrane glycolipids of bacteria that colonize mucosal surfaces (eg, *Neisseria meningitidis*, *N. gonorrhoeae*, *Haemophilus influenzae*, and *Haemophilus ducreyi*) have relatively short, multiantennary (ie, branched) glycans. These smaller glycolipids have been compared with the “R-type” truncated LPS structures, which lack O antigens and are produced by rough mutants of enteric bacteria such as *E. coli*. However, the structures of these glycolipids more closely resemble those of the glycosphingolipids of mammalian cell membranes, and they are more properly termed **lipooligosaccharides (LOS)**. These molecules exhibit extensive antigenic and structural diversity even within a single strain. LOS is an

important virulence factor. Epitopes have been identified on LOS that mimic host structures and may enable these organisms to evade the immune response of the host. Some LOS (eg, those from *N. gonorrhoeae*, *N. meningitidis*, and *H. ducreyi*) have a terminal *N*-acetylglucosamine (Gal β -1 \rightarrow 4-GlcNAc) residue that is immunochemically similar to the precursor of the human erythrocyte I antigen. In the presence of a bacterial enzyme called **sialyltransferase** and a host or bacterial substrate (cytidine monophospho-*N*-acetylneuraminic acid, CMP-NANA), the *N*-acetylglucosamine residue is sialylated. This sialylation, which occurs in vivo, provides the organism with the environmental advantages of molecular mimicry of a host antigen and the biologic masking thought to be provided by sialic acids.

3. Lipoprotein—Molecules of an unusual **lipoprotein** cross-link the outer membrane and peptidoglycan layers (see Figure 2-19). The lipoprotein contains 57 amino acids, representing repeats of a 15-amino-acid sequence; it is peptide-linked to DAP residues of the peptidoglycan tetrapeptide side chains. The lipid component, consisting of a diglyceride

thioether linked to a terminal cysteine, is noncovalently inserted in the outer membrane. Lipoprotein is numerically the most abundant protein of Gram-negative cells (ca 700,000 molecules per cell). Its function (inferred from the behavior of mutants that lack it) is to stabilize the outer membrane and anchor it to the peptidoglycan layer.

4. The periplasmic space—The space between the inner and outer membranes, called the **periplasmic space**, contains the peptidoglycan layer and a gel-like solution of proteins. The periplasmic space is approximately 20–40% of the cell volume, which is far from insignificant. The periplasmic proteins include binding proteins for specific substrates (eg, amino acids, sugars, vitamins, and ions), hydrolytic enzymes (eg, alkaline phosphatase and 5'-nucleotidase) that break down nontransportable substrates into transportable ones, and detoxifying enzymes (eg, β -lactamase and aminoglycoside-phosphorylase) that inactivate certain antibiotics. The periplasm also contains high concentrations of highly branched polymers of D-glucose, 8 to 10 residues long, which are variously substituted with glycerol phosphate and phosphatidylethanolamine residues; some contain O-succinyl esters. These so-called **membrane-derived oligosaccharides** appear to play a role in osmoregulation because cells grown in media of low osmolarity increase their synthesis of these compounds 16-fold.

D. The Acid-Fast Cell Wall

Some bacteria, notably the tubercle bacillus (*M. tuberculosis*) and its relatives, have cell walls that contain substantial amounts of **waxes**, complex branched hydrocarbons (70–90 carbons long) known as **mycolic acids**. The cell wall is composed of peptidoglycan and an external asymmetric lipid bilayer; the inner leaflet contains mycolic acids linked to an arabinoglycan, and the outer leaflet contains other extractable lipids. This is a highly ordered lipid bilayer in which proteins are embedded, forming water-filled pores through which nutrients and certain drugs can pass slowly. Some compounds can also penetrate the lipid domains of the cell wall albeit slowly. This hydrophobic structure renders these bacteria resistant to many harsh chemicals, including detergents and strong acids. If a dye is introduced into these cells by brief heating or treatment with detergents, the dye cannot be removed by dilute hydrochloric acid, as in other bacteria. These organisms are therefore called **acid fast**. The permeability of the cell wall to hydrophilic molecules is 100- to 1000-fold lower than for *E. coli* and may be responsible for the slow growth rate of mycobacteria.

E. Cell Walls of the Archaea

The *Archaea* do not have cell walls like the *Bacteria*. Some have a simple S-layer (see next) often composed of glycoproteins. Some *Archaea* have a rigid cell wall composed of polysaccharides or a macromolecule called **pseudomurein**. The pseudomurein differs from the peptidoglycan of bacteria by having

L-amino acids rather than D-amino acids and disaccharide units with an α -1 \rightarrow 3 rather than a β 1 \rightarrow 4 linkage. *Archaea* that have a pseudomurein cell wall are Gram-positive.

F. Crystalline Surface Layers

Many bacteria, both Gram-positive and Gram-negative bacteria as well as Archaeobacteria, possess a two-dimensional crystalline, subunit-type layer lattice of protein or glycoprotein molecules (**S-layer**) as the outermost component of the cell envelope. In both Gram-positive and Gram-negative bacteria, this structure is sometimes several molecules thick. In some *Archaea*, it is the only layer external to the cell membrane.

S-layers are generally composed of a single kind of protein molecule, sometimes with carbohydrates attached. The isolated molecules are capable of self-assembly (ie, they make sheets similar or identical to those present on the cells). S-layer proteins are resistant to proteolytic enzymes and protein-denaturing agents. The function of the S-layer is uncertain but is probably protective. In some cases, it has been shown to protect the cell from wall-degrading enzymes, from invasion by *Bdellovibrio bacteriovorus* (a predatory bacterium), and from bacteriophages. It also plays a role in the maintenance of cell shape in some species of Archaeobacteria, and it may be involved in cell adhesion to host epidermal surfaces.

G. Enzymes That Attack Cell Walls

The β 1 \rightarrow 4 glycan linkage of the peptidoglycan backbone is hydrolyzed by the enzyme **lysozyme** (see Figure 2-17), which is found in animal secretions (tears, saliva, nasal secretions) as well as in egg white. Gram-positive bacteria treated with lysozyme in low-osmotic-strength media lyse; if the osmotic strength of the medium is raised to balance the internal osmotic pressure of the cell, free spherical bodies called **protoplasts** are liberated. The outer membrane of the Gram-negative cell wall prevents access of lysozyme unless disrupted by an agent such as ethylene-diaminetetraacetic acid (EDTA), a compound that chelates divalent cations; in osmotically protected media, cells treated with EDTA-lysozyme form **spheroplasts** that still possess remnants of the complex Gram-negative wall, including the outer membrane.

Bacteria themselves possess a number of **autolysins**, hydrolytic enzymes that attack peptidoglycan, including muramidases, glucosaminidases, endopeptidases, and carboxypeptidases. These enzymes catalyze the turnover or degradation of peptidoglycan in bacteria. These enzymes presumably participate in cell wall growth and turnover and in cell separation, but their activity is most apparent during the dissolution of dead cells (autolysis).

Enzymes that degrade bacterial cell walls are also found in cells that digest whole bacteria (eg, protozoa and the phagocytic cells of higher animals).

H. Cell Wall Growth

Cell wall synthesis is necessary for cell division; however, the incorporation of new cell wall material varies with the

shape of the bacterium. Rod-shaped bacteria (eg, *E. coli* and *Bacillus subtilis*) have two modes of cell wall synthesis; new peptidoglycan is inserted along a helical path leading to elongation of the cell and is inserted in a closing ring around the future division site, leading to the formation of the division septum. Coccoid cells such as *S. aureus* do not seem to have an elongation mode of cell wall synthesis. Instead, new peptidoglycan is inserted only at the division site. A third form of cell wall growth is exemplified by *S. pneumoniae*, which are not true cocci, because their shape is not totally round but instead have the shape of a rugby ball. *S. pneumoniae* synthesizes cell wall not only at the septum but also at the so-called **equatorial rings** (Figure 2-22).

I. Protoplasts, Spheroplasts, and L Forms

Removal of the bacterial wall may be accomplished by hydrolysis with lysozyme (as described above) or by blocking peptidoglycan synthesis with an antibiotic such as penicillin. In osmotically protective media, such treatments liberate **protoplasts** from Gram-positive cells and **spheroplasts** (which retain outer membrane and entrapped peptidoglycan) from Gram-negative cells.

If such cells are able to grow and divide, they are called **L forms**. L forms are difficult to cultivate and usually require a medium that is solidified with agar as well as having the right osmotic strength. L forms are produced more readily with penicillin than with lysozyme, suggesting the need for residual peptidoglycan.

Some L forms can revert to the normal bacillary form upon removal of the inducing stimulus. Thus, they can resume normal cell wall synthesis. Others are stable and never revert. The factor that determines their capacity to revert may again be the presence of residual peptidoglycan, which normally acts as a primer in its own biosynthesis.

Some bacterial species produce L forms spontaneously. The spontaneous or antibiotic-induced formation of L forms in the host may produce chronic infections, the organisms persisting by becoming sequestered in protective regions of the body. Because L-form infections are relatively resistant to antibiotic treatment, they present special problems in chemotherapy. Their reversion to the bacillary form can produce relapses of the overt infection.

J. The Mycoplasmas

The **mycoplasmas** are cell wall-lacking bacteria containing no peptidoglycan (see Figure 25-1). There are also wall-less *Archaea*, but they have been less well studied. Genomic analysis places the mycoplasmas close to the Gram-positive bacteria from which they may have been derived. Mycoplasmas lack a target for cell wall-inhibiting antimicrobial agents (eg, penicillins and cephalosporins) and are therefore resistant to these drugs. Some, such as *Mycoplasma pneumoniae*, an agent of pneumonia, contain sterols in their membranes. The difference between L forms and mycoplasmas is that when the murein is allowed to reform, L forms revert to their original bacteria shape, but mycoplasmas never do.

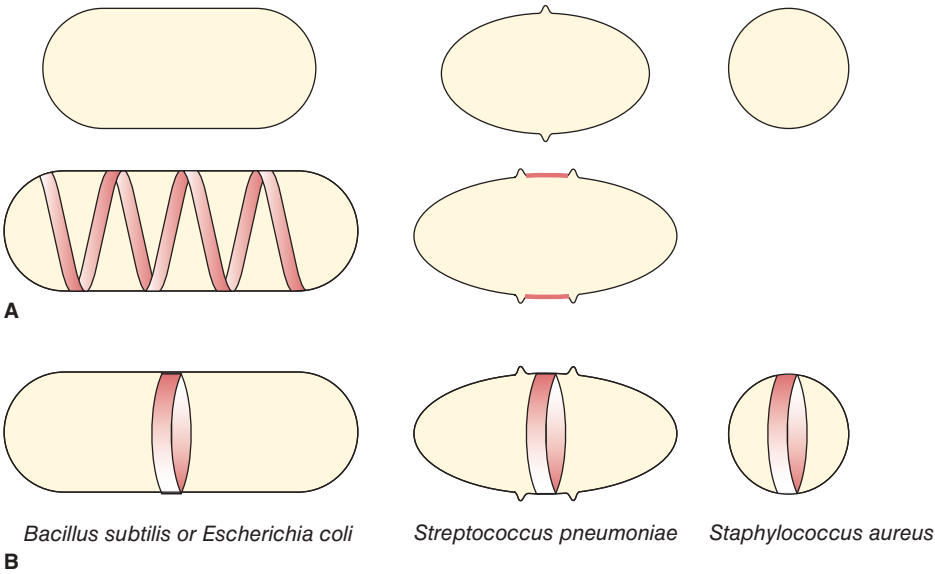

FIGURE 2-22 Incorporation of new cell wall in differently shaped bacteria. Rod-shaped bacteria such as *B. subtilis* or *E. coli* have two modes of cell wall synthesis: New peptidoglycan is inserted along a helical path (**A**), leading to elongation of the lateral wall and is inserted in a closing ring around the future division site, leading to the formation of the division septum (**B**). *S. pneumoniae* cells have the shape of a rugby ball and elongate by inserting new cell wall material at the so-called **equatorial rings** (**A**), which correspond to an outgrowth of the cell wall that encircles the cell. An initial ring is duplicated, and the two resultant rings are progressively separated, marking the future division sites of the daughter cells. The division septum is then synthesized in the middle of the cell (**B**). Round cells such as *S. aureus* do not seem to have an elongation mode of cell wall synthesis. Instead, new peptidoglycan is inserted only at the division septum (**B**). (Reproduced with permission from Scheffers DJ, Pinho MG: Bacterial cell wall synthesis: new insights from localization studies. *Microbiol Mol Biol Rev* 2005;69:585.)

Capsule and Glycocalyx

Many bacteria synthesize copious amounts of extracellular polymers when growing in their natural environments. With few exceptions (the poly-D-glutamic acid capsules of *Bacillus anthracis* and *Bacillus licheniformis*), and the mixed amino acid capsule of *Yersinia pestis*, the extracellular material is polysaccharide (Table 2-2). The terms **capsule** and **slime layer** are frequently used to describe polysaccharide layers; the more inclusive term **glycocalyx** is also used. Glycocalyx is defined as the polysaccharide-containing material lying outside the cell. A condensed, well-defined layer closely surrounding the cell that excludes particles, such as India ink, is referred to as a capsule (Figure 2-23). If the glycocalyx is loosely associated with the cell and does not exclude particles, it is referred to as a slime layer. Extracellular polymer is synthesized by enzymes located at the surface of the bacterial cell. *Streptococcus mutans*, for example, uses two enzymes—glucosyl transferase and fructosyl transferase—to synthesize long-chain dextrans (poly-D-glucose) and levans (poly-D-fructose) from sucrose. These polymers are called **homopolymers**. Polymers containing more than one kind of monosaccharide are called **heteropolymers**.

The capsule contributes to the invasiveness of pathogenic bacteria—encapsulated cells are protected from phagocytosis unless they are coated with anticapsular antibody. The glycocalyx plays a role in the adherence of

bacteria to surfaces in their environment, including the cells of plant and animal hosts or inanimate surfaces to form **biofilms**. *S. mutans*, for example, owes its capacity to adhere tightly to tooth enamel to its glycocalyx. Bacterial cells of the same or different species become entrapped in the glycocalyx, which forms the layer known as plaque on the tooth surface; acidic products excreted by these bacteria cause dental caries (see Chapter 10). The essential role of the glycocalyx in this process—and its formation from sucrose—explains the correlation of dental caries with sucrose consumption by the human population. Because outer polysaccharide layers bind a significant amount of water, the glycocalyx layer may also play a role in resistance to desiccation.

Flagella

A. Structure

Bacterial flagella are thread-like appendages composed entirely of protein, approximately 20 nm in diameter. They are the organs of locomotion for the forms that possess them. Four types of arrangement are known: **monotrichous** (single polar flagellum), **lophotrichous** (multiple polar flagella), **amphitrichous** (single flagellum found at each of two opposite poles), and **peritrichous** (multiple flagella distributed over the entire cell). The arrangement of flagella is unique to the species observed. Three of the types are illustrated in Figure 2-24.

TABLE 2-2 Chemical Composition of the Extracellular Polymer in Selected Bacteria

Organism	Polymer	Chemical Subunits
<i>Bacillus anthracis</i>	Polypeptide	D-Glutamic acid
<i>Enterobacter aerogenes</i>	Complex polysaccharide	Glucose, fructose, glucuronic acid
<i>Haemophilus influenzae</i>	Serogroup b	Ribose, ribitol, phosphate
<i>Neisseria meningitidis</i>	Homopolymers and heteropolymers, eg,	
	Serogroup A	Partially O-acetylated N-acetylmannosaminephosphate
	Serogroup B	N-Acetylneuraminic acid (sialic acid)
	Serogroup C	Acetylated sialic acid
	Serogroup 135	Galactose, sialic acid
<i>Pseudomonas aeruginosa</i>	Alginate	D-Manuronic acid, L-glucuronic acid
<i>Streptococcus pneumoniae</i> (pneumococcus)	Complex polysaccharide (many types), eg,	
	Type II	Rhamnose, glucose, glucuronic acid
	Type III	Glucose, glucuronic acid
	Type VI	Galactose, glucose, rhamnose
	Type XIV	Galactose, glucose, N-acetylglucosamine
	Type XVIII	Rhamnose, glucose
<i>Streptococcus pyogenes</i> (group A)	Hyaluronic acid	N-Acetylglucosamine, glucuronic acid
<i>Streptococcus salivarius</i>	Levan	Fructose

FIGURE 2-23 Bacterial capsules. **A:** *B. anthracis* M'Faydean capsule stain, grown at 35°C, in defibrinated horse blood. **B:** Demonstration of the presence of a capsule in *B. anthracis* by negative staining with India ink. This method is useful for improving visualization of encapsulated bacteria in clinical samples such as blood, blood culture bottles, or cerebrospinal fluid. (CDC, courtesy of Larry Stauffer, Oregon State Public Health Laboratory.)

A bacterial flagellum is made up of several protofilaments, each made up of thousands of molecules of a protein subunit called **flagellin**. In a few organisms (eg, *Caulobacter* species), flagella are composed of two types of flagellin, but in most, only a single type is found. The flagellum is formed by the aggregation of subunits to form a helical structure. If flagella are removed by mechanically agitating a suspension

of bacteria, new flagella are rapidly formed by the synthesis, aggregation, and extrusion of flagellin subunits; motility is restored within 3–6 minutes. The flagellins of different bacterial species presumably differ from one another in primary structure. They are highly antigenic (**H antigens**), and some of the immune responses to infection are directed against these proteins.

FIGURE 2-25 **A:** General structure of the flagellum of a Gram-negative bacterium, such as *E. coli* or *S. typhimurium*. The filament-hook-basal body complex has been isolated and extensively characterized. The location of the export apparatus has not been demonstrated. **B:** An exploded diagram of the flagellum showing the substructures and the proteins from which they are constructed. The FliF protein is responsible for the M-ring feature, S-ring feature, and collar feature of the substructure shown, which is collectively termed the MS ring. The location of FliE with respect to the MS ring and the rod—and the order of the FlgB, FlgC, and FlgF proteins within the proximal rod—is not known. (From Macnab RM: Genetics and biogenesis of bacterial flagella. *Annu Rev Genet* 1992;26:131. Reproduced with permission from *Annual Review of Genetics*, Volume 26, © 1992 by Annual Reviews.)

The flagellum is attached to the bacterial cell body by a complex structure consisting of a hook and a basal body. The hook is a short curved structure that appears to act as the universal joint between the motor in the basal structure and the flagellum. The basal body bears a set of rings, one pair in Gram-positive bacteria and two pairs in Gram-negative bacteria. An interpretative diagram of the Gram-negative structure is shown in Figure 2-25; the rings labeled L and P are absent in Gram-positive cells. The complexity of the bacterial flagellum is revealed by genetic studies, which show that over 40 gene products are involved in its assembly and function.

Flagella are made stepwise (see Figure 2-25). First, the basal body is assembled and inserted into the cell envelope. Then the hook is added, and finally, the filament is assembled progressively by the addition of flagellin subunits to its growing tip. The flagellin subunits are extruded through a hollow central channel in the flagella; when it reaches the tip, it condenses with its predecessors, and thus the filament elongates.

B. Motility

Bacterial flagella are semirigid helical rotors to which the cell imparts a spinning movement. Rotation is driven by the flow of protons into the cell down the gradient produced by the primary proton pump (see earlier discussion); in the absence of a metabolic energy source, it can be driven by a proton motive force generated by ionophores. Bacteria living in alkaline environments (alkalophiles) use the energy of the

sodium ion gradient—rather than the proton gradient—to drive the flagellar motor (Figure 2-26).

All the components of the flagellar motor are located in the cell envelope. Flagella attached to isolated, sealed cell envelopes rotate normally when the medium contains a suitable substrate for respiration or when a proton gradient is artificially established.

When a peritrichous bacterium swims, its flagella associate to form a posterior bundle that drives the cell forward in a straight line by counterclockwise rotation. At intervals, the flagella reverse their direction of rotation and momentarily dissociate, causing the cell to tumble until swimming resumes in a new, randomly determined direction. This behavior makes possible the property of **chemotaxis**: A cell that is moving away from the source of a chemical attractant tumbles and reorients itself more frequently than one that is moving toward the attractant, the result being the net movement of the cell toward the source. The presence of a chemical attractant (eg, a sugar or an amino acid) is sensed by specific receptors located in the cell membrane (in many cases, the same receptor also participates in membrane transport of that molecule). The bacterial cell is too small to be able to detect the existence of a spatial chemical gradient (ie, a gradient between its two poles); rather, experiments show that it detects temporal gradients, that is, concentrations that decrease with time during which the cell is moving away from the attractant source and increase with time during which the cell is moving toward it.

FIGURE 2-26 Structural components within the basal body of the flagellum allow the inner portion of this structure, the rods of the basal body, and the attached hook–filament complex to rotate. The outer rings remain statically in contact with the inner and outer cell membranes and cell wall (murein), anchoring the flagellum complex to the bacterial cell envelope. Rotation is driven by the flow of protons through the motor from the periplasmic space, outside the cell membrane, into the cytoplasm in response to the electric field and proton gradient across the membrane, which together constitute the proton motive force. A switch determines the direction of rotation, which in turn determines whether the bacteria swim forward (by counterclockwise rotation of the flagellum) or tumble (caused by clockwise rotation of the flagellum). (Reproduced with permission from Saier MH Jr: Peter Mitchell and his chemiosmotic theories. *ASM News* 1997;63:13.)

Some compounds act as repellants rather than attractants. One mechanism by which cells respond to attractants and repellents involves a cGMP-mediated methylation and demethylation of specific proteins in the membrane. Whereas attractants cause a transient inhibition of demethylation of these proteins, repellents stimulate their demethylation.

The mechanism by which a change in cell behavior is brought about in response to a change in the environment is called **sensory transduction**. Sensory transduction is responsible not only for chemotaxis but also for **aerotaxis** (movement toward the optimal oxygen concentration), **phototaxis** (movement of photosynthetic bacteria toward the light), and **electron acceptor taxis** (movement of respiratory bacteria toward alternative electron acceptors, such as nitrate and fumarate). In these three responses, as in chemotaxis, net movement is determined by regulation of the tumbling response.

Pili (Fimbriae)

Many Gram-negative bacteria possess rigid surface appendages called **pili** (L “hairs”) or **fimbriae** (L “fringes”). They are shorter and thinner than flagella; similar to flagella, they

are composed of structural protein subunits termed **pilins**. Some pili contain a single type of pilin, others more than one. Minor proteins termed **adhesins** are located at the tips of pili and are responsible for the attachment properties. Two classes can be distinguished: ordinary pili, which play a role in the adherence of symbiotic and pathogenic bacteria to host cells; and sex pili, which are responsible for the attachment of donor and recipient cells in bacterial conjugation (see Chapter 7). Pili are illustrated in Figure 2-27, in which the sex pili have been coated with phage particles for which they serve as specific receptors.

Motility via pili is completely different from flagellar motion. Pilin molecules are arranged helically to form a straight cylinder that does not rotate and lacks a complete basal body. Their tips strongly adhere to surfaces at a distance from the cells. Pili then depolymerize from the inner end, thus retracting inside the cell. The result is that the bacterium moves in the direction of the adhering tip. This kind of surface motility is called **twitching** and is widespread among pilated bacteria. Unlike flagella, pili grow from the inside of the cell outward.

The virulence of certain pathogenic bacteria depends on the production not only of toxins but also of “colonization

FIGURE 2-27 Pili. Pili on an *E. coli* cell. The short pili (fimbriae) mediate adherence; the sex pilus is involved in DNA transfer. (Courtesy of Dr. Charles Brinton, Jr.)

antigens,” which are ordinary pili that provide the cells with adherent properties. In enteropathogenic *E. coli* strains, both the enterotoxins and the colonization antigens (pili) are genetically determined by transmissible plasmids, as discussed in Chapter 7.

Pili of different bacteria are antigenically distinct and elicit the formation of antibodies by the host. Antibodies against the pili of one bacterial species will not prevent the attachment of another species. Some bacteria (see Chapter 21), such as *N. gonorrhoeae*, can make pili of different antigenic types (**antigenic variation**) and thus can still adhere to cells in the presence of antibodies to their original type of pili. Like capsules, pili inhibit the phagocytic ability of leukocytes.

Endospores

Members of several bacterial genera can form **endospores** (Figure 2-28). The two most common are Gram-positive rods: the obligately aerobic genus *Bacillus* and the obligately anaerobic genus *Clostridium*. The other bacteria known to form endospores are *Thermoactinomyces*, *Sporolactobacillus*, *Sporosarcina*, *Sporotomaculum*, *Sporomusa*, and *Sporohalobacter* spp. These organisms undergo a cycle of differentiation in response to environmental conditions: The process, **sporulation**, is triggered by near depletion of any of several nutrients (carbon, nitrogen, or phosphorous). Each cell forms a single internal spore that is liberated when the mother cell undergoes autolysis. The spore is a resting cell, highly resistant to desiccation, heat, and chemical agents; when returned to favorable nutritional conditions and activated (see below), the spore **germinates** to produce a single vegetative cell. The location of an endospore within a cell is species-specific and can be used to determine the identity of a bacterium.

A. Sporulation

The sporulation process begins when nutritional conditions become unfavorable, near depletion of the nitrogen or carbon source (or both) being the most significant factor. Sporulation occurs massively in cultures that have terminated exponential growth because of this near depletion.

Sporulation involves the production of many new structures, enzymes, and metabolites along with the disappearance of many vegetative cell components. These changes represent a true process of **differentiation**: A series of genes whose products determine the formation and final composition of the spore are activated. These changes involve alterations in

FIGURE 2-28 Sporulating cells of bacillus species. **A:** Unidentified bacillus from soil. **B:** *B. cereus*. **C:** *B. megaterium*. (Reproduced with permission from Robinow CF: Structure. In Gunsalus IC, Stanier RY [editors]. *The Bacteria: A Treatise on Structure and Function*, Vol 1. Academic Press, 1960.)

the transcriptional specificity of RNA polymerase, which is determined by the association of the polymerase core protein with one or another promoter-specific proteins called **sigma factors**. During vegetative growth, a sigma factor designated σ^A predominates. Then, during sporulation, five other sigma factors are formed that cause various spore genes to be expressed at various times in specific locations.

The sequence of events in sporulation is highly complex: Differentiation of a vegetative cell of *B. subtilis* into an endospore takes about 7 hours under laboratory conditions.

Different morphologic and chemical events occur at sequential stages of the process. Seven distinct stages have been identified.

Morphologically, sporulation begins with the formation of an axial filament (Figure 2-29). The process continues with an infolding of the membrane to produce a double-membrane structure whose facing surfaces correspond to the cell wall-synthesizing surface of the cell envelope. The growing points move progressively toward the pole of the cell to engulf the developing spore.

FIGURE 2-29 The stages of endospore formation. (Reproduced with permission from Merrick MJ: Streptomyces. In: Parish JH [editor]. *Developmental Biology of Prokaryotes*. Univ California Press, 1979.)

The two spore membranes now engage in the active synthesis of special layers that will form the cell envelope: the **spore wall** and the **cortex**, lying outside the facing membranes. In the newly isolated cytoplasm, or core, many vegetative cell enzymes are degraded and are replaced by a set of unique spore constituents.

B. Properties of Endospores

1. Core—The core is the spore protoplast. It contains a complete chromosome, all the components of the protein-synthesizing apparatus, and an energy-generating system based on glycolysis. Cytochromes are lacking even in aerobic species, the spores of which rely on a shortened electron transport pathway involving flavoproteins. A number of vegetative cell enzymes are increased in amount (eg, alanine racemase), and a number of unique enzymes are formed (eg, dipicolinic acid synthetase). Spores contain no reduced pyridine nucleotides or ATP. The energy for germination is stored as 3-phosphoglycerate rather than as ATP.

The heat resistance of spores is partly attributable to their dehydrated state and in part to the presence in the core of substantial amounts (5–15% of the spore dry weight) of **calcium dipicolinate**, which is formed from an intermediate of the lysine biosynthetic pathway (see Figure 6-19). In some way not yet understood, these properties result in the stabilization of the spore enzymes, most of which exhibit normal heat lability when isolated in soluble form.

2. Spore wall—The innermost layer surrounding the inner spore membrane is called the spore wall. It contains normal peptidoglycan and becomes the cell wall of the germinating vegetative cell.

3. Cortex—The cortex is the thickest layer of the spore envelope. It contains an unusual type of peptidoglycan, with many fewer cross-links than are found in cell wall peptidoglycan. Cortex peptidoglycan is extremely sensitive to lysozyme, and its autolysis plays a role in spore germination.

4. Coat—The coat is composed of a keratin-like protein containing many intramolecular disulfide bonds. The impermeability of this layer confers on spores their relative resistance to antibacterial chemical agents.

5. Exosporium—The exosporium is composed of proteins, lipids, and carbohydrates. It consists of a paracrystalline basal layer and a hairlike outer region. The function of the exosporium is unclear. Spores of some *Bacillus* species (eg, *B. anthracis* and *B. cereus*) possess an exosporium, but other species (eg, *B. atropheus*) have spores that lack this structure.

C. Germination

The germination process occurs in three stages: activation, initiation, and outgrowth.

1. Activation—Most endospores cannot germinate immediately after they have formed. But they can germinate after they have rested for several days or are first activated in a nutritionally rich medium by one or another agent that damages the spore coat. Among the agents that can overcome spore dormancy are heat, abrasion, acidity, and compounds containing free sulfhydryl groups.

2. Initiation—After activation, a spore will initiate germination if the environmental conditions are favorable. Different species have evolved receptors that recognize different effectors (ie, **germinants**) as signaling a rich medium: Thus, initiation is triggered by L-alanine in one species and by adenosine in another. Binding of the effector activates an autolysin that rapidly degrades the cortex peptidoglycan. Water is taken up, calcium dipicolinate is released, and a variety of spore constituents are degraded by hydrolytic enzymes.

3. Outgrowth—Degradation of the cortex and outer layers results in the emergence of a new vegetative cell consisting of the spore protoplast with its surrounding wall. A period of active biosynthesis follows; this period, which terminates in cell division, is called outgrowth. Outgrowth requires a supply of all nutrients essential for cell growth.

STAINING

Stains combine chemically with the bacterial protoplasm; if the cell is not already dead, the staining process itself will kill it. The process is thus a drastic one and may produce artifacts.

The commonly used stains are salts. **Basic stains** consist of a colored cation with a colorless anion (eg, methylene blue⁺ chloride⁻); **acidic stains** are the reverse (eg, sodium⁺ eosinate⁻). Bacterial cells are rich in nucleic acid, bearing negatively charged phosphate groups. These combine with the positively charged basic dyes. Acidic dyes do not stain bacterial cells and hence can be used to stain background material a contrasting color (see Negative Staining).

The basic dyes stain bacterial cells uniformly unless the cytoplasmic RNA is destroyed first. Special staining techniques can be used, however, to differentiate flagella, capsules, cell walls, cell membranes, granules, nucleoids, and spores.

The Gram Stain

An important taxonomic characteristic of bacteria is their response to Gram-stain. The Gram-staining property appears to be a fundamental one because the Gram reaction is correlated with many other morphologic properties in phylogenetically related forms (see Chapter 3). An organism that is potentially Gram-positive may appear so only under a particular set of environmental conditions and in a young culture.

The Gram-staining procedure (see Chapter 47) begins with the application of a basic dye, crystal violet. A solution

of iodine is then applied, which forms a complex with crystal violet. All bacteria will be stained blue at this point in the procedure. The cells are then treated with alcohol. Gram-positive cells retain the crystal violet–iodine complex, remaining blue; Gram-negative cells are completely decolorized by alcohol. As a last step, a counterstain (eg, the red dye safranin) is applied so that the decolorized Gram-negative cells will take on a contrasting color; the Gram-positive cells now appear purple (Table 2-1).

The basis of the differential Gram reaction is the structure of the cell wall, as discussed earlier in this chapter.

The Acid-Fast Stain

Acid-fast bacteria are those that retain carbolfuchsin (basic fuchsin dissolved in a phenol–alcohol–water mixture) even when decolorized with hydrochloric acid in alcohol. A smear of cells on a slide is flooded with carbolfuchsin and heated on a steam bath. After this, the decolorization step with acid-alcohol is carried out, and finally a contrasting (blue or green) counterstain is applied (see Chapter 47). Acid-fast bacteria (mycobacteria and some of the related actinomycetes) appear red; others take on the color of the counterstain.

Negative Staining

This procedure involves staining the background with an acidic dye, leaving the cells contrastingly colorless. The black dye nigrosin is commonly used. This method is used for cells or structures that are difficult to stain directly (see Figure 2-23B).

The Flagella Stain

Flagella are too fine (ca 20 nm in diameter) to be visible in the light microscope. However, their presence and arrangement can be demonstrated by treating the cells with an unstable colloidal suspension of tannic acid salts, causing a heavy precipitate to form on the cell walls and flagella. In this manner, the apparent diameter of the flagella is increased to such an extent that subsequent staining with basic fuchsin makes the flagella visible in the light microscope. Figure 2-30 shows cells stained by this method.

In peritrichous bacteria, the flagella form into bundles during movement, and such bundles may be thick enough to be observed on living cells by dark-field or phase-contrast microscopy.

The Capsule Stain

Capsules are usually demonstrated by the negative staining procedure or a modification of it (see Figure 2-23). One such “capsule stain” (Welch method) involves treatment with hot crystal violet solution followed by a rinsing with copper sulfate solution. The latter is used to remove excess stain because the conventional washing with water would dissolve the capsule. The copper salt also gives color to the background, with

FIGURE 2-30 Flagella stain of *Pseudomonas* species. (Reproduced with permission from Leifson E: Staining, shape and arrangement of bacterial flagella. *J Bacteriol* 1951;62:377.)

the result that the cell and background appear dark blue and the capsule a much paler blue.

Staining of Nucleoids

Nucleoids are stainable with the Feulgen stain, which is specific for DNA. The DNA-intercalating stains DAPI and ethidium bromide are widely used for fluorescence microscopy of nucleoids.

The Spore Stain

Spores are most simply observed as intracellular refractile bodies (see Figure 2-28) in unstained cell suspensions or as colorless areas in cells stained by conventional methods. The spore wall is relatively impermeable, but dyes can be made to penetrate it by heating the preparation. The same impermeability then serves to prevent decolorization of the spore by a period of alcohol treatment sufficient to decolorize vegetative cells. The latter can finally be counterstained. Spores are commonly stained with malachite green or carbolfuchsin (Figure 2-31).

MORPHOLOGIC CHANGES DURING GROWTH

Cell Division

Most bacteria divide by **binary fission** into two equal progeny cells. In a growing culture of a rod-shaped bacterium such as *E. coli*, cells elongate and then form a partition that eventually

FIGURE 2-31 Endospore stain. Endospores retain the green primary stain, malachite green. Counterstaining with safranin imparts a red color to other cells. (Courtesy of Larry Stauffer, Oregon State Public Health Laboratory. Source: Centers for Disease Control and Prevention, Public Health Image Library, ID# 1895, 2002.)

separates the cell into two daughter cells. The partition is referred to as a **septum** and is a result of the inward growth of the cytoplasmic membrane and cell wall from opposing directions until the two daughter cells are pinched off. The chromosomes, which have doubled in number preceding the division, are distributed equally to the two daughter cells.

Although bacteria lack a mitotic spindle, the septum is formed in such a way as to separate the two sister chromosomes formed by chromosomal replication. This is accomplished by the attachment of the chromosome to the cell membrane. According to one model, completion of a cycle of DNA replication triggers active membrane synthesis between the sites of attachment of the two sister chromosomes. The chromosomes are then pushed apart by the inward growth of the septum, one copy going to each daughter cell.

Cell Groupings

If the cells remain temporarily attached after division, certain characteristic groupings result. Depending on the plane of division and the number of divisions through which the cells remain attached, the following may occur in the coccal forms: chains (streptococci), pairs (diplococci), cubical bundles (sarcinae), grape-like clusters (staphylococci), or flat plates. Rods may form pairs or chains.

After fission of some bacteria, characteristic postdivision movements occur. For example, a “whipping” motion can bring the cells into parallel positions; repeated division and whipping result in the “palisade” arrangement characteristic of diphtheria bacilli.

CHAPTER SUMMARY

- Microscopy has played a significant role in our understanding of cell structure.

- Eukaryotic cells are characterized by a membrane-bound nucleus, an endoplasmic reticulum, 80S ribosomes, and plastids (mitochondria and chloroplasts). The plasma membrane is characterized by the presence of sterols (cholesterol). Prokaryotic cells lack a true nucleus and are haploid. The cytoplasm contains 70S ribosomes, and they do not have mitochondria and chloroplasts.
- The major functions of the cell membrane of prokaryotic cells are (1) selective permeability and transport of solutes; (2) electron transport and oxidative phosphorylation, in aerobic species; (3) excretion of hydrolytic enzymes and other proteins; (4) bearing the enzymes and carrier molecules that function in the biosynthesis of DNA, cell wall polymers, and membrane lipids; and (5) bearing the receptors and proteins of the chemotactic and other sensory transduction systems.
- Most bacteria are classified as Gram-positive or Gram-negative according to their response to the Gram-staining procedure. The differences between these two groups are reflected by fundamental differences in their cell envelopes.
- Gram-positive cell wall consists of a plasma membrane and thick peptidoglycan layer; the Gram-negative cell wall consists of a plasma membrane, a thin peptidoglycan layer, and an asymmetric outer membrane containing lipopolysaccharide (endotoxin). The space between the plasma membrane and outer membrane is referred to as the periplasmic space.
- Many bacteria synthesize substantial amounts of extracellular polymers. When this polymer forms a condensed, well-defined layer surrounding the cell that excludes particles such as India ink, it is referred to as a capsule. Capsules are an important virulence factor and protect the cell from phagocytosis.
- Cell surface structures such as pili and flagella are important for attachment and motility, respectively.
- The formation of endospores is a characteristic of the genera *Bacillus* and *Clostridium* and is triggered by near depletion of nutrients in the environment. Endospores (spores) are resting cells, highly resistant to desiccation, heat, and chemical agents; when returned to favorable nutritional conditions and activated, the spore germinates to produce a vegetative cell.

REVIEW QUESTIONS

1. A 22-year-old man presents with a painless 1-cm ulcer on the shaft of his penis. Inguinal lymphadenopathy is present. The patient admits trading drugs for sex and has several sexual partners. An RPR test result is positive, and syphilis is suspected; however, a Gram-stain of a swab specimen from the ulcer shows no bacteria. *T. pallidum*, the causative agent of syphilis, cannot be visualized by light microscopy because
 - (A) It is transparent.
 - (B) It cannot be stained by ordinary stains.
 - (C) It has a diameter of less than 0.2 μm .
 - (D) The wavelength of white light is too long.
 - (E) Rapid movement of the organism prevents visualization.

2. Chloramphenicol, an antibiotic that inhibits bacterial protein synthesis, will also affect which of the following eukaryotic organelles?
 - (A) Mitochondria
 - (B) Golgi complex
 - (C) Microtubules
 - (D) Endoplasmic reticulum
 - (E) Nuclear membrane
3. Which of the following structures is not part of the bacterial cell envelope?
 - (A) Peptidoglycan
 - (B) Lipopolysaccharide
 - (C) Capsule
 - (D) Gas vacuole
 - (E) S-layer
4. A group of teenagers became ill with nausea, vomiting, severe abdominal cramps, and diarrhea after eating undercooked hamburgers from a local restaurant. Two of the teenagers were hospitalized with hemolytic-uremic syndrome. *E. coli* O157:H7 was isolated from the patient's stools as well as from uncooked hamburgers. The O157 refers to which bacterial structure?
 - (A) Lipopolysaccharide
 - (B) Capsule
 - (C) Flagella
 - (D) Fimbriae
 - (E) S-layer
5. Which of the following components is present in Gram-negative bacteria but not in Gram-positive bacteria?
 - (A) Peptidoglycan
 - (B) Lipid A
 - (C) Capsule
 - (D) Flagella
 - (E) Pili
6. Group A streptococci are the most common bacterial cause of pharyngitis in school-age children 5–15 years of age. The most important cell component involved in adherence of this bacteria to fibronectin, which covers the epithelial surface of the nasopharynx is
 - (A) Capsule
 - (B) Lipoteichoic acid
 - (C) Flagella
 - (D) Lipoprotein
 - (E) O-antigen
7. In the fall of 2001, a series of letters containing spores of *B. anthracis* were mailed to members of the media and to U.S. Senate offices. The result was 22 cases of anthrax, with five deaths. The heat resistance of bacterial spores, such as those of *B. anthracis*, is partly attributable to their dehydrated state and partly to the presence of substantial amounts of
 - (A) Diaminopimelic acid
 - (B) D-Glutamic acid
 - (C) Calcium dipicolinate
 - (D) Sulfhydryl-containing proteins
 - (E) Lipid A
8. Which of the following terms does NOT describe the bacterial chromosome?
 - (A) Haploid
 - (B) Diploid
 - (C) Circular
 - (D) Nucleoid
 - (E) Feulgen positive
9. Lysozyme cleaves the $\beta 1 \rightarrow 4$ linkage between
 - (A) D-Alanine and the pentaglycine bridge
 - (B) N-Acetylmuramic acid and D-alanine
 - (C) Lipid A and KDO
 - (D) N-Acetylmuramic acid and N-acetylglucosamine
 - (E) D-Alanine and D-alanine
10. *Mycoplasma* species lack which of the following components?
 - (A) Ribosomes
 - (B) Plasma membrane
 - (C) Both DNA and RNA
 - (D) Lipids
 - (E) Peptidoglycan

Classification of Bacteria

TAXONOMY—THE VOCABULARY OF MEDICAL MICROBIOLOGY

One has only to peruse the table of contents of this book to appreciate the diversity of medical pathogens that are associated with infectious diseases. It has been estimated that we currently have the capacity to identify a surprisingly small number of the pathogens responsible for causing human disease. In part this is due to our inability to culture or target these organisms using molecular probes. The diversity of even these identifiable pathogens alone is so great that it is important to appreciate the subtleties associated with each infectious agent. The reason for understanding these differences is significant because each infectious agent has specifically adapted to a particular mode(s) of transmission, the capacity to grow in a human host (colonization), and a mechanism(s) to cause disease (pathology). As such, a vocabulary that consistently communicates the unique characteristics of infectious organisms to students, microbiologists, and health care workers is critical to avoid the chaos that would ensue without the organizational guidelines of bacterial **taxonomy** (*Gk. taxon* = arrangement; eg, the classification of organisms in an ordered system that indicates a natural relationship).

Identification, classification, and nomenclature are three separate but interrelated areas of bacterial taxonomy. Each area is critical to the ultimate goal of accurately studying the infectious diseases and precisely communicating these to others in the field.

Identification is the practical use of a classification scheme (1) to isolate and distinguish specific organisms among the mix of complex microbial flora, (2) to verify the authenticity or special properties of a culture in a clinical setting, and (3) to isolate the causative agent of a disease. The latter may lead to the selection of specific pharmacologic treatments directed toward their eradication, a vaccine mitigating their pathology, or a public health measure (eg, hand-washing) that prevents further transmission.

Identification schemes are not classification schemes, although there may be some superficial similarity. For example, the popular literature has reported *Escherichia coli* as the causative agent of hemolytic uremic syndrome (HUS)

in infants. There are hundreds of different strains that are classified as *E. coli* but only a few that are associated with HUS. These strains can be “identified” from the many other *E. coli* strains by antibody reactivity with their O-, H-, and K-antigens, as described in Chapter 2 (eg, *E. coli* O157:H7). However, they are more broadly classified as a member of the family Enterobacteriaceae.

In a microbiologic context, **classification** is the categorization of organisms into taxonomic groups. Experimental and observational techniques are required for taxonomic classification. This is because biochemical, physiologic, genetic, and morphologic properties are historically necessary for establishing a taxonomic rank. This area of microbiology is necessarily dynamic as the tools continue to evolve (eg, new methods of microscopy, biochemical analysis, and computational nucleic acid biology).

Nomenclature refers to the naming of an organism by an established group of scientific and medical professionals. This is arguably the most important component of taxonomy because it allows medical professionals to communicate with each other. Just as our societal vocabulary evolves, so does the vocabulary of medical microbiology. Any professional associated with infectious disease should be aware of the evolving taxonomy of infectious microorganisms.

Ultimately, the taxonomic ranks form the basis for the organization of bacteria. Linnaean taxonomy is the system most familiar to biologists. It uses the formal ranks of kingdom, phylum, class, order, family, genus, species, and subtype. The lower ranks are approved by a consensus of experts in the scientific community. Of these ranks, the family, genus, and species are the most useful (Table 3-1).

CRITERIA FOR IDENTIFICATION OF BACTERIA

Growth on Media

Suitable criteria for bacterial classification include many of the properties that were described in the preceding chapter. One criterion is growth on different types of bacteriologic media. The general cultivation of most bacteria requires media rich

TABLE 3-1 Taxonomic Ranks

Formal Rank	Example
Kingdom	Prokaryotae
Division	Gracilicutes
Class	Scotobacteria
Order	Eubacteriales
Family	Enterobacteriaceae
Genus	<i>Escherichia</i>
Species	<i>coli</i>
Subtype	<i>Escherichia coli</i> O157:H7

in metabolic nutrients. These media generally include agar, a carbon source, and an acid hydrolysate or enzymatically degraded source of biologic material (eg, casein). Additionally, these types of media may be supplemented by vitamins and even intact red blood cells in the case of blood agar media. Because of their undefined composition, these types of media are referred to as **complex media**.

Clinical samples from normally nonsterile sites (eg, the throat or the colon) contain multiple species of organisms, including potential pathogens and resident microbial flora. Media can be **nonselective** or **selective**; the latter are used to distinguish among the various bacteria in a clinical sample containing many different organisms.

A. Nonselective Media

Blood agar and chocolate agar are examples of complex, nonselective media, which support the growth of many different bacteria. Different bacterial species growing on these types of agar often give rise to colonies with distinctive morphologies—for example, large or small, yellow versus white, serrated or smooth. Colonial growth patterns on different types of media can be useful in the identification of a particular bacterial species.

B. Selective Media

Because of the diversity of microorganisms that typically reside at some sampling sites (eg, the skin, respiratory tract, intestines, vagina), selective media are used to eliminate (or reduce) the large numbers of irrelevant bacteria in these specimens. The basis for selective media is the incorporation of an inhibitory agent that specifically selects against the growth of irrelevant bacteria. Examples of such agents are:

- Sodium azide selects for Gram-positive bacteria over Gram-negative bacteria.
- Bile salts (sodium deoxycholate) select for Gram-negative enteric bacteria and inhibit Gram-negative mucosal and most Gram-positive bacteria.
- Colistin and nalidixic acid inhibit the growth of many Gram-negative bacteria.

Examples of selective media are MacConkey agar (containing bile) that selects for the Gram-negative rods and CNA blood agar (containing colistin and nalidixic acid) that selects for Gram-positive cocci.

C. Differential Media

Upon culture, some bacteria produce characteristic pigments, and others can be differentiated based on their complement of extracellular enzymes; the activity of these enzymes often can be detected as zones of clearing surrounding colonies grown in the presence of insoluble substrates (eg, **hemolysis** around colonies on agar medium containing intact animal red blood cells).

Many of the members of the Enterobacteriaceae can be differentiated by their ability to metabolize lactose. For example, pathogenic salmonellae and shigellae that do not ferment lactose on a MacConkey plate form white colonies, while lactose-fermenting members of the Enterobacteriaceae (eg, *E. coli*) form red or pink colonies. There are many types of differential media, far too many to describe in a chapter focused on taxonomy.

Microscopy

Historically, the Gram-stain, together with visualization by light microscopy, has been among the most informative methods for classifying the eubacteria. This staining technique broadly divides bacteria based on their fundamental differences in the structure of their cell walls (see Chapter 2). This typically represents the first step in identifying individual microbial specimens (eg, are they Gram-negative or Gram-positive) grown in culture or even directly from patient specimens (eg, urine or cerebral spinal fluids).

Biochemical Tests

Tests such as the **oxidase test**, which uses an artificial electron acceptor, can be used to distinguish organisms by detecting the presence or absence of a respiratory enzyme, cytochrome C, the lack of which differentiates the Enterobacteriaceae from other Gram-negative rods. Similarly, **catalase** activity can be used, for example, to differentiate between the Gram-positive cocci; the species staphylococci are catalase positive, whereas the species streptococci are catalase negative. If the organism is demonstrated to be catalase positive (*Staphylococcus* spp.), the species can be subdivided by a coagulase test into *Staphylococcus aureus* (coagulase positive) or *Staphylococcus epidermidis* (coagulase negative) as demonstrated in Figure 3-1.

Ultimately, there are many examples of biochemical tests that can ascertain the presence of characteristic metabolic functions and be used to group bacteria into a specific *taxon*. A list of common biochemical tests is given in Table 3-2.

Immunologic Tests—Serotypes, Serogroups, and Serovars

The designation “sero” simply indicates the use of antibodies (polyclonal or monoclonal) that react with specific

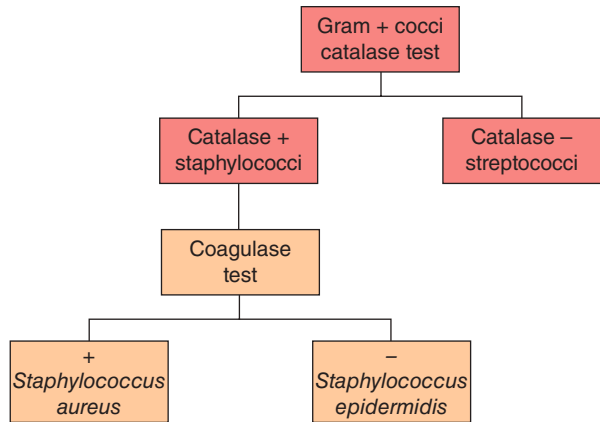

FIGURE 3-1 Algorithm for differentiating the Gram-positive cocci.

bacterial cell surface structures such as lipopolysaccharide (LPS), flagella, or capsular antigens. The terms “serotype,” “serogroups,” and “serovars” are, for all practical purposes, identical—they all use the specificity of these antibodies to

subdivide strains of a specific bacterial species. In essence, these reagents are “forensic” agents, establishing a fingerprint that links the source of an organism to a disease caused in an individual. In certain circumstances (eg, an epidemic), it is important to distinguish among strains of a given species or to identify a specific strain. This is called **subtyping** and is accomplished by examining bacterial isolates for characteristics that allow discrimination below the species level. Classically, subtyping has been accomplished by biotyping, serotyping, antimicrobial susceptibility testing, and bacteriophage typing. For example, more than 130 serogroups of *Vibrio cholerae* have been identified based on antigenic differences in the O-polysaccharide of their LPS; however, only the O1 and O139 serogroups are associated with epidemic and pandemic cholera. Within these serogroups, only strains that produce a toxin-coregulated pili and cholera toxin are virulent and cause the disease cholera. By contrast, nontoxicogenic *V. cholerae* strains, which are not associated with epidemic cholera, are generally isolated from environmental specimens, from food, or from patients with sporadic diarrhea.

TABLE 3-2 Common Microbial Biochemical Tests Used to Differentiate Among Bacteria

<p>1. Carbohydrate breakdown. The ability to produce acidic metabolic products, fermentatively or oxidatively, from a range of carbohydrates (eg, glucose, sucrose, and lactose) has been applied to the identification of most groups of bacteria (eg, <i>Escherichia</i> spp. ferment lactose, whereas <i>Salmonella</i> spp. do not). Such tests are crude and imperfect in defining mechanisms but have proved useful for taxonomic purposes. More recently, gas chromatographic identification of specific short-chain fatty acids produced by fermentation of glucose has proved useful in classifying many anaerobic bacteria.</p> <p>2. Catalase production. The enzyme catalase catalyzes the conversion of hydrogen peroxide to water and oxygen. When a colony is placed in hydrogen peroxide, liberation of oxygen as gas bubbles can be seen. The test is particularly useful in differentiation of staphylococci (positive) from streptococci (negative), but it also has taxonomic application to Gram-negative bacteria.</p> <p>3. Citrate utilization. An agar medium that contains sodium citrate as the sole carbon source may be used to determine ability to use citrate. Bacteria such as <i>Klebsiella pneumoniae</i> that grow on this medium are termed citrate-positive.</p> <p>4. Coagulase. The enzyme coagulase acts with a plasma factor to convert fibrinogen to a fibrin clot. It is used to differentiate <i>Staphylococcus aureus</i> from other, less pathogenic staphylococci.</p> <p>5. Decarboxylases and deaminases. The decarboxylation or deamination of the amino acids lysine, ornithine, and arginine is detected by the effect of the amino products on the pH of the reaction mixture or by the formation of colored products. These tests are used primarily with Gram-negative rods.</p> <p>6. Hydrogen sulfide. The ability of some bacteria to produce H₂S from amino acids or other sulfur-containing compounds is helpful in taxonomic classification. The black color of the sulfide salts formed with heavy metals such as iron is the usual means of detection. This test is useful in distinguishing between the Gram-negative rods.</p> <p>7. Indole. The indole reaction tests the ability of the organism to produce indole, a benzopyrrole, from tryptophan. Indole is detected by the formation of a red dye after addition of a benzaldehyde reagent. A spot test can be done in seconds using isolated colonies. <i>Proteus vulgaris</i> is positive for indole.</p> <p>8. Nitrate reduction. Bacteria may reduce nitrates by several mechanisms. This ability is demonstrated by detection of the nitrites and/or nitrogen gas formed in the process. This test is included in a standard urinalysis test to detect the presence of Gram-negative rods causing urinary tract infections.</p> <p>9. O-Nitrophenyl-β-D-galactoside (ONPG) breakdown. The ONPG test is related to lactose fermentation. Organisms that possess the β-galactoside necessary for lactose fermentation but lack a permease necessary for lactose to enter the cell are ONPG-positive and lactose-negative.</p> <p>10. Oxidase production. The oxidase tests detect the c component of the cytochrome-oxidase complex. The reagents used change from clear to colored when converted from the reduced to the oxidized state. The oxidase reaction is commonly demonstrated in a spot test, which can be done quickly from isolated colonies. This test can be used to distinguish between the Gram-negative rods, <i>Pseudomonas aeruginosa</i> (oxidase +) from <i>E. coli</i> (oxidase –).</p> <p>11. Proteinase production. Proteolytic activity is detected by growing the organism in the presence of substrates such as gelatin or coagulated egg. Protease-producing strains such as <i>P. aeruginosa</i> and <i>S. aureus</i> are positive in this assay.</p> <p>12. Urease production. Urease hydrolyzes urea to yield two molecules of ammonia and one of CO₂. This reaction can be detected by the increase in medium pH caused by ammonia production. Urease-positive species vary in the amount of enzyme produced; bacteria can thus be designated as positive, weakly positive, or negative. <i>P. vulgaris</i> can be differentiated from other enteric rods using this assay.</p> <p>13. Voges-Proskauer test. The Voges-Proskauer test detects acetylmethylcarbinol (acetoin), an intermediate product in the butene glycol pathway of glucose fermentation. This test differentiates among the enteric rods.</p>

Clonality with respect to isolates of microorganisms from a common source outbreak (**point source spread**) is an important concept in the epidemiology of infectious diseases. Etiologic agents associated with these outbreaks are generally **clonal**; in other words, they are the progeny of a single cell and, for all practical purposes, are genetically identical. Thus, subtyping plays an important role in discriminating among these microorganisms. Recent advances in biotechnology have dramatically improved our ability to subtype microorganisms. Hybridoma technology has resulted in the development of monoclonal antibodies against cell surface antigens, which have been used to create highly standardized antibody-based subtyping systems that describe bacterial **serotypes**. This is an important tool for defining the epidemiologic spread of a bacterial infection.

Some organisms cannot be identified as unique serotypes. For example, some bacteria (eg, *Neisseria gonorrhoeae*) or viruses (eg, human immunodeficiency virus [HIV] and hepatitis C) are transmitted as an inoculum composed of **quasispecies** (meaning that there is extensive antigenic variation among the bacteria present in the inoculum). In these cases, groups of hybridomas that recognize variants of the original organisms are used to categorize serovariants or **serovars**.

Genetic Diversity

The value of a taxonomic criterion depends on the biologic group being compared. Traits shared by all or none of the members of a group cannot be used to distinguish its members, but they may define a group (eg, all staphylococci produce the enzyme catalase). Developments in DNA sequencing now make it possible to investigate the relatedness of genes or genomes by comparing sequences among different bacteria. It should be noted that genetic instability can cause some traits to be highly variable within a biologic group or even within a specific taxonomic group. For example, antibiotic resistance genes or genes encoding toxins may be carried on **plasmids** or **bacteriophages** (see Chapter 7), extrachromosomal genetic elements that may be transferred among unrelated bacteria or that may be lost from a subset of bacterial strains identical in all other respects. Many organisms are difficult to cultivate, and in these instances, techniques that reveal relatedness by measurement of DNA sequence analysis may be of value.

CLASSIFICATION SYSTEMS

Dichotomous Keys

Dichotomous keys organize bacterial traits in a manner that permits logical identification of organisms. The ideal system should contain the minimum number of features required for a correct categorization. Groups are split into smaller subgroups based on the presence (+) or absence (–) of a diagnostic character. Continuation of the process with different characteristics guides the investigator to the smallest defined subgroup containing the analyzed organism. In the early stages of this process, organisms may be assigned to subgroups based on characteristics that do not reflect genetic relatedness. It would be perfectly reasonable, for example, for a bacterial key to include a group such as “bacteria forming red pigments when propagated on a defined medium” even though this would include such unrelated forms as *Serratia marcescens* (see Chapter 15) and purple photosynthetic bacteria (see Chapter 6). These two disparate bacterial assemblages occupy distinct niches and depend on entirely different forms of energy metabolism. Nevertheless, preliminary grouping of the assemblages would be useful because it would immediately make it possible for an investigator having to identify a red-pigmented culture to narrow the range of possibilities to relatively few groups. An example of a dichotomous key is shown in Figure 3-1.

Numerical Taxonomy Using Biochemical Measures of Activity

Numerical taxonomy became widely used in the 1970s. These classification schemes use a number of unweighted, taxonomically useful characteristics. For these assays, an individual bacterial colony must be isolated and used to inoculate the test format. One example of this is the Analytical Profile Index (API), which uses numerical taxonomy to identify a wide range of medically important microorganisms. APIs consist of several plastic strips, each of which has about 20 miniature compartments containing biochemical reagents (Figure 3-2). Almost all cultivatable bacterial groups and more than 550 different species can be identified using the results of these API tests. These identification systems have extensive databases of microbial biochemical reactions. The numerical clusters derived from these tests identify different

FIGURE 3-2 API test demonstrating how bacteria can be differentiated using a series of biochemical tests. Each small compartment contains a dehydrated powder that is inoculated from a bacterial culture. After incubation, the colorimetric changes can be scored numerically to produce a number that matches to a specific bacterial species and genus. (Courtesy of bioMérieux, Inc.)

strains at selected levels of overall similarity (usually >80% at the species level) based on the frequency with which they share traits. In addition, numerical classification provides percentage frequencies of positive character states for all strains within each cluster. The limitation of this approach is that it is a **static system**. As such, it does not allow for the evolution of bacteria and routine discovery of new bacterial pathogens.

Nucleic Acid–Based Taxonomy

Since 1975, developments in nucleic acid isolation, amplification, and sequencing have spurred the evolution of nucleic acid–based subtyping systems. These include plasmid profile analysis, restriction fragment endonuclease analysis, repetitive sequence analysis, ribotyping, 16S ribosomal sequencing, and genomic sequencing. These methods are individually described as follows.

Plasmid Analysis

Plasmids are extrachromosomal genetic elements (see Chapter 7). These can be isolated from an isolated bacterium and separated by agarose gel electrophoresis to determine their number and size. Plasmid analysis has been shown to be most useful for examining outbreaks that are restricted in time and place (eg, an outbreak in a hospital), particularly when they are combined with other identification methods.

Restriction Endonuclease Analysis

The use of restriction enzymes to cleave DNA into discrete fragments is one of the most basic procedures in molecular biology. Restriction endonucleases recognize short DNA sequences (restriction sequences), and they cleave double-stranded DNA within or adjacent to this sequence. Restriction sequences range from 4 to more than 12 bases in length and occur throughout the bacterial chromosome. Restriction enzymes that recognize short sequences (eg, 4-base pairs) occur more frequently than those that are specific for longer sequences (eg, 12-base pairs). Thus, enzymes that recognize short DNA sequences produce more fragments than enzymes that recognize infrequently occurring long DNA sequences. Several subtyping methods use restriction endonuclease–digested DNA approaches.

One method involves isolating the **plasmid** DNA, which is generally of the size of several kilobases, and digesting this nucleic acid with a restriction enzyme. After enzymatic cleavage, fragmented plasmid segments are separated using agarose gel electrophoresis. Because plasmids carry genetic material that directly contribute to disease and are commonly moved from one organism to another, the presence of a common fragment may confirm that a specific bacterial isolate was identical to other isolates associated with an outbreak.

Another method involves the analysis of **genomic DNA**, which is of the size of several megabases. In this case,

restriction endonucleases that cut at infrequently occurring restriction sites within the bacterial genome are used. Digestion of DNA with these enzymes generally results in 5–20 fragments ranging from approximately 10 to 800 kb in length. Separation of these large DNA fragments is accomplished by a technique called **pulsed field gel electrophoresis** (PFGE), which requires specialized equipment. Theoretically, all bacterial isolates can be typed by this method. Its advantage is that the restriction profile consists of a finite number of well-resolved bands representing the entire bacterial chromosome in a single DNA fragment pattern.

Genomic Analysis

In biology, the classic definition of a species is typically defined as the largest group of organisms in which two individuals can produce fertile offspring, typically by sexual reproduction. The multiplication of bacteria is almost entirely vegetative, and their mechanisms of genetic exchange rarely involve recombination among large portions of their genomes (see Chapter 7). Therefore, the concept of a **species**—the fundamental unit of eukaryotic phylogeny—has an entirely different meaning when applied to bacteria, making bacterial genome sequencing extremely useful.

The routine use of DNA genome sequencing allows the precise comparison of divergent DNA sequences, which can give a measure of their relatedness. Genes for different functions, such as those encoding surface antigens to escape immune surveillance, diverge at different rates relative to “housekeeping” genes such as those that encode cytochromes. Thus, DNA sequence differences among rapidly diverging genes can be used to ascertain the genetic distance between closely related groups of bacteria. Sequence differences among housekeeping genes then represent the relatedness of widely divergent bacterial groups.

There is considerable genetic diversity among bacterial species. Chemical characterization of bacterial genomic DNA reveals a wide range of nucleotide base compositions among different bacterial species. One measure of this is the guanine + cytosine (G + C) content. If the G + C content of two different bacterial species is similar, it indicates taxonomic relatedness.

Repetitive Sequence Analysis

In the current genomic era of molecular medicine, hundreds of microbial genomes have now been sequenced. With this era have come bioinformatical tools to mine this wealth of DNA sequence information to identify novel targets for pathogen subtyping, such as the **repetitive sequences** that have been found in different species (see Chapter 7). These repetitive sequences have been termed **satellite DNA** and have repeating units that range from 10 to 100 bp. They are commonly referred to as **variable number tandem repeats (VNTRs)**. VNTRs have been found in regions controlling gene expression and within open reading frames. The repeat unit and

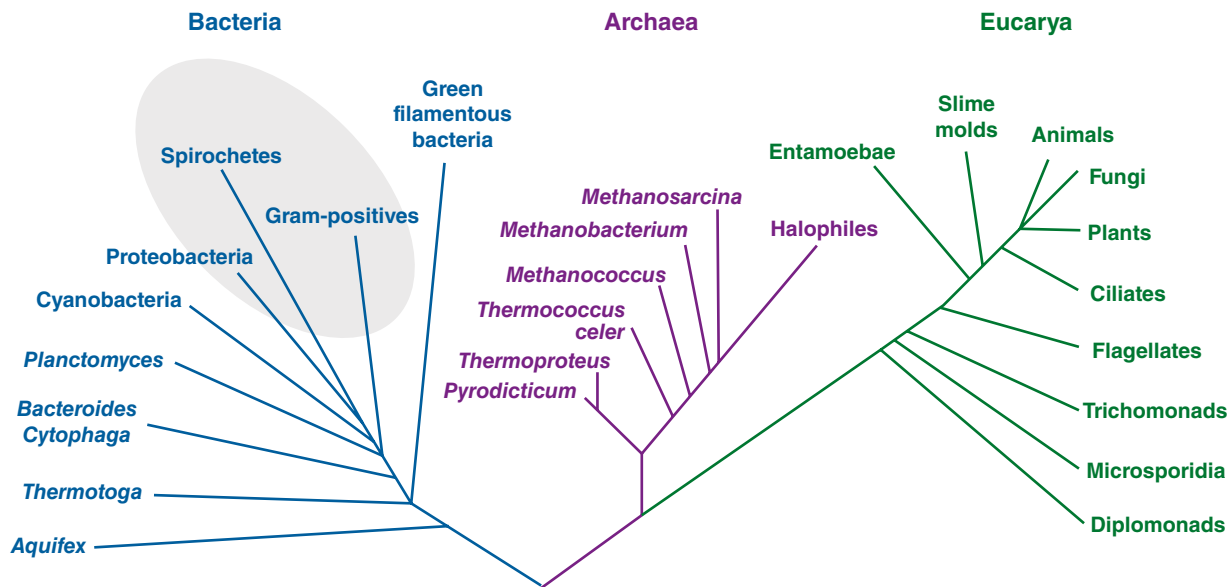

FIGURE 3-3 A phylogenetic tree based on rRNA sequencing data, showing the separation of bacteria, archaea, and eukaryotes families. The groups of the major known pathogenic bacteria are designated in gray. The only group of pathogenic bacteria that does not cluster in this shaded area is the *Bacteroides* group.

the number of copies repeated side by side define each VNTR locus. A genotyping approach using polymerase chain reaction (PCR), referred to as **multiple-locus VNTR analysis** (MLVA), takes advantage of the levels of diversity generated by both repeat unit size variation and copy number among several well-characterized loci. It has proved especially useful in subtyping monomorphic species such as *Bacillus anthracis*, *Yersinia pestis*, and *Francisella tularensis*.

Ribosomal RNA sequencing

Ribosomes have an essential role in protein synthesis for all organisms and as such are indispensable. Genetic sequence encodings both ribosomal RNAs (rRNA) and ribosomal proteins (both of which are required to comprise a functional ribosome) are highly conserved throughout evolution and have diverged more slowly than other chromosomal genes. Comparison of the nucleotide sequence of 16S rRNA from a range of prokaryotic sources revealed evolutionary relationships among widely divergent organisms and has led to the elucidation of a new kingdom, the **archaeobacteria**. The phylogenetic tree based on rRNA data, showing the separation of bacteria, archaea, and eukaryote families, is depicted in Figure 3-3, which shows the three major domains of biological life as they are currently understood. From this diagram, two kingdoms, the eubacteria (true bacteria) and the archaeobacteria, are distinct from the Eukaryotic branch.

Ribotyping

The technique of Southern blot analysis was named after its inventor, Edwin Mellor Southern, and has been used as a subtyping method to identify isolates associated with outbreaks.

For this analysis, DNA preparations from bacterial isolates are subjected to restriction endonuclease digestion. After agarose gel electrophoresis, the separated restriction fragments are transferred to a nitrocellulose or nylon membrane. These double-stranded DNA fragments are first converted into single-stranded linear sequences. Using a labeled fragment of DNA as a probe, it is possible to identify the restriction fragments containing sequences (loci) that are homologous to the probe by complementation to the bound single-stranded fragments (Figure 3-4).

Southern blot analysis can be used to detect polymorphisms of rRNA genes, which are present in all bacteria. Because ribosomal sequences are highly conserved, they can be detected with a common probe prepared from the 16S and 23S rRNA of a eubacterium (see Figure 3-6). Many organisms have multiple copies (five to seven) of these genes, resulting in patterns with enough fragments to provide good discriminatory power; however, ribotyping are of limited value for some microorganisms, such as mycobacteria, which have only a single copy of these genes.

DESCRIPTION OF THE MAJOR CATEGORIES AND GROUPS OF BACTERIA

Bergey's Manual of Systematic Bacteriology

The definitive work on the taxonomic organization of bacteria is the latest edition of *Bergey's Manual of Systematic Bacteriology*. First published in 1923, this publication taxonomically classifies, in the form of a key, known bacteria that have or have not been cultured or well described.

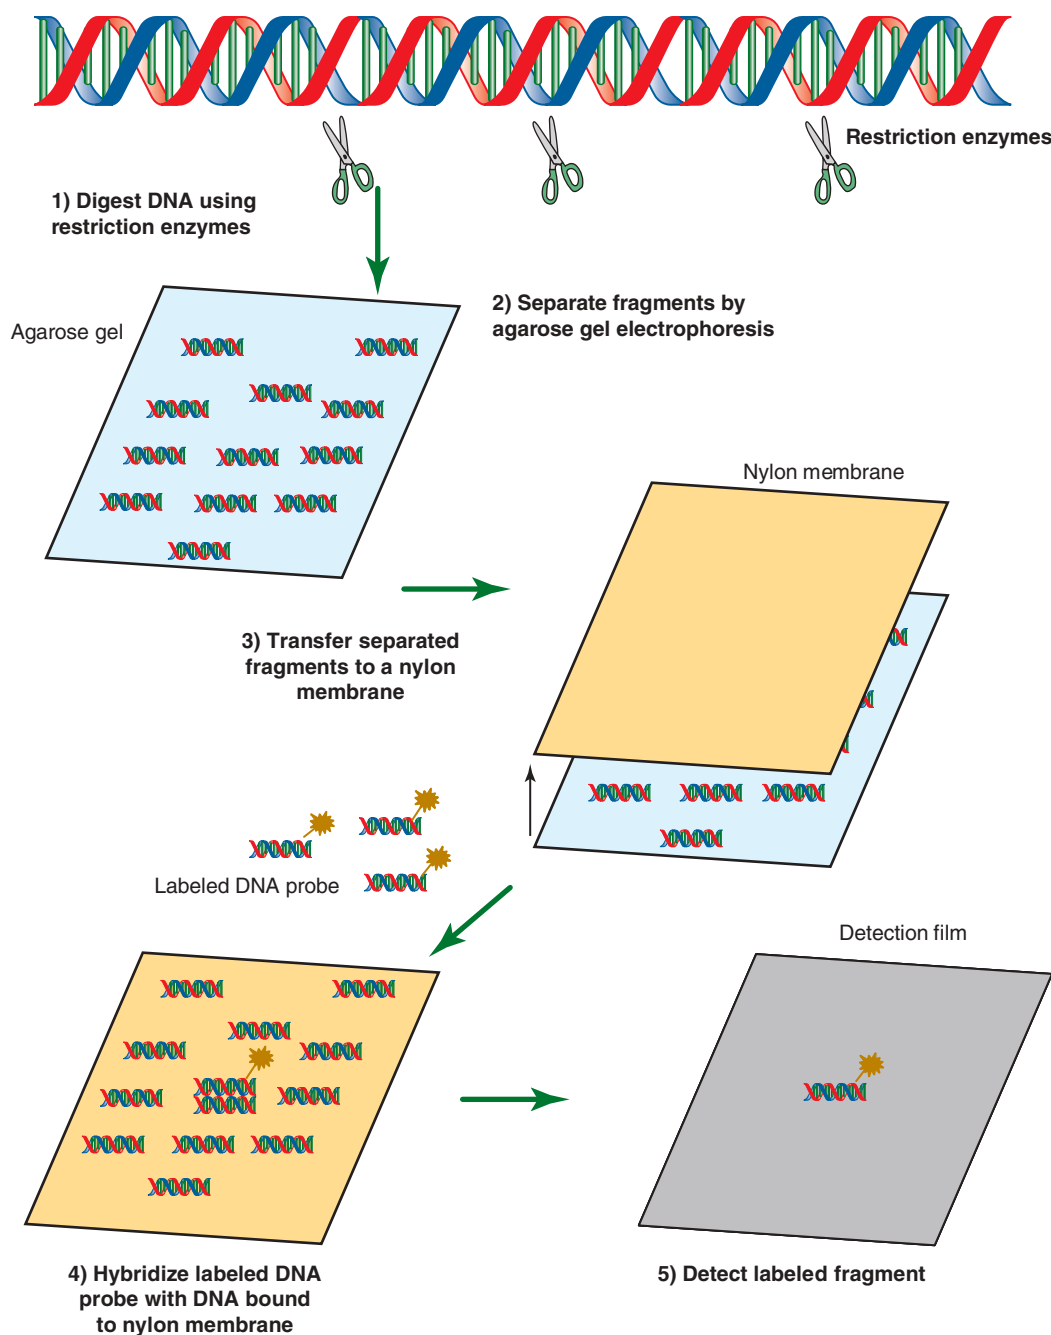

FIGURE 3-4 Southern blot procedure showing how specific loci on separated DNA fragments can be detected with a labeled DNA probe. This procedure in essence allows for the discrimination of DNA at three levels: (1) at the level of restriction enzyme recognition, (2) by the size of the DNA fragment, and (3) by the hybridization of a DNA probe to a specific locus defined by a specific band at a specific position of the membrane.

A companion volume, *Bergey's Manual of Determinative Bacteriology*, serves as an aid in the identification of bacteria that have been described and cultured. The major bacteria that cause infectious diseases, as categorized in *Bergey's Manual*, are listed in Table 3-3. Because it is likely that emerging information concerning phylogenetic relationships will lead to further modifications in the organization of bacterial groups within *Bergey's Manual*, its designations must be regarded as a work in progress.

As discussed in Chapter 2, there are two different groups of prokaryotic organisms: eubacteria and archaeobacteria. Both are small unicellular organisms that replicate asexually. Eubacteria refer to classic bacteria as science has historically understood them. They lack a true nucleus, have characteristic lipids that make up their membranes, possess a peptidoglycan cell wall, and have a protein and nucleic acid synthesis machinery that can be selectively inhibited by antimicrobial agents. In contrast, archaeobacteria do not have a

Group 35: Extremely thermophilic and hyperthermophilic sulfur metabolizers	None

classic peptidoglycan cell wall and have many characteristics (eg, protein synthesis and nucleic acid replication machinery) that are similar to those of eukaryotic cells.

The Eubacteria

A. Gram-Negative Eubacteria

This is a heterogeneous group of bacteria that have a complex (Gram-negative type) cell envelope consisting of an outer membrane, a periplasmic space containing a thin peptidoglycan layer, and a cytoplasmic membrane. The cell shape (Figure 3-5) may be spherical, oval, straight or curved rods, helical, or filamentous; some of these forms may be sheathed or encapsulated. Reproduction is by binary fission, but some groups reproduce by budding. Fruiting bodies and myxospores may be formed by the myxobacteria. Motility, if present, occurs by means of flagella or by gliding motility. Members of this category may be **phototrophic** or **nonphototrophic** (see Chapter 5) bacteria and include **aerobic**, **anaerobic**, **facultatively anaerobic**, and **microaerophilic** species.

B. Gram-Positive Eubacteria

These bacteria have a cell wall profile of the Gram-positive type; cells generally, but not always, stain Gram-positive. The

cell envelope of Gram-positive organisms consists of a thick cell wall that determines cellular shape and a cytoplasmic membrane. These cells may be encapsulated and can exhibit flagellar-mediated motility. Cells may be spherical, rods, or filaments; the rods and filaments may be nonbranching or may show true branching. Reproduction is generally by binary fission. Some bacteria in this category produce **spores** (eg, *Bacillus* and *Clostridium* spp.) as resting forms that are highly resistant to disinfection. The Gram-positive eubacteria are generally **chemosynthetic heterotrophs** (see Chapter 5) and include aerobic, anaerobic, and facultatively anaerobic species. The groups within this category include simple asporogenous and sporogenous bacteria as well as the structurally complex actinomycetes and their relatives.

C. Eubacteria Lacking Cell Walls

These are microorganisms that lack cell walls (commonly called **mycoplasmas** and making up the class Mollicutes) and do not synthesize the precursors of peptidoglycan. They are enclosed by a unit membrane, the plasma membrane (Figure 3-6). They resemble the **L-forms** that can be generated by breaking down the cell wall of notably Gram-positive eubacteria; unlike L-forms, however, mycoplasmas never revert to the walled state.

FIGURE 3-5 The cell shapes that occur among unicellular true bacteria. **A:** Coccus. **B:** Rod. **C:** Spiral. (Phase contrast, 1500 \times .) (Reproduced with permission from Stanier RY, Doudoroff M, Adelberg EA: *The Microbial World*, 3rd ed. Copyright © 1970. Reprinted by permission of Pearson Education, Inc., New York, New York.)

FIGURE 3-6 Electron micrograph of cells of a member of the mycoplasma group, the agent of bronchopneumonia in the rat (1960x). (Reproduced with permission from Klieneberger-Nobel E, Cuckow FW: A study of organisms of the pleuropneumonia group by electron microscopy. *J Gen Microbiol* 1955;12:99.)

Six genera have been designated as mycoplasmas based on their habitat; however, only two genera contain animal pathogens. Mycoplasmas are highly pleomorphic organisms and range in size from vesicle-like forms to very small (0.2 μm), filterable forms (meaning that they are too small to be captured on filters that routinely trap most bacteria). Reproduction may be by budding, fragmentation, or binary fission, singly or in combination. Most species require a complex medium for growth and tend to form characteristic “fried egg” colonies on a solid medium. A unique characteristic of the Mollicutes is that some genera require cholesterol for growth; unesterified cholesterol is a unique component of the membranes of both sterol-requiring and non-sterol-requiring species.

The Archaeobacteria

These organisms are predominantly inhabitants of extreme terrestrial and aquatic environments (high salt, high temperature, anaerobic) and are often referred to as *extremophiles*; some are symbionts in the digestive tract of humans and animals. The archaeobacteria consist of aerobic, anaerobic, and facultatively anaerobic organisms that are **chemolithotrophs**, **heterotrophs**, or **facultative heterotrophs**. Some species are **mesophiles**, but others can grow at temperatures above 100°C. These hyperthermophilic archaeobacteria are uniquely adapted for growth at high temperatures. With few exceptions, enzymes isolated from these organisms are intrinsically more thermostable than their counterparts from mesophilic organisms. Some of these thermostable enzymes,

TABLE 3-4 Key Characteristics Shared by Archaeobacteria and Eukaryotic Cells That Are Absent From Eubacteria

Characteristic	Eubacteria	Archaeobacteria, Eukaryotes
Elongation factor-2 (EF-2) contains the amino acid diphthamide and is therefore ADP-ribosylable by diphtheria toxin	No	Yes
The methionyl initiator tRNA is not formylated	No	Yes
Some tRNA genes contain introns	No	Yes in eukaryotes
Protein synthesis is inhibited by anisomycin but not by chloramphenicol	No	Yes
DNA-dependent RNA polymerases are multicomponent enzymes insensitive to the antibiotics rifampin and streptomycin	No	Yes
DNA-dependent RNA polymerases are multicomponent enzymes and are insensitive to the antibiotics rifampin and streptolydigin	No	Yes

such as the DNA polymerase from *Thermus aquaticus* (Taq polymerase), are important components of DNA amplification methods such as the PCR.

Archaeobacteria can be distinguished from eubacteria in part by their lack of a peptidoglycan cell wall, possession of isoprenoid diether or diglycerol tetraether lipids, and characteristic rRNA sequences. Archaeobacteria also share some molecular features with eubacteria (Table 3-4). Cells may have a diversity of shapes, including spherical, spiral, and plate or rod shaped; unicellular and multicellular forms in filaments or aggregates also occur. Multiplication occurs by binary fission, budding, constriction, fragmentation, or other unknown mechanisms.

NONCULTURE METHODS FOR THE IDENTIFICATION OF PATHOGENIC MICROORGANISMS

Attempts to estimate total numbers of eubacteria and archaeobacteria are problematic because of difficulties such as detection in and recovery from the environment. As indicated earlier, estimates indicate that the numbers of unculturable microbial taxa greatly exceed those of the culturable organisms. Recent estimates suggest that the number of bacterial species in the world is between 10⁷ and 10⁹. Until very recently, microbial

identification required the isolation of pure cultures followed by testing for multiple physiologic and biochemical traits. Clinicians have long been aware of human diseases that are associated with visible but nonculturable microorganisms. Scientists are now using a PCR-assisted approach using rRNA as a target to identify pathogenic microorganisms in situ. The first phase of this approach involves the extraction of DNA from a suitable specimen, the PCR amplification of the ribosomal DNA, the sequencing of the rRNA sequence information, and a comparative analysis of the retrieved sequences. This yields information on the identity or relatedness of the sequences in comparison with the available database. This approach has been used in the identification of pathogenic microorganisms. For example, a previously uncharacterized pathogen has been identified as the Whipple-disease-associated rod-shaped bacterium now designated *Tropheryma whippelii*. This rRNA approach has also been used to identify the etiologic agent of bacillary angiomatosis as *Bartonella henselae* and to show that the opportunistic pathogen *Pneumocystis jirovecii* is a member of the fungi. Undoubtedly, these and other techniques will identify additional etiologic agents in the future.

UPDATES TO TAXONOMIC CHANGES

The technologic advances in the fields of molecular genetics and microbiome research have led to an explosion in the number of newly identified species compared with the rate at which they were discovered even a decade ago. Because of this, new updates need to be systematically added to the literature. For medical microbiology, biennial updates to the field of microbiology taxonomy are published in the *Journal of Clinical Microbiology*.

OBJECTIVES

1. Understand how the vocabulary of taxonomy is critical to communicating the science of infectious diseases.
2. Know the taxonomic ranks.
3. Appreciate the growth, biochemical, and genetic characteristics that are used in differentiating bacteria.
4. Understand the differences between the eubacteria, archaeobacteria, and eukaryotes.
5. Understand the different tools for nucleic acid-based taxonomy.

REVIEW QUESTIONS

1. Eubacteria that lack cell walls and do not synthesize the precursors of peptidoglycan are called
 - (A) Gram-negative bacteria
 - (B) Viruses
 - (C) Mycoplasmas
 - (D) Serovar
 - (E) Bacilli

2. Archaeobacteria can be distinguished from eubacteria by their lack of
 - (A) DNA
 - (B) RNA
 - (C) Ribosomes
 - (D) Peptidoglycan
 - (E) Nucleus
3. A 16-year-old cystic fibrosis patient is admitted to the hospital. A sputum culture yields *Burkholderia cepacia*. Subsequently, there are two other patients with *B. cepacia* bacteremia, and the organism is cultured from the sputum of four additional patients. During this nosocomial outbreak of *B. cepacia*, 50 environmental and 7 patient isolates are being subtyped to identify the source of the outbreak. Which of the following techniques would be most useful in this endeavor?
 - (A) Culture
 - (B) Ribotyping
 - (C) 16S rRNA sequencing
 - (D) Antimicrobial susceptibility testing
 - (E) Nucleic acid sequencing
4. An unculturable Gram-positive microorganism has been visualized in tissue specimens obtained from patients with a previously undescribed disease. Which of the following techniques would be most useful in identifying this organism?
 - (A) Serology
 - (B) PCR amplification and sequencing of rRNA genes
 - (C) Multilocus VNTR analysis
 - (D) SDS-polyacrylamide gel electrophoresis
 - (E) PFGE
5. The DNA polymerase from *T. aquaticus* is an important component of DNA amplification methods such as the PCR. This organism can grow at temperatures above 100°C. Organisms that are capable of growth at these temperatures are referred to as
 - (A) Mesophiles
 - (B) Psychrophiles
 - (C) Halophiles
 - (D) Thermophiles
 - (E) Chemolithotrophs
6. A bacterium with a genome having a G + C content of 45% harbors a plasmid encoding a gene with a G + C content of 55%. Which one of the following conclusions could be drawn?
 - (A) This gene codes for a cell wall peptidyl transferase.
 - (B) This gene codes for a critical bacterial cytochrome.
 - (C) This gene codes for a unique transfer RNA.
 - (D) This gene codes for a plasmid RNA-dependent DNA-polymerase.
 - (E) This gene codes for an antigenically diverse capsular polysaccharide.

Growth, Survival, and Death of Microorganisms

SURVIVAL OF MICROORGANISMS IN THE NATURAL ENVIRONMENT

The population of microorganisms in the biosphere remains roughly constant because the growth of microorganisms is balanced by the death of these organisms. The survival of any microbial group within an environmental niche is ultimately influenced by successful competition for nutrients and by maintenance of a pool of all living cells, often composed of human cells and a consortium of different microorganisms (referred to as the microbiome or microbiota). Understanding competition for nutritional resources within a given microenvironment is essential to understanding the growth, survival, and death of bacterial species (also known as physiology).

Much of our understanding of microbial physiology has come from the study of isolated cultures grown under optimal conditions in laboratories (nutrient excess). However, most microorganisms compete in the natural environment under nutritional stress. Furthermore, a vacant environmental microbial niche will soon be filled with a different microbiome. In the end, appreciating the complex interactions that ensure the survival of a specific microbiome is a balance between availability of nutrients and physiologic efficiency.

THE MEANING OF GROWTH

Growth is the orderly increase in the sum of all the components of an organism. The increase in size that results when a cell takes up water or deposits lipid or polysaccharide is not true growth. Cell multiplication is a consequence of binary fission that leads to an increase in the number of single bacteria making up a population, referred to as a culture.

The Measurement of Microbial Concentrations

Microbial concentrations can be measured in terms of cell concentration (the number of viable cells per unit volume of culture) or of biomass concentration (dry weight of cells per unit volume of culture). These two parameters are not always

equivalent because the average dry weight of the cell varies at different stages of a culture. Nor are they of equal significance: For example, in studies of microbial genetics and the inactivation of microbes, cell concentration is the significant quantity; in studies on microbial biochemistry or nutrition, biomass concentration is the significant quantity.

A. Viable Cell Count

The **viable cell count** (Table 4-1) is typically considered the measure of cell concentration. For this, a 1-mL volume is removed from a bacterial suspension and serially diluted 10-fold followed by plating 0.1-mL aliquots on a suitable agar medium. Each single invisible bacterium (or clump of bacteria) will grow into a visible colony that can be counted (see Chapter 5). For statistical purposes, plates containing between 30 and 300 colonies give the most accurate data. The plate count \times the dilution \times 10 will give the number of colony forming units (CFU)/mL in the undiluted bacterial suspension. Using this method, dead bacteria within the suspension do not contribute to the final bacterial count.

B. Turbidity

Turbidity is the cloudiness or haziness of a fluid caused by large numbers of individual particles that are generally invisible to the naked eye. For most purposes, the **turbidity** of a culture, measured by photoelectric means, can be related to the viable count using a **standard curve**. As an alternative a rough visual estimate is sometimes possible: For example, a barely turbid suspension of *Escherichia coli* contains about 10^7 cells per milliliter, and a fairly turbid suspension contains about 10^8 cells per milliliter. The correlation between turbidity and viable count can vary during the growth and death of a culture; cells may lose viability without producing a loss in turbidity of the culture.

C. Biomass Density

In principle, biomass can be measured directly by determining the dry weight of a microbial culture after it has been washed with distilled water. In practice, this procedure is cumbersome, and the investigator customarily prepares a standard curve that correlates dry weight with viable cell

TABLE 4-1 Example of a Viable Count

Dilution	Plate Count (Colonies) ^a
Undiluted	Too many to count
10 ⁻¹	Too many to count
10 ⁻²	510
10 ⁻³	72
10 ⁻⁴	6
10 ⁻⁵	1

^aEach count is the average of three replicate plates.

count. Alternatively, the concentration of biomass can be estimated indirectly by measuring an important cellular component such as protein or by determining the volume occupied by cells that have settled out of suspension.

EXPONENTIAL GROWTH

The Growth Rate Constant

The growth rate of cells unlimited by nutrient is first order: The rate of growth (measured in grams of biomass produced per hour) is the product of **time** (*t*), the **growth rate constant** (*k*), and the **biomass concentration** *B*:

$$\frac{dB}{dt} = kB$$

(1)

Rearrangement of equation (1) demonstrates that the growth rate constant is the rate at which cells are producing more cells:

$$k = \frac{Bdt}{dB}$$

(2)

A growth rate constant of 4.3 h⁻¹, one of the highest recorded, means that each gram of cells produces 4.3 g of cells per hour during this period of growth. Slower growing organisms may have growth rate constants as low as 0.02 h⁻¹. With this growth rate constant, each gram of cells in the culture produces 0.02 g of cells per hour.

Integration of equation (2) yields

$$\ln \frac{B_1}{B_0} = 2.3 \log_{10} \frac{B_1}{B_0} = k(t_1 - t_0)$$

(3)

The natural logarithm of the ratio of *B*₁ (the biomass at time 1 [*t*₁]) to *B*₀ (the biomass at time zero [*t*₀]) is equal to the product of the growth rate constant (*k*) and the difference in time (*t*₁ - *t*₀). Growth obeying equation (3) is termed exponential because biomass increases exponentially with respect to time. Linear correlations of exponential growth are produced by plotting the logarithm of biomass concentration (*B*) as a function of time (*t*).

FIGURE 4-1 A graph of biomass versus doubling time showing the linear exponential growth which would occur in a closed system. The biomass (*B*) doubles with each doubling time (*t*_d).

Calculation of the Growth Rate Constant and Prediction of the Amount of Growth

Bacteria reproduce by **binary fission**, and the average time required for the population, or the biomass, to double is known as the **generation time** or **doubling time** (*t*_d). Usually the *t*_d is determined by plotting the amount of growth on a semi-logarithmic scale as a function of time; the time required for doubling the biomass is *t*_d (Figure 4-1). The growth rate constant can be calculated from the doubling time by substituting the value 2 for *B*₁/*B*₀ and *t*_d for *t*₁ - *t*₀ in equation (3), which yields

$$\ln 2 = kt_d$$

$$k = \ln 2 / t_d$$

(4)

A rapid doubling time corresponds to a high growth rate constant. For example, a doubling time of 10 minutes (0.17 hour) corresponds to a growth rate constant of 4.1 h⁻¹. The relatively long doubling time of 35 hours indicates a growth rate constant of 0.02 h⁻¹.

The calculated growth rate constant can be used either to determine the amount of growth that will occur in a specified period of time or to calculate the amount of time required for a specified amount of growth.

The amount of growth within a specified period of time can be predicted on the basis of the following rearrangement of equation (3):

$$\log_{10} \frac{B_1}{B_0} = \frac{k(t_1 - t_0)}{2.3}$$

(5)

It is possible to determine the amount of growth that would occur if a culture with a growth rate constant of 4.1 h^{-1} grew exponentially for 5 hours:

$$\log_{10} \frac{B_1}{B_0} = \frac{4.1\text{ h}^{-1} \times 5\text{ h}}{2.3} \tag{6}$$

In this example, the increase in biomass is 10^{-9} g; a single bacterial cell with a dry weight of 2×10^{-13} g would give rise to 2×10^{-4} g (0.2 mg) of biomass, a quantity that would densely populate a 5 mL culture. Another 5 hours of growth at this rate would produce 200 kg dry weight of biomass, or roughly 1 ton of cells. This assumes that nutrients are unlimited, which is an assumption that does not occur in nature.

Another rearrangement of equation (3) allows calculation of the amount of time required for a specified amount of growth to take place. In equation (7), shown below, N , cell concentration, is substituted for B , biomass concentration, to permit calculation of the time required for a specified increase in cell number.

$$t_1 - t_0 = \frac{2.3 \log_{10}(N_1/N_0)}{k} \tag{7}$$

Using equation (7), it is possible, for example, to determine the time required for a slowly growing organism with a growth rate constant of 0.02 h^{-1} to grow from a single cell into a barely turbid cell suspension with a concentration of 10^7 cells per milliliter.

$$t_1 - t_0 = \frac{2.3 \times 7}{0.02\text{ h}^{-1}} \tag{8}$$

Solving equation (8) reveals that about 800 hours—slightly more than a month—would be required for this amount of growth to occur. The survival of slowly growing organisms implies that the race for biologic survival is not always to the swift—those species flourish that compete successfully for nutrients and avoid annihilation by predators and other environmental hazards.

THE GROWTH CURVE IN BATCH CULTURE

If a fixed volume of liquid medium is inoculated with microbial cells taken from a culture that has previously been grown to saturation and the number of viable cells per milliliter is determined periodically and plotted, a curve of the type shown in Figure 4-2 is usually obtained. The phases of the bacterial growth curve shown in Figure 4-2 are reflections of the events in a population of cells, not in individual cells. This type of culture is referred to as a **batch culture**. The typical growth curve may be discussed in terms of four phases (Table 4-2). Batch culture is a closed system with finite resources; this is very different from the environment of the human host where nutrients are metabolized by bacteria and human cells. Nonetheless, understanding growth in

FIGURE 4-2 Idealized bacterial growth curve plotting the log viable cell concentration versus time. Noted in the figure are the lag, log, stationary, and death phases with the approximate rates of increase or decrease representing what one would see upon inoculating a single bacterial colony in a closed batch culture system.

batch culture provides fundamental insight into the genetics and physiology of bacterial replication, including the lag, exponential, stationary, and death phases that comprise this process.

Lag Phase

The lag phase represents a period during which cells, depleted of metabolites and enzymes as the result of the unfavorable conditions that existed at the end of their previous culture history, adapt to their new environment. Enzymes and intermediates are formed and accumulate until they are present in concentrations that permit growth to resume.

If the cells are taken from an entirely different medium, it often happens that they are genetically incapable of growth in the new medium. In such cases, a long lag in growth may occur, representing the period necessary for a few variants in the inoculum to multiply sufficiently for a net increase in cell number to be apparent.

Exponential Phase

During the exponential phase, the cells are in a steady state and grow as modeled in equations 5–7. New cell material is being synthesized at a constant rate, but the new material is itself catalytic, and the mass increases in an exponential manner. This continues until one of two things happens: either

TABLE 4-2 Phases of the Microbial Growth Curve	
Phase	Growth Rate
Lag	Zero
Exponential	Constant
Maximum stationary	Zero
Decline	Negative (death)

one or more nutrients in the medium become exhausted or toxic metabolic products accumulate and inhibit growth. For aerobic organisms, the nutrient that becomes limiting is usually oxygen. When the cell concentration exceeds about $1 \times 10^7/\text{mL}$, the growth rate decreases unless oxygen is forced into the medium by agitation or by bubbling in air. When the bacterial concentration reaches $4\text{--}5 \times 10^9/\text{mL}$, the rate of oxygen diffusion cannot meet the demand even in an aerated medium, and growth is progressively slowed.

Stationary Phase

Eventually, the exhaustion of nutrients or the accumulation of toxic products causes growth to cease completely. In most cases, however, cell turnover takes place in the stationary phase: There is a slow loss of cells through death, which is balanced by the formation of new cells through growth and division. When this occurs, the total cell count slowly increases, although the viable count stays constant.

Death Phase

After a period of time in the stationary phase, cell viability begins to decrease at a defined rate. This varies with the organism and with the culture conditions; the death rate increases until it reaches a steady level. The mathematics of steady-state death is discussed as follows. In most cases, the rate of cell death is much slower than that of exponential growth. Frequently, after the majority of cells have died, the death rate decreases drastically, so that a small number of survivors may persist for months or even years. This persistence may in some cases reflect cell turnover, a few cells growing at the expense of nutrients released from cells that die and lyse.

A bacterial culture phenomenon referred to as **viable but not culturable (VBNC)** cells, is thought to be the result of a genetic response triggered in starving, stationary phase cells. Just as some bacteria form spores as a survival mechanism, others can become dormant without changes in morphology. When the appropriate conditions are available (eg, passage through an animal), VNBC microbes resume growth.

MAINTENANCE OF CELLS IN THE EXPONENTIAL PHASE

The Chemostat

Cells can be maintained in the exponential phase by transferring them repeatedly into fresh medium of identical composition while they are still growing exponentially. This is referred to as **balanced growth**. In the laboratory, cultures can be maintained in a state of balanced growth over a range of growth rates using a continuous culture device, or chemostat. This device consists of a culture vessel equipped with

an overflow siphon and a metering pump or a valve, which adds fresh medium from a reservoir at a regulated rate. The medium in the culture vessel is stirred by a stream of sterile air; each drop of fresh medium that enters causes a drop of culture to siphon out. The medium is prepared such that one nutrient limits growth yield. The vessel is inoculated, and the cells grow until the limiting nutrient is exhausted; fresh medium from the reservoir is then allowed to flow in at such a rate that the cells use up the limiting nutrient as fast as it is supplied. Under these conditions, the cell concentration, which is determined by the concentration of the limiting nutrient, remains constant; the growth rate is directly proportionate to the flow rate of the medium. Continuous culture is more like conditions that organisms encounter in the real world (eg, the human body), where limiting nutrients are constantly being replaced.

GROWTH IN BIOFILMS

It has been increasingly recognized that many infections are caused by bacteria that do not grow individually (planktonically); rather, they exist in complex multicellular communities in which the microbes are sessile. Typically, microbial communities form on surfaces, hence “biofilm.” For example, it is routine to debride our teeth every day to remove the bacterial biofilm that accumulates while we sleep. Similarly, biofilms are associated with *Streptococcus viridians* on heart valves, *Pseudomonas aeruginosa* lung infections, *Staphylococcus aureus* on catheters, or *Legionella pneumophila* colonization of hospital water systems, among many others. In nature, biofilms often consist of several different microbial species (see Chapter 10). Understanding the growth of bacterial biofilms has become an increasingly important aspect of medical microbiology.

A variety of stressors trigger biofilm formation, and each microorganism is unique in the signals it responds to. Biofilms begin with a single bacterium attaching on a surface followed by binary fission and ultimately to the formation of an intimate community of progeny bacteria (see Chapter 10). Eventually this bacterial community surrounds itself with a glycocalyx for environmental protection. The glycocalyx also serves to keep the biofilm community intact. Bacteria within a biofilm produce small molecules, such as homoserine lactones, which are taken up by adjacent bacteria and functionally serve as a colony “telecommunication” system, informing individual bacteria to turn on certain genes at a particular time (**Quorum Sensing**). These signals are known as quorum sensors.

Conceptually, the strategy of biofilm formation is logical. It promotes increased metabolic diversity. For example, bacteria on the periphery of the biofilm may have more access to oxygen and other nutrients than organisms on the inner portions of the film. On the other hand, cells on the inner portions may be shielded from predation by immune cells, or from antibiotics. Intimately attached bacteria may be able

to efficiently transfer genes that would result in phenotypic versatility when compared to planktonic cells. Because of all these variables it is difficult to mathematically model biofilm growth as compared to growth in batch culture. This is an important area of medical microbiology that needs to be considered in the larger context of infectious disease.

DEFINITION AND MEASUREMENT OF DEATH

The Meaning of Bacterial Death

For a microbial cell, death means the irreversible loss of the ability to reproduce (grow and divide). Noting the exception of VBMC organisms described previously, the empirical test of death is culture of cells on solid media: A cell is considered dead if it fails to give rise to a colony on appropriate medium. Obviously, then, the reliability of the test depends on the choice of medium and conditions: For example, a culture in which 99% of the cells appear “dead” in terms of the ability to form colonies on one medium may prove to be 100% viable if tested on another medium. Furthermore, the detection of a few viable cells in a large clinical specimen may not be possible by directly plating a sample because the sample fluid itself may be inhibitory to microbial growth. In such cases, the sample may have to be diluted first into liquid medium, permitting the outgrowth of viable cells before plating.

The conditions of incubation in the first hour after treatment are also critical in the determination of “killing.” For example, if bacterial cells are irradiated with ultraviolet light and plated immediately on any medium, it may appear that 99.99% of the cells have been killed. If such irradiated cells are first incubated in a suitable medium for 20 minutes, plating may indicate only 10% killing. In other words, irradiation determines that a cell will “die” if plated immediately but will live if allowed to repair radiation damage before plating. A microbial cell that is not physically disrupted is thus “dead” only in terms of the conditions used to test viability.

The Measurement of Bacterial Death

When dealing with microorganisms, one does not customarily measure the death of an individual cell but the death of a population. This is a statistical problem: Under any condition that may lead to cell death, the probability of a given cell's dying is constant per unit time. For example, if a condition is used that causes 90% of the cells to die in the first 10 minutes, the probability of any one cell dying in a 10-minute interval is 0.9. Thus, it may be expected that 90% of the surviving cells will die in each succeeding 10-minute interval, and a death curve can be generated. The number of cells dying in each time interval is thus a function of the number of survivors

present, so that death of a population proceeds as an exponential process according to the general formula:

$$S = S_0 e^{-kt} \quad (9)$$

where S_0 is the number of survivors at time zero and S is the number of survivors at any later time t . As in the case of exponential growth, $-k$ represents the rate of exponential death when the fraction $\ln(S/S_0)$ is plotted against time.

The kinetics of bacterial cell killing is also a function of the number of targets required to be hit by a particular agent to kill a specific planktonic microbe. For example, a single “hit” could target the haploid chromosome of a bacterium or target its cell membrane. By contrast, a cell that contains several copies of the target to be inactivated exhibits a multihit curve. This analysis is graphically shown in Figure 4-3.

ENVIRONMENTAL CONTROL OF MICROBIAL GROWTH

The robust nature of uncontrolled microbial growth clearly presents a conflict with human life. To coexist with bacteria, higher species have to control bacterial growth. We, as humans, do this in a biologic context using an immune system and nutrient limitation. We also use physical methods to prevent exposure to microorganisms. Terms like **sterilization**, **disinfection**, **pasteurization**, and **aseptic** need to be precisely understood so as to articulate them in a proper sense. A list of these terms and their definitions are provided in Table 4-3.

As an example of the importance of understanding these terms, we speak of **sterilization** as the process of killing all the organisms, including spores, in a given preparation. Understanding this concept would be particularly important for surgical instruments because one would not want to introduce spores into the surgical site. By contrast, “disinfecting” these instruments may eliminate the vegetative cells but not the spores. Further, physically “cleaning” the instruments may not remove all the vegetative cells and spores but simply decrease the bioburden on the instrument. The point is that an understanding of the terms used in Table 4-3 is critical to controlling the environmental impact of microorganisms in the context of human health.

STRATEGIES TO CONTROL BACTERIA AT THE ENVIRONMENTAL LEVEL

In medical microbiology one often considers the control of bacteria infecting humans with antibiotics as the gold standard in treating infections. While true, the real first line is to prevent exposure to infectious agents. For example, nearly 240,000 deaths annually occur worldwide as a result of neonatal tetanus. Yet this disease is very rare in developed countries. A major contributing factor is the inability to “sterilize” instruments (in addition to routine immunization with the tetanus

FIGURE 4-3 Death curve of a suspension of 10^6 viable microorganisms per milliliter. **A:** Single-hit curve. The one-hit curve is typical of the kinetics of inactivation observed with many antimicrobial agents. The fact that it is a straight line from time zero (dose zero) as opposed to exhibiting an initial shoulder, means that a single “hit” by the inactivating agent is sufficient to kill the cell (ie, only a single target must be damaged for the entire cell to be inactivated). **B:** Multihit curve. A cell that contains several copies of the target to be inactivated. The straight-line portion extrapolates to 6.5, corresponding to 4×10^6 cells. The number of targets is thus 4×10^6 , or four per cell.

TABLE 4-3 Common Terms Related to Microbial Control

Term	Definition
Sterilization	A process that destroys or eliminates all forms of microbial life from an object or environment. This includes highly resistant bacterial spores.
Disinfection	A process that eliminates many or all pathogenic microorganisms, except bacterial spores, from an object or an environment.
Pasteurization	The process of applying heat, usually to milk or cheese, for a specified period for the purpose of killing or retarding the growth of pathogenic bacteria.
Sanitization	The process whereby pathogenic organisms are reduced to safe levels on inanimate objects, thereby reducing the likelihood of cross-infection.
Cleaning	The removal of visible soil (eg, organic and inorganic material) from objects and surfaces normally accomplished manually or mechanically using water with detergents or enzymatic products.
Biocide	A chemical or physical agent, usually broad spectrum, that inactivates microorganisms.
Bactericidal	A specific term referring to the property by which a biocide can kill bacteria. Bactericidal action differs from bacteriostasis only in being irreversible (ie, the “killed” organism can no longer reproduce even after being removed from contact with the agent). In some cases, the agent causes lysis (dissolution) of the cells; in other cases, the cells remain intact and may even continue to be metabolically active. (The terms fungicidal , sporicidal , and virucidal refer to the property whereby biocides can kill fungi, spores, and viruses, respectively.)
Bacteriostatic	A specific term referring to the property by which a biocide inhibits bacterial multiplication; upon removal of the agent, multiplication resumes. (The terms fungistatic and sporostatic refer to biocides that inhibit the growth of fungi and spores, respectively.)
Septic	Characterized by the presence of pathogenic microbes in living tissues or associated fluids.
Aseptic	Free of, or using methods to keep free of, microorganisms.
Antiseptic	An agent that destroys or inhibits the growth of microorganisms in or on living tissue or biologic fluids.
Preservative	A substance added to food products or to an organic solution to prevent chemical change or bacterial action.
Antibiotic	A natural or semi-synthetic substance that either kills (bactericidal) or inhibits the growth (bacteriostatic) of a bacterium.

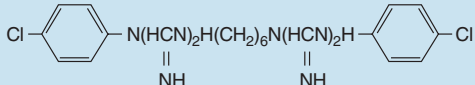

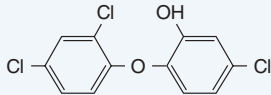

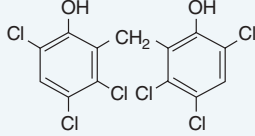

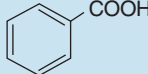

vaccine) in many developing countries. If proper practices were used in underdeveloped regions, the prevalence of this disease could be substantially reduced. Thus, one must understand methods of *sterilization*, *disinfection*, and *pasteurization*, among others. The techniques used to mitigate microbial infection should be understood at the mechanism of action level in order to apply them in the appropriate situation. Table 4-4 represents a nonexhaustive list of routinely used **biocides**. It is important to understand the terms **bacteriostatic** and **bactericidal** as defined in Table 4-4. The general mechanisms by which these biocides accomplish their antimicrobial activity are summarized in the following section.

GENERAL MECHANISMS OF BIOCIDES ACTION

Disruption of the Cell Membrane or Wall

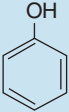

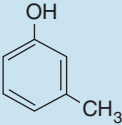

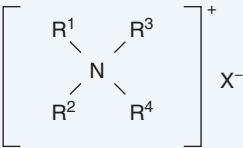

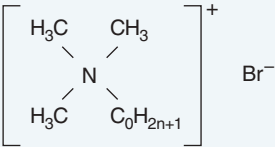

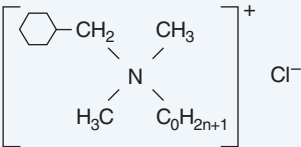

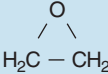

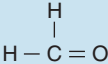

The cell membrane acts as a selective barrier, allowing some solutes to pass through and excluding others. Many compounds are actively transported through the membrane, becoming concentrated within the cell. The membrane is also the site of enzymes involved in the biosynthesis of components of the cell envelope. Substances that concentrate at the cell surface may alter the physical and chemical properties of

TABLE 4-4 Some Common Biocides Used for Antisepsis, Disinfection, Preservation, and Other Purposes

Agent	Formula	Uses
Alcohols		
Ethanol	$\text{CH}_3\text{--CHOH}$	Antisepsis, disinfection, preservation
Isopropanol	$\begin{array}{c} \text{CH}_3 \\ \text{CH}_3 \end{array} \text{>CHOH}$	
Aldehydes		
Glutaraldehyde	$\begin{array}{c} \text{H} \qquad \qquad \text{H} \\ \qquad \qquad \\ \text{O}=\text{CCH}_2\text{CH}_2\text{CH}_2\text{C}-\text{O} \end{array}$	Disinfection, sterilization, preservation
Formaldehyde	$\begin{array}{c} \text{H} \\ \\ \text{H}-\text{C}=\text{O} \end{array}$	
Biguanides		
Chlorhexidine		Antisepsis, antiplaque activity, preservation, disinfection
Bisphenols		
Triclosan		Antisepsis, antiplaque activity
Hexachlorophene		Deodorant, preservation
Halogen-releasing agents		
Chlorine compounds	$\rightarrow \text{OCl}^-, \text{HOCl}, \text{Cl}_2$	Disinfection, antisepsis
Iodine compounds	$\rightarrow \text{I}_2$	
Heavy metal derivatives		
Silver compounds	Ag	Preservation, antisepsis
Mercury compounds	Hg	Disinfection
Organic acids		
Benzoic acid		Preservation
Propionic acid	$\text{CH}_3\text{--CH}_2\text{--COOH}$	Sodium or calcium salt used for preservation
Peroxygens		
Hydrogen peroxide	H_2O_2	Disinfection, sterilization
Ozone	O_3	
Peracetic acid	CH_3COOOH	

(Continued)

Vapor phase		
Ethylene oxide		Sterilization, disinfection
Formaldehyde		
Hydrogen peroxide	H ₂ O ₂	

the membrane, preventing its normal functions and therefore killing or inhibiting the cell.

The cell wall acts as a corseting structure (best characterized as a fishing net), protecting the cell against osmotic lysis. Thus, agents that destroy the wall (eg, lysozyme, which cleaves the sugar linkages of peptidoglycan) or prevent its normal synthesis (eg, penicillin, which interrupts peptidyl cross-linkages) may bring about lysis of the cell.

Protein Denaturation

Proteins exist in a folded, three-dimensional state determined primarily by intramolecular noncovalent interactions such as ionic, hydrophobic, and hydrogen bonds or covalent disulfide linkages. This state is called the tertiary structure of the protein; it is readily disrupted by a number of physical (eg,

heat) or chemical (eg, alcohol) agents, causing the protein to become nonfunctional. The disruption of the tertiary structure of a protein is called **protein denaturation**.

Disruption of Free Sulfhydryl Groups

Enzymes containing cysteine have side chains terminating in sulfhydryl groups. In addition to these, coenzymes such as coenzyme A and dihydrolipoate contain free sulfhydryl groups. Such enzymes and coenzymes cannot function unless the sulfhydryl groups remain free and reduced. Oxidizing agents thus interfere with metabolism by forming disulfide linkages between neighboring sulfhydryl groups:

Many metals such as mercuric ions likewise interfere by combining with sulfhydryls. There are many sulfhydryl-containing enzymes in the cell, so oxidizing agents and heavy metals do widespread damage.

Damage to DNA

A number of physical and chemical agents act by damaging DNA; these include ionizing radiations, ultraviolet light, and DNA-reactive chemicals. Among the last category are alkylating agents and other compounds that react covalently with purine and pyrimidine bases to form DNA adducts or interstrand cross-links. Radiation can damage DNA in several ways: Ultraviolet light, for example, induces cross-linking between adjacent pyrimidines on one or the other of the two polynucleotide strands, forming pyrimidine dimers; ionizing radiations produce breaks in single and double strands. Radiation-induced and chemically-induced DNA lesions kill the cell mainly by interfering with DNA replication. See Chapter 7 for a discussion of DNA repair systems.

Chemical Antagonism

The interference by a chemical agent with the normal reaction between a specific enzyme and its substrate is known as **chemical antagonism**. The **antagonist** acts by combining with some part of the holoenzyme (the protein apoenzyme, the mineral activator, or the coenzyme), thereby preventing attachment of the normal substrate. (Substrate here is used in the broad sense to include cases in which the inhibitor combines with the apoenzyme, thereby preventing attachment of the coenzyme.)

An antagonist combines with an enzyme because of its chemical affinity for an essential site on that enzyme. Enzymes perform their catalytic function by virtue of their affinity for their natural substrates; hence any compound structurally resembling a substrate in essential aspects may also have an affinity for the enzyme. If this affinity is great enough, the “analog” will displace the normal substrate and prevent the proper reaction from taking place.

Many holoenzymes include a mineral ion as a bridge either between enzyme and coenzyme or between enzyme and substrate. Chemicals that combine readily with these minerals will again prevent attachment of coenzyme or substrate (eg, carbon monoxide and cyanide combine with the iron atom in heme-containing enzymes and prevent their function in respiration).

Chemical antagonists can be conveniently discussed under two headings: (a) antagonists of energy-yielding processes and (b) antagonists of biosynthetic processes. The former include poisons of respiratory enzymes (carbon monoxide, cyanide) and of oxidative phosphorylation (dinitrophenol); the latter include amino acid and nucleic acid analogs. In some cases, the analog simply prevents incorporation of the normal metabolite (eg, 5-methyltryptophan prevents

incorporation of tryptophan into proteins), and in other cases, the analog replaces the normal metabolite in the macromolecule, causing it to be nonfunctional. The incorporation of *p*-fluorophenylalanine in place of phenylalanine in proteins is an example of the latter type of antagonism.

SPECIFIC ACTIONS OF SELECTED BIOCIDES

Selected important physical and chemical agents are described in the following sections.

Physical Methods

A. Heat

Application of heat is the simplest means of sterilizing materials, provided the material is itself resistant to heat damage. A temperature of 100°C will kill all but the spores of eubacteria within 2–3 minutes in laboratory-scale cultures; a temperature of 121°C for 15 minutes is used to kill spores. Steam is generally used, both because bacteria are more quickly killed when moist and because steam provides a means for distributing heat to all parts of the sterilizing vessel. At sea level, steam must be kept at a pressure of 15 lb/sq inch (psi) in excess of atmospheric pressure to obtain a temperature of 121°C; autoclaves or pressure cookers are used for this purpose. At higher altitudes, the pressure would need to be higher than 15 psi to reach 121°C. For sterilizing materials that must remain dry, circulating hot air electric ovens are available; because heat is less effective on dry material, it is customary to apply a temperature of 160–170°C for 1 hour or more. Under these conditions (ie, excessive temperatures applied for long periods of time), heat acts by denaturing cell proteins and nucleic acids and by disrupting cell membranes. This treatment, if performed appropriately, is sporicidal.

B. Radiation

Ultraviolet (UV) radiation that has a wavelength of about 260 nm causes thymidine dimers resulting in the inability of bacterial DNA to be replicated. This is generally bactericidal but may not be sporicidal.

Ionizing radiation of 1 nm or less (gamma or x-ray) causes free radical formation that damage proteins, DNA, and lipids. These treatments are both bactericidal and sporicidal.

Chemical Agents

The chemical structures and uses of biocides are shown in Table 4-4; selective activities of these are described in the following sections.

C. Alcohols

These agents effectively remove water from biologic systems. Thus, they functionally act as “liquid desiccants.” Ethyl

alcohol, isopropyl alcohol, and *n*-propanol exhibit rapid, broad-spectrum antimicrobial activity against vegetative bacteria, viruses, and fungi but are not sporicidal. Activity is optimal when they are diluted to a concentration of 60–90% with water. This treatment strategy is generally considered bactericidal but not sporicidal.

D. Aldehydes

Compounds like glutaraldehyde or formaldehyde are used for low-temperature disinfection and sterilization of instruments, endoscopes, and surgical tools. They are normally used as a 2% solution to achieve sporicidal activity. These compounds are generally bactericidal and sporicidal.

E. Biguanides

Chlorhexidine is widely used in hand washing and oral products and as a disinfectant and preservative. These compounds are bactericidal but not sporicidal. The mycobacteria, because of their unique waxy cell envelope, are generally highly resistant to these compounds.

F. Bisphenols

The bisphenols are widely used in antiseptic soaps and hand rinses. In general, they have broad-spectrum microbicidal activity but have little activity against *P. aeruginosa* and molds. Triclosan and hexachlorophene are bactericidal and sporostatic (not sporicidal).

G. Halogen-Releasing Agents

The most important types of chlorine-releasing agents are sodium hypochlorite, chlorine dioxide, and sodium dichloroisocyanurate, which are oxidizing agents that destroy the cellular activity of proteins. Hypochlorous acid is the active compound responsible for the bactericidal effect of these compounds. At higher concentrations, this group is sporicidal. Iodine (I_2) is rapidly bactericidal and sporicidal. Iodophors (eg, povidone-iodine) are complexes of iodine and a solubilizing agent or carrier, which acts as a reservoir of the active I_2 .

H. Heavy Metal Derivatives

Silver (Ag^+) sulfadiazine, a combination of two antibacterial agents, Ag^+ and sulfadiazine, has a broad spectrum of activity. Binding to cell components such as DNA is principally responsible for its inhibitory properties. These compounds are not sporicidal.

I. Organic Acids

Organic acids are used as preservatives in the pharmaceutical and food industries. Benzoic acid is fungistatic, while propionic acid is both bacteriostatic and fungistatic. Neither is sporicidal.

J. Peroxygens

Hydrogen peroxide (H_2O_2) has broad-spectrum activity against viruses, bacteria, yeasts, and bacterial spores. Sporicidal activity requires higher concentrations (10–30%) of H_2O_2 and longer contact times.

K. Phenols

Phenol and many phenolic compounds have antiseptic, disinfectant, or preservative properties. In general, these are not sporicidal.

L. Quaternary Ammonium Compounds

These compounds have two regions in their molecular structures, one a water-repelling (hydrophobic) group and the other a water-attracting (hydrophilic) group. Cationic detergents, as exemplified by quaternary ammonium compounds (QACs), are useful antiseptics and disinfectants. QACs have been used for a variety of clinical purposes (eg, preoperative disinfection of unbroken skin) as well as for cleaning hard surfaces. They are sporostatic; they inhibit the outgrowth of spores but not the actual germination process. QACs have an effect on enveloped but not nonenveloped viruses. In general, these are not sporicidal.

M. Vapor-Phase Sterilants

Heat-sensitive medical devices and surgical supplies can be effectively sterilized by vapor-phase systems using ethylene oxide, formaldehyde, hydrogen peroxide, or peracetic acid. These are sporicidal.

RELATIONSHIP OF BIOCIDES CONCENTRATION AND TIME ON ANTIMICROBIAL KILLING

When biocides described previously are used to effect microbial populations, the variables of time and concentration need to be considered. It is commonly observed that the concentration of the substance used is related to the time required to kill a given fraction of the population by the following expression:

$$C^n t = K \quad (10)$$

In this equation, C is the biocide concentration, t is the time required to kill a given fraction of the cells, and n and K are constants.

This expression says that, for example, if $n = 6$ (as it is for phenol), then doubling the concentration of the drug will reduce the time required to achieve the same extent of inactivation 64-fold. That the effectiveness of a biocide varies with the sixth power of the concentration suggests that six molecules of the biocide are required to inactivate a

cell, although there is no direct chemical evidence for this conclusion.

To determine the value of n for any biocide, inactivation curves are obtained for each of several concentrations, and the time required at each concentration to inactivate a fixed fraction of the population is determined. For example, let the first concentration used be noted as C_1 and the time required to inactivate 99% of the cells be t_1 . Similarly, let C_2 and t_2 be the second concentration and time required to inactivate 99% of the cells. From equation (10), we see that:

$$C_1^n t_1 = C_2^n t_2$$

(11)

Solving for n gives:

$$n = \frac{\log t_2 - \log t_1}{\log C_1 - \log C_2}$$

(12)

Thus, n can be determined by measuring the slope of the line that results when $\log t$ is plotted against $\log C$ (Figure 4-4). If n is experimentally determined in this manner, K can be determined by substituting observed values for C , t , and n in equation (10).

Reversal of Biocide Action

In addition to time- and concentration-dependent kinetics, other considerations of biocide activity involve the ability of antimicrobial activity to be reversed. Table 4-5 summarizes a list of mechanisms that can reverse the activity of biocides. These include agent removal, substrate competition, and agent

TABLE 4-5 Examples of Mechanisms That Can Reverse the Activity of Biocides

Mechanism	Example
Agent removal	When cells that are inhibited by the presence of a bacteriostatic agent are removed by flushing the surface or centrifugation that removes bacteria from the bacteriostatic substance, they will resume normal multiplication.
Substrate competition	When a chemical antagonist of the analog type binds reversibly to an enzyme, it is possible to displace it by adding a high concentration of its normal substrate. Such cases are termed competitive inhibition . The ratio of the inhibitor concentration to the concentration of substrate that reverses the inhibition is called the antimicrobial index ; it is usually very high (100–10,000), indicating that the enzyme has a much greater affinity for the analog than for its normal substrate.
Agent inactivation	An agent can often be inactivated by adding a substance that combines with it to the medium, thus preventing its interaction with cellular constituents. For example, mercuric ion can be inactivated by the addition of sulfhydryl compounds such as thioglycolic acid to the medium.

inactivation. Neutralization of biocides needs to be considered as part of the sterilization/disinfection strategy.

SUMMARY

Appreciating the growth and death of bacteria is fundamental to understanding the complex interaction that exists between pathogenic bacteria and their hosts. If unchecked by an intact immune system and nutrient limitation, logarithmic growth of bacteria would quickly outcompete the host for nutrients. The environmental control of microbial growth by biocides limits exposure to potentially pathogenic microorganisms. The concepts of sterilization, disinfection, pasteurization, and others are central to bacterial control and ultimately to human health. In the end, understanding microbial growth and death is the first step toward effectively managing infectious diseases.

KEY CONCEPTS

1. Bacteria in humans exist as complex biosystems known as microbiota.
2. Quantification of bacterial cells can be accomplished using viable cell count, turbidity, and biomass.
3. Biomass and generation time are mathematically related.
4. Inoculating a single bacterial colony into a fixed volume of liquid medium is known as batch culture. In this

FIGURE 4-4 Relationship between biocide concentration (C) and time (t) required to kill a given fraction of a cell population.

system, bacterial growth exhibits four phases—lag, log, stationary, and death.

5. Some bacteria exist in a state that is defined as viable but not culturable.
6. Growth in continuous culture or as a biofilm more closely approximates bacterial growth within the human host.
7. Sterilization, disinfection, pasteurization, as well as other terms (see Table 4-3) are critical to understanding and communicating the science of microbiology.
8. The general structures of biocides (see Table 4-4) and mechanisms of action should be understood.
9. Depending on the mechanism of action, different biocides are bacteriostatic, bactericidal, and/or sporicidal.
10. Biocide activity is dependent on time and concentration. This activity can be reversed by agent removal, substrate competition, and agent inactivation.

REVIEW QUESTIONS

1. A 23-year-old woman has 10 *E. coli* introduced into her bladder while having sex. This organism has a generation time of 20 minutes. After a lag of 20 minutes, the *E. coli* enter the logarithmic phase of growth. After 3 hours, the total number of cells is
 - (A) 2056
 - (B) 5012
 - (C) 90
 - (D) 1028
 - (E) 1,000,000
2. A 73-year-old woman is admitted to the hospital for intravenous treatment of an abscess caused by *Staphylococcus aureus*. Subsequent to her treatment and discharge from the hospital, it is necessary to disinfect the hospital room. One thousand of the *S. aureus* cells are exposed to a disinfectant. After 10 minutes, 90% of the cells are killed. How many cells remain viable after 20 minutes?
 - (A) 500
 - (B) 100
 - (C) 10
 - (D) 1
 - (E) 0
3. The action of which of the following agents or processes on non-spore forming bacteria can be reversed?
 - (A) A disinfectant
 - (B) A bactericidal agent
 - (C) A bacteriostatic agent
 - (D) Autoclaving at 121°C for 15 minutes
 - (E) Dry heat at 160–170°C for 1 hour
4. The growth rate of bacteria during the exponential phase of growth is
 - (A) Zero
 - (B) Increasing
 - (C) Constant
 - (D) Decreasing
 - (E) Negative
5. A physician obtains a sputum specimen from a patient suffering from tuberculosis. This sputum sample contains one viable *Mycobacterium tuberculosis*, an organism with a slow doubling time in vitro of 48 hours, which corresponds to a growth rate constant (k) in vitro of 0.04 h^{-1} . Estimating that the biomass of this single mycobacterial organism is $2.3 \times 10^{-13} \text{ g}$ and assuming that this organism is immediately going to enter log phase growth, how many hours will it take to produce 10^{-6} g of biomass?
 - (A) 4 hours
 - (B) 40 hours
 - (C) 400 hours
 - (D) 4000 hours
 - (E) 40,000 hours
6. A specimen of pasteurized goat's milk is cultured for the presence of *Brucella melitensis*, an organism known to infect animals on an adjacent farm. The milk is declared safe to consume; however, some of those who consume it develop brucellosis. Which one of the following would best explain the disparity between the culture results and the patients' illnesses?
 - (A) Bacteria in the milk were viable but not cultivatable
 - (B) Incomplete pasteurization of the milk
 - (C) The organisms in the milk were in the lag phase when tested
 - (D) The milk contained a high concentration of a bactericidal antibiotic when tested
 - (E) There was post-test contamination of the milk
7. Working as a medical missionary in rural India, you spray the umbilicus of a newly born infant with a solution containing the chemical structure in the associated figure to prevent a tetanus infection. Which class of chemical agent does this structure belong?

$$\left[\begin{array}{cc} \text{R}^1 & \text{R}^3 \\ & \diagdown \quad \diagup \\ & \text{N} \\ & \diagup \quad \diagdown \\ \text{R}^2 & \text{R}^4 \end{array} \right]^+ \text{X}^-$$

 - (A) Alcohol class
 - (B) Aldehyde class
 - (C) Bisphenol class
 - (D) Peroxygen class
 - (E) Quaternary ammonium class
8. Your superior requests that you sterilize some surgical instruments. Which one of the following agents would you use?
 - (A) Benzoic acid (2%)
 - (B) Isopropyl alcohol (2%)
 - (C) Glutaraldehyde (2%)
 - (D) Hydrogen peroxide (2%)
 - (E) Quaternary ammonium compound (2%)
9. The growth rate of bacteria during the maximum stationary phase of growth is
 - (A) Zero
 - (B) Increasing
 - (C) Constant
 - (D) Decreasing
 - (E) Negative

10. Chemical agents can interfere with the normal reaction between a specific enzyme and its substrate (chemical antagonism). Which one of the following inhibits energy-yielding cellular processes?
- (A) 5-Methyltryptophan
 - (B) Cyanide
 - (C) Hydrogen peroxide
 - (D) Ethanol
 - (E) Lysozyme
11. Which of the following is the most resistant to destruction by chemicals and heat?
- (A) Spores of *Aspergillus fumigatus*
 - (B) *Mycobacterium tuberculosis*
 - (C) Ebola virus
 - (D) *E. coli*
 - (E) Spores of *Bacillus anthracis*

Cultivation of Microorganisms

Cultivation is the process of propagating organisms by providing the proper environmental conditions. Parasites, bacteria, and viruses all generally require cultivation for detailed study. The field of microbiology has the greatest experience in the cultivation of bacteria and as such, this is the focus of this chapter.

Bacteria divide by **binary fission**, asexual reproduction where a single cell divides giving rise to two cells. Those two cells give rise to a total of four cells and so on. This process of replication requires the acquisition of elements that make up their chemical composition. Nutrients from the environment provide these elements in metabolically accessible forms. In addition, organisms require metabolic energy to synthesize macromolecules and maintain essential chemical gradients across their membranes. Factors that must be controlled during growth include the nutrients, pH, temperature, aeration, salt concentration, and ionic strength of the medium.

REQUIREMENTS FOR GROWTH

Most of the dry weight of microorganisms is organic matter containing the elements carbon, hydrogen, nitrogen, oxygen, phosphorus, and sulfur. In addition, inorganic ions such as potassium, sodium, iron, magnesium, calcium, and chloride are required to facilitate enzymatic catalysis and to maintain chemical gradients across the cell membrane.

For the most part, the organic matter is in macromolecules formed by the introduction of **anhydride bonds** between building blocks. Synthesis of the anhydride bonds requires chemical energy, which is provided by the two phosphodiester bonds in adenosine triphosphate (ATP; see Chapter 6). Additional energy required to maintain a relatively constant cytoplasmic composition during growth in a range of extracellular chemical environments is derived from the **proton motive force**. The proton motive force is the potential energy that can be derived by passage of a proton across a membrane. In eukaryotes, the membrane may be part of the mitochondrion or the chloroplast. In prokaryotes, the membrane is the cytoplasmic membrane of the cell.

The proton motive force is an electrochemical gradient with two components: a difference in pH (hydrogen ion concentration) and a difference in ionic charge. The charge on

the outside of the bacterial membrane is more positive than the charge on the inside, and the difference in charge contributes to the free energy released when a proton enters the cytoplasm from outside the membrane. Metabolic processes that generate the proton motive force are discussed in Chapter 6. The free energy may be used to move the cell, to maintain ionic or molecular gradients across the membrane, to synthesize anhydride bonds in ATP, or for a combination of these purposes. Alternatively, cells given a source of ATP may use its anhydride bond energy to create the proton motive force that in turn may be used to move the cell and to maintain chemical gradients.

To grow, a bacterium requires all the elements in its organic matter as well as the full complement of ions required for energetics and catalysis. In addition, there must be a source of energy to establish the proton motive force and to allow macromolecular synthesis. Microorganisms vary widely in their nutritional demands and their sources of metabolic energy.

SOURCES OF METABOLIC ENERGY

The three major mechanisms for generating metabolic energy are **fermentation**, **respiration**, and **photosynthesis**. At least one of these mechanisms must be used if an organism is to grow.

Fermentation

The formation of ATP in fermentation is not coupled to the transfer of electrons. Fermentation is characterized by **substrate phosphorylation**, an enzymatic process in which a pyrophosphate bond is donated directly to adenosine diphosphate (ADP) by a phosphorylated metabolic intermediate. The phosphorylated intermediates are formed by metabolic rearrangement of a fermentable substrate such as glucose, lactose, or arginine. Because fermentations are not accompanied by a change in the overall oxidation–reduction state of the fermentable substrate, the elemental composition of the products of fermentation must be identical to those of the substrates. For example, fermentation of a molecule of glucose ($C_6H_{12}O_6$) by the Embden-Meyerhof pathway (see Chapter 6)

yields a net gain of two pyrophosphate bonds in ATP and produces two molecules of lactic acid (C₃H₆O₃).

Respiration

Respiration is analogous to the coupling of an energy-dependent process to the discharge of a battery. Chemical reduction of an oxidant (electron acceptor) through a specific series of electron carriers in the membrane establishes the proton motive force across the bacterial membrane. The reductant (electron donor) may be organic or inorganic (eg, lactic acid serves as a reductant for some organisms, and hydrogen gas is a reductant for other organisms). Gaseous oxygen (O₂) is the oxidant most commonly used by aerobic bacteria, but alternative oxidants that are used by some organisms include carbon dioxide (CO₂), sulfate (SO₄²⁻), and nitrate (NO₃⁻).

Photosynthesis

Photosynthesis is like respiration in that the reduction of an oxidant via a specific series of electron carriers establishes the proton motive force. The difference in the two processes is that in photosynthesis, the reductant and the oxidant are created photochemically by light energy absorbed by pigments in the membrane; thus, photosynthesis can continue only if there is a source of light energy. Plants and some bacteria can invest a substantial amount of light energy in making water a reductant for carbon dioxide. Oxygen is evolved in this process, and organic matter is produced. Respiration, the energetically favorable oxidation of organic matter by an electron acceptor such as oxygen, can provide photosynthetic organisms with energy in the absence of light.

NUTRITION

Nutrients in growth media must contain all the elements necessary for the biologic synthesis of new organisms. In the following discussion, nutrients are classified according to the elements they supply.

Carbon Source

As already mentioned, plants and some bacteria can use photosynthetic energy to reduce carbon dioxide at the expense of water. These organisms are referred to as **autotrophs**, bacteria that do not require organic nutrients for growth. Other autotrophic microorganisms are the **chemolithotrophs**, organisms that use an inorganic substrate such as hydrogen or thiosulfate as a reductant and carbon dioxide as a carbon source.

Heterotrophs require organic carbon for growth, and the organic carbon must be in a form that can be assimilated. Naphthalene, for example, can provide all the carbon and energy required for respiratory heterotrophic growth, but very few organisms possess the metabolic pathway necessary

for naphthalene assimilation. Glucose, on the other hand, can support the fermentative or respiratory growth of many organisms. It is important that growth substrates be supplied at levels appropriate for the microbial strain that is being grown—Levels that support the growth of one organism may inhibit the growth of another organism.

Carbon dioxide is required for several biosynthetic reactions. Many respiratory organisms produce more than enough carbon dioxide to meet this requirement, but others require a source of carbon dioxide in their growth medium.

Nitrogen Source

Nitrogen is a major component of proteins, nucleic acids, and other compounds, accounting for approximately 5% of the dry weight of a typical bacterial cell. Inorganic dinitrogen (N₂) is prevalent, comprising 80% of the earth’s atmosphere. It is also a very stable compound, primarily because of the high activation energy required to break the nitrogen–nitrogen triple bond. However, nitrogen may be supplied in different forms and microorganisms vary in their abilities to assimilate nitrogen (Table 5-1). The end product of all pathways for nitrogen assimilation is the most reduced form of the element, ammonia (NH₃). When NH₃ is available, it diffuses into most bacteria through transmembrane channels as dissolved gaseous NH₃ rather than ionic ammonium ion (NH₄⁺).

The ability to assimilate N₂ reductively via NH₃, which is called **nitrogen fixation**, is a property unique to prokaryotes, and relatively few bacteria can break the nitrogen–nitrogen triple bond. This process (see Chapter 6) requires a large amount of metabolic energy and is readily inactivated by oxygen. The capacity for nitrogen fixation is found in widely divergent bacteria that have evolved quite different biochemical strategies to protect their nitrogen-fixing enzymes from oxygen.

Most microorganisms can use NH₃ as a sole nitrogen source, and many organisms possess the ability to produce NH₃ from amines (R–NH₂) or from amino acids (RCHNH₂COOH), generally intracellularly. Production of NH₃ from the deamination of amino acids is called **ammonification**. Ammonia is introduced into organic matter by biochemical pathways involving glutamate and glutamine. These pathways are discussed in Chapter 6.

TABLE 5-1 Sources of Nitrogen in Bacterial Nutrition

Compound	Valence of N
NO ₃ ⁻	+5
NO ₂ ⁻	+3
N ₂	0
NH ₄ ⁺	–3
R-NH ₂ ^a	–3

^aR, organic radical.

Many microorganisms possess the ability to assimilate nitrate (NO_3^-) and nitrite (NO_2^-) reductively by conversion of these ions into NH_3 . These processes are termed **assimilatory nitrate reduction** and **assimilatory nitrite reduction**, respectively. These pathways for assimilation differ from pathways used for **dissimilation** of nitrate and nitrite. The dissimilatory pathways are used by organisms that use these ions as terminal electron acceptors in respiration. Some autotrophic bacteria (eg, *Nitrosomonas*, *Nitrobacter* spp.) can convert NH_3 to gaseous N_2 under anaerobic conditions; this process is known as **denitrification**.

Our understanding of the nitrogen cycle continues to evolve. In the mid-1990s, the **anammox** reaction was discovered. The reaction

in which ammonia is oxidized by nitrite is a microbial process that occurs in anoxic waters of the ocean and is a major pathway by which nitrogen is returned to the atmosphere.

Sulfur Source

Like nitrogen, sulfur is a component of many organic cell substances. It forms part of the structure of several coenzymes and is found in the cysteinyl and methionyl side chains of proteins. Sulfur, in its elemental form, cannot be used by plants or animals. However, some autotrophic bacteria can oxidize sulfur to sulfate (SO_4^{2-}). Most microorganisms can use sulfate as a sulfur source, reducing the sulfate to the level of hydrogen sulfide (H_2S). Some microorganisms can assimilate H_2S directly from the growth medium, but this compound can be toxic to many organisms.

Phosphorus Source

Phosphate (PO_4^{3-}) is required as a component of ATP, nucleic acids, and such coenzymes as NAD, NADP, and flavins. In addition, many metabolites, lipids (phospholipids, lipid A), cell wall components (teichoic acid), some capsular polysaccharides, and some proteins are phosphorylated. Phosphate is always assimilated as free inorganic phosphate (P_i).

Mineral Sources

Numerous minerals are required for enzyme function. Magnesium (Mg^{2+}) and ferrous (Fe^{2+}) ions are found in porphyrin derivatives: magnesium in the chlorophyll molecule, and iron as part of the coenzymes of the cytochromes and peroxidases. Mg^{2+} and K^+ are both essential for the function and integrity of ribosomes. Ca^{2+} is required as a constituent of Gram-positive cell walls, although it is dispensable for Gram-negative bacteria. Many marine organisms require high concentrations of Na^+ for growth.

In formulating a medium for the cultivation of most microorganisms, it is necessary to provide sources of potassium, magnesium, calcium, and iron, usually as their ions (K^+ , Mg^{2+} , Ca^{2+} , and Fe^{2+}). Many other minerals (eg, Mn^{2+} , Mo^{2+} , Co^{2+} , Cu^{2+} , and Zn^{2+}) are required in trace quantities—These frequently can be provided in tap water or as contaminants of other medium ingredients.

The uptake of iron, which forms insoluble hydroxides at neutral pH, is facilitated in many bacteria and fungi by their production of **siderophores**—compounds that chelate iron and promote its transport as a soluble complex. These include hydroxamates ($-\text{CONH}_2\text{OH}$) called sideramines and derivatives of catechol (eg, 2,3-dihydroxy-benzoylserine). Plasmid-determined siderophores play a major role in the invasiveness of some bacterial pathogens (see Chapter 7). Siderophore- and nonsiderophore-dependent mechanisms of iron uptake by bacteria are discussed in Chapter 9.

Growth Factors

A growth factor is an organic compound that a cell must have to grow but that it is unable to synthesize. Many microorganisms, when provided with the nutrients listed above, can synthesize all of the building blocks for macromolecules (Figure 5-1), which are amino acids, purines, pyrimidines, and pentoses (the metabolic precursors of nucleic acids), additional carbohydrates (precursors of polysaccharides), fatty acids, and isoprenoid compounds. In addition, free-living organisms must be able to synthesize the complex vitamins that serve as precursors of coenzymes.

Each of these essential compounds is synthesized by a discrete sequence of enzymatic reactions; each enzyme is produced under the control of a specific gene. When an organism undergoes a genetic mutation resulting in failure of one of these enzymes to function, the chain is broken, and the end-product is no longer produced. The organism must then obtain that compound from the environment: The compound has become a **growth factor** for the organism.

Different microbial species vary widely in their growth factor requirements. The compounds involved are found in and are essential to all organisms; the differences in requirements reflect differences in synthetic abilities. Some species require no growth factors, but others—such as some of the lactobacilli—have lost, during evolution, the ability to synthesize as many as 30–40 essential compounds and hence require them in their cultivation medium. By inference, many organisms that cannot be cultured require growth factors that are as yet unidentified.

ENVIRONMENTAL FACTORS AFFECTING GROWTH

A suitable growth medium must contain all the nutrients required by the organism to be cultivated, and such factors as pH, temperature, and aeration must be carefully controlled.

FIGURE 5-1 Macromolecular synthesis. Polymerization of building blocks into macromolecules is achieved largely by the introduction of anhydride bonds. Formation of fatty acids from acetate requires several steps of biochemical reduction using organic hydrogen donors ($D \cdot H_2$).

This is typically accomplished using liquid medium or on a semi-solid medium gelled by the addition of agar (typically at 1.5% weight per volume). Agar, a polysaccharide extract of a marine alga, is uniquely suitable for microbial cultivation because it is resistant to microbial action and because it dissolves at 100°C but does not gel until cooled below 45°C; cells (eg, sheep red blood cells) can be suspended in the medium at 45°C and the medium quickly cooled to a gel without harming them. One aspect to consider about agar is that it is a negatively charged sugar that may bind positively charged molecules, restricting their delivery to growing bacteria. For example, freely diffusible antibiotics are routinely tested for their ability to inhibit bacterial growth. However, cationic (positively charged) antimicrobial peptides are inhibited on agar medium because they are bound by the negatively charged agar in the medium.

Nutrients

Earlier in this chapter, the function of each type of nutrient was described, and a list of suitable substances presented. In general, the following must be provided: (1) hydrogen donors and acceptors, about 2 g/L; (2) carbon source, about 1 g/L; (3) nitrogen source, about 1 g/L; (4) minerals: sulfur and phosphorus, about 50 mg/L of each, and trace elements, 0.1–1 mg/L of each; (5) growth factors: amino acids, purines, and pyrimidines, about 50 mg/L of each, and vitamins, 0.1–1 mg/L of each. For many organisms, a single compound (eg, an amino acid) may serve as an energy, carbon, and nitrogen source; others require a separate compound for each.

For studies of microbial metabolism, it is usually necessary to prepare a completely synthetic medium in which the exact characteristics and concentration of every ingredient

are known. This type of medium is referred to as **defined media**. Otherwise, it is much cheaper and simpler to use natural materials such as yeast extract, protein digest, or similar substances. Most free-living microbes grow well on yeast extract. Nevertheless, some bacterial pathogens cannot be grown in vitro.

Hydrogen-Ion Concentration (pH)

Most organisms have a fairly narrow optimal pH range. The optimal pH must be empirically determined for each species. Most organisms (**neutrophiles**) grow best at a pH of 6.0–8.0, although some forms (**acidophiles**) have optima as low as pH 3.0, and others (**alkaliphiles**) have optima as high as pH 10.5.

Microorganisms regulate their internal pH over a wide range of external pH values by pumping protons in or out of their cells. Acidophiles maintain an internal pH of about 6.5 over an external range of 1.0–5.0, neutrophiles maintain an internal pH of about 7.5 over an external range of 5.5–8.5, and alkaliphiles maintain an internal pH of about 9.5 over an external range of 9.0–11.0. Internal pH is regulated by a set of proton transport systems in the cytoplasmic membrane, including a primary, ATP-driven proton pump and a Na^+/H^+ exchanger. A K^+/H^+ exchange system has also been proposed to contribute to internal pH regulation in neutrophiles.

Temperature

Different microbial species vary widely in their optimal temperature ranges for growth (Figure 5-2): **Psychrophilic**

FIGURE 5-2 Temperature requirements for growth. Prokaryotes are commonly divided into five groups based on their optimum growth temperatures. Note that the optimum temperature, the point at which the growth rate is highest, is near the upper limit of the range. (Reproduced with permission from Nester EW, Anderson DG, Roberts CE, et al: *Microbiology: A Human Perspective*, 6th ed. McGraw-Hill, 2009, p. 91. © McGraw-Hill Education.)

forms grow best at low temperatures (–5 to 15°C) and are usually found in such environments as the Arctic and Antarctic regions; **psychrotrophs** have a temperature optimum between 20°C and 30°C but grow well at lower temperatures. They are an important cause of food spoilage and in the case of *Listeria monocytogenes* can cause significant human gastrointestinal and nervous system diseases. **Mesophilic** forms grow best at 30–37°C, and most **thermophilic** forms grow best at 50–60°C. Some organisms are **hyperthermophilic** and can grow at well above the temperature of boiling water, which exists under high pressure in the depths of the ocean. Most organisms are mesophilic; 30°C is optimal for many free-living forms, and the body temperature of the host is optimal for symbionts of warm-blooded animals.

The upper end of the temperature range tolerated by any given species correlates well with the general thermal stability of that species’ proteins as measured in cell extracts. Microorganisms share with plants and animals the **heat-shock response**, a transient synthesis of a set of “heat-shock proteins,” when exposed to a sudden rise in temperature above the growth optimum. These proteins appear to be unusually temperature-resistant and stabilize other cellular heat-sensitive proteins.

The relationship of growth rate to temperature for any given microorganism is seen in a typical Arrhenius plot (Figure 5-3). Arrhenius showed that the logarithm of the velocity of any chemical reaction ($\log k$) is a linear function of the reciprocal of the temperature ($1/T$); because cell growth is the result of a set of chemical reactions, it might be expected to show this relationship. Figure 5-3 shows this to be the case

FIGURE 5-3 General form of an Arrhenius plot of bacterial growth. (Reproduced with permission from Ingraham JL: Growth of psychrophilic bacteria. *J Bacteriol* 1958;76(1):75–80.)

over the normal range of temperatures for a given species; $\log k$ decreases linearly with $1/T$. Above and below the normal range, however, $\log k$ drops rapidly, so that maximum and minimum temperature values are defined.

Beyond their effects on growth rate, extremes of temperature kill microorganisms. Extreme heat is used to sterilize preparations (see Chapter 4); extreme cold also kills microbial cells, although it cannot be used for effective sterilization. Bacteria also exhibit a phenomenon called **cold shock**, which is the killing of cells by rapid—as opposed to slow—cooling. For example, the rapid cooling of *Escherichia coli* from 37°C to 5°C can kill 90% of the cells. A number of compounds protect cells from either freezing or cold shock; glycerol and dimethyl sulfoxide are most commonly used.

Aeration

The role of oxygen as hydrogen acceptor is discussed in Chapter 6. Many organisms are **obligate aerobes**, specifically requiring oxygen as hydrogen acceptor. Some are **facultative anaerobes**, able to live aerobically or anaerobically; some are **microaerophiles**, which require small amounts of oxygen (2–10%) for aerobic respiration (higher concentrations are inhibitory); some are **obligate anaerobes** requiring a substance other than oxygen as hydrogen acceptor and are sensitive to oxygen inhibition; and others are **aerotolerant anaerobes**, which are indifferent to oxygen. They can grow in its presence, but they do not use it as a hydrogen acceptor (Figure 5-4).

FIGURE 5-4 Oxygen (O₂) requirements of prokaryotes. (Reproduced with permission from Nester EW, Anderson DG, Roberts CE, et al: *Microbiology: A Human Perspective*, 6th ed. McGraw-Hill, 2009, p. 92. © McGraw-Hill Education.)

The natural by-products of aerobic metabolism are the reactive compounds hydrogen peroxide (H₂O₂) and superoxide (O₂⁻). In the presence of iron, these two species can generate hydroxyl radicals (•OH), which can damage any biologic macromolecule:

Many aerobes and aerotolerant anaerobes are protected from these products by the presence of superoxide dismutase, an enzyme that catalyzes the reaction

and by the presence of catalase, an enzyme that catalyzes the reaction

Some fermentative organisms (eg, *Lactobacillus plantarum*) are aerotolerant but do not contain catalase or superoxide dismutase. Oxygen is not reduced, and therefore H₂O₂ and O₂⁻ are not produced. All strict anaerobes lack both superoxide dismutase and catalase. Some anaerobic organisms (eg, *Peptococcus anaerobius*) have considerable tolerance to oxygen because of their ability to produce high levels of NADH oxidase that reduces oxygen to water according to the reaction

Hydrogen peroxide owes much of its toxicity to the damage it causes to DNA. DNA repair-deficient mutants are exceptionally sensitive to hydrogen peroxide; the *recA* gene product, which functions in both genetic recombination and repair, has been shown to be more important than either catalase or superoxide dismutase in protecting *E. coli* cells against hydrogen peroxide toxicity.

The supply of air to liquid cultures of aerobes is a major technical problem. Vessels are usually shaken mechanically to

introduce oxygen into the medium or air is forced through the medium by pressure. The diffusion of oxygen often becomes the limiting factor in growing aerobic bacteria; when a cell concentration of $4\text{--}5 \times 10^9/\text{mL}$ is reached, the rate of diffusion of oxygen to the cells sharply limits the rate of further growth.

Obligate anaerobes, on the other hand, present the problem of oxygen exclusion. Many methods are available for this—reducing agents such as sodium thioglycolate can be added to liquid cultures, tubes of agar can be sealed with a layer of petrolatum and paraffin, the culture vessel can be placed in a container from which the oxygen is removed by evacuation or by chemical means, or the organism can be handled within an anaerobic glove box.

Ionic Strength and Osmotic Pressure

Most bacteria can tolerate a wide range of external ionic strengths and osmotic pressures because of their ability to regulate internal osmolality and ion concentration. Osmolality is regulated by the active transport of K⁺ ions into the cell; internal ionic strength is kept constant by a compensating excretion of the positively charged organic polyamine putrescine. Because putrescine carries several positive charges per molecule, a large drop in ionic strength is affected at only a small cost in osmotic strength.

In a small subset of highly adapted bacteria, factors such as osmotic pressure and salt concentration are part of their environment and must be controlled for cultivation in vitro. For example, marine bacteria require growth in the presence of high salt concentrations and are called **halophiles**; organisms capable of growing in high concentrations of sugars are called **osmophiles**.

CULTIVATION METHODS

There are two practical problems that need to be considered in the cultivation of a microorganism—(1) the choice of a suitable medium and (2) the isolation of a bacterial organism in pure culture.

The Medium

The technique used and the type of medium selected depend on the nature of the investigation. In general, three situations may be encountered: (1) To amplify a defined bacterial clone for the purposes of increasing the amount of a desired product (eg, nucleic acid or protein); (2) To determine the numbers and types of organisms present in a given specimen; or (3) To isolate a particular type of microorganism from a natural source.

A. Amplifying a Defined Bacterial Clone

Bacteria have evolved to grow in specific environments. Certain organisms such as *E. coli* that are used in routine gene amplification and protein production grow with very few restrictions. Other organisms such as *Legionella pneumophila* are **fastidious** and require growth conditions that simulate their natural environment. For these fastidious organisms, pH, temperature, and aeration are easy to duplicate. It is the formulation of nutrients that present the major problem.

A fastidious bacterium may require an extract of the host tissue to include all of the growth factors necessary for their expansion. Considerable experimentation may be necessary to determine the requirements of the organism, and success depends on providing a suitable source of each category of nutrient listed at the beginning of this chapter. Some organisms such as the Chlamydiae and the Rickettsiae are obligate intracellular bacteria and require viable eukaryotic cells within which they can grow. In these cases, laboratory eukaryotic cell culture followed by bacterial infection is required to amplify the bacterium for study.

B. Microbiologic Examination of Natural Specimens

The total population of bacteria that exist within a given specimen, eg, pond water or urine, is referred to as the **microbiome**. Within any specimen there exists many microenvironments. For example, the oxygen concentration at the top of a pond is much higher than at the bottom of the pond. Growth of aerobic bacteria would be favored at the top of the pond whereas microaerophilic bacteria are favored at the bottom of the pond. Nonetheless, a specimen of water from that pond will contain both species of bacteria. Determining what organisms comprise the total biome of the pond water specimen will depend on how the sample is cultivated. Plating a sample of the material under one set of conditions (eg, in the presence of oxygen) will allow a selected group (in this case aerobes) to produce colonies but will cause many other types (in this example microaerophiles) to be overlooked. For this reason, it is customary to plate out samples of the material using as many different media and conditions of incubation as practicable. Six to eight different culture conditions are not an unreasonable number if most of the forms present are to be discovered.

C. Isolation of a Particular Type of Microorganism

A small sample of soil, if handled properly, will yield a different type of organism for every microenvironment present. For fertile soil (moist, aerated, rich in minerals and organic matter), this means that hundreds or even thousands of types can be isolated. This is done by selecting for the desired type. For example, if organisms such as aerobic nitrogen fixers (*Azotobacter*) are present they can be isolated from a gram of fertile soil by inoculating liquid medium favoring their growth. In this case, the medium will contain no combined nitrogen and be incubated aerobically. If cells of *Azotobacter* are present in the soil, they will grow well in this medium; bacteria unable to fix nitrogen will grow only to the extent that the soil has introduced contaminating fixed nitrogen into the medium. When the culture is fully grown the percentage of *Azotobacter* in the total population will have increased greatly. This method is called **enrichment culture**. Transfer of a sample of this culture to fresh medium will result in further enrichment of *Azotobacter*; after several serial transfers, the culture can be plated out on a solidified enrichment medium and colonies of *Azotobacter* isolated. Enrichment culture simulates the natural environment ("niche") of the desired microorganism, thereby selecting for it (Figure 5-5). An important principle involved in such selection is the following: The organism selected for will be the type whose nutritional requirements are barely satisfied. *Azotobacter*, for example, grows best in a medium containing organic nitrogen, but its minimum requirement is the presence of N_2 ; hence, it is selected for in a medium containing N_2 as the sole nitrogen source. If organic nitrogen is added to the medium, the conditions no longer select for *Azotobacter* but rather for a form for which organic nitrogen is the minimum requirement.

When searching for a particular type of organism that is part of a mixed population, **selective** and **differential media** are used. Selective media inhibit the growth of organisms other than the one being sought. For example, Thayer-Martin agar is used to isolate *Neisseria gonorrhoeae*, the cause of gonorrhea, from vaginal specimens that contain the complex flora of the cervix. This media contains vancomycin, which is able to kill most Gram-positive organisms, colistin which is added to kill most Gram-negative organisms except *Neisseria*, and nystatin which kill most fungi. A vaginal swab plated on Thayer-Martin agar from a patient presenting with gonorrhea will predominantly grow only the strain of *N. gonorrhoeae* causing the patient's symptoms.

Differential media contain a substance(s) that certain bacteria change in a recognizable way. In another example, colonies of *E. coli* have a characteristic iridescent sheen on agar containing the dyes eosin and methylene blue (EMB agar). EMB agar containing a high concentration of one sugar will also cause them to ferment that sugar and form reddish colonies. Differential media are used for such purposes as recognizing the presence of enteric bacteria in water or milk and the presence of certain pathogens in clinical specimens. Table 5-2 presents characteristics of representative media used to cultivate bacteria.

FIGURE 5-5 Enrichment culture. Medium and incubation conditions favor the growth of the desired species over other bacteria in the same sample. Isolation of Microorganisms in Pure Culture

To study the properties of a given organism, it is necessary to handle it in pure culture free of all other types of organisms. To do this, a single cell must be isolated from all other cells and cultivated in such a manner that its collective progeny also remains isolated. Several methods are available as follows.

A. Plating

Unlike cells in a liquid medium, cells in or on a gelled medium are immobilized. Therefore, if few enough bacteria are placed in agar medium, each bacterium will grow by binary fission into an isolated colony. The **pour-plate method** uses a diluted suspension of cells mixed with melted agar at 50°C and poured into a Petri dish. When the agar solidifies, the cells are immobilized in the agar and grow into colonies. If the cell suspension is sufficiently dilute, the colonies will be

TABLE 5-2 Characteristics of Representative Media Used to Cultivate Bacteria

Medium	Characteristic
Blood agar	Complex medium used routinely in clinical labs. Differential because colonies of hemolytic organisms are surrounded by a zone of clearing of the red blood cells. Not selective.
Chocolate agar	Complex medium used to culture fastidious bacteria, particularly those found in clinical specimens. Not selective or differential.
Glucose-salts	Chemically defined medium. Used in laboratory experiments to study nutritional requirements of bacteria. Not selective or differential.
MacConkey agar	Complex medium used to isolate Gram-negative rods that typically reside in the intestine. Selective because bile salts and dyes inhibit Gram-positive organisms and Gram-negative cocci. Differential because the pH indicator turns pink-red when the sugar in the medium, lactose, is fermented.
Nutrient agar	Complex medium used for routine laboratory work. Supports the growth of a variety of nonfastidious bacteria. Not selective or differential.
Thayer-Martin	Complex medium used to isolate <i>Neisseria</i> species, which are fastidious. Selective because it contains antibiotics that inhibit most organisms except <i>Neisseria</i> species. Not differential.

FIGURE 5-6 The pour-plate technique. The original sample is diluted several times to thin out the population sufficiently. The most diluted samples are then mixed with warm agar and poured into Petri dishes. Isolated cells grow into colonies and are used to establish pure cultures. The surface colonies are circular; subsurface colonies are lenticular (lens shaped). (Reproduced with permission from Willey JM, Sherwood LM, Woolverton CJ: *Prescott, Harley, & Klein’s Microbiology*, 7th ed. McGraw-Hill, 2008, p. 115. © McGraw-Hill Education.)

well separated, so that each has a high probability of being derived from a single cell (Figure 5-6). To make certain of this, however, it is necessary to pick a colony of the desired type, suspend it in sterile medium, and replate. Repeating this procedure several times ensures that a pure culture will be obtained.

Alternatively, the original suspension can be streaked on the surface of an agar plate with a wire loop (**streak-plate technique**). As the streaking continues, fewer and fewer cells are left on the loop, and finally the loop may deposit single cells on the agar (Figure 5-7). The plate is incubated, and any well-isolated colony is then removed, resuspended in sterile

Note: This method only works if the spreading tool (usually an inoculating loop) is resterilized after each of steps 1–4.

FIGURE 5-7 Streak-plate technique. **A:** A typical streaking pattern. (Reproduced with permission from Willey JM, Sherwood CJ, Woolverton CJ: *Prescott, Harley, & Klein’s Microbiology*, 7th ed. McGraw-Hill, 2008, p. 115. © McGraw-Hill Education.) **B:** An example of a streak plate. (Reproduced with permission from Kathy Park Talaro.)

medium, and again streaked on agar. If a suspension (and not just a bit of growth from a colony or slant) is streaked, this method is just as reliable as and much faster than the pour-plate method.

In the **spread plate technique**, a small volume of dilute microbial suspension containing ca 30–300 cells is transferred to the center of an agar plate and spread evenly over the surface with a sterile bent-glass rod. The dispersed cells develop into isolated colonies. Because the number of colonies should equal the number of viable organisms in a sample, spread plates can be used to count the microbial population.

B. Dilution

A much less reliable method is that of extinction dilution. The suspension is serially diluted, and samples of each dilution are plated. If only a few samples of a particular dilution exhibit growth, it is presumed that some of the colonies started from single cells. This method is not used unless plating is for some reason impossible. An undesirable feature of this method is that it can only be used to isolate the predominant type of organism in a mixed population.

CHAPTER SUMMARY

- An organism requires all the elements in its organic matter and the full complement of ions required for energetics in order to grow. Nutrients are classified according to the elements they provide, including carbon source, nitrogen source, sulfur source, phosphorous source, and mineral sources.
- Growth factors are organic compounds that a cell must have to grow but that it is unable to synthesize.
- There must be a source of energy present to establish a proton motive force and to allow macromolecular synthesis. The three major mechanisms for generating metabolic energy are fermentation, respiration, and photosynthesis.
- Environmental factors such as pH, temperature, and aeration are important for growth. Most human pathogens are neutrophiles (grow best at pH of 6.0–8.0) and mesophilic (grow best at 30–37°C).
- Organisms vary widely in their ability to use oxygen as a hydrogen acceptor and in their ability to inactivate toxic by-products of aerobic metabolism. They may be grouped as obligate aerobes, facultative anaerobes, obligate anaerobes, microaerophiles, and aerotolerant anaerobes.
- Microbiologic media can be formulated to permit the growth of a microorganism present in low numbers (enrichment culture), identify specific types of microorganisms (differential medium), or isolate a specific organism from a mixed population (selective medium).

REVIEW QUESTIONS

1. Most microorganisms pathogenic for humans grow best in the laboratory when cultures are incubated at
 - (A) 15–20°C
 - (B) 20–30°C
 - (C) 30–37°C
 - (D) 38–50°C
 - (E) 50–55°C
2. The process by which microorganisms form ATP during the fermentation of glucose is characterized by
 - (A) Coupling of ATP production with the transfer of electrons
 - (B) Denitrification
 - (C) The reduction of oxygen
 - (D) Substrate phosphorylation
 - (E) Anaerobic respiration
3. The major effect of a temperature of 60°C on the growth of a mesophile such as *E. coli* is to
 - (A) Destroy the cell wall
 - (B) Denature proteins
 - (C) Destroy nucleic acids
 - (D) Solubilize the cytoplasmic membrane
 - (E) Cause formation of endospores
4. Polymerization of building blocks (eg, amino acids) into macromolecules (eg, proteins) is achieved largely by
 - (A) Dehydration
 - (B) Reduction
 - (C) Oxidation
 - (D) Assimilation
 - (E) Hydrolysis
5. A strain of *E. coli* does not require vitamins when grown in a defined medium consisting of glucose, mineral salts, and ammonium chloride. This is because *E. coli*
 - (A) Does not use vitamins for growth
 - (B) Obtains vitamins from its human host
 - (C) Is a chemoheterotroph
 - (D) Can synthesize vitamins from the simple compounds provided in the medium
 - (E) Ammonium chloride and mineral salts contain trace amounts of vitamins
6. Which of the following is NOT a mechanism for generating metabolic energy by microorganisms?
 - (A) Fermentation
 - (B) Protein synthesis
 - (C) Respiration
 - (D) Photosynthesis
 - (E) C and D
7. Which of the following terms best describes a microorganism that grows at 20°C?
 - (A) Neutrophile
 - (B) Psychrotroph
 - (C) Mesophile
 - (D) Osmophile
 - (E) Thermophile
8. The ability to assimilate N₂ reductively via NH₃ is called
 - (A) Ammonification
 - (B) Anammox
 - (C) Assimilatory nitrate reduction

- (D) Deamination
- (E) Nitrogen fixation
- 9. Which of the following is NOT assimilated by eukaryotic cells?
 - (A) Glucose
 - (B) Lactate
 - (C) Sulfate (SO_4^{2-})
 - (D) Nitrogen (N_2)
 - (E) Phosphate (PO_4^{3-})
- 10. Bacteria that are obligate intracellular pathogens of humans (eg, *Chlamydia trachomatis*) are considered to be
 - (A) Autotrophs
 - (B) Photosynthetic
 - (C) Chemolithotrophs
 - (D) Hyperthermophiles
 - (E) Heterotrophs

Answers

Microbial Metabolism

ROLE OF METABOLISM IN BIOSYNTHESIS AND GROWTH

Microbial growth requires the polymerization of biochemical building blocks into proteins, nucleic acids, polysaccharides, and lipids. The building blocks must either be present in the growth medium or synthesized by the growing cells. Additional biosynthetic demands are placed by the requirement for coenzymes that participate in enzymatic catalysis. Biosynthetic polymerization reactions demand the transfer of anhydride bonds from adenosine triphosphate (ATP). Growth demands a source of metabolic energy for the synthesis of anhydride bonds and for the maintenance of transmembrane gradients of ions and metabolites.

Metabolism is composed of two components: **catabolism** and **anabolism** (Figure 6-1). Catabolism encompasses processes that harvest energy released from the breakdown of compounds (eg. glucose), and using that energy to synthesize ATP. In contrast, anabolism, or **biosynthesis**, includes processes that utilize the energy stored in ATP to synthesize and assemble the subunits, or building blocks, of macromolecules that make up the cell. The sequence of building blocks within a macromolecule is determined in one of two ways. In nucleic acids and proteins, it is **template-directed**: DNA serves as the template for its own synthesis and for the synthesis of the various types of RNA; messenger RNA serves as the template for the synthesis of proteins. In carbohydrates and lipids, on the other hand, the arrangement of building blocks is determined entirely by enzyme specificities. Once the macromolecules have been synthesized, they self-assemble to form the supramolecular structures of the cell, for example, ribosomes, membranes, cell wall, flagella, and pili.

The rate of macromolecular synthesis and the activity of metabolic pathways must be regulated so that biosynthesis is balanced. All of the components required for macromolecular synthesis must be present for orderly growth, and control must be exerted so that the resources of the cell are not expended on products that do not contribute to growth or survival.

This chapter contains a review of microbial metabolism and its regulation. Microorganisms represent extremes of evolutionary divergence, and a vast array of metabolic pathways

is found within the group. For example, any of more than half a dozen different metabolic pathways may be used for assimilation of a relatively simple compound, benzoate, and a single pathway for benzoate assimilation may be regulated by any of more than half a dozen control mechanisms. Our goal is to illustrate the principles that underlie metabolic pathways and their regulation. The primary principle that determines metabolic pathways is that they are achieved by organizing relatively few biochemical-type reactions in a specific order. Many biosynthetic pathways can be deduced by examining the chemical structures of the starting material, the end product, and perhaps one or two metabolic intermediates. The primary principle underlying metabolic regulation is that enzymes tend to be called into play only when their catalytic activity is required. The activity of an enzyme may be changed by varying either the amount of enzyme or the amount of substrate. In some cases, the activity of enzymes may be altered by the binding of specific **effectors**, metabolites that modulate enzyme activity.

FOCAL METABOLITES AND THEIR INTERCONVERSION

Glucose 6-Phosphate and Carbohydrate Interconversions

The biosynthetic origins of building blocks and coenzymes can be traced to relatively few precursors, called **focal metabolites**. Figures 6-2–6-5 illustrate how the respective focal metabolites glucose 6-phosphate (G6PD), phosphoenolpyruvate, oxaloacetate, and α -ketoglutarate give rise to most biosynthetic end products.

Figure 6-2 illustrates how G6PD is converted to a range of biosynthetic end products via phosphate esters of carbohydrates with different chain lengths. Carbohydrates possess the empirical formula $(CH_2O)_n$, and the primary objective of carbohydrate metabolism is to change n , the length of the carbon chain. Mechanisms by which the chain lengths of carbohydrate phosphates are interconverted are summarized in Figure 6-6. In one case, oxidative reactions are used to remove a single carbon from G6PD, producing the pentose derivative ribulose 5-phosphate. Isomerase and epimerase

FIGURE 6-1 The relationship between catabolism and anabolism. Catabolism encompasses processes that harvest energy released during disassembly of compounds, using it to synthesize adenosine triphosphate (ATP); it also provides precursor metabolites used in biosynthesis. Anabolism, or biosynthesis, includes processes that utilize ATP and precursor metabolites to synthesize and assemble subunits of macromolecules that make up the cell. (Reproduced with permission from Nester EW, Anderson DG, Roberts CE, et al: *Microbiology: A Human Perspective*, 6th ed. McGraw-Hill, 2009, p. 127. © McGraw-Hill Education.)

reactions interconvert the most common biochemical forms of the pentoses: ribulose 5-phosphate, ribose 5-phosphate, and xylulose 5-phosphate. Transketolases transfer a two-carbon fragment from a donor to an acceptor molecule. These reactions allow pentoses to form or to be formed from carbohydrates of varying chain lengths. As shown in Figure 6-6, two pentose 5-phosphates ($n = 5$) are interconvertible with triose 3-phosphate ($n = 3$) and heptose 7-phosphate ($n = 7$); pentose 5-phosphate ($n = 5$) and tetrose 4-phosphate ($n = 4$) are interconvertible with triose 3-phosphate ($n = 3$) and hexose 6-phosphate ($n = 6$).

The six-carbon hexose chain of fructose 6-phosphate can be converted to two three-carbon triose derivatives by the consecutive action of a kinase and an aldolase on fructose 6-phosphate. Alternatively, aldolases, acting in conjunction with phosphatases, can be used to lengthen carbohydrate molecules: Triose phosphates give rise to fructose 6-phosphate; a triose phosphate and tetrose 4-phosphate form heptose

7-phosphate. The final form of carbohydrate chain length interconversion is the transaldolase reaction, which interconverts heptose 7-phosphate and triose 3-phosphate with tetrose 4-phosphate and hexose 6-phosphate.

The coordination of different carbohydrate rearrangement reactions to achieve an overall metabolic goal is illustrated by the hexose monophosphate shunt (Figure 6-7). This metabolic cycle is used by cyanobacteria for the reduction of NAD^+ (nicotinamide adenine dinucleotide) to NADH (reduced nicotinamide adenine dinucleotide), which serves as a reductant for respiration in the dark. Many organisms use the hexose monophosphate shunt to reduce NADP^+ (nicotinamide adenine dinucleotide phosphate) to NADPH (reduced nicotinamide adenine dinucleotide phosphate), which is used for biosynthetic reduction reactions. The first steps in the hexose monophosphate shunt are the oxidative reactions that shorten six hexose 6-phosphates (abbreviated as six C_6 in Figure 6-7) to six pentose 5-phosphates (abbreviated as six C_5). Carbohydrate rearrangement reactions convert the six C_5 molecules to five C_6 molecules so that the oxidative cycle may continue.

Clearly, all reactions for interconversion of carbohydrate chain lengths are not called into play at the same time. Selection of specific sets of enzymes, essentially the determination of the metabolic pathway taken, is dictated by the source of carbon and the biosynthetic demands of the cell. For example, a cell given triose phosphate as a source of carbohydrate will use the aldolase-phosphatase combination to form fructose 6-phosphate; the kinase that acts on fructose 6-phosphate in its conversion to triose phosphate would not be expected to be active under these circumstances. If demands for pentose 5-phosphate are high, as in the case of photosynthetic carbon dioxide assimilation, transketolases that can give rise to pentose 5-phosphates are very active.

In sum, G6PD can be regarded as a focal metabolite because it serves both as a direct precursor for metabolic building blocks and as a source of carbohydrates of varying length that are used for biosynthetic purposes. G6PD itself may be generated from other phosphorylated carbohydrates by selection of pathways from a set of reactions for chain length interconversion. The reactions chosen are determined by the genetic potential of the cell, the primary carbon source, and the biosynthetic demands of the organism. Metabolic regulation is required to ensure that reactions that meet the requirements of the organism are selected.

Formation and Utilization of Phosphoenolpyruvate

Triose phosphates, formed by the interconversion of carbohydrate phosphoesters, are converted to phosphoenolpyruvate by the series of reactions shown in Figure 6-8. Oxidation of glyceraldehyde 3-phosphate by NAD^+ is accompanied by the formation of the acid anhydride bond on the one carbon of 1,3-diphosphoglycerate. This phosphate anhydride is transferred in a **substrate phosphorylation** to adenosine

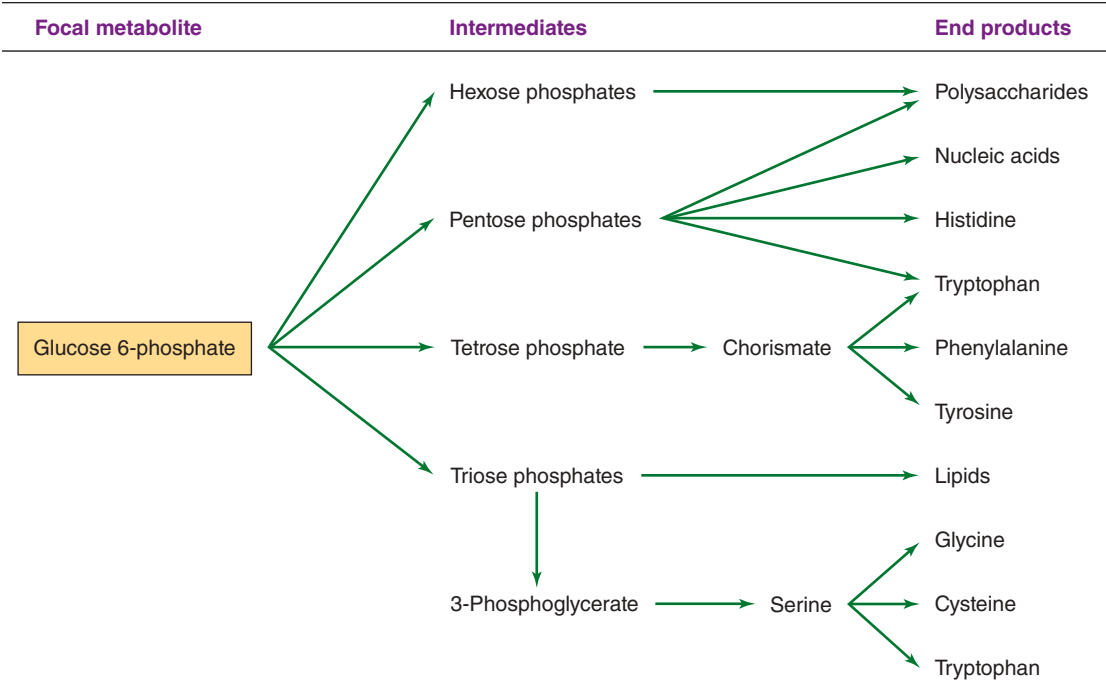

FIGURE 6-2 Biosynthetic end products formed from glucose 6-phosphate. Carbohydrate phosphate esters of varying chain length serve as intermediates in the biosynthetic pathways.

diphosphate (ADP), yielding an energy-rich bond in ATP. Another energy-rich phosphate bond is formed by dehydration of 2-phosphoglycerate to phosphoenolpyruvate; via another substrate phosphorylation, phosphoenolpyruvate can donate the energy-rich bond to ADP, yielding ATP and pyruvate. Thus, two energy-rich bonds in ATP can be obtained by the metabolic conversion of triose phosphate to pyruvate. This is an oxidative process, and in the absence of an exogenous electron acceptor, the NADH generated by oxidation of glyceraldehyde 3-phosphate must be oxidized to

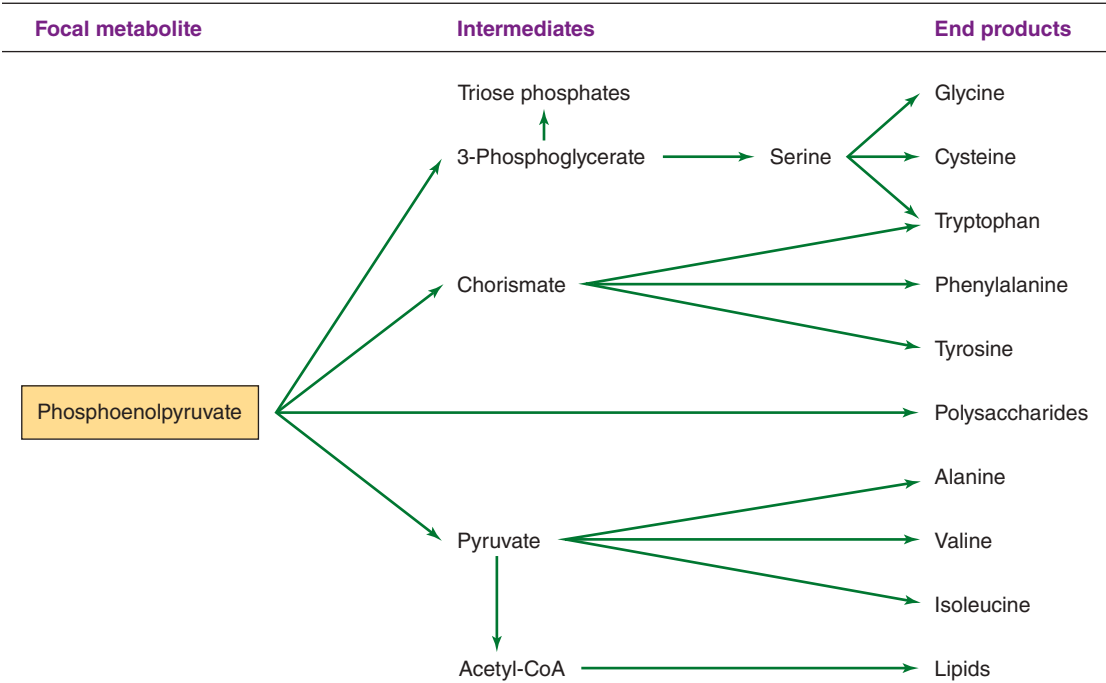

FIGURE 6-3 Biosynthetic end products formed from phosphoenolpyruvate.

FIGURE 6-6 Biochemical mechanisms for changing the length of carbohydrate molecules. The general empirical formula for carbohydrate phosphate esters, (C_nH_{2n}O_n)-N-phosphate, is abbreviated (C_n) to emphasize changes in chain length.

precursors from acetate is achieved by coupling reactions of the tricarboxylic acid cycle with two additional reactions catalyzed by isocitrate lyase and malate synthase. As shown in Figure 6-12, these reactions allow the *net* oxidative

conversion of two acetyl moieties from acetyl-CoA to one molecule of succinate. Succinate may be used for biosynthetic purposes after its conversion to oxaloacetate, α-ketoglutarate, phosphoenolpyruvate, or G6PD.

FIGURE 6-7 The hexose monophosphate shunt. Oxidative reactions (see Figure 6-6) reduce NAD⁺ (nicotinamide adenine dinucleotide phosphate) and produce CO₂, resulting in the shortening of the six hexose phosphates (abbreviated C₆) to six pentose phosphates (abbreviated C₅). Carbohydrate rearrangements (see Figure 6-6) convert the pentose phosphates to hexose phosphates so that the oxidative cycle may continue.

**Growth With Carbon Dioxide:
The Calvin Cycle**

Similar to plants and algae, a number of microbial species can use carbon dioxide as a sole source of carbon. In almost all of these organisms, the primary route of carbon assimilation is via the Calvin cycle, in which carbon dioxide and ribulose diphosphate combine to form two molecules of 3-phosphoglycerate (Figure 6-13A). 3-Phosphoglycerate is phosphorylated to 1,3-diphosphoglycerate, and this compound

is reduced to the triose derivative, glyceraldehyde 3-phosphate. Carbohydrate rearrangement reactions (see Figure 6-6) allow triose phosphate to be converted to the pentose derivative ribulose 5-phosphate, which is phosphorylated to regenerate the acceptor molecule, ribulose 1,5-diphosphate (Figure 6-13B). Additional reduced carbon, formed by the reductive assimilation of carbon dioxide, is converted to focal metabolites for biosynthetic pathways.

Cells that can use carbon dioxide as a sole source of carbon are termed **autotrophic**, and the demands for this pattern

FIGURE 6-8 Formation of phosphoenolpyruvate and pyruvate from triose phosphate. The figure draws attention to two sites of substrate phosphorylation and to the oxidative step that results in the reduction of NAD⁺ (nicotinamide adenine dinucleotide phosphate) to NADH (nicotinamide adenine dinucleotide hydride). Repetition of this energy-yielding pathway demands a mechanism for oxidizing NADH to NAD⁺. Fermentative organisms achieve this goal by using pyruvate or metabolites derived from pyruvate as oxidants.

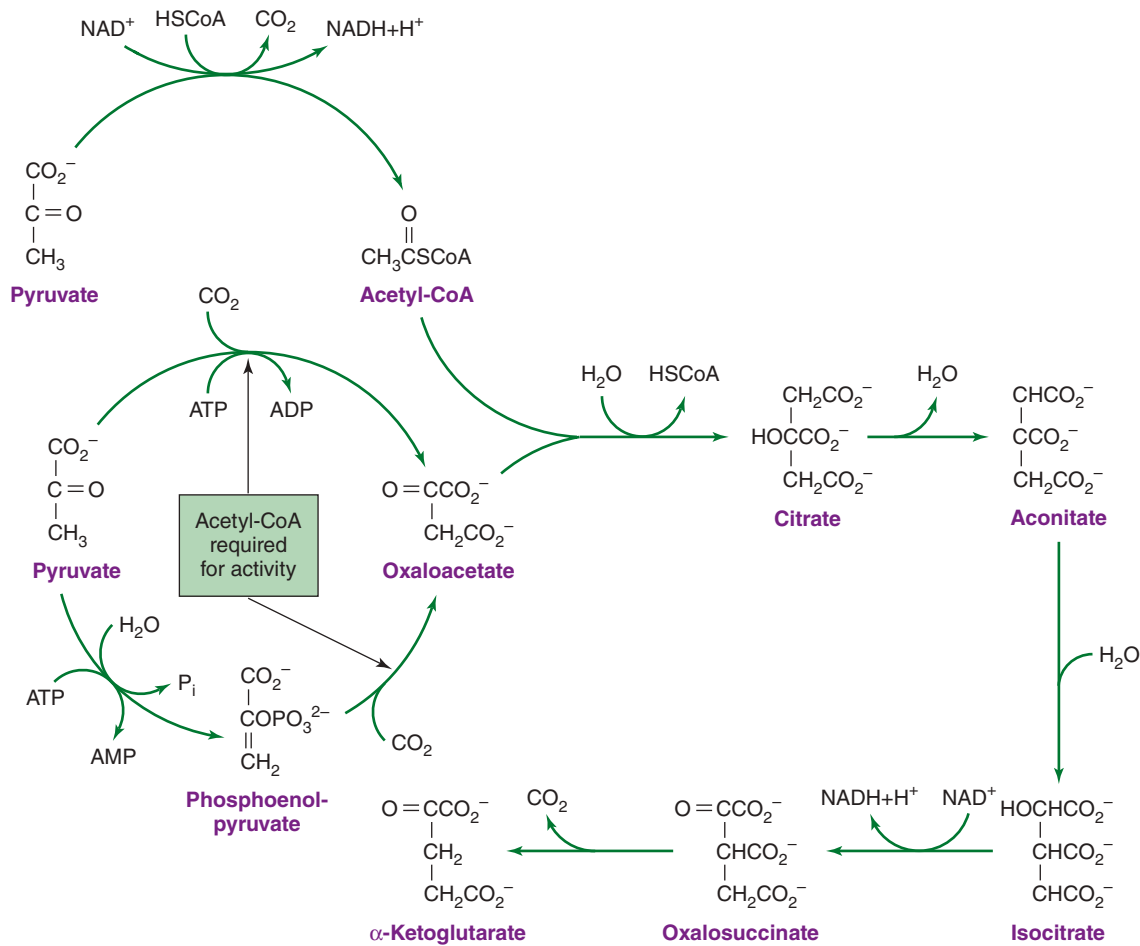

FIGURE 6-9 Conversion of pyruvate to α -ketoglutarate. Pyruvate is converted to α -ketoglutarate by a branched biosynthetic pathway. In one branch, pyruvate is oxidized to acetyl-CoA; in the other, pyruvate is carboxylated to oxaloacetate.

FIGURE 6-10 Biochemical sources of acetyl-CoA. AMP, adenosine monophosphate; ATP, adenosine triphosphate.

FIGURE 6-11 The tricarboxylic acid cycle. There are four oxidative steps, three giving rise to NADH (nicotinamide adenine dinucleotide hydride) and one giving rise to a reduced flavoprotein, Enz(FADH₂). The cycle can continue only if electron acceptors are available to oxidize the NADH and reduced flavoprotein. GDP, guanosine diphosphate; GTP, guanosine triphosphate.

of carbon assimilation can be summarized briefly as follows: In addition to the primary assimilatory reaction giving rise to 3-phosphoglycerate, there must be a mechanism for regenerating the acceptor molecule, ribulose 1,5-diphosphate. This process demands the energy-dependent reduction of 3-phosphoglycerate to the level of carbohydrate. Thus, autotrophy requires carbon dioxide, ATP, NADPH, and a specific set of enzymes.

Depolymerases

Many potential growth substrates occur as building blocks within the structure of biologic polymers. These large molecules are not readily transported across the cell membrane and often are affixed to even larger cellular structures. Many microorganisms elaborate extracellular depolymerases that hydrolyze proteins (ie, proteases), nucleic acids (ie, nucleases),

polysaccharides (eg, amylase), and lipids (eg, lipases). The pattern of depolymerase activities can be useful in the identification of microorganisms.

Oxygenases

Many compounds in the environment are relatively resistant to enzymatic modification, and utilization of these compounds as growth substrates demands a special class of enzymes, oxygenases. These enzymes directly use the potent oxidant molecular oxygen as a substrate in reactions that convert a relatively intractable compound to a form in which it can be assimilated by thermodynamically favored reactions. The action of oxygenases is illustrated in Figure 6-14, which shows the role of two different oxygenases in the utilization of benzoate.

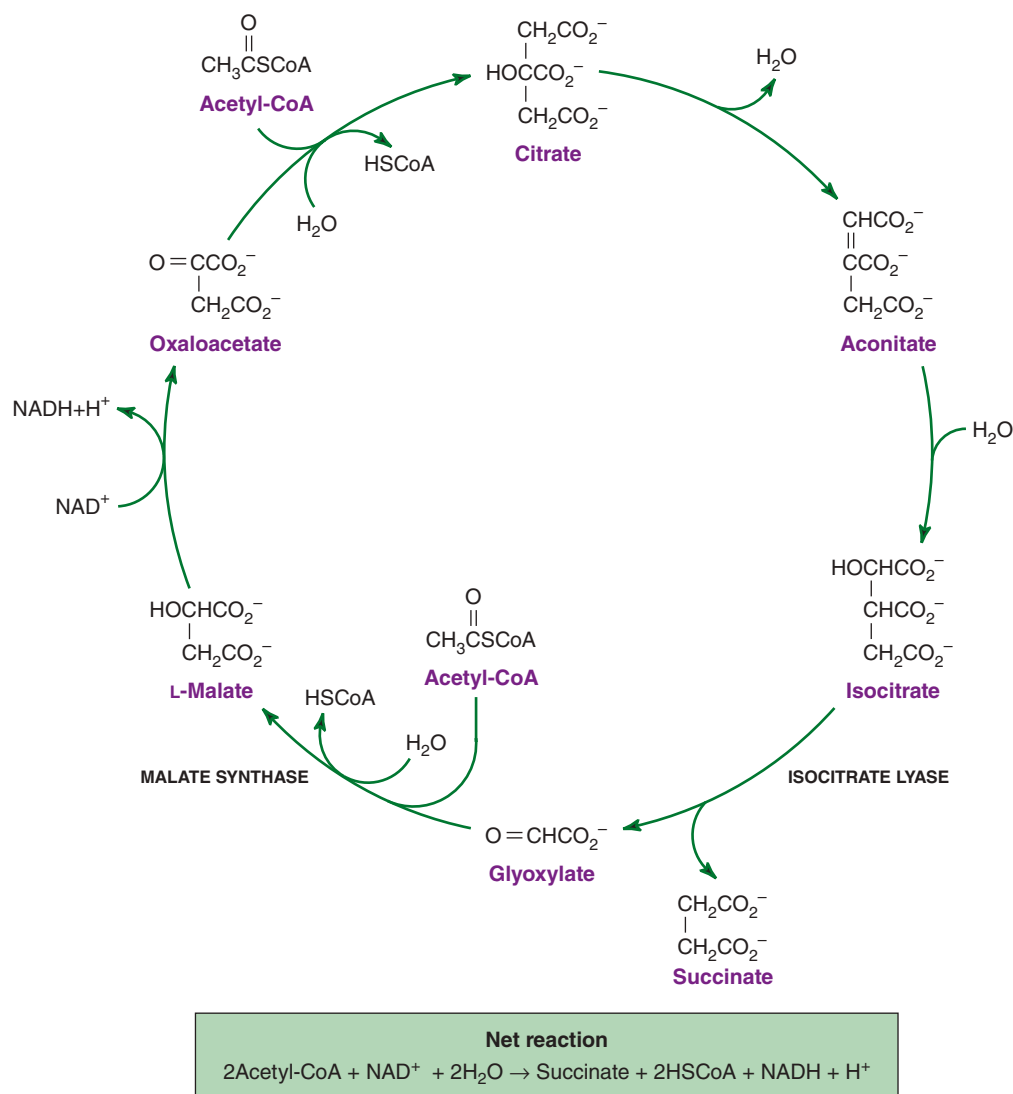

FIGURE 6-12 The glyoxylate cycle. Note that the reactions that convert malate to isocitrate are shared with the tricarboxylic acid cycle (see Figure 6-11). Metabolic divergence at the level of isocitrate and the action of two enzymes, isocitrate lyase and malate synthase, modify the tricarboxylic acid cycle so that it reductively converts two molecules of acetyl-CoA to succinate.

Reductive Pathways

Some microorganisms live in extremely reducing environments that favor chemical reactions that would not occur in organisms using oxygen as an electron acceptor. In these organisms, powerful reductants can be used to drive reactions that allow the assimilation of relatively intractable compounds. An example is the reductive assimilation of benzoate, a process in which the aromatic ring is reduced and opened to form the dicarboxylic acid pimelate. Further metabolic reactions convert pimelate to focal metabolites.

Nitrogen Assimilation

The reductive assimilation of molecular nitrogen, also referred to as **nitrogen fixation**, is required for continuation of life on our planet. Nitrogen fixation is accomplished by a

variety of bacteria and cyanobacteria using a multicomponent **nitrogenase enzyme complex**. Despite the variety of organisms capable of fixing nitrogen, the nitrogenase complex is similar in most of them (Figure 6-15). Nitrogenase is a complex of two enzymes—one enzyme (dinitrogenase reductase) contains iron and the other (dinitrogenase) contains iron and molybdenum. Together, these enzymes catalyze the following reaction:

Because of the high activation energy of breaking the very strong triple bond that joins two nitrogen atoms, this reductive assimilation of nitrogen demands a substantial amount of metabolic energy. Somewhere between 20 and 24 molecules of ATP are hydrolyzed as a single N₂ molecule is reduced to 2 molecules of NH₃.

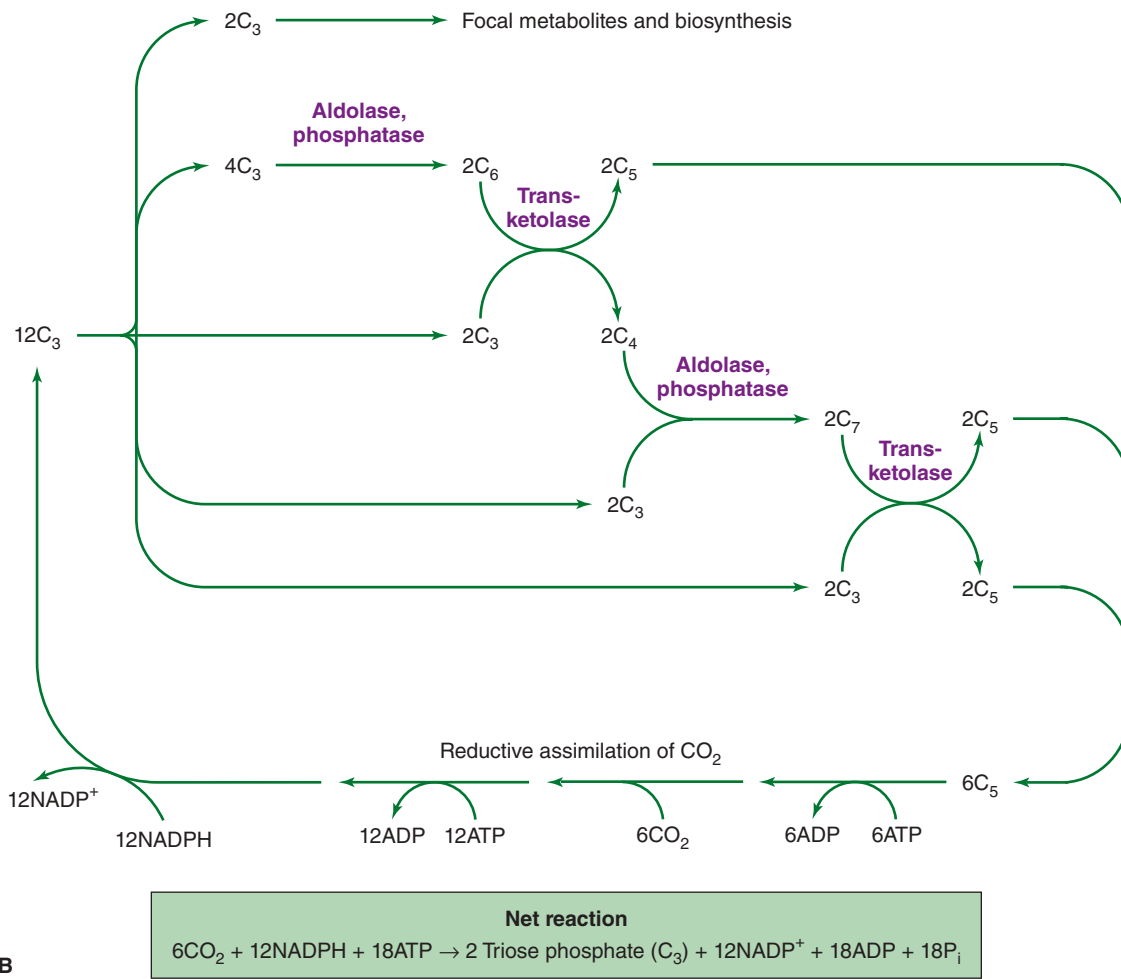

FIGURE 6-13 The Calvin cycle. **A:** Reductive assimilation of CO₂. Adenosine triphosphate (ATP) and NADPH (nicotinamide adenine dinucleotide phosphate) are used to reductively convert pentose 5-phosphate (C₅) to two molecules of triose phosphate (C₃). **B:** The Calvin cycle is completed by carbohydrate rearrangement reactions (Figure 6-6) that allow the net synthesis of carbohydrate and the regeneration of pentose phosphate so that the cycle may continue. ADP, adenosine diphosphate.

Additional physiologic demands are placed by the fact that nitrogenase is readily inactivated by oxygen. Aerobic organisms that use nitrogenase have developed elaborate mechanisms to protect the enzyme against inactivation. Some form specialized cells in which nitrogen fixation takes place, and others have developed elaborate electron transport chains to protect nitrogenase against inactivation by oxygen.

The most significant of these bacteria in agriculture are the Rhizobiaceae, organisms that fix nitrogen symbiotically in the root nodules of leguminous plants.

The capacity to use ammonia as a nitrogen source is widely distributed among organisms. The primary portal of entry of nitrogen into carbon metabolism is glutamate, which is formed by reductive amination of α-ketoglutarate.

FIGURE 6-14 The role of oxygenases in aerobic utilization of benzoate as a carbon source. Molecular oxygen participates directly in the reactions that disrupt the aromaticity of benzoate and catechol.

As shown in Figure 6-16, there are two biochemical mechanisms by which this can be achieved. One, the single-step reduction catalyzed by glutamate dehydrogenase (Figure 6-16A) is effective in environments in which there is an ample supply of ammonia. The other, a two-step process in which glutamine is an intermediate (Figure 6-16B), is used in environments in which ammonia is in short supply. The latter mechanism allows cells to invest the free energy formed by hydrolysis of a pyrophosphate bond in ATP into the assimilation of ammonia from the environment.

The amide nitrogen of glutamine, an intermediate in the two-step assimilation of ammonia into glutamate (see Figure 6-16B), is also transferred directly into organic nitrogen

appearing in the structures of purines, pyrimidines, arginine, tryptophan, and glucosamine. The activity and synthesis of glutamine synthase are regulated by the ammonia supply and by the availability of metabolites containing nitrogen derived directly from the amide nitrogen of glutamine.

Most of the organic nitrogen in cells is derived from the α -amino group of glutamate, and the primary mechanism by which the nitrogen is transferred is **transamination**. The usual acceptor in these reactions is an α -keto acid, which is transformed to the corresponding α -amino acid. α -Ketoglutarate, the other product of the transamination reaction, may be converted to glutamate by reductive amination (see Figure 6-16).

FIGURE 6-15 Reduction of N_2 to two molecules of NH_3 . In addition to reductant, the nitrogenase reaction requires a substantial amount of metabolic energy. The number of adenosine triphosphate (ATP) molecules required for reduction of a single nitrogen molecule to ammonia is uncertain; the value appears to lie between 20 and 24. The overall reaction requires $8NADH + H^+$ (reduced nicotinamide adenine dinucleotide). Six of these are used to reduce N_2 to $2NH_3$, and two are used to form H_2 . The uptake hydrogenase returns H_2 to the system, thus conserving energy. (Redrawn and reproduced, with permission, from Moat AG, Foster JW, Spector MP: *Microbial Physiology*, 4th ed. FIGURE 6-16 Mechanisms for the assimilation of NH_3 . **A:** When the NH_3 concentration is high, cells are able to assimilate the compound via the glutamate dehydrogenase reaction. **B:** When, as most often is the case, the NH_3 concentration is low, cells couple the glutamine synthase and glutamate synthase reactions to invest the energy produced by hydrolysis of a pyrophosphate bond into ammonia assimilation.

BIOSYNTHETIC PATHWAYS

Tracing the Structures of Biosynthetic Precursors: Glutamate and Aspartate

In many cases, the carbon skeleton of a metabolic end product may be traced to its biosynthetic origins. Glutamine, an obvious example, clearly is derived from glutamate (Figure 6-17). The glutamate skeleton in the structures of arginine and proline (see Figure 6-17) is less obvious but readily discernible. Similarly, the carbon skeleton of aspartate, directly derived from the focal metabolite oxaloacetate, is evident in the structures of asparagine, threonine, methionine, and pyrimidines (Figure 6-18). In some cases, different carbon skeletons combine in a biosynthetic pathway. For example, aspartate semialdehyde and pyruvate combine to form the metabolic precursors of lysine, diaminopimelic acid, and dipicolinic acid (Figure 6-19). The latter two compounds are found only

in prokaryotes. Diaminopimelic acid is a component of peptidoglycan in the cell wall, and dipicolinic acid represents a major component of endospores.

Synthesis of Cell Wall Peptidoglycan

The structure of peptidoglycan is shown in Figure 2-17; the pathway by which it is synthesized is shown in simplified form in Figure 6-20A. The synthesis of peptidoglycan begins with the stepwise synthesis in the cytoplasm of UDP-*N*-acetylmuramic acid-pentapeptide. *N*-Acetylglucosamine is first attached to uridine diphosphate (UDP) and then converted to UDP-*N*-acetylmuramic acid by condensation with phosphoenolpyruvate and reduction. The amino acids of the pentapeptide are sequentially added. Ribosomes and tRNA are not involved in forming the peptide bonds. Instead, each addition is catalyzed by a different enzyme and involves the split of ATP to ADP + P_i .

FIGURE 6-17 Amino acids formed from glutamate.

FIGURE 6-18 Biosynthetic end products formed from aspartate.

The UDP-*N*-acetylmuramic acid-pentapeptide is attached to bactoprenol (a lipid of the cell membrane) and receives a molecule of *N*-acetylglucosamine from UDP. Some bacteria (eg, *Staphylococcus aureus*) form a pentaglycine derivative in a series of reactions using glycyl-tRNA as the donor; the completed disaccharide is polymerized to an oligomeric intermediate before being transferred to the growing end of a glycopeptide polymer in the cell wall.

Final cross-linking (Figure 6-20B) is accomplished by a transpeptidation reaction in which the free amino group of a pentaglycine residue displaces the terminal D-alanine residue of a neighboring pentapeptide. Transpeptidation is catalyzed by one of a set of enzymes called penicillin-binding proteins (PBPs). PBPs bind penicillin and other β -lactam antibiotics covalently, partly because of a structural similarity between these antibiotics and the pentapeptide precursor. Some PBPs have transpeptidase or carboxypeptidase activities, their relative rates perhaps controlling the degree of cross-linking in peptidoglycan (a factor important in cell septation).

The peptidoglycan biosynthetic pathway is of particular importance in medicine because it provides a basis for the selective antibacterial action of several chemotherapeutic agents. Unlike their host cells, bacteria are not isotonic with the body fluids. Their contents are under high osmotic pressure, and their viability depends on the integrity of

the peptidoglycan lattice in the cell wall being maintained throughout the growth cycle. Any compound that inhibits any step in the biosynthesis of peptidoglycan causes the wall of the growing bacterial cell to be weakened and the cell to lyse. The sites of action of several antibiotics are shown in Figure 6-20A and B.

Synthesis of Cell Envelope Lipopolysaccharide

The general structure of the antigenic lipopolysaccharide of Gram-negative cell envelopes is shown in Figure 2-21. The biosynthesis of the repeating end-group, which gives the cell envelope its antigenic specificity, is shown in Figure 6-21. Note the resemblance to peptidoglycan synthesis: In both cases, a series of subunits is assembled on a lipid carrier in the membrane and then transferred to open ends of the growing polymer.

Synthesis of Extracellular Capsular Polymers

The capsular polymers, a few examples of which are listed in Table 2-2, are enzymatically synthesized from activated subunits. No membrane-bound lipid carriers have been implicated in this process. The presence of a capsule is often environmentally determined: Dextrans and levans, for example, can only be synthesized using the disaccharide sucrose (fructose-glucose) as the source of the appropriate subunit, and their synthesis thus depends on the presence of sucrose in the growth environment.

Synthesis of Reserve Food Granules

When nutrients are present in excess of the requirements for growth, bacteria convert certain of them to intracellular reserve food granules. The principal ones are starch, glycogen, poly- β -hydroxybutyrate, and volutin, which consists mainly of inorganic polyphosphate (see Chapter 2). The type of granule formed is species specific. The granules are degraded when exogenous nutrients are depleted.

PATTERNS OF MICROBIAL ENERGY-YIELDING METABOLISM

As described in Chapter 5, there are two major metabolic mechanisms for generating the energy-rich acid pyrophosphate bonds in ATP: **substrate phosphorylation** (the direct transfer of a phosphate anhydride bond from an organic donor to ADP) and phosphorylation of ADP by P_i . The latter reaction is energetically unfavorable and must be driven by a transmembrane electrochemical gradient, the **proton motive force**. In respiration, the electrochemical gradient is created from externally supplied reductant and oxidant. Energy released by transfer of electrons from the reductant to the oxidant through membrane-bound carriers is coupled to the formation of the transmembrane electrochemical gradient. In photosynthesis, light energy generates membrane-associated reductants and oxidants; the proton motive force is generated as these electron carriers return to the ground state. These processes are discussed below.

Pathways of Fermentation

A. Strategies for Substrate Phosphorylation

In the absence of respiration or photosynthesis, cells are entirely dependent on substrate phosphorylation for their energy: Generation of ATP must be coupled to chemical rearrangement of organic compounds. Many compounds can serve as fermentable growth substrates, and many pathways for their fermentation have evolved. These pathways have the following three general stages: (1) Conversion of the fermentable compound to the phosphate donor for substrate phosphorylation (this stage often contains metabolic reactions in which NAD^+ is reduced to NADH); (2) phosphorylation of ADP by the energy-rich phosphate donor; and (3) metabolic steps that bring the products of the fermentation into chemical balance with the starting materials. The most frequent requirement in the last stage is a mechanism for oxidation of NADH, generated in the first stage of fermentation, to NAD^+ so that the fermentation may proceed. In the following sections, examples of each of the three stages of fermentation are considered.

B. Fermentation of Glucose

The diversity of fermentative pathways is illustrated by consideration of some of the mechanisms used by microorganisms to achieve substrate phosphorylation at the expense of glucose. In principle, the phosphorylation of ADP to ATP can be coupled to either of two chemically balanced transformations:

The biochemical mechanisms by which these transformations are achieved vary considerably.

In general, the fermentation of glucose is initiated by its phosphorylation to G6PD. There are two mechanisms by which this can be achieved: (1) Extracellular glucose may be transported across the cytoplasmic membrane into the cell and then phosphorylated by ATP to yield G6PD and ADP and (2) in many microorganisms, extracellular glucose is phosphorylated as it is being transported across the cytoplasmic membrane by an enzyme system in the cytoplasmic membrane that phosphorylates extracellular glucose at the expense of phosphoenolpyruvate, producing intracellular G6PD and pyruvate. The latter process is an example of **vectorial metabolism**, a set of biochemical reactions in which both the structure and the location of a substrate are altered (see Chapter 2). It should be noted that the choice of ATP or phosphoenolpyruvate as a phosphorylating agent does not alter the ATP yield of fermentation because phosphoenolpyruvate is used as a source of ATP in the later stages of fermentation (see Figure 6-8).

C. The Embden-Meyerhof Pathway

This pathway (Figure 6-22), a commonly encountered mechanism for the fermentation of glucose, uses a kinase and an aldolase (see Figure 6-6) to transform the hexose (C_6) phosphate to two molecules of triose (C_3) phosphate. Four substrate phosphorylation reactions accompany the conversion of the triose phosphate to two molecules of pyruvate. Thus, taking into account the two ATP pyrophosphate bonds required to form triose phosphate from glucose, the Embden-Meyerhof pathway produces a net yield of two ATP pyrophosphate bonds. Formation of pyruvate from triose phosphate is an oxidative process, and the NADH formed in the first metabolic step (see Figure 6-22) must be oxidized to NAD^+ for the fermentation to proceed; two of the simpler mechanisms for achieving this goal are illustrated in Figure 6-23. Direct reduction of pyruvate by NADH produces lactate as the end product of fermentation and thus results in acidification of the medium. Alternatively, pyruvate may be decarboxylated to acetaldehyde, which is then used to oxidize NADH, resulting in the formation of the neutral product ethanol. The pathway taken is determined by the evolutionary history of the organism and, in some microorganisms, by the growth conditions.

D. The Entner-Doudoroff and Heterolactate Fermentations

Alternative pathways for glucose fermentation include some specialized enzyme reactions, and these are shown in Figure 6-24. The Entner-Doudoroff pathway diverges from other pathways of carbohydrate metabolism by a dehydration of 6-phosphogluconate followed by an aldolase reaction that produces pyruvate and triose phosphate (Figure 6-24A). The heterolactate fermentation and some other fermentative pathways depend upon a phosphoketolase reaction (Figure 6-24B) that phosphorytically cleaves a ketosephosphate to produce acetyl phosphate and triose phosphate. The acid anhydride acetyl phosphate may be used to synthesize ATP or the further metabolism of the triose phosphate may allow the oxidation of two NADH molecules to NAD^+ as it is reduced to ethanol.

The overall outlines of the respective Entner-Doudoroff and heterolactate pathways are shown in Figures 6-25 and 6-26. The pathways yield only a single molecule of triose phosphate from glucose, and the energy yield is correspondingly low: Unlike the Embden-Meyerhof pathway, the Entner-Doudoroff and heterolactate pathways yield only a single net substrate phosphorylation of ADP per molecule of glucose fermented. Why have the alternative pathways for glucose fermentation been selected in the natural environment? In answering this question, two facts should be kept in mind. First, in direct growth competition between two microbial species, the rate of substrate utilization can be more important than the amount of growth. Second, glucose is but one of many carbohydrates encountered by microorganisms in their natural environment. Pentoses, for example, can be fermented quite efficiently by the heterolactate pathway.

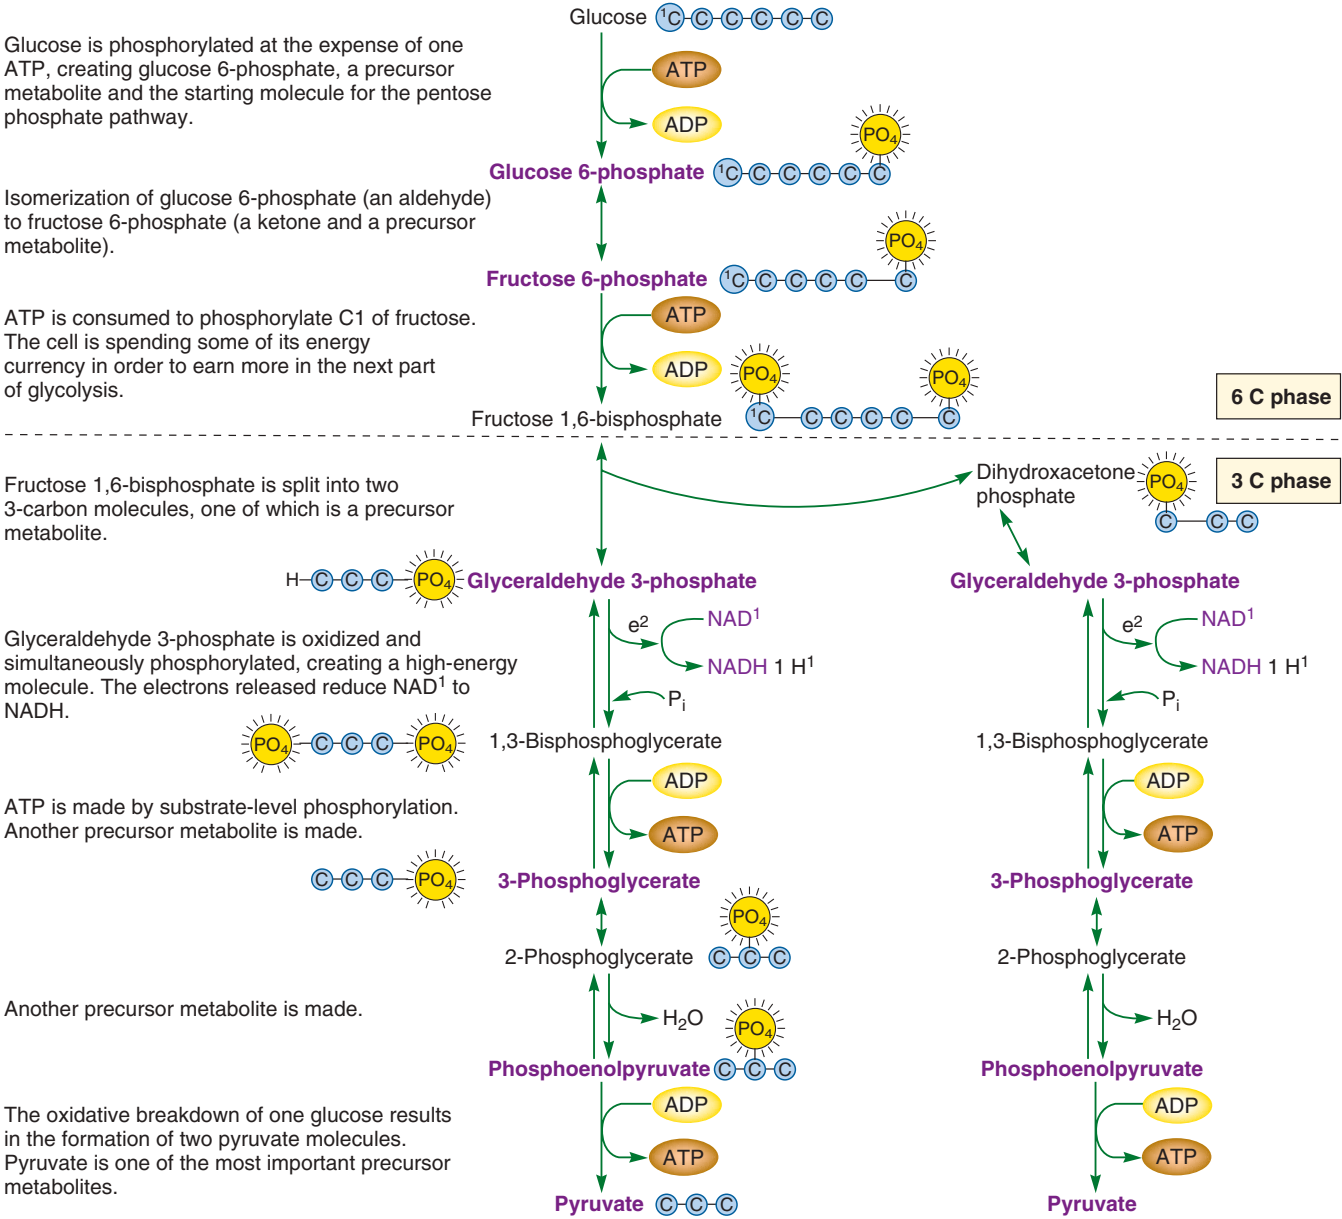

FIGURE 6-22 The Embden-Meyerhof pathway. This is one of three glycolytic pathways used to catabolize glucose to pyruvate, and it can function during aerobic respiration, anaerobic respiration, and fermentation. When used during a respiratory process, the electrons accepted by NAD^+ (nicotinamide adenine dinucleotide phosphate) are transferred to an electron transport chain and are ultimately accepted by an exogenous electron acceptor. When used during fermentation, the electrons accepted by NAD^+ are donated to an endogenous electron acceptor (eg, pyruvate). The Embden-Meyerhof pathway is also an important amphibolic pathway because it generates several precursor metabolites (shown in blue). ADP, adenosine diphosphate; ATP, adenosine triphosphate. (Reproduced with permission from Willey JM, Sherwood LM, Woolverton CJ: *Prescott, Harley, & Klein's Microbiology*, 7th ed., McGraw-Hill, 2008, p. 195. © McGraw-Hill Education.)

E. Additional Variations in Carbohydrate Fermentations

Pathways for carbohydrate fermentation can accommodate many more substrates than described here, and the end products may be far more diverse than suggested thus far. For example, there are numerous mechanisms for oxidation of NADH at the expense of pyruvate. One such pathway is the reductive formation of succinate. Many clinically significant bacteria form pyruvate from glucose via the

Embden-Meyerhof pathway, and they may be distinguished on the basis of reduction products formed from pyruvate, reflecting the enzymatic constitution of different species. The major products of fermentation, listed in Table 6-1, form the basis for many diagnostic tests used in the clinical laboratory.

F. Fermentation of Other Substrates

Carbohydrates are by no means the only fermentable substrates. Metabolism of amino acids, purines, and pyrimidines

FIGURE 6-23 Two biochemical mechanisms by which pyruvate can oxidize NADH (nicotinamide adenine dinucleotide hybrid). **Left:** Direct formation of lactate, which results in net production of lactic acid from glucose. **Right:** Formation of the neutral products carbon dioxide and ethanol.

may allow substrate phosphorylations to occur. For example, arginine may serve as an energy source by giving rise to carbamoyl phosphate, which can be used to phosphorylate ADP to ATP. Some organisms ferment pairs of amino acids, using one as an electron donor and the other as an electron acceptor.

Patterns of Respiration

Respiration requires a closed membrane. In bacteria, the membrane is the cell membrane. Electrons are passed from a chemical reductant to a chemical oxidant through a specific set of electron carriers within the membrane, and as a result, the proton motive force is established (Figure 6-27); return of protons across the membrane is coupled to the synthesis of ATP. As suggested in Figure 6-27, the biologic reductant for respiration frequently is NADH, and the oxidant often is oxygen.

Tremendous microbial diversity is exhibited in the sources of reductant used to generate NADH, and many microorganisms can use electron acceptors other than oxygen. Organic growth substrates are converted to focal metabolites that may reduce NAD^+ to NADH either by the hexose monophosphate shunt (see Figure 6-7) or by the tricarboxylic acid cycle (see Figure 6-11). Additional reductant may be generated during the breakdown of some growth substrates, such as fatty acids (see Figure 6-10).

Some bacteria, called **chemolithotrophs**, are able to use inorganic reductants for respiration. These energy sources

FIGURE 6-24 Reactions associated with specific pathways of carbohydrate fermentation. **A:** Dehydratase and aldolase reactions used in the Entner-Doudoroff pathway. **B:** The phosphoketolase reaction. This reaction, found in several pathways for fermentation of carbohydrates, generates the mixed acid anhydride acetyl phosphate, which can be used for substrate phosphorylation of adenosine diphosphate (ADP).

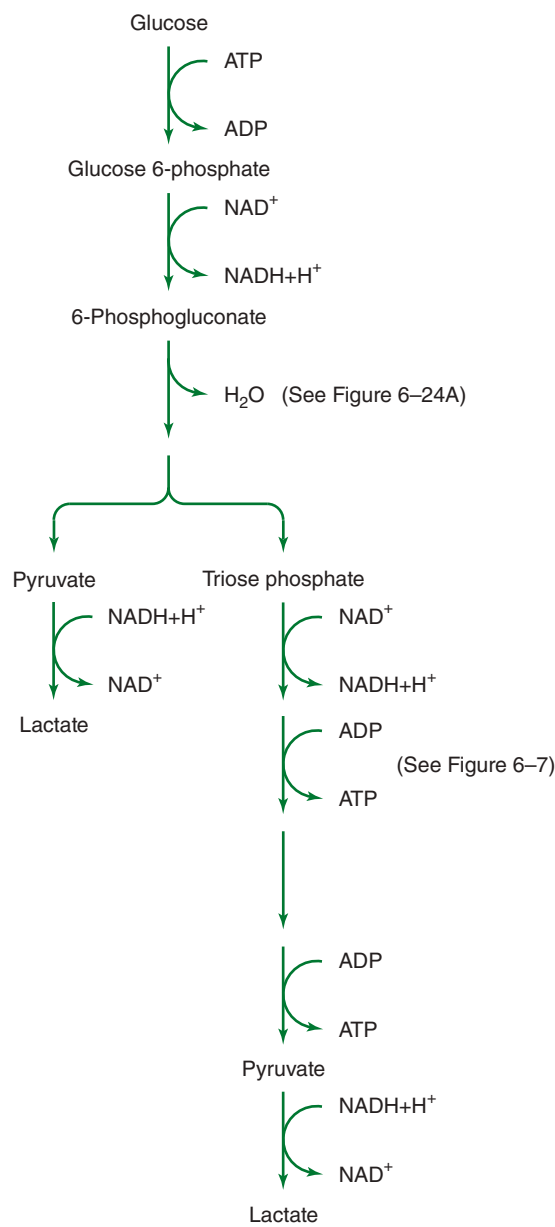

FIGURE 6-25 The Entner-Doudoroff pathway. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

include hydrogen, ferrous iron, and several reduced forms of sulfur and nitrogen. ATP derived from respiration and NADPH generated from the reductants can be used to drive the Calvin cycle (see Figure 6-13).

Compounds and ions other than O₂ may be used as terminal oxidants in respiration. This ability, that is, **anaerobic respiration**, is a widespread microbial trait. Suitable electron acceptors include nitrate, sulfate, and carbon dioxide. Respiratory metabolism dependent on carbon dioxide as an electron acceptor is a property found among representatives of a large microbial group, the **archaeobacteria**. Some archaeobacteria (ie, **methanogens**) are the only organisms capable of producing methane (**methanogenesis**). Methanogenesis is the final

FIGURE 6-26 The heterolactic fermentation of glucose. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

step in the decay of organic matter, and hence in the carbon cycle. Methane formation can be viewed as a form of anaerobic respiration. During the decay process, electron acceptors (eg, oxygen, Fe³⁺, sulfate, and nitrate) become depleted while hydrogen gas (H₂) and carbon dioxide gas (CO₂) accumulate along with other fermentation products (eg, acetate, formate). Methanogens do not use oxygen to respire; oxygen inhibits their growth. In the simplest case, hydrogen gas is the electron donor and carbon dioxide gas is the terminal electron acceptor:

Eight electrons are transferred from four molecules of hydrogen to a molecule of carbon dioxide in order to make

one molecule of methane. In the process, eight protons are transferred across the membrane to create a proton motive force that can be used to generate ATP or drive other energy-utilizing cellular processes. This unique process requires

FIGURE 6-27 The coupling of electron transport in respiration to the generation of adenosine triphosphate (ATP). The indicated movements of protons and electrons are mediated by carriers (flavoprotein, quinone, cytochromes) associated with the membrane. The flow of protons down their electrochemical gradient, via the membrane ATPase, furnishes the energy for the generation of ATP from adenosine diphosphate (ADP) and inorganic phosphate (P_i). See text for explanation.

specialized enzymes with dedicated cofactors not found elsewhere in nature. There are three variations on this general theme: (1) hydrogen can be replaced by an organic compound (eg, formate, ethanol, 2-butanol); (2) carbon dioxide can be replaced by a methyl-group containing compound (eg, methanol, trimethylamine, dimethyl sulfide); and (3) acetate can serve as both a donor and acceptor according to the following equation:

Methanogenesis is an essential process in ruminant animals. In the rumen, anaerobic microorganisms, including methanogens, digest cellulose into compounds nutritious to the animal. Without these microorganisms, animals such as cattle would not be able to consume grasses. The useful products are absorbed by the gut, but methane (a greenhouse gas) is released from the animal by belching. The average cow emits around 250 L of methane per day. As in the rumen, hydrogen is also a fermentation waste product in the human intestine and, if not removed, will accumulate and feedback inhibit (see below) the activities of the fermentative bacteria. To prevent this, methanogens (eg, *Methanobrevibacter smithii*) remove the hydrogen gas and carbon dioxide gas as well as the formate produced fermentatively and make methane. Passing gas (flatulence) helps expel the methane and any unutilized hydrogen gas and carbon dioxide gas, so fermentation can proceed efficiently.

Bacterial Photosynthesis

Photosynthetic organisms use light energy to separate electronic charge to create membrane-associated reductants and oxidants as a result of a photochemical event. Transfer of electrons from the reductant to the oxidant creates a proton motive force. Many bacteria carry out a photosynthetic metabolism that is entirely independent of oxygen. Light is

used as a source of metabolic energy, and carbon for growth is derived either from organic compounds (**photoheterotroph**) or from a combination of an inorganic reductant (eg, thiosulfate) and carbon dioxide (**photolithotroph**). These bacteria possess a single photosystem that, although sufficient to provide energy for the synthesis of ATP and for the generation of essential transmembrane ionic gradients, does not allow the highly exergonic reduction of NADP⁺ at the expense of water. This process, essential for oxygen-evolving photosynthesis, rests upon additive energy derived from the coupling of two different photochemical events driven by two independent photochemical systems. Among prokaryotes, this trait is found solely in the cyanobacteria (blue-green bacteria). Among eukaryotic organisms, the trait is shared by algae and plants in which the essential energy-providing organelle is the chloroplast.

REGULATION OF METABOLIC PATHWAYS

In their normal environment, microbial cells generally regulate their metabolic pathways so that no intermediate is made in excess. Each metabolic reaction is regulated not only with respect to all others in the cell but also with respect to the concentrations of nutrients in the environment. Thus, when a sporadically available carbon source suddenly becomes abundant, the enzymes required for its catabolism increase in both amount and activity; conversely, when a building block (eg, an amino acid) suddenly becomes abundant, the enzymes required for its biosynthesis decrease in both amount and activity.

The regulation of enzyme activity as well as enzyme synthesis provides both **fine control** and **coarse control** of metabolic pathways. For example, the inhibition of enzyme activity by the end product of a pathway constitutes a mechanism of fine control because the flow of carbon through that pathway is instantly and precisely regulated. The inhibition of enzyme synthesis by the same end product, on the other hand, constitutes a mechanism of coarse control. The preexisting enzyme molecules continue to function until they are diluted out by further cell growth, although unnecessary protein synthesis ceases immediately.

The mechanisms by which the cell regulates enzyme activity are discussed in the following section. The regulation of enzyme synthesis is discussed in Chapter 7.

The Regulation of Enzyme Activity

A. Enzymes as Allosteric Proteins

In many cases, the activity of an enzyme catalyzing an early step in a metabolic pathway is inhibited by the end product of that pathway. Such inhibition cannot depend on competition for the enzyme's substrate binding site, however, because the structures of the end product and the early intermediate (substrate) are usually quite different. Instead, inhibition depends

on the fact that regulated enzymes are **allosteric**: Each enzyme possesses not only a catalytic site, which binds substrate, but also one or more other sites that bind small regulatory molecules, or **effectors**. The binding of an effector to its site causes a conformational change in the enzyme such that the affinity of the catalytic site for the substrate is reduced (allosteric inhibition) or increased (allosteric activation).

Allosteric proteins are usually oligomeric. In some cases, the subunits are identical, each subunit possessing both a catalytic site and an effector site; in other cases, the subunits are different, one type possessing only a catalytic site and the other only an effector site.

B. Feedback Inhibition

The general mechanism that has evolved in microorganisms for regulating the flow of carbon through biosynthetic pathways is the most efficient that one can imagine. The end product in each case allosterically inhibits the activity of the first—and only the first—enzyme in the pathway. For example, the first step in the biosynthesis of isoleucine not involving any other pathway is the conversion of L-threonine to α -ketobutyric acid, catalyzed by threonine deaminase. Threonine deaminase is allosterically and specifically inhibited by L-isoleucine and by no other compound (Figure 6-28); the other four enzymes of the pathway are not affected (although their synthesis is repressed).

C. Allosteric Activation

In some cases, it is advantageous to the cell for an end product or an intermediate to activate rather than inhibit a particular enzyme. In the breakdown of glucose by *E. coli*, for example, overproduction of the intermediates G6PD and phosphoenolpyruvate signals the diversion of some glucose to the pathway of glycogen synthesis; this is accomplished by the allosteric activation of the enzyme converting glucose 1-phosphate to ADP-glucose (Figure 6-29).

D. Cooperativity

Many oligomeric enzymes, possessing more than one substrate binding site, show cooperative interactions of substrate molecules. The binding of substrate by one catalytic site increases the affinity of the other sites for additional substrate molecules. The net effect of this interaction is to produce an exponential increase in catalytic activity in response to an arithmetic increase in substrate concentration.

E. Covalent Modification of Enzymes

The regulatory properties of some enzymes are altered by covalent modification of the protein. For example, the response of glutamine synthetase to metabolic effectors is altered by adenylation, the covalent attachment of ADP to a specific tyrosyl side chain within each enzyme subunit. The enzymes controlling adenylation also are controlled by covalent modification. The activity of other enzymes is altered by their phosphorylation.

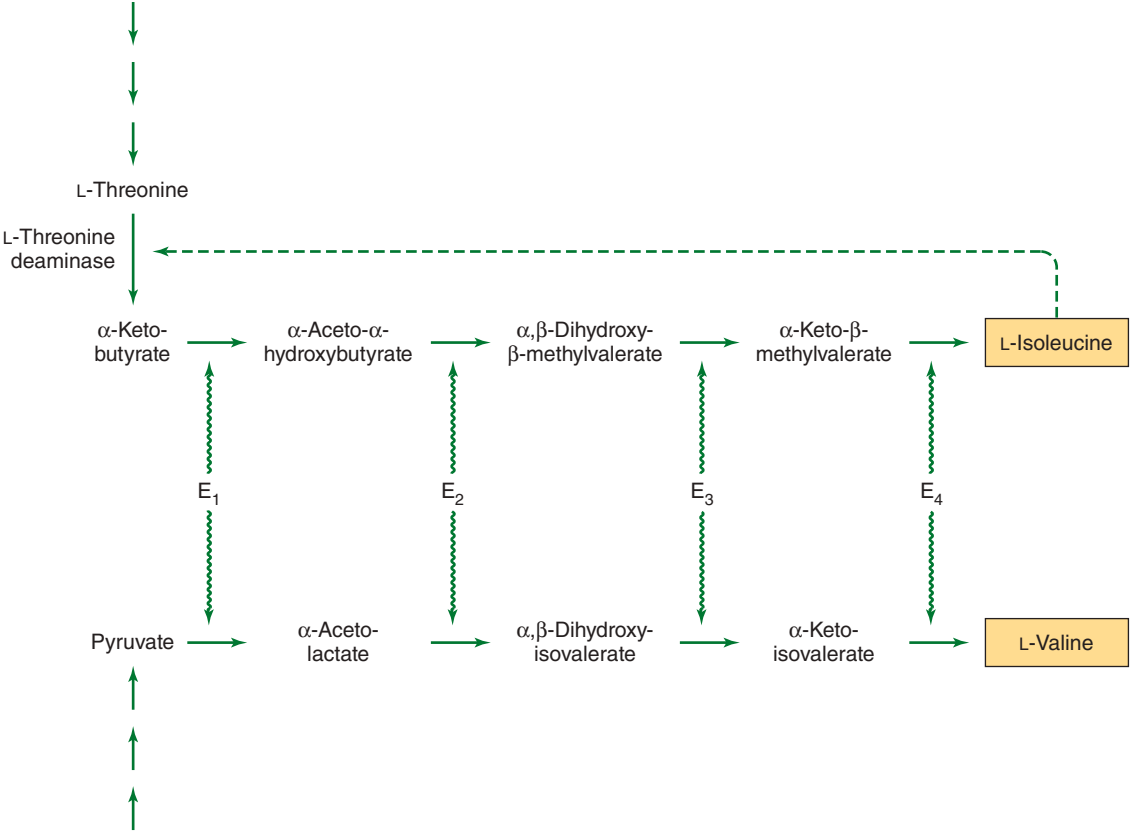

FIGURE 6-28 Feedback inhibition of L-threonine deaminase by L-isoleucine (*dashed line*). The pathways for the biosynthesis of isoleucine and valine are mediated by a common set of four enzymes, as shown.

FIGURE 6-29 Regulation of glucose utilization by a combination of allosteric activation (●) and allosteric inhibition (■). AMP, adenosine monophosphate; ATP, adenosine triphosphate. (Reproduced with permission from Stanier RY, Adelberg EA, Ingraham JL: *The Microbial World*, 4th ed. © 1976. Reprinted by permission of Pearson Education, Inc., New York, New York.)

F. Enzyme Inactivation

The activity of some enzymes is removed by their hydrolysis. This process can be regulated and sometimes is signaled by covalent modification of the enzyme targeted for removal.

CHAPTER SUMMARY

- Metabolism consists of two components: catabolism and anabolism. Catabolism consists of processes that harvest energy from the breakdown of compounds and using that energy to synthesize ATP. Anabolism (or biosynthesis) consists of processes that use the energy stored in ATP to synthesize the subunits (or building blocks) of macromolecules that make up the cell.
- The biosynthetic origins of the building blocks can be traced to relatively few precursors, called focal metabolites.
- Peptidoglycan biosynthesis is unique to bacteria. Some antibiotics kill bacteria by selectively inhibiting steps in peptidoglycan biosynthesis.
- The Embden-Meyerhof, Entner-Doudoroff, and heterolactate pathways are three pathways used for glucose catabolism in bacteria. The pattern of end products is a characteristic used in the identification of bacterial species.
- In the absence of respiration or photosynthesis, bacteria are entirely dependent on substrate phosphorylation for their energy.
- Reductive assimilation of molecular nitrogen (or nitrogen fixation) is required for continuation of life on our planet. It is an energy-intensive process accomplished by a variety of bacteria and cyanobacteria using a multicomponent nitrogenase enzyme complex.
- The regulation of enzyme activity provides both fine control and coarse control of metabolic pathways so that no intermediate is made in excess.

REVIEW QUESTIONS

- The synthesis of which of the following cell components is dependent on a template?
 - Lipopolysaccharide
 - Peptidoglycan
 - Capsular polysaccharide
 - Deoxyribonucleic acid
 - Phospholipids
- The synthesis of which of the following cell components is determined entirely by enzyme specificities?
 - DNA
 - Ribosomal RNA
 - Flagella
 - Lipopolysaccharide
 - Protein
- The steps leading to the synthesis of peptidoglycan occur in the cytoplasm, on the cytoplasmic membrane, and extracellularly. Which antibiotic inhibits an extracellular step in peptidoglycan biosynthesis?
 - Cycloserine
 - Rifampin
 - Penicillin
 - Bacitracin
 - Streptomycin
- Amino acids are found in the protein, peptidoglycan, and capsule of bacteria. Which of the following amino acids is found only in peptidoglycan?
 - L-Lysine
 - Diaminopimelic acid
 - D-Glutamate
 - L-Alanine
 - None of the above
- The ability to use compounds and ions other than oxygen as terminal oxidants in respiration is a widespread microbial trait. This capacity is called
 - Photosynthesis
 - Fermentation
 - Anaerobic respiration
 - Substrate phosphorylation
 - Nitrogen fixation
- The primary route of carbon assimilation used by organisms that can use CO₂ as a sole source of carbon is
 - Hexose monophosphate shunt
 - Entner-Doudoroff pathway
 - Embden-Meyerhof pathway
 - Glyoxylate cycle
 - Calvin cycle
- The peptidoglycan biosynthetic pathway is of particular importance in medicine because it provides a basis for selective antibacterial action of several chemotherapeutic agents. All of the following antibiotics inhibit steps in peptidoglycan biosynthesis EXCEPT
 - Cycloserine
 - Vancomycin
 - Bacitracin
 - Streptomycin
 - Penicillin
- The regulation of enzyme activity provides fine control of metabolic pathways. Which of the following regulatory mechanisms provides fine control of a biosynthetic pathway?
 - Catabolite repression
 - Induction
 - Feedback inhibition
 - Attenuation
 - None of the above
- The biosynthetic origin of building blocks and coenzymes can be traced back to relatively few precursors called focal metabolites. Which of the following are focal metabolites?
 - α -Ketoglutarate
 - Oxaloacetate
 - Phosphoenolpyruvate
 - G6PD
 - All of the above

10. Which of the following is NOT a component of peptidoglycan?
 - (A) N-Acetyl muramic acid
 - (B) N-Acetyl glucosamine
 - (C) Lipid A
 - (D) Pentaglycine
 - (E) Diaminopimelic acid
11. Which of these pathways gives a cell the potential to produce the most ATP?
 - (A) TCA cycle
 - (B) Pentose phosphate pathway
 - (C) Glycolysis
 - (D) Lactic acid fermentation
 - (E) Entner-Doudoroff pathway
12. During the process of oxidative phosphorylation, the energy of the proton motive force is used to generate
 - (A) NADH
 - (B) ADP
 - (C) NADPH
 - (D) Acetyl CoA
 - (E) ATP

Microbial Genetics

The science of **genetics** defines and analyzes **heredity** of the vast array of structural and physiologic functions that form the properties of organisms. The basic unit of heredity is the **gene**, a segment of deoxyribonucleic acid (**DNA**) that encodes in its nucleotide sequence information for a specific physiologic property. The traditional approach to genetics has been to identify genes based on their contribution to **phenotype**, the collective structural and physiologic properties of an organism. A phenotypic property, be it eye color in humans or resistance to antibiotics in a bacterium, is generally observed at the level of the organism. The chemical basis for variation in phenotype is change in **genotype**, or alteration in the DNA sequence, within a gene, or within the organization of genes.

DNA as the fundamental element of heredity was suggested in the 1930s from a seminal experiment performed by Frederick Griffith (Figure 7-1). In this experiment, killed virulent *Streptococcus pneumoniae* type III-S (possessing a capsule), when injected into mice along with living but non-virulent type II-R pneumococci (lacking a capsule), resulted in a lethal infection from which viable type III-S pneumococci were recovered. The implication was that some chemical entity transformed the live, nonvirulent strain to the virulent phenotype. A decade later, Avery, MacLeod, and McCarty discovered that DNA was the transforming agent. This formed the foundation for molecular biology as we understand it today.

Recombinant DNA technology was born in the 1960s and 1970s when investigations with bacteria revealed the presence of **restriction enzymes**, proteins that cleave DNA at specific sites, giving rise to DNA **restriction fragments**. At about the same time, **plasmids** were identified as small genetic elements carrying genes and capable of independent replication in bacteria and yeasts. In a single cell, as many as 1000 copies of an identical plasmid can exist.

Amplification of specific regions of DNA can be achieved with archaeobacterial enzymes using **polymerase chain reaction (PCR)** or other enzyme-based method of nucleic acid amplification. DNA isolated from these sources and digested with appropriate restriction enzymes can be ligated into plasmids for engineered amplification. Genes can be placed under control of high-expression bacterial **promoters** that allow encoded proteins to be expressed at increased levels. Bacterial

genetics have fostered the development of **genetic engineering** not only in prokaryotes but also in eukaryotes. This technology is responsible for the tremendous advances in the field of medicine realized today.

NUCLEIC ACIDS AND THEIR ORGANIZATION IN EUKARYOTIC, PROKARYOTIC, AND VIRAL GENOMES

Genetic information in bacteria is stored as a sequence of **DNA bases** (Figure 7-2). DNA exists as a complex of two double linear strands hydrogen bonded by **complementary bases**, adenine paired with thymine (A–T) and guanine paired with cytosine (G–C) (Figure 7-3). Each of the four bases is bonded to phospho-2'-deoxyribose to form a **nucleotide**. The negatively charged phosphodiester backbone of DNA faces the solvent. The orientation of the two DNA strands is **antiparallel**: One strand is chemically oriented in a 5'→3' direction, and its complementary strand runs 3'→5'. The complementarity of the bases enables one strand (**template strand**) to provide the information for copying or expression of information in the other strand (**coding strand**). The base pairs are stacked within the center of the DNA double helix, and they determine its genetic information. Each turn of the helix has one major groove and one minor groove.

The length of a DNA molecule is usually expressed in thousands of base pairs, or **kilobase pairs (kbp)**. Whereas a small virus may contain a single DNA molecule of less than 0.5 kbp, the single DNA genome that encodes *E. coli* is greater than 4000 kbp. In either case, each base pair is separated from the next by about 0.34 nm, or 3.4×10^{-7} mm, so that the total length of the *E. coli* chromosome is roughly 1 mm. Because the overall dimensions of the bacterial cell are roughly 1000-fold smaller than this length, it is evident that a substantial amount of folding, or **supercoiling**, contributes to the physical structure of the molecule in vivo.

Ribonucleic acid (RNA) most frequently occurs in single-stranded form. The uracil base (U) replaces thymine base (T) in DNA, so the complementary bases that determine the structure of RNA are A–U and C–G. The overall structure of single-stranded RNA (ssRNA) molecules is determined

FIGURE 7-1 Griffith's experiment demonstrating evidence for a transforming factor, later identified as DNA. In a series of experiments, mice were injected with live or killed encapsulated or nonencapsulated *S. pneumoniae*, as indicated in experiments A through D. The key experiment is D, showing that the killed encapsulated bacteria could supply a factor that allowed the nonencapsulated bacteria to kill mice. Besides providing key support for the importance of the capsule for pneumococcal virulence, experiment D also illustrates the principle of DNA as the fundamental basis of genetic transformation. (Reproduced by permission from McClane BA, Mietzner TA: *Microbial Pathogenesis: A Principles-Oriented Approach*. Fence Creek Publishing, 1999.)

by pairing between bases within the intrastrand-forming loops, with the result that ssRNA molecules assume a compact structure capable of expressing genetic information contained in DNA.

The most general function of RNA is communication of DNA gene sequences in the form of **messenger RNA (mRNA)** to **ribosomes**. These processes are referred to as **transcription** and **translation**. mRNA (referred to as +ssRNA) is transcribed as the RNA complement to the coding DNA strand. This mRNA is then translated by ribosomes. The ribosomes, which contain both **ribosomal RNA (rRNA)** and proteins, translate this message into the primary structure of proteins via aminoacyl-**transfer RNAs (tRNAs)**. RNA molecules range in size from the small tRNAs, which contain fewer than 100 bases, to mRNAs, which may carry genetic

messages extending to several thousand bases. Bacterial ribosomes contain three kinds of rRNA, with respective sizes of 120, 1540, and 2900 bases, and several proteins (Figure 7-4). Corresponding rRNA molecules in eukaryotic ribosomes are somewhat larger. The need for expression of an individual gene changes in response to physiologic demand and requirements for flexible gene expression are reflected in the rapid metabolic turnover of most mRNAs. On the other hand, tRNAs and rRNAs—which are associated with the universally required function of protein synthesis—tend to be stable and together account for more than 95% of the total RNA in a bacterial cell. A few RNA molecules have been shown to function as enzymes (**ribozymes**). For example, the 23S RNA in the 50S ribosomal subunit (see Figure 7-4) catalyzes the formation of the peptide bond during protein synthesis.

The Eukaryotic Genome

The **genome** is the totality of genetic information in an organism. Nearly all the eukaryotic genome is carried on two or more linear chromosomes separated from the cytoplasm within the membrane of the nucleus. **Diploid** eukaryotic cells contain two **homologues** (divergent evolutionary copies) of each chromosome. **Mutations**, or genetic changes, frequently cannot be detected in diploid cells because the contribution of one gene copy compensates for changes in the function of its homologue. Whereas a gene that does not achieve phenotypic expression in the presence of its homologue is **recessive**, a gene that overrides the effect of its homologue is **dominant**. The effects of mutations can be most readily

FIGURE 7-3 Normal base pairing in DNA. **Top:** Adenine–thymidine (A–T) pairing; **bottom:** guanine–cytosine (G–C) pair. Hydrogen bonds are indicated by dotted lines. Note that the G–C pairing shares three sets of hydrogen bonds, but the A–T pairing has only two. Consequently, a G–C interaction is stronger than an A–T interaction. dR, deoxyribose of the sugar-phosphate DNA backbone.

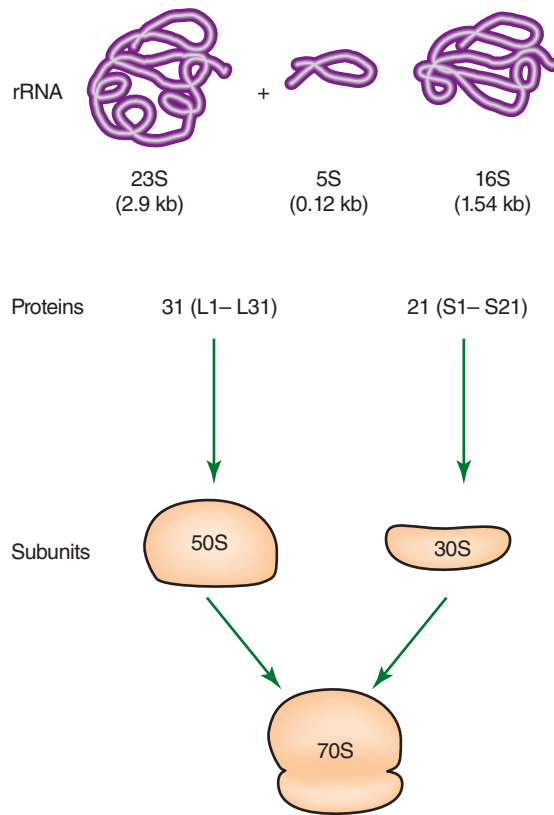

FIGURE 7-4 The composition of a ribosome containing one copy each of the 16S, 23S, and 5S RNAs as well as many proteins. The proteins of the large 50S subunit are designated L1–L31. The proteins of the small 30S subunit are designated S1–S21. (Reproduced with permission from Snyder L, Champness W: *Molecular Genetics of Bacteria*, 2nd ed. Washington, DC: ASM Press, 2003. © 2003 American Society for Microbiology.)

discerned in **haploid** cells, which carry only a single copy of most genes. Yeast cells (which are eukaryotic) are frequently studied because they can be maintained and analyzed in the haploid state.

Eukaryotic cells contain **mitochondria** and, in the case of plants, **chloroplasts**. Within each of these organelles is a circular molecule of DNA that contains a few genes whose function relates to that organelle. Most genes associated with organelle function, however, are carried on eukaryotic chromosomes. Many yeast contain an additional genetic element, an independently replicating 2-µm circle containing about 6.3 kbp of DNA. Such small circles of DNA, termed **plasmids** or **episomes**, are frequently associated with prokaryotes. The small size of plasmids renders them amenable to genetic manipulation and, after their alteration, may allow their introduction into cells.

Repetitive DNA, which occurs in large quantities in eukaryotic cells, is infrequently associated with coding regions and is located primarily in extragenic regions. These short-sequence repeats (SSRs) or short tandemly repeated (STR) sequences occur in several to thousands of copies dispersed throughout the genome. The presence of SSRs and STRs is well documented, and some show extensive length-polymorphisms. Many eukaryotic genes are interrupted by **introns**, intervening sequences of DNA that are missing in processed mRNA when it is translated. Introns have been observed in archaeobacterial genes but with a few rare exceptions are not found in eubacteria (see Table 3-4).

The Prokaryotic Genome

Most prokaryotic genes are carried on a single, haploid, copy found on the bacterial chromosome. Genome sequence data from more than 340 microbial genomes demonstrate that most prokaryotic genomes (>90%) consist of a single circular DNA molecule containing from 580 kbp to more than 5220 kbp of DNA (Table 7-1). A few bacteria (eg, *Brucella melitensis*, *Burkholderia pseudomallei*, and *Vibrio cholerae*) have genomes consisting of two circular DNA molecules. Many bacteria contain additional genes on plasmids that range in size from several to 100 kbp. In contrast to eukaryotic genomes, 98% of bacterial genomes are coding sequences.

Covalently closed DNA circles (bacterial chromosomes and plasmids), which contain genetic information necessary for their own replication, are called **replicons** or **episomes**. Because prokaryotes do not contain a nucleus, a membrane does not separate bacterial genes from cytoplasm as in eukaryotes. Therefore, transcription of mRNA and translation by ribosomes occur at the same time.

Some bacterial species are efficient at causing disease in higher organisms because they possess specific genes for pathogenic determinants. These genes are often clustered together in the DNA and are referred to as **pathogenicity islands**. These gene segments can be quite large (up to 200 kbp) and encode a collection of virulence genes. Pathogenicity islands (1) have a different G + C content from the rest of the genome; (2)

TABLE 7-1 Comparison of Genome Sizes in Selected Prokaryotes, Bacteriophages, and Viruses

Organism		Size (kbp)
Prokaryotes		
Archae	<i>Methanococcus jannaschii</i>	1660
	<i>Archaeoglobus fulgidus</i>	2180
Eubacteria	<i>Mycoplasma genitalium</i>	580
	<i>M. pneumoniae</i>	820
	<i>Borrelia burgdorferi</i>	910
	<i>Chlamydia trachomatis</i>	1040
	<i>Rickettsia prowazekii</i>	1112
	<i>Treponema pallidum</i>	1140
	<i>C. pneumoniae</i>	1230
	<i>Helicobacter pylori</i>	1670
	<i>Haemophilus influenzae</i>	1830
	<i>Francisella tularensis</i>	1893
	<i>Coxiella burnetii</i>	1995
	<i>Neisseria meningitidis</i> serogroup A	2180
	<i>N. meningitidis</i> serogroup B	2270
	<i>B. melitensis</i> ^a	2117 + 1178
	<i>Mycobacterium tuberculosis</i>	4410
	<i>Escherichia coli</i>	4640
	<i>Bacillus anthracis</i>	5227
	<i>Burkholderia pseudomallei</i> ^a	4126 + 3182
Bacteriophage	Lambda	48
Viruses	Ebola	19
	Variola major	186
	Vaccinia	192
	Cytomegalovirus	229

^aOrganism contains two chromosomes of sizes X and Y.

are closely linked on the chromosome to tRNA genes; (3) are flanked by direct repeats; and (4) contain diverse genes important for pathogenesis, including antibiotic resistance, adhesins, invasins, and exotoxins, as well as genes that can be involved in genetic mobilization.

Genes essential for bacterial growth (often referred to as “housekeeping genes”) are typically carried on the chromosome but may be found on plasmids carrying genes associated with specialized functions (Table 7-2). Many plasmids also encode genetic sequences that mediate their transfer from one organism to another (eg, those involved with sex pili) as well as others associated with genetic acquisition or rearrangement of DNA (eg, transposase). Therefore, genes with independent evolutionary origins may be assimilated

TABLE 7-2 Examples of Metabolic Activities Determined by Plasmids

Organism	Activity
<i>Pseudomonas</i> species	Degradation of camphor, toluene, octane, salicylic acid
<i>Bacillus stearothermophilus</i>	Thermostable α -amylase
<i>Alcaligenes eutrophus</i>	Utilization of H ₂ as oxidizable energy source, heavy-metal resistance
<i>E. coli</i>	Sucrose uptake and metabolism, citrate uptake
<i>Klebsiella</i> species	Nitrogen fixation
<i>Streptococcus</i> (group N)	Lactose utilization, galactose phosphotransferase system, citrate metabolism
<i>Rhodospirillum rubrum</i>	Synthesis of photosynthetic pigment
<i>Flavobacterium</i> species	Nylon degradation

by plasmids that are widely disseminated among bacterial populations. A consequence of such genetic events has been observed in the swift spread among bacterial populations of plasmid-borne resistance to antibiotics after their liberal use in hospitals.

Transposons are genetic elements that contain several genes, including those necessary for their migration from one genetic locus to another. In doing so, they create **insertion mutations**. The involvement of relatively short transposons (0.75–2.0 kbp long), known as **insertion elements**, produces the majority of insertion mutations. These insertion elements (also known as insertion sequence [IS] elements) carry only the genes for enzymes needed to promote their own transposition to another genetic locus but cannot replicate on their own. Almost all bacteria carry IS elements, with each species harboring its own characteristic IS elements. Related IS elements can sometimes be found in different bacteria, implying that at some point in evolution they have crossed species barriers. Plasmids also carry IS elements, which are important in the formation of high-frequency recombinant (**Hfr**) strains. Complex transposons carry genes for specialized functions such as antibiotic resistance and are flanked by insertion sequences.

Transposons do not carry the genetic information required to encode their own replication, and therefore their propagation depends on their physical integration with a bacterial replicon. This association is fostered by enzymes that confer the ability of transposons to form copies of themselves; these enzymes (**transposases**) may allow the transposons to integrate within the same replicon or an independent replicon. The specificity of sequence at the insertion site is generally low, so that transposons often seem to insert in a random pattern, but they tend to favor regions of the chromosome encoding tRNAs. Many plasmids are transferred

among bacterial cells, and insertion of a transposon into such a plasmid is a vehicle that leads to the transposon’s dissemination throughout a bacterial population.

The Viral Genome

Viruses are capable of survival, but not growth, in the absence of a cell host. Replication of the viral genome depends on the metabolic energy and the macromolecular synthetic machinery of the host. Frequently, this form of genetic parasitism results in debilitation or death of the host cell. Therefore, successful propagation of the virus requires (1) a stable form that allows the virus to survive in the absence of its host, (2) a mechanism for invasion of a host cell, (3) genetic information required for replication of the viral components within the cell, and (4) additional information that may be required for packaging the viral components and liberating the resulting virus from the host cell.

Distinctions are frequently made between viruses associated with eukaryotes and viruses associated with prokaryotes, the latter being termed **bacteriophage** or **phage**. When viral DNA is integrated into the eukaryotic genome, it is called a **provirus**; when a phage is integrated into a bacterial genome or episome, it is called a **prophage**. With more than 5000 isolates of known morphology, phages constitute the largest of all viral groups. Much of our understanding of viruses—indeed, many fundamental concepts of molecular biology—has emerged from investigation of bacteriophages.

Bacteriophages occur in more than 140 bacterial genera and in many different habitats. The nucleic acid molecule of bacteriophages is surrounded by a protein coat. Considerable variability is found in the nucleic acid of phages. Phage genomes can be comprised of double-stranded DNA (dsDNA), double-stranded RNA (dsRNA), ssRNA, or single-stranded DNA (ssDNA). Unusual bases such as hydroxymethylcytosine are sometimes found in the phage nucleic acid. Many phages contain specialized syringe-like structures (tails) that bind to receptors on the cell surface and inject the phage nucleic acid into a host cell (Figure 7-5).

Phages are distinguished based on their mode of propagation. **Lytic phages** produce many copies of themselves as

FIGURE 7-5 Illustrations of phage T2 with or without nucleic acid. Note that when the phage is loaded with nucleic acid, it takes on a different form than when the nucleic acid is absent. These diagrams are redrawn from electron micrographic observations.

they kill their host cell. The most thoroughly studied lytic phages, the T-even (eg, T2, T4) phages of *E. coli*, demonstrate the need for precisely timed expression of viral genes to coordinate events associated with phage formation. **Temperate phages** enter a nonlytic **prophage** state in which replication of their nucleic acid is linked to replication of host cell DNA. Bacteria carrying prophages are termed **lysogenic** because a physiologic signal can trigger a lytic cycle resulting in death of the host cell and liberation of many copies of the phage. The best characterized temperate phage is the *E. coli* phage λ (lambda). **Filamentous phages**, exemplified by the well-studied *E. coli* phage M13, are exceptional in several respects. Their filaments contain ssDNA complexed with protein and are extruded from their bacterial hosts, which are debilitated but not killed by the phage infection. Engineering of DNA into phage M13 has provided single strands that are valuable sources for DNA analysis and manipulation.

REPLICATION

dsDNA is synthesized by **semiconservative replication**. As the parental duplex unwinds, each strand serves as a template for DNA replication. New strands are synthesized with their bases in an order complementary to that in the preexisting strands. When synthesis is complete, each daughter molecule contains one parental strand and one newly synthesized strand.

Bacterial DNA Replication

The replication of bacterial DNA begins at one point and moves in both directions (ie, **bidirectional replication**). In the process, the two old strands of DNA are separated and used as templates to synthesize new strands (**semiconservative replication**). The structure where the two strands are separated, and the new synthesis is occurring, is referred to as the **replication fork**. Replication of the bacterial chromosome is tightly controlled, and the number of each chromosome (when more than one is present) per growing cell falls between one and four. Some bacterial plasmids may have as many as 30 copies in one bacterial cell, and mutations causing relaxed control of plasmid replication can result in 10-fold higher copy numbers.

The replication of circular double-stranded bacterial DNA begins at the *ori* locus and involves interactions with several proteins. In *E. coli*, chromosome replication terminates in a region called **ter**. The **origin** (*ori*) and **termination sites** (*ter*) for replication are located at opposite points on the circular DNA chromosome. The two daughter chromosomes are separated, or resolved, before cell division so that each progeny cell gets one of the daughter DNAs. This is accomplished with the aid of **topoisomerases**, enzymes that alter the supercoiling of dsDNA. The topoisomerases act by transiently cutting one or both strands of the DNA to relax the coil and extend the DNA molecule. Because bacterial

topoisomerases are essential and unique, they are targets of **antibiotics** (eg, quinolones). Similar processes used in the replication of bacterial chromosomes are used in the replication of plasmid DNA, except that, in some cases, replication is unidirectional.

Phage Replication

Bacteriophages exhibit considerable diversity in the nature of their nucleic acid genome, and this diversity is reflected in different modes of replication. Fundamentally different propagation strategies are exhibited by lytic and temperate phages. Lytic phages produce many copies of themselves in a single burst of growth. Temperate phages establish themselves as prophages either by becoming part of an established replicon (chromosome or plasmid) or by forming an independent replicon.

The dsDNA of many lytic phages is linear, and the first stage in their replication is the formation of circular DNA. This process depends upon **cohesive ends**, complementary single-stranded tails of DNA that hybridize. **Ligation**, formation of a phosphodiester bond between the 5' and 3' DNA ends, gives rise to covalently closed circular DNA that may undergo replication similar to that used for other replicons. Cleavage of the circles produces linear DNA that is packaged inside protein coats to form daughter phages.

The ssDNA of filamentous phages is converted to a circular double-stranded replicative form. One strand of the replicative form is used as a template in a continuous process that produces ssDNA. The template is a rolling circle, and the ssDNA it produces is cleaved and packaged with protein for extracellular extrusion.

The ssRNA phages are among the smallest extracellular particles containing information that allows for their own replication. The RNA of phage MS2, for example, contains (in fewer than 4000 nucleotides) three genes that can act as mRNA following infection. One gene encodes the coat protein, and another encodes an RNA polymerase that forms a dsRNA replicative form. ssRNA produced from the replicative form is the core of new infective particles.

The temperate bacteriophage *E. coli* phage P1 genome, when undergoing a lysogenic cycle, exists as an autonomous plasmid in the bacterium. The dsDNA of other temperate bacteriophages is established as a prophage by its insertion into the bacterial host chromosome. The site of insertion may be quite specific, as typified by integration of *E. coli* phage λ at a single *int* locus on the bacterial chromosome. The specificity of integration is determined by identity of the shared DNA sequence by the *int* chromosomal locus and a corresponding region of the phage genome. Other temperate phages, such as *E. coli* phage Mu, integrate in any of a wide range of chromosomal sites and in this aspect resemble transposons.

Prophages contain genes required for lytic replication (also called **vegetative replication**), and expression of these

genes is repressed during maintenance of the prophage state. A manifestation of repression is that an established prophage frequently confers cellular immunity against lytic infection by similar phage. A cascade of molecular interactions triggers **derepression** (release from repression) so that a prophage undergoes vegetative replication, leading to formation of a burst of infectious particles. Stimuli such as ultraviolet (UV) light may cause derepression of the prophage. The switch between lysogeny—propagation of the phage genome with the host—and vegetative phage growth at the expense of the cell may be determined in part by the cell's physiologic state. A nonreplicating bacterium will not support vegetative growth of phage, but a vigorously growing cell contains enough energy and building blocks to support rapid phage replication.

TRANSFER OF DNA

The haploid nature of the bacterial genome might be presumed to limit the genomic plasticity of a bacterium. However, the ubiquity of diverse bacteria in a complex microbiome provides a fertile gene pool that contributes to their remarkable genetic diversity through mechanisms of genetic exchange. Bacterial genetic exchange is typified by transfer of a relatively small fragment of a donor genome to a recipient cell followed by genetic recombination. Bacterial genetic recombination is quite unlike the fusion of gametes observed with eukaryotes; it demands that this donor DNA be replicated in the recombinant organism. Replication can be achieved either by integration of the donor DNA into the recipient's chromosome or by establishment of donor DNA as an independent episome.

Restriction and Other Constraints on Gene Transfer

Restriction enzymes (restriction endonucleases) provide bacteria with a mechanism to distinguish between their own DNA and DNA from other biologic sources. These enzymes hydrolyze (cleave) DNA at restriction sites determined by specific DNA sequences ranging from 4 to 13 bases. Each bacterial strain that possesses a restriction system can disguise these recognition sites in its own DNA by modifying them through methylation of adenine or cytosine residues within the site. These restriction–modification systems fall into two broad classes: type I systems, in which the restriction and modification activities are combined in a single multisubunit protein, and type II systems, which consist of separate endonucleases and methylases. A direct biologic consequence of restriction can be cleavage of donor DNA before it has an opportunity to become established as part of a recombinant replicon, rendering the bacterium “immune” to incoming DNA.

Compatibility of plasmids is an additional constraint on gene transfer. Some plasmids exhibit a narrow host

range and replicate only in a closely related set of bacteria. Other plasmids, exemplified by some drug resistance plasmids, replicate in a broad range of bacterial genera. In some cases, two or more plasmids can stably coexist in a cell, but other pairs will interfere with the replication or partitioning. If two such plasmids are introduced into the same cell, one or the other will be lost at a higher than normal rate when the cell divides. This phenomenon is called **plasmid incompatibility**; two plasmids that cannot stably coexist belong to the same **incompatibility (Inc) group**, and two plasmids that can stably coexist belong to different Inc groups.

Mechanisms of Recombination

Donor DNA that does not carry information necessary for its own replication must recombine with recipient DNA to become established in a recipient strain. The recombination may be **homologous**, a consequence of close similarity in the sequences of donor and recipient DNA, or **nonhomologous**, the result of enzyme-catalyzed recombination between two dissimilar DNA sequences. Homologous recombination almost always involves exchange between genes that share common ancestry. The process requires a set of genes designated *rec*. Nonhomologous recombination depends on enzymes encoded by the integrated DNA and is most clearly exemplified by the insertion of DNA into a recipient to form a copy of a donor transposon.

The mechanism of recombination mediated by *rec* gene products is reciprocal: Introduction of a donor sequence into a recipient is mirrored by transfer of the homologous recipient sequence into the donor DNA. Increasing scientific attention is being paid to the role of **gene conversion**—the nonreciprocal transfer of DNA sequences from donor to recipient—in the acquisition of genetic diversity.

Mechanisms of Gene Transfer

The DNA composition of microorganisms is remarkably fluid. DNA can be transferred from one organism to another, and that DNA can be stably incorporated in the recipient, permanently changing its genetic composition. This process is called **horizontal gene transfer** (HGT) to differentiate it from the inheritance of parental genes, a process called **vertical inheritance**. Three broad mechanisms mediate efficient movement of DNA between cells—**conjugation**, **transduction**, and **transformation**.

Conjugation requires donor cell-to-recipient cell contact to transfer only one strand of DNA (Figure 7-6). The recipient completes the structure of dsDNA by synthesizing the strand that complements the strand acquired from the donor. In **transduction**, donor DNA is carried by a phage coat and is transferred into the recipient by the mechanism used for phage infection. **Transformation**, the direct uptake of “naked” donor DNA by the recipient cell, may be natural or forced. Forced transformation is induced in the laboratory,

where, after treatment with high salt and temperature shock, many bacteria are rendered competent for the uptake of extracellular plasmids. The capacity to force bacteria to incorporate extracellular plasmids by transformation is fundamental to genetic engineering.

FIGURE 7-6 Mechanism of DNA transfer during conjugation. The donor cell produces a pilus, which is encoded by the plasmid, and contacts a potential recipient cell that does not contain the plasmid. Retraction of the pilus brings the cells into close contact, and a pore forms in the adjoining cell membranes. Formation of the mating pair signals the plasmid to begin transfer from a single-stranded nick at *oriT*. The nick is made by plasmid-encoded *tra* functions. The 5' end of a single strand of the plasmid is transferred to the recipient through the pore. During transfer, the plasmid in the donor is replicated, its DNA synthesis being primed by the 3' OH of the *oriT* nick. Replication of the single strand in the recipient proceeds by a different mechanism with RNA primers. Both cells now contain double-stranded plasmids, and the mating pair separates. (Reproduced with permission from Snyder L, Champness W: *Molecular Genetics of Bacteria*, 2nd ed. Washington, DC: ASM Press, 2003. © 2003 American Society for Microbiology.)

A. Conjugation

Plasmids are most frequently transferred by conjugation. Genetic functions required for transfer are encoded by the *tra* genes, which are carried by self-transmissible **plasmids**. Some self-transmissible plasmids can mobilize other plasmids or portions of the chromosome for transfer. In some cases, mobilization is achieved because the *tra* genes provide functions necessary for transfer of an otherwise nontransmissible plasmid (Figures 7-7 and 7-8). In other cases, the self-transmissible plasmid integrates with the DNA of another replicon and, as an extension of itself, carries a strand of this DNA into a recipient cell.

FIGURE 7-7 Mechanism of plasmid mobilization. The donor cell carries two plasmids, a self-transmissible plasmid, F, which encodes the *tra* functions that promote cell contact and plasmid transfer, and a mobilizable plasmid. The *mob* functions encoded by the mobilizable plasmid make a single-stranded nick at *oriT* in the *mob* region. Transfer and replication of the mobilizable plasmid then occur. The self-transmissible plasmid may also transfer. (Reproduced with permission from Snyder L, Champness W: *Molecular Genetics of Bacteria*, 2nd ed. Washington, DC: ASM Press, 2003. © 2003 American Society for Microbiology.)

FIGURE 7-8 **A:** A male and a female cell joined by an F pilus (sex pilus). **B:** Mating pairs of *E. coli* cells. Hfr cells are elongated. **C:** Electron micrograph of a thin section of a mating pair. The cell walls of the mating partners are in intimate contact in the “bridge” area. (Photograph [A]: Courtesy of Carnahan J and Brinton C. Photographs [B] and [C] reproduced with permission from Gross JD, Caro LG: DNA transfer in bacterial conjugation. *J Mol Biol* 1966;16:269.)

Genetic analysis of *E. coli* was greatly advanced by elucidation of **fertility** factors carried on a plasmid designated F^+ . This plasmid confers certain donor characteristics upon cells; these characteristics include a sex pilus, an extracellular multimeric protein extrusion that attaches donor cells to recipient organisms lacking the fertility factor. A bridge between the cells allows a strand of the F^+ plasmid, synthesized by the donor, to pass into the recipient, where the complementary strand of DNA is formed. The F^+ fertility factor can integrate into numerous loci in the chromosome of donor cells. The integrated fertility factor creates high-frequency recombination (Hfr) donors from which chromosomal DNA is transferred (from the site of insertion) in a direction determined by the orientation of insertion (Figure 7-9).

The rate of chromosomal transfer from Hfr cells is constant, and compilation of results from many conjugation experiments has allowed preparation of an *E. coli* **genetic map** in which distances between loci are measured in number of minutes required for transfer in conjugation. A similar map has been constructed for the related coliform (*E. coli*-like) bacterium *Salmonella typhimurium*, and comparison of the two maps shows related patterns of genomic organization. This type of mapping has now been replaced by high-throughput genomic DNA sequencing.

Integration of chromosomal DNA into a conjugal plasmid can produce a recombinant replicon—an **F** (fertility) prime, or **R** (resistance) prime, depending on the plasmid—in which the integrated chromosomal DNA can be replicated on the plasmid independently of the chromosome. This occurs when the integrated plasmid (eg, F) is bracketed by two copies of an IS element. Bacteria carrying gene copies, a full set on the chromosome and a partial set on a prime, are **partial diploids**, or **merodiploids**, and are useful for complementation studies. A wild-type gene frequently complements its mutant

homologue, and selection for the wild-type phenotype can allow maintenance of merodiploids in the laboratory. Such strains can allow analysis of interactions between different **alleles**, genetic variants of the same gene. Merodiploids frequently are genetically unstable because recombination between the plasmid and the homologous chromosome can result in loss or exchange of mutant or wild-type alleles. This problem can frequently be circumvented by maintenance of merodiploids in a genetic background in which *recA*, a gene required for recombination between homologous segments of DNA, has been inactivated.

Homologous genes from different organisms may have diverged to an extent that prevents homologous recombination between them but does not alter the capacity of one gene to complement the missing activity of another. For example, the genetic origin of an enzyme required for amino acid biosynthesis is unlikely to influence catalytic activity in the cytoplasm of a biologically distant host. A merodiploid carrying a gene for such an enzyme would also carry flanking genes derived from the donor organism. Therefore, conventional microbial genetics, based on selection of prime plasmids, can be used to isolate genes from fastidious (difficult to grow) organisms in easily cultivatable organism such as *E. coli* or *Pseudomonas aeruginosa*.

B. Transduction

Transduction is phage-mediated genetic recombination in bacteria. In simplest terms, a transducing particle (phage) is generally regarded as bacterial nucleic acid in a phage-encoded protein coat. In some instances, a lytic-phage population may contain some particles in which the phage coat surrounds DNA derived from the bacterium rather than from the phage. Such populations have been used to transfer genes from one bacterium to another. Temperate phages are preferred

FIGURE 7-9 Transfer of chromosomal DNA by an integrated plasmid. Formation of mating pairs, nicking of the F *oriT* sequence, and transfer of the 5' end of a single strand of F DNA proceed as in transfer of the F plasmid. Transfer of a covalently linked chromosomal DNA will also occur as long as the mating pair is stable. Complete chromosome transfer rarely occurs, and so the recipient cell remains F⁻, even after mating. Replication in the donor usually accompanies DNA transfer. Some replication of the transferred single strand may also occur. Once in the recipient cell, the transferred DNA may recombine with homologous sequences in the recipient chromosome. (Reproduced with permission from Snyder L, Champness W: *Molecular Genetics of Bacteria*, 2nd ed. Washington, DC: ASM Press, 2003. © 2003 American Society for Microbiology.)

vehicles for gene transfer because infection of recipient bacteria under conditions that favor lysogeny minimizes cell lysis and thus favors survival of recombinant strains. Indeed, a recipient bacterium carrying an appropriate prophage may form a repressor that renders the cell immune to lytic superinfection; such cells may still take up bacterial DNA from transducing particles. Transducing mixtures carrying donor

DNA can be prepared under conditions that favor the lytic-phage cycle.

The size of DNA in transducing particles is usually no more than a few percent of the bacterial chromosome, and therefore **cotransduction**—transfer of more than one gene at a time—is limited to linked bacterial genes. The speed and capacity by which phages recombine and replicate has made them central subjects for study of bacterial genetics and genetic engineering.

In nature, **pathogenicity islands** are often transported by phages. For example, two phages transport pathogenicity islands responsible for converting a benign form of *V. cholerae* into the pathogenic form responsible for epidemic cholera (see Chapter 17). These phages encode genes for cholera toxin (responsible for symptoms) and toxin co-regulated pili (responsible for attachment) that in combination substantially increase the virulence of *V. cholerae*.

C. Transformation

As described above, forced transformation is typically thought of as a laboratory phenomenon. However, it is now clear that low-frequency **HGT** has been responsible for common mechanisms of antibiotic resistance among diverse species of bacteria. This is not surprising given the complex diversity and density of the intestinal flora or the biofilms that form on our teeth overnight. Couple this with the therapeutic administration of antibiotics that select for resistant organisms and a “perfect storm” exists for the spread of genetic material across species boundaries.

In contrast to forced transformation (described above), natural competence is unusual among bacteria. Direct uptake of donor DNA by recipient bacteria depends on their **competence** for transformation. Naturally competent transformable bacteria, of medical importance, are found in several genera and include *H. influenzae*, *Neisseria gonorrhoeae*, *N. meningitidis*, and *S. pneumoniae*. Natural transformation is an active process demanding specific proteins produced by the recipient cell. In addition, specific DNA sequences (**uptake sequences**) are required for uptake of the DNA. These uptake sequences are species specific, thus restricting genetic exchange to a single species. The DNA that is not incorporated can be degraded and used as a source of nutrients to support microbial growth. It is clear that genetic transformation is a major force in microbial evolution.

MUTATION AND GENE REARRANGEMENT

Spontaneous Mutations

Spontaneous mutations for a given gene in a wild-type background generally occur with a frequency of 10^{-6} – 10^{-8} in a population derived from a single bacterium (depending on the bacterial species and conditions used to identify the mutation). The mutations include **base substitutions**, **deletions**, **insertions**, and **rearrangements**. Base substitutions can

arise because of mispairing between complementary bases during replication. In *E. coli*, this occurs about once every 10^{10} times the DNA polymerase incorporates a nucleotide—a remarkably rare process. Occurrence of a mispaired base is minimized by enzymes associated with **mismatch repair**, a mechanism that essentially proofreads a newly synthesized strand to ensure that it perfectly complements its template. Mismatch repair enzymes distinguish the newly synthesized strand from the preexisting strand based on methylation of adenine in GATC sequences of the preexisting strand. When DNA damage is too extensive, a special DNA repair system, the **SOS response**, rescues cells. The SOS response is a postreplication DNA repair system that allows DNA replication to bypass extensive DNA errors.

Many base substitutions escape detection at the phenotypic level because they do not significantly disrupt the function of the gene product. For example, **missense mutations**, which result in substitution of one amino acid for another, may be without discernible phenotypic effect. On the other hand, **nonsense mutations** terminate synthesis of proteins and thus result in a protein truncated at the site of mutation. The gene products of nonsense mutations are inactive.

Rearrangements are the result of deletions that remove large portions of genes or even sets of genes. These large deletions involve recombination between directly repeated sequences (eg, IS elements) and almost never revert. Other mutations cause duplication, frequently in tandem, of comparable lengths of DNA. Such mutations usually are unstable and readily revert. Still other mutations can invert lengthy DNA sequences or transpose such sequences to new loci. Comparative gene maps of related bacterial strains have shown that such rearrangements can be fixed in natural populations. These observations point to the fact that linear separation of DNA loci on a bacterial chromosome does not completely disrupt possibilities for physical and chemical interaction among them.

Mutagens

The frequency of mutation is greatly enhanced by exposure of cells to mutagens. UV light is a **physical mutagen** that damages DNA by linking neighboring thymine bases to form dimers. Sequence errors can be introduced during enzymatic repair of this genetic damage. **Chemical mutagens** may act by altering either the chemical or the physical structure of DNA. Reactive chemicals alter the structure of bases in DNA. For example, nitrous acid (HNO_2) substitutes hydroxyl groups for amino groups on DNA bases. The resulting DNA has altered template activity during subsequent rounds of replication. A **frameshift mutation** is a **genetic mutation** caused by **insertions** or **deletions** of several **nucleotides** in a DNA sequence that is not divisible by 3. This is caused by polymerase slippage and is favored by exposure to acridine dyes (eg, acridine orange), which can intercalate between bases.

In general, the direct effect of chemical or physical mutagens is damage to DNA. The resulting mutations are introduced by the replication process and escape the repair enzymes described above. Mutations that change the activity of replication or repair enzymes can make a bacterium more susceptible to biologic mutagens and are referred to as *mutator strains*.

Reversion and Suppression

Regaining an activity lost as a consequence of mutation, termed **phenotypic reversion**, may or may not result from restoration of the original DNA sequence, as would be demanded by **genotypic reversion**. Frequently, a mutation at a second locus, called a **suppressor mutation**, restores the lost activity. In **intragenic suppression**, after a primary mutation has changed an enzyme's structure so that its activity has been lost, a second mutation at a different site in the enzyme's gene restores the structure required for activity. **Extragenic suppression** is caused by a second mutation lying outside the originally affected gene restores activity.

GENE EXPRESSION

The tremendous evolutionary separation of eukaryotic and prokaryotic genomes is illustrated by comparing their mechanisms of gene expression, which share only a small subset of properties. In both groups, genetic information is encoded by DNA, transcribed into mRNA, and translated on ribosomes through tRNA into the structure of proteins. The triplet nucleotide codons used in translation are generally shared, and many enzymes associated with macromolecular synthesis in the two biologic groups have similar properties. The mechanism by which the sequence of nucleotides in a gene determines the sequence of amino acids in a protein is largely similar in prokaryotes and eukaryotes and is as follows:

1. RNA polymerase forms a single polyribonucleotide strand, called **mRNA**, using DNA as a template; this process is called **transcription**. The mRNA has a nucleotide sequence complementary to a template strand in the DNA double helix if read in the 3'–5' direction. Thus, an mRNA is oriented in a 5'–3' direction.
2. Amino acids are enzymatically activated and transferred to specific adapter molecules of RNA, called **tRNA**. Each adapter molecule has a triplet of bases (**anticodon**) complementary to a triplet of bases on mRNA, and at one end its specific amino acid. The triplet of bases on mRNA is called the **codon** specific for that amino acid.
3. mRNA and tRNA come together on the surface of the ribosome. As each tRNA finds its complementary mRNA codon, the amino acid carried by the tRNA is put into peptide linkage with the amino acid of the preceding tRNA molecule. The enzyme **peptidyltransferase** (which is the 23S rRNA, ie, a **ribozyme**) catalyzes the formation of the

FIGURE 7-10 Four stages in the lengthening of a polypeptide chain on the surface of a 70S ribosome. **Top left:** A tRNA molecule bearing the anticodon complementary to codon 1 at one end and AA₁ at the other binds to site A. AA₁ is attached to the tRNA through its carboxyl group; its amino nitrogen bears a formyl group (F). **Top right:** A tRNA molecule bearing AA₂ binds to site B; its anticodon is complementary to codon 2. **Bottom right:** An enzyme complex catalyzes the transfer of AA₁ to the amino group of AA₂, forming a peptide bond. (Note that transfer in the opposite direction is blocked by the prior formylation of the amino group of AA₁.) **Bottom left:** The ribosome moves to the right so that sites A and B are now opposite codons 2 and 3; in the process, tRNA₁ is displaced and tRNA₂ moves to site A. Site B is again vacant and is ready to accept tRNA₃ bearing AA₃. (When the polypeptide is completed and released, the formyl group is enzymatically removed.) (Reproduced by permission from Adelberg EA, Doudoroff MJ, Fowls RL, et al.: *The Microbial World* (Stanier), 3rd ed. © 1970. Reprinted by permission of Pearson Education, Inc., New York, New York.)

peptide bond. The ribosome moves along the mRNA with the nascent polypeptide growing sequentially until the entire mRNA molecule has been translated into a corresponding sequence of amino acids. This process, called **translation**, is diagrammed in Figure 7-10.

In prokaryotes, genes associated with related functions are typically clustered in **operons**. Because there is no nucleus, the processes of transcription and translation are coupled, meaning that the nascent mRNA attaches to a ribosome and is translated at the same time the mRNA is being transcribed.

In addition bacterial mRNA is rapidly turned over, having a half-life of the order of seconds to minutes. This coupled transcription and translation allows for the rapid response to changes in the bacterial environment.

In eukaryotes, clustering on related genes is unusual. **Enhancer sequences** are regions of eukaryotic DNA that increase transcription and may lie distantly upstream from the transcribed gene. Eukaryotic genes carry **introns**, DNA insertions that are not found in prokaryotic genes. Introns separate **exons**, the coding regions of eukaryotic genes. Transcribed introns are removed from eukaryotic transcripts

during RNA processing, a series of enzymatic reactions that takes place in the nucleus. The mRNA of eukaryotes is polyadenylated at the 3' end, protecting it from exonucleases so that it can traverse the nuclear membrane into the cytosol, where the ribosomes are located; in this case, translation is uncoupled from transcription. Because of this polyadenylation, eukaryotic mRNAs have half-lives of the order of hours to days.

Eukaryotic and prokaryotic ribosomes differ in many respects. Eukaryotic ribosomes are larger and have a sedimentation coefficient of 80S compared with the 70S sedimentation coefficient of prokaryotic ribosomes. The 40S and 60S eukaryotic ribosomal subunits are larger than the corresponding 30S and 50S ribosomal subunits of prokaryotes, and the eukaryotic ribosomes are relatively rich in protein. Significant differences are inherent in the sensitivity of the ribosomal activities to antibiotics (eg, tetracycline), many of which selectively inhibit prokaryotic, but not eukaryotic protein synthesis (see Chapter 9). Recall however that **mitochondrial** ribosomes in eukaryotes resemble those from prokaryotes and are susceptible to bacterial protein synthesis inhibitors.

Regulation of Prokaryotic Gene Expression

Specific proteins, the products of regulatory genes, govern expression of structural genes that encode enzymes. Transcription of DNA into mRNA begins at the **promoter**, the DNA sequence that binds RNA polymerase. The level of gene expression is determined by the ability of a promoter to bind the polymerase, and the intrinsic effectiveness of promoters differ widely. Further controls over gene expression are exerted by regulatory proteins that can bind to regions of DNA near promoters.

Many prokaryotic structural genes that encode a related series of metabolic reactions are clustered on **operons**. This contiguous series of genes are expressed as a single mRNA transcript, and expression of the transcript may be governed by a single regulatory gene. For example, five genes associated with tryptophan biosynthesis are clustered in the *trp* operon of *E. coli*. Gene expression is governed by attenuation, as described below, and is also controlled by repression: Binding of the amino acid tryptophan by a **repressor protein** gives this protein a conformation that allows it to attach to the *trp* **operator**, a short DNA sequence that helps to regulate gene expression. Binding of the repressor protein to the operator prevents transcription of the *trp* genes because the bacterium senses that there is enough tryptophan present and making more would not be in the best interests of the organism's metabolic resources. **Repression** can be viewed as a course-control mechanism, an all-or-none approach to gene regulation. This form of control is independent of attenuation, a fine-tuning mechanism that also is used to govern *trp* gene expression.

Attenuation is a regulatory mechanism of some biosynthetic pathways (eg, the tryptophan biosynthetic pathway)

that controls the efficiency of transcription after transcription has been initiated but before mRNA synthesis of the operon's genes takes place, especially when the end product of the pathway is in short supply. For example, under normal growth conditions, most *trp* mRNA transcripts terminate before they reach the structural genes of the *trp* operon. However, during conditions of severe tryptophan starvation, the premature termination of transcription is abolished, allowing expression of the operon at 10-fold higher levels than under normal conditions. The explanation for this phenomenon resides in the 162 bp regulatory sequence upstream of the *trp* structural genes (Figure 7-11) referred to as the **leader sequence** or *trpL*. The *trp* leader sequence can be transcribed into mRNA and subsequently translated into a 14 amino acid polypeptide with two adjacent tryptophan residues, a sequence that occurs at a very rare occurrence. At the end of *trpL* and upstream of the regulatory signals that control translation of the *trp* structural genes is a **Rho-independent terminator**. The DNA sequence of this region suggests that the encoded mRNA has a high probability of forming **stem loop secondary structures**. These have been named the **pause loop** (1:2), the **terminator loop** (3:4), and the **antiterminator loop** (2:3). Attenuation of the *trp* operon uses the secondary structure of the mRNA to sense the amount of tryptophan in the cell (as *trp*-tRNA) according to the model shown in Figure 7-11.

Prevention of transcription by a repressor protein is called **negative control**. The opposite form of transcriptional regulation—initiation of transcription in response to binding of an **activator protein**—is termed **positive control**. Both forms of control are exerted over expression of the *lac* operon genes associated with fermentation of lactose in *E. coli*. The operon contains three structural genes. Transport of lactose into the cell is mediated by the product of the *lacY* gene. β -Galactosidase, the enzyme that hydrolyzes lactose to galactose and glucose, is encoded by the *lacZ* gene. The product of the third gene (*lacA*) is a transacetylase; the physiologic function of this enzyme for lactose utilization has not been clearly elucidated.

As a by-product of its normal function, β -galactosidase produces allolactose, a structural isomer of lactose. Lactose itself does not influence transcriptional regulation; rather, this function is served by allolactose, which is the **inducer** of the *lac* operon because it is the metabolite that most directly elicits gene expression. In the absence of allolactose, the *lac* repressor, a product of the independently controlled *lacI* gene, exerts negative control over transcription of the *lac* operon by binding to the *lac* operator. In the presence of the inducer, the repressor is released from the operator, and transcription takes place.

Expression of the *lac* operon and many other operons associated with energy generation is enhanced by the binding of **cyclic AMP-binding protein (CAP)** to a specific DNA sequence near the promoter for the regulated operon. The protein exerts positive control by enhancing RNA polymerase activity. The metabolite that triggers the positive

FIGURE 7-11 The attenuation model of bacterial replication. (1) Coupled transcription/translation takes place as for any bacterial gene. (2) RNA polymerase pauses and a 1:2 stem loop forms. (3) The ribosome disrupts the 1:2 stem loop and encounters the two *trp* codons. (4) If enough tryptophan is present, charged *trp*-tRNAs will be present and the ribosomes will translate *trpL*. This causes the RNA polymerase to stop at the Rho-independent terminator composed of a 3:4 stem loop. (Alternate 4) If tryptophan is limiting (no *Trp*-tRNA), the ribosome stalls at the two *trp* codons, while RNA polymerase continues. The 2:3 stem loop forms. (Alternate step 5) The 3:4 terminator cannot form and the RNA polymerase continues transcribing into the *trp* structural genes. This exposes the ribosome binding site (RBS) upstream of *trpE*, allowing translation. (Reproduced with permission from Trun N, Trempey J: *Fundamental Bacterial Genetics*. Copyright © 2004 by Blackwell Science Ltd. With permission from Wiley.)

control by binding to CAP is 3',5'-cyclic AMP (cAMP). This compound, formed in energy-deprived cells, acts through CAP to enhance expression of catabolic enzymes that give rise to metabolic energy.

Cyclic AMP is not alone in its ability to exert control over unlinked genes in *E. coli*. Numerous genes respond to the nucleotide ppGpp (in which "pp" denotes phosphodiester and "G" denotes guanine) as a signal of amino acid starvation,

and unlinked genes are expressed as part of the SOS response to DNA damage.

GENETIC ENGINEERING

Engineering is the application of science to address social needs. Over the past four decades, engineering based on bacterial genetics has transformed biology. Specified DNA fragments can be isolated and amplified, and their genes can be expressed at high levels. The nucleotide specificity required for cleavage by restriction enzymes allows fragments containing genes or parts of genes to be ligated (incorporated) into plasmids (vectors) that can in turn be used to transform bacterial cells. **Clones** carrying specified genes can be identified by **hybridization** of DNA or RNA with labeled **probes** (like that shown in Figure 3-4). Alternatively, protein products encoded by the genes can be recognized either by enzyme activity or by immunologic techniques. Thus, genetic engineering techniques can be used to isolate virtually any gene so that a biochemically recognizable property can be studied or exploited.

Isolated genes can be used for a variety of purposes. **Site-directed mutagenesis** can identify and alter the DNA sequence of a gene. Nucleotide residues essential for gene function can thus be determined and, if desired, altered. With hybridization techniques, DNA can be used as a probe that recognizes nucleic acids corresponding to the complementary sequence of its own DNA. For example, a latent virus in animal tissue can be detected with a DNA probe even in the absence of overt viral infection. The protein products of isolated viral genes offer great promise as vaccines because they can be prepared without genes that encode the replication of viral nucleic acid. For example, the capsid proteins of human papilloma virus have been cloned and expressed. These are referred to as noninfectious virus-like particles (VLPs) and form the basis for a vaccine against transforming strains of this virus. Moreover, proteins such as insulin that have useful functions can be prepared in large quantities from bacteria that express cloned genes.

Preparation of DNA Fragments with Restriction Enzymes

The genetic diversity of bacteria is reflected in their extensive range of **restriction enzymes**, which possess remarkable selectivity that allows them to recognize specific regions of DNA for cleavage. DNA sequences recognized by restriction enzymes are predominantly palindromes (inverted sequence repetitions). A typical sequence palindrome, recognized by the frequently used restriction enzyme *EcoRI*, is GAATTC; the inverted repetition, inherent in the complementarity of the G–C and A–T base pairs, results in the 5' sequence TTC being reflected as AAG in the 3' strand.

The length of DNA fragments produced by restriction enzymes varies tremendously because of the individuality of

DNA sequences. The average length of the DNA fragment is determined in large part by the number of specific bases recognized by an enzyme. Most restriction enzymes recognize four, six, or eight base sequences; however, other restriction enzymes recognize 10, 11, 12, or 15 base sequences. Statistically a restriction enzyme that recognizes four bases yields fragments with an average DNA length of 250 base pairs and therefore is generally useful for analysis or manipulation of small gene fragments. Complete genes are frequently encompassed by restriction enzymes that recognize six bases and produce fragments with an average size of about 4 kbp. Restriction enzymes that recognize eight bases produce fragments with a typical size of 64 kbp and are useful for analysis of large genetic regions. Restriction enzymes that recognize more than 10 bases are useful for construction of a physical map and for molecular typing by pulsed-field gel electrophoresis.

Physical Separation of Differently Sized DNA Fragments

Much of the simplicity underlying genetic engineering techniques lies in the fact that **gel electrophoresis** permits DNA fragments to be separated based on size (Figure 7-12): The smaller the fragment, the more rapid the rate of migration. The overall rate of migration and optimal range of size for separation are determined by the chemical nature of the gel and by the degree of its cross-linking. Highly cross-linked gels optimize the separation of small DNA fragments. The dye **ethidium bromide** forms brightly fluorescent adducts as it binds to DNA so that small amounts of separated DNA fragments can be visualized on gels (Figure 7-12A). Specific DNA fragments can be recognized by probes containing complementary sequences (Figure 7-12B and C).

Pulsed-field gel electrophoresis allows the separation of DNA fragments containing up to 100 kbp that are separated on high-resolution polyacrylamide gels. Characterizations of such large fragments have allowed construction of a physical map for the chromosomes from several bacterial species and have been invaluable in fingerprinting bacterial isolates associated with infectious disease outbreaks.

Cloning of DNA Restriction Fragments

Many restriction enzymes cleave asymmetrically and produce DNA fragments with **cohesive (sticky) ends** that may hybridize with one another. This DNA can be used as a donor with plasmid recipients to form genetically engineered recombinant plasmids. For example, cleavage of DNA with *EcoRI* produces DNA containing the 5' tail sequence AATT and the complementary 3' tail sequence TTAA (Figure 7-13). Cleavage of a plasmid with the same restriction enzyme produces a linear fragment with cohesive ends that are identical to one another. Enzymatic removal of the free phosphate groups from the ends of the digested plasmid ensures that

FIGURE 7-12 **A:** Separation of DNA fragments on the basis of size by electrophoresis through a gel. Smaller fragments migrate more rapidly than large fragments, and over a range determined by the properties of the gel, the distance migrated is roughly proportionate to the logarithm of the size of the fragment. DNA fragments can be visualized on the basis of their fluorescence after staining with a dye. **B:** The size of restriction fragments is determined by the location of restriction sites within the DNA. In this example, a 4.0-kilobase pair (kbp) fragment formed by restriction enzyme *EcoRI* (E) contains respective sites for restriction enzymes *HindIII* (H) and *SalI* (S) at positions corresponding to 1.0 and 3.5 kbp. The electrophoretic pattern in **A** reveals that restriction enzyme E does not cut the 4.0-kbp fragment (first lane); cleavage with restriction enzyme H produces fragments of 3.0 and 1.0 kbp (second lane); cleavage with restriction enzyme S yields fragments of 3.5 and 0.5 kbp (third lane); and cleavage with both H and S forms fragments of 2.5, 1.0, and 0.5 kbp (fourth lane). The 0.5-kbp fragment lying between the S and E sites was selected as a probe to determine DNA with hybridizing sequences as shown in **C**. **C:** Identification of hybridizing fragments. Restriction fragments were separated as in **A**. The hybridization procedure reveals those fragments that hybridized with the 0.5-kbp probe. These are the 4.0-kbp fragment formed by restriction enzyme E, the 3.0-kbp fragment lying between the E and H sites, and the 0.5-kbp fragment lying between the S and H sites.

they will not be ligated to form the original circular plasmid. Ligation in the presence of other DNA fragments containing free phosphate groups produces **recombinant plasmids**, which have DNA fragments as inserts in covalently closed circular DNA. Plasmids must be in a circular form to replicate in a bacterial host.

Recombinant plasmids may be introduced into a bacterial host, frequently *E. coli*, by **forced transformation**. Alternatively, **electroporation** is a procedure that introduces DNA into bacteria using an electrical gradient. Transformed cells may be selected for one or more drug resistance factors encoded by plasmid genes. The resulting bacterial population contains a **library** of recombinant plasmids carrying various cloned inserted restriction fragments derived from the donor DNA. Hybridization techniques may be used to identify bacterial colonies carrying specific DNA fragments (Figure 7-14), or, if the plasmid expresses the inserted gene,

colonies can be screened for the gene product by an antibody specific for the protein produced.

CHARACTERIZATION OF CLONED DNA

Restriction Mapping

Manipulation of cloned DNA requires an understanding of its nucleic acid sequence. Preparation of a **restriction map** is the first step in gaining this understanding. A restriction map is constructed like a jigsaw puzzle from fragment sizes produced by **single digests**, which are prepared with individual restriction enzymes, and by **double digests**, which are formed with pairs of restriction enzymes. Restriction maps are also the initial step toward DNA sequencing because they identify fragments that will provide **subclones** (increasingly smaller fragments of DNA) that may be subjected to

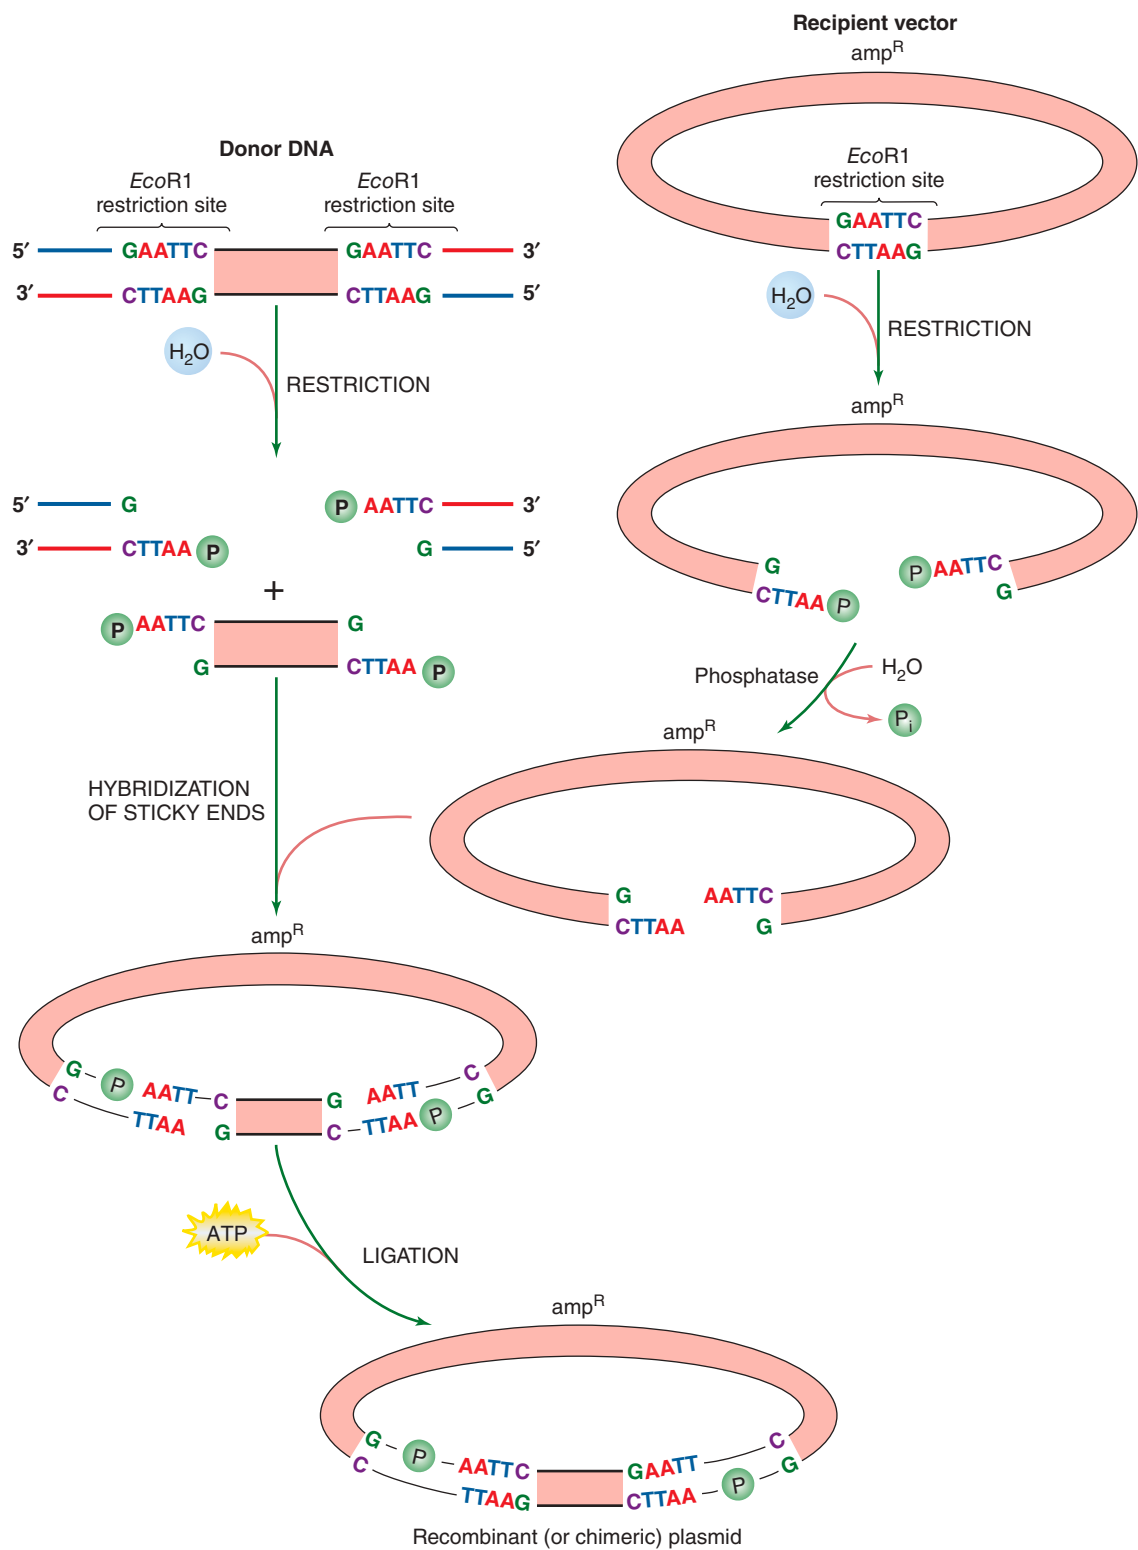

FIGURE 7-13 Formation of a recombinant, or chimeric, plasmid from donor DNA and a recipient vector. The vector, a plasmid that carries an *Eco*R1 restriction site, is cleaved by the enzyme and prepared for ligation by removal of the terminal phosphate groups. This step prevents the sticky ends of the plasmid from being ligated in the absence of an insert. The donor DNA is treated with the same restriction enzyme, and covalently bound circles are formed by ligation. A drug resistance marker, shown as *amp^R* on the plasmid, can be used to select the recombinant plasmids after their transformation into *E. coli*. Enzymes of the host bacterium complete covalent bonding of the circular DNA and mediate its replication.

FIGURE 7-14 Use of probes to identify clones containing a specific fragment of DNA. Colonies may be transferred to a filter and baked so that the cells lyse and the DNA adheres to the filter. The filter can then be treated with a solution containing a suitably labeled DNA probe, which specifically hybridizes to the desired clones. Subsequent autoradiography of the filter identifies these clones (*dark circles*). Alternatively, the clones may be probed with antibodies to determine whether they have synthesized a specific protein product.

more rigorous analysis such as DNA sequencing. In addition, restriction maps provide a highly specific information base that allows DNA fragments, identified based on size, to be associated with specific gene function.

Sequencing

DNA sequencing displays gene structure and enables researchers to deduce the amino acid sequence of gene products. In turn, this information makes it possible to manipulate genes to understand or alter their function. In addition, DNA sequence analysis reveals regulatory regions that control gene expression and genetic “hot spots” particularly susceptible to mutation. Comparison of DNA sequences reveals evolutionary relationships that provide a framework for unambiguous classification of bacterial species. Such comparisons may facilitate identification of conserved regions that may prove particularly useful as specific hybridization probes to detect the organisms or viruses in clinical samples.

The original method of DNA sequence determination used the **Maxam–Gilbert technique**, which relies on the relative chemical lability of different nucleotide bonds. The field now has largely moved to the **Sanger (dideoxy termination) method**, which interrupts elongation of DNA sequences by incorporating dideoxynucleotides into the sequences. Both techniques produce a nested set of oligonucleotides starting from a single origin and entail separation on a sequencing gel of DNA strands that differ by the increment of a single nucleotide. A polyacrylamide sequencing gel separates strands that

differ in length from one to several hundred nucleotides and reveals DNA sequences of varying lengths.

Four parallel lanes on the same gel reveal the relative length of strands undergoing dideoxy termination at adenine, cytosine, guanine, and thymine. Comparison of four lanes containing reaction mixes that differ solely in the method of chain terminating dideoxy nucleotide makes it possible to determine DNA sequence by the Sanger method (Figure 7-15). The relative simplicity of the Sanger method has led to its more general use, but the Maxam–Gilbert technique is widely used because it can expose regions of DNA that are protected by specific binding proteins against chemical modification.

DNA sequencing is greatly facilitated by genetic manipulation of *E. coli* bacteriophage M13, which contains ssDNA. The replicative form of the phage DNA is a covalently closed circle of dsDNA that has been engineered so that it contains a multiple cloning site that permits integration of specific DNA fragments that have been previously identified by restriction mapping. Bacteria infected with the replicative form secrete modified phages containing, within their protein coat, ssDNA that includes the inserted sequence. This DNA serves as the **template** for elongation reactions. The origin for elongation is determined by a DNA **primer**, which can be synthesized by highly automated machines for **chemical oligonucleotide synthesis**. Such machines, which can produce DNA strands containing 75 or more oligonucleotides in a predetermined sequence, are essential for sequencing and for the modification of DNA by site-directed mutagenesis.

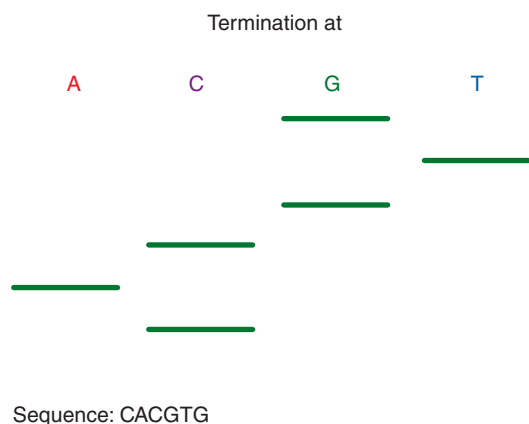

FIGURE 7-15 Determination of a DNA sequence by the Sanger (dideoxy termination) method. Enzymatic elongation of DNA is interrupted by inclusion of dideoxy analogs of the trinucleotides corresponding to A, C, G, and T separately in parallel reaction mixes. The resulting sets of interrupted elongated strands are separated on a sequencing gel, and the sequence can be deduced by noting the base corresponding to each increment of chain length. The sequencing gel is read from the bottom up; each band corresponds to an increase of one base.

Chemically synthesized oligonucleotides can serve as primers for PCR, a procedure that allows amplification and sequencing of DNA lying between the primers. Thus, in many instances, DNA need not be cloned to be sequenced or to be made available for engineering.

The study of biology has been revolutionized by the development of technology that allows sequencing and analysis of entire genomes, ranging from viruses to unicellular prokaryotic and eukaryotic microorganisms to humans. This is facilitated by use of the procedure known as **shotgunning**. In this procedure, the DNA is broken into random smaller fragments to create a fragment library. These unordered fragments are sequenced by automated DNA sequencers and reassembled in the correct order using powerful computer software. Enough fragments are sequenced to ensure adequate coverage of the genome so that when they are assembled, most of the genome is represented without leaving too many gaps. (To achieve this, the entire genome is usually covered five- to eightfold, leaving about 0.1% of the total DNA unsequenced.) After the random fragments have been assembled by areas of overlapping sequence, any remaining gaps can be identified and closed. Advanced data processing permits annotation of the sequence data in which putative coding regions, operons, and regulatory sequences are identified. Already, thousands of microbial genomes have been sequenced. The continued analysis of sequence data from important human pathogens, combined with studies on molecular pathogenesis, will facilitate our understanding of how these organisms cause disease and, ultimately, will lead to better prophylactic and therapeutic strategies.

SITE-DIRECTED MUTAGENESIS

Chemical synthesis of oligonucleotides enables researchers to perform controlled introduction of base substitutions into a DNA sequence. The specified substitution may be used to explore the effect of a predesigned mutation on gene expression, to examine the contribution of a substituted amino acid to protein function, or—based on prior information about residues essential for function—to inactivate a gene. Single-stranded oligonucleotides containing the specified mutation are synthesized chemically and hybridized to single-stranded phage DNA, which carries the wild-type sequence as an insert (Figure 7-16). The resulting partially dsDNA is enzymatically converted to the fully double-stranded replicative form. This DNA, which contains the wild-type sequence on one strand and the mutant sequence on the other, is used to infect a bacterial host by transformation. Replication results in segregation of wild-type and mutant DNA, and the double-stranded mutant gene can be isolated and subsequently cloned from the replicative form of the phage.

ANALYSIS OF DNA, RNA, OR PROTEIN-EXPRESSING CLONES

Hybridization probes (Southern blotting; see Figure 3-4) are used routinely in the cloning of DNA. The amino acid sequence of a protein can be used to deduce the DNA sequence from which a probe may be constructed and used to detect a bacterial colony containing the cloned gene. **Complementary DNA**, or **cDNA**, encoded by mRNA, can be used to detect the gene that encoded that mRNA. Hybridization of cDNA to RNA by **Northern blots** can provide quantitative information about RNA synthesis. Specific DNA sequences in restriction fragments separated on gels can be revealed by **Southern blots**, a method that uses hybridization of DNA to DNA. These blots can be used to detect overlapping restriction fragments. Cloning of these fragments makes it possible to isolate flanking regions of DNA by a technique known as **chromosomal walking**. With **Western blots**, another frequently used detection technique, antibodies are used to detect expression of protein from cloned genes through antibody binding to their protein products.

Probes can be used in a broad range of analytic procedures. Some regions of human DNA exhibit substantial variability in the distribution of restriction sites. This variability is termed **restriction fragment length polymorphism (RFLP)**. Oligonucleotide probes that hybridize with RFLP DNA fragments can be used to trace DNA from a small sample to its human donor. Thus, this technique is valuable to forensic science. Applications of RFLP to medicine include identification of genetic regions that are closely linked to human genes with dysfunctions coupled to genetic disease. This information has been and will continue to be a valuable aid in **genetic counseling**.

FIGURE 7-16 Site-directed mutagenesis. A chemically synthesized primer containing mutation G (in box) is hybridized to a wild-type sequence inserted in DNA from a single-stranded phage. Polymerization reactions are used to form the double-stranded heteroduplex carrying the mutation on one strand. Introduction of this heteroduplex into a host bacterium followed by segregation produces derivation strains carrying replicative forms with either the wild-type insert or an insert that has acquired the chemically designed mutation.

DNA probes offer the promise of techniques for rapidly identifying fastidious organisms in clinical specimens that are difficult to grow in a microbiology laboratory. Furthermore, extensions of the technique afford opportunities to identify pathogenic agents rapidly and directly in infected tissue. Kits for identification of many bacterial and viral pathogens are commercially available.

Application of diagnostic DNA probes requires an appreciation of (1) designing the probes themselves, (2) systems used to label and detect the probes, (3) targets (the DNA to which the probes hybridize), and (4) the conditions of hybridization. Probes may be relatively large restriction fragments derived from cloned DNA or oligonucleotides corresponding to a specific region of DNA. Larger probes may provide greater accuracy because they are less sensitive to single base changes in target DNA. On the other hand, hybridization reactions occur more rapidly with small probes, and they can be designed against conserved regions of DNA in which base substitutions are unlikely to have occurred. Amplification of a target by PCR followed by a detection of the amplified product after hybridization to a probe has proved more sensitive than direct detection methods.

Recently, significant improvements have occurred in molecular diagnostic testing methods, especially those that incorporate nucleic acid amplification technologies such as PCR. Several commercial instruments have become available that combine PCR amplification of target DNA with detection of amplicons in the same closed vessel. This technology has been referred to as **real-time PCR**, implying that PCR amplicons can be detected and quantified as a function of

time. In actuality, “real time” refers to the detection of amplicons after each PCR cycle. Probe detection formats involve detecting fluorophores. Results are semi-quantitative and can be obtained in considerably less time than it takes to perform a conventional PCR assay.

MANIPULATION OF CLONED DNA

Genetic engineering techniques permit separation and entirely independent expression of genes associated with pathogens. Vaccines prepared with engineered genes afford previously unattainable measures of safety. For example, the current Hepatitis B vaccine is comprised only the Hepatitis B surface antigen, absence of any genes associated with replicative viral functions. Vaccination with this cloned product entails no risk of introducing functional virus and it elicits an immune response that prevents hepatitis B virus infection.

Recombinant Strains in the Environment

Major scientific advances have sometimes elicited adverse public reactions, so it is prudent to consider the potential consequences of genetic engineering. Of most immediate concerns are known pathogens that have undergone relatively slight genetic modification. These have been and should be investigated in laboratories specially designed to contain them. The need for containment diminishes after genes for specific functions, such as protein coats, are separated from genes associated with replication or toxicity of a pathogen.

For the most part, standard precautions associated with microbiology laboratories should be observed if for no other reason than they foster habits that are valuable if a potential pathogen should enter the laboratory.

Interesting exceptions to this general rule are engineered organisms that may provide a social benefit if introduced into the environment. Many such organisms derive from nonpathogenic bacteria that occur naturally with a frequency as high as 10^5 /g of soil. The available evidence suggests that predation and competition rapidly eliminate engineered bacterial strains after they are introduced into the environment. The primary challenge would ideally be to maintain biologically beneficial, engineered organisms in the environment rather than to eliminate them. However, this is not without social consequence. Among the examples of engineered organisms are *Pseudomonas* strains that produce a protein favoring formation of ice crystals. The value of these wild-type organisms is appreciated by ski slope owners, who have deliberately introduced the bacteria into the environment without arousing any public concern. An unfortunate side effect of the introduction of these organisms is that the ice crystals they promote can injure sensitive crops such as lettuce during seasons in which light frost is likely. Mutant bacteria that do not form ice crystals were designed by microbiologists who hoped that the mutant organisms might protect lettuce crops by temporarily occupying the niche normally inhabited by the ice-forming strains; however, attempts to use the mutant organisms in field studies were met with substantial protest, and studies were conducted only after lengthy and expensive legal delays. The legal precedents that have emerged from this and more recent related applications will establish guidelines for the progressive and beneficial use of genetic engineering techniques and facilitate determination of situations in which extreme caution is justified.

CHAPTER SUMMARY

- Describe the basic structure of a nucleotide, base pairing, and the linear and three-dimensional structure of double-stranded DNA.
- Understand the differences between RNA and DNA with regard to structure, complexity, and relative sizes.
- Know the different functions of RNA, for example, mRNA, rRNA, tRNA, and ribozymes.
- Be able to detail the basic differences between a prokaryotic and eukaryotic chromosome.
- Specifically explain the terms associated with bacterial recombination and genetic transfer—transposons, conjugation, transformation, and transduction.
- Describe the mechanisms of bacterial mutation and gene rearrangement.
- Be able to articulate the fundamental means by which bacterial genes are transcribed, including the concepts of coupled transcription and translation, activator, repressor, and attenuation.
- Appreciate the differences between eukaryotic versus prokaryotic ribosomes and describe the steps in prokaryotic ribosomal translation.
- Understand the concept of genetic engineering and discuss the important tools involved in this process (eg, restriction enzymes, ligation, cloning, and expression).
- Describe the tools involved in the characterization of DNA—restriction mapping, sequencing, mutagenesis, hybridization, and other detection methods.
- Appreciate the benefits and possible negative aspects of recombinant bacteria in the environment.

REVIEW QUESTIONS

- Mutations in bacteria can occur by which of the following mechanisms?
 - Base substitutions
 - Deletions
 - Insertions
 - Rearrangements
 - All of the above
- The form of genetic exchange in which donor DNA is introduced to the recipient by a bacterial virus is
 - Transformation
 - Conjugation
 - Transfection
 - Transduction
 - Horizontal transfer
- The enzyme DNase degrades naked DNA. If two strains of bacteria from the same species were mixed in the presence of DNase, which method of gene transfer would be the most likely inhibited?
 - Conjugation
 - Transduction
 - Transformation
 - Transposition
 - All of the above
- Replication of which of the following requires physical integration with a bacterial replicon?
 - Single-stranded DNA bacteriophage
 - Double-stranded DNA bacteriophage
 - Single-stranded RNA bacteriophage
 - Plasmid
 - Transposon
- The formation of a mating pair during the process of conjugation in *E. coli* requires
 - Lysis of the donor
 - A sex pilus
 - Transfer of both strands of DNA
 - A restriction endonuclease
 - Integration of a transposon
- Why do bacteria contain restriction enzymes?
 - To cleave RNA for incorporation into ribosome
 - To extend the length of bacterial chromosomes
 - To prevent foreign DNA from incorporating into a bacterial genome
 - To process the exons from prokaryotic mRNA
 - To proteolytically cleave nuclear promoters

7. If the arrangement of bases on the coding DNA strand is 5'CATTAG3', then a corresponding strand of mRNA will be which one of the following?
- (A) 5'GTAATC3'
 - (B) 5'CUAAUG3'
 - (C) 5'CTAATG3'
 - (D) 5'GUAUUC3'
 - (E) 5'CATTAG3'

SECTION II IMMUNOLOGY

C H A P T E R

8

Immunology

OVERVIEW

The daunting role of the immune system is to afford protection. It serves as a host defense system against infectious diseases and foreign (nonself) antigens. To accomplish this goal, the immune system is equipped with a rapid response mechanism, exquisite specificity, adaptability, an intricate regulatory network, and memory.

Over the past several decades, dramatic progress has taken place in the field of immunology. As a consequence, significant advances have been realized not only in the research realm but also in the diagnostic and clinical arena. These advances have allowed us to better understand how the immune system works and have provided insight into a variety of immune disorders, such as infectious diseases, allergy, autoimmunity, immunodeficiency, cancer, and transplantation. This information has led to better diagnosis, new treatment strategies, and improved management for patients with these disorders.

This chapter focuses on the basic principles of immunology, particularly as they relate to response to infection. More detailed discussions on the various aspects of the immune system are available in the reference section.

The Immune Response

As the immune system defends the host against pathogens, it uses different recognition systems to effectively eliminate the invading pathogen or its products. A response generated against a potential pathogen is called an **immune response**. The first line of defense, which is nonspecific to the invading pathogen, is rapidly mobilized at the initial site of infection but

lacks immunologic memory and is called **innate immunity**. The second defense system is called **adaptive immunity**. It is specific for the pathogen and confers protective immunity to reinfection with that pathogen. Adaptive immunity can specifically recognize and destroy the pathogen because lymphocytes carry specialized cellular receptors and produce specific antibodies. A protein that is produced in response to a particular pathogen is called the **antibody**, and the substance that induces the production of antibodies is called the **antigen**. In summary, the innate immune response is effective and critical in eliminating most pathogens. However, if this initial mechanism fails, the adaptive immune response is induced that specifically confronts the pathogen and establishes immunity to that invading pathogen. Hence, both systems interact and collaborate to achieve the final goal of destroying the pathogen.

INNATE IMMUNITY

Innate immunity is an immediate response to a pathogen that does not confer long-lasting protective immunity. It is a non-specific defense system and includes barriers to infectious agents, such as the skin (epithelium) and mucous membranes. It also includes many immune components important in the adaptive immune response, including phagocytic cells, natural killer (NK) cells, toll-like receptors (TLRs), cytokines, and complement.

Barrier Functions of Innate Immunity

Few microorganisms can penetrate body surfaces. These surfaces have an **epithelial cell layer** as their barrier, which is

present in the **skin**, airways, gastrointestinal (GI) tract, and genitourinary tract. The epithelial cell layer has tight junctions and produces a number of powerful antimicrobial peptides that help provide protection against invading pathogens. Lysozyme is an example of an antimicrobial peptide that dissolves some bacterial cell walls. Another major peptide of innate host defense with antimicrobial properties is **defensin**. Defensins are positively charged peptides located primarily in the GI and lower respiratory tracts that create holes in bacterial cell walls and hence disrupt the bacterial membrane. Neutrophils in the small intestine contain azurophilic granules that house the α -defensins that are released following TLR activation, whereas epithelial cells in the respiratory tract secrete a different defensin, called **β -defensin**. The α -defensins have also been shown to possess antiviral activity. For example, α -defensins can inhibit HIV (human immunodeficiency virus) binding to the CXCR4 (C-X-C chemokine receptor type 4) receptor and in this way interfere with virus entry into the cell.

The mucosal epithelium of the respiratory tract offers another mode of protection from infection. **Mucus**, a complex mixture of mucins, proteins, proteases, and protease inhibitors, is a major component of the mucosal epithelium. Some bacteria attach to the surface epithelial cells by means of adhesive bacterial surface proteins (eg, the pili of gonococci and *Escherichia coli*). However, the presence of mucus limits bacterial adhesion to these cell surfaces. Also, once entrapped in the mucus, the bacteria are removed by ciliary clearance. Thus, the mucosal surface and the ciliated epithelial cells tend to inhibit microbial adhesion and limit exposure time. Likewise, the GI tract has mechanisms to inhibit bacteria. The acidity of the stomach and the proteolytic enzymes of the small intestine make this environment hostile to many bacteria.

An additional barrier to microbial invasion is the effect of the chemical environment. For example, the presence of an acidic pH in sweat and sebaceous secretions and, as mentioned previously, the low pH of the stomach have antimicrobial properties. Moreover, the production of fatty acids on the skin also tends to eliminate pathogenic organisms.

Mechanisms of Innate Immunity

Although innate immunity does not generate antigen specific protective immunity and does not rely on specific pathogen recognition, it, nevertheless, provides a powerful line of defense. In addition, to the physiologic barriers of protection, the innate system has both cells and proteins (such as, cytokines and complement) at its disposal. Phagocytic leukocytes, such as polymorphonuclear neutrophilic leukocytes (neutrophils), and macrophages along with NK cells are the primary cellular components to combat microbes. The interaction of the invading microbe with these cells and other cells throughout the body triggers the release of complement and numerous cytokines. Many of these cytokines are pro-inflammatory molecules such as interleukin-1 (IL-1), tumor

necrosis factor- α (TNF- α), interleukin-6 (IL-6), and the interferons (IFNs), and are induced through TLR interactions. Armed with these special tools, the host initiates its defense against the invading pathogen.

A. Microbial Sensors

When a pathogen enters the skin, it is confronted by macrophages and other phagocytic cells possessing “microbial sensors.” There are three major groups of microbial sensors: (1) **TLRs**, (2) **NOD-like receptors (NLRs)**, and (3) **RIG-I-like helicases and MDA-5**. The TLRs are the best studied of the microbial sensors. They are a family of evolutionary conserved pattern recognition receptors (PRRs) that recognize pathogen-associated molecular patterns (PAMPs). They constitute a first line of defense against a variety of pathogens and play a critical role in initiating the innate immune response. TLRs are type 1 transmembrane proteins with an extracellular domain, a single transmembrane α -helix, and a cytoplasmic domain. TLR recognition of these specific microbial patterns leads to a signal transduction cascade that generates a rapid and robust inflammatory response marked by cellular activation and cytokine release.

To date, 10 human TLRs have been identified, and each receptor appears to be involved in the recognition of a unique set of microbial patterns. For example, TLR2 recognizes various ligands (eg, lipoteichoic acid) expressed by Gram-positive bacteria, whereas TLR3 engages double-stranded RNA (dsRNA) in viral replication. TLR1 and TLR6 recognize multiple diacyl peptides (eg, mycoplasma), whereas TLR4 is specific for Gram-negative lipopolysaccharides (LPS). TLR5, on the other hand, recognizes bacterial flagellin, and TLR7 and TLR8 interact with single-stranded RNA (ssRNA) in viral replication and TLR9 binds bacterial and viral DNA. At present, TLR10 remains an orphan receptor.

Another large family of innate receptors, NLRs, are located in the cytoplasm and serve as intracellular sensors for microbial products. They activate the nuclear factor kappa-light-chain-enhancer of activated B cells (NF- κ B) pathway and drive inflammatory responses similar to the TLRs. The third group of microbial sensors is the RIG-I-like helicases and melanoma differentiation-associated protein 5 (MDA5). These are cytoplasmic sensors of viral ssRNA. The engagement of ssRNA with these sensors triggers the production of the type 1 IFNs. These IFNs are highly effective inhibitors of viral replication.

B. Cellular Components and Phagocytosis

The key elements of effective innate immunity are responses that are rapid, nonspecific, and of short duration. These features are the hallmark of the phagocytic process. During infection, circulating phagocytic cells increase and can participate in **chemotaxis, migration, ingestion, and microbial killing**. Any antigen (microorganism) that enters the body through the lymphatics, lung, or bloodstream is engulfed by phagocytic cells.

Therefore, phagocytes, present in the blood, lymphoid tissue, liver, spleen, lung, and other tissues, are the cells responsible for the uptake and removal of foreign antigen. Phagocytes include (1) **monocytes** and **macrophages**; (2) **granulocytes**, including **neutrophils**, **eosinophils**, and **basophils**; and (3) **dendritic cells**. **Monocytes** are small leukocytes that circulate in the blood and mature into **macrophages** that can be found in almost all tissues. For example, they are known as Kupffer cells in the liver and microglial cells in the nervous tissue. Macrophages are critical cells that engulf and kill pathogens, process and present antigen, and regulate immune reactivity by producing a variety of molecules (eg, cytokines).

Granulocytes are leukocytes that contain densely staining granules. **Neutrophils** have a short half-life and are important phagocytic cells that destroy pathogens within intracellular vesicles. **Eosinophils** and **basophils** are less abundant and store granules containing enzymes and toxic proteins that can be released upon activation of the cells. **Dendritic cells** are also phagocytic and can degrade pathogens; however, their main role is to activate T cells in the adaptive immune response by acting as an antigen-presenting cell and by producing regulatory cytokines (eg, IFN- α).

Phagocytosis is a multistep process whereby a phagocytic cell, like a neutrophil, recognizes the pathogen, ingests it, and then destroys the engulfed organism. Once a pathogen enters the blood or tissue, the phagocytic cell migrates to that site. This migration is dependent on the release of chemoattractant signals produced by either the cells of the host or the pathogen. One chemoattractant is IL-8 (CXCL8), a potent chemotactic cytokine, that attracts neutrophils. More recently IL-17 has been shown to induce IL-8 and as a consequence, this chemokine now recruits immune cells to peripheral tissues. In the initial stage of the migration process, neutrophils attach to the endothelial cell surface by means of adhesion molecules, such as P-selectin. Neutrophils follow the chemokine attraction and migrate from the circulation through the endothelium into the tissues and to the site of infection. Here the neutrophil recognizes, engulfs, and internalizes the pathogen into an endocytic vesicle called a **phagosome**. Once inside the neutrophil, the pathogen is killed.

There are several antimicrobial mechanisms used by phagocytes to eliminate the pathogen. For example, (1) acidification occurs within the phagosome. The phagosome pH is 3.5–4.0, and this level of acidity is bacteriostatic or bactericidal. (2) Toxic oxygen-derived products are generated and include superoxide O_2^- , hydrogen peroxide H_2O_2 , and singlet oxygen O_2^+ . (3) Toxic nitrogen oxides are also produced, and nitric oxide NO is formed. (4) Phagocytic cells generate antimicrobial peptides that participate in pathogen killing. In the macrophage, cathelicidin and macrophage elastase-derived peptides are found. The neutrophil, on the other hand, is rich in α -defensins, β -defensin, cathelicidin, and lactoferricin. All of these mechanisms are used by the phagocytes to destroy the pathogen. When the neutrophil completes its mission, it undergoes apoptosis and dies.

As already mentioned, phagocytosis can occur without antibody. However, phagocytosis is more efficient when antibodies are available to coat the surface of bacteria and facilitate their ingestion. This process is called **opsonization**, and it can occur by the following mechanisms: (1) antibody alone can act as opsonin, (2) antibody and antigen can trigger the complement system (via the classic pathway) to generate opsonin, and (3) opsonin may be produced when the alternative pathway is activated and C3 is generated. Macrophages have receptors on their membranes for the Fc portion of an antibody and for the complement component C3. Both of these receptors facilitate the phagocytosis of the antibody-coated pathogen.

C. Natural Killer Cells

Natural killer (NK) cells are large, granular lymphocytes morphologically related to T cells, which make up 10–15% of blood leukocytes. NK cells contribute to innate immunity by providing protection against viruses and other intracellular pathogens. NK cells have the ability to recognize and kill virus-infected cells and tumor cells. NK cells express two types of surface receptors: (1) lectin-like NK-cell receptors that bind proteins not carbohydrates and (2) killer immunoglobulin-like receptors (KIRs) that recognize the major histocompatibility complex (MHC) class I molecules. These NK-cell receptors have both activation and inhibition properties. NK cells contain large amounts of granzyme and perforin, substances that mediate the cytotoxic actions of NK cells.

In addition, when antibody production is initiated in the adaptive immune response, NK cells play a critical role in **antibody-dependent cellular cytotoxicity (ADCC)**. In this process, specific antibody binds to the target cell surface. The NK cell has Fc receptors that bind to the Fc portion of the attached antibody and kill the cell. This property allows the NK cell another opportunity to inhibit the replication of viruses and intracellular bacteria.

NK cells and the IFN system are both integral parts of innate immunity that communicate with each other. NK cells are one of the three primary sources of IFN- γ , a potent antiviral and immunoregulating cytokine. Moreover, the lytic activity of NK cells is enhanced by the type 1 IFNs (IFN- α and IFN- β). These two cytokines are actually induced by the invading virus.

Innate lymphoid cells (ILCs) are a recently described group of innate immune cells that play a key role in regulating tissue immunity. Although these cells can be found in lymphoid and non-lymphoid organs, they have been reported to preferentially populate the barrier tissues of the skin, intestine, and lung. Because of their unique location, ILCs are among the first immune cells to respond to pathogens. These cells are defined by their lymphoid morphology and their lack of cell lineage markers for T cells, B cells, and other immune cells. To date, three types of ILCs have been identified by their cytokine profile and distinct transcription

factors: ILC1 produces IFN- γ , ILC2 produces IL-5 and IL-13, and ILC3 produces IL-17A and IL-22. In the main, these cells play a major role in protecting the individual; however, recently they have been implicated in pathogenesis of certain inflammatory skin disorders, such as psoriasis.

D. Complement System

The complement system is another key component of innate immunity. This system consists of approximately 30 proteins found in the serum or on the membrane of selected cells that interact in a cascade. When complement is activated, it initiates a series of biochemical reactions that ultimately culminate in cellular lysis or destruction of the pathogen. As described later in this chapter, there are three complement pathways: classical, alternative, and lectin. Even though each has a different initiating mechanism, they all result in the lysis of the offending invader. The alternative and lectin pathways serve as critical first lines of defense and provide immediate protection against microorganisms. The alternative complement pathway can be activated by microbial surfaces and it can proceed in the absence of antibody. Likewise, the lectin pathway also bypasses antibody and uses a lectin, mannose-binding lectin (MBL), to initiate events. The complement proteins can achieve their defense mission in several ways, including opsonization, lysis of bacteria, and amplification of inflammatory responses through the anaphylatoxins, C5a and C3a. The complement system is described in more detail later in this chapter.

Some microbes have acquired mechanisms to sabotage the complement system and evade the immune response. For example, poxviruses, such as vaccinia virus and smallpox, encode a soluble protein with complement regulatory activity that leads to inhibition of the complement system.

E. Mediators of Inflammation and the Interferons

In the section on mechanisms of innate immunity, it was mentioned that various cells and complement components of innate immunity orchestrate their effects through the production of soluble mediators. These mediators include cytokines, prostaglandins, and leukotrienes. Here in this section, the role of these mediators in inflammation is outlined. A separate detailed description on cytokines is found in the section on adaptive immune response.

Injury to tissue initiates an inflammatory response. This response is dominated mainly by soluble mediators, referred to as cytokines. **Cytokines** may include inflammatory and anti-inflammatory cytokines, chemokines, adhesion molecules, and growth factors. During the innate immune response, leukocytes, such as macrophages, release a variety of cytokines, including IL-1, TNF- α , and IL-6. The other mediators released from activated macrophages and other cells include prostaglandins and leukotrienes. These inflammatory mediators regulate changes in local blood vessels. This begins with dilation of local arterioles and capillaries. During dilation, plasma escapes and accumulates in the

area of injury. Fibrin is formed which occludes the lymphatic channels, limiting the spread of organisms.

A second effect of these mediators is to induce changes in the expression of adhesion molecules expressed on the surface of endothelial cells and leukocytes. Adhesion molecules (eg, selectins and integrins) cause leukocytes to attach to the endothelial cells and thereby promote their movement across the vessel wall. Thus, cells stick to the capillary walls and then migrate out (extravasation) of the capillaries in the direction of the irritant. This migration (**chemotaxis**) is stimulated by proteins in the inflammatory exudate, including some chemokines. A variety of cell types, including macrophages and endothelial cells, can produce chemokines. Once the phagocytic cells migrate to the site of infection, they can initiate the engulfment of microorganisms.

Fever is another common systemic manifestation of the inflammatory response and is a cardinal symptom of infectious disease. The main regulator of body temperature is the thermoregulatory center in the hypothalamus. Among the substances capable of inducing fever (pyrogens) are endotoxins of Gram-negative bacteria and cytokines (eg, IL-1, IL-6, TNF- α , and the interferons) released from a variety of cells.

The **interferons** are critical cytokines that play a key role in defense against virus infections and other intracellular organisms, such as *Toxoplasma gondii*. Although the IFNs were first identified in 1957 as antiviral proteins, they are now recognized as critical immunoregulating proteins capable of altering various cellular processes, including cell growth, differentiation, gene transcription, and translation. The IFN family consists of three groups. Type I IFNs comprise numerous genes and primarily include IFN- α and IFN- β . Type II IFN consists of a single gene that produces IFN- γ . IFN- λ is a third group of IFN-like cytokines that have more recently been described. Virus infection itself triggers the production of type I IFNs. Following virus entry into a cell, the virus initiates replication and the viral nucleic acid interacts with specific microbial sensors (TLR3, TLR7, TLR 9, RIG-1, and MDA-5). This interaction triggers cellular production of IFN that is secreted from the infected cell. In contrast, the type II IFN, IFN- γ , is produced by activated NK cells in innate immune responses and by specifically sensitized T cells in adaptive immune responses. Moreover, the cytokines IL-2 and IL-12 can trigger T cells to produce IFN- γ .

The IFN system consists of a series of events leading to protection of a cell from virus replication. Once the IFN is produced by the infected cell or an immune activated NK cell or T cell, the IFN binds to its specific receptor on the surface of an uninfected cell. The IFN receptor interaction activates the JAK, STAT signaling pathways. This process triggers activation of genes that initiate production of selected proteins that inhibit virus replication. All of the IFNs share overlapping biological activities such as antiviral actions, antiproliferative actions, and immunoregulatory actions. However, they also have unique functions that are not overlapping. For example, IFN- β is used successfully to treat patients with multiple sclerosis, whereas IFN- γ has been shown to exacerbate this

disease. These potent actions of the IFNs and the advances in biotechnology are the underlying factors that have identified the clinical relevance of the IFNs. In fact, many of the IFNs have been approved by the U.S. Food and Drug Administration (FDA) for the treatment of infections, malignancies, autoimmunity, and immunodeficiency.

ADAPTIVE IMMUNITY

Unlike innate immunity, adaptive immunity is highly specific, has immunologic memory, and can respond rapidly and vigorously to a second antigen exposure (Table 8-1). The adaptive immune response involves antibody-mediated and cell-mediated immune responses. An overview of the components and their interactions during the adaptive immune response is outlined as follows, and details are presented throughout this chapter.

Cellular Basis of the Adaptive Immune Response

Lymphoid cells play a significant role in the adaptive immune response. During embryonic development, blood cell precursors (hematopoietic stem cells) originate in the fetal liver and other tissues; in postnatal life, the stem cells reside in the bone marrow. Stem cells may differentiate into cells of the myeloid or lymphoid series. The lymphoid progenitor cells develop into two main lymphocyte populations: B cells and T cells.

Stem cells destined to become B lymphocytes develop in the bone marrow. They rearrange their immunoglobulin genes and express a unique receptor for antigen on their cell surface. Following this step, they migrate to a secondary

lymphoid organ (eg, the spleen) and may be activated by an encounter with antigen to become antibody-secreting plasma cells.

T cells are lymphocytes that are produced in the bone marrow but travel to the thymus to mature. Here, they undergo variable diverse joining (VDJ) recombination of their β chain T-cell receptor (TCR) DNA and their α chain TCR DNA. Once TCR rearrangement has occurred and positive and negative selection has terminated, these cells form T-cell subclasses with specific functions (eg, CD4 T cells and CD8 T cells). They are the source of cell-mediated immunity.

Figure 8-1 presents a summary of the specific immune processes that are reviewed in this section. The two arms of the immune response, cell-mediated and antibody-mediated, develop concurrently. In the **antibody-mediated** immune response, CD4 T lymphocytes recognize the pathogen’s antigens bound to the class II MHC molecules on the surface of an antigen-presenting cell (APC) (eg, macrophage, dendritic, and B cell), and as a consequence of this interaction, cytokines are produced that stimulate B cells to express antibodies that display specificity for the antigen. The B cells undergo clonal proliferation and differentiate into plasma cells. In the **cell-mediated** immune response, the antigen–MHC class II complex is recognized by the CD4 T lymphocyte, whereas the antigen–MHC class I complex is recognized by CD8 T lymphocytes. Both subsets of T cells produce cytokines, become activated, and expand by clonal proliferation. The **CD4** T cells that develop stimulate B cells to produce antibodies and promote delayed hypersensitivity while the **CD8** T cells direct their activity mainly at the destruction of cells in tissue grafts, tumor cells, or virus-infected cells.

Antigens

An antigen is a substance that reacts with an antibody. Immunogens induce an immune response and most antigens are also immunogens. There are a wide variety of features that largely determine immunogenicity. They include the following: (1) **Recognition of foreignness:** Generally, molecules recognized as “self” are not immunogenic. To be immunogenic, molecules must be recognized as foreign (“nonself”). (2) **Size:** The most potent immunogens are usually large, complex proteins. Molecules with a molecular weight less than 10,000 are weakly immunogenic, and as expected very small molecules are nonimmunogenic. Some small molecules, called **haptens**, become immunogenic only when linked to a carrier protein. An example is seen with lipids and amino acids that are nonimmunogenic haptens. They require conjunction with a carrier protein or polysaccharide before they can be immunogenic or generate an immune response. (3) **Chemical and structural complexity:** Chemical complexity is another key feature of immunogenicity. For example, amino acid homopolymers are less immunogenic than heteropolymers that contain two or more different amino acids. (4) **Genetic constitution of the host:** Because of differences in MHC alleles, two strains of the same species of

TABLE 8-1 Major Features: Innate vs. Adaptive Immune Response

Innate	Adaptive
Characteristics	
Rapid, immediate response	Slow response
Antigen nonspecific	Highly antigen specific
No memory, not long-lasting protection	Induces memory, responds rapidly and vigorously to second antigen exposure
Immunologic Components	
Natural barriers to infection: skin, mucous membranes	
Cells: Phagocytes, NK cells, innate lymphoid cells	T lymphocytes-cell mediated, B lymphocytes-antibody mediated, APCs
Mediators: Complement, defensins, cytokines, sensors (TLR, NOD-like receptors, RAG-1)	Secreted molecules (cytokines, chemokines, complement)

FIGURE 8-1 Schematic diagram of the cellular interactions in the immune response.

animal may respond differently to the same antigen. (5) **Dosage, route, and timing of antigen administration:** Other factors that affect immunogenicity include concentration of antigen administered, route of administration, and timing of antigen administration.

These concepts of immunogenicity are important for designing vaccines in which enhancing immunogenicity is key. However, methods to reduce immunogenicity are also a consideration in protein drug design. This can be seen in an individual who may respond to a certain drug and produce anti-drug antibodies. These anti-drug antibodies may inhibit drug efficacy.

Finally, it should be noted that it is possible to enhance the immunogenicity of a substance by combining it with an **adjuvant**. Adjuvants are substances that stimulate the immune response by facilitating uptake into APCs.

Antigen Recognition Molecules

During the immune response a recognition system capable of distinguishing self from nonself is essential for effective

immunity. This section of the chapter concentrates on the molecules used to recognize foreign antigens. Molecules of the MHC and antigen presentation are reviewed first, followed by an overview of the structure and function of antibodies and lastly, an outline of the specific receptors for antigen recognition (ie, the B-cell receptor [BCR] and the TCR for antigen) is presented.

The Major Histocompatibility Complex

Historically, the major histocompatibility complex (MHC) was first discovered as a genetic locus that encoded a group of antigens responsible for the rejection of tumor grafts. It is now known that the gene products of this region are the major antigens recognized in transplantation rejection. It is also clear that the MHC molecules bind peptide antigens and present them to T cells. Hence, these molecules are responsible for T-cell antigen recognition and play a significant role in controlling a variety of basic immunologic functions. It should also be noted that the TCR is different from antibody. Antibody molecules bind antigen directly, whereas the TCR

TABLE 8-2 Important Features of Human MHC Classes I and II Gene Products

	Class I	Class II
Genetic loci (partial list)	HLA-A, -B, and -C	HLA-DP, -DQ, and -DR
Polypeptide composition	MW 45,000 + β_2 M (MW 12,000)	α chain (MW 33,000), β chain (MW 29,000), Ii chain (MW 30,000)
Cell distribution	Most nucleated somatic cells, except cells of the brain and retina	Antigen-presenting cells (macrophages, dendritic cells, B cells, etc) and IFN- γ -activated cells
Present peptide antigens to	CD8 T cells	CD4 T cells
Size of peptide bound	8–10 residues	10–30 or more residues

only recognizes peptide antigens presented in the context of the MHC molecule on the APC. The TCR is specific for antigen, but the antigen must be presented on a self-MHC molecule. The TCR is also specific for the MHC molecule. This is known as *MHC restriction*.

The MHC is a cluster of well-studied genes closely associated in humans on chromosome 6. The human MHC is called the **human leukocyte antigen (HLA)** complex. Among the many important genes in the human MHC are those that encode the classes I, II, and III MHC proteins. As outlined in Table 8-2, MHC class I proteins are encoded by the HLA-A, B, and C genes. These proteins are made up of two chains: (1) a transmembrane glycoprotein of MW 45,000, non-covalently associated with (2) a non-MHC-encoded polypeptide of MW 12,000 that is known as β_2 -microglobulin. MHC class I molecules are expressed on nearly all nucleated cells in the body. Key exceptions are observed on cells in the retina and brain.

Class II proteins are encoded by the HLA-D region. The MHC class II proteins consist of three main families: the HLA-DP-, DQ-, and DR-encoded molecules (Table 8-2). This locus controls immune responsiveness and different allelic forms of these genes confer differences in the ability of an individual to mount an immune response.

The HLA-D locus-encoded molecules are cell surface heterodimers that contain two subunits designated α and β that have molecular weights of approximately 33,000 and 29,000 Da, respectively. Unlike class I proteins, the MHC class II proteins have a rather restricted tissue distribution and are constitutively expressed on macrophages, dendritic cells, and B cells. However, the expression of these molecules on other cell types (eg, endothelial cells or epithelial cells) requires induction by IFN- γ .

The MHC class I locus also contains genes that encode proteins required in antigen processing (eg, transporters associated with antigen processing [TAPs]) (Figure 8-2). The

MHC class III locus encodes complement proteins and several cytokines.

The MHC classes I and II genes exhibit extraordinary genetic variability. Genetic mapping studies showed that there is a high degree of polymorphism in the MHC and different individuals generally express different MHC allelic variants (MHC restriction). It has been noted that over 300 different allelic variants have been defined at some HLA loci. Currently, the MHC genes are the most polymorphic genes known. Each individual inherits a restricted set of alleles from his or her parent. A cluster of tightly linked MHC genes are inherited as a block or **haplotype**.

In 1987, the three-dimensional structure of the MHC classes I and II proteins was revealed using x-ray crystallography. This elegant work provided critical information on how the MHC proteins function and trigger the immune response. X-ray analysis of the **MHC class I protein** (Figure 8-3) demonstrates that the entire structure looks like a **cleft** whose sides are formed by the α helices and whose floor is shaped by the β -pleated sheets. The x-ray analysis also shows that the cleft is occupied by a peptide. In essence, the TCR sees the peptide antigen bound in a cleft provided by the MHC protein. Figure 8-4A illustrates this interaction.

The MHC proteins display broad specificity for peptide antigens. In fact, many different peptides can be presented by a different MHC allele. A key to this model is that the MHC polymorphism allows for the binding of many specific and different peptides in the cleft. This means that different alleles can bind and present different peptide antigens.

Antigen Processing and Presentation

Antigen processing and presentation represent the hallmark of the adaptive immune response. This complex mechanism of antigen recognition begins with antigens that become associated with self-MHC molecules for presentation to T cells with appropriate receptors. Proteins from exogenous antigens, such as bacteria, are internalized by the APC (dendritic cells or macrophages) and undergo denaturation or partial proteolysis in the endocytic vesicles within the APC. While in the endosomal compartment, these peptide fragments fuse with exocytic vesicles containing MHC class II molecules. As noted in Figure 8-2, this step exposes the appropriate linear peptide fragment that eventually becomes expressed on the surface of the APC (as the peptide-MHC complex).

The MHC class II molecules are synthesized in the rough endoplasmic reticulum (ER) and then they proceed out through the Golgi apparatus. The invariant chain, a polypeptide that helps transport the MHC molecules, complexes with the MHC class II complex in an endosome. This vesicle is called the **MHC class II compartment**. This invariant chain is useful and blocks the binding of self-endogenous cellular peptides into the MHC class II complex. The invariant chain is now enzymatically removed. Through a series of steps, the MHC class II binds exogenous antigen (peptide fragments) and is transported to the cell membrane for presentation.

FIGURE 8-2 Antigen-processing pathways (MHC classes I and II). (Modified and reproduced with permission from Parslow TG, Stites DP, Terr AI, et al [editors]: *Medical Immunology*, 10th ed. McGraw-Hill, 2001, p. 89. © McGraw-Hill Education.)

The interaction of endogenous antigens within a virus-infected cell and the MHC class I molecule is outlined in Figure 8-2. In brief, cytosolic proteins are broken down by a proteolytic complex called the **proteasome**. The cytosolic peptides gain access to nascent MHC class I molecules in the rough ER via the peptide transporter systems (TAPs). The TAP genes are also encoded in the MHC. Within the lumen of the ER, peptide antigens approximately 8–10 residues in length complex with nascent MHC class I proteins and cooperate with β_2 -microglobulin to create a stable, fully folded MHC class I-peptide antigen complex that is then transported to the cell surface for display and recognition by CD8 cytotoxic T cells. The binding groove of the class I molecule is more constrained than that of the class II molecule, and therefore, shorter peptides are found in class I than in

class II MHC molecules. Once the cytotoxic T cell recognizes the MHC class I peptide antigen, it can now kill the virus-infected cell.

Several viruses attempt to defeat the immune response by interfering with the antigen-processing pathways. For example, an HIV Tat protein is able to inhibit expression of class I MHC molecules. A herpesvirus protein binds to the TAPs, preventing transport of viral peptides into the ER, where class I molecules are being synthesized. A consequence of these inhibitory mechanisms is that the infected cells are not recognized by cytotoxic lymphocytes.

Some bacterial and viral antigens are able to activate large numbers of T cells through a special pathway. These proteins are called **superantigens**. Superantigens do not require processing and therefore are able to bind to MHC molecules

FIGURE 8-3 Diagrammatic structure of a class I HLA molecule. (Reproduced with permission from Macmillan Publishers Ltd: Bjorkman PJ, et al: Structure of the human class I histocompatibility antigen, HLA-A2. *Nature* 1987;329:506. Copyright © 1987.)

outside the peptide-binding cleft (Figure 8-4B). Compared to the standard antigen-induced T-cell response where a small number of T cells are activated, superantigens can stimulate much larger numbers (~25% more) of the T cells.

Classic examples of superantigens include certain bacterial toxins, including the staphylococcal enterotoxins, toxic shock syndrome toxin, and group A streptococcal pyrogenic exotoxin A. A consequence of this massive activation of T cells is the overproduction of cytokines, in particular, IFN- γ . IFN- γ in turn activates macrophages to produce IL-1, IL-6, and TNF- α , all which may contribute to a “cytokine storm” causing severe symptoms of shock and multiple organ failure.

B Cells and Antibodies

Humoral immunity is mediated by antibodies. Each individual has a large pool of unique B lymphocytes (~10¹¹) that have a life span of days or weeks and are found in the blood, lymph, bone marrow, lymph nodes, and gut-associated lymphoid tissues (eg, tonsils, Peyer patches, and appendix).

A. B Cell Receptor for Antigen

B cells display a single homogenous clonal immunoglobulin molecule (~10⁵ copies/cell) on their surface. These immunoglobulins serve as receptors (B-cell receptors [BCRs]) for a specific antigen so that each B cell can respond to only one antigen or a closely related group of antigens. All immature B cells carry IgM immunoglobulin on their surface, and most also express IgD. Additionally, B cells have surface receptors for the Fc portion of immunoglobulins as well as for several complement components.

An antigen interacts with the B lymphocyte that shows the best “fit” by virtue of its immunoglobulin surface receptor. When antigen binds to this BCR, the B cell is stimulated to divide and form a clone (**clonal selection**). Such selected B cells proliferate and differentiate to become plasma cells that secrete antibody. Because each person can make approximately 10¹¹ different antibody molecules, there is an antigen-binding site on a B cell to fit almost any antigenic determinant.

The initial step in antibody formation begins with the binding of antigen to the surface immunoglobulin via the

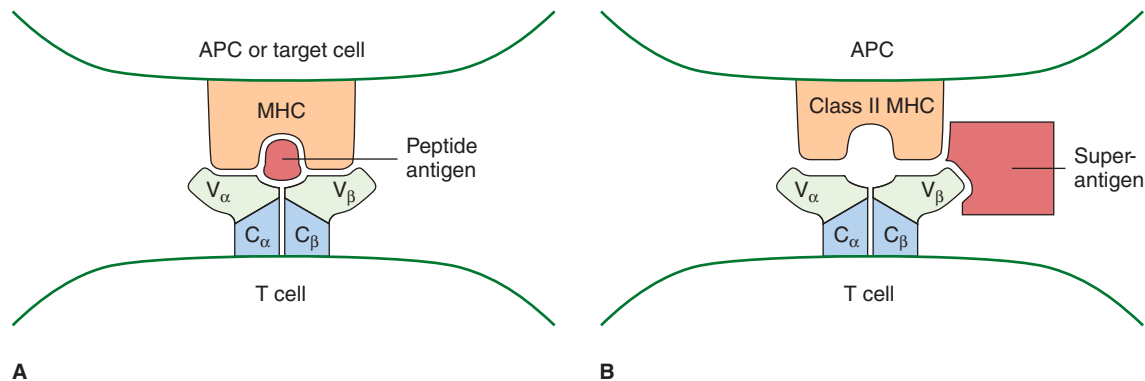

FIGURE 8-4 Binding of antigen by MHC and T-cell receptor (TCR). In **panel A**, a model of the interaction between peptide antigen, MHC, and the TCR is shown. The V α and V β regions of the TCR are shown interacting with the α helices that form the peptide-binding groove of MHC. In **panel B**, a model of the interaction between a superantigen, MHC, and the TCR, is shown. The superantigen interacts with the V β region of the TCR and with class II MHC outside the peptide-binding groove. (Adapted with permission from Stites DG, Terr AI, Parslow TG [editors]: *Medical Immunology*, 9th ed. McGraw-Hill, 1997, p. 132. © McGraw-Hill Education.)

BCR. Then the following steps ensue: (1) The BCR with its bound antigen is internalized by the B cell and the antigen is degraded to yield peptides that are then returned to the cell surface bound to MHC class II molecules. (2) This MHC class II–peptide complex on B cells is recognized by antigen-specific helper (CD4) T cells. These T cells have already interacted with antigen-presenting dendritic cells and have differentiated in response to the same pathogen. This interaction can occur because the B cell and the T cell that have encountered antigen migrate toward the boundaries between B- and T-cell areas in the secondary lymphoid tissue. (3) Chemokines, such as CXCL13 and its receptor, CXCR5, play an important role in this migration process. (4) The CD40 ligand on T cells binds to CD40 on B cells, and the T cell produces IL-4, IL-5, and IL-6, which induce B-cell proliferation. (5) Finally, the activated B cells migrate into follicles and proliferate to form germinal centers; here somatic hypermutation and immunoglobulin class switching occur. Germinal center B cells that survive this process now differentiate into either antibody-producing plasma cells or memory B cells. Additional details on this topic can be found in Murphy et al (2017).

It should be noted that some bacterial antigens can directly stimulate this antibody production and do not require T cell help to activate B cells. These antigens are usually bacterial polysaccharides and LPS. These thymus T-cell-independent antigens induce B-cell responses with limited class switching and do not induce memory B cells. Bypassing T-cell participation can be an advantage for the host because

an expedited immune response (IgM production) can be generated against selected organisms, such as *Haemophilus influenzae* and *Streptococcus pneumoniae*.

B. Antibody Structure and Function

Antibodies are immunoglobulins, which react specifically with the antigen that stimulated their production. They make up about 20% of the plasma proteins. Antibodies generated in response to a single complex antigen are heterogeneous because they are formed by many different clones of cells. Each clone expresses an antibody capable of reacting with a different antigenic determinant on the complex antigen. These antibodies are called **polyclonal**. In contrast, immunoglobulins that arise from a single clone of cells, such as a plasma cell tumor (myeloma), are homogeneous and are called **monoclonal** antibodies. Monoclonal antibodies can be produced in vitro by fusing a myeloma cell with an antibody-producing B lymphocyte.

The immunoglobulin (Ig) molecules share common structural features; that is, all the Ig molecules are composed of light and heavy polypeptide chains. The terms *light* and *heavy* refer to their molecular weight. The light chains have a molecular weight of approximately 25,000, whereas the heavy chains have a molecular weight of approximately 50,000. Each Ig molecule consists of two identical **light (L) chains** and two identical **heavy (H) chains** linked by disulfide bridges. The L chains can be either κ (kappa) or λ (lambda) and their classification is made based on the amino acid differences in their constant regions (Figure 8-5). Both light chain types

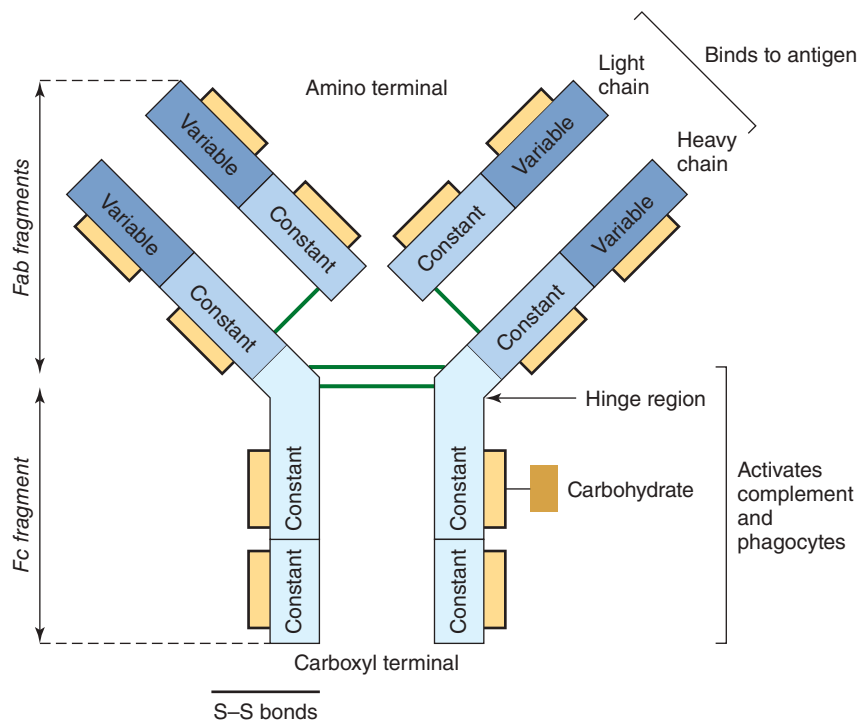

FIGURE 8-5 Schematic representation of an IgG molecule, indicating the location of the constant and the variable regions on the light and heavy chains. Fab fragment is fragment antigen binding, Fc fragment is fragment crystallizable.

TABLE 8-3 Properties of Human Immunoglobulins

	IgG	IgA	IgM	IgD	IgE
Heavy chain symbol	γ	α	μ	δ	ε
Valence	2	4 ^a	5	2	2
Molecular weight (daltons)	143,000–160,000	159,000–447,000 ^a	900,000	177,000–185,000	188,000–200,000
Serum concentration (mg/mL) (adult)	8–16	1.4–4.0	0.4–2.0	0.03	Trace amounts
Serum half-life (days)	21 ^b	7	7	2	2

Complement fixing capacity	Yes (+)	No	Yes (++)	No	No
Placental transfer to fetus ^c	+	–	–	–	–

^aIn secretions, eg, saliva, milk, and tears, and in respiratory, intestinal, and genital tract secretions, IgA is generally found as a dimer or a tetramer, but in serum it exists primarily as a monomer.

^bSubclasses 1, 2, 4. Subclass 3 has half-life of 7 days.

^cPrimarily subclasses IgG1 and IgG3, but all the subclasses have been detected.

can occur in all classes of immunoglobulins (IgG, IgM, IgA, IgD, and IgE), but any one Ig molecule contains only one type of L chain. The amino terminal portion of each L chain contains part of the antigen-binding site. Similarly, the **H chains** are distinct for each of the five immunoglobulin classes and are designated γ (gamma), μ (mu), α (alpha), δ (delta), and ε (epsilon) (Table 8-3). The amino terminal portion of each H chain participates in the antigen-binding site; the other (carboxyl) terminal portion forms the Fc fragment (Figure 8-5). The Fc portion of the Ig molecule participates in various biologic activities such as complement activation.

Therefore, an individual antibody molecule consists of identical H chains and identical L chains. The simplest antibody molecule has a Y shape (Figure 8-5) and consists of four polypeptide chains: two H chains and two L chains. The four chains are covalently linked by disulfide bonds.

When studying the Ig molecule structure, it was identified experimentally that an antibody molecule, such as IgG, can be split into two fragments by the proteolytic enzyme, papain. When this happens, the peptide bonds in the hinge region are broken. The antigen-binding activity is associated with one of these fragments, the Fab portion. The second fragment is the Fc portion that is involved in placental transfer, complement fixation, attachment to various cells, and other biologic activities.

The L and H chains of an Ig molecule are subdivided into **variable regions** and **constant regions**. The regions are composed of three-dimensionally folded, repeating segments called **domains**. By using high-resolution x-ray crystallography, the structure of these domains has been determined. An L chain is composed of one variable domain (V_L) and one constant domain (C_L) whereas most H chains have one variable domain (V_H) and three or more constant domains (C_H). Each domain is approximately 110 amino acids in length. The variable regions of the Ig molecule are involved in antigen

binding, whereas the constant regions are responsible for the biologic functions described later in this section.

Within the variable regions of both the L and H chains are subregions consisting of extremely variable amino acid sequences, called **hypervariable**, that cooperate in space to form the antigen-binding site. The hypervariable regions form the area of the Ig molecule complementary in structure to the antigenic determinant (epitope). This area is known as the complementarity-determining region (CDR). Only 5–10 amino acids in each hypervariable region constitute the antigen-binding site. Antigen binding is noncovalent, involving van der Waals and electrostatic as well as other weak forces.

Immunoglobulin Classes

A. IgG

IgG is the major class of immunoglobulin present in the serum. The IgG molecule consists of two L chains and two H chains (H₂L₂) (Figure 8-5). There are four subclasses of IgG: IgG1, IgG2, IgG3, and IgG4. Each subtype contains a distinct but related H chain and each differs somewhat regarding their biological activities. IgG1 represents 65% of the total IgG. IgG2 is directed against polysaccharide antigens and may be an important host defense against encapsulated bacteria. IgG3 is an effective activator of complement due to its rigid hinge region, whereas IgG4 does not activate complement due to its compact structure.

IgG is the only immunoglobulin class to cross the placenta and therefore is the most abundant immunoglobulin in newborns. Isotype-specific transport of IgG across the placenta occurs with preference for IgG1 and IgG3 subclasses. IgG also mediates opsonization of antigen through binding of antigen-antibody complexes to Fc receptors on macrophages and other cells.

FIGURE 8-6 Schematic diagram of the pentameric structure of human IgM. The IgM monomers are connected to each other and the J chain by disulfide bonds.

B. IgM

The first immunoglobulin produced in response to an antigen is IgM. IgM is secreted as a pentamer and is composed of five H_2L_2 units (similar to one IgG unit) and one molecule of a J chain (Figure 8-6). The pentamer (MW 900,000) has a total of 10 identical antigen-binding sites and thus a valence of 10. It is the most efficient immunoglobulin in agglutination, complement fixation, and other antigen-antibody reactions and is important also in defense against bacteria and viruses. Because its interaction with antigen can involve all 10 binding sites, it has the highest binding capacity and cross-linking of all the immunoglobulins. Evaluating the presence of serum IgM may be useful in the diagnosis of certain infectious diseases. For example, IgM does not cross the placenta, and the presence of the IgM antibody in the fetus or newborn provides evidence of intrauterine infection.

C. IgA

IgA is the major immunoglobulin responsible for mucosal immunity. The levels of IgA in the serum are low, consisting of only 10–15% of total serum immunoglobulins present. In contrast, IgA is the predominate class of immunoglobulin found in extravascular secretions. Thus, plasma cells located in glands and mucous membranes mainly produce IgA. Therefore, IgA is found in secretions such as milk, saliva, and tears, and in other secretions of the respiratory, intestinal, and genital tracts. These locations place IgA in contact with the external environment and therefore can be the first line of defense against bacteria and viruses.

The properties of the IgA molecule are different depending on where IgA is located. In serum, IgA is secreted as a monomer resembling IgG. In mucous secretions, IgA is a dimer and

is referred to as secretory IgA. This secretory IgA consists of two monomers that contain two additional polypeptides: the J chain that stabilizes the molecule and a secretory component that is incorporated into the secretory IgA when it is transported through an epithelial cell. There are at least two IgA subclasses: IgA1 and IgA2. Some bacteria (eg, *Neisseria* spp.) can destroy IgA1 by producing a protease and can thus overcome antibody-mediated resistance on mucosal surfaces.

D. IgE

The IgE immunoglobulin is present in very low quantities in the serum. The Fc region of IgE binds to its high-affinity receptor on the surface of mast cells, basophils, and eosinophils. This bound IgE acts as a receptor for the specific antigen that stimulated its production and the resulting antigen-antibody complex triggers allergic responses of the immediate (anaphylactic) type through the release of inflammatory mediators such as histamine.

E. IgD

Serum IgD is present only in trace amounts. However, IgD is the major surface bound immunoglobulin on mature B lymphocytes that have not yet encountered antigen. These B cells contain IgD and IgM at a ratio of 3:1. At the present time, the function of IgD is unclear.

Immunoglobulin Genes and Generation of Diversity

The ability of an individual to produce an extremely large number of immunoglobulin molecules ($\sim 3 \times 10^{11}$) with a relatively small number of genes has evolved through special genetic mechanisms. This occurs because the immunoglobulin genes undergo somatic recombination, which generates an enormous diversity of antibody specificities.

Each immunoglobulin chain consists of a variable (V) and a constant (C) region. For each type of immunoglobulin chain, that is, kappa light chain (κ), lambda light chain (λ), and the five heavy chains (γ H, μ H, α H, δ H, and ϵ H), there is a separate pool of gene segments located on different chromosomes. In humans the multigene families are found on the following chromosomes: λ , chromosome 22; κ , chromosome 2; and the heavy chain family, chromosome 14. Each of the three gene loci contains a set of different V gene segments that are separated from the C gene segments. During B-cell differentiation, the DNA is rearranged to bring the identified gene segments adjacent to each other in the genome.

In summary, the gene rearrangement process is complex and involves a number of steps. The variable region of each L chain is encoded by two gene segments: V and J. The variable region of each H chain is encoded by three gene segments: V, D, and J. The segments are united into one functional V-variable gene by DNA rearrangement. Each assembled V-variable gene is then transcribed with the appropriate C-constant gene to produce a messenger RNA (mRNA) that encodes for the complete

peptide chain. L and H chains are synthesized separately on polysomes and then assembled in the cytoplasm to form H_2L_2 chain units. The carbohydrate portion of the Ig molecule is then added during passage through the membrane components of the cell (eg, Golgi apparatus), and the immunoglobulin molecule is released from the cell.

This gene rearrangement mechanism generates an enormous variety of immunoglobulin molecules. Antibody diversity depends on (1) multiple V, D, and J gene segments; (2) combinatorial association, that is, the association of any V gene segment with any D or J segment; (3) the random combining of different L and H chains; (4) somatic hypermutation; and (5) junctional diversity produced by imprecise joining during rearrangement.

Immunoglobulin Class Switching

Initially, all B cells bound to an antigen carry IgM specific for that antigen and produce IgM in response to this antigen. Later, gene rearrangement generates antibodies of the same antigenic specificity but of different immunoglobulin classes. In **class switching**, the same assembled V_H gene can sequentially associate with different C_H genes so that the immunoglobulin produced later (IgG, IgA, or IgE) has the same specificity as the original IgM but with different biologic characteristics. Class switching is dependent on cytokines released from T cells. Recently, IL-4, IL-5, IFN- γ , and transforming growth factor-beta (TGF- β) have been shown to play a role in regulating Ig class switching.

Antibody Responses

A. The Primary Response

When an individual encounters an antigen for the first time, the antibody produced in response to that antigen is detectable in the serum within days or weeks. This time can vary depending on the nature and dose of the antigen and the route of administration (eg, oral or parenteral). The serum antibody concentration continues to rise for several weeks and then declines; the antibody level may drop to very low levels (Figure 8-7). The first antibodies produced are IgM. Then, IgG and IgA are made. IgM levels tend to decline sooner than IgG levels.

B. The Secondary Response

In the event of a second encounter with the same antigen months or years after the primary response, the second antibody response is more rapid and generates higher levels than during the primary response (Figure 8-7). This change in response is attributed to the persistence of antigen-sensitive memory cells that were generated during the primary immune response. In the secondary response, the amount of IgM produced is qualitatively similar to that produced after the first contact with the antigen; however, more IgG is produced, and the level of IgG tends to persist much longer than that produced in the primary response. Furthermore,

FIGURE 8-7 Rate of antibody production following initial antigen administration and a second “booster” injection.

such antibody tends to bind antigen more firmly (with higher affinity) and thus to dissociate less easily.

Protective Functions of Antibodies

The protective role of antibodies is based on the fact that specific antibodies are generated that recognize and bind to specific pathogens. This interaction triggers a series of host defense responses. Antibodies can produce resistance to infection by five major mechanisms:

- 1. Enhanced phagocytosis**—Antibodies produce resistance by opsonizing (coating) organisms, which make them more readily ingested by phagocytes. In addition, antibody-mediated immunity against the pathogen is most effective when directed against microbial infections in which virulence is related to polysaccharide capsules (eg, pneumococcus, *Haemophilus* spp., and *Neisseria* spp.). In these infections, antibodies complex with the capsular antigens and make the organisms susceptible to ingestion by phagocytic cells. This engulfment leads to pathogen destruction.
- 2. Virus neutralization**—Antibodies directed against specific viral proteins can bind to the virus and block the ability of the virus particle to attach to its cellular receptor. Because the virus can no longer invade the cell, it cannot replicate.
- 3. Neutralization of toxins**—Antibodies can neutralize toxins of microorganisms (eg, diphtheria, tetanus, and botulism) and inactivate their harmful effects.
- 4. Complement-mediated lysis**—The attachment of antibodies to viral proteins on virus-infected cells, tumor cells, or to a microbial cell wall can activate the complement system leading to cell lysis.

5. Antibody-dependent cell cytotoxicity (ADCC)—

The attachment of viral-specific antibodies to viral proteins on a virus-infected cell can lead to the lytic destruction of the infected cell. This lysis is mediated by a NK cell, macrophage or neutrophil. These lymphoid cells bind to the Fc portion of the virus-specific antibody bound to the infected cell and kill the infected cell. ADCC by eosinophils is an important defense mechanism against helminthes. IgE coats the worms and eosinophils attach to the Fc portion of IgE triggering eosinophil degranulation.

Forms of Immunity

Because antibodies are protective, strategies have been developed to induce their production (active immunity) or to administer preformed antibodies to the host (passive immunity).

A. Active Immunity

Active immunity is conferred when an individual comes in contact with a foreign antigen (infectious agent). This immunity can occur in the setting of a clinical or subclinical infection, immunization with live or killed organism, exposure to microbial products (eg, toxins and toxoids), or transplantation of foreign tissue. In all these cases the individual actively produces antibodies. The antibody produced during active immunity is long lasting. However, protection is delayed until antibody production reaches an effective level.

B. Passive Immunity

Passive immunity is generated by the administration of preformed antibodies. The main advantage of passive immunization is that the recipient receives a large concentration of antibody immediately. This does not confer long-term protection but is useful when the patient has no time to produce an antibody response. Passive immunity is helpful against certain viruses (eg, hepatitis B virus) after a needle-stick injury to someone who has not been vaccinated or in cases of immune deficiency where antibody cannot be produced.

In addition to the antibody-mediated protective effects, harmful effects from antibody administration can also be seen. In passive immunity it is possible to initiate hypersensitivity reactions if the antibody is from another species. In active immunity, the binding of antibodies to the antigen leads to the formation of circulating immune complexes. The deposition of these complexes may be an important feature in the development of organ dysfunction. For example, immune complexes may deposit in the kidney and induce glomerulonephritis, which can result following streptococcal infections.

T Cells

A. Cell-Mediated Immunity

Within the adaptive immune response, the cooperative interaction of both antibody- and cell-mediated immunity

provides the best opportunity for combating infection. In fact, effective antibody responses depend on the activation of T cells. This section directs attention to T-cell activation, T-cell recognition of antigen, and T-cell subsets and their function as well as T-cell development, proliferation, and differentiation.

1. Development of T cells—As previously mentioned, T cells are derived from the same hematopoietic stem cells as are the B cells. Within the thymus, T cells mature and undergo differentiation. Under the influence of thymic hormones, T cells differentiate into committed cells expressing a specific TCR. These T cells have undergone VDJ recombination of their β chain and then rearrangement of their α chains. Now these T cells undergo two processes: one positive and one negative. During positive selection, cells that recognize self-peptide plus self-MHC with weak affinity will survive. These cells are now termed self-MHC restricted. During negative selection, the cells that recognize self-peptide plus self-MHC with high affinity are killed. The survivor cells, $CD4^+$ $CD8^+$ double positive T cells, continue to mature into either $CD4^+$ or $CD8^+$ T cells. Only a minority of developing T cells express the appropriate receptors to be retained and enter the periphery where they join the mature T-cell pool.

2. T-cell receptor for antigen—The TCR is the recognition molecule for T cells. The TCR is a transmembrane heterodimeric protein containing two disulfide-linked chains. It is composed of two different classes of TCR called: **alpha-beta (α and β)** and **gamma-delta (γ and δ)**. The majority of the T cells contain the $\alpha\beta$ TCR phenotype. However, a smaller percentage of T cells express the $\gamma\delta$ TCR. The $\alpha\beta$ T cells are subdivided by their surface markers: $CD4$ or $CD8$. Little is known about the activities of the $\gamma\delta$ T cells. The $\gamma\delta$ T cells are primarily located in the epithelial linings of the reproductive and GI tracts.

The structure of the TCR resembles the Fab fragment of an immunoglobulin molecule; that is, the TCR has both variable and constant regions. More specifically, each chain has two extracellular domains: a variable region and a constant region. The constant region is closest to the cell membrane, whereas the variable region binds the peptide-MHC complex. When the TCR engages the antigen peptide-MHC complex, a series of biochemical events occur. These are discussed later in the text.

As outlined for the immunoglobulins, the diversity of the TCR is similar to that described for the BCR. The α chain of the TCR is the result of VJ recombination, whereas the β chain is generated by VDJ recombination. These segments can combine randomly in different ways to generate the complex TCR.

The TCR complex is formed by the highly variable α and β chains of the TCR plus the invariant $CD3$ proteins. The invariant proteins of the $CD3$ complex are responsible for transducing the signal received by the TCR when antigen recognition occurs. The different proteins of the $CD3$ complex

are transmembrane proteins that can interact with cytosolic tyrosine kinases that initiate signal transduction leading to gene transcription, cell activation, and initiation of the functional activities of T cells.

In addition to the TCR complex, the T cell signal is also enhanced by the presence of coreceptors. The CD4 and CD8 molecules on the T cell membrane function as coreceptor molecules. During recognition of antigen, the CD4 and CD8 molecules interact with the TCR complex and with MHC molecules on the APC. CD4 binds to MHC class II molecules and CD8 binds to MHC class I molecules.

3. T-cell proliferation and differentiation—T-cell proliferation depends on a series of events. In MHC class II presentation, two signals are required for the naïve CD4 T cell activation to occur. The first signal comes from the TCR on the T cell interacting with an MHC–peptide complex presented on the APC. The CD4 glycoprotein on the naïve T cell acts as a coreceptor, binding to MHC class II molecules. This binding event helps ensure stability between the T cell and the APC. The second signal (costimulation) that is required for T-cell activation is derived from the interaction of the B7 family costimulatory molecules (B7-1/B7-2 also identified as CD80 and CD86) on the APC with CD28 on the T cell. These are the major costimulatory molecules. Upon completion of these two stimulation steps (eg, TCR binding to MHC class II–peptide complex and CD28 binding to B7-1/B7-2), a set of biochemical pathways are triggered in the cell that results in DNA synthesis and proliferation. During these events, the T cell secretes cytokines, mainly IL-2 and IFN- γ , and increases the expression of IL-2 receptors. These T cells are able to proliferate and differentiate into effector cells.

CD8 T-cell activation occurs when the TCR interacts with the MHC class I–peptide complex on the infected cell. The CD8 glycoprotein on the T cell acts as a coreceptor, binding to MHC class I molecule on the APC. Again, this interaction keeps the two cells bound together during antigen-specific activation. Once activated, the cytotoxic T cell produces IL-2 and IFN- γ , growth and differentiation factors for T cells. Unlike CD4 cell activation, CD8 T-cell activation in most cases is independent of costimulation, and the virus-infected cell is destroyed through cytotoxic granules released from the CD8 T cell.

Because the immune system is highly regulated, it can also downregulated immune activation to limit overwhelming or excessive responses and hence avoid inadvertent damage to the host. The immune system is equipped with a checkpoint system and several negative regulatory checkpoints, which perform this function. CTLA-4 and PD-1 are two cell surface receptors that can turn off activated T cells when they interact with their ligand. For example, CTLA-4 blocks signal 2 and therefore prevents T cell activation.

B. T-Cell Effector Functions

1. CD4 effector cells—Proliferating CD4 T cells can become one of five main categories of effector T cells: **Th1**

cells, Th2 cells, Th17 cells, Tfh, or T regulatory (T reg) cells (Figure 8-8).

Th1—Th1 cells are triggered by IL-2 and IL-12 and either activate macrophages or cause B cells to switch to produce different subclasses of IgG. In either case, this can promote bacterial clearance either by direct destruction in the IFN- γ -activated macrophage or by destruction after phagocytosis of opsonized particles. These Th1 cells also produce IL-2 and IFN- γ .

Th2—In an environment where IL-4 is being produced, Th2 cells predominate and activate mast cells and eosinophils and cause B cells to synthesize IgE. This aids in the response to helminths. The Th2 cells secrete IL-4, IL-5, IL-9, and IL-13.

Th17—When TGF- β , IL-6, and IL-23 are present CD4 T cells can become Th17 cells. These cells produce IL-17, IL-21, and IL-22. IL-17 is a cytokine that induces stromal and epithelial cells to produce IL-8 (CXCL8). IL-8 is a potent chemokine that is responsible for the recruitment of neutrophils and macrophages to infected tissues.

Tfh Cells—CD4+ follicular helper T cells (Tfh) are a recently recognized cell type that populate the lymph node follicles and participate in antigen-specific B cell help. These cells assist with isotype switching and antibody production. The Tfh cells express the chemokine receptor CXCR5 and produce the cytokine, IL-21, both of which are required for their contribution to germinal center formation.

T regs—CD4 T cells can become T regulatory (T regs) when they are exposed to TGF- β alone. T reg cells function by suppressing T-cell responses. They are identified by expression of CD4 and CD25 molecules on their surface and the transcription factor, Foxp3. T reg cells produce TGF- β and IL-10, which can suppress immune responses.

2. CD8 effector cells—CD8 cells differentiate into effector cytotoxic cells by engagement of their TCR and recognition of class I MHC–peptide complex on the surface on an infected cell. Following recognition, the CD8 T cell proceeds to kill the infected cell. The primary method of killing is through cytotoxic granules containing perforin, the family of granzymes, and a third protein recently identified, granulysin. The CD8 T cell releases perforin that helps granzyme and granulysin enter the infected cell. Granzyme initiates apoptosis (programmed cell death) by activating cellular caspases. It should be noted that a similar process occurs with CD8 T cell recognition of tumor cells. For additional information on this topic, see Murphy et al (2017).

COMPLEMENT

The complement system, a complex and sophisticated cascade of various proteins, is designed to provide defense against microbial invaders. The complement system includes serum and membrane-bound proteins that participate in both innate and adaptive immunity. These proteins are highly regulated and interact via a series of proteolytic cascades. Many

FIGURE 8-8 CD4 T Cells: peptide + MHC class II. (Reproduced with permission from Murphy K, Weaver C: *Janeway's Immunobiology*, 9th ed., Figure 9.30. Copyright © 2017 by Garland Science, Taylor & Francis Group, LLC. Used by permission of W. W. Norton & Company, Inc.)

of the complement components are proenzymes, which must be cleaved to form active enzymes.

Biologic Effects of Complement

Activated complement proteins initiate a variety of functions that result in four major outcomes: (1) cytolysis, (2) chemotaxis, (3) opsonization, and (4) anaphylatoxins.

- 1. *Cytolysis* is the lysis of cells, such as bacteria, virus-infected cells, and tumor cells. This process occurs through the development of the membrane attack complex (MAC) (C5b, 6, 7, 8, 9), which inserts into the membrane of an organism or cell. The MAC creates holes in the cell membrane, which leads to loss of osmotic integrity and rupture of the microbe or cell.
- 2. *Chemotaxis* is the directed movement of leukocytes up a gradient concentration toward the site of infection. This movement is in response to a chemotactic factor. One of the most important chemotactic substances is C5a, a fragment of C5 that stimulates movement of neutrophils and monocytes to sites of inflammation.

- 3. *Opsonization* is a term used to describe how antibodies or C3b can enhance phagocytic engulfment of microbes. Macrophages and neutrophils have receptors for C3b and therefore can bind C3b-coated organisms. This binding triggers phagocytosis.
- 4. *Anaphylatoxins* promote vasodilation and increase vascular permeability. Two complement components, C3a and C5a, are potent anaphylatoxins. Both bind to receptors on mast cells and basophils triggering them to release histamine. This event results in an increased blood flow to the site of infection, allowing more complement, antibodies, and immune cells to enter the site of infection.

Complement Pathways

There are three major pathways that activate complement: the classical pathway, alternative pathway, and MBL pathway (Figure 8-9). Each of these pathways results in the formation of the MAC. All three pathways lead to the release of C5 convertase, which breaks down C5 into C5a and C5b. As mentioned previously, C5a is an anaphylatoxin as well as a chemotactic factor. C5b binds to C6 and C7 to form a complex

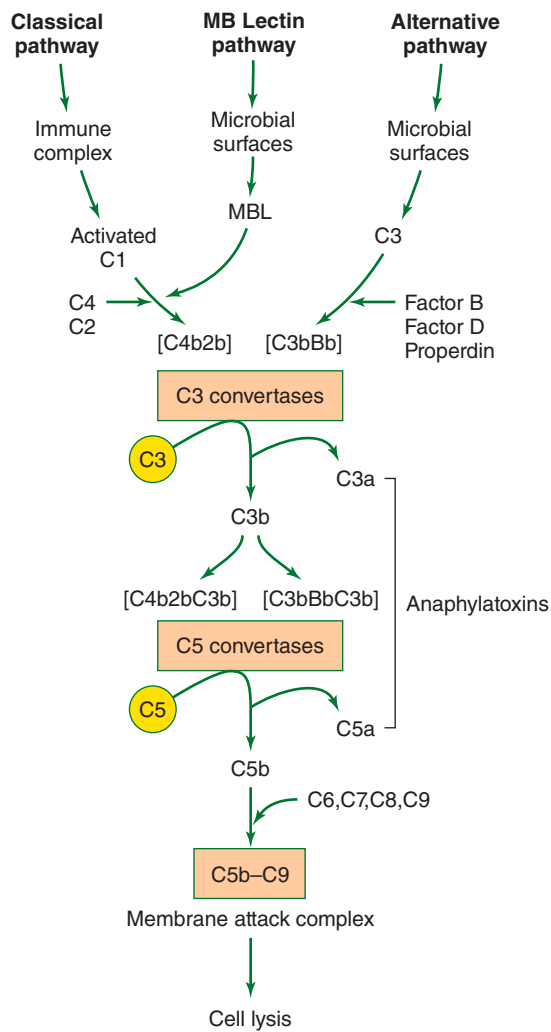

FIGURE 8-9 Complement reaction sequence.

that inserts into the membrane bilayer. C8 then binds to the C5b–C6–C7 complex followed by polymerization of up to 16 C9 molecules to produce the MAC. The MAC now generates a pore in the membrane and causes cytolysis by allowing free passage of water across the cell membrane.

The Classical Pathway

C1, which binds to the Fc region of an immunoglobulin, is composed of three proteins: C1q, C1r, and C1s. C1q is an aggregate of polypeptides that bind to the Fc portion of IgG and IgM. The antibody–antigen immune complex bound to C1 activates C1s, which cleaves C4 and C2 to form C4b2b. The latter protein (C4b2b) is an active C3 convertase, which splits C3 molecules into two fragments: C3a and C3b. As mentioned earlier, C3a is a potent anaphylatoxin. C3b forms a complex with C4b2b, producing a new enzyme, C5 convertase, which cleaves C5 to form C5a and C5b. C5b is now available to bind to C6 and C7 and form the C5b/C6/C7 complex. Finally, C9 binds to this newly formed complex to produce

the formation of the MAC. Once the MAC is formed, cell lysis ensues shortly thereafter. Only IgM and IgG fix complement via the classic pathway. Furthermore, only IgG subclass 1, 2, and 3 fix complement whereas IgG4 does not. An example of the classical complement pathway in action can be observed in herpes simplex virus (HSV) infections. HSV replication within cells is accompanied by the insertion of virus proteins into the cell surface membrane. A specific anti-HSV antibody can bind to the surface of the infected cell by its Fab site. The Fc portion of the antigen–antibody complex is now exposed and ready for C1 to attach. The classical pathway is now activated, and the infected cell is destroyed by the MAC.

The Alternative Pathway

The alternative pathway of complement can be activated by infectious agents that activate the complement system by triggering the cellular production of factors B, D, and properdin. These factors cleave C3 and generate C3 convertase. C3 convertase (C3bBb) that was generated during the alternative pathway produces more C3b. The additional C3b binds to the C3 convertase to form C3bBbC3b. This enzyme is the alternative pathway C5 convertase that generates C5b, leading to production of the MAC described earlier.

Mannose-Binding Lectin Pathway

The lectin pathway is an important component of the innate immune response and is similar to the classical pathway at the point of cleavage of C4. However, the major difference is that it is initiated by the binding of mannose-binding lectin (MBL) to polysaccharides on bacterial surfaces. The binding of MBL to a pathogen results in the formation of a tricomplex of MBL with two serine proteases (MASP-1 and MASP-2). This tricomplex is now activated to cleave C4 into C4a and C4b and C2 into C2a and C2b. The new complex C4bC2a is a C3 convertase and proceeds to cascade as the classic pathway.

A. Regulation of the Complement System

In order to avoid constant complement activation, a regulatory network exists to terminate complement activity. Several serum proteins regulate the complement system at different stages: (1) C1-inhibitor protein binds to and inactivates the serine protease activity of C1r and C1s, causing them to dissociate from C1q; (2) factor I cleaves C3b and C4b, thereby reducing the amount of C5 convertase available; (3) factor H enhances the effect of factor I on C3b; and (4) factor P (properdin) protects C3b and stabilizes the C3 convertase of the alternative pathway. Regulation is also provided by proteins that have the ability to accelerate the decay of the complement proteins, such as decay-accelerating factor (DAF expressed on blood and endothelial cells) that can act to accelerate dissociation of the C3 convertases of all three pathways.

Complement Deficiencies and Pathogen Evasion

Many genetic deficiencies of complement proteins have been described, and these generally lead to enhanced susceptibility to infectious disease (eg, C2 deficiency frequently leads to serious pyogenic bacterial infections). Deficiency in components of the MAC greatly enhances susceptibility to neisserial infections. Deficiencies in components of the alternative pathway are also known (eg, properdin deficiency is associated with greater susceptibility to meningococcal disease). There are also deficiencies in complement regulating proteins. For example, lack of the C1 inhibitor protein leads to hereditary angioedema.

The complement system is an important host protective system. However, some bacteria have evolved mechanisms to evade complement activity. For example, they can interfere with opsonization or obstruct the insertion of the MAC. Complement activation can also be inhibited by the presence of microbial generated proteins, such as protein A and protein C, that bind IgG Fc. Finally, they can generate enzymes that degrade complement components. Organisms that possess these inhibitory properties are usually more pathogenic.

The complement system has also evolved strategies to attack cell-free virus and the virus-infected cells. In response, viruses have developed mechanisms to dodge complement attack. Some viruses, such as the smallpox virus, encode proteins that can inhibit host complement function. Other enveloped viruses, such as cytomegalovirus, can pick up some of the complement regulatory proteins as they mature by budding from the infected cell. These regulatory proteins (CD46, CD55, and CD59) on the virus envelope can downregulate complement activation. Finally, several viruses (Epstein-Barr virus [EBV], measles virus) use complement receptors to enter and infect cells.

CYTOKINES

Over the last two decades, we have witnessed an explosion in cytokine biology. Cytokines are potent, low-molecular-weight protein cell regulators produced transiently and locally by numerous cell types. Today, we recognize that cytokines are multifunctional proteins whose biological properties suggest a key role in hematopoiesis, immunity, infectious disease, tumorigenesis, homeostasis, tissue repair, and cellular development and growth.

Cytokines usually act as signaling molecules by binding to their own glycoprotein receptors on cell membranes. This initial interaction is followed by a relay of the signal to the cell nucleus. Signal transduction is mediated as in many hormone-receptor systems via kinase-mediated phosphorylation of cytoplasmic proteins. In fact, tyrosine kinase activity is intrinsic to many cytokine receptors. Because of their role in multiple immunologic activities, cytokines are mentioned

throughout this chapter. In following text we describe major cytokines and their functions.

Classification and Functions

Cytokines can be categorized into groups based on their common functions. Examples of functional categories include immunoregulatory, proinflammatory, anti-inflammatory, chemokines, adhesion molecules, and growth and differentiation. Because of its major role in antigen presentation, an important immunoregulatory cytokine is IFN- γ . Proinflammatory cytokines are commonly seen in infectious diseases, and they include IL-1, IL-6, TNF- α , and the IFNs. The anti-inflammatory cytokines include TGF- β , IL-10, IL-11, and IFN- β . These may be required to dampen or downregulate an overactive inflammatory response. Cytokines that have a key role in growth and differentiation include the colony-stimulating factors (CSFs) and stem cell factor. Selected cytokines, their sources, and their main activities are identified in Table 8-4.

Cytokines in Immune Cell Development and Host Defense to Infections

Naïve CD4⁺ T cells can differentiate into different lineages depending on the exogenous cytokine environment. Th1 cells develop in the presence of IL-12; Th2 cells develop in the presence of IL-4; Th17 cells develop in the presence of TGF- β , IL-6, and IL-23; Tfh cell differentiation begins in the presence of IL-6; and T reg cells are formed in the presence of TGF- β alone. Each of these five T-cell lineages produces cytokines that play a pivotal role in host defense against selective microorganisms. Th1 cells produce IL-2 and IFN- γ , cytokines that can effectively control virus infections and intracellular organisms such as mycobacteria and *T. gondii*. IFN- γ is a key activator of macrophages and cytotoxic CD8⁺ T cells. Th2 cells produce IL-4, IL-5, IL-6, IL-10, and IL-13, cytokines that drive IgE responses and help control parasitic infections. Th17 cells produce IL-17, a cytokine that attracts neutrophils and plays protective host defense roles at the epithelial and mucosal barriers. IL-17 has been shown to limit infections in the skin against *Staphylococcus aureus*, in the colon against *Citrobacter rodentium*, in the lung against *Klebsiella pneumoniae*, in the mouth against *Candida albicans*, and in the vagina against *Chlamydia*. IL-17 has also been shown to inhibit fungal infections caused by *Pneumocystis carinii*. Recent studies have shown that mutations in IL-17 and IL-17 receptor genes predispose individuals to chronic mucocandidiasis caused by *C. albicans*. Tfh cells participate in antibody production. Finally, T regs are regulatory T cells that help suppress T-cell proliferation and maintain tolerance to self-antigens. It has been suggested that T regs functions are facilitated, in part, by the production of immunosuppressive cytokines, IL-10 and TGF- β .

This analysis of T-cell differentiation demonstrates how T-cell subsets secrete their own set of cytokines that have distinct regulatory properties. Thus, cytokines orchestrate the type of protective immune response that is generated.

TABLE 8-4 Selected Cytokines: Production and Activities

Cytokine Family	Primary Cell Type	Activity
Interferons		
Alpha	Leukocytes	Antiviral, immunoregulatory (enhance MHC class I, NK-cell activity), antiproliferative
Beta	Fibroblasts, epithelial cells	Antiviral, immunoregulatory (enhance MHC class I, NK cell activity), antiproliferative
Gamma	T cells, NK cells, and ILC1 cells	Antiviral, immunoregulatory (enhance MHC classes I and II and macrophage activation), antiproliferative
TNF		
Alpha	Macrophages, lymphocytes	Activate macrophages and cytotoxic cells, induce cachexia, acute phase proteins, cytokines such as IL-1 and IL-6
Beta	T cells	Activate macrophages, induce cytokines (IL-1, IL-6)
Interleukins		
IL-1	Most cells, macrophages, dendritic cells	Induce inflammation, fever, and sepsis, activate TNF- α
IL-2	T cells	Induce proliferation and maturation of T cells
IL-4	Mast cells, Th2 cells, eosinophils, and basophils	Th2 cell–mediated immunity and IgE class switching
IL-6	Most cells	B-cell stimulation, mediator of acute-phase reactions Activates cytotoxic T cells, major inducer of proinflammatory responses
IL-10	T cells, monocytes/macrophages	Inhibits production of proinflammatory cytokines such as IFN- γ , IL-12, TNF- α , and IL-6
IL-11	Bone marrow (BM) stromal cells, mesenchymal cells	Synergistic effects on hematopoiesis and thrombopoiesis, cytoprotective effects on epithelial cells, induce immunosuppression
IL-12	Dendritic cells, macrophages, B cells	Induce production of IFN- γ , TNF- α , and IL-2 by resting and activated T and NK cells
IL-15	T cells, astrocytes, microglia, fibroblasts, epithelial cells	Biological activities similar to IL-2, induce proliferation of peripheral blood mononuclear cells, maturation of NK cells (IL-1, IFN- γ , TNF- α)
IL-17 (A-F)	Th17 cells	Stimulate epithelial, endothelial, and fibroblastic cells to produce IL-6, IL-8, G-CSF, ICAM-1 and induces proinflammatory responses
IL-22	T cells, NK cells, ILC cells, and neutrophils	Promotes epithelial antimicrobial responses
IL-23	Macrophages and dendritic cells	Similar to IL-12 (induce IFN- γ), help differentiate CD4 T cells to TH17
Growth Factors		
M-CSF	Monocytes	Proliferation of macrophage precursors
G-CSF	Macrophages	Proliferation, differentiation, and activation of neutrophils
GM-CSF	T cells, macrophages	Proliferation of granulocytes and macrophages precursors
Stem cell factor	BM stromal cells, fibroblasts, fetal liver cells	Proliferation and differentiation of early myeloid and lymphoid cells (synergizes with other cytokines)
TGF- β	Most cells	Anti-inflammatory, drive differentiation of CD4 T cells to T regs; in presence of IL-6 drives CD4 T cells to Th17
VEGF-A	Most cells	Stimulate vasculogenesis and angiogenesis
Chemokines		
IL-8 (CXCL8)	Most cells	Neutrophil activation and chemotaxis
RANTES (CCL5)	Most cells	Chemotactic for T cells, monocytes, eosinophils, and basophils
CXCL9 CXCL10 CXCL11	Most cells	Chemotactic for Th1 cells (CXCR3-positive T cells) and are induced by the IFNs
Adhesion Molecules		
ICAM-1	Endothelial cells	Adhesion and migration
VCAM-1	Leukocytes	Adhesion and migration
E-selectin	Endothelial cells	Adhesion and migration

*This list is not inclusive; primary cells have been identified.

Clinical Applications

Today, there are at least four major clinical applications of cytokines. First, cytokines can serve as biomarkers of disease and provide clues for mechanisms of disease. For example, the proinflammatory cytokines TNF- α , IL-1, and IL-6 can be detected in the sera of patients with septic shock. These cytokines appear to play a critical role in the development of septic shock, and tracking their presence may be of prognostic value in severe sepsis. Second, the measurement of cytokine production in vitro is a useful monitor of immune status. T-cell function can be monitored by the ability of the T cells to produce IFN- γ . This is currently being used to identify tuberculosis (TB) reactivity and is discussed later. Third, recombinant cytokines are key therapeutic agents. An example of this is seen with the IFN molecules. The FDA has approved the use of IFN- α for hepatitis C infections, IFN- β for multiple sclerosis, and IFN- γ for chronic granulomas disease (CGD). Fourth, cytokines can be targets of therapy. Recently, cytokine receptor antagonists and anticytokine monoclonal antibodies both that downregulate pathogenic responses to exaggerated cytokine production have been used as effective treatments. Examples of this approach are the inhibitors of TNF- α used to manage rheumatoid arthritis (RA) and inhibitors of IL-2 and IL-15 used in transplantation and cancer.

MICROBIOME AND IMMUNE SYSTEM

All microbes are not invaders. In fact, the presence of selected species of microbes on the mucosal surfaces supports their role as key players in a variety of immune responses. The concept of identifying microbial species, such as bacteria, fungi, viruses, and other microorganisms in individual human mucosal surfaces, was realized with the advent of high-throughput DNA sequencing techniques. Using this new knowledge, it has become clear that the presence of gastrointestinal and other mucosal microbiomes can influence the development and differentiation of the immune system. For example, microbes can influence B cell development and IgA production, neutralize pathogens and exotoxins, and encourage development of Th17 and T regulatory cells. This is a rapidly evolving field of study that expands the appreciation of symbiotic relationships. A more comprehensive discussion of this topic is available in the reference section.

HYPERSENSITIVITY

Hypersensitivity is a condition in which an exaggerated or augmented immune response occurs that is harmful to the host. Hypersensitivity requires a presensitized state. For example, in a given individual, such reactions typically occur after the second encounter with that specific antigen (allergen).

In 1963, Coombs and Gell classified hypersensitivity into four types: Types I, II, III (antibody mediated), and IV (T-cell mediated).

Type I: Immediate Hypersensitivity (Allergy)

Type I hypersensitivity manifests itself in tissue reactions occurring within seconds after the antigen combines with specific IgE antibody. Its symptoms may manifest as a systemic anaphylaxis (eg, after intravenous administration of heterologous proteins) or as a local reaction (eg, an atopic allergy involving rhinitis such as occurs with hay fever).

The general mechanism of immediate hypersensitivity involves a series of steps. An antigen induces the formation of IgE antibody, which binds firmly by its Fc portion to high-affinity IgE receptors on mast cells, basophils, and possibly eosinophils. Some time later, an individual experiences a second exposure to same antigen. This second exposure results in the cross-linking of the cell-bound IgE molecules and the release of pharmacologically active mediators. Cyclic nucleotides and calcium are essential in the release of mediators.

Pharmacologic mediators of type I hypersensitivity are listed as follows:

1. Histamine—Histamine exists in a preformed state in platelets and in granules of mast cells, basophils, and eosinophils. The release of histamine causes vasodilation, increased capillary permeability, and smooth muscle contraction (eg, bronchospasm). Antihistamine drugs can block histamine receptor sites and are relatively effective in allergic rhinitis. Histamine is one of the primary mediators of a type I reaction.

2. Prostaglandins and leukotrienes—Prostaglandins and leukotrienes are newly formed mediators derived from arachidonic acid via the cyclooxygenase pathway. Prostaglandins induce edema and bronchoconstriction. Leukotriene B₄ is a chemoattractant that activates and recruits leukocytes to the site of injury. Leukotrienes C₄ and D₄ cause vasodilation and vascular permeability. These mediators, along with TNF- α and IL-4, are referred to as secondary mediators of a type I reaction.

A. Atopy

Atopic hypersensitivity disorders exhibit a strong familial predisposition and are associated with elevated IgE levels. Predisposition to atopy is clearly genetic, but the symptoms are induced by exposure to specific allergens. These antigens are typically environmental (eg, respiratory allergy to pollens, ragweed, or house dust) or foods (eg, intestinal allergy to shellfish). Common clinical manifestations include hay fever, asthma, eczema, and urticaria. Many patients experience immediate-type reactions to skin tests (injection, patch, scratch) involving the offending antigen.

B. Treatment and Prevention of Anaphylactic Reactions

Treatment aims to reverse the action of mediators by maintaining the airway, providing artificial ventilation if

necessary, and supporting cardiac function. Epinephrine, antihistamines, and corticosteroids are often given. However, the best prevention relies on the identification of the antigen (detected by skin test or IgE antibody serology) and subsequent avoidance. New treatment approaches include the induction of tolerance to the antigen.

Type II: Hypersensitivity

Type II hypersensitivity involves the binding of IgG antibodies to cell surface antigens or extracellular matrix molecules. Antibody directed at cell surface antigens can activate complement to damage the cells. The result may be complement-mediated lysis, which occurs in hemolytic anemia, ABO transfusion reactions, and Rh hemolytic disease.

Drugs such as penicillin can attach to surface proteins on red blood cells and initiate antibody formation. Such autoimmune antibodies may then combine with the cell surface and cause hemolysis. In Goodpasture syndrome, antibody is generated to the basement membranes of the kidney and lung. This results in complement activation, leukocyte chemotaxis, and severe membrane damage. In some cases, antibodies to cell surface receptors alter cell function without cell injury (eg, in Graves disease, an autoantibody binds to the thyroid-stimulating hormone receptor, which generates stimulation of the thyroid, and hyperthyroidism).

Type III: Immune Complex Hypersensitivity

When antibody combines with its specific antigen, immune complexes are formed. Normally, these immune complexes are promptly removed, but occasionally, they persist and are deposited in tissues. In persistent microbial or viral infections, immune complexes may be deposited in organs (eg, the kidneys), resulting in tissue and organ dysfunction. In autoimmune disorders, “self” antigens may elicit antibodies that bind to organ antigens or are deposited in organs and tissues as complexes, especially in the joints (arthritis), kidneys (nephritis), and blood vessels (vasculitis). Finally, environmental antigens such as fungal spores and certain drugs can cause immune complex formation with similar tissue and organ damage.

Wherever immune complexes are deposited, they can activate complement. Once complement is activated, macrophages and neutrophils migrate to the site and inflammation and tissue injury ensue. There are two major forms of immune complex-mediated hypersensitivity. One type of immune complex-mediated hypersensitivity is produced locally and is called **Arthus** reaction. This reaction occurs when a low dose of antigen is injected into the skin. This induces the production of IgG antibodies and complement activation. In addition, mast cells and neutrophils are stimulated to release their mediators that enhance vascular permeability. This reaction usually occurs within 12 hours. Another example of type III hypersensitivity involves a systemic immune complex disease such as acute poststreptococcal glomerulonephritis.

Acute poststreptococcal glomerulonephritis is a well-known immune complex disease. Its onset takes place several weeks after a group A β -hemolytic streptococcal infection, particularly of the skin, and often occurs with infection due to nephritogenic types of streptococci. The complement level is typically low, suggesting an antigen–antibody reaction with consumption of complement. Lumpy deposits of immunoglobulin and complement component, C3, are observed along the glomerular basement membrane. These membranes can be stained by immunofluorescence and visualized under UV microscopy. This type of pattern reveals antigen–antibody complexes. It is likely that streptococcal antigen–antibody complexes are filtered out by glomeruli, fix complement, and attract neutrophils. This series of events results in an inflammatory process that damages the kidney.

Type IV: Cell-Mediated (Delayed) Hypersensitivity

Cell-mediated hypersensitivity is a T cell-mediated response. The interaction of an antigen with specifically sensitized T cells results in T-cell proliferation, release of potent inflammatory cytokines (IFN- γ and IL-2), and activation of macrophages. This inflammatory response most often begins 2 or 3 days after contact with the antigen and typically lasts for several days.

A. Contact Hypersensitivity

Contact hypersensitivity occurs after sensitization with simple chemicals (eg, nickel and formaldehyde), plant materials (poison ivy, poison oak), topically applied medications (eg, sulfonamides and neomycin), some cosmetics, soaps, and other substances. In all cases, small molecules enter the skin and then, acting as haptens, attach to body proteins to serve as complete antigens. Cell-mediated hypersensitivity is induced, particularly in the skin. When the skin again comes in contact with the offending agent, the sensitized person develops erythema, itching, vesication, eczema, or necrosis of skin within 12–48 hours. Avoidance of the inciting material will prevent recurrences. A skin test may identify the antigen in question. Langerhans cells in the epidermis, which interact with CD4 Th1 cells, appear to play a role in driving this response.

B. Tuberculin-Type Hypersensitivity

Delayed hypersensitivity to antigens of microorganisms occurs in many infectious diseases and it has been used as an aid in diagnosis. The tuberculin reaction is a good example of a delayed-type hypersensitivity (DTH) response. When a small amount of tuberculin is injected into the epidermis of a patient previously exposed to *Mycobacterium tuberculosis*, there is little immediate reaction. Gradually, however, induration and redness develop and reach a peak in 24–72 hours. Mononuclear cells, especially CD4 Th1 cells, accumulate in the subcutaneous tissue. A positive skin test indicates that the

person has been infected with the microorganism but does not imply the presence of current disease. However, a recent change of skin test response from negative to positive suggests recent infection and possible current activity.

DEFECTS OF THE IMMUNE RESPONSE

Immunodeficiency Diseases

Immunodeficiency can be divided into two categories: primary immunodeficiency diseases and secondary immunodeficiency diseases. Primary immunodeficiency diseases consist of disorders of the immune system in which the defect is intrinsic to the cells of the immune system. Secondary immunodeficiency diseases consist of disorders of the immune system in which the defect is induced by external factors, such as viruses, malignancy, and drugs. This section is clearly relevant to medical microbiology because the primary immunodeficiency diseases are usually identified first by the type of organism, duration, and frequency of infectious disease.

A. Primary Immunodeficiencies

Primary immunodeficiencies are a heterogeneous group of immune system disorders. Most of the primary immunodeficiencies are genetically determined and inherited as a single-gene defect. To date, more than 150 genetically based diseases have been identified. The genetic defect results in the loss of number or function of B cells, T cells, phagocytic cells, complement components, cytokines, or TLRs. Clearly, the loss of these functional elements leads to increased susceptibility to infections. One example is chronic granulomatous disease (CGD), which is an impairment of phagocytic cell function. Patients have normal levels of immunoglobulins, T and B cells, and phagocytic cells. However, the phagocytic cells do not kill microbes due to genetic defect in cytochrome *b*-558. This leads to a metabolic defect in the ability of phagocytic cells to produce peroxide and superoxide. The phagocytic defect can be identified by using the nitroblue tetrazolium (NBT) test. These cells are unable to efficiently kill some bacteria or fungi, such as *Staphylococcus*, *E. coli*, and *Aspergillus* spp. Unless treated, CGD is usually fatal within the first decade of life. IFN- γ has been shown to restore phagocytic function in these cells. Therefore, in most cases, administration of IFN- γ and bone marrow transplantation are the effective treatments. A second example is severe combined immunodeficiency (SCID). This syndrome is now known to be the final expression of several different genetic defects leading to defects in both B and T cell function. These individuals are susceptible to infection by virtually any microbe, and if untreated, they will die within the first year of life.

B. Secondary Immunodeficiencies

Secondary immunodeficiencies are a major predisposing cause of infection. Secondary immunodeficiency states are associated with infections, malignancies, and drugs.

C. Infections

Infections can induce immunosuppression in the host. Historically, it is well known that patients infected with EBV and who present with mononucleosis have a depressed DTH skin test for TB and other antigens. This negative skin test indicates a depressed T-cell response. Analysis of EBV replication has revealed a possible mechanism for this immunosuppression. Interestingly, the EBV genome codes for a human IL-10 analog. IL-10 is an immunosuppressive cytokine that inhibits Th1 cells from proliferating and producing cytokines, such as IFN- γ . This may account for the negative DTH skin test.

The most obvious example of a virus-induced immunodeficiency is HIV infection and the resulting disease, AIDS. HIV primarily infects CD4 T cells. This is possible because the virus uses the CD4 molecule itself as the virus receptor and the chemokine receptor, CCR5, as a coreceptor to enter the cell. HIV replication in CD4 T cells leads to a progressive loss of CD4 T cells and the development of AIDS. As a consequence of this infection, HIV patients develop multiple opportunistic infections. As noted earlier in this chapter, CD4 T cells are critically important for generating Th1, Th2, Th17, Tfh, and T reg cell populations. These cell types are needed for a variety of immune reactions. These cells also provide help to B cells during antibody production and serve as a source of IL-2 and IFN- γ . Therefore, replication of a cytotoxic virus in this cell type is devastating to the immune response.

D. Malignancy

Selected leukemias, lymphomas, multiple myeloma, and other cancers can lead to immunodeficiency and increased infections. For example, patients with leukemia can have a deficiency in neutrophils, which results in loss of phagocytosis and increased infections with bacteria and fungi. Some tumors secrete high levels of TGF- β that can suppress a variety of responses, including Th1 responses.

E. Drugs

Cytotoxic drugs used to treat cancer (eg, cisplatin), immunosuppressive drugs (eg, cyclosporine) that are used to manage transplant patients, and newer anticytokine (anti-TNF- α) drugs used to treat autoimmune diseases (eg, RA) can lead to increased risk of infection.

TUMOR IMMUNOLOGY

Over the last decade significant progress has been made in our understanding of human tumors and how to amplify the “killing power” of the immune system against these tumors. As a consequence of these advancements, a new focus in the clinical arena, immuno-oncology, has evolved. Immuno-oncology is a new therapeutic strategy currently being used for a number of human cancers. Unlike the traditional approaches to cancer treatment, which involve directly destroying the tumor, immunotherapy and the use of

immunotherapeutic agents, such as the immune checkpoint inhibitors, have unleashed the immune system to attack the tumor. This approach focuses on the development of drugs targeting immune costimulatory and inhibitory “check-point” pathways.

As noted in the T Cell-Mediated Immunity section of this chapter, immune cells (i.e. T cells and B cells) have inhibitory receptors, called **immune checkpoints**, that downregulate immune activation to avoid overstimulation or excessive immune activation. Tumors have developed ways to exploit this control system and manipulate these inhibitory pathways. Antibodies directed at these checkpoint molecules reverse the tumor’s ability to block antitumor immunity. Cytotoxic T-lymphocyte antigen 4 (CTLA-4) and programmed death-1 (PD-1) are two popular co-inhibitory checkpoint molecules currently in use.

To date, a variety of immune checkpoint inhibitors have been approved and have generated promising results in the treatment of melanoma, non-small cell lung cancer, renal cell carcinoma, head and neck squamous cell carcinoma, Hodgkin’s lymphoma, bladder cancer, and gastric cancer. These treatments are revolutionary; however, this success is not without adverse side effects, such as toxicities and autoimmunity. Overcoming these challenges along with interest in the next generation of immune checkpoint agents, used either alone or in combination with other immunotherapies (engineered T cells, vaccines, etc), offers great optimism for future cancer management.

CLINICAL IMMUNOLOGY LABORATORY (DIAGNOSTIC TESTING)

Exciting discoveries in molecular biology, recombinant DNA and proteins, cytokine biology, and human genetics have enhanced our understanding of immune-mediated diseases. With these advancements, clinical laboratory immunology has matured, and its applications have increased extensively. Hence, the scope of the clinical immunology laboratory now extends to a wide variety of disciplines, such as transplantation, rheumatology, oncology, dermatology, infectious disease, allergy, and immunodeficiencies. The goal of the clinical immunology laboratory is to provide laboratory testing to support the diagnosis and monitoring of patients with immune disorders. A variety of technologies are used to evaluate both the antibody and cellular components of the immune response. For a comprehensive review of current test systems used in the clinical immunology hospital setting, see Detrick et al (2016). Selected assays are highlighted.

Antibody Evaluation Assays

A. Enzyme-Linked Immunosorbent Assay

The enzyme immunoassay (EIA) testing system is one of the most popular tests used in the clinical laboratory to monitor a variety of antibody specificities. This method depends on

the conjugation of an enzyme to an antibody. The enzyme is detected by assaying for enzyme activity with its substrate. To measure antibody concentration, known antigens are bound to a solid phase (eg, plastic microtiter plate), incubated with test antibody dilutions, washed, and reincubated with an anti-immunoglobulin labeled with an enzyme (eg, horseradish peroxidase). The enzyme conjugated to the detection moiety produces a color when the specific substrate is added. The more antigen that binds to antibody results in higher concentrations of enzyme that leads to stronger color development. Thus, the intensity of the color developed is a direct function of the concentration of antibody bound. This serologic test is used to detect antibodies to a number of infectious diseases, such as antibodies to HIV proteins in blood samples or antibodies to the syphilis organism, *Treponema pallidum*. This assay is also widely used to detect autoantibodies present in the circulation of patients with systemic and organ-specific autoimmune diseases (eg, antibodies in systemic lupus erythematosus, scleroderma, or Sjögren syndrome). Variations of the traditional enzyme-linked immunosorbent assay include some of the newer technologies, such as chemiluminescence assay (CIA) and multiplex particle-based assays.

B. Multiplex Assays

The multiplex technology, which has become an indispensable tool for the clinical and research laboratory, enables the detection and quantification of multiple analytes (antigens, antibodies, and other analytes such as cytokines) in a single sample volume. The principle of a multiplex system is similar to the classic EIA “sandwich” immunoassay with some important differences. For example, the use of small magnetic beads complexed to the capture antibody provides for efficient bound/free separation and provides near solution phase assay kinetics, labeling the beads with multiple fluorescent dyes allow beads to be made assay specific and a universal fluorescent dye marker, coupled to the assay-specific second antibody by the biotin–streptavidin reaction, allows each assay to be quantitative. The steps are straightforward: first beads are incubated with the analyte being tested, then a biotinylated antibody is added and then streptavidin coupled to a fluorescent probe is added and the mixtures analyzed in a flow cytometer.

C. Immunofluorescence

When an antibody is labeled with a fluorescent dye (eg, fluorescein and rhodamine), the presence of the antibody can be observed using an ultraviolet light source in a fluorescence microscope. This assay system can be applied in two ways: a direct immunofluorescence assay or an indirect immunofluorescence assay. In the **direct immunofluorescence assay**, a known specific antibody is labeled with a fluorescent dye. A specimen with unknown organisms is added to a slide and the slide is incubated with the fluorescein-labeled specific antibody (eg, antistreptococcal antibody). The slide is washed and evaluated under a fluorescence microscope.

If the unknown specimen contains streptococcus organisms, they will appear green. In the **indirect immunofluorescence assay**, a two-step procedure is used to detect the presence of organism-specific antibodies (such as treponemal antibodies) in a serum specimen. First, a known antigen (treponema) is attached to a slide. A serum sample is incubated with the slide, the sample is removed, the slide is washed, and a second fluorescein-labeled anti-immunoglobulin is added. The slide is washed and examined under a fluorescence microscope. If the patient's serum contained antitreponemal antibodies, the organism will appear green under the fluorescence microscope. Historically this assay has been used to detect antibodies to certain microorganisms (eg, *T. pallidum*) and is the standard procedure for the detection of autoantibodies in autoimmune diseases (eg, antinuclear antibodies).

D. Immunoblot

Immunoblot or Western blot is used to identify an antigen in a complex mixture of proteins. The complex mixture of proteins (eg, microorganism) is subjected to sodium dodecyl sulfate (SDS)–polyacrylamide gel electrophoresis (PAGE). This separates the proteins according to charge and molecular size. The gel is then covered with a membrane (such as nitrocellulose), and the proteins are transferred to the membrane. The nitrocellulose membrane (blot) now contains the separated proteins. The membrane is incubated with a serum sample. If the serum contains specific antibody that reacts with a protein on the membrane, the antibody will remain on the membrane. The membrane is now incubated with an enzyme-labeled anti-immunoglobulin. The membrane is washed and incubated with the enzyme substrate. The enzyme and enzyme substrate mixture allows for colorimetric detection. The antigen–antibody complex is visible as a separate band. This method is widely used as a secondary test for HCV and Lyme disease. More recently, this technology is being applied to identification of autoantibodies in selected autoimmune diseases (eg, polymyositis). Variations of the immunoblot techniques include dot or slot blot assays, both of which use purified antigens. In these techniques, purified antigens are attached to the nitrocellulose membrane.

E. Other Laboratory Assays

Other technologies often available in the clinical immunology laboratory include protein electrophoresis and immunofixation electrophoresis, which are essential tests used to identify abnormal immunoglobulin production in the serum or urine of patients with myeloma. Nephelometry is another laboratory test that quantifies a wide variety of analytes in serum or plasma. This is the method of choice for quantitating complement components, immunoglobulins, and other serum analytes. These assays can also be used to evaluate other abnormalities associated with these selected infectious diseases (eg, HCV can be associated with a monoclonal protein and the presence of cryoglobulins).

Evaluation of Cellular Responses

A. Flow Cytometry

Flow cytometry is a laser-based method used for the analysis of cells and selected cell components. One of the most popular applications of flow cytometry is immunophenotyping of cell populations. In this method, single-cell suspensions stream through a flow cell in which the cells pass through a laser beam for sensing. As the cells pass through the laser, they scatter light. If cells also contain fluorescent molecules, this will be detected. Both scattered light and fluorescent light information is recorded and analyzed to identify subpopulations within the sample. It is relatively easy to separate the cells into major classes, such as small lymphocytes separated from granulocytes that are larger and contain more granules (scatter more light).

A second way to analyze these cells is to evaluate cell surface molecules that can be labeled with a fluorescent dye. The cluster of differentiation (CD) nomenclature is used for the identification of cell surface molecules. Presently there are over 300 CD molecules that have been identified. Monoclonal antibodies directed against the CD molecules have been generated and can be tagged with fluorescent labels. Incubation of the cells with a variety of different CD labeled antibodies allows the flow cytometric analysis of distinct populations of cells in the mixture. Using this method, one can identify CD4-positive cells, CD8-positive cells, B cells, macrophages, and cells expressing a variety of cytokines. This technology is widely used both in clinical laboratory and in biomedical research (eg, to enumerate CD4 T cells in HIV-positive patients or to distinguish tumor cells from normal white blood cells).

B. Functional Cellular Assays

In order to measure T cell function in vitro, the cells' ability to proliferate or produce specific cytokines, such as IFN- γ , is analyzed. This assay is the in vitro counterpart of type IV hypersensitivity reactions, with TB skin test as a model. In the skin, the administered TB antigen interacts with specific T cells to proliferate, produce IFN- γ , and give a positive skin reaction. In this in vitro assay, peripheral blood leukocytes (PBLs) are incubated with a specific antigen for 24–72 hours. When specifically sensitized T cells in the PBLs interact with their specific antigen (eg, TB antigen), the cells will proliferate and produce IFN- γ . Proliferation can be measured by H^3 thymidine incorporation, or IFN- γ production can be monitored by EIA or flow cytometry. This assay can be used to assess the immune status of an individual, particularly patients who are immunocompromised because of an infectious disease, malignancy, or drug therapy.

CHAPTER SUMMARY

- **Innate immunity** is an immediate, nonspecific response to a pathogen. The components of this response include phagocytic cells (macrophages and neutrophils), NK cells, ILCs, TLRs, cytokines, and complement.

- **Phagocytosis** is an immune response that detects and destroys pathogens. The process includes the following steps: chemotaxis, migration, ingestion, and microbial killing.
- **Adaptive immunity** is that arm of the immune response that is highly specific, has immunologic memory, and can respond rapidly and vigorously to a second antigen exposure. It involves either antibody-mediated or cell-mediated immune responses or both responses.
- **Antigen presentation** is a critical component of adaptive immunity. Proteins from exogenous antigens are processed by APCs and then returned to the cell surface as an MHC class II–peptide complex. This complex is recognized by a TCR on a CD4 T cell. CD4 molecule acts as a coreceptor. A second signal required for T-cell activation is derived from the interaction of CD80 on the APC with CD28 on the T cell. T cells now proliferate and differentiate into effector T cells. Endogenous antigens are processed by APCs via an MHC class I–peptide complex. This complex is recognized by a TCR on CD8 T cells.
- **Antibody production:** B cells rearrange immunoglobulin genes and express a receptor (BCR) for antigen. When antigen interacts with the BCR, the B cell is stimulated to divide and form a clone. B cell differentiates to become plasma cells and secrete antibody or the B cell becomes a memory B cell.
- **Functions of antibody:** Antibody can perform several protective functions. Antibody can enhance phagocytosis, induce neutralization of viruses and bacterial toxins, and participate in complement-mediated lysis and ADCC.
- **Functions of T cells.** (1) CD4 T cells can become Th1, Th2, Th17, Tfh, or T reg cells. Th1 cells can produce cytokines (IL-2, IFN- γ), activate macrophages, or trigger B cell switching to IgG synthesis. Th2 cells activate mast cells and eosinophils and trigger B cell switching to IgE synthesis. Th17 cells can produce IL-17 triggering production of IL-8 and recruitment of neutrophils and macrophages. Tfh (follicular helper T cells) populate the lymph node follicles and participate in antigen-specific B cell help and IL-21 production. T reg cells produce TGF- β and IL-10, which can suppress immune responses. (2) CD8 T cells function as cytotoxic T cells.
- **Complement system:** There are three major pathways to activate the **complement**: the classical, the alternative, and the mannan-binding lectin pathway. Each pathway results in the formation of MAC, leading to cell lysis. Complement provides protection from pathogens by four mechanisms: (1) cytolysis, (2) chemotaxis, (3) opsonization, and (4) vasodilation and vascular permeability.
- **Cytokines** are potent, low-molecular-weight cell regulators produced transiently and locally by a broad range of cells, including macrophages, dendritic cells, NK cells, T cells, and B cells. IFNs are potent antiviral and immunoregulatory molecules.
- **Hypersensitivity reactions:**
 - **Type I, immediate:** IgE antibody is induced by the allergen and binds via its Fc receptor to mast cells and eosinophils. After encountering the antigen again, the fixed IgE becomes cross-linked, which induces degranulation and release of mediators, especially histamine.
 - **Type II:** Antigens on a cell surface combine with antibody, which leads to complement-mediated lysis (eg, transfusion or Rh reactions) or other cytotoxic membrane damage (eg, autoimmune hemolytic anemia).
 - **Type III, immune complex:** Antigen–antibody immune complexes are deposited in tissues, complement is activated, and PMNs are attracted to the site, causing tissue damage.
 - **Type IV, delayed:** T lymphocyte-mediated reaction in which the T cells are sensitized by an antigen and release cytokines upon second contact with the same antigen. The cytokines induce inflammation and activate macrophages.

REVIEW QUESTIONS

1. Which of the following characteristics does not apply to adaptive immunity?
 - (A) Highly antigen specific
 - (B) Induces memory
 - (C) Rapid, immediate response
 - (D) Induces cytokine production
2. NK cells contribute to innate immunity in all of the following ways except:
 - (A) Killing virus infected cells
 - (B) Killing tumor cells
 - (C) Inducing IFN-gamma production
 - (D) Participate in antibody-dependent cellular cytotoxicity (ADCC)
 - (E) Initiating antigen presentation
3. As part of the innate immune response, which cells participate in phagocytosis?
 - (A) Macrophages and mast cells
 - (B) Macrophages and plasma cells
 - (C) NK cells and neutrophils
 - (D) Macrophages and neutrophils
 - (E) T cells and mast cells
4. The immunoglobulin class most frequently responsible for inhibition of bacteria on mucosal surfaces is:
 - (A) IgG
 - (B) IgM
 - (C) IgA
 - (D) IgE
 - (E) IgD
5. Which of the following properties is associated with MHC?
 - (A) Binds peptide antigen and presents it to T cells
 - (B) Binds virus particles and neutralizes the virus
 - (C) Binds LPS and interferes with bacterial phagocytosis
 - (D) Binds self-antigens and presents them to NK cells

6. Which of the following items regarding T cells located in lymph node follicles participate in B cell help with isotype switching and antibody production?
 - (A) Th1 cells
 - (B) Th2 cells
 - (C) Th17 cells
 - (D) T reg
 - (E) Tfh cells
7. Which of the following functional properties are not associated with IFN-gamma?
 - (A) Induces production of other pro-inflammatory cytokines
 - (B) Anti-proliferative activity
 - (C) Anti-viral activity
 - (D) Triggers plasma cell formation and antibody production
8. Which of the following cytokines can inhibit or downregulate the immune response?
 - (A) IFN-beta and IL-10
 - (B) IFN-gamma and IL-10
 - (C) IFN-beta and IL-2
 - (D) IL-17 and IL-2
9. The initial step in antibody formation begins with the binding of antigen to the B cell surface immunoglobulin via:
 - (A) MHC class I molecule
 - (B) MHC class II molecule
 - (C) B cell receptor (BCR)
 - (D) KIRS
10. Which of the cytokines attracts neutrophils and inhibit bacteria?
 - (A) IFN-gamma
 - (B) IL-8 (CXCL8)
 - (C) IL-2
 - (D) IL-6
 - (E) TGF- β
11. MHC class I molecules are critically important in what immunologic process?
 - (A) IgE-mediated histamine release
 - (B) Phagocytosis
 - (C) Immunoglobulin class switching
 - (D) CD8⁺ T-cell cytotoxicity
 - (E) Opsonization
12. The host response to the interaction of a pathogen with its specific TLR generates which of the following?
 - (A) IgG production
 - (B) Cell activation and production of cytokines and chemokines
 - (C) Immunoglobulin class switching
 - (D) Phagocytosis
 - (E) Presentation of pathogen to helper T cells
13. The interaction of two IgG molecules binding to antigen followed by the binding of C1 to the Fc portion of the antibody results in which of the following?
 - (A) Initiation of antigen presentation
 - (B) Initiation of classical complement pathway
 - (C) Initiation of alternative complement pathway
 - (D) Initiation of the mannose-binding lectin-binding complement pathway
14. Which genetic mechanism generates antibodies of the same specificity but different immunoglobulin classes?
 - (A) V gene segment recombination
 - (B) Class switching
 - (C) Somatic hypermutation
 - (D) Junctional variability due to imprecise V, D, and J joining
 - (E) Gene duplication, ie, multiple V, D, and J gene segments
15. Which major antibody molecule has the ability to cross the placenta?
 - (A) IgG
 - (B) IgA
 - (C) IgM
 - (D) IgE
 - (E) IgD
16. A man in his twenties presents in the emergency room with shortness of breath and fatigue. He is also very pale. Two days earlier he was given penicillin for an infection. He had penicillin previously without problems and stated that he had "no allergy" to penicillin. Laboratory testing shows that antibodies to penicillin are present in the patient's serum and that he is breaking down his own red blood cells. He is diagnosed with immune hemolytic anemia. The patient has which type of hypersensitivity reaction?
 - (A) Type I
 - (B) Type II
 - (C) Type III
 - (D) Type IV (DTH)
17. Which one of the following cell types expresses receptors for IgE on its cell surface that stimulate the cell to mount a response to parasites such as worms?
 - (A) T cells
 - (B) B cells
 - (C) NK cells
 - (D) Mast cells
 - (E) Dendritic cells
18. IgE-mediated histamine release is classified as what type of hypersensitivity reaction?
 - (A) Type I
 - (B) Type II
 - (C) Type III
 - (D) Type IV
19. Which two cytokines play an important role in attracting neutrophils to the site of an infection?
 - (A) IFN-alpha and IFN-gamma
 - (B) IL-8 and IL-17
 - (C) IL-2 and IL-4
 - (D) IL-6 and IL-12
20. Which one of the following laboratory assays is considered to be an in vitro counterpart of the type IV hypersensitivity reactions seen in the TB skin test?
 - (A) Immunoblot for TB antigen
 - (B) EIA analysis of sera from TB patient
 - (C) Immunofluorescence assay for TB antibody
 - (D) IFN-gamma production by white blood cell (WBC) treated with TB antigen

21. Which of the following laboratory assays can be used to detect the number and types of immune cells in the peripheral blood?
- (A) Immunofixation electrophoresis
 - (B) EIA
 - (C) Flow cytometry
 - (D) Immunoblot
22. PD-1 and CTLA-4 are targets for cancer immune therapy and are both expressed on what cell type:
- (A) Plasma cells
 - (B) Mast cells
 - (C) Neutrophils
 - (D) Activated T cells
 - (E) Tumor cells

SECTION III

BACTERIOLOGY

Pathogenesis of Bacterial Infection

C H A P T E R

9

The pathogenesis of bacterial infection includes initiation of the infectious process and the mechanisms that lead to the development of signs and symptoms of disease. The biochemical, structural, and genetic factors that play important roles in bacterial pathogenesis are introduced in this chapter and may be revisited in the organism-specific sections. Characteristics of bacteria that are pathogens include transmissibility, adherence to host cells, persistence, invasion of host cells and tissues, toxigenicity, and the ability to evade or survive the host's immune system. Resistance

to antimicrobials and disinfectants can also contribute to **virulence**, or an organism's capacity to cause disease. Many infections caused by bacteria that are commonly considered to be pathogens are inapparent or asymptomatic. Disease occurs if the bacteria or immunologic reactions to their presence cause sufficient harm to the person.

Terms frequently used in describing aspects of pathogenesis are defined in the Glossary (see below). Refer to the Glossary in Chapter 8 for definitions of terms used in immunology and in describing aspects of the host's response to infection.

GLOSSARY

<p>Adherence (adhesion, attachment): The process by which bacteria stick to the surfaces of host cells. After bacteria have entered the body, adherence is a major initial step in the infection process. The terms <i>adherence</i>, <i>adhesion</i>, and <i>attachment</i> are often used interchangeably.</p> <p>Carrier: A person or animal with asymptomatic infection that can be transmitted to another susceptible person or animal.</p> <p>Infection: Multiplication of an infectious agent within the body. Multiplication of the bacteria that are part of the normal microbiota of the gastrointestinal tract, skin, and so on is generally not considered an infection; on the other hand, multiplication of pathogenic bacteria (eg, <i>Salmonella</i> species)—even if the person is asymptomatic—is deemed an infection.</p>	<p>Invasion: The process whereby bacteria, animal parasites, fungi, and viruses enter host cells or tissues and spread in the body.</p> <p>Microbiota: Microbial flora harbored by normal, healthy individuals.</p> <p>Nonpathogen: A microorganism that does not cause disease; may be part of the normal microbiota.</p> <p>Opportunistic pathogen: An agent capable of causing disease only when the host's resistance is impaired (ie, when the patient is "immunocompromised").</p> <p>Pathogen: A microorganism capable of causing disease.</p> <p>Pathogenicity: The ability of an infectious agent to cause disease. (See also virulence.)</p>
---	--

Superantigens: Protein toxins that activate the immune system by binding to major histocompatibility complex (MHC) molecules and T-cell receptors (TCR) and stimulate large numbers of T cells to produce massive quantities of cytokines.

Toxigenicity: The ability of a microorganism to produce a toxin that contributes to the development of disease.

Virulence: The quantitative ability of an agent to cause disease. Virulent agents cause disease when introduced into the host in small numbers. Virulence involves adherence, persistence, invasion, and toxigenicity (see above).

IDENTIFYING BACTERIA THAT CAUSE DISEASE

Humans and animals have abundant normal **microbiota** that usually do not produce disease (see Chapter 10) but achieve a balance that ensures the survival, growth, and propagation of both the bacteria and the host. Some bacteria that are important causes of disease are cultured commonly with the normal microbiota (eg, *Streptococcus pneumoniae* and *Staphylococcus aureus*). Sometimes bacteria that are clearly pathogens (eg, *Salmonella* serotype Typhi) are present, but infection remains latent or subclinical, and the host is a “carrier” of the bacteria.

It can be difficult to show that a specific bacterial species is the cause of a particular disease. In 1884, Robert Koch proposed a series of postulates that have been applied broadly to link many specific bacterial species with particular diseases. **Koch’s postulates** are summarized in Table 9-1.

Koch’s postulates have remained a mainstay of microbiology; however, since the late 19th century, many microorganisms that do not meet the criteria of the postulates

have been shown to cause disease. For example, *Treponema pallidum* (syphilis) and *Mycobacterium leprae* (leprosy) cannot be grown in vitro; however, there are animal models of infection with these agents. In another example, there is no animal model of *Neisseria gonorrhoeae* (gonorrhea) infection even though the bacteria can readily be cultured in vitro; experimental infection in humans has been produced that substitutes for an animal model.

In other instances, Koch’s postulates have been at least partially satisfied by showing bacterial pathogenicity in an in vitro model of infection rather than in an animal model. For example, some forms of *Escherichia coli*-induced diarrhea (see Chapter 15) have been defined by the interaction of the *E. coli* with host cells in tissue culture.

The host’s immune responses also should be considered when an organism is being investigated as the possible cause of a disease. Thus, development of a rise in specific antibody during recovery from disease is an important adjunct to Koch’s postulates.

Modern-day microbial genetics has opened new frontiers to study pathogenic bacteria and differentiate them from

TABLE 9-1 Guidelines for Establishing the Causes of Infectious Diseases

Koch’s Postulates	Molecular Koch’s Postulates	Molecular Guidelines for Establishing Microbial Disease Causation
<div>1. The microorganism should be found in all cases of the disease in question, and its distribution in the body should be in accordance with the lesions observed.</div> <div>2. The microorganism should be grown in pure culture in vitro (or outside the body of the host) for several generations.</div> <div>3. When such a pure culture is inoculated into susceptible animal species, the typical disease must result.</div> <div>4. The microorganism must again be isolated from the lesions of such experimentally produced disease.</div>	<div>1. The phenotype or property under investigation should be significantly associated with pathogenic strains of a species and not with nonpathogenic strains.</div> <div>2. Specific inactivation of the gene or genes associated with the suspected virulence trait should lead to a measurable decrease in pathogenicity or virulence.</div> <div>3. Reversion or replacement of the mutated gene with the wild-type gene should lead to restoration of pathogenicity or virulence.</div>	<div>1. The nucleic acid sequence of a putative pathogen should be present in most cases of an infectious disease and preferentially in anatomic sites where pathology is evident.</div> <div>2. The nucleic acid sequence of a putative pathogen should be absent from most healthy control participants. If the sequence is detected in healthy control participants, it should be present with a lower prevalence as compared with patients with disease and in lower copy numbers.</div> <div>3. The copy number of a pathogen-associated nucleic acid sequence should decrease or become undetectable with resolution of the disease (eg, with effective treatment) and should increase with relapse or recurrence of disease.</div> <div>4. The presence of a pathogen-associated nucleic acid sequence in healthy subjects should help predict the subsequent development of disease.</div> <div>5. The nature of the pathogen inferred from analysis of its nucleic acid sequence should be consistent with the known biologic characteristics of closely related organisms and the nature of the disease. The significance of a detected microbial sequence is increased when microbial genotype predicts microbial morphology, pathology, clinical features of disease, and host response.</div>

nonpathogens. Molecular cloning has allowed investigators to isolate and modify specific virulence genes and study them with models of infection. The ability to study genes associated with virulence has led to a proposed form of **molecular Koch's postulates**. These postulates are summarized in Table 9-1.

Some pathogens are difficult or impossible to grow in culture, and for that reason, it is not possible with Koch's postulates or the molecular Koch's postulates to establish the cause of their associated diseases. The polymerase chain reaction is used to amplify microorganism-specific nucleic acid sequences from host tissues or fluids. The sequences are used to identify the infecting organisms. The molecular guidelines for establishing microbial disease causation are listed in Table 9-1. This approach has been used to establish the causes of several diseases, including Whipple's disease (*Tropheryma whipplei*), bacillary angiomatosis (*Bartonella henselae*), human monocytic ehrlichiosis (*Ehrlichia chaffeensis*), hantavirus pulmonary syndrome (Sin Nombre virus), and Kaposi sarcoma (human herpesvirus 8).

Analysis of infection and disease through the application of principles such as Koch's postulates leads to classification of bacteria as pathogens, opportunistic pathogens, or nonpathogens. Some bacterial species are always considered to be pathogens, and their presence is abnormal; examples include *Mycobacterium tuberculosis* (tuberculosis) and *Yersinia pestis* (plague). Such bacteria readily meet the criteria of Koch's postulates. Other species are commonly part of the normal microbiota of humans (and animals) but also can frequently cause disease. For example, *E. coli* is part of the gastrointestinal microbiota of normal humans but is also a common cause of urinary tract infections, traveler's diarrhea, and other diseases. Strains of *E. coli* that cause disease are differentiated from those that do not by determining whether (1) they are virulent in animals or in vitro models of infection and (2) they have a genetic makeup that is significantly associated with production of disease. Other bacteria (eg, *Pseudomonas* species, *Stenotrophomonas maltophilia*, and many yeasts and molds) only cause disease in immunosuppressed and debilitated persons and are **opportunistic pathogens**.

TRANSMISSION OF INFECTION

Bacteria (and other microorganisms) can adapt to a variety of environments that include external sources such as soil, water, and organic matter or internal milieu as found within insect vectors, animals, and humans, where they normally reside and subsist. In doing so, the bacteria ensure their survival and enhance the possibility of transmission. By producing asymptomatic infection or mild disease rather than death of the host, microorganisms that normally live in people enhance the possibility of transmission from one person to another.

Some bacteria that commonly cause disease in humans exist primarily in animals and incidentally infect humans.

For example, *Salmonella* and *Campylobacter* species typically infect animals and are transmitted in food products to humans. Other bacteria produce infection of humans that is inadvertent, a mistake in the normal life cycle of the organism; the organisms have not adapted to humans, and the disease they produce may be severe. For example, *Y. pestis* (plague) has a well-established life cycle in rodents and rodent fleas, and transmission by the fleas to humans is inadvertent; *Bacillus anthracis* (anthrax) lives in the environment, occasionally infects animals, and is transmitted to humans by products such as raw hair from infected animals. The *Clostridium* species are ubiquitous in the environment and are transmitted to humans by ingestion (eg, *Clostridium perfringens* gastroenteritis and *Clostridium botulinum* [botulism]) or when wounds are contaminated by soil (eg, *C. perfringens* [gas gangrene] and *Clostridium tetani* [tetanus]). Both *B. anthracis* and the *Clostridium* species elaborate spores to protect the organisms' nucleic acid from harsh environmental factors such as ultraviolet light, desiccation, chemical detergents, and pH extremes. These spores ensure survival in external environments, including foods ingested by humans. After being ingested or inoculated, the spores germinate into the vegetative, metabolically active form of the pathogen.

The clinical manifestations of diseases (eg, diarrhea, cough, and genital discharge) produced by microorganisms often promote transmission of the agents. Examples of clinical syndromes and how they enhance transmission of the causative bacteria are as follows: *Vibrio cholerae* can cause voluminous diarrhea, which may contaminate salt and fresh water; drinking water or seafood such as oysters and crabs may be contaminated; ingestion of contaminated water or seafood can produce infection and disease. Similarly, contamination of food products with sewage containing *E. coli* that causes diarrhea results in transmission of the bacteria. *M. tuberculosis* (tuberculosis) naturally infects only humans; it produces respiratory disease with cough and production of aerosols, resulting in transmission of the bacteria from one person to another.

Many bacteria are transmitted from one person to another on hands. A person with *S. aureus* carriage in the anterior nares may rub his nose, pick up the staphylococci on the hands, and spread the bacteria to other parts of the body or to another person, where infection results. Many opportunistic pathogens that cause nosocomial infections are transmitted from one patient to another on the hands of hospital personnel. Handwashing is thus an important component of infection control.

The most frequent **portals of entry of pathogenic bacteria** into the body are the sites where mucous membranes meet with the skin, which are the respiratory (upper and lower airways), gastrointestinal (primarily mouth), genital, and urinary tracts. Abnormal areas of mucous membranes and skin (eg, cuts, burns, and other injuries) are also frequent sites of entry. Normal skin and mucous membranes provide the primary defense against infection. To cause disease, pathogens must overcome these barriers.

THE INFECTIOUS PROCESS

In the body, most bacteria that cause disease do so first by attaching or adhering to host cells, usually epithelial cells. After the bacteria have established a primary site of infection, they multiply and spread directly through tissues or via the lymphatic system to the bloodstream. This infection (bacteremia) can be transient or persistent. Bacteremia allows bacteria to spread widely in the body and permits them to reach tissues particularly suitable for their multiplication.

Pneumococcal pneumonia is an example of the infectious process. *S. pneumoniae* can be cultured from the nasopharynx of 5–40% of healthy people. Occasionally, pneumococci from the nasopharynx are aspirated into the lungs; aspiration occurs most commonly in debilitated people and in settings such as coma when normal gag and cough reflexes are diminished. Infection develops in the terminal air spaces of the lungs in persons who do not have protective antibodies against that particular pneumococcal capsular polysaccharide type. Multiplication of the pneumococci and resultant inflammation lead to pneumonia. The pneumococci enter the lymphatics of the lung and move to the bloodstream. Between 10% and 20% of persons with pneumococcal pneumonia have bacteremia at the time when the diagnosis of pneumonia is made. When bacteremia occurs, the pneumococci can spread to secondary sites of infection (eg, cerebrospinal fluid, heart valves, and joint spaces). The major complications of pneumococcal pneumonia are meningitis, septic arthritis, and rarely endocarditis.

The infectious process in cholera involves ingestion of *V. cholerae*, chemotactic attraction of the bacteria to the gut epithelium, motility of the bacteria by a single polar flagellum, and penetration of the mucous layer on the intestinal surface. The *V. cholerae* adherence to the epithelial cell surface is mediated by pili and possibly other adhesins. Production of cholera toxin results in flow of chloride and water into the lumen of the gut, causing diarrhea and electrolyte imbalance.

GENOMICS AND BACTERIAL PATHOGENICITY

Bacteria are haploid (see Chapter 7) and limit genetic interactions that might change their chromosomes and potentially disrupt their adaptation and survival in specific environmental niches. One important result of the conservation of chromosomal genes in bacteria is that the organisms are clonal. For many pathogens, there are only one or a few clonal types that are spread in the world during a period of time. For example, epidemic serogroup A meningococcal meningitis occurs in Asia, the Middle East, and Africa and occasionally spreads into Northern Europe and the Americas. On several occasions, over a period of decades, single clonal types of serogroup A *Neisseria meningitidis* have been observed to appear in one geographic area and subsequently spread to others with resultant epidemic disease. There are two clonal types of *Bordetella pertussis*, both associated with disease. There are, however,

mechanisms that bacteria use, or have used a long time in the past, to transmit virulence genes from one to another.

Mobile Genetic Elements

Primary mechanisms for exchange of genetic information between bacteria include natural transformation and transmissible mobile genetic elements such as plasmids, transposons, and bacteriophages (often referred to as “phages”). Transformation occurs when DNA from one organism is released into the environment and is taken up by a different organism that is capable of recognizing and binding DNA. In other cases, the genes that encode many bacterial virulence factors are carried on plasmids, transposons, or phages. Plasmids are extrachromosomal pieces of DNA and are capable of replicating. Transposons are highly mobile segments of DNA that can move from one part of the DNA to another. This can result in recombination between extrachromosomal DNA and the chromosome (illegitimate or nonhomologous recombination; Chapter 7). If this recombination occurs, the genes coding for virulence factors may become chromosomal. Finally, bacterial viruses or phages are another mechanism by which DNA can be moved from one organism to another. Transfer of these mobile genetic elements between members of one species or, less commonly, between species can result in transfer of virulence factors, including antimicrobial resistance genes. A few examples of plasmid- and phage-encoded virulence factors are given in Table 9-2.

Pathogenicity Islands

Large groups of genes that are associated with pathogenicity and are located on the bacterial chromosome are termed

TABLE 9-2 Examples of Virulence Factors Encoded by Genes on Mobile Genetic Elements

Genus and Species	Virulence Factor and Disease
Plasmid encoded	
<i>E. coli</i>	Heat-labile and heat-stable enterotoxins that cause diarrhea
<i>E. coli</i>	Hemolysin (cytotoxin) of invasive disease and urinary tract infections
<i>E. coli</i> and <i>Shigella</i> species	Adherence factors and gene products involved in mucosal invasion
<i>B. anthracis</i>	Capsule essential for virulence (on one plasmid) Edema factor, lethal factor, and protective antigen are all essential for virulence (on other plasmids)
Phage encoded	
<i>C. botulinum</i>	Botulinum toxin that causes paralysis
<i>Corynebacterium diphtheriae</i>	Diphtheria toxin that inhibits human protein synthesis
<i>V. cholerae</i>	Cholera toxin that can cause a severe watery diarrhea

TABLE 9-3 A Few Examples of the Very Large Number of Pathogenicity Islands of Human Pathogens

Genus and Species	PAI Name	Virulence Characteristics
<i>E. coli</i>	PAI I ₅₃₆ , II ₅₃₆	Alpha hemolysin, fimbriae, adhesions, in urinary tract infections
<i>E. coli</i>	PAI I _{J96}	Alpha hemolysin, P-pilus in urinary tract infections
<i>E. coli</i> (EHEC)	O157	Macrophage toxin of enterohemorrhagic <i>E. coli</i>
<i>Salmonella</i> serotype Typhimurium	SPI-1	Invasion and damage of host cells; diarrhea
<i>Y. pestis</i>	HPI/pgm	Genes that enhance iron uptake
<i>V. cholerae</i> El Tor O1	VPI-1	Neuraminidase, utilization of amino sugars
<i>S. aureus</i>	SCC mec	Methicillin and other antibiotic resistance
<i>S. aureus</i>	SaPI1	Toxic shock syndrome toxin-1, enterotoxin
<i>Enterococcus faecalis</i>	NP ^m	Cytolysin, biofilm formation

PAI, pathogenicity island; SPI, *Salmonella* pathogenicity island; HPI, high pathogenicity island; VPI, *Vibrio* pathogenicity island; SCC, staphylococcal cassette chromosome mec; SaPI, *Staphylococcus aureus* pathogenicity island; NP, non-protease.

pathogenicity islands (PAIs). They are large organized groups of genes, usually 10–200 kb in size. The major properties of PAIs are as follows: they have one or more virulence genes; they are present in the genome of pathogenic members of a species but absent in the nonpathogenic members; they are large; they typically have a different guanine plus cytosine (G + C) content than the rest of the bacterial genome; they are commonly associated with tRNA genes; they are often found with parts of the genome associated with mobile genetic elements; they often have genetic instability; and they often represent mosaic structures with components acquired at different times. Collectively, the properties of PAIs suggest that they originate from gene transfer from foreign species. A few examples of PAI virulence factors are provided in Table 9-3.

REGULATION OF BACTERIAL VIRULENCE FACTORS

Pathogenic bacteria (and other pathogens) have adapted both to saprophytic or free-living states, possibly environments outside the body, and to the human host. They have evolved complex signal transduction systems to regulate the genes important for virulence. Environmental signals often control the expression of the virulence genes. Common signals include temperature, iron availability, osmolality, growth phase, pH, and specific ions (eg, Ca²⁺) or nutrient factors. A few examples are presented in the following paragraphs.

The gene for diphtheria toxin from *Corynebacterium diphtheriae* is carried on temperate bacteriophages. Toxin is produced only by strains lysogenized by the phages. Toxin production is greatly enhanced when *C. diphtheriae* is grown in a medium with low iron.

Expression of virulence genes of *B. pertussis* is enhanced when the bacteria are grown at 37°C and suppressed when they are grown at lower temperatures or in the presence of high concentrations of magnesium sulfate or nicotinic acid.

The virulence factors of *V. cholerae* are regulated on multiple levels and by many environmental factors. Expression of the cholera toxin is higher at a pH of 6.0 than at a pH of 8.5 and higher also at 30°C than at 37°C.

Osmolality and amino acid composition also are important. As many as 20 other genes of *V. cholerae* are similarly regulated.

Y. pestis produces a series of virulence plasmid-encoded proteins. One of these is an antiphagocytic fraction 1 capsular protein that results in antiphagocytic function. This protein is expressed maximally at 35–37°C, the host temperature, and minimally at 20–28°C, the flea temperature at which antiphagocytic activity is not needed. The regulation of other virulence factors in *Yersinia* species also is influenced by environmental factors.

Motility of bacteria enables them to spread and multiply in their environmental niches or in patients. *Yersinia enterocolitica* and *Listeria monocytogenes* are common in the environment where motility is important to them. Presumably, motility is not important in the pathogenesis of the diseases caused by these bacteria. *Y. enterocolitica* is motile when grown at 25°C but not when grown at 37°C. Similarly, *Listeria* is motile when grown at 25°C and not motile or minimally motile when grown at 37°C.

BACTERIAL VIRULENCE FACTORS

Many factors determine bacterial virulence or the ability to cause infection and disease.

Adherence Factors

When bacteria enter the body of the host, they must adhere to cells of a tissue surface. If they did not adhere, they would be swept away by mucus and other fluids that bathe the tissue surface. Adherence, which is only one step in the infectious

process, is followed by development of microcolonies and subsequent steps in the pathogenesis of infection.

The interactions between bacteria and tissue cell surfaces in the adhesion process are complex. Several factors play important roles, including surface hydrophobicity and net surface charge, binding molecules on bacteria (ligands), and host cell receptor interactions. Bacteria and host cells commonly have net negative surface charges and therefore repulsive electrostatic forces. These forces are overcome by hydrophobic and other more specific interactions between bacteria and host cells. In general, the more hydrophobic the bacterial cell surface, the greater the adherence to the host cell. Different strains of bacteria within a species may vary widely in their hydrophobic surface properties and ability to adhere to host cells.

Bacteria also have specific surface molecules that interact with host cells. Many bacteria have **pili**, thick rodlike appendages or **fimbriae**, shorter “hairlike” structures that extend from the bacterial cell surface and help mediate adherence of the bacteria to host cell surfaces. For example, some *E. coli* strains have type 1 pili, which adhere to epithelial cell receptors; adherence can be blocked in vitro by addition of D-mannose to the medium. *E. coli* organisms that cause urinary tract infections commonly do not have D-mannose-mediated adherence but have P-pili, which attach to a portion of the P blood group antigen; the minimal recognition structure is the disaccharide α -D-galactopyranosyl-(1-4)- β -D-galactopyranoside (GAL-GAL binding adhesin). The *E. coli* that causes diarrheal diseases (see Chapter 15) have pilus (fimbriae)-mediated adherence to intestinal epithelial cells. The type of pili and specific molecular mechanisms of adherence appear to be different depending on the form of the *E. coli* that induce the diarrhea.

Other specific ligand-receptor mechanisms have evolved to promote bacterial adherence to host cells, illustrating the diverse mechanisms used by bacteria. Group A streptococci (*Streptococcus pyogenes*) (see Chapter 14) also have hairlike appendages, termed **fimbriae** that extend from the cell surface. **Lipoteichoic acid**, protein F, and M protein are found on the fimbriae. The lipoteichoic acid and protein F cause adherence of the streptococci to buccal epithelial cells; this adherence is mediated by fibronectin, which acts as the host cell receptor molecule. M protein acts as an antiphagocytic molecule and is a major virulence factor.

Antibodies that act against the specific bacterial ligands that promote adherence (eg, pili and lipoteichoic acid) can block adherence to host cells and protect the host from infection.

After adherence occurs, conformational changes in the host cell ensue that can lead to cytoskeletal changes allowing organism uptake by the cell. Sometimes, changes in the adhesin molecule after attachment may trigger activation of virulence genes that promote invasion or that result in other pathogenic changes as described in the following pages.

Invasion of Host Cells and Tissues

Invasion is the term commonly used to describe the entry of bacteria into host cells and for many disease-causing bacteria,

invasion of the host's epithelium is central to the infectious process. Some bacteria (eg, *Salmonella* species) invade tissues through the junctions between epithelial cells. Other bacteria (eg, *Yersinia* species, *N. gonorrhoeae*, and *Chlamydia trachomatis*) invade specific types of the host's epithelial cells and may subsequently enter the tissue. In many infections, the bacteria produce virulence factors that cause the host cells to engulf (ingest) the bacteria. The host cells play a very active role in the process.

When inside the host cell, bacteria may remain enclosed in a vacuole composed of the host cell membrane, or the vacuole membrane may be dissolved and bacteria may be dispersed in the cytoplasm. Some bacteria (eg, *Shigella* species) multiply within host cells, but other bacteria do not.

Toxin production and other virulence properties are generally independent of the ability of bacteria to invade cells and tissues. For example, *C. diphtheriae* is able to invade the epithelium of the nasopharynx and causes symptomatic sore throat even when the *C. diphtheriae* strains are nontoxicogenic.

In vitro studies with cells in tissue culture have helped characterize the mechanisms of invasion for some pathogens; however, the in vitro models have not necessarily provided a complete picture of the invasion process. Full understanding of the invasion process, as it occurs in naturally acquired infection, has required study of genetically engineered mutants and their ability to infect susceptible animals and humans. Thus, understanding of eukaryotic cell invasion by bacteria requires satisfying much of Koch's postulates and the molecular Koch's postulates. The following paragraphs contain examples of bacterial invasion of host cells as part of the infectious process.

Shigella species adhere to host cells in vitro. Commonly, HeLa cells are used; these undifferentiated unpolarized cells were derived from a cervical carcinoma. The adherence causes actin polymerization in the nearby portion of the HeLa cell, which induces the formation of pseudopods by the HeLa cells and engulfment of the bacteria. Adherence and invasion are mediated at least in part by products of genes located on a large plasmid common to many shigellae. There are multiple proteins, including the **invasion plasmid antigens** (IpA-D) that contribute to the process. Inside the HeLa cells, the shigellae either are released or escape from the phagocytic vacuole, where they multiply in the cytoplasm. Actin polymerization propels the shigellae within a HeLa cell and from one cell into another. In vivo the shigellae adhere to integrins on the surface of M cells in Peyer's patches and not to the polarized absorptive cells of the mucosa. M cells normally sample antigens and present them to macrophages in the submucosa. The shigellae are phagocytosed by the M cells and pass through the M cells into the underlying collection of macrophages. Shigellae inside the M cells and macrophages can cause these cells to die by activating the normal cell death process (apoptosis). The shigellae spread to adjacent mucosal cells in a manner similar to the in vitro model by actin polymerization that propels the bacteria.

From studies using cells in vitro, it appears that the adherence-invasion process with *Y. enterocolitica* is similar to that of *Shigella*. Yersiniae adhere to the host cell membrane and cause it to extrude protoplasmic projections. The bacteria are then engulfed by the host cell with vacuole formation. Invasion is enhanced when the bacteria are grown at 22°C rather than at 37°C. When yersiniae have entered the cell, the vacuolar membrane dissolves and the bacteria are released into the cytoplasm. In vivo, the yersiniae are thought to adhere to and invade the M cells of Peyer’s patches rather than the polarized absorptive mucosal cells, much like shigellae.

L. monocytogenes from the environment is ingested in food. Presumably, the bacteria adhere to and invade the intestinal mucosa, reach the bloodstream, and disseminate. The pathogenesis of this process has been studied in vitro. *L. monocytogenes* adheres to and readily invades macrophages and cultured undifferentiated intestinal cells. The listeriae induce engulfment by the host cells. Proteins, called **internalins**, have a primary role in this process. The engulfment process, movement within a cell and movement between cells, requires actin polymerization to propel the bacteria, as with shigellae.

Legionella pneumophila infects pulmonary macrophages and causes pneumonia. Adherence of the legionellae to the macrophage induces formation of a long, thin pseudopod that then coils around the bacteria, forming a vesicle (**coiling phagocytosis**). The vesicle remains intact, phagolysosome fusion is inhibited, and the bacteria multiply within the vesicle.

N. gonorrhoeae uses pili as primary adhesins and **opacity-associated proteins (Opa)** as secondary adhesins to host cells. Certain Opa proteins mediate adherence to polymorphonuclear cells. Some gonococci survive after phagocytosis

by these cells. Pili and Opa together enhance the invasion of cells cultured in vitro. In uterine (fallopian) tube organ cultures, the gonococci adhere to the microvilli of nonciliated cells and appear to induce engulfment by these cells. The gonococci multiply intracellularly and migrate to the subepithelial space by an unknown mechanism.

Toxins

Toxins produced by bacteria are generally classified into two groups: endotoxin, which is present in the outer membrane of Gram-negative rods, and toxins that are secreted, such as enterotoxins and exotoxins. Enterotoxins and exotoxins are often classified by mechanisms of action and the impact on host cells and they are discussed in more detail below. The primary features of the two groups are listed in Table 9-4.

A. Exotoxins

Many Gram-positive and Gram-negative bacteria produce exotoxins of considerable medical importance. Some of these toxins have had major roles in world history. For example, tetanus caused by the toxin of *C. tetani* killed as many as 50,000 soldiers of the Axis powers in World War II; the Allied forces, however, immunized military personnel against tetanus, and very few died of that disease. Vaccines have been developed for some of the exotoxin-mediated diseases and continue to be important in the prevention of disease. These vaccines—called **toxoids**—are made from exotoxins, which are modified so that they are no longer toxic. Many exotoxins consist of A and B subunits (often referred to as binary toxins or type III toxins). The B subunit generally mediates adherence of the

TABLE 9-4 Characteristics of Exotoxins and Endotoxins (Lipopolysaccharides)

Exotoxins	Endotoxins
Excreted by living cell; high concentrations in liquid medium	Integral part of the cell wall of Gram-negative bacteria; released on bacterial death and in part during growth; may not need to be released to have biologic activity
Produced by both Gram-positive and Gram-negative bacteria	Found only in Gram-negative bacteria
Polypeptides with a molecular weight of 10,000–900,000	Lipopolysaccharide complexes; lipid A portion probably responsible for toxicity
Relatively unstable; toxicity often destroyed rapidly by heating at temperatures above 60°C	Relatively stable; withstand heating at temperatures above 60°C for hours without loss of toxicity
Highly antigenic; stimulate formation of high-titer antitoxin; antitoxin neutralizes toxin	Weakly immunogenic; antibodies are antitoxic and protective; relationship between antibody titers and protection from disease is less clear than with exotoxins
Converted to antigenic, nontoxic toxoids by formalin, acid, heat, and so on; toxoids are used to immunize (eg, tetanus toxoid)	Not converted to toxoids
Highly toxic; fatal to animals in microgram quantities or less	Moderately toxic; fatal for animals in tens to hundreds of micrograms
Usually bind to specific receptors on cells	Specific receptors not found on cells
Usually do not produce fever in the host	Usually produce fever in the host by release of interleukin-1 and other mediators
Frequently controlled by extrachromosomal genes (eg, plasmids)	Synthesis directed by chromosomal genes

toxin complex to a host cell and aids entrance of the exotoxin into the host cell. The A subunit provides the toxic activity. Examples of some pathogenetic mechanisms associated with exotoxins are given below. Other toxins of specific bacteria are discussed in the chapters covering those bacteria.

C. diphtheriae is a Gram-positive rod that can grow on the mucous membranes of the upper respiratory tract or in minor skin wounds (see Chapter 12). Strains of *C. diphtheriae* that carry a lysogenic, temperate corynebacteriophage (β -phage or ω -phage) with the structural gene for the toxin are toxigenic and produce **diphtheria toxin** and cause **diphtheria**. Many factors regulate toxin production; when the availability of inorganic iron is the factor limiting the growth rate, then maximal toxin production occurs. The toxin molecule is secreted as a single polypeptide molecule (molecular weight [MW], 62,000). This native toxin is enzymatically degraded into two fragments, A and B, linked together by a disulfide bond. Fragment B (MW 40,700) binds to specific host cell receptors and facilitates the entry of fragment A (MW 21,150) into the cytoplasm. Fragment A inhibits peptide chain elongation factor EF-2 by catalyzing a reaction that attaches an adenosine diphosphate-ribosyl group to EF-2, yielding an inactive adenosine diphosphate-ribose-EF-2 complex. Arrest of protein synthesis disrupts normal cellular physiologic functions. Diphtheria toxin is very potent.

C. tetani is an anaerobic Gram-positive rod that causes tetanus (see Chapter 11). *C. tetani* from the environment contaminates wounds, and the spores germinate in the anaerobic environment of the devitalized tissue. Infection often is minor and not clinically apparent. The vegetative forms of *C. tetani* produce the toxin **tetanospasmin** (MW 150,000) that is cleaved by a bacterial protease into two peptides (MW 50,000 and 100,000) linked by a disulfide bond. The toxin initially binds to receptors on the presynaptic membranes of motor neurons. It then migrates by the retrograde axonal transport system to the cell bodies of these neurons to the spinal cord and brainstem. The toxin diffuses to terminals of inhibitory cells, including both glycinergic interneurons and γ -aminobutyric acid (GABA)-secreting neurons from the brainstem. The toxin degrades synaptobrevin, a protein required for docking of neurotransmitter vesicles on the presynaptic membrane. Release of the inhibitory glycine and GABA is blocked, and the motor neurons are not inhibited. Spastic paralysis results. Extremely small amounts of toxin can be lethal for humans. Tetanus is totally preventable in immunologically normal people by immunization with tetanus toxoid.

C. botulinum causes botulism. This anaerobic, Gram-positive spore-forming organism is found in soil or water and may grow in foods (eg, canned and vacuum packed) if the environment is appropriately anaerobic. An exceedingly potent toxin (the most potent toxin known) is produced. It is heat labile and is destroyed by sufficient heating. There are seven distinct serologic types of toxin. Types A, B, E, and F are most commonly associated with human disease. The toxin is very similar to tetanus toxin, with a 150,000 MW protein that is cleaved into 100,000-MW and 50,000-MW proteins

linked by a disulfide bond. Botulinum toxin is absorbed from the gut and binds to receptors of presynaptic membranes of motor neurons of the peripheral nervous system and cranial nerves. Proteolysis, by the light chain of botulinum toxin, of target proteins in the neurons inhibits the release of acetylcholine at the synapse, resulting in lack of muscle contraction and flaccid paralysis.

Spores of *C. perfringens* are introduced into wounds by contamination with soil or feces. In the presence of necrotic tissue (an anaerobic environment), spores germinate and vegetative cells can produce several different toxins. Many of these are necrotizing and hemolytic and—together with distention of tissue by gas formed from carbohydrates and interference with blood supply—favor the spread of **gas gangrene**. The **alpha toxin** of *C. perfringens* is a **lecithinase** that damages cell membranes by splitting lecithin to phosphorylcholine and diglyceride. Theta toxin also has a necrotizing effect. Collagenases and DNases are produced by clostridia as well.

Some *S. aureus* strains growing on mucous membranes (eg, the vagina in association with menstruation) or in wounds, elaborate **toxic shock syndrome toxin-1 (TSST-1)**, which causes **toxic shock syndrome** (see Chapter 13). The illness is characterized by shock, high fever, and a diffuse red rash that later desquamates; multiple other organ systems are involved as well. TSST-1 is a superantigen (also referred to as a type I toxin), and superantigens do not need to enter cells to cause their potent cellular disruption. TSST-1 stimulates most T-cells by binding directly to MHC-II and T-cell receptors. The net result is the production of large amounts of the cytokines interleukin-2 (IL-2), interferon γ , and tumor necrosis factor (TNF) (see Chapter 8). The major clinical manifestations of the disease appear to be secondary to the effects of the cytokines. The systemic effects of TSST-1 are due to the massive cytokine stimulation. Some strains of group A β -hemolytic streptococci produce **pyrogenic exotoxins A and C**. Rapidly progressive soft tissue infection by streptococci that produce the pyrogenic exotoxin A has many clinical manifestations similar to those of staphylococcal toxic shock syndrome. The pyrogenic exotoxins A and C are also superantigens that act in a manner similar to TSST-1.

Type II toxins are proteins that typically affect cell membranes facilitating invasion by the pathogen secreting them (see also Tissue-Degrading Enzymes later in the chapter). Examples include hemolysins and phospholipases that are also discussed in the appropriate organism chapters.

B. Exotoxins Associated with Diarrheal Diseases and Food Poisoning

Exotoxins associated with diarrheal diseases are frequently called enterotoxins and many belong to the type III toxin family. (See also Table 48-4) Characteristics of some important enterotoxins are discussed as follows.

V. cholerae has produced epidemic diarrheal disease (**cholera**) in many parts of the world (see Chapter 17) and is another toxin-produced disease of historical and current

importance. After entering the host via contaminated food or drink, *V. cholerae* penetrates the intestinal mucosa and attaches to microvilli of the brush border of gut epithelial cells. *V. cholerae*, usually of the serotype O1 (and O139), can produce an enterotoxin with a MW of 84,000. The toxin consists of two subunits—A, which is split into two peptides: A₁ and A₂, linked by a disulfide bond, and B. Subunit B has five identical peptides and rapidly binds the toxin to cell membrane ganglioside molecules. Subunit A enters the cell membrane and causes a large increase in adenylate cyclase activity and in the concentration of cAMP. The net effect is rapid secretion of electrolytes into the small bowel lumen, with impairment of sodium and chloride absorption and loss of bicarbonate. Life-threatening massive diarrhea (eg, 20–30 L/day) can occur, and acidosis develops. The deleterious effects of cholera are due to fluid loss and acid–base imbalance; treatment, therefore, is by electrolyte and fluid replacement.

Some strains of *S. aureus* produce enterotoxins while growing in meat, dairy products, or other foods. In typical cases, the food has been recently prepared but not properly refrigerated. There are at least seven distinct types of the **staphylococcal enterotoxin**. After the preformed toxin is ingested, it is absorbed in the gut, where it stimulates vagus nerve receptors. The stimulus is transmitted to the vomiting center in the central nervous system. Vomiting, often projectile, results within hours. Diarrhea is less frequent. Staphylococcal food poisoning is the most common form of food poisoning. *S. aureus* enterotoxins are superantigens.

Enterotoxins are also produced by some strains of *Y. enterocolitica* (see Chapter 19), *Vibrio parahaemolyticus* (see Chapter 17), *Aeromonas* species (see Chapter 17), and other bacteria, but the role of these toxins in pathogenesis is not as well defined. The enterotoxin produced by *C. perfringens* is discussed in Chapter 11.

C. Lipopolysaccharides of Gram-Negative Bacteria

The LPS (endotoxin) of Gram-negative bacteria is bacterial cell wall components that are often liberated when the bacteria lyse. The substances are heat stable, have MWs between 3000 and 5000 (**lipooligosaccharides, LOS**), and several million (**lipopolysaccharides**) can be extracted (eg, with phenol-water). They have three main regions (see Figure 2-19). The lipid A domain is the region recognized by the immune system and is the component that is responsible for cytokine stimulation (see below). The other two components are an oligosaccharide core and an outermost O-antigen polysaccharide.

The **pathophysiologic effects of LPS** are similar regardless of their bacterial origin except for those of *Bacteroides* species, which have a different structure and are less toxic (see Chapter 21). LPS in the bloodstream is initially bound to circulating proteins, which then interact with receptors on macrophages, neutrophils, and other cells of the reticuloendothelial system. Proinflammatory cytokines, such as IL-1, IL-6, IL-8, TNF- α , and other cytokines, are released,

and the complement and coagulation cascades are activated. The following can be observed clinically or experimentally: fever, leukopenia, and hypoglycemia; hypotension and shock resulting in impaired perfusion of essential organs (eg, brain, heart, and kidney); intravascular coagulation; and death from massive organ dysfunction.

Injection of LPS produces **fever** after 60–90 minutes, the time needed for the body to release IL-1. Injection of IL-1 produces fever within 30 minutes. Repeated injection of IL-1 produces the same fever response each time, but repeated injection of LPS causes a steadily diminishing fever response because of tolerance partly caused by reticuloendothelial blockade and partly caused by IgM antibodies to LPS.

Injection of LPS produces early **leukopenia**, as does bacteremia with Gram-negative organisms. Secondary leukocytosis occurs later. The early leukopenia coincides with the onset of fever caused by liberation of IL-1. LPS enhances glycolysis in many cell types and can lead to **hypoglycemia**.

Hypotension occurs early in Gram-negative bacteremia or after injection of LPS. There may be widespread arteriolar and venular constriction followed by peripheral vascular dilation, increased vascular permeability, decrease in venous return, lowered cardiac output, stagnation in the microcirculation, peripheral vasoconstriction, shock, and impaired organ perfusion and its consequences. Disseminated intravascular coagulation (DIC) also contributes to these vascular changes.

LPS is among the many different agents that can activate the alternative pathway of the **complement cascade**, precipitating a variety of complement-mediated reactions (eg, anaphylatoxins, chemotactic responses, and membrane damage) and a drop in serum levels of complement components (C3, C5–C9).

Disseminated intravascular coagulation is a frequent complication of Gram-negative bacteremia and can also occur in other infections. LPS activates factor XII (Hageman factor)—the first step of the intrinsic clotting system—and sets into motion the coagulation cascade, which culminates in the conversion of fibrinogen to fibrin. At the same time, plasminogen can be activated by LPS to plasmin (a proteolytic enzyme), which can attack fibrin with the formation of fibrin split products. Reduction in platelet and fibrinogen levels and detection of fibrin split products are evidence of DIC. Heparin can sometimes prevent the lesions associated with DIC.

LPS causes platelets to adhere to vascular endothelium and occlusion of small blood vessels, causing ischemic or hemorrhagic necrosis in various organs.

Endotoxin levels can be assayed by the limulus test: A lysate of amoebocytes from the horseshoe crab (*limulus*) gels or coagulates in the presence of 0.0001 $\mu\text{g/mL}$ of endotoxin. This test is rarely used in clinical laboratories because it is difficult to perform accurately.

D. Peptidoglycan of Gram-Positive Bacteria

The peptidoglycan of Gram-positive bacteria is made up of cross-linked macromolecules that surround the bacterial cells (see Chapter 2 and Figure 2-15). Vascular changes leading to

shock may also occur in infections caused by Gram-positive bacteria that contain no LPS. Gram-positive bacteria have considerably more cell wall-associated peptidoglycan than do Gram-negative bacteria. Peptidoglycan released during infection may yield many of the same biologic activities as LPS, although peptidoglycan is invariably much less potent than LPS.

Enzymes

Many species of bacteria produce enzymes that are not intrinsically toxic but do play important roles in the infectious process. Some of these enzymes are discussed as follows.

A. Tissue-Degrading Enzymes

Many bacteria produce tissue-degrading enzymes. The best-characterized are enzymes from *C. perfringens* (see Chapter 11), and, to a lesser extent, anaerobic bacteria (see Chapter 21), *S. aureus* (see Chapter 13), and group A streptococci (see Chapter 14). The roles of tissue-degrading enzymes in the pathogenesis of infections appear obvious but have been difficult to prove, especially those of individual enzymes. For example, antibodies against the tissue-degrading enzymes of streptococci do not modify the features of streptococcal disease.

In addition to **lecithinase**, *C. perfringens* produces the proteolytic enzyme **collagenase**, which degrades collagen, the major protein of fibrous connective tissue, and promotes spread of infection in tissue.

S. aureus produces **coagulase**, which works in conjunction with blood factors to coagulate plasma. Coagulase contributes to the formation of fibrin walls around staphylococcal lesions, which helps them persist in tissues. Coagulase also causes deposition of fibrin on the surfaces of individual staphylococci, which may help protect them from phagocytosis or from destruction within phagocytic cells.

Hyaluronidases are enzymes that hydrolyze hyaluronic acid, a constituent of the ground substance of connective tissue. They are produced by many bacteria (eg, staphylococci, streptococci, and anaerobes) and aid in their spread through tissues.

Many hemolytic streptococci produce **streptokinase (fibrinolysin)**, a substance that activates a proteolytic enzyme of plasma. This enzyme is then able to dissolve coagulated plasma and probably aids in the rapid spread of streptococci through tissues. Streptokinase has been used in treatment of acute myocardial infarction to dissolve fibrin clots.

Many bacteria produce substances that are **cytolysins**—that is, they dissolve red blood cells (**hemolysins**) or kill tissue cells or leukocytes (**leukocidins**). **Streptolysin O**, for example, is produced by group A streptococci and is lethal for mice and hemolytic for red blood cells from many animals. Streptolysin O is oxygen labile and can therefore be oxidized and inactivated, but it is reactivated by reducing agents. It is antigenic. The same streptococci also produce oxygen-stable, serum-inducible **streptolysin S**, which is not antigenic. Clostridia produce various hemolysins, including the lecithinase described earlier. Hemolysins are produced by most strains of *S. aureus*; staphylococci also produce leukocidins. Most

Gram-negative rods isolated from sites of disease produce hemolysins. For example, whereas *E. coli* strains that cause urinary tract infections typically produce hemolysins, strains that are part of the normal gastrointestinal flora may or may not produce hemolysins.

B. IgA1 Proteases

Immunoglobulin A is the secretory antibody on mucosal surfaces. It has two primary forms, IgA1 and IgA2 that differ near the center, or hinge region of the heavy chains of the molecules (see Chapter 8). IgA1 has a series of amino acids in the hinge region that are not present in IgA2. Some bacteria that cause disease produce enzymes, **IgA1 proteases** that split IgA1 at specific proline–threonine or proline–serine bonds in the hinge region and inactivate its antibody activity. IgA1 protease is an important virulence factor of the pathogens *N. gonorrhoeae*, *N. meningitidis*, *Haemophilus influenzae*, and *S. pneumoniae*. The enzymes are also produced by some strains of *Prevotella melaninogenica*, some streptococci associated with dental disease, and a few strains of other species that occasionally cause disease. Nonpathogenic species of the same genera do not have genes coding for the enzyme and do not produce it. Production of IgA1 protease allows pathogens to inactivate the primary antibody found on mucosal surfaces and thereby eliminate protection of the host by the antibody.

Antiphagocytic Factors

Many bacterial pathogens are rapidly killed after they are ingested by polymorphonuclear cells or macrophages. Some pathogens evade phagocytosis or leukocyte microbicidal mechanisms by adsorbing normal host components to their surfaces. For example, *S. aureus* has surface protein A, which binds to the Fc portion of IgG. Other pathogens have surface factors that impede phagocytosis (eg, *S. pneumoniae* and *N. meningitidis*); many other bacteria have polysaccharide capsules. *S. pyogenes* (group A streptococci) has M protein. *N. gonorrhoeae* (gonococci) has pili. Most of these antiphagocytic surface structures show much antigenic heterogeneity. For example, there are more than 90 pneumococcal capsular polysaccharide types and more than 150 M protein types of group A streptococci. Antibodies against one type of the antiphagocytic factor (eg, capsular polysaccharide and M protein) protect the host from disease caused by bacteria of that type but not from those with other antigenic types of the same factor.

A few bacteria (eg, *Capnocytophaga* and *Bordetella* species) produce soluble factors or toxins that inhibit chemotaxis by leukocytes and thus evade phagocytosis by a different mechanism.

Intracellular Pathogenicity

Some bacteria (eg, *M. tuberculosis*, *L. monocytogenes*, *Brucella* species, and *Legionella* species) live and grow in the hostile environment within polymorphonuclear cells, macrophages, or monocytes. The bacteria accomplish this feat by several

mechanisms: they may avoid entry into phagolysosomes and live within the cytosol of the phagocyte; they may prevent phagosome–lysosome fusion and live within the phagosome; or they may be resistant to lysosomal enzymes and survive within the phagolysosome.

Many bacteria can live within nonphagocytic cells (see previous section, Invasion of Host Cells and Tissues).

Antigenic Heterogeneity

The surface structures of bacteria (and of many other microorganisms) have considerable antigenic heterogeneity. Often these antigens are used as part of a serologic classification system for the bacteria. The classification of the 2000 or so different salmonellae is based principally on the types of the O (LPS side chain) and H (flagellar) antigens. Similarly, there are more than 150 *E. coli* O types and more than 100 *E. coli* K (capsule) types. The antigenic type of the bacteria may be a marker for virulence, related to the clonal nature of pathogens, although it may not actually be the virulence factor (or factors). *V. cholerae* O antigen type 1 and O antigen type 139 typically produce cholera toxin, but very few of the many other O types produce the toxin. Only some of the group A streptococcal M protein types are associated with a high incidence of poststreptococcal glomerulonephritis. *N. meningitidis* capsular polysaccharide types A and C are associated with epidemic meningitis. In the examples cited earlier and in other typing systems that use surface antigens in serologic classification, antigenic types for a given isolate of the species remain constant during infection and on subculture of the bacteria.

Some bacteria and other microorganisms have the ability to make frequent shifts in the antigenic form of their surface structures in vitro and presumably in vivo. One well-known example is *Borrelia recurrentis*, which causes relapsing fever. A second widely studied example is *N. gonorrhoeae* (see Chapter 20). The gonococcus has three surface-exposed antigens that switch forms at very high rates of about one in every 1000; lipooligosaccharide, 6–8 types; pili, innumerable types; and Opa, 10–12 types for each strain. The number of antigenic forms is so large that each strain of *N. gonorrhoeae* appears to be antigenically distinct from every other strain. Switching of forms for each of the three antigens appears to be under the control of different genetic mechanisms. It is presumed that frequent switching of antigenic forms allows gonococci to evade the host’s immune system; gonococci that are not attacked by the immune system survive and cause disease.

Bacterial Secretion Systems

Bacterial secretion systems are important in the pathogenesis of infection and are essential for the interaction of bacteria with the eukaryotic cells of the host. The Gram-negative bacteria have cell walls with cytoplasmic membranes and outer membranes; a thin layer of peptidoglycan is present. Gram-positive bacteria have a cytoplasmic membrane and a very thick layer of peptidoglycan (see Chapter 2). Some Gram-negative bacteria and some

Gram-positive bacteria have capsules as well. The complexity and rigidity of the cell wall structures necessitate mechanisms for the translocation of proteins across the membranes. These secretion systems are involved in cellular functions such as the transport of proteins that make pili or flagella and in the secretion of enzymes or toxins into the extracellular environment. The differences in cell wall structure between Gram-negative and Gram-positive bacteria result in some differences in the secretion systems. The basic mechanisms of the different bacterial secretion systems are discussed in Chapter 2. (Note: The specific bacterial secretion systems were named in the order of their discovery and not by their mechanisms of action.)

Both Gram-negative and Gram-positive bacteria have a general secretion pathway (Sec) as the major mechanism for protein secretion. This pathway is involved in the insertion of most of the bacterial membrane proteins and provides the major pathway for proteins crossing the bacterial cytoplasmic membrane. Gram-negative organisms have an additional six mechanisms, secretion systems (SS) 1–6 (sometimes denoted I–VI), for protein secretion. These can be further characterized as Sec dependent (types 2 and 5) and Sec independent (types 1, 3, 4, 6). Type 2 SS uses the general Sec to transport the proteins to the periplasm and then create an outer membrane channel made by a special pore-forming protein complex. This type 2 SS is used to secrete portions of bacterial A B type toxins, such as cholera toxin. Similarly, the **type 5 SS** uses the general Sec to export an autotransporter to the periplasm; from there it transports itself across the outer membrane. An example of this type of SS includes the IgA proteases secreted by *H. influenzae*. The sec-independent pathways include the **type 1 secretion system** or **ABC secretion system** (ATP-binding cassette) and the **type 3 secretion system**. The type 1 and 3 pathways do not interact with proteins that have been transported across the cytoplasmic membrane by the Sec system. Instead, these systems translocate proteins across both the cytoplasmic and outer membranes. The type 3, which is activated upon contact with a eukaryotic host cell, promotes transport of proteins directly from inside the bacterium to the inside of the host cell using a needlelike structure called an injectosome; when in the host cell cytoplasm, the transported proteins can manipulate host cell function. *Pseudomonas aeruginosa* possesses a type 3 secretion system that when expressed may be associated with more serious disease. The **type 4 secretion pathway** consists of a protein complex that forms a “tunnel” that is able to directly transport proteins or DNA. The most recent SS to be discovered is the **type 6 SS**. This SS plays a role in the secretion of virulence proteins in *V. cholerae* and *P. aeruginosa* among other Gram-negative pathogens. A seventh SS has been described in *M. tuberculosis* and is not well understood. Its function appears to be transport of proteins across both the inner and outer membranes. Some other examples of the secretion systems and their roles in pathogenesis are shown in Table 9-5. These examples are a small sample designed to illustrate the roles of the large number of molecular secretion activities used by bacteria to provide nutrients and facilitate their pathogenesis.

TABLE 9-5 Examples of Molecules Translocated by Bacterial Secretion Systems and Their Relevance to Pathogenesis

Secretion System	Genus Species	Substrate and Role in Pathogenesis
Type 1 (Sec-independent)	<i>E. coli</i>	α-Hemolysin makes holes in cell membranes
	<i>Proteus vulgaris</i>	Hemolysin
	<i>Morganella morganii</i>	Hemolysin
	<i>B. pertussis</i>	Adenylate cyclase which catalyzes synthesis of cAMP
	<i>P. aeruginosa</i>	Alkaline protease
	<i>Serratia marcescens</i>	Zn protease yields host cell damage
Type 2 (Sec dependent)	<i>P. aeruginosa</i>	Elastase, exotoxin A, phospholipase C, others
	<i>L. pneumophila</i>	Acid phosphatase, lipase, phospholipase, protease, RNase
	<i>V. cholera</i>	Cholera toxin
	<i>S. marcescens</i>	Hemolysin
Type 3 (Sec-independent; contact-dependent)	<i>Yersinia</i> species	Ysc-Yop system; toxins that block phagocytosis and induce apoptosis
	<i>P. aeruginosa</i>	Cytotoxin
	<i>Shigella</i> species	Controls host cell signaling, invasion, and death
	<i>Salmonella enterica</i> subspecies <i>enterica</i> serotypes Choleraesuis, Dublin, Paratyphi, Typhi, Typhimurium, etc	Effectors from <i>Salmonella</i> pathogenicity islands I and II (SPI1 and SPI2), which promote attachment to and invasion of host cells
	<i>E. coli</i>	Enterohemorrhagic (EHEC) and enteropathogenic (EPEC); disruption of epithelial barriers and tight junctions
	<i>V. parahaemolyticus</i>	Direct cytotoxicity
Type 4 (Sec-dependent and Sec-independent)		
Protein substrates	<i>B. pertussis</i>	Pertussis toxin
	<i>H. pylori</i>	Cytotoxin
DNA substrates	<i>N. gonorrhoeae</i>	DNA export system
	<i>H. pylori</i>	DNA uptake and release system
Type 5 (Sec dependent)	<i>N. gonorrhoeae</i>	IgA1 protease splits IgA1 in hinge region and destroys antibody activity (sec-dependent)
	<i>H. influenzae</i>	IgA1 protease, adhesins
	<i>E. coli</i>	Serine protease, adhesins, type 1 pili, P-pili
	<i>Shigella flexneri</i>	Serine protease
	<i>S. marcescens</i>	Proteases
	<i>Bordetella</i> species	Adhesins
	<i>B. pertussis</i>	Filamentous hemagglutinin
	<i>Y. pestis</i>	Capsular antigen
Type 6 (Sec Independent)	<i>P. aeruginosa</i>	Pore-forming toxin Hcp1
	<i>V. cholerae</i>	Virulence proteins
Type 7 (Sec dependent)	<i>M. tuberculosis</i>	CFP-10, ESAT-6 T-cell antigen target

CFP, culture filtrate protein 10 kDa; ESAT-6, early secretory antigenic target-6 kDa.

The Requirement for Iron

Iron is an essential nutrient for the growth and metabolism of nearly all microorganisms and is an essential cofactor of numerous metabolic and enzymatic processes. The availability

of iron in humans for microbial assimilation is limited because the iron is sequestered by the high-affinity iron-binding proteins transferrin in serum and lactoferrin on mucosal surfaces. The ability of a microbial pathogen to efficiently obtain iron

from the host environment is critical to its ability to cause disease. The requirement for iron, how bacteria acquire iron, and bacterial iron metabolism are discussed in Chapter 5.

Iron availability affects the virulence of many pathogens. For example, iron is an essential virulence factor in *P. aeruginosa*. The use of animal models in *L. monocytogenes* infection has demonstrated that increased iron results in enhanced susceptibility to infection, but iron depletion results in prolonged survival; iron supplementation therapy yields an increase in lethal infections.

Decreased iron availability can also be important in pathogenesis. For example, the gene for diphtheria toxin resides on a lysogenic bacteriophage, and only strains of *C. diphtheriae* that carry the lysogenic bacteriophage are toxigenic. In the presence of low iron availability, there is increased production of diphtheria toxin and potentially more severe disease. The virulence of *N. meningitidis* for mice is increased 1000-fold or more when the bacteria are grown under iron-limited conditions.

Human iron deficiency also plays a role in the infectious process. Iron deficiency affects hundreds of millions of people worldwide. Iron deficiency can affect multiple organ systems, including the immune system, and can result in impaired cell-mediated immunity and decreased polymorphonuclear cell function. Providing iron therapy during an active infection probably should be delayed because many pathogenic microorganisms can use the small amounts of supplemental iron, resulting in an increase in virulence.

The Role of Bacterial Biofilms

A biofilm is an aggregate of interactive bacteria attached to a solid surface or to each other and encased in an exopolysaccharide matrix. This is distinct from planktonic or free-living bacteria, in which interactions of the microorganisms do not occur in the same way. Biofilms form a slimy coat on solid surfaces and occur throughout nature. A single species of bacteria may be involved or more than one species may coaggregate to form a biofilm. Fungi, including yeasts, are occasionally involved. After a biofilm is formed, quorum-sensing molecules produced by the bacteria in the biofilm accumulate, resulting in a modification of the metabolic activity of the bacteria. The basic biology of biofilm exopolysaccharide (glycocalyx) is discussed in Chapter 2; the quorum-sensing molecules are discussed in Chapter 1.

The bacteria in the exopolysaccharide matrix may be protected from the host’s immune mechanisms. This matrix also functions as a diffusion barrier for some antimicrobials, but other antimicrobials may bind to it. Some of the bacteria within the biofilm show marked resistance to antimicrobials compared with the same strain of bacteria grown free living in broth, which helps to explain why it is so difficult to treat infections associated with biofilms.

Biofilms are important in human infections that are persistent and difficult to treat. A few examples include *Staphylococcus epidermidis* and *S. aureus* infections of central venous catheters, eye infections such as what occur with contact lenses and intraocular lenses, in dental plaque, and in

prosthetic joint infections. Perhaps the most profound example of a biofilm in human infection is in *P. aeruginosa* airway infections in cystic fibrosis patients.

THE DAMAGE-RESPONSE FRAMEWORK—A NEW PARADIGM OF MICROBIAL VIRULENCE AND PATHOGENICITY

As evidenced from this chapter, discussions regarding the host-pathogen relationship and microbial pathogenesis have been focused primarily on what microorganisms bring to the picture rather than how the host affects the development of clinical disease. In 1999, Casadevall and Pirofski redefined the concepts of virulence and pathogenicity by introducing the **damage-response framework** to correct the inadequacies which arose as our understanding of microbial pathogens and the host immune response to microbial pathogens evolved. In this new paradigm of microbial pathogenesis, the host immune response is given a more dynamic role in the outcome of infection. Adoption of this new paradigm requires adopting a new lexicon which at first may seem counter-intuitive. For example, **infection** is simply defined as acquisition of a microorganism by a host. Infection is generally followed by multiplication of the microbe within the host environment.

The two extremes of primary infection are **elimination**—removal of the microbe from the host by physical factors, an immune response, therapy, or outcompetition by existing microbes; or if the microbe causes sufficient damage to the host, **death**. **Damage** is defined as the interruption of normal tissue structure and/or function at the cellular, tissue, or organ level. If the microbe persists within the host and causes no damage or clinically inapparent damage over time, then the microorganism is considered a **commensal**. Commensals that benefit from infecting the host and provide a benefit to the host are **symbionts**. **Pathogens** are microbes capable of causing host damage. If infection results in a continuum of host damage from none to great, then the host is said to be **colonized**. If host damage increases over time while colonized, the host immune response may eliminate or retain the microbe. If retained, infection is said to be **chronic** or **persistent**.

There have been several refinements to the damage response framework over the years, with the most recent updates redefining our concept of “host” as our knowledge of microbiomes expands.

CHAPTER SUMMARY

- Animals and humans are colonized with abundant microbiota, normal commensals that do not cause disease and are protective to the host.
- Virulent bacteria cause disease through the elaboration of factors that facilitate adherence, persistence, invasion, and toxigenicity.

- Genes that encode virulence factors may be carried on mobile genetic elements such as plasmids or bacteriophages or are found on large pathogenicity islands on bacterial chromosomes.
- Pili and fimbriae are rodlike or hairlike structures, respectively, that facilitate attachment to host cells.
- Invasion of host cells is a complex mechanism that involves elaboration of proteins that facilitate entry.
- Bacterial toxins may be extracellular (exotoxins) or are a component of the bacterial cell membrane (endotoxin, LPS) and are among the most powerful toxins in nature (eg, botulinum toxin).
- Other mechanisms important to bacterial survival and virulence include tissue-degrading enzymes, antiphagocytic factors, IgA proteases, antigenic heterogeneity, and the ability to chelate iron.
- There are at least seven known bacterial secretion systems, protein complexes, or channels that ensure transport of structural and toxigenic proteins through the bacterial cell after translation.
- A new paradigm of microbial pathogenesis called the host damage framework has been developed to better understand the concepts of virulence and pathogenicity.

REVIEW QUESTIONS

1. A 22-year-old woman who works in a plant nursery presents with a history of fever and cough for 2 months. Over this period of time she has lost 5 kg. Chest radiography shows bilateral upper lobe infiltrates with cavities. A stain of her sputum shows acid-fast bacilli. The likely means by which the patient acquired her infection is
 - (A) Sexual activity
 - (B) Ingesting the microorganisms in her food
 - (C) Holding onto contaminated hand rails when she takes public transportation
 - (D) Handling potting soil
 - (E) Breathing aerosolized droplets containing the microorganism
2. During a pandemic of a well-characterized disease, a group of 175 airline passengers flew from Lima, Peru, to Los Angeles. Lunch on the plane included crab salad, which was eaten by about two-thirds of the passengers. After landing in Los Angeles, many of the passengers transferred to other flights with destinations in other parts of California and other Western states. Two of the passengers who stayed in Los Angeles developed severe watery diarrhea. The status of the other passengers was unknown. The likely cause of the diarrhea in the two passengers is
 - (A) *E. coli* O157:H7 (lipopolysaccharide O antigen 157; flagellar antigen 7)
 - (B) *V. cholerae* type O139 (lipopolysaccharide O antigen 139)
 - (C) *Shigella dysenteriae* type 1
 - (D) *Campylobacter jejuni*
 - (E) *Entamoeba histolytica*
3. A 65-year-old woman has a long-term central venous catheter for intravenous therapy. She develops fever and subsequently has multiple blood cultures positive for *S. epidermidis*. All of the *S. epidermidis* isolates have the same colony morphology and antimicrobial susceptibility pattern, suggesting that they are the same strain. An *S. epidermidis* biofilm is thought to be present on the catheter. Which one of the following statements about such an infection is correct?
 - (A) The biofilm containing the *S. epidermidis* is likely to wash off the catheter.
 - (B) Production of an extracellular polysaccharide inhibits growth of the *S. epidermidis*, limiting the infection.
 - (C) The *S. epidermidis* in the biofilm are likely to be more susceptible to antimicrobial therapy because the bacteria have decreased rates of metabolism.
 - (D) The quorum-sensing ability of *S. epidermidis* results in increased susceptibility to antimicrobial therapy.
 - (E) The complex molecular interactions within the biofilm make it difficult to provide effective antimicrobial therapy, and it is likely the catheter will have to be removed to cure the infection
4. The first microorganism to satisfy Koch's postulates (in the late 19th century) was
 - (A) *T. pallidum*
 - (B) *S. maltophilia*
 - (C) *M. leprae*
 - (D) *B. anthracis*
 - (E) *N. gonorrhoeae*
5. Which of the following statements about lipopolysaccharide is correct?
 - (A) It interacts with macrophages and monocytes yielding release of cytokines.
 - (B) The toxic component is the O side chain.
 - (C) It forms holes in red blood cell membranes yielding hemolysis.
 - (D) It causes hypothermia.
 - (E) It causes paralysis.
6. A 27-year-old man had a rhinoplasty. A nasal tampon was placed to control the bleeding. Approximately 8 hours later, he developed headache, muscle aches, and abdominal cramps with diarrhea. He then developed an erythematous rash (resembling sunburn) over much of his body, including the palms and soles. His blood pressure is 80/50 mm Hg. The nasal tampon remained in place. His liver enzyme tests were elevated, and there was evidence of moderate renal failure. This patient's illness was likely to be caused by which of the following?
 - (A) Lipopolysaccharide
 - (B) Peptidoglycan
 - (C) A toxin that is a superantigen
 - (D) A toxin that has A and B subunits
 - (E) Lecithinase (alpha toxin)
7. The organism most likely to be responsible for the patient's disease (Question 6) is
 - (A) *E. coli*
 - (B) *C. diphtheriae*
 - (C) *C. perfringens*
 - (D) *N. meningitidis*
 - (E) *S. aureus*
8. Which of the following is most likely to be associated with the formation of a bacterial biofilm?
 - (A) Airway colonization in a cystic fibrosis patient with a mucoid (alginate-producing) strain of *P. aeruginosa*
 - (B) Urinary tract infection with *E. coli*
 - (C) Meningitis with *N. meningitidis*

- (D) Tetanus
(E) Impetigo caused by *S. aureus*
9. Regarding bacterial type III secretions systems, which of the following statements is correct?
- (A) They are commonly found in Gram-positive commensal bacteria.
(B) They play an important role in the pathogenesis of toxin-induced diseases of *Clostridium* species, tetanus, botulism, gas gangrene, and pseudomembranous colitis.
(C) They cause release of effectors of pathogenesis into the extracellular environment, promoting bacterial colonization and multiplication.
(D) They directly inject bacterial proteins into host cells across bacterial and host cell membranes, promoting pathogenesis of infections.
(E) Mutations that prevent the bacterial type III secretion from functioning enhance pathogenesis.
10. Which of the following statements is correct?
- (A) Lipopolysaccharide is part of the cell wall of *E. coli*.
(B) Cholera toxin is attached to the flagella of *V. cholerae*.
(C) The lecithinase of *C. perfringens* causes diarrhea.
(D) Toxic shock syndrome toxin-1 is produced by hemolytic strains of *S. epidermidis*.
11. A 15-year-old Bangladeshi girl develops severe watery diarrhea. The stool looks like “rice water.” It is voluminous—more than 1 L in the last 90 minutes. She has no fever and seems otherwise normal except for the effects of loss of fluid and electrolytes. The most likely cause of her illness is
- (A) *Clostridium difficile* enterotoxin
(B) A toxin with A and B subunits
(C) *S. dysenteriae* type 1 that produces Shiga toxin
(D) Enterotoxigenic *E. coli* that produces heat-labile and heat-stable toxins
(E) Staphylococcal enterotoxin F
12. The most important thing that can be done to treat the patient (Question 11) is
- (A) To give her ciprofloxacin
(B) To give her a toxoid vaccine
(C) To give her the appropriate antitoxin
(D) To treat her with fluid and electrolyte replacement
(E) To culture her stool to make the correct diagnosis and then treat specifically
13. A 23-year-old woman has a history of recurrent urinary tract infections, including at least one episode of pyelonephritis. Blood typing shows the P blood group antigen. Which of the following is likely to be the primary cause of her infections?
- (A) *E. coli* that produce heat-stable toxin
(B) *E. coli* with K1 (capsular type 1) antigen
(C) *E. coli* O139 (lipopolysaccharide O antigen 139)
(D) *E. coli* with P-pili (fimbriae)
(E) *E. coli* O157:H7 (lipopolysaccharide O antigen 157; flagellar antigen 7)
14. A 55-year-old man presents with gradually increasing weight loss, abdominal pain, diarrhea, and arthropathy. During the evaluation process, a small bowel biopsy is done. After processing, examination of the specimen by light microscopy reveals periodic acid–Schiff-positive inclusions in the bowel wall. Which of the following tests could be done to confirm the diagnosis of Whipple disease caused by *T. whipplei*?
- (A) Culture on agar media
(B) Polymerase chain reaction amplification and sequencing of an appropriate segment of DNA
(C) Cocultivation with *E. coli*
(D) In situ hybridization
(E) Direct fluorescent antibody test
15. Which of the following best describes the mechanism of action of diphtheria toxin?
- (A) Forms pores in red blood cells causing hemolysis
(B) Degrades lecithin in eukaryotic cell membranes
(C) Causes release of tumor necrosis factor
(D) Inhibits elongation factor 2
(E) Causes increased adenylate cyclase activity

Normal Human Microbiota

The term “normal microbial flora” denotes the population of microorganisms that inhabit the skin and mucous membranes of healthy normal persons. Previous estimates suggested that the microorganisms that live inside and on humans (now referred to as the **normal microbiota**) outnumber human somatic and germ cells by a factor of 10. More recent estimates indicate the ratio is much closer to 1:1. The genomes of these microbial symbionts are collectively defined as the **microbiome**. Research has shown that the “**normal microbiota**” provides a first line of defense against microbial pathogens, assists in digestion, plays a role in toxin degradation, and contributes to maturation of the immune system. Shifts in the normal microbiota or stimulation of inflammation by these commensals may cause diseases such as bacterial vaginosis, periodontitis, and inflammatory bowel disease.

HUMAN MICROBIOME PROJECT

In a broad attempt to understand the role played by resident microbial ecosystems in human health and disease, the National Institutes of Health Common Fund supported the Human Microbiome Project (HMP; <https://commonfund.nih.gov/hmp>). One of the main goals of this project was to understand the range of human genetic and physiologic diversity, the microbiome, and the factors that influence the distribution and evolution of the constituent microorganisms. One aspect of this project involved having several research groups simultaneously embark upon surveying the microbial communities on human skin and in mucosal areas, such as the mouth, esophagus, stomach, colon, and vagina using small-subunit (16S) ribosomal RNA gene sequencing. Among the questions that have been addressed by the HMP are: How stable and resilient is an individual’s microbiota throughout one day and during his or her life span? How similar are the microbiomes between members of a family or members of a community or across communities in different environments? Do all humans have an identifiable “core” microbiome, and if so, how is it acquired and transmitted? What affects the genetic diversity of the microbiome, and how does this diversity affect adaptation by the microorganisms and the host to markedly different lifestyles and to various physiological or pathophysiological states?

Since 2017, HMP investigators have published over 650 studies that have been cited over 70,000 times. Readers should be aware that this field is rapidly evolving, and our understanding of the human microbiota will necessarily change as more information about resident microbial communities becomes available through the HMP.

ROLE OF THE RESIDENT MICROBIOTA

The human body harbors a variety of microorganisms that can be arranged into two groups: (1) the **resident microbiota** consists of relatively fixed types of microorganisms regularly found in a given area at a given age; if disturbed, it promptly reestablishes itself; and (2) the **transient microbiota** consists of nonpathogenic or potentially pathogenic microorganisms that inhabit body sites for hours, days, or weeks. The transient microbiota is derived from the environment, does not produce disease, and does not establish itself permanently. Members of the transient microbiota are generally of little significance so long as the normal resident flora remains intact. However, if the resident microbiota is disturbed, transient microorganisms may colonize, proliferate, and produce disease.

Organisms frequently encountered in specimens obtained from various areas of the human body—and considered normal microbiota—are listed in Table 10-1. The classification of anaerobic normal bacterial flora is discussed in Chapter 21.

It is likely that microorganisms that can be cultured in the laboratory represent only a fraction of those that are part of the normal resident or transient microbiota. When the broad range polymerase chain reaction (PCR) is used to amplify bacterial 16S rDNA, many previously unidentified bacteria can be detected, as in secretions from patients with bacterial vaginosis. The number of species that make up the normal microbiota has been shown to be much greater than previously recognized. Thus, the understanding of normal microbiota is in transition. As already mentioned, the relationship of previously unidentified microorganisms, which are potentially part of the normal microbiota, to disease is likely to change.

The microorganisms that are constantly present on body surfaces are frequently described as **commensals** (ie, one partner benefits, while the other seems unaffected). However, in some sites (eg, gut), **mutualistic** (ie, both parties derive

TABLE 10-1 Normal Bacterial Microbiota

Skin
<i>Staphylococcus epidermidis</i>
<i>Staphylococcus aureus</i> (in small numbers)
<i>Micrococcus</i> species
α-Hemolytic and non-hemolytic streptococci (eg, <i>Streptococcus mitis</i>)
<i>Corynebacterium</i> species
<i>Propionibacterium</i> species
<i>Peptostreptococcus</i> species
<i>Acinetobacter</i> species
Small numbers of other organisms (<i>Candida</i> species, <i>Pseudomonas aeruginosa</i> , etc)
Nasopharynx
Any amount of the following: diphtheroids, nonpathogenic <i>Neisseria</i> species, α-hemolytic streptococci, <i>S. epidermidis</i> , non-hemolytic streptococci, anaerobes (too many species to list; varying amounts of <i>Prevotella</i> species, anaerobic cocci, <i>Fusobacterium</i> species, etc)
Lesser amounts of the following when accompanied by organisms listed above: yeasts, <i>Haemophilus</i> species, pneumococci, <i>S. aureus</i> , Gram-negative rods, <i>Neisseria meningitidis</i>
Gastrointestinal tract and rectum
Various Enterobacteriaceae except <i>Salmonella</i> , <i>Shigella</i> , <i>Yersinia</i> , <i>Vibrio</i> , and <i>Campylobacter</i> species
Glucose non-fermenting Gram-negative rods
Enterococci
α-Hemolytic and non-hemolytic streptococci
Diphtheroids
<i>S. aureus</i> in small numbers
Yeasts in small numbers
Anaerobes in large numbers (too many species to list)
Genitalia
Any amount of the following: <i>Corynebacterium</i> species, <i>Lactobacillus</i> species, α-hemolytic and non-hemolytic streptococci, non-pathogenic <i>Neisseria</i> species
The following when mixed and not predominant: enterococci, Enterobacteriaceae and other Gram-negative rods, <i>S. epidermidis</i> , <i>Candida albicans</i> , and other yeasts
Anaerobes (too many to list); the following may be important when in pure growth or clearly predominant: <i>Prevotella</i> , <i>Clostridium</i> , and <i>Peptostreptococcus</i> species

benefit) may be a better description of this relationship. Their flourishing in a given area depends on physiologic factors of temperature, moisture, and the presence of certain nutrients and inhibitory substances. Their presence is not essential to life because “germ-free” animals can be reared in the complete absence of a normal microbiota. Yet the resident flora of certain areas plays a definite role in maintaining health and

normal function. Members of the resident microbiota in the intestinal tract synthesize vitamin K, bioactive compounds such as 3-indolepropionic acid (IPA), and aid in the absorption of nutrients. IPA is a potent neuroprotective antioxidant that scavenges hydroxyl radicals. IPA binds to the pregnane X receptor on intestinal epithelial cells. After absorption from the intestine and distribution to the brain, IPA is thought to exert a neuroprotective effect against cerebral ischemia and Alzheimer’s disease. On mucous membranes and skin, the resident microbiota may prevent colonization by pathogens and possible disease through “bacterial interference.” The mechanism of bacterial interference may involve competition for receptors or binding sites on host cells, competition for nutrients, mutual inhibition by metabolic or toxic products, mutual inhibition by antibiotic materials or bacteriocins, or other mechanisms. Suppression of the normal microbiota clearly creates a partial local void that tends to be filled by organisms from the environment or from other parts of the body. Such organisms behave as opportunists and may become pathogens.

On the other hand, members of the normal microbiota may themselves produce disease under certain circumstances. These organisms are adapted to a noninvasive mode of life defined by the limitations of the environment. If forcefully removed from the restrictions of that environment and introduced into the bloodstream or tissues, these organisms may become pathogenic. For example, streptococci of the viridans group are the most common resident organisms of the upper respiratory tract. If large numbers of them are introduced into the bloodstream (eg, after tooth extraction or oral surgery), they may settle on deformed or prosthetic heart valves and produce infective endocarditis. Small numbers occur transiently in the bloodstream with minor trauma (eg, dental scaling or vigorous brushing). *Bacteroides* species are the most common resident bacteria of the large intestine and are quite harmless in that location. However, if introduced into the peritoneal cavity or into pelvic tissues along with other bacteria as a result of trauma, they cause suppuration and bacteremia. There are many other examples, but the important point is that the normal resident microbiota is harmless and may be beneficial in their normal location in the host and in the absence of coincident abnormalities. They may produce disease if introduced into foreign locations in large numbers and if predisposing factors are present.

NORMAL MICROBIOTA OF THE SKIN

The skin is the human body’s largest organ, colonized by a diverse array of microorganisms, most of which are harmless or even beneficial to the host. Because of its constant exposure to and contact with the environment, the skin is particularly apt to contain transient microorganisms. Nevertheless, there is a constant and well-defined resident flora, modified in different anatomic areas by secretions, habitual wearing of clothing, or proximity to mucous membranes (mouth, nose, and perineal areas) (Figure 10-1).

FIGURE 10-1 Topographical distribution of bacteria on skin sites. The skin microbiome is highly dependent on the microenvironment of the sampled site. The family-level classification of bacteria colonizing an individual subject is shown with the phyla in **bold**. The sites selected were those that show a predilection for skin bacterial infections and are grouped as sebaceous or oily (**blue circles**); moist (typically skin creases; **green circles**); and dry, flat surfaces (**red circles**). The sebaceous sites are the glabella (between the eyebrows), alar crease (side of the nostril; external auditory canal [inside the ear]), retroauricular crease (behind the ear), occiput (back of the scalp), antecubital fossa (inner elbow), interdigital web space (between the middle and ring fingers), inguinal crease (side of the groin), gluteal crease (topmost part of the fold between the buttocks), popliteal fossa (behind the knee), plantar heel (bottom of the heel of the foot), toe web space, and umbilicus (navel). Dry sites are the volar forearm (inside of the midforearm), hypothenar palm (palm of the hand proximal to the little finger), and buttock. (Reprinted by permission from Macmillan Publishers Ltd: Grice EA, Segre JA, The skin microbiome. *Nature Rev Microbiol* 2011;9:244–253. Copyright © 2011.)

The predominant resident microorganisms of the skin are aerobic and anaerobic diphtheroid bacilli (eg, *Corynebacterium*, *Propionibacterium*); nonhemolytic aerobic and anaerobic staphylococci (*Staphylococcus epidermidis* and other coagulase-negative staphylococci, occasionally *Staphylococcus aureus*, and *Peptostreptococcus* species); Gram-positive, aerobic, spore-forming bacilli that are ubiquitous in air, water, and soil; α -hemolytic streptococci (viridans streptococci) and enterococci (*Enterococcus* species); and Gram-negative coliform bacilli and *Acinetobacter*. Fungi and yeasts are often present in skin folds; acid-fast, nonpathogenic mycobacteria occur in areas rich in sebaceous secretions (genitalia, external ear).

Based on 16S rRNA gene copies, recent studies have shown that Archaea comprised up to 4.2% of the prokaryotic skin microbiome. Most of the gene signatures analyzed belonged to the Thaumarchaeota, a recently proposed phylum that includes ammonia oxidizing Archaea (see Chapter 6). It is noteworthy that the human skin is constantly emanating low amounts of ammonia, which may, in turn, provide a suitable environment for these Archaea.

Among the factors that may be important in eliminating nonresident microorganisms from the skin are the low pH, the fatty acids in sebaceous secretions, and the presence of lysozyme. Neither profuse sweating nor washing and bathing can eliminate or significantly modify the normal resident flora. The number of superficial microorganisms may be diminished by vigorous daily scrubbing with soap containing hexachlorophene or other disinfectants, but the flora is rapidly replenished from sebaceous and sweat glands even when contact with other skin areas or with the environment is completely excluded. Placement of an occlusive dressing on the skin tends to result in a large increase in the total microbial population and may also produce qualitative alterations in the flora.

Anaerobes and aerobic bacteria often join to form synergistic infections (gangrene, necrotizing fasciitis, and cellulitis) of skin and soft tissues. The bacteria are frequently part of the normal microbial flora. It is usually difficult to pinpoint one specific organism as being responsible for the progressive lesion because mixtures of organisms are usually involved.

In addition to being a physical barrier, the skin is an immunologic barrier. Keratinocytes continuously sample the microbiota colonizing the skin surface through **pattern recognition receptors** (eg, Toll-like receptors, mannose receptors, NOD-like receptors). The activation of keratinocyte pattern recognition receptors by pathogen-associated molecular patterns initiates the innate immune response, resulting in the secretion of antimicrobial peptides, cytokines, and chemokines. Despite being constantly exposed to large numbers of microorganisms, the skin can distinguish between harmless commensals and harmful pathogenic microorganisms. The mechanism for this selectivity is unclear. For an excellent discussion of the immunological anatomy of skin, readers are referred to a review by Kabashima and colleagues (2019).

NORMAL MICROBIOTA OF THE MOUTH AND UPPER RESPIRATORY TRACT

The flora of the nose consists of prominent corynebacterial, staphylococci (*S. epidermidis*, *S. aureus*), and streptococci.

In direct contrast to the highly differentiated communities of their mothers, neonates harbored bacterial communities that were undifferentiated across multiple body habitats, regardless of delivery mode. Thus, at its earliest stage of community development (<5 minutes postdelivery), the human microbiota is homogeneously distributed across the body. Vaginally delivered infants harbor bacterial communities (in all body habitats) that are most similar in composition to the vaginal communities of the mothers; C-section babies lack bacteria from the vaginal community (eg, *Lactobacillus*, *Prevotella*, *Atopobium*, and *Sneathia* spp.). Infants delivered via C-section harbor bacterial communities (across all body habitats) that are most similar to the skin communities of the mothers (eg, *Staphylococcus*, *Corynebacterium*, or *Propionibacterium* spp.).

Within 4–12 hours after birth, viridans streptococci become established as the most prominent members of the resident flora and remain so for life. These organisms probably originate in the respiratory tracts of the mother and attendants. Early in life, aerobic and anaerobic staphylococci, Gram-negative diplococci (neisseriae, *Moraxella catarrhalis*), diphtheroids, and occasional lactobacilli are added. When teeth begin to erupt, the anaerobic spirochetes, *Prevotella* species (especially *Prevotella melaninogenica*), *Fusobacterium* species, *Rothia* species, and *Capnocytophaga* species (see below) establish themselves along with some anaerobic vibrios and lactobacilli. *Actinomyces* species are normally present in tonsillar tissue and on the gingivae in adults, and various protozoa may also be present. Yeasts (*Candida* species) occur in the mouth.

In the pharynx and trachea, a similar flora establishes itself, but few bacteria are found in normal bronchi. Small bronchi and alveoli are normally sterile. The predominant organisms in the upper respiratory tract, particularly the pharynx, are nonhemolytic and α -hemolytic streptococci and neisseriae. Staphylococci, diphtheroids, haemophili, pneumococci, mycoplasmas, and prevotellae are also encountered.

More than 600 different microbial species have been described from the human oral cavity, but only limited information is available on the normal microbiota of healthy individuals. The human oral microbiome, as represented by the human salivary microbiome, was characterized in samples obtained from 120 healthy individuals from 12 worldwide locations by 16S rRNA sequencing. There is considerable diversity in the saliva microbiome, both within and among individuals; however, it does not vary substantially around the world. The 16S rRNA sequences could be assigned to 101 known bacterial genera, of which 39 were not previously reported from the human oral cavity; phylogenetic analysis suggests that an additional 64 unknown genera are also present.

Infections of the mouth and respiratory tract are usually caused by mixed oronasal flora, including anaerobes. Periodontal

infections, perioral abscesses, sinusitis, and mastoiditis may involve predominantly *P. melaninogenica*, *Fusobacterium* spp., and *Peptostreptococcus* spp. Aspiration of saliva (containing up to 10² of these organisms and aerobes) may result in necrotizing pneumonia, lung abscess, and empyema.

The Role of the Normal Mouth Microbiota in Dental Plaque and Caries

Dental plaque, which has come to be viewed and managed as a complex biofilm, can be defined simplistically as an

adherent deposit that forms on the tooth surface composed almost entirely of bacteria derived from the normal flora of the mouth (Figure 10-2). Dental plaque is the most prevalent and densest of human biofilms. The advantages for the microbes in the biofilm include protection from environmental hazards (including antimicrobials) and optimization of spatial arrangements that maximize energy through movement of nutrients. Organisms within the biofilm interact dynamically at multiple metabolic and molecular levels. The biofilm first forms in relation to the **dental pellicle**, which is a physiologic thin organic film covering

FIGURE 10-2 Dental plaque biofilm. The stages of formation of the bacterial biofilm called dental plaque are shown. Early colonizers bind to the pellicle, and late colonizers bind to the other bacteria. (Reproduced with permission from Willey J, Sherwood L, Woolverton C [editors]: *Prescott's Principles of Microbiology*. McGraw-Hill, 2008. © McGraw-Hill Education.)

the mineralized tooth surface composed of proteins and glycoproteins derived from saliva and other oral secretions (see Figure 10-2). As the plaque biofilm evolves, it does so in relation to the pellicle and not the mineralized tooth itself. Plaque formation takes place in stages and layers at two levels. The first is the anatomical location of the plaque in relation to the gingival line; the earliest plaque is supragingival, which may then extend to subgingival plaque. The second level is the layering within the plaque, the bacterial species involved, and the bacteria–pellicle and bacteria–bacteria binding mechanisms involved. The initial colonizing organisms are mainly Gram-positive bacteria that use specific ionic and hydrophobic interactions as well as lectin-like surface structures to adhere to the pellicle and to each other. The prototype early colonizer is *Streptococcus sanguis*, but other streptococci (*Streptococcus mutans*, *Streptococcus mitis*, *Streptococcus salivarius*, *Streptococcus oralis*, *Streptococcus gordonii*), lactobacilli, and *Actinomyces* species are usually present. Late colonizers can appear in the biofilm in as little as 2–4 days and consist primarily of Gram-negative anaerobes (eg, *Porphyromonas*, *Prevotella*, *Fusobacterium*, *Veillonella* species), including anaerobic spirochetes (eg, *Treponema denticola*), and more *Actinomyces* species. These bacteria use similar mechanisms to bind to the early colonizers and to each other. High-molecular-weight extracellular glucan polymers are synthesized, which act like a cement binding the plaque biofilm together. The carbohydrate polymers (glucans) are produced mainly by streptococci (*S. mutans*), perhaps in association with *Actinomyces* species. In all, there are thought to be 300–400 bacterial species present in mature dental plaque.

Caries is a disintegration of the teeth beginning at the surface and progressing inward. First the surface enamel, which is entirely noncellular, is demineralized. This has been attributed to the effect of acid products of glycolytic metabolic activity when the plaque bacteria are fed the right substrate. Subsequent decomposition of the dentin and cementum of the exposed root surface involves bacterial digestion of the protein matrix. *S. mutans* is considered to be the dominant organism for the initiation of caries; however, multiple members of the plaque biofilm participate in the evolution of the lesions. These include other streptococci (*S. salivarius*, *S. sanguis*, *Streptococcus sobrinus*), lactobacilli (*Lactobacillus acidophilus*, *Lactobacillus casei*), and actinomycetes (*Actinomyces viscosus*, *Actinomyces naeslundii*). The large amounts of organic acid products produced from carbohydrates by the interaction of *S. mutans* with these other species in plaque are the underlying cause of caries. The accumulation of these acid products causes the pH of the plaque to drop to levels sufficient to react with the hydroxyapatite of the enamel, demineralizing it to soluble calcium and phosphate ions. Production of acid and decreased pH is maintained until the substrate is depleted after which the plaque pH returns to its more neutral pH resting level and some recovery can take place.

Dietary monosaccharides (eg, glucose, fructose) and disaccharides (eg, sucrose, lactose, and maltose) provide an appropriate substrate for bacterial glycolysis (see Chapter 6) and acid production to cause tooth demineralization. Foods with high sugar content, particularly sucrose, which adhere to the teeth and have long oral clearance times, are more cariogenic than less retentive food stuffs such as sugar-containing liquids. A possible advantage for *S. mutans* is its ability to metabolize sucrose more efficiently than other oral bacteria. An additional factor is that sucrose is also used for the synthesis of extracellular polyglycans such as dextrans and levans by transferase enzymes on the bacterial cell surface. Polyglycan production contributes to aggregation and accumulation of *S. mutans* on the tooth surface and may also serve as an extracellular storage form of substrate for other plaque bacteria.

Periodontal pockets in the gingiva are particularly rich sources of organisms, including anaerobes that are rarely encountered elsewhere. Plaque-induced periodontal disease encompasses two separate disease entities, **gingivitis** and **chronic periodontitis**. Both conditions are caused by bacteria in the subgingival dental plaque found within the gingival crevice or the sulcus around the necks of the teeth. Periodontitis is a biofilm-induced chronic inflammatory disease which affects the tooth-supporting tissues. Although the tooth-associated biofilm plays a crucial role in the initiation and progression of periodontitis, it is primarily the host inflammatory response that is responsible for the damage to the periodontium, leading to tooth loss in some cases. It has been hypothesized that *Porphyromonas gingivalis* impairs innate immunity in ways that alter the growth and development of the entire biofilm, triggering a breakdown in the normally homeostatic host–microbiota interplay in the periodontium. A recent study established a correlation between the presence of periodontal disease and the presence of archaeal DNA, the severity of periodontal disease and the relative abundance of archaeal DNA in the subgingival plaque, and between disease resolution and diminished archaeal DNA abundance. The Archaea were comprised of two distinct phylotypes within the genus *Methanobrevibacter*. A causative association has not been established.

Although the microorganisms within the biofilm may participate in periodontal disease and tissue destruction, attention is drawn to them when they are implanted elsewhere (eg, producing infective endocarditis or bacteremia in a granulocytopenic host). Examples are *Capnocytophaga* species and *Rothia dentocariosa*. *Capnocytophaga* species are fusiform, Gram-negative, gliding anaerobes; *Rothia* species are pleomorphic, aerobic, Gram-positive rods. In granulocytopenic immunodeficient patients, they can lead to serious opportunistic lesions in other organs.

Control of caries involves physical removal of plaque, limitation of sucrose intake, good nutrition with adequate protein intake, and reduction of acid production in the mouth by limitation of available carbohydrates and frequent cleansing. The application of fluoride to teeth or its ingestion in water results

in enhancement of acid resistance of the enamel. Control of periodontal disease requires removal of calculus (calcified deposit) and good mouth hygiene.

Normal Microbiota of the Intestinal Tract

The human gastrointestinal tract is divided into sections, allowing digestion and nutrient absorption in the proximal region to be separate from the vast microbial populations in the large intestine. At birth, the intestine is sterile, but organisms are soon introduced with food. The environment (eg, maternal vaginal, fecal, or skin microbiota) is a major factor in determining the early microbial profile. Many early studies reported that the intestinal microbiota of breastfed children is dominated by *Bifidobacteria*. However, recent studies employing microarrays and quantitative PCR suggested that in most babies, *Bifidobacteria* did not appear until several months after birth and thereafter persisted as a minority population. In bottle-fed children, a more mixed flora exists in the bowel, and lactobacilli are less prominent. As food habits develop toward the adult pattern, the bowel flora changes. Diet has a marked influence on the relative composition of the intestinal and fecal flora. For example, individuals on an animal-based diet have been shown to have an increased abundance of bile-tolerant microorganisms (*Alistipes*, *Bilophila*, and *Bacteroides*) and decreased levels of Firmicutes that metabolize dietary plant polysaccharides (*Roseburia*, *Eubacterium rectale*, and *Ruminococcus bromii*). Bowels of newborns in intensive care nurseries tend to be colonized by *Enterobacteriaceae*, such as *Klebsiella*, *Citrobacter*, and *Enterobacter*.

In normal adults, the esophagus contains microorganisms arriving with saliva and food. The stomach's acidity keeps the number of microorganisms at a minimum (10^2 – 10^3 /mL of contents) unless obstruction at the pylorus favors the proliferation of Gram-positive cocci and bacilli. From the hundreds of phylotypes detected in the human stomach, only *Helicobacter pylori* persists in this environment. The normal acid pH of the stomach markedly protects against infection with some enteric pathogens (eg, *Vibrio cholerae*). Administration of antacids, H_2 -receptor antagonists, and proton pump inhibitors for peptic ulcer disease and gastroesophageal reflux disease leads to a great increase in microbial flora of the stomach, including many organisms usually prevalent in feces. As the pH of intestinal contents becomes alkaline, the resident flora gradually increases. In the adult duodenum, there are 10^3 – 10^4 bacteria/mL of effluent; with higher populations in the jejunum, 10^4 – 10^5 bacteria/mL, and ileum, 10^8 bacteria/mL; and in the cecum and transverse colon, 10^{11} – 10^{12} bacteria/mL, which is the highest recorded for any microbial habitat. In the upper intestine, the bacterial population associated with the mucosa include the phylum *Bacteroidetes* and members of the *Clostridiales*, and those of the lumen can include members of the *Enterobacteriales* and enterococci. In the sigmoid colon and rectum, the bacteria constitute about 60% of the fecal mass. Anaerobes outnumber facultative organisms by 1000-fold. In diarrhea, the bacterial content may diminish greatly, but in intestinal stasis, the count rises.

In a normal adult colon, 96–99% of the resident bacterial flora consists of anaerobes. Six major phyla predominate; these are *Bacteroidetes*, *Firmicutes*, *Actinobacteria*, *Verrucomicrobiota*, *Fusobacteria*, and *Proteobacteria*. More than 100 distinct types of organisms, which can be cultured routinely in the laboratory, occur regularly in normal fecal flora. *Archae* are represented primarily by the methane producers *Methanobrevibacter smithii* and *Methanosphaera stadtmanae*. *M. smithii* is found in more than 50% of the human population where it is the second or third most prevalent prokaryotic species (11–14%) in the microbiota. *M. stadtmanae* has been found in 20–33% of the human population and is of low prevalence in the microbiota. *Archae* may play an important role in stabilizing gut microbial communities. There probably are more than 500 species of bacteria in the colon, including many that are likely unidentified. In addition to *Bacteria* and *Archae*, other types of microbes are present, such as protozoans and fungi, whose functions are less well understood. Viruses, mostly phages whose hosts are prominent members of the microbiota, are remarkably common in the colon. Minor trauma, which occurs in about 10% of procedures (eg, sigmoidoscopy, barium enema), may result in transient bacteremia.

The important functions of intestinal microbiota can be divided into three major categories (see review by O'Hara and Shanahan, 2006). The first of these are protective functions in which the resident bacteria displace and inhibit potential pathogens indirectly by competing for nutrients and receptors or directly through the production of antimicrobial factors, such as bacteriocins and lactic acid. Second, commensal organisms are important for the development and function of the mucosal immune system. They induce the secretion of IgA, influence the development of the intestinal humoral immune system, and modulate local T-cell responses and cytokine profiles. The third category consists of a broad range of metabolic functions. The microbiota of the small intestine can contribute to the amino acid requirements of the host if they are not provided by the diet itself. Intestinal bacteria produce short-chain fatty acids that control intestinal epithelial cell differentiation. They synthesize vitamin K, biotin, and folate and enhance ion absorption. Certain bacteria metabolize dietary carcinogens and assist with fermentation of nondigestible dietary residue. There is now evidence that gut bacteria can influence fat deposition in the host, leading to obesity.

Methanogenic archae are often significant components of the gut microbiota. Their ability to reduce small organic compounds (eg, CO_2 , acetic acid, formic acid, methanol, or methyl compounds [eg, mono-, di-, and trimethylamine]) into methane in the presence of H_2 has significant consequences because the removal of excess hydrogen through methanogenesis prevents the inhibition of bacterial NADH dehydrogenase. This will, in turn, lead to an increased yield of ATP from bacterial metabolism (see Chapter 6) and a greater harvest of energy from the diet. The reduction of trimethylamine, which is produced during the metabolism of choline, betaine, lecithin, and carnitine by the gut microbiota, to form methane may help prevent cardiovascular disease and trimethylaminuria.

Antimicrobial drugs taken orally can, in humans, temporarily suppress the drug-susceptible components of the fecal flora. The acute effects of antibiotic treatment on the native gut microbiota range from self-limiting diarrhea to life-threatening pseudomembranous colitis. Intentional suppression of the fecal flora is commonly done by the preoperative oral administration of insoluble drugs. For example, neomycin plus erythromycin can in 1–2 days suppress part of the bowel flora, especially aerobes. Metronidazole accomplishes that for anaerobes. If lower bowel surgery is performed when the counts are at their lowest, some protection against infection by accidental spill can be achieved. However, soon thereafter, the counts of fecal flora rise again to normal or higher than normal levels, principally of organisms selected out because of relative resistance to the drugs used. The drug-susceptible microorganisms are replaced by drug-resistant ones, particularly *Staphylococcus* spp., *Enterobacter* spp., *Enterococcus* spp., *Proteus* spp., *Pseudomonas* spp., *Clostridium difficile*, and yeasts.

The feeding of large quantities of *L. acidophilus* may result in the temporary establishment of this organism in the gut and the concomitant partial suppression of other gut microflora.

Fecal microbiota transplantation (FMT), also known as **stool transplant**, is the process of transplantation of fecal bacteria from a healthy individual into a recipient. It has been used successfully as a treatment for patients suffering from *C. difficile* infection (see Chapter 11). The hypothesis behind the success of FMT rests on the concept of **bacterial interference**, that is, using harmless bacteria to displace pathogenic bacteria. FMT restores the colonic microbiota to its natural state by replacing missing *Bacteroidetes* and *Firmicutes* species. However, recent studies suggest that other factors may be important.

The anaerobic flora of the colon, including *Bacteroides fragilis*, clostridia, and peptostreptococci, plays a main role in abscess formation originating in perforation of the bowel. *Prevotella bivia* and *Prevotella disiens* are important in abscesses of the pelvis, originating in the female genital organs. Similar to *B. fragilis*, these species are penicillin resistant; therefore, another agent should be used.

Although the intestinal microbiota is normally an asset for the host, in genetically susceptible individuals, some components of the flora can result in disease. For example, inflammatory bowel diseases are believed to be associated with a loss of immune tolerance to bacterial antigens. This leads to intense inflammation caused by an exuberant immune response. Similar mechanisms may be important in intestinal malignancy such as colon cancer.

NORMAL MICROBIOTA OF THE URETHRA

The anterior urethras of both sexes contain small numbers of the same types of organisms found on the skin and perineum. These organisms regularly appear in normal voided urine in numbers of 10^2 – 10^4 /mL.

NORMAL MICROBIOTA OF THE VAGINA

Soon after birth, aerobic lactobacilli appear in the vagina and persist as long as the pH remains acidic (several weeks). When the pH becomes neutral (remaining so until puberty), a mixed flora of cocci and bacilli is present. At puberty, aerobic and anaerobic lactobacilli reappear in large numbers and contribute to the maintenance of acid pH through the production of acid from carbohydrates, particularly glycogen. This appears to be an important mechanism in preventing the establishment of other, possibly harmful microorganisms in the vagina. If lactobacilli are suppressed by the administration of antimicrobial drugs, yeasts or various bacteria increase in numbers and cause irritation and inflammation (**vaginitis**). **Bacterial vaginosis** is a syndrome marked by dramatic shifts in the types and relative proportions of the vaginal microbiota as the vaginal ecosystem changes from a healthy state, characterized by the presence of lactobacilli, to a diseased state characterized by the presence of organisms belonging to genera such as *Gardnerella*, *Atopobium*, *Leptotrichia*, *Megasphaera*, *Prevotella*, *Sneathia*, and others. A recent study on the vaginal microbiome of 396 asymptomatic reproductive-age women found variations in the vaginal pH and vaginal microbiome of different ethnic groups (ie, white, black, Hispanic, and Asian), suggesting the need to consider ethnicity as an important factor in assessing normal or abnormal flora.

After menopause, lactobacilli again diminish in number, and a mixed flora returns. The normal vaginal flora includes group B streptococci in as many as 25% of women of child-bearing age. During the birth process, a baby can acquire group B streptococci, which subsequently may cause neonatal sepsis and meningitis. The normal vaginal flora often also includes α -hemolytic streptococci, anaerobic streptococci (peptostreptococci), *Prevotella* species, clostridia, *Gardnerella vaginalis*, *Ureaplasma urealyticum*, and sometimes *Listeria* or *Mobiluncus* species. The cervical mucus has antibacterial activity and contains lysozyme. In some women, the vaginal introitus contains a heavy flora resembling that of the perineum and perianal area. This may be a predisposing factor in recurrent urinary tract infections. Vaginal organisms present at time of delivery may infect the newborn (eg, group B streptococci).

NORMAL MICROBIOTA OF THE PLACENTA AND UTERUS

Until recently the placenta and uterus were considered to be sterile environments. Commensal, nonpathogenic bacterial species and genera that reside in placental tissue have been identified. A variety of microorganisms inhabit the uterus of healthy, asymptomatic women of reproductive age. The microbiome of the uterus differs significantly from that of the vagina and gastrointestinal tract.

NORMAL MICROBIOTA OF THE CONJUNCTIVA

The predominant organisms of the conjunctiva are diphtheroids, *S. epidermidis*, and nonhemolytic streptococci. Neisseriae and Gram-negative bacilli resembling haemophili (*Moraxella* species) are also frequently present. The conjunctival flora is normally held in check by the flow of tears, which contain antibacterial lysozyme.

CHAPTER SUMMARY

- The normal microbiota denotes the population of microorganisms that inhabit the skin and mucous membranes of healthy normal persons. The normal microbiota provides a first line of defense against microbial pathogens, assists in digestion, and contributes to maturation of the immune system.
- The skin and mucous membranes always harbor a variety of microorganisms that can be divided into (1) resident microbiota, which are fixed types of microorganisms regularly found in a given area at a given age that, if disturbed, promptly reestablish themselves, and (2) transient microbiota, which are nonpathogenic or potentially pathogenic microorganisms that inhabit the skin or mucous membranes for hours, days, or weeks.
- Various sites on the skin or mucous membranes are unique environments with a characteristic microbiota.
- Results from the Human Microbiome Project reveal that the microbiota is far more complex than previously thought.
- Dental plaque is a complex biofilm composed of normal microbiota. Metabolism of carbohydrates by organisms in dental plaque such as *S. mutans* is responsible for the initiation of caries.
- More than 500 species of bacteria have been identified in the colon. Anaerobes outnumber facultative organisms in the colon by 1000-fold.

REVIEW QUESTIONS

1. A 26-year-old woman visits her physician because of an unusual vaginal discharge. On examination, the physician observes a thin, homogeneous, white-gray discharge that adheres to the vaginal wall. The pH of the discharge is 5.5 (normal, <4.3). On Gram-stain, many epithelial cells covered with Gram-variable rods are seen. Bacterial vaginosis is diagnosed. Which one of the following normal genital flora microorganisms is greatly decreased in bacterial vaginosis?
 - (A) *Corynebacterium* species
 - (B) *Staphylococcus epidermidis*
 - (C) *Prevotella* species
 - (D) *Candida albicans*
 - (E) *Lactobacillus* species
2. Certain microorganisms are never considered to be members of the normal flora. They are always considered to be pathogens. Which one of the following organisms fits into that category?
 - (A) *Streptococcus pneumoniae*
 - (B) *Escherichia coli*
 - (C) *Mycobacterium tuberculosis*
 - (D) *Staphylococcus aureus*
 - (E) *Neisseria meningitidis*
3. A 9-year-old girl develops fever and severe pain on the right side of her throat. On examination, redness and swelling in the right peritonsillar area are seen. A peritonsillar abscess is diagnosed. The most likely organisms to be cultured from this abscess are
 - (A) *Staphylococcus aureus*
 - (B) *Streptococcus pneumoniae*
 - (C) *Corynebacterium* species and *Prevotella melaninogenica*
 - (D) Normal oral nasal flora
 - (E) Viridans streptococci and *Candida albicans*
4. A 70-year-old man with a history of diverticulosis of the sigmoid colon experiences a sudden onset of severe left lower quadrant abdominal pain. Fever develops. The severe pain gradually subsides and is replaced by a constant aching pain and marked abdominal tenderness. A diagnosis of probable ruptured diverticulum is made, and the patient is taken to the operating room. The diagnosis of ruptured diverticulum is confirmed, and an abscess next to the sigmoid colon is found. The most likely bacteria to be found in the abscess are
 - (A) Mixed normal gastrointestinal flora
 - (B) *Bacteroides fragilis* alone
 - (C) *Escherichia coli* alone
 - (D) *Clostridium perfringens* alone
 - (E) *Enterococcus* species alone
5. Antimicrobial therapy can decrease the amount of susceptible bowel flora and allow proliferation of relatively resistant colonic bacteria. Which one of the following species can proliferate and produce a toxin that causes diarrhea?
 - (A) *Enterococcus* species
 - (B) *Staphylococcus epidermidis*
 - (C) *Pseudomonas aeruginosa*
 - (D) *Clostridium difficile*
 - (E) *Bacteroides fragilis*
6. Which one of the following microorganisms can be part of the normal vaginal flora and cause meningitis in newborns?
 - (A) *Candida albicans*
 - (B) *Corynebacterium* species
 - (C) *Staphylococcus epidermidis*
 - (D) *Ureaplasma urealyticum*
 - (E) Group B streptococci
7. Dental plaque and periodontal disease can be thought of as a continuum of what type of physiological process?
 - (A) Biofilm formation
 - (B) Normal aging
 - (C) Abnormal digestion
 - (D) Exaggerated immune response
 - (E) Chewing gum
8. Which one of the following microorganisms is closely associated with dental caries?
 - (A) *Candida albicans*
 - (B) *Streptococcus mutans*
 - (C) *Prevotella melaninogenica*
 - (D) *Neisseria subflava*
 - (E) *Staphylococcus epidermidis*

9. Anaerobic bacteria such as *Bacteroides fragilis* occur in the sigmoid colon in a concentration of about 10^{11} /g of stool. At what concentration do facultative organisms such as *Escherichia coli* occur?
 - (A) 10^{11} /g
 - (B) 10^{10} /g
 - (C) 10^9 /g
 - (D) 10^8 /g
 - (E) 10^7 /g
10. *Streptococcus pneumoniae* can be part of the normal flora of 5–40% of people. At what anatomic site can it be found?
 - (A) Conjunctiva
 - (B) Nasopharynx
 - (C) Colon
 - (D) Urethra
 - (E) Vagina
11. Hundreds of phylotypes have been identified in the human stomach; however, the only microorganism that has been shown to persist is
 - (A) *Lactobacillus casei*
 - (B) *Lactobacillus acidophilus*
 - (C) *Escherichia coli*
 - (D) *Helicobacter pylori*
 - (E) *Bifidobacteria*
12. Resident flora is commonly found in the
 - (A) Liver
 - (B) Urethra
 - (C) Kidneys
 - (D) Salivary glands
 - (E) Gallbladder
13. Resident flora is absent from the
 - (A) Pharynx
 - (B) Lungs
 - (C) Small intestine
 - (D) Synovial fluid
 - (E) Conjunctiva
14. A 65-year-old woman was admitted with squamous cell carcinoma of the cervix. She underwent extensive gynecologic surgery and was maintained postoperatively on broad-spectrum intravenous antibiotics. The patient had a central venous catheter placed on the day of surgery. Beginning 3 days postoperatively, the patient became febrile. On day 8, cultures of blood and of the tip of the central line both grew Gram-positive organisms that were ovoid and reproduced by budding. Which of the following microorganisms is most likely responsible for the patient's condition?
 - (A) *Staphylococcus aureus*
 - (B) *Staphylococcus epidermidis*
 - (C) *Enterococcus faecalis*
 - (D) *Candida albicans*
 - (E) *Saccharomyces cerevisiae*
15. The most likely portal of entry for the organism in Question 14 is
 - (A) During gynecologic surgery
 - (B) Aspiration
 - (C) During placement of the central venous catheter
 - (D) During placement of IV line for administration of antibiotics
 - (E) Intubation while under anesthesia

Spore-Forming Gram-Positive Bacilli: *Bacillus* and *Clostridium* Species

The Gram-positive spore-forming bacilli are the *Bacillus* and *Clostridium* species. These bacilli are ubiquitous, and because they form spores, they can survive in the environment for many years. *Bacillus* species are aerobes, and the *Clostridium* species are anaerobes (see also Chapter 21).

Of the many species of *Bacillus* and related genera, most do not cause disease and are not well characterized in medical microbiology. There are a few species, however, that cause important diseases in humans. Anthrax, a classical disease in the history of microbiology, is caused by *Bacillus anthracis*. Anthrax remains an important disease of animals and occasionally of humans. Because of its potent toxins, *B. anthracis* is a major potential agent of bioterrorism and biologic warfare. *B. cereus* causes food poisoning and occasionally eye or other localized infections.

The genus *Clostridium* is extremely heterogeneous, and more than 200 species have been described. The list of pathogenic organisms, as well as novel species isolated from human feces whose pathogenic potential remains undetermined, continues to grow. Clostridia cause several important toxin-mediated diseases, including tetanus (*Clostridium tetani*), botulism (*C. botulinum*), gas gangrene (*C. perfringens*), and antibiotic-associated diarrhea and pseudomembranous colitis (*C. difficile*). Other clostridia are also found in mixed anaerobic infections in humans (see Chapter 21).

BACILLUS SPECIES

The genus *Bacillus* includes large aerobic, Gram-positive rods occurring in chains. The members of this genus are closely related but differ both phenotypically and in terms of pathogenesis. Pathogenic species possess virulence plasmids. Most members of this genus are saprophytic organisms prevalent in soil, water, and air, and on vegetation (eg, *B. subtilis*). Some are insect pathogens, such as *B. thuringiensis*. *B. cereus* can grow in foods and cause food poisoning by producing either an enterotoxin (diarrhea) or an emetic toxin (vomiting). *B. cereus* may occasionally produce disease in immunocompromised humans (eg, meningitis, endocarditis, endophthalmitis, conjunctivitis, or acute gastroenteritis). *B. anthracis*, which causes **anthrax**, is the principal pathogen of the genus.

Morphology and Identification

A. Typical Organisms

The typical cells, measuring $1 \times 3\text{--}4\ \mu\text{m}$, have square ends and are arranged in long chains; spores are located in the center of the bacilli.

B. Culture

Colonies of *B. anthracis* are round and have a “cut glass” appearance in transmitted light. Hemolysis is uncommon with *B. anthracis* but common with *B. cereus* and the saprophytic bacilli. Gelatin is liquefied, and growth in gelatin stabs resembles an inverted fir tree.

C. Growth Characteristics

The saprophytic bacilli use simple sources of nitrogen and carbon for energy and growth. The spores are resistant to environmental changes, withstand dry heat and certain chemical disinfectants for moderate periods, and persist for years in dry earth. Items contaminated with anthrax spores can be sterilized by autoclaving or irradiation.

BACILLUS ANTHRACIS

Pathogenesis

Anthrax is primarily a disease of herbivores—goats, sheep, cattle, horses, and so on; other animals (eg, rats) are relatively resistant to the infection. Anthrax is endemic among agrarian societies in developing countries in Africa, the Middle East, and Central America. A website maintained by the World Health Organization provides current information on disease in animals (www.who.int/csr/disease/Anthrax/en/). Humans become infected incidentally by contact with infected animals or their products. In animals, the portal of entry is the mouth and the gastrointestinal tract. Spores from contaminated soil find easy access when ingested with spiny or irritating vegetation. In humans, the infection is usually acquired by the entry of spores through injured skin (cutaneous anthrax) or rarely the mucous membranes (gastrointestinal anthrax) or by inhalation of spores into the lung (inhalation anthrax). A fourth category of the disease, injection anthrax, has caused

outbreaks among persons who inject heroin that has been contaminated with anthrax spores. The spores germinate in the tissue at the site of entry, and growth of the vegetative organisms results in formation of a gelatinous edema and congestion. Bacilli spread via lymphatics to the bloodstream, and they multiply freely in the blood and tissues shortly before and after the animal's death.

B. anthracis (Figure 11-1) isolates that do not produce a capsule are not virulent and do not induce anthrax in test animals. The poly- γ -D-glutamic acid capsule is antiphagocytic. The capsule gene is present on a plasmid, pXO2.

Anthrax toxins are made up of three proteins: protective antigen (PA), edema factor (EF), and lethal factor (LF). PA is a

protein that binds to specific cell receptors, and after proteolytic activation, it forms a membrane channel that mediates entry of EF and LF into the cell. EF is an adenylate cyclase; with PA, it forms a toxin known as edema toxin. Edema toxin is responsible for cell and tissue edema. LF plus PA form lethal toxin, which is a major virulence factor and cause of death in infected animals and humans. When injected into laboratory animals (eg, rats), the lethal toxin can quickly kill the animals by impairing both innate and adaptive immunity, allowing organism proliferation and cell death. The anthrax toxin genes are encoded on another plasmid, pXO1. In inhalation anthrax (wool sorters' disease), the spores from the dust of wool, hair, or hides are inhaled; phagocytosed in the lungs; and transported by the lymphatic drainage to the mediastinal lymph nodes, where germination occurs. This is followed by toxin production and the development of hemorrhagic mediastinitis and sepsis, which are usually rapidly fatal. In anthrax sepsis, the number of organisms in the blood exceeds 10^7 /mL just before death. In the Sverdlovsk, inhalation anthrax outbreak of 1979 and the U.S. bioterrorism inhalation cases of 2001, the pathogenesis was the same as in inhalation anthrax from animal products.

Pathology

In susceptible animals and humans, the organisms proliferate at the site of entry. The capsules remain intact, and the organisms are surrounded by a large amount of proteinaceous fluid containing few leukocytes from which they rapidly disseminate and reach the bloodstream.

In resistant animals, the organisms proliferate for a few hours, by which time there is massive accumulation of leukocytes. The capsules gradually disintegrate and disappear. The organisms remain localized.

Clinical Findings

In humans, approximately 95% of cases are cutaneous anthrax, and 5% are inhalation. Gastrointestinal anthrax is very rare; it has been reported from Africa, Asia, and the United States when people have eaten meat from infected animals.

The bioterrorism events in the fall of 2001 resulted in 22 cases of anthrax—11 inhalation and 11 cutaneous. Five of the patients with inhalation anthrax died. All of the other patients survived.

Cutaneous anthrax generally occurs on exposed surfaces of the arms or hands followed in frequency by the face and neck. A pruritic papule develops 1–7 days after entry of the organisms or spores through a scratch. Initially, it resembles an insect bite. The papule rapidly changes into a vesicle or small ring of vesicles that coalesce, and a necrotic ulcer develops. The lesions typically are 1–3 cm in diameter and have a characteristic central black eschar. Marked edema occurs. Lymphangitis, lymphadenopathy, and systemic signs and symptoms of fever, malaise, and headache may occur.

A

B

FIGURE 11-1 **A:** *B. anthracis* in broth culture (original magnification $\times 1000$). **B:** In tissue (original magnification $\times 400$). (Courtesy of PS Brachman.)

After 7–10 days, the eschar is fully developed. Eventually, it dries, loosens, and separates; healing is by granulation and leaves a scar. It may take many weeks for the lesion to heal and the edema to subside. Antibiotic therapy does not appear to change the natural progression of the disease but prevents dissemination. In as many as 20% of patients, cutaneous anthrax can lead to sepsis, the consequences of systemic infection—including meningitis—and death.

The incubation period in inhalation anthrax may be as long as 6 weeks. The early clinical manifestations are associated with marked hemorrhagic necrosis and edema of the mediastinum. Substernal pain may be prominent, and there is pronounced mediastinal widening visible on chest radiographs. Hemorrhagic pleural effusions follow involvement of the pleura; cough is secondary to the effects on the trachea. Sepsis occurs, and there may be hematogenous spread to the gastrointestinal tract, causing bowel ulceration, or to the meninges, causing hemorrhagic meningitis. The fatality rate in inhalation anthrax is high in the setting of known exposure; it is higher when the diagnosis is not initially suspected.

Animals acquire anthrax through ingestion of spores and spread of the organisms from the intestinal tract. This is rare in humans, and gastrointestinal anthrax is extremely uncommon. Abdominal pain, vomiting, and bloody diarrhea are clinical signs.

Injection anthrax is characterized by extensive, painless, subcutaneous edema and the notable absence of the eschar characteristic of cutaneous anthrax. Patients may progress to hemodynamic instability due to septicemia.

Diagnostic Laboratory Tests

Specimens to be examined are fluid or pus from a local lesion, blood, pleural fluid, and cerebrospinal fluid in inhalational anthrax associated with sepsis and stool or other intestinal contents in the case of gastrointestinal anthrax. Stained smears from the local lesion or of blood from dead animals often show chains of large Gram-positive rods. Anthrax can be identified in dried smears by immunofluorescence staining techniques.

When grown on blood agar plates, the organisms produce nonhemolytic gray to white, tenacious colonies with a rough texture and a ground-glass appearance. Comma-shaped outgrowths (Medusa head, “curled hair”) may project from the colony. Demonstration of capsule requires growth on bicarbonate-containing medium in 5–7% carbon dioxide. Gram-stain shows large Gram-positive rods. Carbohydrate fermentation is not useful. In semisolid medium, anthrax bacilli are always nonmotile, but related organisms (eg, *B. cereus*) exhibit motility by “swarming.” Clinical laboratories that recover large Gram-positive rods from blood, cerebrospinal fluid, or suspicious skin lesions, which phenotypically match the description of *B. anthracis* as mentioned, should immediately contact their public health laboratory and send the organism for confirmation. Definitive identification requires lysis by a specific anthrax γ -bacteriophage,

detection of the capsule by fluorescent antibody, or identification of toxin genes by polymerase chain reaction (PCR). These tests are available in most public health laboratories.

A rapid enzyme-linked immunoassay (ELISA) that measures total antibody to PA has been approved by the U.S. Food and Drug Administration (FDA), but the test result is not positive early in disease.

Resistance and Immunity

Immunization to prevent anthrax is based on the classic experiments of Louis Pasteur. In 1881, he proved that cultures grown in broth at 42–52°C for several months lost much of their virulence and could be injected live into sheep and cattle without causing disease; subsequently, such animals proved to be immune. Active immunity to anthrax can be induced in susceptible animals by vaccination with live attenuated bacilli, with spore suspensions, or with PA from culture filtrates. Animals that graze in known anthrax districts should be immunized for anthrax annually.

In the United States, the current FDA-approved vaccine (AVA BioThrax®, Emergent BioSolutions, Inc, Rockville, MD) is made from the supernatant of a cell-free culture of an unencapsulated but toxigenic strain of *B. anthracis* that contains PA adsorbed to aluminum hydroxide. The dose schedule is 0.5 mL administered intramuscularly at 0 and 4 weeks and then at 6, 12, and 18 months followed by annual boosters. The vaccine is available only to the U.S. Department of Defense and to persons at risk for repeated exposure to *B. anthracis*. Because the current anthrax vaccines provide short-lived immunity and hence require repeated vaccinations, a number of new recombinant PA vaccines (rPA) have been developed. These novel vaccines have been shown to be very well tolerated and highly immunogenic (see discussion under Treatment).

Treatment

Many antibiotics are effective against anthrax in humans, but treatment must be started early. Ciprofloxacin is recommended for treatment; other agents with activity include penicillin G, doxycycline, erythromycin, and vancomycin. In the setting of potential exposure to *B. anthracis* as an agent of biologic warfare, prophylaxis with ciprofloxacin or doxycycline should be given for 60 days, and three doses of vaccine (AVA BioThrax) should be administered.

Raxibacumab (Abthrax®, GlaxoSmithKline, London, UK), a recombinant human monoclonal antibody, was FDA approved for treatment of and prophylaxis against inhalational anthrax in late 2012. The mechanism of action is prevention of binding of PA to its receptors in host cells. The drug is used in combination with appropriate antimicrobial agents.

Anthrax immune globulin intravenous (AIGIV, Can-gene Corp. Winnipeg, Manitoba, CA) is not FDA approved but could be made available through the Centers for Disease

Control and Prevention. AIGIV is a human polyclonal anti-serum that also inhibits binding of PA to its receptors. Like Raxibacumab, it is used as an adjunct to antimicrobial agents for the treatment of severe forms of anthrax.

Epidemiology, Prevention, and Control

Soil is contaminated with anthrax spores from the carcasses of dead animals. These spores remain viable for decades. Perhaps, spores can germinate in soil at a pH of 6.5 at proper temperature. Grazing animals infected through injured mucous membranes serve to perpetuate the chain of infection. Contact with infected animals or with their hides, hair, and bristles is the source of infection in humans. Control measures include (1) disposal of animal carcasses by burning or by deep burial in lime pits, (2) decontamination (usually by autoclaving) of animal products, (3) protective clothing and gloves for handling potentially infected materials, and (4) active immunization of domestic animals with live attenuated vaccines. Persons with high occupational risk should be immunized.

BACILLUS CEREUS

Food poisoning caused by *B. cereus* has two distinct forms: the emetic type, which is associated with fried rice, milk, and pasta, and the diarrheal type, which is associated with meat dishes and sauces. *B. cereus* produces toxins that cause disease that is more of intoxication than a food-borne infection. The emetic form is manifested by nausea, vomiting, abdominal cramps, and occasionally diarrhea and is self-limiting, with recovery occurring within 24 hours. It begins 1–5 hours after ingestion of a plasmid-encoded preformed cyclic peptide (emetic toxin) in the contaminated food products. *B. cereus* is a soil organism that commonly contaminates rice. When large amounts of rice are cooked and allowed to cool slowly, the *B. cereus* spores germinate, and the vegetative cells produce the toxin during log-phase growth or during sporulation. The diarrheal form has an incubation period of 1–24 hours and is manifested by profuse diarrhea with abdominal pain and cramps; fever and vomiting are uncommon. In this syndrome, ingested spores that develop into vegetative cells of *B. cereus* secrete one of three possible enterotoxins which induce fluid accumulation and other physiological responses in the small intestine. The presence of *B. cereus* in a patient's stool is not sufficient to make a diagnosis of *B. cereus* disease because the bacteria may be present in normal stool specimens; a concentration of 10^5 bacteria or more per gram of food is considered diagnostic.

B. cereus is an important cause of eye infections, such as severe keratitis and endophthalmitis. Typically, the organisms are introduced into the eye by foreign bodies associated with trauma but infections can also occur after surgery. *B. cereus* has also been associated with localized infections, such as wound infections, and with systemic infections,

including endocarditis, catheter-associated bacteremia, central nervous system infections, osteomyelitis, and pneumonia; the presence of a medical device or intravenous drug use predisposes to these infections. Outbreaks of bacteremia in neonatal intensive care units and other hospital units during construction in health care facilities have been reported. *B. cereus* is resistant to a variety of antimicrobial agents, including penicillins and cephalosporins. Serious non-foodborne infections should be treated with vancomycin or clindamycin with or without an aminoglycoside. Ciprofloxacin has been useful for the treatment of wound infections.

CHAPTER SUMMARY

- *Bacillus* species constitute a large group of mostly saprophytic, aerobic, spore-forming organisms ubiquitous in soil.
- The major pathogen in the *Bacillus* genus is *B. anthracis*, a virulent and toxic organism of historical importance.
- Humans acquire infection from spores inoculated via contact with animals or animal products, such as hides.
- *B. anthracis* causes four categories of disease in humans depending on the point of entry of the spores: cutaneous (95%), inhalational (5%), gastrointestinal (rare), and injection.
- PA combines with two factors, EF and LF, to form potent toxins, edema toxin and lethal toxin, respectively, both of which have cytotoxic and immunomodulating effects. These toxins are responsible for the edema, tissue destruction, and the hemorrhage characteristic of anthrax.
- *B. cereus* causes food poisoning and opportunistic infections in immunocompromised patients.
- *B. cereus* can be differentiated from *B. anthracis* on the basis of colony morphology, β -hemolysis, motility, and antimicrobial susceptibility patterns.

CLOSTRIDIUM SPECIES

The clostridia are large anaerobic, Gram-positive, motile rods. Many decompose proteins or form toxins, and some do both. Their natural habitat is the soil, marine sediments, sewage, or the intestinal tract of animals and humans, where they live as saprophytes. The clostridia continue to increase in number as new species are discovered and several species have been sequenced. There are 19 clusters based on 16S rRNA gene sequence analysis. Most clinically related species are in RNA Cluster I. Among the pathogens in this cluster are the organisms causing **botulism**, **tetanus**, **gas gangrene**, and **pseudomembranous colitis**.

Morphology and Identification

A. Typical Organisms

Spores of clostridia are usually wider than the diameter of the rods in which they are formed. In the various species, the

FIGURE 11-2 *Clostridium* Gram-stain. Individual Gram-positive bacilli are present. Many are in chains. Some of the bacilli have spores, which are the unstained or clear ovoid shapes (arrows).

spore is placed centrally, subterminally, or terminally. Most species of clostridia are motile and possess peritrichous flagella. A Gram-stain of a *Clostridium* species with terminal spores is shown in Figure 11-2.

B. Culture

Clostridia are anaerobes and grow under anaerobic conditions; a few species are aerotolerant and also grow in ambient air. Anaerobic culture conditions are discussed in Chapter 21. In general, the clostridia grow well on the blood-enriched media or other media used to grow anaerobes.

C. Colony Forms

Some clostridia produce large raised colonies (eg, *C. perfringens*); others produce smaller colonies (eg, *C. tetani*). Some clostridia form colonies that spread or swarm on the agar surface (*C. septicum*). Many clostridia produce a zone of β -hemolysis on blood agar. *C. perfringens* characteristically produces a double zone of β -hemolysis around colonies.

D. Growth Characteristics

Clostridia can ferment a variety of sugars (saccharolytic), and many can digest proteins (proteolytic); some species do both. These metabolic characteristics are used to divide the clostridia into groups. Milk is turned acid by some and digested by others and undergoes “stormy fermentation” (ie, clot torn by gas) with a third group (eg, *C. perfringens*). Various enzymes are produced by different species. *Clostridium* species produce more toxins than any other group of bacteria (see next).

CLOSTRIDIUM BOTULINUM

C. botulinum, which causes the disease **botulism**, is world-wide in distribution; it is found in soil and occasionally in animal feces.

Types of *C. botulinum* are distinguished by the antigenic type of toxin they produce. Spores of the organism are highly resistant to heat, withstanding 100°C for several hours. Heat resistance is diminished at acid pH or high salt concentration.

Toxins

During the growth of *C. botulinum* and during autolysis of the bacteria, toxin is liberated into the environment. Seven antigenic varieties of toxin (serotypes A–G) are known. Types A, B, E, and F are the principal causes of human illness. Types A and B have been associated with a variety of foods and type E predominantly with fish products. Type C produces limberneck in birds; type D causes botulism in mammals. Type G is not associated with disease. Botulinum toxins have three domains. Two of the domains facilitate binding to and entry of toxin into the nerve cell. The third domain is the toxin which is a 150 kDa protein that is cleaved into a heavy chain (H, 100 kDa) and a light chain (L, 50 kDa) that are linked by a disulfide bond. Botulinum toxin is absorbed from the gut, enters the blood circulation, and binds to receptors of presynaptic membranes of motor neurons of the peripheral nervous system and cranial nerves. The toxin does not cross the blood brain barrier or affect the central nervous system. Proteolysis—by the L chain of botulinum toxin—of the target SNARE proteins (soluble-N-ethyl maleimide-sensitive factor attachment protein) in the neurons inhibits the release of acetylcholine at the synapse, resulting in lack of muscle contraction and paralysis. The SNARE proteins are synaptobrevin (also known as vesicle-associated membrane protein or VAMP), SNAP 25, and syntaxin. The toxins of *C. botulinum* types A, C, and E cleave the 25,000 kDa SNAP 25. Type C also cleaves syntaxin. Types B, D, F, and G toxins cleave only synaptobrevin. *C. botulinum* toxins are among the most toxic substances known: The lethal dose for a human is probably about 1–2 $\mu\text{g/kg}$. The toxins are destroyed by heating for 20 minutes at 100°C. Strains that produce toxins A, B, or F are associated with infant botulism. Additional details on toxin production and function are described in the review by Rossetto et al (see References).

Pathogenesis

Resurgence of wound botulism caused by types A or B toxin has occurred recently in the United States, in the United Kingdom, and in Germany in association with skin-popping using contaminated “black tar” heroin. However, most cases of botulism represent an intoxication resulting from the ingestion of food in which *C. botulinum* has grown and produced toxin. The most common offenders are spiced, smoked, vacuum packed, or canned alkaline foods that are eaten without cooking. In such foods, spores of *C. botulinum* germinate;

that is, under anaerobic conditions, vegetative forms grow and produce toxin.

In infant botulism, honey is the most frequent vehicle of infection. The pathogenesis differs from the way that adults acquire infection. The infant ingests the spores of *C. botulinum*, and the spores germinate within the intestinal tract. The vegetative cells produce toxin as they multiply; the neurotoxin then gets absorbed into the bloodstream. In rare instances, adults with gastrointestinal anatomical abnormalities or functional disorders may develop “infant botulism.”

Wound botulism is the result of tissue contamination with spores and is seen primarily in injection drug users. Very rarely, inhalational botulism occurs when toxin enters the respiratory tract.

The toxin acts by blocking release of acetylcholine at synapses and neuromuscular junctions (see earlier discussion). The result is flaccid paralysis. The electromyogram and edrophonium strength test results are typical.

Clinical Findings

Symptoms begin 18–24 hours after ingestion of the toxic food, with visual disturbances (incoordination of eye muscles, double vision), inability to swallow, and speech difficulty; signs of bulbar paralysis are progressive, and death occurs from respiratory paralysis or cardiac arrest. Gastrointestinal symptoms are not prominent. There is no fever. The patient remains fully conscious until shortly before death. The mortality rate is high. Patients who recover do not develop antitoxin in the blood.

In the United States, infant botulism is as common as or more common than the classic form of paralytic botulism associated with the ingestion of toxin-contaminated food. The infants in the first months of life develop poor feeding, weakness, and signs of paralysis (floppy baby). Infant botulism may be one of the causes of sudden infant death syndrome. *C. botulinum* and botulinum toxin are found in feces but not in serum.

Diagnostic Laboratory Tests

Clinicians who suspect a case of botulism should contact the appropriate public health authorities before submitting specimens to the laboratory. Detection of toxin and not the organism is required for definitive diagnosis. Toxin can often be demonstrated in serum, gastric secretions, or stool from the patient, and toxin may be found in leftover food. Clinical swabs or other specimens obtained from patients should be transported using anaerobe containers. Suspect foods should be left in their original containers. Mice injected intraperitoneally with such specimens from these patients die rapidly. The antigenic type of toxin is identified by neutralization with specific antitoxin in mice. This mouse bioassay is the test of choice for the confirmation of botulism. *C. botulinum* may be grown from food remains and tested for toxin production, but this is rarely done and is of questionable significance.

In infant botulism, *C. botulinum* and toxin can be demonstrated in bowel contents but not in serum. Other methods used to detect toxin include ELISAs and PCR, but the latter may detect organisms that carry the gene but do not express toxin.

Treatment

Supportive care, especially intensive care, is key in the management of patients with botulism. Adequate respiration must be maintained by mechanical ventilation if necessary and in severe cases may need to be maintained for up to 8 weeks. These measures have reduced the mortality rate from 65% to below 25%. Potent antitoxins to three types of botulinum toxins have been prepared in horses. Because the type responsible for an individual case is usually not known, trivalent (A, B, E) antitoxin must be promptly administered intravenously with customary precautions. Antitoxin does not reverse the paralysis, but if administered early, it can prevent its advancement. Although most infants with botulism recover with supportive care alone, treatment with human-derived botulinum immune globulin (BIG) is recommended.

Epidemiology, Prevention, and Control

Because spores of *C. botulinum* are widely distributed in soil, they often contaminate vegetables, fruits, and other materials. A large restaurant-based outbreak was associated with sautéed onions. When such foods are canned or otherwise preserved, they either must be sufficiently heated to ensure destruction of spores or must be boiled for 20 minutes before consumption. Strict regulation of commercial canning has largely overcome the danger of widespread outbreaks, but commercially prepared foods have caused deaths. A chief risk factor for botulism lies in home-canned foods, particularly string beans, corn, peppers, olives, peas, and smoked fish or vacuum-packed fresh fish in plastic bags. Toxic foods may be spoiled and rancid, and cans may “swell,” or the appearance may be innocuous. The risk from home-canned foods can be reduced if the food is boiled for more than 20 minutes before consumption.

Botulinum toxin is considered to be a major potential agent for bioterrorism and biologic warfare.

CLOSTRIDIUM TETANI

C. tetani, which causes **tetanus**, is worldwide in distribution in the soil and in the feces of horses and other animals. Several types of *C. tetani* can be distinguished by specific flagellar antigens. All share a common O (somatic) antigen, which may be masked, and all produce the same antigenic type of neurotoxin, tetanospasmin.

Toxin

The vegetative cells of *C. tetani* produce the plasmid-encoded toxin tetanospasmin (150 kDa) that is cleaved by a bacterial

protease into two peptides (50 and 100 kDa) linked by a disulfide bond. The larger peptide initially binds to receptors on the presynaptic membranes of motor neurons. It then migrates by the retrograde axonal transport system to the cell bodies of these neurons to the spinal cord and brainstem. The toxin diffuses to terminals of inhibitory cells, including both glycinergic interneurons and γ -aminobutyric acid (GABA)-secreting neurons from the brainstem. The smaller peptide degrades synaptobrevin (also called VAMP2, see above under *C. botulinum* toxin), a protein required for docking of neurotransmitter vesicles on the presynaptic membrane. Release of the inhibitory glycine and GABA is blocked, and the motor neurons are not inhibited. Hyperreflexia, muscle spasms, and spastic paralysis result. Extremely small amounts of toxin can be lethal for humans.

Pathogenesis

C. tetani is not an invasive organism. The infection remains strictly localized in the area of devitalized tissue (wound, burn, injury, umbilical stump, surgical suture) into which the spores have been introduced. The volume of infected tissue is small, and the disease is almost entirely a toxemia. Germination of the spore and development of vegetative organisms that produce toxin are aided by (1) necrotic tissue, (2) calcium salts, and (3) associated pyogenic infections, all of which aid establishment of low oxidation–reduction potential.

The toxin released from vegetative cells reaches the central nervous system and rapidly becomes fixed to receptors in the spinal cord and brainstem and exerts the actions described.

Clinical Findings

The incubation period may range from 4 to 5 days up to 3 weeks. The disease is characterized by tonic contraction of voluntary muscles. Muscular spasms often involve first the area of injury and infection and then the muscles of the jaw (trismus, lockjaw), which contract so that the mouth cannot be opened. Gradually, other voluntary muscles become involved, resulting in tonic spasms. Any external stimulus may precipitate a tetanic generalized muscle spasm. The patient is fully conscious, and pain may be intense. Death usually results from interference with the mechanics of respiration. The mortality rate in generalized tetanus is very high.

Diagnosis

The diagnosis rests on the clinical picture and a history of injury, although only 50% of patients with tetanus have an injury for which they seek medical attention. The primary differential diagnosis of tetanus is strychnine poisoning. Anaerobic culture of tissues from contaminated wounds may yield *C. tetani*, but neither preventive nor therapeutic use of antitoxin should ever be withheld pending such demonstration.

Proof of isolation of *C. tetani* must rest on production of toxin and its neutralization by specific antitoxin.

Prevention and Treatment

The results of treatment of tetanus are not satisfactory. Therefore, prevention is all important. Prevention of tetanus depends on (1) active immunization with toxoids, (2) aggressive wound care, (3) prophylactic use of antitoxin, and (4) administration of penicillin.

The intramuscular administration of 250–500 units of human antitoxin (tetanus immune globulin) gives adequate systemic protection (0.01 unit or more per milliliter of serum) for 2–4 weeks. It neutralizes the toxin that has not been fixed to nervous tissue. Active immunization with tetanus toxoid should accompany antitoxin prophylaxis.

Patients who develop symptoms of tetanus should receive muscle relaxants, sedation, and assisted ventilation. Sometimes, they are given very large doses of antitoxin (3000–10,000 units of tetanus immune globulin) intravenously in an effort to neutralize toxin that has not yet been bound to nervous tissue. However, the efficacy of antitoxin for treatment is doubtful except in neonatal tetanus, in which it may be lifesaving.

Surgical debridement is vitally important because it removes the necrotic tissue that is essential for proliferation of the organisms. Hyperbaric oxygen has no proven effect.

Penicillin strongly inhibits the growth of *C. tetani* and stops further toxin production. Antibiotics may also control associated pyogenic infection.

When a previously immunized individual sustains a potentially dangerous wound, an additional dose of toxoid should be injected to restimulate antitoxin production. This “recall” injection of toxoid may be accompanied by a dose of antitoxin if the patient has not had current immunization or boosters or if the history of immunization is unknown.

Control

Tetanus is a totally preventable disease. Universal active immunization with tetanus toxoid should be mandatory. Tetanus toxoid is produced by detoxifying the toxin with formalin and then concentrating it. Aluminum salt-adsorbed toxoids are used. Three injections comprise the initial course of immunization followed by another dose about 1 year later. Initial immunization should be carried out in all children during the first year of life. A “booster” injection of toxoid is given upon entry into school. Thereafter, “boosters” can be spaced 10 years apart to maintain serum levels of more than 0.01 unit antitoxin per milliliter. In young children, tetanus toxoid is often combined with diphtheria toxoid and acellular pertussis vaccine.

Environmental control measures are not possible because of the wide dissemination of the organism in the soil and the long survival of its spores.

CLOSTRIDIA THAT PRODUCE INVASIVE INFECTIONS

Many different toxin-producing clostridia (*C. perfringens* and related clostridia) (Figure 11-3) can produce invasive infection (including **myonecrosis** and **gas gangrene**) if introduced into damaged tissue. About 30 species of clostridia may produce such an effect, but the most common in invasive disease is *C. perfringens* (90%). An enterotoxin of *C. perfringens* is a common cause of food poisoning.

Toxins

The invasive clostridia produce a large variety of toxins and enzymes that result in a spreading infection. Many of these toxins have lethal, necrotizing, and hemolytic properties. In some cases, these are different properties of a single substance; in other instances, they are attributable to different chemical entities. The alpha toxin of *C. perfringens* type A is a lecithinase, and its lethal action is proportionate to the rate at which it splits lecithin (an important constituent of cell membranes) to phosphorylcholine and diglyceride. Alpha toxin also aggregates platelets, thereby leading to formation of thrombi in small blood vessels and adding to poor tissue perfusion and extending the consequences of anaerobiosis, namely, destruction of viable tissue (gas gangrene). The theta toxin has similar hemolytic and necrotizing effects but is not a lecithinase. It is a member of the cholesterol-dependent cytolysins that act by forming pores in cell membranes. Epsilon toxin is a protein that causes edema, and hemorrhage is very potent. DNase and hyaluronidase, a collagenase that

FIGURE 11-3 Gas gangrene bacilli. *C. perfringens* typically does not form spores when grown on laboratory media.

digests collagen of subcutaneous tissue and muscle, are also produced.

Some strains of *C. perfringens* produce a powerful enterotoxin (*C. perfringens* enterotoxin, CPE), especially when grown in meat dishes. When more than 10^8 vegetative cells are ingested and sporulate in the gut, CPE is formed. CPE is a protein (35 kDa) that may be a nonessential component of the spore coat; it is distinct from other clostridial toxins. It induces intense diarrhea in 7–30 hours. The action of *C. perfringens* enterotoxin involves marked hypersecretion in the jejunum and ileum, with loss of fluids and electrolytes in diarrhea. Much less frequent symptoms include nausea, vomiting, and fever. This illness is similar to that produced by *B. cereus* and tends to be self-limited. Enterotoxin-producing strains of *C. perfringens* may also play a role in antibiotic-associated diarrhea and necrotizing enterocolitis in infants.

Pathogenesis

In invasive clostridial infections, spores reach tissue either by contamination of traumatized areas (soil, feces) or from the intestinal tract. The spores germinate at low oxidation–reduction potential; vegetative cells multiply, ferment carbohydrates present in tissue, and produce gas. The distention of tissue and interference with blood supply, together with the secretion of necrotizing toxins and hyaluronidase, favor the spread of infection. Tissue necrosis extends, providing an opportunity for increased bacterial growth, hemolytic anemia, and, ultimately, severe toxemia and death.

In gas gangrene (clostridial myonecrosis), a mixed infection is the rule. In addition to the toxigenic clostridia, proteolytic clostridia and various cocci and Gram-negative organisms are also usually present. *C. perfringens* occurs in the genital tracts of 5% of women. Before legalization of abortion in the United States, clostridial uterine infections followed instrumented abortions. *C. sordellii* has many of the properties of *C. perfringens*. *C. sordellii* has been reported to cause a toxic shock syndrome after medical abortion with mifepristone and intravaginal misoprostol. Endometrial infection with *C. sordellii* is implicated. Clostridial bacteremia, especially that caused by *C. septicum*, is a frequent occurrence in patients with neoplasms. In New Guinea, *C. perfringens* type C produces necrotizing enteritis (pigbel) that can be highly fatal in children. Immunization with type C toxoid appears to have preventive value.

Clinical Findings

From a contaminated wound (eg, a compound fracture, postpartum uterus), the infection spreads in 1–3 days to produce crepitation in the subcutaneous tissue and muscle, foul-smelling discharge, rapidly progressing necrosis, fever, hemolysis, toxemia, shock, and death. Treatment is with early surgery (amputation) and antibiotic administration. Until

the advent of specific therapy, early amputation was the only treatment. At times, the infection results only in anaerobic fasciitis or cellulitis.

C. perfringens food poisoning usually follows the ingestion of large numbers of clostridia that have grown in warmed meat dishes. The toxin forms when the organisms sporulate in the gut, with the onset of diarrhea—usually without vomiting or fever—in 7–30 hours. The illness lasts only 1–2 days.

Diagnostic Laboratory Tests

Specimens consist of material from wounds, pus, and tissue. The presence of large Gram-positive rods in Gram-stained smears suggests gas gangrene clostridia; spores are not regularly present.

Material is inoculated into chopped meat–glucose medium and thioglycolate medium and onto blood agar plates incubated anaerobically. After pure cultures have been obtained by selecting colonies from anaerobically incubated blood plates, they are identified by biochemical reactions (various sugars in thioglycolate, action on milk), hemolysis, and colony morphology. Lecithinase activity is evaluated by the precipitate formed around colonies on egg yolk media. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) is a rapid and sensitive method for identification of invasive *Clostridium* species recovered in culture. *C. perfringens* rarely produces spores when cultured on agar in the laboratory.

Treatment

The most important aspect of treatment is prompt and extensive surgical debridement of the involved area and excision of all devitalized tissue, in which the organisms are prone to grow. Administration of antimicrobial drugs, particularly penicillin, is begun at the same time. Hyperbaric oxygen may be of help in the medical management of clostridial tissue infections. It is said to “detoxify” patients rapidly.

Antitoxins are available against the toxins of *C. perfringens*, *C. novyi*, *C. histolyticum*, and *C. septicum*, usually in the form of concentrated immune globulins. Polyvalent antitoxin (containing antibodies to several toxins) has been used. Although such antitoxin is sometimes administered to individuals with contaminated wounds containing much devitalized tissue, there is no evidence for its efficacy. Food poisoning caused by *C. perfringens* enterotoxin usually requires only symptomatic care.

Prevention and Control

Early and adequate cleansing of contaminated wounds and surgical debridement, together with the administration of antimicrobial drugs directed against clostridia (eg, penicillin), are the best available preventive measures. Antitoxins should not be relied on. Although toxoids for active

immunization have been prepared, they have not come into practical use.

CLOSTRIDIUM DIFFICILE AND DIARRHEAL DISEASE

Pseudomembranous Colitis

Pseudomembranous colitis is diagnosed by detection of one or both *C. difficile* toxins in stool and by endoscopic observation of pseudomembranes or microabscesses in patients who have diarrhea and have been given antibiotics. Plaques and microabscesses may be localized to one area of the bowel. The diarrhea may be watery or bloody, and the patient frequently has associated abdominal cramps, leukocytosis, and fever. Although many antibiotics have been associated with pseudomembranous colitis, the most common are ampicillin and clindamycin and, more recently, the fluoroquinolones. The disease is treated by discontinuing administration of the offending antibiotic and orally giving metronidazole, vancomycin, or fidaxomicin. Fecal transplantation has become a successful and routine method for recurrent and refractory disease. This usually involves administration of the feces of a healthy related donor by way of colonoscopy or less commonly via a nasogastric tube into the gastrointestinal tract of the patient.

Administration of antibiotics results in proliferation of drug-resistant *C. difficile* that produces two toxins. Toxin A, a potent enterotoxin that also has some cytotoxic activity, binds to the brush border membranes of the gut at receptor sites. Toxin B is a potent cytotoxin. *C. difficile* toxins have glycosyltransferase activity and act by modifying signaling molecules that control various cellular functions. This results in apoptosis, capillary leakage, cytokine stimulation, and other consequences that lead to colitis. Both toxins are usually found in the stools of patients with pseudomembranous colitis. However, toxin A–negative, toxin B–positive infections have been described. Not all strains of *C. difficile* produce the toxins, and the toxin genes are found on a large, chromosomal pathogenicity island along with three other genes that regulate toxin expression.

Diagnosis is made clinically and supported by demonstration of toxin in the stool by a variety of methods that includes anaerobic toxigenic culture, enzyme immunoassay, and molecular tests that detect the genes that encode toxins A or B. See the reference by Burnham for a more complete discussion of *C. difficile* diagnosis.

The surge in *C. difficile* infections since the beginning of the 21st century is believed to be related to a combination of host and organism factors. The responsible host factors include the aging population, the increase in survival of immunocompromised susceptible individuals, and the increase in administration of antibiotics and gastric acid-suppressant agents. Organism factors relate primarily to

emergence of certain strain types that are more virulent due to mutations in the pathogenicity locus.

Antibiotic-Associated Diarrhea

The administration of antibiotics frequently leads to a mild to moderate form of diarrhea, termed **antibiotic-associated diarrhea**. This disease is generally less severe than the classic form of pseudomembranous colitis. As many as 25% of cases of antibiotic-associated diarrhea are caused by *C. difficile* infection. Other *Clostridium* species such as *C. perfringens* and *C. sordellii* have also been implicated. The latter two species are not associated with pseudomembranous colitis.

Concept Checks

- *Clostridium* species are large, spore-forming, anaerobic Gram-positive rods that are found in the environment and in the gastrointestinal tracts of a large number of animals and humans.
- The clostridia are categorized by their ability to ferment carbohydrates and to digest proteins as well as by the toxins they produce.
- Toxins produced by pathogenic clostridia are responsible for a variety of serious diseases that include botulism, tetanus, and gas gangrene.
- *C. botulinum* produces botulinum toxin, one of the most potent neurotoxins on the planet, responsible for botulism, a disease characterized by flaccid paralysis.
- *C. tetani* also produces a neurotoxin, tetanospasmin, that blocks release of inhibitory neurotransmitters resulting in tetanus, a disease characterized by spastic paralysis.
- Other *Clostridium* species cause invasive wound infections (gangrene), septicemia, antibiotic-associated diarrhea, and food poisoning depending on the epidemiologic circumstances and the types of enzymes or toxins elaborated.

REVIEW QUESTIONS

1. A housewife who lives on a small farm is brought to the emergency department complaining of double vision and difficulty talking. Within the past 2 hours, she noted a dry mouth and generalized weakness. Last night she served home-canned green beans as part of the meal. She tasted the beans before they were boiled. None of the other family members are ill. On examination, there is symmetrical descending paralysis of the cranial nerves, upper extremities, and trunk. The correct diagnosis is which one of the following?
 - (A) Tetanus
 - (B) Strychnine poisoning
 - (C) Botulism
 - (D) Morphine overdose
 - (E) Ricin intoxication
2. Which one of the following is an important virulence factor of *Bacillus anthracis*?
 - (A) Protective antigen
 - (B) Lipopolysaccharide
 - (C) Pili
 - (D) A toxin that inhibits peptide chain elongation factor EF-2
 - (E) Lecithinase
3. A young man sustains major soft tissue injury and open fractures of his right leg after a motorcycle accident. One day later, he has a temperature of 38°C, increased heart rate, sweating, and restlessness. On examination, the leg is swollen and tense, with thin, dark serous fluid draining from the wounds. The skin of the leg is cool, pale, white, and shining. Crepitus can be felt in the leg. His hematocrit is 20% (~50% of normal), and his circulating hemoglobin is normal. His serum shows free hemoglobin. Which of the following microorganisms is the most likely cause of this infection?
 - (A) *Clostridium tetani*
 - (B) *Staphylococcus aureus*
 - (C) *Escherichia coli*
 - (D) *Bacillus anthracis*
 - (E) *Clostridium perfringens*
4. For the patient described in Question 3, which of the following is likely to be responsible for the hemolysis?
 - (A) Elongation factor
 - (B) Tetanospasmin
 - (C) Lecithinase
 - (D) Streptolysin O
 - (E) Toxin B
5. The reported incubation period for inhalational anthrax can be up to
 - (A) 2 days
 - (B) 10 days
 - (C) 3 weeks
 - (D) 6 weeks
 - (E) 6 months
6. A food commonly associated with *Bacillus cereus* food poisoning is
 - (A) Fried rice
 - (B) Baked potato
 - (C) Hot freshly steamed rice
 - (D) Green beans
 - (E) Honey
7. Tetanus toxin (tetanospasmin) diffuses to terminals of inhibitory cells in the spinal cord and brainstem and blocks which of the following?
 - (A) Release of acetylcholine
 - (B) Cleavage of SNARE proteins
 - (C) Release of inhibitory glycine and γ -aminobutyric acid
 - (D) Release of protective antigen
 - (E) Activation of acetylcholine esterase
8. A 45-year-old man who immigrated to the United States 5 years ago sustained a puncture injury to the lower part of his right leg when his rotary lawn mower threw a small stick into his leg. Six days later, he noticed spasms in the muscles of his right leg; on day 7, the spasms increased. Today—day 8—he had generalized muscle spasms, particularly noticeable in the muscles of his jaw. He was unable to open his jaw and came to the emergency department (ED). In the ED, you see a man who is alert and lying quietly in bed. A door slams down the hall, and suddenly

he has general muscle spasm with arching of his back. The correct diagnosis is which of the following?

- (A) Botulism
 - (B) Anthrax
 - (C) Gas gangrene
 - (D) Tetanus
 - (E) Toxic shock syndrome
9. Which of the following statements about tetanus and tetanus toxoid is correct?
- (A) Tetanus toxin kills neurons.
 - (B) Tetanus toxoid immunization has a 10% failure rate.
 - (C) The mortality rate of generalized tetanus is less than 1%.
 - (D) Double vision is commonly the first sign of tetanus.
 - (E) Tetanus toxin acts on inhibitor interneuron synapses.
10. A 67-year-old man had surgery for a ruptured sigmoid colon diverticulum with an abscess. A repair was done, and the abscess was drained. He was treated with intravenous gentamicin and ampicillin. Ten days later and 4 days after being discharged from the hospital, the patient developed malaise, fever, and cramping abdominal pain. He had multiple episodes of diarrhea. His stool was positive for occult blood and the presence of polymorphonuclear cells. On sigmoidoscopy, the mucosa was erythematous and appeared to be inflamed, and there were many raised white to yellowish plaques 4–8 mm in diameter. Which of the following is the likely cause of the patient's problem?
- (A) *Staphylococcus aureus* enterotoxin
 - (B) *Bacillus cereus* toxin
 - (C) *Clostridium difficile* toxins
 - (D) *Clostridium perfringens* toxin
 - (E) Enterohemorrhagic *Escherichia coli*
11. Which of the following food items is most frequently associated with infant botulism?
- (A) Corn syrup
 - (B) Canned infant formula
 - (C) Liquid multivitamins
 - (D) Honey
 - (E) Jarred baby food
12. Which of the following statements regarding vaccination for *Bacillus anthracis* is correct?
- (A) It is routinely available for all citizens of the United States.
 - (B) Recombinant vaccine trials have shown good safety and efficacy.
 - (C) The current vaccine is well tolerated.
 - (D) A single dose is adequate after exposure to spores.
 - (E) Vaccination of animals is not useful.

Aerobic Non-Spore-Forming Gram-Positive Bacilli: *Corynebacterium*, *Listeria*, *Erysipelothrix*, *Nocardia*, and Related Pathogens

The non-spore-forming Gram-positive bacilli are a diverse group of aerobic and anaerobic bacteria. This chapter focuses on the aerobic members of this group. The anaerobic, non-spore-forming Gram-positive bacilli such as *Propionibacterium* species and *Actinomyces* species are discussed in Chapter 21 on anaerobic infections. Specific genera of both groups, namely, *Corynebacterium* species and *Propionibacterium* species, are members of the normal microbiota of skin and mucous membranes of humans and, as such, are frequently contaminants of clinical specimens submitted for diagnostic evaluation. However, among the aerobic Gram-positive bacilli are significant pathogens such as *Corynebacterium diphtheriae*, an organism that produces a powerful exotoxin that causes diphtheria in humans, and *Mycobacterium tuberculosis* (see Chapter 23), the causative agent of tuberculosis. *Listeria monocytogenes* and *Erysipelothrix rhusiopathiae* are primarily found in animals and occasionally cause severe disease in humans. *Nocardia* and *Rhodococcus* species are found in the soil and are significant pathogens among immunocompromised patients.

Corynebacterium species and related bacteria tend to be clubbed or irregularly shaped; although not all isolates have the irregular shapes, the terms “coryneforms” or “diphtheroid bacteria” are convenient ones for denoting this broad group. These bacteria have a high guanosine plus cytosine content and include the genera *Corynebacterium*, *Arcanobacterium*, *Mycobacterium*, and others (Table 12-1). *Actinomyces* and *Propionibacterium* are classified as anaerobes, but some isolates grow well aerobically (aerotolerant) and must be differentiated from the aerobic coryneform bacteria. Other non-spore-forming Gram-positive bacilli have more regular shapes and a lower guanosine plus cytosine content. The genera include *Listeria* and *Erysipelothrix*; these bacteria are more closely related to the anaerobic *Lactobacillus* species, which sometimes grow well in air, to the spore-forming *Bacillus* and *Clostridium* species—and to the Gram-positive cocci of the *Staphylococcus* and

Streptococcus genera—than they are to the coryneform bacteria. The medically important genera of aerobic Gram-positive bacilli are listed in Table 12-1. Anaerobic bacteria are discussed in Chapter 21.

There is no unifying method for identification of the Gram-positive bacilli. Few laboratories are equipped to measure guanosine plus cytosine content. Growth only under anaerobic conditions implies that the isolate is an anaerobe, but many isolates of *Lactobacillus*, *Actinomyces*, and *Propionibacterium* species and others are aerotolerant. Most isolates of *Mycobacterium*, *Nocardia*, and *Rhodococcus* species are acid fast and are therefore readily distinguished from the coryneform bacteria. Many, but not all, genera of *Bacillus* and *Clostridium* produce spores, and the presence of spores readily distinguishes the isolate from the coryneform bacteria when present. Determination that an isolate is a *Lactobacillus* (or *Propionibacterium*) may require gas-liquid chromatography to measure lactic acid (or propionic acid) metabolic products, but this is generally not practical. Other tests that are used to help identify an isolate of non-spore-forming Gram-positive bacilli as a member of a genus or species include catalase production, indole production, nitrate reduction, and fermentation of carbohydrates, among others. Many clinical laboratories have developed sequencing technologies targeting the 16S rRNA gene or other gene targets for identification of many of these organisms, but especially for *Mycobacterium* and *Nocardia* species recovered from clinical specimens. A relatively new technology introduced into microbiology laboratories involves the use of matrix-assisted laser desorption/ionization time-of-flight mass spectroscopy (MALDI-TOF MS) that allows for assessment of ribosomal proteins whose spectral patterns are unique enough to identify organisms to the species level. This technology works well for identification of a broad range of bacteria including corynebacteria and anaerobes, although less data are available on more complex bacteria such as *Mycobacterium* species. This technology is discussed in more detail in Chapter 47.

TABLE 12-1 Common Aerobic Gram-Positive Bacilli and Their Disease Associations

Organism	General Characteristics	Disease Associations
<i>Corynebacterium</i> <i>C. diphtheriae</i> <i>C. ulcerans</i> <i>C. pseudotuberculosis</i>	Club-shaped rods that form metachromatic granules; black colonies on tellurite media Grayish white colonies; urease positive Yellowish white colonies; urease positive	Toxigenic strains—diphtheria Nontoxigenic strains—bacteremia, endocarditis Toxigenic strains may cause diphtheria Toxigenic strains may cause diphtheria Hospital-acquired infections, esp. lower respiratory
<i>Arcanobacterium hemolyticum</i>	Catalase negative coccobacilli; β-hemolytic	Pharyngitis; wound infections; septicemia
<i>Listeria monocytogenes</i>	Short, thin, Gram-positive rods; catalase-positive motile, non-spore-forming; exhibit β-hemolysis	Foodborne gastroenteritis in immunocompetent hosts; neonatal sepsis and meningitis; postpartum infections; meningoen­cephalitis, bacteremia, septicemia in immunocompromised patients
<i>Erysipelothrix rhusiopathiae</i>	Appears singly, as short chains or branching filaments; α-hemolytic on blood agar; produces H ₂ S	Erysipeloid; bacteremia; endocarditis
<i>Nocardia</i> <i>N. brevicatena</i> / <i>N. paucivorans</i> complex <i>N. abscessus</i> complex <i>N. nova</i> complex <i>N. transvalensis</i> complex <i>N. farcinica</i> complex <i>N. cyriacigeorgica</i> complex	Thin, branching, and beaded modified acid-fast positive rods	Respiratory infections, wounds, brain abscess
<i>Rhodococcus equi</i>	Coccoid organisms that are modified acid-fast positive; salmon pink smooth colonies	Pneumonia, often with cavity formation in immunocompromised patients

CORYNEBACTERIUM DIPHTHERIAE

Morphology and Identification

Corynebacteria are 0.5–1 μm in diameter and several micrometers long. Characteristically, they possess irregular swellings at one end that give them the “club-shaped” appearance (Figure 12-1). Irregularly distributed within the rod (often near the poles) are granules staining deeply with aniline dyes (metachromatic granules) that give the rod a beaded appearance. Individual corynebacteria in stained smears tend to lie parallel or at acute angles to one another. True branching is rarely observed in cultures.

On blood agar, the *C. diphtheriae* colonies are small, granular, and gray with irregular edges and may have small zones of hemolysis. On agar containing potassium tellurite, the colonies are brown to black with a brown-black halo because the tellurite is reduced intracellularly (staphylococci and streptococci can also produce black colonies). Four biotypes of *C. diphtheriae* have been widely recognized and each of them produces the potent exotoxin: gravis, mitis, intermedius, and belfanti. These variants have been classified on the basis of growth characteristics such as colony morphology, biochemical reactions, and severity of disease produced by infection. Very few reference laboratories are equipped with methods to provide reliable biotype characterization. The incidence of diphtheria has greatly decreased and the association of severity of disease with biovar is no longer important to clinical or public health management of cases or outbreaks. If necessary, in the setting of an outbreak, immunochemical

and preferably molecular methods such as ribotyping can be used to type the *C. diphtheriae* isolates.

C. diphtheriae and other corynebacteria grow aerobically on most ordinary laboratory media. On Löffler’s serum medium, corynebacteria grow much more readily than other

FIGURE 12-1 *Corynebacterium diphtheriae* from Pai medium stained with methylene blue. Typically, they are 0.5–1 × 3–4 μm. Some of the bacteria have clubbed ends (original magnification ×1000).

respiratory organisms, and the morphology of organisms is typical in smears made from these colonies.

Corynebacteria tend to pleomorphism in microscopic and colonial morphology. When some nontoxigenic diphtheria organisms are infected with bacteriophage from certain toxigenic diphtheria bacilli, the offspring of the exposed bacteria are lysogenic and toxigenic, and this trait is subsequently hereditary. When toxigenic diphtheria bacilli are serially subcultured in specific antiserum against the temperate phage that they carry, they tend to become nontoxigenic. Thus, acquisition of phage leads to toxigenicity (lysogenic conversion). The actual production of toxin occurs perhaps only when the prophage of the lysogenic *C. diphtheriae* becomes induced and lyses the cell. Whereas toxigenicity is under the control of the phage gene, invasiveness is under the control of bacterial genes.

Pathogenesis

The principal human pathogen of the genus *Corynebacterium* is *C. diphtheriae*, the causative agent of respiratory or cutaneous diphtheria. In nature, *C. diphtheriae* occurs in the respiratory tract, in wounds, or on the skin of infected persons or normal carriers. It is spread by droplets or by contact to susceptible individuals; the bacilli then grow on mucous membranes or in skin abrasions, and those that are toxigenic start producing toxin.

All toxigenic *C. diphtheriae* are capable of elaborating the same disease-producing exotoxin. In vitro production of this toxin depends largely on the concentration of iron. Toxin production is optimal at 0.14 µg of iron per milliliter of medium but is virtually suppressed at 0.5 µg/mL. Other factors influencing the yield of toxin in vitro are osmotic pressure, amino acid concentration, pH, and availability of suitable carbon and nitrogen sources. The factors that control toxin production in vivo are not well understood.

Diphtheria toxin is a heat-labile, single-chain, three-domain polypeptide (62 kDa) that can be lethal in a dose of 0.1 µg/kg body weight. If disulfide bonds are broken, the molecule can be split into two fragments. Fragment B (38 kDa), which has no independent activity, is functionally divided into a receptor domain and a translocation domain. The binding of the receptor domain to host cell membrane proteins CD-9 and heparin-binding epidermal growth factor (HB-EGF) triggers the entry of the toxin into the cell through receptor-mediated endocytosis. Acidification of the translocation domain within a developing endosome leads to creation of a protein channel that facilitates movement of Fragment A into the host cell cytoplasm. Fragment A inhibits polypeptide chain elongation—provided nicotinamide adenine dinucleotide (NAD) is present—by inactivating the elongation factor EF-2. This factor is required for translocation of polypeptidyl-transfer RNA from the acceptor to the donor site on the eukaryotic ribosome. Toxin Fragment A inactivates EF-2 by catalyzing a reaction that yields free nicotinamide plus an inactive adenosine diphosphate-ribose-EF-2 complex (ADP-ribosylation). It is assumed that the abrupt

arrest of protein synthesis is responsible for the necrotizing and neurotoxic effects of diphtheria toxin. An exotoxin with a similar mode of action can be produced by strains of *Pseudomonas aeruginosa*.

Pathology

Diphtheria toxin is absorbed into the mucous membranes and causes destruction of epithelium and a superficial inflammatory response. The necrotic epithelium becomes embedded in exuding fibrin and red and white cells so that a grayish “pseudomembrane” is formed—commonly over the tonsils, pharynx, or larynx. Any attempt to remove the pseudomembrane exposes and tears the capillaries and thus results in bleeding. The regional lymph nodes in the neck enlarge, and there may be marked edema of the entire neck, with distortion of the airway, often referred to as “bull neck” clinically. The diphtheria bacilli within the membrane continue to produce toxin actively. This is absorbed and results in distant toxic damage, particularly parenchymatous degeneration, fatty infiltration, and necrosis in heart muscle (myocarditis), liver, kidneys (tubular necrosis), and adrenal glands, sometimes accompanied by gross hemorrhage. The toxin also produces nerve damage (demyelination), often resulting in paralysis of the soft palate, eye muscles, or extremities.

Wound or skin diphtheria occurs chiefly in the tropics, although cases have also been described in temperate climates among alcoholic, homeless individuals, and other impoverished groups. A membrane may form on an infected wound that fails to heal. However, absorption of toxin is usually slight and the systemic effects negligible. The small amount of toxin that is absorbed during skin infection promotes development of antitoxin antibodies. The “virulence” of diphtheria bacilli is attributable to their capacity for establishing infection, growing rapidly, and then quickly elaborating toxin that is effectively absorbed. *C. diphtheriae* does not need to be toxigenic to establish localized infection—in the nasopharynx or skin, for example—but nontoxigenic strains do not yield the localized or systemic toxic effects. *C. diphtheriae* does not typically invade deep tissues and practically never enters the bloodstream. However, notably over the last two decades, reports of invasive infections such as endocarditis and septicemia due to nontoxigenic *C. diphtheriae* have increased.

Clinical Findings

When diphtheritic inflammation begins in the respiratory tract, sore throat and low-grade fever usually develop. Prostration and dyspnea soon follow because of the obstruction caused by the membrane. This obstruction may even cause suffocation if not promptly relieved by intubation or tracheostomy. Irregularities of cardiac rhythm indicate damage to the heart. Later, there may be difficulties with vision, speech, swallowing, or movement of the arms or legs. All of these manifestations tend to subside spontaneously.

In general, var *gravis* tends to produce more severe disease than var *mitis*, but similar illness can be produced by all types.

Diagnostic Laboratory Tests

These serve to confirm the clinical impression and are of epidemiologic significance. **Note:** Specific treatment must never be delayed for laboratory reports if the clinical picture is strongly suggestive of diphtheria. Physicians should notify the clinical laboratory before collecting or submitting samples for culture.

Dacron swabs from the nose, throat, or other suspected lesions must be obtained before antimicrobial drugs are administered. Swabs should be collected from beneath any visible membrane. The swab should then be placed in semi-solid transport media such as Amies. Smears stained with alkaline methylene blue or Gram-stain show beaded rods in typical arrangement.

Specimens should be inoculated to a blood agar plate (to rule out hemolytic streptococci) and a selective medium such as a tellurite plate (eg, cystine-tellurite blood agar [CTBA] or modified Tinsdale's medium) and incubated at 37°C in 5% CO₂. Plates should be examined in 18–24 hours. In 36–48 hours, the colonies on tellurite medium are sufficiently definite for recognition of *C. diphtheriae*. On cystine tellurite agar, the colonies are black with a brown halo.

A presumptive *C. diphtheriae* isolate should be subjected to testing for toxigenicity. Such tests are performed only in reference public health laboratories. There are several methods, as follows:

1. Modified Elek immunoprecipitation method described by the World Health Organization Diphtheria Reference Unit.

A filter paper disk containing antitoxin (10 IU/disk) is placed on an agar plate. The cultures to be tested (at least 10 colonies should be chosen) for toxigenicity are spot inoculated 7–9 mm away from the disk. After 48 hours of incubation, the antitoxin diffusing from the paper disk has precipitated the toxin diffusing from toxigenic cultures and has resulted in precipitin bands between the disk and the bacterial growth.

2. Polymerase chain reaction (PCR)-based methods have been described for detection of the diphtheria toxin gene (*tox*). PCR assays for *tox* can also be used directly on patient specimens before culture results are available. A positive culture result confirms a positive PCR assay. A negative culture result after antibiotic therapy along with a positive PCR assay result suggests that the patient probably has diphtheria.
3. Enzyme-linked immunosorbent assays can be used to detect diphtheria toxin from clinical *C. diphtheriae* isolates.
4. An immunochromatographic strip assay allows detection of diphtheria toxin in a matter of hours. This assay is highly sensitive.

The latter two assays are not widely available.

Resistance and Immunity

Because diphtheria is principally the result of the action of the toxin formed by the organism rather than invasion by the organism, resistance to the disease depends largely on the availability of specific neutralizing antitoxin in the bloodstream and tissues. It is generally true that diphtheria occurs only in persons who possess no antitoxin antibodies (IgG) (or less than 0.1 IU/mL). Assessment of immunity to diphtheria toxin for individual patients can best be made by review of documented diphtheria toxoid immunizations and primary or booster immunization if needed.

Treatment

The treatment of diphtheria rests largely on rapid suppression of toxin-producing bacteria by antimicrobial drugs and the early administration of specific antitoxin against the toxin formed by the organisms at their site of entry and multiplication. Diphtheria antitoxin is produced in various animals (horses, sheep, goats, and rabbits) by the repeated injection of purified and concentrated toxoid. Treatment with antitoxin is mandatory when there is strong clinical suspicion of diphtheria. From 20,000 to 120,000 units are injected intramuscularly or intravenously depending on the duration of symptoms and severity of illness after suitable precautions have been taken (skin test) to rule out hypersensitivity to the animal serum. The antitoxin should be given intravenously on the day the clinical diagnosis of diphtheria is made and need not be repeated. Intramuscular injection may be used in mild cases. Diphtheria antitoxin will only neutralize circulating toxin that is not bound to tissue.

Antimicrobial drugs (penicillin, macrolides) inhibit the growth of diphtheria bacilli. Although these drugs have virtually no effect on the disease process, they arrest toxin production and assist public health efforts. They also help to eliminate coexistent streptococci and *C. diphtheriae* from the respiratory tracts of patients or carriers. Antimicrobial resistance to these agents is rare.

Epidemiology, Prevention, and Control

Before artificial immunization, diphtheria was mainly a disease of small children. The infection occurred either clinically or subclinically at an early age and resulted in the widespread production of antitoxin in the population. An asymptomatic infection during adolescence and adult life served as a stimulus for maintenance of high antitoxin levels. Thus, most members of the population, except children, were immune.

By age 6–8 years, approximately 75% of children in developing countries where skin infections with *C. diphtheriae* are common have protective serum antitoxin levels. Absorption of small amounts of diphtheria toxin from the skin infection presumably provides the antigenic stimulus for the immune response; the amount of absorbed toxin does not produce disease.

By the late 20th century, most developed countries predicted the elimination of diphtheria as a result of successful childhood vaccination strategies. However, from 1990 to 1998, a resurgence of epidemic diphtheria, primarily among adults, occurred in the Russian Federation and the Newly Independent States (NIS) of the former Soviet Union. This likely resulted from reduced vaccination coverage, among other social factors. Currently, India has the largest total number of reported cases of diphtheria, followed by Indonesia and Madagascar. These outbreaks clearly emphasize the importance of maintaining global immunization.

Active immunization in childhood with diphtheria toxoid yields antitoxin levels that are generally adequate until adulthood. Young adults should be given boosters of toxoid because toxigenic diphtheria bacilli are not sufficiently prevalent in the population of many developed countries to provide the stimulus of subclinical infection with stimulation of resistance. Levels of antitoxin decline with time, and many older persons have insufficient amounts of circulating antitoxin to protect them against diphtheria.

The principal aims of prevention are to limit the distribution of toxigenic diphtheria bacilli in the population and to maintain as high a level of active immunization as possible.

To limit contact with diphtheria bacilli to a minimum, patients with diphtheria should be isolated. Without treatment, a large percentage of infected persons continue to shed diphtheria bacilli for weeks or months after recovery (convalescent carriers). This danger may be greatly reduced by active early treatment with antibiotics.

Diphtheria toxoids are commonly combined with tetanus toxoid (Td) and with acellular pertussis vaccine (DaPT) as a single injection to be used in initial immunization of children (three doses in the first year of life, 15–18 months of age, and 4–6 years of age). For booster injection of adolescents and adults, only Td toxoids or Td toxoids combined with acellular pertussis vaccine (Tdap) (for a one-time injection for those individuals who received whole-cell pertussis vaccine as children) are used; these combine a full dose of tetanus toxoid with a 10-fold smaller dose of diphtheria toxoid to diminish the likelihood of adverse reactions.

All children must receive an initial course of immunizations and boosters. Regular boosters with Td are particularly important for adults who travel to developing countries, where the incidence of clinical diphtheria may be 1000-fold higher than in developed countries, where immunization is universal.

OTHER CORYNEFORM BACTERIA

There are more than 88 valid species in the *Corynebacterium* genus and 53 of these have been recovered from human clinical infections. The coryneform bacteria are classified as nonlipophilic or lipophilic depending on the enhancement of growth by the addition of lipid to the growth medium. The lipophilic corynebacteria grow slowly on sheep blood agar, producing

colonies smaller than 0.5 mm in diameter after 24 hours of incubation. Additional key reactions for the classification of the coryneform bacteria include but are not limited to the following tests: fermentative or oxidative metabolism, catalase production, motility, nitrate reduction, urease production, and esculin hydrolysis. *Corynebacterium* species are typically nonmotile and catalase positive. The coryneform bacteria are normal inhabitants of the mucous membranes of the skin, respiratory tract, urinary tract, and conjunctiva.

C. ulcerans and *C. pseudotuberculosis* are closely related to *C. diphtheriae* and may carry the diphtheria *tox* gene. Whereas the toxigenic *C. ulcerans* can cause disease similar to clinical diphtheria, *C. pseudotuberculosis* rarely causes disease in humans. Recently, sporadic reports of toxigenic *C. ulcerans* carriage in domestic pets raise concern of a potential new reservoir of diphtheria transmission to humans.

Other Coryneform Genera

There are many other genera and species of coryneform bacteria. *Arcanobacterium haemolyticum* produces β -hemolysis on blood agar. It is occasionally associated with pharyngitis in adolescents and adults and can grow in media selective for streptococci. *A. haemolyticum* is catalase negative, similar to group A streptococci, and must be differentiated by Gram-stain morphology (rods vs. cocci) and biochemical characteristics. *A. haemolyticum* has also been associated with wound infections and septicemia. Most of the coryneform bacteria in the other genera are infrequent causes of disease and are not commonly identified in the clinical laboratory.

Concept Checks

- The group of aerobic Gram-positive bacilli incorporates a large number of species that range from normal microbiota to virulent pathogens.
- The genus *Corynebacterium* includes the pathogenic organism *C. diphtheriae*, which causes disease through elaboration of a potent exotoxin, diphtheria toxin that inhibits protein synthesis.
- Diphtheria toxin is encoded on a lysogenic bacteriophage and is responsible for both the local (usually membranous pharyngitis) and systemic manifestations of disease, such as myocarditis and renal failure.
- In developed countries, diphtheria is rare as it is prevented by sustained primary and booster vaccination programs; resurgence in epidemic form has been seen with lapses of primary vaccination.

LISTERIA MONOCYTOGENES

There are several species in the genus *Listeria*. Of these, *L. monocytogenes* is important as a cause of a wide spectrum of disease in animals and in humans. *L. monocytogenes* is capable of growing and surviving over a wide range of environmental

conditions. It can survive at refrigerator temperatures (4°C) under conditions of low-pH and high-salt conditions. Therefore, it is able to overcome food preservation and safety barriers, making it an important foodborne pathogen. Recent data from the Centers for Disease Control and Prevention indicate that outbreaks of foodborne listeriosis may be increasing, from 1998 to 2008, there were an average of 3 outbreaks per year. From 2009 to 2016, the average number of outbreaks increased to 7 per year with a peak of 11 outbreaks in 2014. Most of these outbreaks are associated with dairy products or prepackaged raw produce. These outbreaks emphasize the ubiquitous nature of this organism and its ability to easily contaminate foods during any stage of the food handling process.

Morphology and Identification

L. monocytogenes is a short, Gram-positive, non-spore-forming rod (Figure 12-2). It is catalase positive and has a tumbling end-over-end motility at 22–28°C but not at 37°C; the motility test rapidly differentiates *Listeria* from diphtheroids that are members of the normal microbiota of the skin.

Culture and Growth Characteristics

Listeria grows well on media such as 5% sheep blood agar on which it exhibits the characteristic small zone of hemolysis around and under colonies. The organism is a facultative anaerobe and is catalase positive, esculin hydrolysis positive, and motile. *Listeria* produces acid but not gas from utilization of a variety of carbohydrates.

FIGURE 12-2 Gram-stain of the Gram-positive bacillus *L. monocytogenes* in a blood culture. Original magnification $\times 1000$. Red blood cells are present in the background. *Listeria* organisms isolated from clinical specimens frequently show variation in length and often in shape as well. Typically, they are 0.4–0.5 μm in diameter and 0.5–2 μm long. (Courtesy of H. Tran.)

The motility at room temperature and hemolysin production are primary findings that help differentiate *Listeria* from coryneform bacteria.

Antigenic Classification

Serologic classification is done only in reference laboratories and is primarily used for epidemiologic studies. There are 13 known serovars based on O (somatic) and H (flagellar) antigens. Serotypes 1/2a, 1/2b, and 4b make up more than 95% of the isolates from humans. Serotype 4b causes most of the foodborne outbreaks. Less labor intensive, genomic-based methods have been developed but serotyping remains the gold standard.

Pathogenesis and Immunity

L. monocytogenes enters the body through the gastrointestinal tract after ingestion of contaminated foods such as cheese, fruit, or vegetables. The organism has several adhesin proteins (Ami, Fbp A, and flagellin proteins) that facilitate bacterial binding to the host cells and that contribute to virulence. It has cell wall surface proteins called **internalins A and B** that interact with E-cadherin, a receptor on epithelial cells, promoting phagocytosis into the epithelial cells. After phagocytosis, the bacterium is enclosed in a phagolysosome, where the low pH activates the bacterium to produce listeriolysin O. This enzyme, along with two phospholipases, lyses the membrane of the phagolysosome and allows the listeriae to escape into the cytoplasm of the epithelial cell. The organisms proliferate, and ActA, another listerial surface protein, induces host cell actin polymerization, which propels them to the cell membrane. Pushing against the host cell membrane, they cause formation of elongated protrusions called **filopods**. These filopods are ingested by adjacent epithelial cells, macrophages, and hepatocytes, the listeriae are released, and the cycle begins again. *L. monocytogenes* can move from cell to cell without being exposed to antibodies, complement, or polymorphonuclear cells. *Shigella flexneri* and rickettsiae also usurp the host cells' actin and contractile system to spread their infections.

Iron is an important virulence factor. Listeriae produce siderophores and are able to obtain iron from transferrin.

Immunity to *L. monocytogenes* is primarily cell mediated, as demonstrated by the intracellular location of infection and by the marked association of infection with conditions of impaired cell-mediated immunity such as pregnancy, advanced age, AIDS, lymphoma, and organ transplantation. Immunity can be transferred by sensitized lymphocytes but not by antibodies.

Clinical Findings

There are two forms of perinatal human listeriosis. Early-onset syndrome (**granulomatosis infantiseptica**) is the result of infection in utero and is a disseminated form of the disease

characterized by neonatal sepsis, pustular lesions, and granulomas containing *L. monocytogenes* in multiple organs. Death may occur before or after delivery. The late-onset syndrome causes the development of meningitis between birth and the third week of life; it is often caused by serotype 4b and has a significant mortality rate.

Healthy persons exposed to *L. monocytogenes* in food may not become ill or may develop a mild, self-limiting febrile gastroenteritis lasting 1–3 days. This develops after an incubation period of 6–48 hours. Symptoms include fever, chills, headache, myalgias, abdominal pain, and diarrhea. Immuno-compromised individuals can develop *Listeria* meningoen- cephalitis, bacteremia, and (rarely) focal infections. *Listeria* is one of the more common causes of meningitis in this group of patients. Clinical presentation of *Listeria* meningitis varies from insidious to fulminate and is nonspecific. Most clinical laboratories do not routinely culture for *Listeria* from rou- tine stool samples. The diagnosis of systemic listeriosis rests on isolation of the organism in cultures of blood and spinal fluid.

Spontaneous infection occurs in many domestic and wild animals. In ruminants (eg, sheep), *Listeria* may cause meningoencephalitis with or without bacteremia. In smaller animals (eg, rabbits, chickens), there is septicemia with focal abscesses in the liver and heart muscle and marked monocytosis.

Many antimicrobial drugs inhibit *Listeria* species in vitro. Clinical cures have been obtained with ampicillin, erythromycin, or intravenous trimethoprim–sulfamethoxa- zole. Cephalosporins and fluoroquinolones are not active against *L. monocytogenes*. Ampicillin plus gentamicin is often recommended for therapy, but gentamicin does not enter host cells and may not help treat the *Listeria* infection. Trimethoprim–sulfamethoxazole is the drug of choice for central nervous system infections in patients who are allergic to penicillin.

ERYSIPELOTHRIX RHUSIOPATHIAE

E. rhusiopathiae is a Gram-positive bacillus that produces small, transparent glistening colonies. It may be α -hemolytic on blood agar. On Gram-stains, it sometimes looks Gram-negative because it decolorizes easily. The bacteria may appear singly, in short chains, randomly, or in long nonbranching filaments. The colony morphology and Gram-stain appear- ance vary depending on the growth medium, incubation temperature, and pH. *Erysipelothrix* is catalase, oxidase, and indole negative. When *Erysipelothrix* is grown on triple sugar iron (TSI) agar, hydrogen sulfide (H_2S) is produced, turning the TSI butt black.

E. rhusiopathiae must be differentiated from *L. mono- cytogenes* and *A. haemolyticum*, but these two species are β -hemolytic and do not produce H_2S when grown on TSI medium. It is more difficult to differentiate *E. rhusiopathiae* from aerotolerant lactobacilli; both may be α -hemolytic.

They are catalase negative and vancomycin resistant (80% of lactobacilli). In addition, some strains of lactobacilli produce H_2S much like *E. rhusiopathiae*.

E. rhusiopathiae is distributed in land and sea animals worldwide, including a variety of vertebrates and inverte- brates. It causes disease in domestic swine, turkeys, ducks, and sheep, but not in fish. The most important impact is in swine, in which it causes erysipelas. In humans, erysipelas is caused by group A β -hemolytic streptococci and is much dif- ferent from erysipelas of swine. People obtain *E. rhusiopathiae* infection by direct inoculation from animals or animal prod- ucts. Persons at greatest risk are fishermen, fish handlers, abattoir workers, butchers, and others who have contact with animal products.

The most common *E. rhusiopathiae* infection in humans is called **erysipeloid**. It usually occurs on the fingers by direct inoculation at the site of a cut or abrasion (and has been called **seal finger** and **whale finger**). After 2–7 days' incubation, pain, which can be severe, and swelling occur. The lesion is raised, well circumscribed, and violaceous in color. Pus is usually not present at the infection site, which helps differen- tiate it from staphylococcal and streptococcal skin infections. Erysipeloid can resolve without treatment after 3–4 weeks or more rapidly with antibiotic treatment. Additional clinical forms of infection (both rare) are a diffuse cutaneous form and bacteremia with or without endocarditis. Septic arthri- tis has also been reported. *Erysipelothrix* is highly susceptible to penicillin G, the drug of choice for severe infections. The organism is intrinsically resistant to vancomycin.

Concept Checks

- Both *L. monocytogenes* and *E. rhusiopathiae* are widely distributed in nature and can cause significant disease in humans.
- *L. monocytogenes* is usually transmitted by ingestion of contaminated processed foods such as deli meats or from vegetables and fruits.
- After ingestion, the organism engineers its phagocytosis by a variety of cell types, and it is capable of intracellu- lar survival and systemic spread, resulting in bacteremia and meningitis among patients with altered cell-mediated immunity.
- *Erysipelothrix* is usually acquired by direct inoculation from a contaminated source such as a fish scale resulting in erysipeloid, a nodular type of cellulitis.
- *E. rhusiopathiae* is unique among Gram-positive rods in that it produces H_2S on TSI slant.
- *E. rhusiopathiae* is susceptible to penicillin, and *L. monocy- togenes* is susceptible to ampicillin.

RHODOCOCCLUS EQUI

R. equi may appear to be a bacillus after a few hours of incu- bation in broth, but with further incubation, the organisms become coccoid in shape. This species of *Rhodococcus* also

frequently produces pigmented colonies after 24 hours of incubation that range from salmon pink to red. The organisms are generally weakly acid-fast positive when stained by the modified Kinyoun method. *R. equi* occasionally causes infections such as necrotizing pneumonia with cavity formation in immunosuppressed patients with abnormal cell-mediated immunity (eg, HIV patients, transplant patients). *R. equi* is present in soil and in dung of herbivores. The organism is a cause of disease in cattle, sheep, and swine and can cause severe pulmonary and extrapulmonary infections in foals. Other species of the diverse genus *Rhodococcus* are present in the environment but rarely cause disease in humans.

NOCARDIOSIS

The genus *Nocardia* continues to undergo extensive taxonomic reclassification. New species continue to be recognized, and at least 30 species have been implicated as causes of human infections.

The most common species associated with the vast majority of cases of human infections are listed in Table 12-1. Each of these is responsible for a broad range of diseases, and each species or complex has unique drug susceptibility patterns. The pathogenic nocardiae, similar to many nonpathogenic species of *Nocardia*, are found worldwide in soil and in water. Nocardiosis is initiated by inhalation of these bacteria. The usual presentation is as a subacute to chronic pulmonary infection that may disseminate to other organs, usually the brain or the skin. Nocardiae are not transmitted from person to person.

Morphology and Identification

Nocardia species are aerobic and grow on a variety of media. Microscopically in clinical specimens, nocardiae appear as filamentous organisms with hyphae-like branching. On standard laboratory media, after incubation at 35–37°C for several days, they develop heaped, irregular, waxy colonies. Strains vary in their pigmentation from white to orange to red. These bacteria are Gram-positive and catalase positive, and they produce urease. Nocardiae form extensive branching substrates and aerial filaments that fragment, breaking into coccobacillary cells. The cell walls contain mycolic acids that are shorter chained than those of *Mycobacteria*. They are considered to be weakly acid fast, that is, they stain with the routine acid-fast reagent (carbol-fuchsin) and retain this dye when decolorized with 1–4% sulfuric acid instead of the stronger acid-alcohol decolorant. The species of *Nocardia* are identified primarily by molecular methods such as 16S rRNA gene sequencing and restriction fragment length polymorphism (RFLP) analysis of amplified gene fragments such as *hsp* or *secA*.

Pathogenesis and Clinical Findings

In most cases, nocardiosis is an opportunistic infection associated with several risk factors, most of which impair

the cell-mediated immune responses, including corticosteroid treatment, immunosuppression, organ transplantation, AIDS, and alcoholism. Pulmonary nocardiosis is the main clinical presentation since inhalation is the primary route of bacterial exposure. A variety of symptoms may occur, including fever, night sweats, weight loss, chest pain, cough with or without sputum production, and shortness of breath. The clinical manifestations are not distinctive and mimic tuberculosis and other infections. Likewise, chest radiographs may show focal infiltrates, multifocal nodules, and even cavity formation. Pulmonary consolidations may develop, but granuloma formation and caseation are rare. The usual pathologic process is abscess formation (neutrophilic inflammation). Hematogenous spread from the lung often involves the central nervous system, where abscesses develop in the brain, leading to a variety of clinical presentations. Some patients have subclinical lung involvement and present with brain lesions. Dissemination may also occur to the skin, kidney, eye, or elsewhere.

Nocardia brasiliensis is associated with most primary cutaneous infections that usually result from trauma. These infections rarely disseminate.

Diagnostic Laboratory Tests

Specimens consist of sputum, pus, spinal fluid, and biopsy material. Gram-stained smears reveal Gram-positive bacilli, coccobacillary cells, and branching filaments. With the modified acid-fast stain, most isolates will be acid fast. *Nocardia* species grow on most laboratory media. Serologic tests are not useful. Molecular methods are required for species-level identification, which is necessary for both epidemiologic and treatment purposes.

Treatment

The treatment of choice is trimethoprim–sulfamethoxazole. If patients fail to respond, a number of other antibiotics have been used with success, such as amikacin, imipenem, meropenem, fluoroquinolones, minocycline, linezolid, and cefotaxime. However, because the susceptibility patterns vary by species, susceptibility testing should be performed to guide treatment approaches. In addition to often prolonged antimicrobial treatment, surgical drainage or resection may be required.

Concept Checks

- *Nocardia* and *R. equi* are modified acid-fast positive.
- *Nocardia* species are branching, beaded Gram-positive rods found in soil and other environmental sources that cause systemic disease primarily in immunocompromised patients.
- *Nocardia* species are best identified after recovery on routine media by using molecular methods such as 16SrRNA gene or other gene target sequencing.

- Trimethoprim–sulfamethoxazole is the drug of choice for treatment of *Nocardia* infections. The use of other agents should be dictated by results of susceptibility testing.

REVIEW QUESTIONS

- Three months ago, a 53-year-old woman had surgery and chemotherapy for breast cancer. Four weeks ago, she developed a cough occasionally productive of purulent sputum. About 2 weeks ago, she noted a slight but progressive weakness of her left arm and leg. On chest examination, rales were heard over the left upper back when the patient breathed deeply. Neurologic examination confirmed weakness of the left arm and leg. Chest radiography showed a left upper lobe infiltrate. Contrast-enhanced computed tomography showed two lesions in the right hemisphere. Gram-stain of a purulent sputum specimen showed branching Gram-positive rods that were partially acid fast. Which of the following organisms is the cause of this patient's current illness?
 - Actinomyces israelii*
 - Corynebacterium ulcerans*
 - Aspergillus fumigatus*
 - Nocardia* species
 - Erysipelothrix rhusiopathiae*
- The drug of choice to treat this patient's infection (Question 1) is
 - Penicillin G
 - Trimethoprim–sulfamethoxazole
 - Gentamicin
 - Amphotericin B
 - A third-generation cephalosporin
- Movement of *Listeria monocytogenes* inside of host cells is caused by
 - Inducing host cell actin polymerization
 - The formation of pili (fimbriae) on the listeriae surface
 - Pseudopod formation
 - The motion of listeriae flagella
 - Tumbling motility
- An 8-year-old boy, who recently arrived in the United States, develops a severe sore throat. On examination, a grayish exudate (pseudomembrane) is seen over the tonsils and pharynx. The differential diagnosis of severe pharyngitis such as this includes group A streptococcal infection, Epstein-Barr virus (EBV) infection, *Neisseria gonorrhoeae* pharyngitis, and diphtheria. The cause of the boy's pharyngitis is most likely:
 - A Gram-negative bacillus
 - A single-stranded positive-sense RNA virus
 - A catalase-positive, Gram-positive coccus that grows in clusters
 - A club-shaped Gram-positive bacillus
 - A double-stranded RNA virus
- The primary mechanism in the pathogenesis of the boy's disease (Question 4) is
 - A net increase in intracellular cyclic adenosine monophosphate
 - Action of pyrogenic exotoxin (a superantigen)
 - Inactivation of acetylcholine esterase
 - Action of enterotoxin A
 - Inactivation of elongation factor 2
- Which of the following aerobic Gram-positive bacilli is modified acid-fast positive?
 - Nocardia brasiliensis*
 - Lactobacillus acidophilus*
 - Erysipelothrix rhusiopathiae*
 - Listeria monocytogenes*
- Skin diphtheria as occurs in children in tropical areas typically
 - Does not occur in children who have been immunized with diphtheria toxoid
 - Is clinically distinct from skin infections (pyoderma, impetigo) caused by *Streptococcus pyogenes* and *Staphylococcus aureus*
 - Is also common in northern latitudes
 - Results in protective antitoxin levels in most children by the time they are 6–8 years old
 - Yields toxin-mediated cardiomyopathy
- A 45-year-old fisherman imbedded a fishhook into his right forefinger. He removed it and did not seek immediate medical therapy. Five days later, he noted fever, severe pain, and nodular-type swelling of the finger. He sought medical therapy. The violaceous nodule was aspirated, and after 48 hours of incubation, colonies of a Gram-positive bacillus that caused greenish discoloration of the agar and formed long filaments in the broth culture were noted. The most likely cause of this infection is
 - Lactobacillus acidophilus*
 - Erysipelothrix rhusiopathiae*
 - Listeria monocytogenes*
 - Rhodococcus equi*
 - Nocardia brasiliensis*
- A biochemical reaction that is useful in the identification of the causative agent of the infection in Question 8 is
 - Catalase positivity
 - Acid fastness using modified Kinyoun stain
 - Esculin hydrolysis
 - Tumbling motility
 - Production of H_2S
- Listeria monocytogenes* is frequently a foodborne pathogen because
 - It can survive at 4°C.
 - It survives under conditions of low pH.
 - It survives in the presence of high-salt concentrations.
 - All of the above are correct.
- Which of the following statements regarding *Rhodococcus equi* is correct?
 - It is transmitted person to person.
 - It causes tuberculosis in cattle.
 - It is a rare cause of pulmonary infection in humans.
 - It produces a black pigment on sheep blood agar.

The Staphylococci

The staphylococci are Gram-positive spherical cells, usually arranged in grapelike irregular clusters. They grow readily on many types of media and are active metabolically, fermenting carbohydrates and producing pigments that vary from white to deep yellow. Some are members of the normal microbiota of the skin and mucous membranes of humans; others cause suppuration, abscess formation, a variety of pyogenic infections, and even fatal septicemia. The pathogenic staphylococci often hemolyze blood, coagulate plasma, and produce a variety of extracellular enzymes and toxins. The most common type of food poisoning is caused by a heat-stable staphylococcal enterotoxin. Staphylococci rapidly develop resistance to many antimicrobial agents, which consequently presents difficult therapeutic problems.

The genus *Staphylococcus* has at least 45 species. The four most frequently encountered species of clinical importance are *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Staphylococcus lugdunensis*, and *Staphylococcus saprophyticus*. *S. aureus* is **coagulase positive**, which differentiates it from the other species. *S. aureus* is a major pathogen for humans. Almost every person will have some type of *S. aureus* infection during a lifetime, ranging in severity from food poisoning or minor skin infections to severe life-threatening infections. The **coagulase-negative** staphylococci (CoNS) are normal human microbiota and sometimes cause infection, often associated with implanted devices, such as joint prostheses, shunts, and intravascular catheters, especially in very young, old, and immunocompromised patients. Approximately 75% of these infections caused by CoNS are caused by *S. epidermidis*; infections caused by *S. lugdunensis*, *Staphylococcus warneri*, *Staphylococcus hominis*, and other species are less common. *S. saprophyticus* is a relatively common cause of urinary tract infections in young women, although it rarely causes infections in hospitalized patients. Other species are important in veterinary medicine.

Morphology and Identification

A. Typical Organisms

Staphylococci are spherical cells about 1 μm in diameter arranged in irregular clusters (Figure 13-1). Single cocci,

pairs, tetrads, and chains are also seen in liquid cultures. Young cocci stain strongly Gram-positive; on aging, many cells become Gram-negative. Staphylococci are nonmotile and do not form spores. Under the influence of drugs such as penicillin, staphylococci are lysed.

Micrococcus species often resemble staphylococci. They are found free living in the environment and form regular packets of four (tetrads) or eight cocci. Their colonies can be yellow, red, or orange. Micrococci are rarely associated with disease.

B. Culture

Staphylococci grow readily on most bacteriologic media under aerobic or microaerophilic conditions. They grow most rapidly at 37°C but form pigment best at room temperature (20–25°C). Colonies on solid media are round, smooth, raised, and glistening (Figure 13-2). *S. aureus* usually forms gray to deep golden yellow colonies. *S. epidermidis* colonies usually are gray to white on primary isolation; many colonies develop pigment only upon prolonged incubation. No pigment is produced anaerobically or in broth. Various degrees of hemolysis are produced by *S. aureus* and occasionally by other species. *Peptostreptococcus* and *Peptoniphilus* species, which are anaerobic cocci, often resemble staphylococci in morphology. The genus *Staphylococcus* contains two species, *Staphylococcus saccharolyticus* and *S. aureus* subsp. *anaerobius*, which initially grow only under anaerobic conditions but become more aerotolerant on subcultures. This may be seen on rare occasions with some strains of *S. epidermidis* as well.

C. Growth Characteristics

The staphylococci produce catalase, which differentiates them from the streptococci. Staphylococci slowly ferment many carbohydrates, producing lactic acid but not gas. Proteolytic activity varies greatly from one strain to another. Pathogenic staphylococci produce many extracellular substances, which are discussed below.

Staphylococci are relatively resistant to drying, heat (they withstand 50°C for 30 minutes), and 10% sodium chloride but are readily inhibited by certain chemicals (eg, 3% hexachlorophene).

FIGURE 13-1 Gram-stain of *Staphylococcus aureus* showing Gram-positive cocci in pairs, tetrads, and clusters. Original magnification $\times 1000$. (Courtesy of L. Ching.)

Staphylococci are variably susceptible to many antimicrobial drugs. Resistance is caused by several mechanisms:

1. β -Lactamase production is common, is under plasmid control, and makes the organisms resistant to many penicillins (penicillin G, ampicillin, piperacillin, and similar

FIGURE 13-2 Colonies of *Staphylococcus aureus* on a blood agar plate after 24 hours incubation. The yellow-gray colonies are 3–4 mm in diameter on the 10-cm plate. The colonies are surrounded by clear zones of hemolysis about 1 cm in diameter. (Courtesy of H. Reyes.)

drugs). The plasmids are transmitted by transduction and perhaps also by conjugation.

2. Resistance to nafcillin (and to methicillin and oxacillin) is independent of β -lactamase production. Resistance to nafcillin is encoded and regulated by a sequence of genes found in a region of the chromosome called the staphylococcal cassette chromosome *mec* (*SCCmec*). Specifically, the *mecA* and *mecC* genes on this locus encode a low-affinity penicillin-binding protein (PBP2a) that is responsible for the resistance. There are 12 different *SCCmec* types. Types I, II, III, VI, and VIII are associated with hospital-acquired methicillin-resistant *S. aureus* (HA-MRSA) infections and may contain genes that encode resistance to other antimicrobials as well. *SCCmec* type IV has principally been found in CA-MRSA strains that tend to be less resistant, more transmissible, and responsible for outbreaks in the United States and some countries in Europe. Types IX and X are associated with animals (livestock-associated MRSA [LA-MRSA]) of which type IX contains *mecC*. The other types have been limited to various geographic locations around the world.
3. In the United States, *S. aureus* and *S. lugdunensis* are considered to be susceptible to vancomycin if the minimum inhibitory concentration (MIC) is 2 $\mu\text{g/mL}$ or less; of intermediate susceptibility if the MIC is 4–8 $\mu\text{g/mL}$; and resistant if the MIC is 16 $\mu\text{g/mL}$ or greater. Strains of *S. aureus* with intermediate susceptibility to vancomycin have been isolated in Japan, the United States, and several other countries. These are often known as vancomycin-intermediate *S. aureus* (VISA). They generally have been isolated from patients with complex infections who have received prolonged vancomycin therapy. Often, there has been vancomycin treatment failure. The mechanism of resistance is associated with increased cell wall synthesis and alterations in the cell wall and is not caused by the *van* genes found in enterococci. *S. aureus* strains of intermediate susceptibility to vancomycin usually are nafcillin resistant but generally are susceptible to oxazolidinones and to quinupristin-dalfopristin.
4. Since 2002, several isolates of vancomycin-resistant *S. aureus* (VRSA) strains (MICs $\geq 16 \mu\text{g/mL}$) have been isolated from patients in the United States. The isolates contained the vancomycin resistance gene *vanA* likely derived from enterococci (see Chapter 14) and the nafcillin resistance gene *mecA* (see above). Both of the initial VRSA strains were susceptible to other antibiotics. Vancomycin resistance in *S. aureus* is of major concern worldwide.
5. Plasmid-mediated resistance to tetracyclines, erythromycins, aminoglycosides, and other drugs is frequent in staphylococci.
6. “Tolerance” implies that staphylococci are inhibited by a drug but not killed by it; that is, there is great difference between minimal inhibitory and minimal lethal concentrations of an antimicrobial drug. Patients with endocarditis caused by a tolerant *S. aureus* may have a prolonged clinical course compared with patients who

have endocarditis caused by a fully susceptible *S. aureus*. Tolerance can at times be attributed to lack of activation of autolytic enzymes in the cell wall.

D. Variation

A culture of staphylococci contains some bacteria that differ from the bulk of the population in expression of colony characteristics (colony size, pigment, hemolysis), in enzyme elaboration, in drug resistance, and in pathogenicity. In vitro, the expression of such characteristics is influenced by growth conditions. When nafcillin-resistant *S. aureus* is incubated at 37°C on blood agar, one in 10⁷ organisms expresses nafcillin resistance; when it is incubated at 30°C on agar containing 2–5% sodium chloride, one in 10³ organisms expresses nafcillin resistance. Some isolates may develop alterations in phenotypes such as smaller size (pin point colonies) and loss of hemolysis. These are referred to as small colony variants (SCVs) and the variations in phenotypic characteristics enable better survival under intracellular conditions, facilitating persistence and leading to chronic infections.

Antigenic Structure

S. aureus has amazing adaptive capacity. Full genome sequencing of numerous isolates (www.ncbi.nlm.nih.gov/genome/genomes/154) has elucidated the evolution of various structures, toxins, and enzymes that this organism has developed over time. *S. aureus* has acquired many mobile genetic elements (eg, insertion sequences, transposons, etc) that determine both pathogenicity and antimicrobial resistance (see Regulation of Virulence Determinants).

Staphylococci contain antigenic polysaccharides and proteins as well as other substances important in cell wall structure. Peptidoglycan, a thick polysaccharide polymer containing linked subunits, provides the rigid exoskeleton of the cell wall and anchors the adhesins (see below). Peptidoglycan is destroyed by strong acid or exposure to lysozyme. It is important in the pathogenesis of infection: It elicits production of interleukin-1 (endogenous pyrogen) and opsonic antibodies by monocytes, and it can be a chemoattractant for polymorphonuclear leukocytes, have endotoxin-like activity, and activate complement. Peptidoglycan assembly is a target of β -lactam and glycopeptide antimicrobial agents.

Teichoic acids, which are polymers of polyribitol-phosphate, are cross-linked to the peptidoglycan and can be antigenic. They are important in cell wall metabolism. Antiteichoic acid antibodies detectable by gel diffusion may be found in patients with active endocarditis caused by *S. aureus*.

Protein A is a cell wall component of *S. aureus* strains and is a bacterial surface protein that has been characterized among a group of adhesins called *microbial surface components recognizing adhesive matrix molecules* (MSCRAMMs). Bacterial attachment to host cells is mediated by MSCRAMMs, and these are important virulence factors. Protein A binds to the Fc portion of IgG molecules

except IgG3. The Fab portion of the IgG bound to protein A is free to combine with a specific antigen. Protein A has become an important reagent in immunology and diagnostic laboratory technology; for example, protein A with attached IgG molecules directed against a specific bacterial antigen agglutinates bacteria that have that antigen (“coagglutination”). Another important MSCRAMM is clumping factor on the cell wall surface; clumping factor binds nonenzymatically to fibrinogen and platelets, yielding aggregation of the bacteria. The remaining MSCRAMMs, too numerous to mention here (see references), play important roles in establishing *S. aureus* colonization and invasion in major infections such as endocarditis.

Most *S. aureus* strains of clinical importance have polysaccharide capsules, which inhibit phagocytosis by polymorphonuclear leukocytes unless specific antibodies are present. At least 11 serotypes have been identified, with types 5 and 8 responsible for the majority of infections. These capsule types are targets for a conjugate vaccine. Serologic tests have limited usefulness in identifying staphylococci.

Enzymes and Toxins

Staphylococci can produce disease both through their ability to multiply and spread widely in tissues and through their production of many extracellular substances. Some of these substances are enzymes; others are considered to be toxins, although they may function as enzymes. Many of the toxins are under the genetic control of plasmids; some may be under both chromosomal and extrachromosomal control; and for others, the mechanism of genetic control is not well defined.

A. Catalase

Staphylococci produce catalase, which converts hydrogen peroxide into water and oxygen. The catalase test differentiates the staphylococci, which are positive, from the streptococci, which are negative.

B. Coagulase and Clumping Factor

S. aureus produces an extracellular coagulase, an enzyme-like protein that clots oxalated or citrated plasma. Coagulase binds to prothrombin; together they become enzymatically active and initiate fibrin polymerization. Coagulase may deposit fibrin on the surface of staphylococci, perhaps altering their ingestion by phagocytic cells or their destruction within such cells. Coagulase production is considered synonymous with invasive pathogenic potential.

Clumping factor is cell wall bound and is another example of an MSCRAMM (see earlier) that is responsible for adherence of the organisms to fibrinogen and fibrin. When mixed with plasma, *S. aureus* forms clumps. Clumping factor is distinct from coagulase. Because clumping factor induces a strong immunogenic response in the host, it has been the focus of vaccine efforts. However, no human vaccines against this factor are available to date.

C. Other Enzymes

Other enzymes produced by staphylococci include a hyaluronidase, or spreading factor—a staphylokinase resulting in fibrinolysis but acting much more slowly than streptokinase, proteinases, lipases, and β -lactamase.

D. Hemolysins

S. aureus possesses four hemolysins that are regulated by *agr* (see Regulation of Virulence Determinants). α -Hemolysin is a heterogeneous protein that acts on a broad spectrum of eukaryotic cell membranes. The β -toxin degrades sphingomyelin and therefore is toxic for many kinds of cells, including human red blood cells. The δ -toxin is heterogeneous and dissociates into subunits in nonionic detergents. It disrupts biologic membranes and may have a role in *S. aureus* diarrheal diseases. The γ -hemolysin is a leukocidin that lyses white blood cells and is composed of two proteins designated S and F. γ -Hemolysin can interact with the two proteins comprising the Panton–Valentine leukocidin (PVL; see later discussion) to form six potential two-component toxins. All six of these protein toxins are capable of efficiently lysing white blood cells by causing pore formation in the cellular membranes that increase cation permeability. This leads to massive release of inflammatory mediators such as IL-8, leukotriene, and histamine, which are responsible for necrosis and severe inflammation.

E. Panton–Valentine Leukocidin

This toxin of *S. aureus* has two components, and unlike the chromosomally encoded hemolysins above, PVL is encoded on a mobile phage. It can kill white blood cells of humans and rabbits. The two components designated as S and F act synergistically on the white blood cell membrane as described for γ -toxin. This toxin is an important virulence factor in CA-MRSA infections.

F. Exfoliative Toxins

These epidermolytic toxins of *S. aureus* are two distinct proteins of the same molecular weight. Exfoliative toxin A is encoded by *eta* located on a phage and is heat stable (resists boiling for 20 minutes). Exfoliative toxin B is plasmid mediated and heat labile. These epidermolytic toxins yield the generalized desquamation of the staphylococcal scalded skin syndrome by dissolving the mucopolysaccharide matrix of the epidermis. The toxins are **superantigens** (see Chapter 8).

G. Toxic Shock Syndrome Toxin

Most *S. aureus* strains isolated from patients with toxic shock syndrome produce a toxin called **toxic shock syndrome toxin-1** (TSST-1), which is the same as enterotoxin F. TSST-1 is the prototypical **superantigen** (see Chapter 9). TSST-1 binds to major histocompatibility class (MHC) class II molecules, yielding T-cell stimulation, which promotes the protean manifestations of the toxic shock syndrome. The toxin

is associated with fever, shock, and multisystem involvement, including a desquamative skin rash. The gene for TSST-1 is found in about 20% of *S. aureus* isolates, including MRSA.

H. Enterotoxins

There are 15 enterotoxins (A–E, G–P) that, similar to TSST-1, are superantigens. Approximately 50% of *S. aureus* strains can produce one or more of them. The enterotoxins are heat stable and resistant to the action of gut enzymes. Important causes of food poisoning, enterotoxins are produced when *S. aureus* grows in carbohydrate and protein foods. Ingestion of 25 μ g of enterotoxin B results in vomiting and diarrhea. The emetic effect of enterotoxin is probably the result of central nervous system stimulation (vomiting center) after the toxin acts on neural receptors in the gut.

The exfoliative toxins, TSST-1, and the enterotoxin genes are on a chromosomal element called a *pathogenicity island*. It interacts with accessory genetic elements—bacteriophages—to produce the toxins.

Pathogenesis

Staphylococci, particularly *S. epidermidis*, are members of the normal microbiota of the human skin and respiratory and gastrointestinal tracts. Nasal carriage of *S. aureus* occurs in 20–50% of humans. Staphylococci are also found regularly on clothing, bed linens, and other fomites in human environments.

The pathogenic capacity of a given strain of *S. aureus* is the combined effect of extracellular factors and toxins together with the invasive properties of the strain. At one end of the disease spectrum is staphylococcal food poisoning, attributable solely to the ingestion of preformed enterotoxin; at the other end are staphylococcal bacteremia and disseminated abscesses in all organs.

Pathogenic, invasive *S. aureus* produces coagulase and tends to produce a yellow pigment and to be hemolytic. Nonpathogenic, noninvasive staphylococci such as *S. epidermidis* are coagulase negative and tend to be nonhemolytic. Such organisms rarely produce suppuration but may infect orthopedic or cardiovascular prostheses or cause disease in immunosuppressed persons. They may be refractory to treatment because of the formation of biofilms. *S. lugdunensis* has emerged as a virulent organism causing a disease spectrum similar to *S. aureus* with whom it shares phenotypic characteristics such as hemolysis and clumping factor. *S. saprophyticus* is typically nonpigmented, novobiocin resistant, and nonhemolytic; it causes urinary tract infections in young women.

Regulation of Virulence Determinants

The expression of staphylococcal virulence determinants is regulated by several systems that sense and respond to environmental signals. The first of these systems consists of two proteins (two-component systems), an example of which is

accessory gene regulator (*agr*). The other two systems consist of DNA-binding proteins (eg, Sar proteins) and small regulatory RNAs, respectively (eg, RNAIII), the latter of which have become more appreciated as having major roles in regulation of gene expression. Binding of sensors to specific extracellular ligands, or to a receptor, results in a phosphorylation cascade that leads to binding of the regulator to specific DNA sequences. This ultimately leads to activation of transcription-regulating functions. There are several well-described two-component regulatory systems in *S. aureus*. These include *agr*, the best described, *sae RS*, *srrAB*, *arlSR*, and *lytRS*. A summary of how these systems interact is briefly described below.

The *agr* is essential in quorum-sensing control of gene expression. It controls the preferential expression of surface adhesins (protein A, coagulase, and fibronectin-binding protein) and production of exoproteins (toxins such as TSST-1) depending on the growth phase (and hence bacterial density).

At low cell density, the promoter P2 is off, and transcriptions of transmembrane protein, AgrB; peptide precursor, AgrD; transmembrane sensor, AgrC; and transcription regulator, AgrA are at low levels. As cell density increases during stationary growth phase, the AgrC sensor activates the regulator AgrA. AgrA is a DNA-binding protein that activates promoter P2 and promoter P3. Promoter P3 initiates transcription of δ -hemolysin and an effector called RNAIII, which downregulates the expression of surface adhesins and activates secretion of exoproteins at both the transcriptional and translational levels. Agr is also positively controlled by a DNA-binding protein called SarA (encoded by *sar*) and possibly by other regulatory systems.

At least 10 two-component regulatory systems have been shown to affect virulence gene expression and are also involved in metabolic control. Those involved in virulence include *sae*, *S. aureus* exoproteins; *srrAB*, staphylococcal respiratory response; *arlS*, autolysis-related locus sensor; and *lytRS*. *Sae* regulates gene expression at the transcriptional level and is essential for production of α -toxin, β -hemolysins, and coagulase. Its activity is independent from that of *agr*. *SrrAB* is important for regulation of virulence factor expression that is influenced by environmental oxygen. The *arlSR* locus is important to the control of autolysis and decreases the activation of the *agr* locus. The *lytRS* locus is also involved in autolysis. More detailed discussions of the regulation of pathogenesis can be found in the reference by Que and Moreillon.

Pathology

The prototype of a staphylococcal lesion is the furuncle or other localized abscess. Groups of *S. aureus* established in a hair follicle lead to tissue necrosis (dermonecrotic factor). Coagulase is produced and coagulates fibrin around the lesion and within the lymphatics, resulting in formation of a wall that limits the process and is reinforced by the accumulation of inflammatory cells and, later, fibrous tissue.

Within the center of the lesion, liquefaction of the necrotic tissue occurs (enhanced by delayed hypersensitivity), and the abscess “points” in the direction of least resistance. Drainage of the liquid center necrotic tissue is followed by slow filling of the cavity with granulation tissue and eventual healing.

Focal suppuration (abscess) is typical of staphylococcal infection. From any one focus, organisms may spread via the lymphatics and bloodstream to other parts of the body. Suppuration within veins, associated with thrombosis, is a common feature of such dissemination. In osteomyelitis, the primary focus of *S. aureus* growth is typically in a terminal blood vessel of the metaphysis of a long bone, leading to necrosis of bone and chronic suppuration. *S. aureus* may cause pneumonia, meningitis, empyema, endocarditis, or sepsis with suppuration in any organ. Staphylococci of low invasiveness are involved in many skin infections (eg, acne, pyoderma, or impetigo). Anaerobic cocci (*Peptostreptococcus* species) participate in mixed anaerobic infections.

Staphylococci also cause disease through the elaboration of toxins without apparent invasive infection. Bullous exfoliation, the scalded skin syndrome, is caused by the production of exfoliative toxins. Toxic shock syndrome is associated with TSST-1.

Clinical Findings

A localized staphylococcal infection appears as a “pimple,” hair follicle infection, or abscess. There is usually an intense, localized, painful inflammatory reaction that undergoes central suppuration and heals quickly when the pus is drained. The wall of fibrin and cells around the core of the abscess tend to prevent spread of the organisms and should not be broken down by manipulation or trauma.

S. aureus infection can also result from direct contamination of a wound, such as a postoperative staphylococcal wound infection or infection after trauma (chronic osteomyelitis subsequent to an open fracture, meningitis after skull fracture).

If *S. aureus* disseminates and bacteremia ensues, endocarditis, acute hematogenous osteomyelitis, meningitis, or pulmonary infection can result. The clinical presentations resemble those seen with other bloodstream infections. Secondary localization within an organ or system is accompanied by the symptoms and signs of organ dysfunction and intense focal suppuration.

Food poisoning caused by staphylococcal enterotoxin is characterized by a short incubation period (1–8 hours); violent nausea, vomiting, and diarrhea; and rapid convalescence. There is no fever.

Toxic shock syndrome is manifested by an abrupt onset of high fever, vomiting, diarrhea, myalgias, a scarlatiniform rash, and hypotension with cardiac and renal failure in the most severe cases. It often occurs within 5 days after the onset of menses in young women who use high-absorbency tampons, but it also occurs in children and men with staphylococcal wound infections. The syndrome can recur. Toxic shock

syndrome-associated *S. aureus* can be found in the vagina, on tampons, in wounds or other localized infections, or in the throat but virtually never in the bloodstream.

Diagnostic Laboratory Tests

A. Specimens

Surface swab pus or aspirate from an abscess, blood, endonasotracheal aspirate, expectorated sputum, or spinal fluid for culture, depending on the localization of the process, are all appropriate specimens for testing. The anterior nares are frequently swabbed to determine nasal colonization, either by culture or by nucleic acid amplification tests, for epidemiological purposes.

B. Smears

Typical staphylococci appear as Gram-positive cocci in clusters in Gram-stained smears of pus or sputum. It is not possible to distinguish non-aureus (eg, *S. epidermidis*) from the pathogenic *S. aureus* organisms on smears.

C. Culture

Specimens planted on blood agar plates give rise to typical colonies in 18 hours at 37°C, but hemolysis and pigment production may not occur until several days later and are optimal at room temperature. *S. aureus* but not other staphylococci ferment mannitol. Specimens contaminated with a mixed microbiota can be cultured on media containing 7.5% NaCl; the salt inhibits most other normal microbiota, but not *S. aureus*. Mannitol salt agar or commercially available chromogenic media are used to screen for nasal carriers of *S. aureus* and to recover *S. aureus* from respiratory specimens of patients with cystic fibrosis.

D. Catalase Test

This test is used to detect the presence of cytochrome oxidase enzymes. A drop of 3% hydrogen peroxide solution is placed on a slide, and a small amount of the bacterial growth is placed in the solution. The formation of bubbles (the release of oxygen) indicates a positive test result.

E. Coagulase Test

Citrated rabbit (or human) plasma diluted 1:5 is mixed with an equal volume of broth culture or growth from colonies on agar and incubated at 37°C. A tube of plasma mixed with sterile broth is included as a control. If clots form in 1–4 hours, the test result is positive. Rapid latex and agglutination assays are more timely and in some cases more sensitive in the differentiation between *S. aureus* and CoNS. These assays detect protein A and clumping factor, and some have monoclonal antibodies against capsular polysaccharides.

F. Susceptibility Testing

Clinical laboratories adopt methods recommended by the Clinical and Laboratory Standards Institute (CLSI) or

European Committee on Antimicrobial Susceptibility Testing (EUCAST) for the performance of susceptibility testing of staphylococci. Broth microdilution using manual or automated commercial methods, or disk diffusion susceptibility testing should be done routinely on staphylococcal isolates from clinically significant infections. Resistance to penicillin G can be predicted by a positive test result for β -lactamase; approximately 90% of *S. aureus* produce β -lactamase. Resistance to nafcillin (and oxacillin and methicillin) occurs in about 65% of *S. aureus* and approximately 75% of *S. epidermidis* isolates. Nafcillin resistance correlates with the presence of *mecA* or *mecC*, the genes that encode for a penicillin-binding protein (PBP2a) not affected by these drugs. These genes can be detected using the polymerase chain reaction (PCR) or other nucleic acid amplification test. Several Food and Drug Administration (FDA)-cleared systems combine identification and *mecA* resistance marker detection directly from positive blood cultures. The Verigene® assay (Luminex, Inc., Chicago, IL) and the BioFire FilmArray® BCID assay (Biomérieux, Durham, NC) are two examples of such tests. Alternatively, an assay for the *mecA* gene product, PBP2a, is commercially available and is much more rapid than PCR for *mecA* or than testing for resistance using traditional phenotypic methods.

When using disk diffusion to detect nafcillin resistance, the cefoxitin disk test is recommended for testing *S. aureus*, *S. lugdunensis*, and *S. saprophyticus*. Zone sizes less than 22 mm indicate resistance. When using broth microdilution, either oxacillin or cefoxitin may be used to detect oxacillin resistance. If the latter drug is tested, 2% NaCl is added to the media and the test must be incubated for a full 24 hours at 35°C.

An organism that is *mecA* or *mecC* positive or phenotypically is nafcillin, oxacillin, or methicillin resistant is also resistant to all extended spectrum penicillins, carbapenems, and cephalosporins with the exception of ceftaroline, a new cephalosporin with activity against MRSA.

G. Serologic and Typing Tests

Serologic tests for diagnosis of *S. aureus* infections have little practical value.

Antibiotic susceptibility patterns may be helpful in tracing *S. aureus* infections and in determining if multiple *S. epidermidis* isolates from blood cultures represent bacteremia caused by the same strain, seeded by a nidus of infection.

Molecular typing techniques have been used to document the spread of epidemic disease-producing clones of *S. aureus*. Pulsed-field gel electrophoresis and multilocus sequence typing are highly discriminatory. *Spa* typing is less discriminatory but easier to perform.

Treatment

Most persons harbor staphylococci on the skin and in the nose or throat. Even if the skin can be cleared of staphylococci (eg, in eczema), reinfection by droplets will occur

almost immediately. Because pathogenic organisms are commonly spread from one lesion (eg, a furuncle) to other areas of the skin by fingers and clothing, scrupulous local antisepsis is important to control recurrent furunculosis.

Serious multiple skin infections (acne, furunculosis) occur most often in adolescents. Similar skin infections occur in patients receiving prolonged courses of corticosteroids. In acne, lipases of staphylococci and corynebacteria liberate fatty acids from lipids and thus cause tissue irritation. Tetracyclines are used for long-term treatment.

Abscesses and other closed suppurating lesions are treated by drainage, which is essential, and antimicrobial therapy. Many antimicrobial drugs have some effect against staphylococci in vitro. However, it is difficult to eradicate pathogenic staphylococci from infected persons because the organisms rapidly develop resistance to many antimicrobial drugs, and the drugs cannot act in the central necrotic part of a suppurative lesion.

It may also be difficult to eradicate the *S. aureus* nasal carrier state. Some success has been reported with treatment of colonized individuals with intranasal mupirocin. Literature demonstrates success in reducing postsurgical wound infections and prevention of bacteremia when treating identified hospitalized patients with 5 days of mupirocin with or without bathing using chlorhexidine, a topical antiseptic.

Acute hematogenous osteomyelitis responds well to antimicrobial drugs. In chronic and recurrent osteomyelitis, surgical drainage and removal of dead bone are accompanied by long-term administration of appropriate drugs, but eradication of the infecting staphylococci is difficult. Hyperbaric oxygen and the application of vascularized myocutaneous flaps have aided healing in chronic osteomyelitis.

Bacteremia, endocarditis, pneumonia, and other severe infections caused by *S. aureus* require prolonged intravenous therapy with a β -lactamase-resistant penicillin. Vancomycin is often reserved for use with nafcillin-resistant staphylococci. In recent years, an increase in MICs to vancomycin among many MRSA strains recovered from hospitalized patients has led physicians to seek alternative therapies. Alternative agents for the treatment of MRSA bacteremia and endocarditis include newer antimicrobials such as daptomycin, linezolid, and quinupristin-dalfopristin (see Chapter 28). Also, these agents may be bactericidal and offer alternatives when allergies preclude the use of other compounds or the patient's infection appears to be failing clinically. However, the use of these agents should be discussed with infectious diseases physicians or pharmacists because the side effect profiles and pharmacokinetics are quite unique to each agent. A novel cephalosporin called ceftaroline, which has activity against MRSA and other Gram-positive and some Gram-negative bacteria, has been approved for the treatment of skin and soft tissue infections and community-acquired pneumonia. When combined with daptomycin, this drug can serve as a salvage therapy for bacteremia. If the infection is found to be caused by non- β -lactamase-producing *S. aureus*, penicillin G is the drug of choice, but these *S. aureus* strains are rarely encountered.

S. epidermidis infections are difficult to cure because they occur in prosthetic devices where the bacteria can sequester themselves in a biofilm. *S. epidermidis* is more often resistant to antimicrobial drugs than is *S. aureus*; approximately 75% of *S. epidermidis* strains are nafcillin resistant. Several newer agents that have activity against CoNS and MSSA and MRSA have recently been FDA-cleared for treatment of skin and skin structure infections. These include dalbavancin, a long-acting intravenous lipoglycopeptide; tedizolid phosphate, an intravenous and oral oxazolidinone, similar to linezolid; and oritavancin, a semisynthetic glycopeptide.

Because of the frequency of drug-resistant strains, meaningful staphylococcal isolates should be tested for antimicrobial susceptibility to help in the choice of systemic drugs. Resistance to drugs of the erythromycin group tends to emerge so rapidly that these drugs should not be used singly for treatment of chronic infection. Drug resistance (to penicillins, tetracyclines, aminoglycosides, erythromycins, and so on) determined by plasmids can be transmitted among staphylococci by transduction and perhaps by conjugation.

Penicillin G-resistant *S. aureus* strains from clinical infections always produce penicillinase. They constitute more than 95% of *S. aureus* isolates in communities in the United States. They are often susceptible to β -lactamase-resistant penicillins, cephalosporins, or vancomycin. Nafcillin resistance is independent of β -lactamase production, and its clinical incidence varies greatly in different countries and at different times. The selection pressure of β -lactamase-resistant antimicrobial drugs may not be the sole determinant for resistance to these drugs: For example, in Denmark, nafcillin-resistant *S. aureus* comprised 40% of isolates in 1970 and only 10% in 1980 without notable changes in the use of nafcillin or similar drugs. In the United States, nafcillin-resistant *S. aureus* accounted for only 0.1% of isolates in 1970 but in the 1990s constituted 20–30% of isolates from infections in some hospitals. Currently, about 60% of nosocomial *S. aureus* among intensive care patients in the United States are resistant to nafcillin. Fortunately, *S. aureus* strains of intermediate susceptibility to vancomycin have been relatively uncommon, and the isolation of vancomycin-resistant strains has been rare.

Epidemiology and Control

Staphylococci are ubiquitous human pathogens. The chief sources of infection are shedding human lesions, fomites contaminated from such lesions, and the human respiratory tract and skin. Contact spread of infection has assumed added importance in hospitals, where a large proportion of the staff and patients may carry antibiotic-resistant staphylococci in the nose or on the skin. Although cleanliness, hygiene, and aseptic management of lesions can control the spread of staphylococci from lesions, few methods are available to prevent the wide dissemination of staphylococci from carriers. Aerosols (eg, glycols) and ultraviolet irradiation of air have little effect.

In hospitals, the areas at highest risk for severe staphylococcal infections are newborn nurseries, intensive care units, operating rooms, and cancer chemotherapy wards. Massive introduction of “epidemic” pathogenic *S. aureus* into these areas may lead to serious clinical disease. Personnel with active *S. aureus* lesions and carriers may have to be excluded from these areas. In such individuals, the application of topical antiseptics such as mupirocin to nasal or perineal carriage sites may diminish shedding of dangerous organisms. Rifampin coupled with a second oral antistaphylococcal drug sometimes provides long-term suppression and possibly cure of nasal carriage; this form of therapy is usually reserved for major problems of staphylococcal carriage because staphylococci can rapidly develop resistance to rifampin.

To diminish transmission within the hospital setting, high-risk patients, such as those in intensive care units and patients transferred from chronic care facilities where prevalence is high, are frequently surveyed for anterior nares colonization. Patients who test positive by culture or PCR are placed on contact precautions to minimize spread on the hands of health care workers. Health care workers should strictly adhere to infection control policies by wearing gloves and washing hands before and after patient contact.

MRSA once was confined primarily to the hospital setting. Worldwide dissemination of a few distinct clones of CA-MRSA and now LA-MRSA has resulted in an increase in skin and soft tissue infections and necrotizing pneumonia, primarily in younger patients without known risk factors for MRSA acquisition. These strains appear to be more virulent. CA-MRSA isolates are characterized by the presence of PVL and the presence of *SCCmec* type IV (see discussion above under Growth Characteristics), which may explain the increased susceptibility to other antimicrobial agents compared with health care-associated MRSA strains.

CHAPTER SUMMARY

- Staphylococci are catalase-positive, Gram-positive organisms that grow in clusters and are common inhabitants of the skin and mucous membranes of humans and animals.
- The pathogenic staphylococci, most importantly *S. aureus*, hemolyze blood, coagulate plasma, and produce a variety of extracellular enzymes and toxins that make them virulent.
- *S. aureus* has complex regulatory systems that respond to environmental stimuli to control the expression of its various virulence genes encoded on pathogenicity islands.
- *S. aureus* causes a broad range of invasive and toxigenic diseases; CoNS are less virulent and more often associated with opportunistic infections (*S. epidermidis*) or specific syndromes, such as *S. saprophyticus* and urinary tract infections.
- Antimicrobial resistance among staphylococci can be quite extensive, encoded by a variety of mechanisms such as β -lactamase production and chromosomal *mecA*, *mecC*, and other resistance determinants.

REVIEW QUESTIONS

1. A 54-year-old woman develops a right shoulder abscess with a strain of *S. aureus* that is resistant to nafcillin. She was treated with a 2-week course of intravenous vancomycin and improved. Three weeks later (week 5), the infection recurred, and she was given 2 more weeks of intravenous vancomycin and again improved. Four weeks later (week 11), the infection recurred and the patient was again started on intravenous vancomycin. The MICs for vancomycin for the *S. aureus* isolates were as follows: initial isolate (day 1), 1 $\mu\text{g/mL}$; week 5, 2 $\mu\text{g/mL}$; and week 11, 8 $\mu\text{g/mL}$. The patient failed to improve with the third course of vancomycin, and alternative therapy was used. The mechanism that best explains the relative resistance of the patient's strain of *S. aureus* to vancomycin is
 - (A) Acquisition of the *vanA* gene from another microorganism
 - (B) Active transport of vancomycin out of the *S. aureus* cell
 - (C) Action of β -lactamase
 - (D) Increased cell wall synthesis and alterations in the cell wall structure
 - (E) Phosphorylation and resultant inactivation of the vancomycin
2. An 11-year-old boy develops a mild fever and pain in his upper arm. A radiograph of his arm shows a lytic lesion (dissolution) in the upper part of the humerus with periosteal elevation over the lesion. The patient is taken to surgery, where the lesion is debrided (dead bone and pus removed). Culture from the lesion yields Gram-positive cocci. A test shows that the organism is a *Staphylococcus* and not a *Streptococcus*. Based on this information, you know the organism is
 - (A) Susceptible to nafcillin
 - (B) β -Lactamase positive
 - (C) A producer of protein A
 - (D) Encapsulated
 - (E) Catalase positive
3. A 36-year-old male patient has an abscess with a strain of *S. aureus* that is β -lactamase positive. This indicates that the organism is resistant to which of the following antibiotics?
 - (A) Penicillin G, ampicillin, and piperacillin
 - (B) Trimethoprim-sulfamethoxazole
 - (C) Erythromycin, clarithromycin, and azithromycin
 - (D) Vancomycin
 - (E) Cefazolin and ceftriaxone
4. Seven days ago, a 27-year-old medical student returned from Central America, where she had spent the summer working in a clinic for indigenous people. Four days ago, she developed an erythematous sunburn-like rash. She also has had headache, muscle aches, and abdominal cramps with diarrhea. Her blood pressure is 70/40 mm Hg. Pelvic examination shows she is having her menstrual period with a tampon in place; otherwise, the pelvic examination is normal. Her kidney function test (serum urea nitrogen and creatinine) results are abnormal, indicating mild renal failure. A blood smear for malaria is negative. Her illness is likely to be caused by which of the following?
 - (A) A toxin that results in greatly increased levels of intracellular cyclic adenosine monophosphate (cAMP)
 - (B) A toxin that degrades sphingomyelin

- (C) A toxin that binds to the class II major histocompatibility complex (MHC) of an antigen-presenting cell and the V β region of a T cell
- (D) A two-component toxin that forms pores in white blood cells and increases cation permeability
- (E) A toxin that blocks elongation factor 2 (EF2)
5. Over a period of 3 weeks, a total of five newborns in the hospital nursery developed *S. aureus* infections with *S. aureus* bacteremia. The isolates all had the same colony morphology and hemolytic properties and identical antimicrobial susceptibility patterns, suggesting that they were the same. (Later molecular methods showed the isolates were identical.) Which of the following should be done now?
- (A) Prophylactic treatment of all newborns with intravenous vancomycin
- (B) Protective isolation of all newborns
- (C) Closing the nursery and referring pregnant women to another hospital
- (D) Hiring all new staff for the hospital nursery
- (E) Culture using mannitol salt agar of the anterior nares of the physicians, nurses, and others who cared for the infected babies
6. The exfoliative toxins, TSST-1, and the enterotoxins are all superantigens. The genes for these toxins are
- (A) Present in all strains of *S. aureus*
- (B) Widely distributed on the staphylococcal chromosome
- (C) On both the staphylococcal chromosome (TSST-1 and exfoliative toxins) and on plasmids (enterotoxins)
- (D) On the staphylococcal chromosome in a pathogenicity island
- (E) On plasmids
7. A 16-year-old bone marrow transplant patient has a central venous line that has been in place for 2 weeks. He also has a urinary tract catheter, which has been in place for 2 weeks as well. He develops fever while his white blood cell count is very low and before the transplant has engrafted. Three blood cultures are done, and all grow *S. epidermidis*. Which one of the following statements is correct?
- (A) The *S. epidermidis* organisms are likely to be susceptible to penicillin G.
- (B) The *S. epidermidis* organisms are likely to be from the surface of the urinary tract catheter.
- (C) The *S. epidermidis* organisms are likely to be resistant to vancomycin.
- (D) The *S. epidermidis* organisms are likely to be from a skin source.
- (E) The *S. epidermidis* organisms are likely to be in a biofilm on the central venous catheter surface.
8. A 65-year-old man develops an abscess on the back of his neck. Culture yields *S. aureus*. The isolate is tested and found to be positive for the *mecA* gene, which means that
- (A) The isolate is susceptible to vancomycin.
- (B) The isolate is resistant to vancomycin.
- (C) The isolate is susceptible to nafcillin.
- (D) The isolate is resistant to nafcillin.
- (E) The isolate is susceptible to clindamycin.
- (F) The isolate is resistant to clindamycin.
9. Antimicrobial resistance has become a significant problem. Which one of the following is of major concern worldwide?
- (A) Nafcillin resistance in *S. aureus*
- (B) Penicillin resistance in *Streptococcus pneumoniae*
- (C) Penicillin resistance in *Neisseria gonorrhoeae*
- (D) Vancomycin resistance in *S. aureus*
- (E) Tobramycin resistance in *Escherichia coli*
10. A group of six children younger than 8 years live in a semitropical country. Each of the children has several crusted weeping skin lesions of impetigo (pyoderma). The lesions are predominantly on the arms and faces. Which of the following microorganisms is a likely cause of the lesions?
- (A) *E. coli*
- (B) *Chlamydia trachomatis*
- (C) *S. aureus*
- (D) *S. pneumoniae*
- (E) *Bacillus anthracis*
11. Which of the following statements regarding the role of protein A in the pathogenesis of infections caused by *S. aureus* is correct?
- (A) It is responsible for the rash in toxic shock syndrome.
- (B) It converts hydrogen peroxide into water and oxygen.
- (C) It is a potent enterotoxin.
- (D) It is directly responsible for lysis of neutrophils.
- (E) It is a bacterial surface protein that binds to the Fc portion of IgG1.
12. Which of the following staphylococcal organisms produces coagulase and has been implicated in infections following a dog bite?
- (A) *Staphylococcus intermedius*
- (B) *S. epidermidis*
- (C) *S. saprophyticus*
- (D) *S. hominis*
- (E) *S. hemolyticus*
13. All of the following statements regarding PVL are correct *except*
- (A) It is a two-component toxin.
- (B) It is commonly produced by community-associated MRSA strains.
- (C) It is an important virulence factor.
- (D) It is identical to one of the staphylococcal enterotoxins.
- (E) It forms pores in the membranes of white blood cells.
14. Which of the following statements best describes the function of the *agr* in *S. aureus*?
- (A) It regulates production of β -hemolysins.
- (B) It is influenced by environmental oxygen.
- (C) It controls the preferential expression of surface adhesins.
- (D) It is important in the control of autolysis.
15. All of the following are important infection control strategies in containing spread of MRSA in hospitals *except*
- (A) Aggressive hand hygiene
- (B) Routine surveillance for nasal colonization among high-risk individuals
- (C) Contact isolation for patients who are colonized or infected with MRSA
- (D) Routine antimicrobial prophylaxis for all patients hospitalized for more than 48 hours
- (E) Aseptic management of skin lesions

The Streptococci, Enterococci, and Related Genera

The streptococci, enterococci, and related organisms are Gram-positive spherical bacteria that characteristically form pairs or chains during growth. They are widely distributed in nature. Some are members of the normal human microbiota; others are associated with important human diseases attributable to the direct effects of infection or in other cases to an immunologic response to them. Streptococci elaborate a variety of extracellular substances and enzymes.

The streptococci are a large and heterogeneous group of bacteria, and no one system suffices to classify them. Yet, understanding their taxonomy is key to understanding their medical importance.

CLASSIFICATION OF STREPTOCOCCI

The classification of streptococci into major categories has been based on a series of observations over many years: (1) colony morphology and hemolytic reactions on blood agar, (2) serologic specificity of the cell wall group-specific substance (Lancefield antigens) and other cell wall or capsular antigens, (3) biochemical reactions and resistance to physical and chemical factors, and (4) ecologic features. More recently, molecular genetics have replaced phenotypic methods in the taxonomic assignment of these organisms. The classification of streptococci of medical importance is summarized in Table 14-1.

A. Hemolysis

Many streptococci are able to hemolyze red blood cells in vitro in varying degrees. Complete disruption of erythrocytes with clearing of the blood around the bacterial growth is called β -**hemolysis**. Incomplete lysis of erythrocytes with reduction of hemoglobin and the formation of green pigment is called α -**hemolysis**. Other streptococci are nonhemolytic (sometimes called γ -hemolysis).

The hemolysis patterns of the streptococci of medical importance to humans are shown in Table 14-1. Clinically important streptococci are traditionally differentiated based on their hemolysis pattern, that is, β -hemolytic vs non-hemolytic streptococci. Beta-hemolytic streptococci are also referred to as pyogenic streptococci, which include

the human-pathogenic species *S. pyogenes*, *S. agalactiae*, and *S. dysgalactiae*. The classification of hemolytic patterns is used primarily with the streptococci although other bacteria that cause disease may also typically produce a variety of hemolysins.

B. Group-Specific Substance (Lancefield Classification)

This carbohydrate is contained in the cell wall of many streptococci and forms the basis of serologic grouping into **Lancefield groups A–H and K–U**. The serologic specificity of the group-specific carbohydrate is determined by an amino sugar. For group A streptococci, this is rhamnose-*N*-acetylglucosamine; for group B, it is rhamnose-glucosamine polysaccharide; for group C, it is rhamnose-*N*-acetylgalactosamine; for group D, it is glycerol teichoic acid containing D-alanine and glucose; and for group F, it is glucopyranosyl-*N*-acetylgalactosamine.

Extracts of group-specific antigen for grouping streptococci are prepared by a variety of methods, including extraction of centrifuged culture treated with hot hydrochloric acid, nitrous acid, or formamide; by enzymatic lysis of streptococcal cells (eg, with pepsin or trypsin); or by autoclaving of cell suspensions. These extracts contain the carbohydrate group-specific substance that yields precipitin reactions specific antisera. This permits arrangement of many streptococci into groups A–H and K–U. Typing is generally done only for groups A, B, C, F, and G (see Table 14-1), which cause disease in humans and for which reagents are available that allow typing using simple agglutination or color reactions.

C. Capsular Polysaccharides

The antigenic specificity of the capsular polysaccharides is used to classify *S. pneumoniae* into more than 90 types and to type the group B streptococci (*S. agalactiae*).

D. Biochemical Reactions

Biochemical tests include sugar fermentation reactions, tests for the presence of enzymes, and tests for susceptibility or resistance to certain chemical agents. Biochemical tests are most often used to classify streptococci after the colony growth and hemolytic characteristics have been observed.

TABLE 14-1 Characteristics of Medically Important Streptococci

Name	Group-Specific Substance ^a	Hemolysis ^b	Habitat	Important Laboratory Criteria	Common and Important Diseases
Pyogenic Streptococci					
<i>Streptococcus pyogenes</i>	A	β	Throat, skin	Large colonies (>0.5 mm), PYR ^c test positive, inhibited by bacitracin	Pharyngitis, impetigo, deep soft tissue infections; bacteremia; rheumatic fever, glomerulonephritis, toxic shock
<i>Streptococcus agalactiae</i>	B	β	Urogenital tract, lower GI tract	Hippurate hydrolysis, CAMP-factor positive ^d	Neonatal sepsis and meningitis; bacteremia, UTIs, ^e meningitis in adults
<i>Streptococcus dysgalactiae</i> subspecies <i>equisimilis</i> ; others	A, C, G	β (human infections), α, none	Throat	Large (>0.5 mm) colonies	Pharyngitis, pyogenic infections similar to group A streptococci
Viridans Streptococci					
<i>Streptococcus bovis</i> group ^f	D	None	Colon, biliary tree	Growth in presence of bile, hydrolyze esculin, no growth in 6.5% NaCl, degrades starch	Endocarditis, common blood isolate in colon cancer, biliary disease
<i>Streptococcus anginosus</i> group (<i>S. anginosus</i> , <i>Streptococcus intermedius</i> , <i>Streptococcus constellatus</i>)	F (A, C, G) and untypeable	α, β, none	Throat, colon, urogenital tract	Small (<0.5 mm) colony variants of β-hemolytic species; group A are bacitracin resistant and PYR negative; carbohydrate fermentation patterns; arginine, esculin, VP ^g positive	Pyogenic infections, including brain, liver, lung abscesses
Mutans group	Usually not typed	α, none	Oral cavity	Carbohydrate fermentation patterns; esculin, VP positive	Dental caries (<i>Streptococcus mutans</i>), endocarditis; abscesses (with many other bacterial species)
Mitis-Sanguinis group					
<i>Streptococcus pneumoniae</i>	None ^o	α	Nasopharynx	Susceptible to optochin; colonies soluble in bile; quellung reaction positive	Pneumonia, meningitis, bacteremia, otitis media, sinusitis
<i>Streptococcus mitis</i>	None	α, none	Oral cavity	VP negative ^g ; carbohydrate fermentation patterns	Endocarditis; bacteremia, sepsis in immunocompromised patients; high-level resistance to penicillin
Salivarius group	None	α, none	Oral cavity	VP positive; carbohydrate fermentation patterns	Bacteremia, endocarditis, meningitis

GI, gastrointestinal.
^aLancefield classification.
^bHemolysis observed on 5% sheep blood agar after overnight incubation.
^cHydrolysis of L-pyrrolidonyl-β-naphthylamide (PYR).
^dCAMP, Christie, Atkins, Munch-Peterson.
^eUTIs, urinary tract infections.
^fIncludes the human species: *Streptococcus gallolyticus* subspecies *gallolyticus*; *Streptococcus gallolyticus* subspecies *macedonicus*; *Streptococcus gallolyticus* subspecies *pasteurianus*; *Streptococcus infantarius* subspecies *infantarius*.
^gVP, Voges Proskauer; all viridans group streptococci are VP positive except the mitis group.

Biochemical tests are used for species that typically do not react with the commonly used antibody preparations for the group-specific substances, groups A, B, C, F, and G. For example, the viridans streptococci are α -hemolytic or non-hemolytic and do not react with the antibodies commonly used for the Lancefield classification. Speciation of the viridans streptococci requires a battery of biochemical tests (see Table 14-1). However, because biochemical reactions are labor intensive and often unreliable, laboratories with molecular capabilities, such as gene sequencing or that have implemented mass spectrometry for organism identification (matrix-assisted laser desorption ionization-time of flight mass spectrometry [MALDI-TOF MS]), are replacing phenotypic tests with these methods when identification of viridans streptococci is required.

STREPTOCOCCI, ENTEROCOCCI, AND RELATED GENERA OF PARTICULAR MEDICAL INTEREST

The following streptococci and enterococci are of particular medical relevance.

STREPTOCOCCUS PYOGENES

Most clinical isolates of streptococci that contain the group A antigen are *S. pyogenes*. It is a prototypical human pathogen. It is used here to illustrate general characteristics of streptococci and specific characteristics of the species. *S. pyogenes* is the main human pathogen associated with local or systemic invasion and poststreptococcal immunologic disorders. *S. pyogenes* typically produces large (1 cm in diameter) zones of β -hemolysis around colonies greater than 0.5 mm in diameter. They are PYR-positive (hydrolysis of L-pyrrolidonyl- β -naphthylamide) and usually are susceptible to bacitracin.

Morphology and Identification

A. Typical Organisms

Individual cocci are spherical or ovoid and are arranged in chains (Figure 14-1). The cocci divide in a plane perpendicular to the long axis of the chain. The members of the chain often have a striking diplococcal appearance, and rodlike forms are occasionally seen. The lengths of the chains vary widely and are conditioned by environmental factors. Streptococci are Gram-positive; however, as a culture ages and the bacteria die, they lose their Gram positivity and can appear to be Gram-negative; for some streptococci, this can occur after overnight incubation.

Most group A strains (see Table 14-1) produce capsules composed of hyaluronic acid. The capsules are most noticeable in very young cultures. They impede phagocytosis. The hyaluronic acid capsule likely plays a greater role in virulence

FIGURE 14-1 Streptococci grown in blood culture showing Gram-positive cocci in chains. Original magnification $\times 1000$.

than is generally appreciated and together with M protein was believed to be an important factor in the resurgence of rheumatic fever (RF) in the United States in the 1980s and 1990s. The capsule binds to hyaluronic-acid-binding protein, CD44, present on human epithelial cells. Binding induces disruption of intercellular junctions allowing microorganisms to remain extracellular as they penetrate the epithelium (see Stollerman and Dale, 2008). Capsules of other streptococci (eg, *S. agalactiae* and *S. pneumoniae*) are different. The *S. pyogenes* cell wall contains proteins (M, T, R antigens), carbohydrates (group specific), and peptidoglycans. Hairlike pili project through the capsule of group A streptococci. The pili consist partly of M protein and are covered with **lipoteichoic acid**. The latter is important in the attachment of streptococci to epithelial cells.

B. Culture

Most streptococci grow in solid media as discoid colonies, usually 1–2 mm in diameter. *S. pyogenes* is β -hemolytic (Figure 14-2); other species have variable hemolytic characteristics (see Table 14-1).

C. Growth Characteristics

Energy is obtained principally from the utilization of glucose with lactic acid as the end product. Growth of streptococci tends to be poor on solid media or in broth unless enriched with blood or tissue fluids. Nutritive requirements vary widely among different species. The human pathogens are most exacting, requiring a variety of growth factors. Growth and hemolysis are aided by incubation in 10% CO₂. Most pathogenic hemolytic streptococci grow best at 37°C. Most streptococci are facultative anaerobes and grow under aerobic and anaerobic conditions.

FIGURE 14-2 Group A β -hemolytic streptococci (*S. pyogenes*) after growth overnight on a 10-cm plate with 5% sheep blood agar. The small (0.5–1 mm diameter) white colonies are surrounded by diffuse zones of β -hemolysis 7–10 mm in diameter. (Courtesy of H Reyes.)

D. Variation

Variants of the same *Streptococcus* strain may show different colony forms. This is particularly marked among *S. pyogenes* strains, giving rise to either matte or glossy colonies. Matte colonies consist of organisms that produce much M protein and generally are virulent. The *S. pyogenes* in glossy colonies tend to produce little M protein and are often not virulent.

Antigenic Structure

A. M Protein

This substance is a major virulence factor of *S. pyogenes*. M protein is a filamentous structure anchored to the cell membrane that penetrates and projects from the streptococcal cell wall. When M protein is present, the streptococci are virulent, and in the absence of M type-specific antibodies, they are able to resist phagocytosis by polymorphonuclear leukocytes by inhibiting activation of the alternate complement pathway. *S. pyogenes* that lack M protein are not virulent. Immunity to infection with group A streptococci is related to the presence of type-specific antibodies to M protein. Because there are more than 150 types of M protein, a person can have repeated infections with *S. pyogenes* of different M types. Both groups C and G streptococci have genes homologous to the genes for M protein of group A, and M proteins similar to those of group A have been found on groups C and G streptococci.

The M protein molecule has a rodlike coiled structure that separates functional domains. The structure allows for a large number of sequence changes while maintaining function, and the M protein immunodeterminants, therefore, can readily change. There are two major structural classes of M protein, classes I and II.

It appears that M protein and perhaps other streptococcal cell wall antigens have an important role in the pathogenesis of rheumatic fever. Purified streptococcal cell wall membranes induce antibodies that react with human cardiac sarcolemma; the characteristics of the cross-reactive antigens are not clear. A component of the cell wall of selected M types induces antibodies that react with cardiac muscle tissue. Conserved antigenic domains on the class I M protein cross-react with human cardiac muscle, and the class I M protein may be a virulence determinant for rheumatic fever.

Toxins and Enzymes

More than 20 extracellular products that are antigenic are elaborated by *S. pyogenes*, including the following.

A. Streptokinase (Fibrinolysin)

Streptokinase is produced by many strains of group A β -hemolytic streptococci. It transforms the plasminogen of human plasma into plasmin, an active proteolytic enzyme that digests fibrin and other proteins, allowing the bacteria to escape from blood clots. This process of digestion may be interfered with by nonspecific serum inhibitors and by a specific antibody, antistreptokinase. Streptokinase has been given intravenously for treatment of pulmonary emboli, coronary artery, and venous thromboses.

B. Deoxyribonucleases

Streptococcal deoxyribonucleases A, B, C, and D degrade DNA (DNases) and similar to streptokinase facilitate the spread of streptococci in tissue by liquefying pus. The enzymatic activity can be measured by the decrease in viscosity of known DNA solutions. Purulent exudates owe their viscosity largely to deoxyribonucleoprotein. Mixtures of streptokinase and DNases are used in “enzymatic debridement.” They help to liquefy exudates and facilitate removal of pus and necrotic tissue; antimicrobial drugs thus gain better access, and infected surfaces recover more quickly. An antibody to DNase develops after streptococcal infections (normal limit, 100 units), especially after skin infections.

C. Hyaluronidase

Hyaluronidase splits hyaluronic acid, an important component of the ground substance of connective tissue. Thus, hyaluronidase aids in spreading infecting microorganisms (spreading factor). Hyaluronidases are antigenic and specific for each bacterial or tissue source. After infection with hyaluronidase-producing organisms, specific antibodies are found in the serum.

D. Pyrogenic Exotoxins (Erythrogenic Toxin)

Pyrogenic exotoxins are elaborated by *S. pyogenes*. There are three antigenically distinct **streptococcal pyrogenic exotoxins (Spe): A, B, and C**. SpeA has been most widely studied. It is produced by group A streptococci that carry a

lysogenic phage. The streptococcal pyrogenic exotoxins have been associated with **streptococcal toxic shock syndrome** and **scarlet fever**. Most strains of group A streptococci isolated from patients with streptococcal toxic shock syndrome either produce Spe A or have the gene that codes for it; in contrast, only about 15% of group A streptococci isolated from other patients have the gene. Spe C, also encoded by a phage, may contribute to the syndrome. Spe B, a potent protease, interferes with phagocytosis. The group A streptococci associated with toxic shock syndrome are primarily of M protein types 1 and 3.

The pyrogenic exotoxins act as superantigens, which stimulate T cells by binding to the class II major histocompatibility complex in the V_{β} region of the T-cell receptor. The activated T cells release cytokines that mediate shock and tissue injury. The mechanisms of action appear to be similar to those caused by staphylococcal toxic shock syndrome toxin-1 and the staphylococcal enterotoxins.

E. Hemolysins

The β -hemolytic group A *S. pyogenes* elaborates two hemolysins (streptolysins) that not only lyse the membranes of erythrocytes but also damage a variety of other cell types. **Streptolysin O** is a protein (molecular weight [MW], 60,000) that is hemolytically active in the reduced state (available-SH groups) but rapidly inactivated in the presence of oxygen. Streptolysin O is responsible for some of the hemolysis seen when growth occurs in cuts made deep into the medium in blood agar plates. It combines quantitatively with **anti-streptolysin O (ASO)**, an antibody that appears in humans after infection with any streptococci that produce streptolysin O. This antibody blocks hemolysis by streptolysin O. This phenomenon forms the basis of a quantitative test for the antibody. An ASO serum titer in excess of 160–200 units is considered abnormally high and suggests either recent infection with *S. pyogenes* or persistently high antibody levels caused by an exaggerated immune response to an earlier exposure in a hypersensitive person. **Streptolysin S** is the agent responsible for the hemolytic zones around streptococcal colonies growing on the surface of blood agar plates. It is elaborated in the presence of serum—hence the name streptolysin S. It is not antigenic. Most isolates of *S. pyogenes* produce both of these hemolysins. Up to 10% produce only one.

Pathogenesis and Clinical Findings

A variety of distinct disease processes are associated with *S. pyogenes* infections. The infections can be divided into several categories.

A. Diseases Attributable to Invasion by *S. pyogenes*, β -Hemolytic Group A Streptococci

The portal of entry determines the principal clinical picture. In each case, however, there is a diffuse and rapidly

spreading infection that involves the tissues and extends along lymphatic pathways with only minimal local suppuration. From the lymphatics, the infection can extend to the bloodstream.

1. **Erysipelas**—If the portal of entry is the skin, erysipelas results. Lesions are raised and characteristically red. There is massive brawny edema and a rapidly advancing, sharply demarcated margin of infection.
2. **Cellulitis**—Streptococcal cellulitis is an acute, rapidly spreading infection of the skin and subcutaneous tissues. It follows infection associated with mild trauma, burns, wounds, or surgical incisions. Pain, tenderness, swelling, and erythema occur. Cellulitis is differentiated from erysipelas by two clinical findings: In cellulitis, the lesion is not raised, and the line between the involved and uninvolved tissue is indistinct.
3. **Necrotizing fasciitis (streptococcal gangrene)**—There is extensive and very rapidly spreading necrosis of the skin, tissues, and fascia. Bacteria other than *S. pyogenes* can also cause necrotizing fasciitis. The group A streptococci that cause necrotizing fasciitis have sometimes been termed *flesh-eating bacteria*.
4. **Puerperal fever**—If the streptococci enter the uterus after delivery, puerperal fever develops, which is essentially a septicemia originating in the infected wound (endometritis).
5. **Bacteremia or sepsis**—Infection of traumatic or surgical wounds with streptococci results in bacteremia, which can rapidly be fatal. *S. pyogenes* bacteremia can also occur with skin infections, such as cellulitis and rarely pharyngitis.

B. Diseases Attributable to Local Infection with *S. pyogenes* and Their By-products

1. **Streptococcal sore throat**—The most common infection caused by β -hemolytic *S. pyogenes* is streptococcal sore throat or pharyngitis. *S. pyogenes* adheres to the pharyngeal epithelium by means of lipoteichoic acid-covered surface pili and by means of hyaluronic acid in encapsulated strains. The glycoprotein fibronectin (MW, 440,000) on epithelial cells probably serves as lipoteichoic acid ligand. In infants and small children, the sore throat occurs as a subacute nasopharyngitis with a thin serous discharge and little fever but with a tendency of the infection to extend to the middle ear and the mastoid. The cervical lymph nodes are usually enlarged. The illness may persist for weeks. In older children and adults, the disease is more acute and is characterized by intense nasopharyngitis, tonsillitis, and intense redness and edema of the mucous membranes, with purulent exudate; enlarged, tender cervical lymph nodes; and (usually) a high fever. Twenty percent of infections are asymptomatic. A similar clinical picture can occur with infectious mononucleosis, diphtheria, gonococcal infection, and adenovirus infection.

S. pyogenes infection of the upper respiratory tract does not usually involve the lungs. Pneumonia, when it does occur, is rapidly progressive and severe and is most commonly a sequela to viral infections, such as influenza or measles, which seem to greatly enhance the predisposition to bacterial superinfection with this and other pathogens, such as *S. pneumoniae*.

2. **Streptococcal pyoderma**—Local infection of superficial layers of skin, especially in children, is called **impetigo**. It consists of superficial vesicles that break down and eroded areas whose denuded surface is covered with pus and later is encrusted. It spreads by continuity and is highly communicable, especially in hot, humid climates. More widespread infection occurs in eczematous or wounded skin or in burns and may progress to cellulitis. Group A streptococcal skin infections are often attributable to M types 49, 57, and 59–61 and may precede glomerulonephritis (GN) but do not lead to rheumatic fever.

A clinically identical infection can be caused by *Staphylococcus aureus* and sometimes both *S. pyogenes* and *S. aureus* are present.

C. Invasive Group A Streptococcal Infections, Streptococcal Toxic Shock Syndrome, and Scarlet Fever

Fulminant, invasive *S. pyogenes* infections with **streptococcal toxic shock syndrome** are characterized by shock, bacteremia, respiratory failure, and multiorgan failure. Death occurs in about 30% of patients. The infections tend to occur after minor trauma in otherwise healthy persons with several presentations of soft tissue infection. These include necrotizing fasciitis, myositis, and infections at other soft tissue sites; bacteremia occurs frequently. In some patients, particularly those infected with group A streptococci of M types 1 or 3, the disease presents with focal soft tissue infection accompanied by fever and rapidly progressive shock with multiorgan failure. Erythema and desquamation may occur. The *S. pyogenes* of the M types 1 and 3 (and types 12 and 28) that make pyrogenic exotoxin A or B are associated with the severe infections.

Pyrogenic exotoxins A–C also cause **scarlet fever** in association with *S. pyogenes* pharyngitis or with skin or soft tissue infection. The pharyngitis may be severe. The rash appears on the trunk after 24 hours of illness and spreads to involve the extremities. Streptococcal toxic shock syndrome and scarlet fever are clinically overlapping diseases.

D. Poststreptococcal Diseases (Rheumatic Fever, Glomerulonephritis)

After an acute *S. pyogenes* infection, there is a latent period of 1–4 weeks (mean 7 days), after which nephritis or rheumatic fever occasionally develops. The latent period suggests that these poststreptococcal diseases are not attributable to the direct effect of disseminated bacteria but instead represent a hypersensitivity response. Nephritis is more commonly

preceded by infection of the skin; rheumatic fever is more commonly preceded by infection of the respiratory tract.

1. **Acute glomerulonephritis**—This sometimes develops 1–5 weeks (mean 7 days) after *S. pyogenes* skin infection (pyoderma, impetigo) or pharyngitis. Some strains are particularly nephritogenic, principally with M types 2, 42, 49, 56, 57, and 60 (skin). Other nephritogenic M types associated with throat infections and glomerulonephritis are 1, 4, 12, and 25. After random streptococcal skin infections, the incidence of nephritis is less than 0.5%.

Glomerulonephritis may be initiated by antigen–antibody complexes on the glomerular basement membrane. The most important antigens are thought to be SpeB and a nephritis-associated plasmin receptor. In acute nephritis, the patient has blood and protein in the urine, edema, high blood pressure, and urea nitrogen retention; serum complement levels are also low. A few patients die, some develop chronic glomerulonephritis with ultimate kidney failure, and the majority recovers completely.

2. **Rheumatic fever**—This is the most serious sequela of *S. pyogenes* because it results in damage to heart muscle and valves. Certain strains of group A streptococci contain cell membrane antigens that cross-react with human heart tissue antigens. Sera from patients with rheumatic fever contain antibodies to these antigens.

The onset of acute rheumatic fever (ARF) is often preceded by *S. pyogenes* pharyngitis 1–5 weeks (mean 19 days) earlier, although the infection may be mild and may not be detected. In general, however, patients with more severe streptococcal sore throats have a greater chance of developing rheumatic fever. Rheumatic fever is not associated with cutaneous streptococcal infections. In the 1950s, untreated streptococcal infections were followed by rheumatic fever in up to 3% of military personnel and 0.3% of civilian children. In the 1980s through 2000 a resurgence of ARF occurred in the United States. M types 1, 3, 5, 6, and 18 were most frequently involved. Since that time, the incidence has once again declined. Rheumatic fever occurs up to 100 times more frequently in tropical countries and is the most important cause of heart disease in young people in developing countries.

Typical symptoms and signs of rheumatic fever include fever, malaise, a migratory nonsuppurative polyarthritis, and evidence of inflammation of all parts of the heart (endocardium, myocardium, and pericardium). The carditis characteristically leads to thickened and deformed valves and to small perivascular granulomas in the myocardium (Aschoff bodies) that are finally replaced by scar tissue. Patients may develop severe and progressive congestive heart failure. Sydenham's chorea is another manifestation of ARF and is characterized by involuntary, uncoordinated movements and associated muscle weakness. It has been hypothesized that other types of neurobehavioral

conditions may also follow streptococcal infections. These are referred to as PANDAS—*post-streptococcal autoimmune, neuropsychiatric disorders associated with streptococci*. More research is required to definitely establish a link to *S. pyogenes* infections.

Erythrocyte sedimentation rates, serum transaminase levels, electrocardiograms, and other tests are used to estimate rheumatic activity.

Whereas rheumatic fever has a marked tendency to be reactivated by recurrent streptococcal infections, nephritis does not. The first attack of rheumatic fever usually produces only slight cardiac damage, which, however, increases with each subsequent attack. It is therefore important to protect such patients from recurrent *S. pyogenes* infections by prophylactic penicillin administration.

Diagnostic Laboratory Tests

A. Specimens

Specimens to be obtained depend on the nature of the streptococcal infection. A throat swab, pus, cerebrospinal fluid or other sterile body fluid, or blood is obtained for culture. Serum is obtained for antibody determinations.

B. Smears

Smears from pus often show single cocci or pairs rather than definite chains. Cocci are sometimes Gram-negative because the organisms are no longer viable and have lost their ability to retain the blue dye (crystal violet) and be Gram-positive. If smears of pus show streptococci but cultures fail to grow, anaerobic organisms must be suspected. Smears of throat swabs are rarely contributory because viridans streptococci are always present and have the same appearance as group A streptococci on stained smears.

C. Culture

Specimens suspected of containing streptococci are cultured on blood agar plates. If anaerobes are suspected, suitable anaerobic media must also be inoculated. Incubation in 10% CO₂ often speeds hemolysis. Slicing the inoculum into the blood agar has a similar effect because oxygen does not readily diffuse through the medium to the deeply embedded organisms, and it is oxygen that inactivates streptolysin O.

Blood cultures will grow hemolytic group A streptococci (eg, in sepsis) within hours or a few days. Certain α -hemolytic streptococci and enterococci may grow slowly, so blood cultures in cases of suspected endocarditis may not turn positive for a few days.

The degree and kind of hemolysis (and colonial appearance) may help place an organism in a definite group. *S. pyogenes* can be identified by rapid tests specific for the presence of the group A-specific antigen and by the PYR test. Streptococci belonging to group A may be presumptively identified by inhibition of growth by bacitracin, but this should be used only when more definitive tests are not available.

D. Antigen Detection Tests

Several commercial kits are available for rapid detection of group A streptococcal antigen from throat swabs. These kits use enzymatic or chemical methods to extract the antigen from the swab, then use enzyme immunoassay (EIA) or agglutination tests to demonstrate the presence of the antigen. The tests can be completed in minutes to hours after the specimen is obtained. They are 60–90% sensitive, depending on the prevalence of the disease in the population, and 98–99% specific compared with culture methods. More sensitive assays that use DNA probes or nucleic acid amplification techniques are now available and are beginning to replace the earlier antigen detection tests, although they remain more costly.

E. Serologic Tests

A rise in the titer of antibodies to many group A streptococcal antigens can be estimated. Such antibodies include ASO, particularly in respiratory disease; anti-DNase B and antihyaluronidase, particularly in skin infections; antistreptokinase; anti-M type-specific antibodies; and others. Of these, the anti-ASO titer is most widely used.

Immunity

Resistance against streptococcal diseases is M type specific. Thus, a host who has recovered from infection by one group A streptococcal M type is relatively immune to reinfection by the same type but fully susceptible to infection by another M type. Anti-M type-specific antibodies can be demonstrated in a test that exploits the fact that streptococci are rapidly killed after phagocytosis. M protein interferes with phagocytosis, but in the presence of type-specific antibody to M protein, streptococci are killed by human leukocytes.

Antibody to streptolysin O develops after infection; it blocks hemolysis by streptolysin O but does not indicate immunity. High titers (>250 units) indicate recent or repeated infections and are found more often in rheumatic individuals than in those with uncomplicated streptococcal infections.

Treatment

All *S. pyogenes* are uniformly susceptible to penicillin G. Macrolides, such as erythromycin and clindamycin, have often been recommended for penicillin-allergic patients and for patients with necrotizing fasciitis. However, resistance to macrolide antibiotics has been increasing in Europe and in the United States. Some are resistant to tetracyclines. Antimicrobial drugs have no effect on established glomerulonephritis and rheumatic fever. In acute streptococcal infections, however, every effort must be made to rapidly eradicate streptococci from the patient, eliminate the antigenic stimulus (before day 8), and thus prevent poststreptococcal disease. Doses of penicillin or erythromycin that result in effective tissue levels for 10 days usually accomplish this. Antimicrobial drugs are also very useful in preventing reinfection with β -hemolytic group A streptococci in patients with rheumatic fever.

Epidemiology, Prevention, and Control

Although humans can be asymptomatic nasopharyngeal or perineal carriers of *S. pyogenes*, the organism should be considered significant if it is detected by culture or other means. The ultimate source of group A streptococci is a person harboring these organisms. The individual may have a clinical or subclinical infection or may be a carrier distributing streptococci directly to other persons via droplets from the respiratory tract or skin. The nasal discharges of a person harboring *S. pyogenes* are the most dangerous source for spread of these organisms.

Many other streptococci (eg, viridans streptococci and enterococci) are members of the normal microbiota of the human body. They produce disease only when established in parts of the body where they do not normally occur (eg, heart valves). To prevent such accidents, particularly in the course of surgical procedures on the respiratory, gastrointestinal, and urinary tracts that result in temporary bacteremia, antimicrobial agents are often administered prophylactically to persons with known heart valve deformity and to those with prosthetic valves or joints. Guidelines published by the American Heart Association and other professional societies have clarified some of these recommendations (see Wilson et al, 2007).

Control procedures are directed mainly at the human source:

1. Detection and early antimicrobial therapy of respiratory and skin infections with group A streptococci. Prompt eradication of streptococci from early infections can effectively prevent the development of poststreptococcal disease. This requires maintenance of adequate penicillin levels in tissues for 10 days (eg, benzathine penicillin G given once intramuscularly). Erythromycin is an alternative drug, although many *S. pyogenes* are now resistant.
2. Antistreptococcal chemoprophylaxis in persons who have suffered an attack of rheumatic fever. This involves giving one injection of benzathine penicillin G intramuscularly every 3–4 weeks or daily oral penicillin or oral sulfonamide. The first attack of rheumatic fever infrequently causes major heart damage; however, such persons are particularly susceptible to reinfections with streptococci that precipitate relapses of rheumatic activity and give rise to cardiac damage. Chemoprophylaxis in such individuals, especially children, must be continued for years. Chemoprophylaxis is not used in glomerulonephritis because of the small number of nephritogenic types of streptococci. An exception may be family groups with a high rate of poststreptococcal nephritis.
3. Eradication of *S. pyogenes* from carriers. This is especially important when carriers are in areas such as obstetric delivery rooms, operating rooms, classrooms, or nurseries. Unfortunately, it is often difficult to eradicate β -hemolytic streptococci from permanent carriers, and individuals may occasionally have to be shifted away from “sensitive” areas for some time.

Concept Checks

- Streptococci are a large group of Gram-positive organisms that are catalase negative and tend to grow in pairs and long chains.
- No one system accurately classifies all streptococci, and the taxonomy continues to evolve. Major classifications include the type of hemolysis (α , β , or no hemolysis) conditions for growth, and capacity to cause disease.
- Streptococci will grow well on 5% sheep blood agar and other media that support the growth of Gram-positive cocci.
- *S. pyogenes* (group A β -hemolytic streptococcus) is the most virulent pathogen in the *Streptococcus* family. It elaborates numerous proteins, hemolysins, enzymes, and toxins responsible for the broad range of suppurative (eg, cellulitis) and immunologic diseases (poststreptococcal GN, RF) associated with this organism.

STREPTOCOCCUS AGALACTIAE

These are the **group B streptococci**. They typically are β -hemolytic and produce zones of hemolysis that are only slightly larger than the colonies (1–2 mm in diameter). The group B streptococci hydrolyze sodium hippurate and give a positive response in the so-called CAMP (Christie, Atkins, Munch-Peterson) test.

Group B streptococci are part of the normal vaginal flora and lower gastrointestinal tract in 5–30% of women. Group B streptococcal infection during the first month of life may present as fulminant sepsis, meningitis, or respiratory distress syndrome. Substantial reductions in the incidence of early-onset neonatal group B streptococcal infections have been observed after the 1996 recommendations for screening pregnant women at 35–37 weeks of pregnancy. This is done by using either broth-enriched culture or molecular methods on rectal and vaginal swabs obtained at the time of screening. Intravenous ampicillin given to mothers who are colonized with group B streptococci and are in labor prevents colonization of their infants and subsequent group B streptococcal disease. Group B streptococcal infections are increasing among nonpregnant adults. Two expanding populations, namely elderly adults and immunocompromised hosts, are most at risk for invasive disease. Predisposing factors include diabetes mellitus, cancer, advanced age, liver cirrhosis, corticosteroid therapy, HIV, and other immunocompromised states. Bacteremia, skin and soft tissue infections, respiratory infections, and genitourinary infections in descending order of frequency are the major clinical manifestations.

GROUPS C AND G

These streptococci occur sometimes in the nasopharynx and may cause pharyngitis, sinusitis, bacteremia, or endocarditis. They often look like group A *S. pyogenes* on blood agar

medium and are β -hemolytic. They are identified by reactions with specific antisera for groups C or G. Groups C and G streptococci have hemolysins and may have M proteins analogous to those of group A *S. pyogenes*. Poststreptococcal sequelae of acute glomerulonephritis (AGN) and RF have been rarely reported.

GROUP D STREPTOCOCCI

The group D streptococci have undergone recent taxonomic changes. There are eight species in this group, many of which do not cause infections in humans. The *S. bovis* group is of most importance to human disease and is further classified into biotypes (old classification), which are important epidemiologically, and more recently into four DNA clusters. Animal species in the bovis group have been assigned to the species *Streptococcus equinus* (DNA cluster I). Biotype I (in DNA cluster II) isolates ferment mannitol and are now designated as *S. gallolyticus* subspecies *gallolyticus*. This organism causes human endocarditis and is frequently epidemiologically associated with colon carcinoma. DNA cluster II also includes *S. gallolyticus* subspecies *pasteurianus* (formerly *S. bovis* biotype II.2) and *S. gallolyticus* subspecies *macedonius*. *S. bovis* biotype II.1 is now in DNA cluster III and has the species name *Streptococcus infantarius*, which includes two subspecies (subsp. *infantarius* and subsp. *coli*). Biotype II bacteremias are often associated with biliary sources and less frequently with endocarditis. Finally, DNA cluster IV has one species, *Streptococcus alactolyticus*. Because of the confusing taxonomy and the failure of most automated or kit systems to discriminate to the subspecies level, most diagnostic microbiology laboratories will likely continue to refer to these organisms as either the *S. bovis* group or group D non-enterococci. All group D streptococci are nonhemolytic and PYR negative. They grow in the presence of bile and hydrolyze esculin (bile esculin positive) but do not grow in 6.5% NaCl. They are part of the normal enteric microbiota of humans and animals.

STREPTOCOCCUS ANGINOSUS GROUP

Other species names in the *S. anginosus* group are *S. constellatus* and *S. intermedius*. These streptococci are part of the normal microbiota of the throat, colon, and urogenital tract. They may be β -, α -, or nonhemolytic. *S. anginosus* group includes β -hemolytic streptococci that form minute colonies (<0.5 mm in diameter) and react with groups A, C, or G antisera and all β -hemolytic group F streptococci. Those that are group A are PYR negative. *S. anginosus* are Voges-Proskauer test positive. They may be classified as viridans streptococci. These organisms are frequently associated with serious infections such as brain, lung, and liver abscesses. They can be easily detected in the laboratory by their characteristic butter-scotch or caramel odor.

GROUPS E, F, G, H, AND K-U STREPTOCOCCI

These streptococci occur primarily in animals. One of the multiple species of group G streptococci, *Streptococcus canis*, can cause skin infections of dogs but uncommonly infects humans; other species of group G streptococci infect humans.

Concept Checks

- Streptococci that have Lancefield antigens other than group A are a diverse group of organisms that include other pyogenic streptococci (groups B, C, and G), streptococci that occur primarily in animals (E, H, and K–U), the *S. bovis* group (group D), and small colony variant members of the *S. anginosus* group (primarily group F).
- *S. agalactiae* (group B streptococci) are important pathogens among pregnant women and their neonates. Rectal and vaginal screening at 35–37 weeks of pregnancy and treatment of colonized moms during labor with penicillin has significantly reduced the incidence of early-onset neonatal group B streptococcal infections.
- Groups C and G streptococci cause infections similar to those of group A streptococci, including rare reports of poststreptococcal sequelae such as AGN and RF.
- The *S. bovis* group (group D non-enterococci) has undergone significant taxonomic reclassification. These organisms are PYR negative and bile esculin positive but do not grow in 6.5% NaCl. They are associated with bacteremia and endocarditis in patients with significant biliary tract disease or colon pathology, including carcinoma.
- Members of the *S. anginosus* group (include *S. intermedius* and *S. constellatus*) may be β -hemolytic, can possess Lancefield antigens A, C, F, and G; tend to be small colony variants (<0.5 mm); and are associated with brain, lung, and liver abscesses.

VIRIDANS STREPTOCOCCI

The many species of the viridans streptococci are classified into groups and include the *S. mitis* group, *S. anginosus* group (see above), *S. mutans* group, *Streptococcus salivarius* group, and *S. bovis* group (see above). Typically they are α -hemolytic, but they may also be nonhemolytic. As discussed earlier, members of the *S. anginosus* group can be β -hemolytic. Their growth is not inhibited by optochin, and colonies are not soluble in bile (deoxycholate). The viridans streptococci are the most prevalent members of the normal microbiota of the upper respiratory tract and are important for the healthy state of the mucous membranes there. They may reach the bloodstream as a result of trauma and are a principal cause of endocarditis on abnormal heart valves. Some viridans streptococci (eg, *S. mutans*) synthesize large polysaccharides, such

as dextrans or levans, from sucrose and contribute importantly to the genesis of dental caries.

In the course of bacteremia, viridans streptococci or enterococci and rarely pneumococci, may settle on normal or previously deformed heart valves, producing **acute endocarditis**. Rapid destruction of the valves frequently leads to fatal cardiac failure in days or weeks unless surgery can be performed to place a prosthetic valve during antimicrobial treatment or following therapy. More frequently, the viridans streptococci are associated with a subacute course.

Subacute endocarditis often involves abnormal valves (congenital deformities and rheumatic or atherosclerotic lesions). Although any organism reaching the bloodstream may establish itself on thrombotic lesions that develop on endothelium injured as a result of circulatory stresses, subacute endocarditis is most frequently caused by members of the normal microbiota of the respiratory or intestinal tract that have accidentally reached the blood. After dental extraction, at least 30% of patients have viridans streptococcal bacteremia. These streptococci, ordinarily the most prevalent members of the upper respiratory microbiota, are also the most frequent cause of subacute bacterial endocarditis. The group D streptococci (enterococci and *S. bovis*) also are common causes of subacute endocarditis. About 5–10% of cases are caused by enterococci originating in the gut or urinary tract. The lesion is slowly progressive, and a certain amount of healing accompanies the active inflammation; vegetations consist of fibrin, platelets, blood cells, and bacteria adherent to the valve leaflets. The clinical course is gradual, but the disease is invariably fatal in untreated cases. The typical clinical picture includes fever, anemia, weakness, a heart murmur, embolic phenomena, an enlarged spleen, and renal lesions.

α -Hemolytic streptococci and enterococci vary in their susceptibility to antimicrobial agents. Particularly in bacterial endocarditis, antibiotic susceptibility tests are useful to determine which drugs may be used for optimal therapy. Aminoglycosides often enhance the rate of bactericidal action of penicillin on streptococci, particularly enterococci.

NUTRITIONALLY VARIANT STREPTOCOCCI

The nutritionally variant streptococci (NVS) are now classified in the genus *Abiotrophia* (*Abiotrophia defectiva* is the sole species) and the genus *Granulicatella* (two species *Granulicatella adiacens* and *Granulicatella elegans*). They have also been known as “nutritionally deficient streptococci” and “pyridoxal-dependent streptococci.” They require pyridoxal or cysteine for growth on blood agar and may grow as satellite colonies around colonies of staphylococci and other bacteria that produce pyridoxal. Routinely supplementing blood agar medium with pyridoxal allows recovery of these organisms. They are usually α -hemolytic but may also

be nonhemolytic. MALDI-TOF MS has been shown to reliably differentiate them from streptococci and other catalase negative Gram-positive cocci. NVS are part of the normal microbiota and occasionally cause bacteremia or endocarditis and can be found in brain abscesses and other infections. Clinically, they are very similar to the viridans streptococci.

PEPTOSTREPTOCOCCUS AND RELATED GENERA

These streptococci grow only under anaerobic or microaerophilic conditions and variably produce hemolysins. They are part of the normal microbiota of the mouth, upper respiratory tract, bowel, and female genital tract. They often participate with many other bacterial species in mixed anaerobic infections (see Chapter 21). Such infections may occur in wounds, in the breast, in postpartum endometritis, after rupture of an abdominal viscus, in the brain, or in chronic suppuration of the lung. The pus usually has a foul odor.

STREPTOCOCCUS PNEUMONIAE

S. pneumoniae (pneumococci) is a member of the *S. mitis* group (see Table 14-1) and are indistinguishable from them on the basis of 16SrRNA. Pneumococci are Gram-positive diplococci, often lancet shaped or arranged in chains, possessing a capsule of polysaccharide that permits typing with specific antisera. Pneumococci are readily lysed by surface-active agents, which probably remove or inactivate the inhibitors of cell wall autolysins. Pneumococci are normal inhabitants of the upper respiratory tract of 5–40% of humans and can cause pneumonia, sinusitis, otitis, bronchitis, bacteremia, meningitis, peritonitis, and other infectious processes.

Morphology and Identification

A. Typical Organisms

The typical Gram-positive, lancet-shaped diplococci (Figure 14-3) are often seen in specimens of young cultures. In sputum or pus, single cocci or chains are also seen. With age, the organisms rapidly become Gram-negative and tend to lyse spontaneously. Autolysis of pneumococci is greatly enhanced by surface-active agents. Lysis of pneumococci occurs in a few minutes when ox bile (10%) or sodium deoxycholate (2%) is added to a broth culture or suspension of organisms at neutral pH. Viridans streptococci do not lyse and are thus easily differentiated from pneumococci. On solid media, the growth of pneumococci is inhibited around a disk of optochin; viridans streptococci are not inhibited by optochin (Figure 14-4).

Other identifying points include almost uniform virulence for mice when injected intraperitoneally and the “capsule swelling test,” or quellung reaction (see below).

FIGURE 14-3 *S. pneumoniae* in sputum are seen as lancet-shaped Gram-positive diplococci. Degenerating nuclei of polymorphonuclear cells are the large darker irregular red shapes (arrow). Mucus and amorphous debris are present in the background. Original magnification $\times 1000$.

B. Culture

Pneumococci form small round colonies, at first dome-shaped and later developing a central depression with an elevated rim. Other colonies may appear glistening because of capsular polysaccharide production. Pneumococci are α -hemolytic on blood agar. Growth is enhanced by 5–10% CO_2 .

C. Growth Characteristics

Most energy is obtained from fermentation of glucose; this is accompanied by the rapid production of lactic acid, which limits growth. Neutralization of broth cultures with alkali at intervals results in massive growth.

D. Variation

Pneumococcal isolates that produce large amounts of capsules appear as large mucoid colonies. Capsule production is not essential for growth on agar medium, and capsular production is therefore lost after a small number of subcultures. The pneumococci will, however, again produce capsules and have enhanced virulence if injected into mice.

Antigenic Structure

A. Component Structures

The pneumococcal cell wall has peptidoglycan and teichoic acid, similar to other streptococci. The capsular polysaccharide is covalently bound to the peptidoglycan and to the cell wall polysaccharide. The capsular polysaccharide is immunologically distinct for each of the 91 types. C-polysaccharide

that is found in the cell wall of all *S. pneumoniae* can be detected in the urine and cerebrospinal fluid (CSF) as useful diagnostic tests for pneumococcal infections.

B. Quellung Reaction

When pneumococci of a certain type are mixed with specific antipolysaccharide serum of the same type—or with polyvalent antiserum—on a microscope slide, the capsule swells markedly, and the organisms agglutinate by cross-linking of the antibodies (see Figure 14-4C). This reaction is useful for rapid identification and for typing of the organisms, either in sputum or in cultures. The polyvalent antiserum, which contains antibody to all of the types (“omniserum”), is a good reagent for rapid microscopic determination of whether or not pneumococci are present in fresh sputum. This test is rarely used because of the high reagent costs and the expertise required in assay performance and interpretation.

Pathogenesis

A. Types of Pneumococci

In adults, types 1–8 are responsible for about 75% of cases of pneumococcal pneumonia and for more than half of all fatalities in pneumococcal bacteremia; in children, types 6, 14, 19, and 23 are frequent causes.

B. Production of Disease

Pneumococci produce disease through their ability to multiply in the tissues. The virulence of the organism is a function of its capsule, which prevents or delays ingestion by phagocytes. A serum that contains antibodies against the type-specific polysaccharide protects against infection. If such a serum is absorbed with the type-specific polysaccharide, it loses its protective power. Animals or humans immunized with a given type of pneumococcal polysaccharide are subsequently immune to that type of pneumococcus and possess precipitating and opsonizing antibodies for that type of polysaccharide.

C. Loss of Natural Resistance

Because 40–70% of humans are at some time carriers of virulent pneumococci, the normal respiratory mucosa must possess great natural resistance to the pneumococcus. Among the factors that probably lower this resistance and thus predispose to pneumococcal infection are the following:

1. Viral and other respiratory tract infections that damage surface cells; abnormal accumulations of mucus (eg, allergy), which protect pneumococci from phagocytosis; bronchial obstruction (eg, atelectasis); and respiratory tract injury caused by irritants disturbing its mucociliary function.
2. Alcohol or drug intoxication, which depresses phagocytic activity, depresses the cough reflex, and facilitates aspiration of foreign material.

A

B

C

FIGURE 14-4 **A:** Optochin inhibition and bile solubility of *S. pneumoniae*. The *S. pneumoniae* were grown overnight on 5% sheep blood agar. The optochin (ethyl hydrocupreine HCl) or P disk was placed when the plate was inoculated. The pneumococci are α-hemolytic with greening of the agar around the colonies. The zone of inhibition around the P disk is larger than 14 mm, indicating that the organisms are pneumococci rather than viridans streptococci. A drop of desoxycholate (“bile”) solution was placed on the overnight growth just to the right of the P disk area (arrow); after about 20 minutes at room temperature, the colonies of pneumococci were solubilized (bile soluble). **B:** The growth of viridans streptococci appears similar to the growth of pneumococci, but growth of the viridans streptococci is not inhibited by optochin. **C:** *S. pneumoniae* quellung reaction: a small amount of growth is mixed with saline, antisera against the capsule polysaccharide, and methylene blue stain. After incubation at room temperature for 1 hour, the reaction is observed under the microscope. The organisms are outlined in light blue. A positive reaction shows clumping because of cross-linking of the antibodies and pneumococci. The halo effect around the pneumococci is apparent capsular swelling. A negative control would show no clumping or capsular swelling. (Courtesy of H. Reyes.)

3. Abnormal circulatory dynamics (eg, pulmonary congestion and heart failure).
4. Other mechanisms, such as malnutrition, general debility, sickle cell anemia, hyposplenism, nephrosis, or complement deficiency.

Pathology

Pneumococcal infection causes an outpouring of fibrinous edema fluid into the alveoli followed by red blood cells and leukocytes, which results in consolidation of portions of the lung. Many pneumococci are found throughout this exudate, and they may reach the bloodstream via the lymphatic drainage of the lungs. The alveolar walls remain normally intact during the infection. Later, mononuclear cells actively phagocytose the debris, and this liquid phase is gradually reabsorbed. The pneumococci are taken up by phagocytes and digested intracellularly.

Clinical Findings

The onset of pneumococcal pneumonia is usually sudden, with fever, chills, and sharp pleural pain. The sputum is similar to the alveolar exudate, being characteristically bloody or rusty colored. Early in the disease, when the fever is high, bacteremia is present in 10–20% of cases. With antimicrobial therapy, the illness is usually terminated promptly; if drugs are given early, the development of consolidation is interrupted.

Pneumococcal pneumonia must be differentiated from pulmonary infarction, atelectasis, neoplasm, congestive heart failure, and pneumonia caused by many other bacteria. Empyema (pus in the pleural space) is a significant complication and requires aspiration and drainage.

From the respiratory tract, pneumococci may reach other sites. The sinuses and middle ear are most frequently involved. Infection sometimes extends from the mastoid to the meninges. Bacteremia from pneumonia has a triad of severe complications: meningitis, endocarditis, and septic arthritis. With the early use of chemotherapy, acute pneumococcal endocarditis and arthritis have become rare.

Diagnostic Laboratory Tests

Blood is drawn for culture; CSF and sputum are collected for demonstration of pneumococci by smear and culture. CSF and urine can be used to detect pneumococcal C-polysaccharide by rapid immunochromatographic membrane assays. Serum antibody tests are impractical. All specimens should be sent to the microbiology laboratory as soon as possible after collection because pneumococci tend to autolyse and delay will significantly impact recovery by culture. Sputum may be examined in several ways.

A. Stained Smears

A Gram-stained film of rusty-red sputum shows typical organisms, many polymorphonuclear neutrophils, and many red blood cells.

B. Capsule Swelling Tests

Fresh emulsified sputum mixed with antiserum causes capsule swelling (the quellung reaction) for identification of pneumococci.

C. Culture

The culture is created by inoculating sputum to blood agar and incubating the plate in CO₂ at 37°C. A blood culture is also usually obtained.

D. Nucleic Acid Amplification Tests

Several manufacturers have included *S. pneumoniae* on panels for identification of positive blood culture bottles and several of these assays are FDA cleared. Also, in development are panel tests for meningitis and separate molecular panels for direct detection of *S. pneumoniae* in respiratory samples obtained from specimens in patients suspected of having community acquired or health care-associated pneumonia.

E. Immunity

Immunity to infection with pneumococci is type specific and depends both on antibodies to capsular polysaccharide and on intact phagocytic function. Vaccines can induce production of antibodies to capsular polysaccharides (see later discussion).

Treatment

Over the last several decades, pneumococci have become increasingly more resistant to a broad range of antimicrobial agents. Penicillin G can no longer be considered the empiric agent of choice. Around 15% of pneumococci from nonmeningeal sources are penicillin resistant (minimum inhibitory concentration [MIC] \geq 8 μ g/mL). High-dose penicillin G appears to be effective in treating pneumonia caused by pneumococci with MICs to penicillin below 8 μ g/mL (resistant breakpoint) but would not be effective in treatment of meningitis caused by the same strains. Some penicillin-resistant strains are resistant to cefotaxime. Resistance to tetracycline, erythromycin, and fluoroquinolones also occurs. Pneumococci remain susceptible to vancomycin. Because resistance profiles are not predictable, routine susceptibility testing using a method that can determine MIC values for isolates from sterile sites should be performed for all pneumococcal infections.

Epidemiology, Prevention, and Control

Pneumococcal pneumonia accounts for about 60% of all bacterial pneumonias. In the development of illness, predisposing factors (see earlier discussion) are more important than exposure to the infectious agent, and a healthy carrier is more important in disseminating pneumococci than a sick patient.

It is possible to immunize individuals with type-specific polysaccharides. Such vaccines can probably provide 90%

protection against bacteremic pneumonia. A polysaccharide vaccine containing 23 types (PPSV23) is licensed in the United States. A pneumococcal conjugate vaccine contains capsular polysaccharides conjugated to diphtheria CRM₁₉₇ protein. The current conjugate vaccine is a 13-valent one (PCV13, Prevnar 13, Wyeth Pharmaceuticals). PCV13 contains the polysaccharide conjugates of the serotypes found in the PCV7 vaccine (4, 6B, 9V, 14, 18C, 19F, 23 F) plus serotypes 1, 3, 5, 6A, 7F, and 19A. It is recommended for all children as a four-dose series at 2, 4, 6, and 12–15 months of age. Children younger than 24 months of age who began their vaccination with PCV-7 and who have received one or more doses can complete the series with PCV-13. Older children and those with underlying medical conditions who were fully vaccinated with PCV-7 should receive a single dose of PCV-13.

Adults 19 years of age or older with immunocompromising conditions should receive both PPSV23 and PCV13. The schedule for vaccine administration depends upon the timing and type of prior vaccination. The reader is referred to the latest recommendations published by the Centers for Disease Control and Prevention for current guidelines and schedules (<http://www.cdc.gov/vaccines/schedules/downloads/adult/adult-combined-schedule.pdf>). In 2014, in addition to the existing recommendation to receive PPSV23, persons more than 65 years of age should now also receive one dose of PCV13. See above-mentioned guidelines for complete information.

ENTEROCOCCI

Enterococci are Gram-positive, catalase-negative, facultatively anaerobic bacteria that are usually oval-shaped and are arranged in pairs or short chains; occasionally, single organisms can be seen as well. The enterococci possess the group D group-specific substance and were therefore previously classified as group D streptococci. Because the group D cell wall-specific antigen is a teichoic acid, it is not an antigenically good marker; enterococci are usually identified by characteristics other than immunologic reactions with group-specific antisera. There are at least 47 species of enterococci, but less than one-third of these are associated with disease in humans, with *Enterococcus faecalis* and *Enterococcus faecium* being the two species most commonly isolated from clinical specimens. Enterococci are part of the normal enteric microbiota.

Morphology and Identification

Enterococcus species grow readily on nonselective media, such as sheep-blood agar and chocolate agar. Enterococci are usually nonhemolytic, but are occasionally α -hemolytic, or rarely β -hemolytic. While enterococci can sometimes resemble *S. pneumoniae* on Gram-stains, prepared directly from clinical specimens, the organisms can be readily differentiated on the basis of various simple biochemical tests. *Enterococcus* species are resistant to optochin and colonies do not dissolve when exposed to bile, whereas *S. pneumoniae* is optochin-susceptible

and bile soluble. Furthermore, enterococci are PYR positive, grow in the presence of bile, hydrolyze esculin (bile-esculin positive), and in contrast to non-enterococcal group D streptococci, enterococci grow well in 6.5% NaCl. Enterococci grow well at a wide temperature range between 10°C and 45°C, streptococci generally grow at a much narrower temperature range. In the laboratory, enterococci can be readily identified using commercially available semiautomated or automated bacterial identification systems; organism identification based on biochemical properties can be cumbersome and time consuming. Alternatively, enterococci can be identified by MALDI-TOF mass spectrometry or by molecular test methods (eg, PCR).

Pathogenesis and Pathology

To date, the pathogenesis of enterococcal infections is poorly understood; however, several potential virulence factors have been identified. Most enterococcal infections appear to arise from the endogenous flora via translocation from their major colonization site (GI tract). In general, virulence is mediated by two major properties, including (intrinsic) antimicrobial resistance of enterococci as well as their ability to adhere to cells and tissues and form biofilms. Several potential virulence factors have been identified and may play a role in the pathogenesis of enterococcal infections. These virulence factors include surface adhesion proteins, membrane glycolipids, secreted toxins (eg, cytolysin and hemolysin), secreted proteases (eg, gelatinase), and extracellular superoxide. However, none of these virulence factors has yet been established as a major contributor and/or cause for enterococcal infections in humans.

Clinical Findings

Enterococci are commensal bacteria and part of the normal enteric microbiota. *E. faecalis* and *E. faecium* are the most commonly isolated enterococcal species causing infections in humans. Other, less frequently encountered enterococci include *Enterococcus gallinarum*, *Enterococcus casseliflavus*, and *E. raffinosus*. Historically, *E. faecalis* has been recognized as the most commonly isolated species causing 85–90% of enterococcal infections; *E. faecium* causes 5–10%. However, in recent years these percentages have been changing, recognizing a rise in infections due to *E. faecium*, particularly as a cause of blood stream infections. In hospitalized patients, the most common sites of infection are the urinary tract, burn and surgical wounds, biliary tract, and blood. Urinary tract infections (UTIs) are by far the most common form of enterococcal infections, and are frequently associated with indwelling catheters, instrumentation, or structural abnormalities of the genitourinary tract. Intraabdominal and pelvic infections are also frequently caused by enterococci. However, these infections are often polymicrobial, as are UTIs and wound infections. In such cases, it may be difficult to define the exact pathogenic role of the enterococci in the infection.

Bacteremia and endocarditis are also common forms of enterococcal infections, and are frequently associated with metastatic abscesses and high mortality rates. Infections of the respiratory tract (eg, pneumonia, otitis, and sinusitis) and/or the central nervous system (eg, meningitis) have been described, but occur rarely. Two forms of enterococcal meningitis have been described: spontaneous and postoperative meningitis. Spontaneous meningitis is typically a community-associated infection in patients with severe comorbidities (eg, diabetes, chronic renal failure, and immunosuppression), whereas postoperative meningitis is a hospital-acquired infection (eg, associated with ventricular shunt devices, CNS electrodes). Neonatal infections due to enterococci have also been described. Enterococci are part of the normal adult vaginal microbiota, and can therefore be acquired by neonates during vaginal delivery. Neonatal enterococcal infections are typically late-onset sepsis, pneumonia, but other infections such as UTIs, surgical site infections, and meningitis have also been described.

Treatment and Antibiotic Resistance

Treatment of enterococcal infection can be challenging to clinicians due to the fact that enterococci are frequently resistant to various antibiotics. Traditionally, therapy for systemic enterococcal infections consists of the combination of a cell-wall active antibiotic (eg, ampicillin or vancomycin) with an aminoglycoside. However, some cell-wall active antibiotics (eg, oxacillin and cephalosporins) have no activity against enterococci. In addition, enterococci have developed resistance against some of the commonly used cell-wall active antibiotics (eg, vancomycin). While newer antibiotics have been developed, including linezolid, quinupristin–dalfopristin, daptomycin, enterococci quickly developed resistance to some of these newer antibiotics as well. *E. faecium* is usually much more resistant to antibiotics when compared to *E. faecalis*. Antimicrobial resistance is classified as either intrinsic or acquired; intrinsic resistance is related to inherent or natural chromosomally encoded resistance patterns, many of which are present in all or most of the enterococci.

A. Intrinsic Resistance

Enterococci are intrinsically resistant to cephalosporins, penicillinase-resistant penicillins, and monobactams. They have intrinsic low-level resistance to many aminoglycosides, are of intermediate susceptibility or resistant to fluoroquinolones, and are less susceptible than streptococci (10- to 1000-fold) to penicillin and ampicillin. Enterococci are inhibited by β -lactams (eg, ampicillin) but generally are not killed by them. High-level resistance to penicillin and ampicillin is most often due to altered penicillin-binding proteins; β -lactamase producing strains have been rarely identified. In addition, few enterococci (ie, *E. casseliflavus* and *E. gallinarum*) are considered to be intrinsically resistant to vancomycin. This is a low-level, constitutive resistance which is chromosomally encoded by the VanC gene.

B. Resistance to Aminoglycosides

Therapy with combinations of a cell wall-active antibiotic (a penicillin or vancomycin) plus an aminoglycoside (streptomycin or gentamicin) is essential for severe enterococcal infections, such as endocarditis. Although enterococci have intrinsic low-level resistance to aminoglycosides (MICs < 500 μ g/mL), they have synergistic susceptibility when treated with a cell wall-active antibiotic plus an aminoglycoside. However, some enterococci have high-level resistance to aminoglycosides (MICs > 500 μ g/mL) and are not susceptible to the synergism. This high-level aminoglycoside resistance is due to enterococcal aminoglycoside-modifying enzymes. The genes that code for most of these enzymes are usually on conjugative plasmids or transposons. The enzymes have differential activity against the aminoglycosides. Resistance to gentamicin predicts resistance to the other aminoglycosides except streptomycin. (Susceptibility to gentamicin does not predict susceptibility to other aminoglycosides.) Resistance to streptomycin does not predict resistance to other aminoglycosides. The result is that only streptomycin or gentamicin (or both or neither) is likely to show synergistic activity with a cell wall-active antibiotic against enterococci. Enterococci from severe infections should have susceptibility tests for high-level aminoglycoside resistance (MICs > 500 μ g/mL for gentamicin and >1000 μ g/mL for streptomycin in broth media) to predict therapeutic efficacy.

C. Vancomycin Resistance

The glycopeptide vancomycin is the primary alternative drug to the beta-lactam/aminoglycoside combination (eg, penicillin plus gentamicin or streptomycin) for treating enterococcal infections. In the United States, enterococci that are resistant to vancomycin have increased in frequency. These enterococci are not synergistically susceptible to vancomycin plus an aminoglycoside. Vancomycin resistance has been most common in *E. faecium*, but vancomycin-resistant strains of *E. faecalis* also occur.

There are multiple **vancomycin resistance genotypes and phenotypes**. The VanA phenotype is manifested by inducible high-level resistance to vancomycin and teicoplanin. VanB phenotypes are inducibly resistant to vancomycin but susceptible to teicoplanin. VanC strains have intermediate to moderate resistance to vancomycin. VanC is constitutive in the less commonly isolated species, *E. gallinarum* (VanC-1) and *E. casseliflavus* (VanC-2/VanC-3). The VanD phenotype is manifested by moderate resistance to vancomycin and low-level resistance or susceptibility to teicoplanin. The VanE phenotype is classified as low-level resistance to vancomycin and susceptibility to teicoplanin. VanG and VanL isolates (usually *E. faecalis*) have low-level resistance to vancomycin and are susceptible to teicoplanin.

Teicoplanin is a glycopeptide with many similarities to vancomycin. It is available for patients in Europe but not in the United States. It has importance in investigation of the vancomycin resistance phenotype of enterococci.

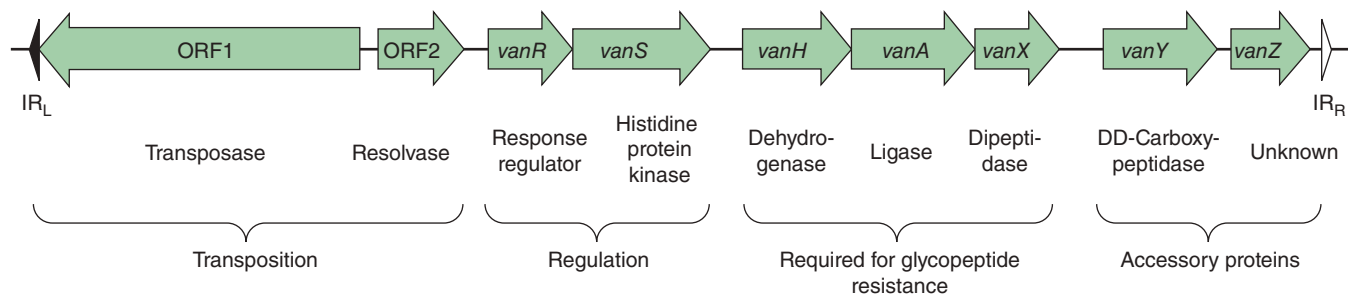

FIGURE 14-5 Schematic map of transposon Tn1546 from *E. faecium* that codes for vancomycin resistance. IR_L and IR_R indicate the left and right inverted repeats of the transposon, respectively. (Adapted and reproduced with permission from Arthur M, Courvalin P: Genetics and mechanisms of glycopeptide resistance in enterococci. *Antimicrob Agents Chemother* 1993;37:1563.)

Vancomycin and teicoplanin interfere with cell wall synthesis in Gram-positive bacteria by interacting with the D-alanyl-D-alanine (D-Ala-D-Ala) group of the pentapeptide chains of peptidoglycan precursors. The best-studied vancomycin resistance determinant is the VanA operon. It is a system of genes packaged in a self-transferable plasmid containing a transposon closely related to Tn1546 (Figure 14-5). There are two open reading frames that code for transposase and resolvase; the remaining seven genes code for vancomycin resistance and accessory proteins. The *vanR* and *vanS* genes are a two-component regulatory system sensitive to the presence of vancomycin or teicoplanin in the environment. *vanH*, *vanA*, and *vanX* are required for vancomycin resistance. *vanH* and *vanA* encode for proteins that manufacture the depsipeptide (D-Ala-D-lactate) rather than the normal peptide (D-Ala-D-Ala). The depsipeptide, when linked to UDP-muramyl-tripeptide, forms a pentapeptide precursor that vancomycin and teicoplanin will not bind to. *vanX* encodes a dipeptidase that depletes the environment of the normal D-Ala-D-Ala dipeptide. *vanY* and *vanZ* are not essential for vancomycin resistance. *vanY* encodes a carboxypeptidase that cleaves the terminal D-Ala from the pentapeptide, depleting the environment of any functional pentapeptide that may have been manufactured by the normal cell wall building process. *vanZ*'s function is unclear.

Similar to *vanA*, *vanB*, and *vanD* code for D-Ala-D-Lac, but *vanC* and *vanE* code for D-Ala-D-Ser.

Because enterococci that are resistant to vancomycin frequently carry plasmids that confer resistance to ampicillin and the aminoglycosides, newer agents such as daptomycin, linezolid, quinupristin-dalfopristin, and tigecycline (among others) are used for treatment of vancomycin-resistant enterococci (VRE) infections (see Chapter 28).

D. Trimethoprim-Sulfamethoxazole Resistance

Enterococci often show susceptibility to trimethoprim-sulfamethoxazole by in vitro testing, but the drugs are not effective in treating infections. This discrepancy is because enterococci are able to utilize exogenous folates available in vivo and thus escape inhibition by the drugs.

Epidemiology, Prevention, and Control

E. faecalis and *E. faecium* are the two most common enterococcal species causing infections in humans. In general, and based on their intrinsic properties, enterococci are capable of surviving under harsh environmental conditions, and have adapted to various ecological niches. In humans, they are predominantly inhabitants of the intestinal microbiota, and are considered an important opportunistic pathogen. Considering the high numbers of enterococci present in feces, combined with their ability to survive harsh environmental conditions, enterococci may also serve as indicators for fecal contamination and hygienic quality (eg, for food and water). The enterococci are among the most frequent causes of health care-associated infections, particularly in intensive care units, and are selected for by therapy with cephalosporins and other antibiotics to which they are resistant. In addition, enterococci can be transmitted from one patient to another patient primarily by the hands of hospital personnel, some of whom may even carry the organisms in their gastrointestinal tracts. The organisms can survive on the hands, gloves, and gowns of health care workers for extended periods of time, representing probably the most common source of transmission of vancomycin-resistant enterococci in health care settings. Enterococci occasionally are transmitted on medical devices. The Society for Healthcare Epidemiology of America has published comprehensive guidelines to prevent such transmission of enterococci. However, prevention and control of enterococcal infections in the health care setting continues to present major challenges; careful and restrictive use of antibiotics and implementation of appropriate infection-control practices remain to be the cornerstones to reduce the risk of colonization and/or infection with enterococci.

OTHER CATALASE-NEGATIVE GRAM-POSITIVE COCCI

There are nonstreptococcal Gram-positive cocci or coccobacilli that are causing disease with increasing frequency (Table 14-2). These organisms have many growth and

TABLE 14-2 Most Frequently Encountered Non-streptococcal Catalase-Negative Gram-Positive Cocci and Coccobacilli

Genus ^a	Catalase	Gram-Stain	Vancomycin Susceptibility	Comments
<i>Abiotrophia</i> ^b (nutritionally variant streptococcus)	Negative	Cocci in pairs, short chains	Susceptible	Normal microbiota of oral cavity; isolated from cases of endocarditis
<i>Aerococcus</i>	Negative to weakly positive	Cocci in tetrads and clusters	Susceptible	Environmental organisms occasionally isolated from blood, urine, or sterile sites
<i>E. faecalis</i> , <i>E. faecium</i> (and other enterococci)	Negative	Cocci in pairs, short chains, or occur as single organisms	Some are resistant, mostly <i>E. faecium</i>	Abdominal abscess, urinary tract infection, endocarditis
<i>Gemella</i>	Negative	Cocci in pairs, tetrads, clusters, and short chains	Susceptible	Decolorize easily and may look Gram-negative; grow slowly (48 hours); part of normal human microbiota; occasionally isolated from blood and sterile sites
<i>Granulicatella</i> ^b (nutritionally variant streptococcus)	Negative	Cocci in chains, clusters	Susceptible	Normal microbiota of oral cavity; isolated from cases of endocarditis
<i>Leuconostoc</i>	Negative	Cocci in pairs and chains; coccobacilli, rods	Resistant	Environmental organisms; look like enterococci on blood agar; isolated from a wide variety of infections
<i>Pediococcus</i>	Negative	Cocci in pairs, tetrads, and clusters	Resistant	Present in food products and human stools; occasionally isolated from blood and abscesses
<i>Lactobacillus</i>	Negative	Coccobacilli, rods in pairs and chains	Resistant (90%)	Aerotolerant anaerobes generally classified as bacilli; normal vaginal flora; occasionally found in deep-seated infections

^aOther genera in which isolates from humans are rare or uncommon include *Dolosicoccus*, *Dolosigranulum*, *Facklamia*, *Globicatella*, *Helcococcus*, *Ignavigranum*, *Lactococcus*, *Tetragenococcus*, *Vagococcus*, and *Weissella*.
^bRequire pyridoxal for growth.

morphologic characteristics similar to viridans streptococci. They may be α -hemolytic or nonhemolytic. Most of them are catalase negative; others may be weakly catalase positive. *Pediococcus* and *Leuconostoc* are the genera whose members are **vancomycin resistant**. Lactobacilli are anaerobes that can be aerotolerant and α -hemolytic, sometimes forming coccobacillary forms similar to the viridans streptococci. Most **lactobacilli** (80–90%) are vancomycin resistant. Other organisms that occasionally cause disease and should be differentiated from streptococci and enterococci include *Lactococcus*, *Aerococcus*, and *Gemella*, genera that generally are **vancomycin susceptible**. *Rothia mucilaginosa* was previously considered a *Staphylococcus*, but it is catalase negative; colonies show a distinct adherence to agar.

CHAPTER SUMMARY

- Viridans streptococci and enterococci are part of the normal microbiota of the human oral and gastrointestinal

tracts, but they can be associated with serious infections, such as bacteremia and endocarditis under certain conditions.

- *S. pneumoniae* is α -hemolytic; optochin susceptible; and virulent largely because of its polysaccharide capsule, which inhibits phagocytosis.
- *S. pneumoniae* is the major cause of community-acquired pneumonia but can also disseminate via the bloodstream to the central nervous system. Invasive disease is preventable through vaccination using either the 23-valent polysaccharide vaccine (adults) or the 13-valent conjugate vaccine (children). Drug resistance has become a problem in certain geographic regions.
- Enterococci are remarkable for the varieties of resistance determinants they have evolved that include β -lactam agents, glycopeptides, and aminoglycosides, among others. Newer agents such as linezolid and tedizolid are used for treatment of VRE infections. These organisms play a prominent role in health care-associated infections.

REVIEW QUESTIONS

1. A 48-year-old alcoholic man is admitted to a hospital because of stupor. He is unkempt and homeless and lives in an encampment with other homeless people, who called the authorities when he could not be easily aroused. His temperature is 38.5°C, and his blood pressure 125/80 mm Hg. He moans when attempts are made to arouse him. He has positive Kernig and Brudzinski signs, suggesting meningeal irritation. Physical examination and chest radiography show evidence of left lower lobe lung consolidation. An endotracheal aspirate yields rust-colored sputum. Examination of a Gram-stained sputum smear shows numerous polymorphonuclear cells and numerous Gram-positive lancet-shaped diplococci. On lumbar puncture, the cerebrospinal fluid is cloudy and has a white blood cell count of 570/ μ L with 95% polymorphonuclear cells; Gram-stain shows numerous Gram-positive diplococci. Based on this information, the likely diagnosis is
 - (A) Pneumonia and meningitis caused by *S. aureus*
 - (B) Pneumonia and meningitis caused by *S. pyogenes*
 - (C) Pneumonia and meningitis caused by *S. pneumoniae*
 - (D) Pneumonia and meningitis caused by *E. faecalis*
 - (E) Pneumonia and meningitis caused by *Neisseria meningitidis*
2. The patient in Question 1 is started on antibiotic therapy to cover many possible microorganisms. Subsequently, culture of sputum and cerebrospinal fluid yields Gram-positive diplococci with a minimum inhibitory concentration to penicillin G of greater than 2 μ g/mL. The drug of choice for this patient until further susceptibility testing can be done is
 - (A) Penicillin G
 - (B) Nafcillin
 - (C) Trimethoprim-sulfamethoxazole
 - (D) Gentamicin
 - (E) Vancomycin
3. This infection (Question 1) might have been prevented by
 - (A) Prophylactic intramuscular benzathine penicillin every 3 weeks
 - (B) A 23-valent capsular polysaccharide vaccine
 - (C) A vaccine against serogroups A, C, Y, and W135 capsular polysaccharide
 - (D) A vaccine of polyribosylribitol capsular polysaccharide covalently linked to a protein
 - (E) Oral penicillin twice daily
4. The pathogenesis of the organism causing the infection (Question 1) includes which of the following?
 - (A) Invasion of cells lining the alveoli and entry into the pulmonary venule circulation
 - (B) Resistance to phagocytosis mediated by M proteins
 - (C) Migration to mediastinal lymph nodes where hemorrhage occurs
 - (D) Lysis of the phagocytic vacuole and release into the circulation
 - (E) Inhibition of phagocytosis by a polysaccharide capsule
5. A 13-valent capsular polysaccharide protein conjugate vaccine for the pathogen in Question 1 is recommended
 - (A) For children up to age 18 years and for selected adults
 - (B) Only on exposure to a patient with disease caused by the organism
 - (C) For all children ages 2–23 months plus selected older children and adults with immunocompromising conditions
 - (D) For children ages 24–72 months
 - (E) For all age groups older than age 2 months
6. An 8-year-old boy develops a severe sore throat. On examination, a grayish-white exudate is seen on the tonsils and pharynx. The differential diagnosis includes group A streptococcal infection, Epstein-Barr virus infection, severe adenovirus infection, and diphtheria. (*Neisseria gonorrhoeae* pharyngitis would also be included, but the patient has not been sexually abused.) The cause of the boy's pharyngitis is most likely
 - (A) A catalase-negative Gram-positive coccus that grows in chains
 - (B) A single-stranded positive-sense RNA virus
 - (C) A catalase-positive Gram-positive coccus that grows in clusters
 - (D) A catalase-negative Gram-positive bacillus
 - (E) A double-stranded RNA virus
7. A primary mechanism responsible for the pathogenesis of the boy's disease (Question 6) is
 - (A) A net increase in intracellular cyclic adenosine monophosphate
 - (B) Action of M protein
 - (C) Action of IgA1 protease
 - (D) Action of enterotoxin A
 - (E) Inactivation of elongation factor 2
8. A 40-year-old woman develops severe headache and fever. Her neurologic examination findings are normal. A brain scan shows a ring-enhancing lesion of the left hemisphere. During surgery, a brain abscess is found. Culture of the abscess fluid grows an anaerobic Gram-negative bacillus (*Fusobacterium nucleatum*) and a catalase-negative Gram-positive coccus that on Gram-stain is in pairs and chains. The organism is β -hemolytic and forms very small colonies (<0.5 mm in diameter). One person thought it smelled like butterscotch. It agglutinates with group F antisera. The organism most likely is
 - (A) *S. pyogenes* (group A)
 - (B) *E. faecalis* (group D)
 - (C) *S. agalactiae* (group B)
 - (D) *S. anginosus* group
 - (E) *S. aureus*
9. Important methods for classifying and speciating streptococci are
 - (A) Agglutination using antisera against the cell wall group-specific substance
 - (B) Biochemical testing
 - (C) Hemolytic properties (α -, β -, nonhemolytic)
 - (D) Capsular swelling (quellung) reaction
 - (E) All of the above
10. An 8-year-old girl develops Sydenham's chorea ("St. Vitus dance") with rapid uncoordinated facial tics and involuntary purposeless movements of her extremities, strongly suggestive of acute rheumatic fever. She has no other major manifestations of rheumatic fever (carditis, arthritis, subcutaneous nodules, skin rash). The patient's throat culture is negative for *S. pyogenes* (group A streptococci). However, she, her brother,

- and her mother all had sore throats 2 months ago. A test that if positive would indicate recent *S. pyogenes* infections is
- (A) Antistreptolysin S antibody titer
 - (B) Polymerase chain reaction for antibodies against M protein
 - (C) ASO antibody titer
 - (D) Esculin hydrolysis
 - (E) Antihyaluronic acid antibody titer
11. All of the following statements regarding the hyaluronic acid capsule of *S. pyogenes* are correct *except*
- (A) It is responsible for the mucoid appearance of the colonies in vitro.
 - (B) It is antiphagocytic.
 - (C) It binds to CD44 on human epithelial cells.
 - (D) It is an important virulence factor.
 - (E) A vaccine against the capsule is currently available.
12. Enterococci can be distinguished from nonenterococcal group D streptococci on the basis of which of the following characteristics?
- (A) γ -Hemolysis
 - (B) Esculin hydrolysis
 - (C) Growth in 6.5% NaCl
 - (D) Growth in the presence of bile
 - (E) Gram-stain morphology
13. Which of the following statements regarding the *S. bovis* group is correct?
- (A) They possess Lancefield group D antigen.
 - (B) Some strains are vancomycin resistant.
 - (C) Infections caused by these organisms are benign.
 - (D) All subspecies are PYR positive.
 - (E) All subspecies are β -hemolytic.
14. Which of the following genera requires pyridoxal for growth?
- (A) *Aerococcus*
 - (B) *Granulicatella*
 - (C) *Enterococcus*
 - (D) *Leuconostoc*
 - (E) *Pediococcus*
15. Which of the following genera is typically resistant to vancomycin?
- (A) *Aerococcus*
 - (B) *Gemella*
 - (C) *Pediococcus*
 - (D) *Streptococcus*
 - (E) *Abiotrophia*

Enteric Gram-Negative Rods (*Enterobacteriaceae*)

The Enterobacteriaceae are a large, heterogeneous group of Gram-negative rods whose natural habitat is the intestinal tract of humans and animals. The family includes many genera (*Escherichia*, *Shigella*, *Salmonella*, *Enterobacter*, *Klebsiella*, *Serratia*, *Proteus*, and others). Some enteric organisms, such as *Escherichia coli*, are part of the normal microbiota and incidentally cause disease, but others, the salmonellae and shigellae, are regularly pathogenic for humans. The Enterobacteriaceae are facultative anaerobes or aerobes, ferment a wide range of carbohydrates, possess a complex antigenic structure, and produce a variety of toxins and other virulence factors. Enterobacteriaceae, enteric Gram-negative rods, and enteric bacteria are the terms used in this chapter, but these bacteria may also be called coliforms.

CLASSIFICATION

The Enterobacteriaceae are the most common group of Gram-negative rods cultured in clinical laboratories and along with staphylococci and streptococci are among the most common bacteria that cause disease. The taxonomy of the Enterobacteriaceae is complex and rapidly changing since the introduction of techniques that measure evolutionary distance, such as nucleic acid hybridization and nucleic acid sequencing. According to the National Library of Medicine's Internet Taxonomy database (available at <https://www.ncbi.nlm.nih.gov/Taxonomy/Browser/wwwtax.cgi?mode=Tree&id=543&lvl=3&lin=f&keep=1&srchmode=1&unlock>), 63 genera have been defined; however, the clinically significant Enterobacteriaceae comprise 20–25 species, and other species are encountered infrequently. In this chapter, taxonomic refinements will be minimized, and the names commonly used in the medical literature are generally used. A comprehensive approach to identification of the Enterobacteriaceae is presented in Chapters 33, 37, and 38 of Jorgensen et al, 2015.

Members of the family Enterobacteriaceae have the following characteristics: They are Gram-negative rods, either motile with peritrichous flagella or nonmotile; grow on peptone or meat extract media without the addition of sodium chloride or other supplements; grow well on MacConkey agar; grow aerobically and anaerobically (are facultative anaerobes); ferment rather than oxidize glucose, often

with gas production; are catalase positive, oxidase negative (except for *Plesiomonas*) and reduce nitrate to nitrite; and have a 39–59% G + C DNA content. Members of the Enterobacteriaceae family can be differentiated to species level by a vast array of biochemical tests. Commercially prepared kits or automated systems are used to a large extent for this purpose by the majority of clinical microbiology laboratories in the United States. However, these traditional methods for organism identification are being replaced by other methods over the past years; the implementation of matrix-assisted laser desorption ionization time of flight mass spectroscopy (MALDI-TOF MS) for identification of culture isolates is in fact replacing the more traditional panels of biochemicals currently in use in most clinical microbiology laboratories. This new technology seems to work quite well for identification of most of the common Enterobacteriaceae encountered in clinical material except for *Shigella* species. MALDI-TOF MS technology is unable to reliably differentiate *Shigella* species from *E. coli*.

The major and clinically relevant genera and species of Enterobacteriaceae are discussed briefly in the following paragraphs. Specific characteristics of salmonellae, shigellae, and the other medically important enteric Gram-negative rods and the diseases they cause are discussed separately in the second part of this chapter.

Morphology and Identification

A. Typical Organisms

The Enterobacteriaceae are short Gram-negative rods (Figure 15-1A). Typical morphology is seen in growth on solid media in vitro, but morphology is highly variable in clinical specimens. Capsules are large and regular in *Klebsiella* species, less so in *Enterobacter* species, and uncommon in the other species.

B. Culture

E. coli and most of the other enteric bacteria form circular, convex, smooth colonies with distinct edges. *Enterobacter* colonies are similar but somewhat more mucoid. *Klebsiella* colonies are large and very mucoid and tend to coalesce with prolonged incubation. The salmonellae and shigellae produce

A

B

FIGURE 15-1 **A:** Gram-stain of *E. coli*. Original magnification $\times 1000$. (Courtesy of H Reyes.) **B:** Antigenic structure of Enterobacteriaceae.

colonies similar to *E. coli* but do not ferment lactose. Some strains of *E. coli* produce hemolysis on blood agar.

C. Growth Characteristics

Carbohydrate fermentation patterns and the activity of amino acid decarboxylases and other enzymes are used in biochemical differentiation. Some tests, such as the production of indole from tryptophan, are commonly used in rapid identification systems, but others, such as the Voges-Proskauer reaction (production of acetylmethylcarbinol from dextrose), are used less often. Culture on “differential” media that contain special dyes and carbohydrates (eg, eosin-methylene blue [EMB], MacConkey, or deoxycholate medium) distinguishes lactose-fermenting (colored) from non-lactose-fermenting colonies (nonpigmented) and may allow rapid presumptive identification of enteric bacteria (Table 15-1).

Many complex media have been devised to help in identification of the enteric bacteria. One such medium is triple sugar iron (TSI) agar, which is often used to help differentiate salmonellae and shigellae from other enteric Gram-negative rods in stool cultures. The medium contains 0.1% glucose, 1% sucrose, 1% lactose, ferrous sulfate (for detection of H_2S production), tissue extracts (protein growth substrate), and a pH indicator (phenol red). It is poured into a test tube to produce a slant with a deep butt and is inoculated by stabbing bacterial growth into the butt. If only glucose is fermented, the slant and the butt initially turn yellow from the small amount of acid produced; as the fermentation products are subsequently oxidized to CO_2 and H_2O and released from the slant and as oxidative decarboxylation of proteins continues with formation of amines, the slant turns alkaline (red). If lactose or sucrose is fermented, so much acid is produced that the

slant and butt remain yellow (acid). Salmonellae and shigellae typically yield an alkaline slant and an acid butt. Although *Proteus*, *Providencia*, and *Morganella* species produce an alkaline slant and acid butt, they can be identified by their rapid formation of red color in Christensen’s urea medium. Organisms producing acid on the slant and acid and gas (bubbles) in the butt are other enteric bacteria.

- 1. **Escherichia**—*E. coli* typically produces positive test results for indole, lysine decarboxylase, and mannitol fermentation and produces gas from glucose. An isolate from urine can be quickly identified as *E. coli* by its hemolysis

TABLE 15-1 Rapid, Presumptive Identification of Gram-Negative Enteric Bacteria

Lactose fermented rapidly <i>Escherichia coli</i> : metallic sheen on differential media; motile; flat, nonviscous colonies <i>Enterobacter aerogenes</i> : raised colonies, no metallic sheen; often motile; more viscous growth <i>Enterobacter cloacae</i> : similar to <i>Enterobacter aerogenes</i> <i>Klebsiella pneumoniae</i> : very viscous, mucoid growth; nonmotile
Lactose fermented slowly <i>Edwardsiella</i> , <i>Serratia</i> , <i>Citrobacter</i> , <i>Salmonella</i> Arizona subgroup, <i>Erwinia</i> , some strains of <i>Shigella sonnei</i> (on extended incubation)
Lactose not fermented <i>Shigella</i> species: nonmotile; no gas from dextrose <i>Salmonella</i> species: motile; acid and usually gas from dextrose <i>Proteus</i> species: “swarming” on agar; urea rapidly hydrolyzed (smell of ammonia) <i>Providencia</i> species, other than <i>P. stuartii</i> <i>Morganella</i> species <i>Yersinia</i> species

on blood agar, typical colonial morphology with an iridescent “sheen” on differential media such as EMB agar, and a positive spot indole test result. More than 90% of *E. coli* isolates are positive for β -glucuronidase using the substrate 4-methylumbelliferyl- β -glucuronide (MUG). Isolates from anatomic sites other than urine, with characteristic properties (above plus negative oxidase test results) often can be confirmed as *E. coli* with a positive MUG test result.

2. ***Klebsiella-Enterobacter-Serratia* group**—*Klebsiella* species exhibit mucoid growth, large polysaccharide capsules, and lack of motility, and they usually give positive test results for lysine decarboxylase and citrate. Most *Enterobacter* species give positive test results for motility, citrate, and ornithine decarboxylase and produce gas from glucose. *Enterobacter aerogenes* has small capsules. Some species of *Enterobacter* have been moved into the genus *Cronobacter*. *Serratia* species produces DNase, lipase, and gelatinase. *Klebsiella*, *Enterobacter*, and *Serratia* species usually give positive Voges-Proskauer reactions.
3. ***Proteus-Morganella-Providencia* group**—The members of this group deaminate phenylalanine, are motile, grow on potassium cyanide medium (KCN), and ferment xylose. *Proteus* species move very actively by means of peritrichous flagella, resulting in “swarming” on solid media (Figure 15-2), unless the swarming is inhibited by

chemicals, such as phenylethyl alcohol or CLED (cystine-lactose-electrolyte-deficient) medium. Whereas *Proteus* species and *Morganella morganii* are urease positive, *Providencia* species usually are urease negative. The *Proteus-Providencia* group ferments lactose very slowly or not at all.

4. ***Citrobacter***—These bacteria typically are citrate positive and differ from the salmonellae in that they do not decarboxylate lysine. They ferment lactose very slowly if at all.
5. ***Shigella***—Shigellae are nonmotile and usually do not ferment lactose but do ferment other carbohydrates, producing acid but not gas. They do not produce H_2S . The four *Shigella* species are closely related to *E. coli*. Many share common antigens with one another and with other enteric bacteria (eg, *Hafnia alvei* and *Plesiomonas shigelloides*).
6. ***Salmonella***—Salmonellae are motile rods that characteristically ferment glucose and mannose without producing gas but do not ferment lactose or sucrose. Most salmonellae produce H_2S . They are often pathogenic for humans or animals when ingested. Organisms originally described in the genus *Arizona* are now included as subspecies in the *Salmonella* group.
7. **Other *Enterobacteriaceae***—*Yersinia* species are discussed in Chapter 19. Other genera occasionally found in human infections include *Cronobacter*, *Edwardsiella*, *Ewingella*, *Hafnia*, *Cedecea*, *Plesiomonas*, and *Kluyvera*.

FIGURE 15-2 *Proteus mirabilis* on sheep blood agar. *Proteus* species exhibit a characteristic swarming pattern, causing a wave-like appearance, and individual colonies are not distinguishable. (Courtesy of S. Riedel.)

Antigenic Structure

Enterobacteriaceae have a complex antigenic structure. They are classified by more than 150 different heat-stable somatic O (lipopolysaccharide) antigens, more than 100 heat-labile K (capsular) antigens, and more than 50 H (flagellar) antigens (Figure 15-1B). In *Salmonella* serotype Typhi, the capsular antigens are called Vi antigens. The antigenic classification of Enterobacteriaceae often indicates the presence of each specific antigen; for example, the antigenic formula of an *E. coli* may be O55:K5:H21.

O antigens are the most external part of the cell wall lipopolysaccharide and consist of repeating units of polysaccharide. Some O-specific polysaccharides contain unique sugars. O antigens are resistant to heat and alcohol and usually are detected by bacterial agglutination. Antibodies to O antigens are predominantly IgM.

Although each genus of Enterobacteriaceae is associated with specific O groups, a single organism may carry several O antigens. Thus, most shigellae share one or more O antigens with *E. coli*; however, *E. coli* may also cross-react with some *Providencia*, *Klebsiella*, and *Salmonella* species. Occasionally, O antigens may be associated with specific human diseases (eg, specific O types of *E. coli* are found in diarrhea and in urinary tract infections).

K antigens are external to O antigens on some but not all Enterobacteriaceae. Some are polysaccharides, including the K antigens of *E. coli*; others are proteins. K antigens may

interfere with agglutination by O antisera, and they may be associated with virulence (eg, *E. coli* strains producing K1 antigen are prominent in neonatal meningitis, and K antigens of *E. coli* cause attachment of the bacteria to epithelial cells before gastrointestinal or urinary tract invasion).

Members of the genus *Klebsiella* form large capsules consisting of polysaccharides (K antigens) covering the somatic (O or H) antigens and can be identified by capsular swelling tests with specific antisera. Human infections of the respiratory tract are caused particularly by capsular types 1 and 2 and those of the urinary tract by types 8, 9, 10, and 24.

H antigens are located on flagella and are denatured or removed by heat or alcohol. They are preserved by treating motile bacterial variants with formalin. Such H antigens agglutinate with anti-H antibodies, mainly IgG. The determinants in H antigens are a function of the amino acid sequence in flagellar protein (flagellin). Within a single serotype, flagellar antigens may be present in either or both of two forms, called **phase 1** (conventionally designated by lowercase letters) and **phase 2** (conventionally designated by Arabic numerals), as shown in Table 15-3. The organism tends to change from one phase to the other; this is called phase variation. H antigens on the bacterial surface may interfere with agglutination by anti-O antibody.

There are many examples of overlapping antigenic structures between Enterobacteriaceae and other bacteria. Most Enterobacteriaceae share the O14 antigen of *E. coli*. The type 2 capsular polysaccharide of *Klebsiella* is very similar to the polysaccharide of type 2 pneumococci. Some K antigens cross-react with capsular polysaccharides of *Haemophilus influenzae* or *Neisseria meningitidis*. Thus, *E. coli* O75:K100:H5 can induce antibodies that react with *H. influenzae* type b.

Toxins and Enzymes

Most Gram-negative bacteria possess complex lipopolysaccharides in their cell walls. These substances, cell envelope (cytoplasmic membrane, peptidoglycan, outer membrane) endotoxins, have a variety of pathophysiologic effects that are summarized in Chapter 9. Many Gram-negative enteric bacteria also produce exotoxins of clinical importance. Some specific toxins are discussed in subsequent sections.

DISEASES CAUSED BY ENTEROBACTERIACEAE OTHER THAN SALMONELLA AND SHIGELLA

Causative Organisms

E. coli are members of the normal intestinal microbiota (see Chapter 10). Other enteric bacteria (*Proteus*, *Enterobacter*, *Klebsiella*, *Morganella*, *Providencia*, *Citrobacter*, and *Serratia* species) are also found as members of the normal intestinal microbiota but are considerably less common than *E. coli*. The enteric bacteria are sometimes found in small numbers

as part of the normal microbiota of the upper respiratory and genital tracts. The enteric bacteria generally do not cause disease, and in the intestine, they may even contribute to normal function and nutrition. When clinically important infections occur, they are usually caused by *E. coli*, but the other enteric bacteria are causes of hospital-acquired infections and occasionally cause community-acquired infections. The bacteria become pathogenic only when they reach tissues outside of their normal intestinal or other less common normal microbiota sites. The most frequent sites of clinically important infection are the urinary tract, biliary tract, and other sites in the abdominal cavity, but any anatomic site (eg, bloodstream, prostate gland, lung, bone, and meninges) can be the site of disease. Some of the enteric bacteria (eg, *S. marcescens* and *E. aerogenes*) are opportunistic pathogens. When the normal host defenses are inadequate—particularly in infancy or old age, in the terminal stages of other diseases, after immunosuppression, or with indwelling venous or urethral catheters—localized clinically important infections can result, and the bacteria may reach the bloodstream and cause sepsis.

Pathogenesis and Clinical Findings

The clinical manifestations of infections with *E. coli* and the other enteric bacteria depend on the site of the infection and cannot be differentiated by symptoms or signs from processes caused by other bacteria.

A. *E. coli*

1. **Urinary tract infection (UTI)**—*E. coli* is the most common cause of urinary tract infection and accounts for approximately 90% of first urinary tract infections in young women (see Chapter 48). The symptoms and signs include urinary frequency, dysuria, hematuria, and pyuria. Flank pain is associated with upper tract infection. None of these symptoms or signs is specific for *E. coli* infection. Urinary tract infection can result in bacteremia with clinical signs of sepsis.

Most of the urinary tract infections that involve the bladder or kidney in an otherwise healthy host are caused by a small number of O antigen types that have specifically elaborated virulence factors that facilitate colonization and subsequent clinical infections. These organisms are designated as uropathogenic *E. coli*. Typically, these organisms produce hemolysin, which is cytotoxic and facilitates tissue invasion. Strains that cause pyelonephritis express K antigen and elaborate a specific type of pilus, P fimbriae, which binds to the P blood group antigen.

Over the last decade, a pandemic clone, *E. coli* O25b/ST131, has emerged as a significant pathogen. This organism has been successful largely as a result of its acquisition of plasmid-mediated resistance factors that encode resistance to β -lactam antibiotics (elaboration of extended spectrum β -lactamases), fluoroquinolones, and aminoglycosides (see the review by Johnson et al, 2010).

2. ***E. coli*-associated diarrheal diseases**—*E. coli* that cause diarrhea are extremely common worldwide. These *E. coli* are classified by the characteristics of their virulence properties (see later discussion), and each group causes disease by a different mechanism—at least six of which have been characterized. The small or large bowel epithelial cell adherence properties are encoded by genes on plasmids. Similarly, the toxins often are plasmid or phage mediated. Some clinical aspects of diarrheal diseases are discussed in Chapter 48.

Enteropathogenic *E. coli* (EPEC) are an important cause of diarrhea in infants, especially in developing countries. EPEC adhere to the mucosal cells of the small bowel. Pathogenicity requires two important factors, the bundle forming pilus encoded by a plasmid EPEC adherence factor (EAF) and the chromosomal locus of enterocyte effacement (LEE) pathogenicity island that promote the tight adherence characteristic of EPEC (attachment and effacement). After attachment, there is loss of microvilli (effacement); formation of filamentous actin pedestals or cuplike structures; and, occasionally, entry of the EPEC into the mucosal cells. Characteristic lesions can be seen on electron micrographs of small bowel biopsy lesions. The result of EPEC infection in infants is characterized by severe, watery diarrhea, vomiting, and fever, which are usually self-limited but can be prolonged or chronic. EPEC diarrhea has been associated with multiple specific serotypes of *E. coli*; strains are identified by O antigen and occasionally by H antigen typing. A two-stage infection model using HEP-2 or HeLa cells also can be performed. Tests to identify EPEC are performed in reference laboratories. The duration of the EPEC diarrhea can be shortened and the chronic diarrhea cured by antibiotic treatment.

Enterotoxigenic *E. coli* (ETEC) are a common cause of “traveler’s diarrhea” and a very important cause of diarrhea in children less than 5 years of age in developing countries. ETEC colonization factors (pili known as colonization factor antigens [CFAs]) specific for humans promote adherence of ETEC to epithelial cells of the small bowel. Some strains of ETEC produce a **heat-labile enterotoxin (LT)** (molecular weight [MW], 80,000) that is under the genetic control of a plasmid and is closely related to cholera toxin. Its subunit B attaches to the GM₁ ganglioside in the apical membrane of enterocytes and facilitates the entry of subunit A (MW, 26,000) into the cell, where the latter activates adenylyl cyclase. This markedly increases the local concentration of cyclic adenosine monophosphate (cAMP) after which ensues a complex cascade that involves the cystic fibrosis transmembrane conductance regulator. The end result is an intense and prolonged hypersecretion of water and chlorides and inhibition of the reabsorption of sodium. The gut lumen is distended with fluid, and hypermotility and diarrhea ensue, lasting for several days. LT is antigenic and cross-reacts with the enterotoxin of *Vibrio cholerae*, which has an identical mechanism of action. LT stimulates the production

of neutralizing antibodies in the serum (and perhaps on the gut surface) of persons previously infected with enterotoxigenic *E. coli*. Persons residing in areas where such organisms are highly prevalent (eg, in some developing countries) are likely to possess antibodies and are less prone to develop diarrhea on reexposure to the LT-producing *E. coli*. Assays for LT include (1) fluid accumulation in the intestines of laboratory animals, (2) typical cytologic changes in cultured Chinese hamster ovary cells or other cell lines, (3) stimulation of steroid production in cultured adrenal tumor cells, (4) binding and immunologic assays with standardized antisera to LT, and (5) detection of the genes that encode the toxins. These assays are done only in reference laboratories.

Some strains of ETEC produce the **heat-stable enterotoxin ST_a** (MW, 1500–4000), which is under the genetic control of a heterogeneous group of plasmids. ST_a activates guanylyl cyclase in enteric epithelial cells and stimulates fluid secretion. Many ST_a-positive strains also produce LT. The strains with both toxins produce a more severe diarrhea.

The plasmids carrying the genes for enterotoxins (LT, ST) also may carry genes for the CFAs that facilitate the attachment of *E. coli* strains to intestinal epithelium. Recognized colonization factors occur with particular frequency in some serotypes. Certain serotypes of ETEC occur worldwide; others have a limited recognized distribution. It is possible that virtually any *E. coli* may acquire a plasmid encoding for enterotoxins. There is no definite association of ETEC with the EPEC strains causing diarrhea in children. Likewise, there is no association between enterotoxigenic strains and those able to invade intestinal epithelial cells.

Care in the selection and consumption of foods potentially contaminated with ETEC is highly recommended to help prevent traveler’s diarrhea. Antimicrobial prophylaxis can be effective but may result in increased antibiotic resistance in the bacteria and probably should not be uniformly recommended. When diarrhea develops, antibiotic treatment effectively shortens the duration of disease.

Shiga toxin-producing *E. coli* (STEC) are named for the cytotoxic toxins they produce. There are at least two antigenic forms of the toxin referred to as Shiga-like toxin 1 and Shiga-like toxin 2. STEC has been associated with mild non-bloody diarrhea, hemorrhagic colitis, a severe form of diarrhea, and with hemolytic uremic syndrome, a disease resulting in acute renal failure, microangiopathic hemolytic anemia, and thrombocytopenia. Shiga-like toxin 1 is identical to the Shiga toxin of *Shigella dysenteriae* type 1, and Shiga-like toxin 2 also has many properties that are similar to the Shiga toxin; however, the two toxins are antigenically and genetically distinct. A low infectious dose (< 200 CFU) is associated with infection. Of the more than 150 *E. coli* serotypes that produce Shiga toxin, O157:H7 is the most common and is the one that can be identified most readily in clinical specimens. STEC O157:H7 does not use sorbitol, unlike most other *E. coli*,

and is negative (clear colonies) on sorbitol MacConkey agar (sorbitol is used instead of lactose); O157:H7 strains also are negative on MUG tests (see earlier discussion). Many of the non-O157 serotypes may be sorbitol positive when grown in culture. Specific antisera are used to identify the O157:H7 strains. Tests for the detection of both Shiga toxins using commercially available enzyme immunoassays (EIAs) are done in many laboratories. Other sensitive test methods include cell culture cytotoxin testing using Vero cells and polymerase chain reaction for the direct detection of toxin genes directly from stool samples. Many cases of hemorrhagic colitis and its associated complications can be prevented by thoroughly cooking ground beef and by avoiding unpasteurized products such as apple cider. In 2011, the largest outbreak of hemorrhagic colitis attributed to a non-O157 serotype—namely, *E. coli* O104:H4—was related to consumption of contaminated sprouts in Germany. This organism had increased virulence characterized by enhanced adherence as well as the production of shiga-like toxins (see reference by Buchholz et al, 2011).

Enteroinvasive *E. coli* (EIEC) produce a disease very similar to shigellosis. The disease occurs most commonly in children in developing countries and in travelers to these countries. Similar to *Shigella*, EIEC strains are nonlactose or late lactose fermenters and are nonmotile. EIEC produce disease by invading intestinal mucosal epithelial cells.

Enterotoxigenic *E. coli* (EAEC) causes acute and chronic diarrhea (>14 days in duration) in persons in developing countries. These organisms also are the cause of foodborne illnesses in industrialized countries and have been associated with traveler's diarrhea and persistent diarrhea in patients with HIV. They are characterized by their specific patterns of adherence to human cells. This group of diarrheagenic *E. coli* is quite heterogeneous, and the exact pathogenic mechanisms are still not completely elucidated. Some strains of EAEC produce ST-like toxin (see earlier discussion on *E. coli* O104:H11); others a plasmid-encoded enterotoxin that produces cellular damage; and still others, a hemolysin. Diagnosis can be suspected clinically but requires confirmation by tissue culture adhesion assays not readily available in most clinical laboratories.

3. **Sepsis**—When normal host defenses are inadequate, *E. coli* may reach the bloodstream and cause sepsis. Newborns may be highly susceptible to *E. coli* sepsis because they lack IgM antibodies. Sepsis may occur secondary to urinary tract infection and often the major clone associated with invasion is *E. coli* O25b/ST131.
4. **Meningitis**—*E. coli* and group B streptococci are the leading causes of meningitis in infants. Approximately 80% of *E. coli* from meningitis cases have the K1 antigen. This antigen cross-reacts with the group B capsular polysaccharide of *N. meningitidis*. The mechanisms of virulence associated with the K1 antigen are reviewed in the reference by Kim et al (2005).

B. *Klebsiella*–*Enterobacter*–*Serratia*; *Proteus*–*Morganella*–*Providencia*; and *Citrobacter*

The pathogenesis of disease caused by these groups of enteric Gram-negative rods is similar to that of the nonspecific factors in disease caused by *E. coli*.

1. ***Klebsiella***—*Klebsiella* species are present in the nasopharynx and feces of about 5% of normal individuals. The most commonly isolated species are *K. pneumoniae* and *K. oxytoca*. While *K. pneumoniae* may be isolated more frequently than *K. oxytoca* by clinical laboratories, both species are important human pathogens, known to cause community- as well as hospital-acquired pneumonia. *K. pneumoniae* can produce a lobar pneumonia with extensive hemorrhagic necrotizing consolidation of the lung, and has distinct clinical features, including its severity and propensity to affect the upper lobes, the production of “currant jelly” sputum as a result of the associated hemoptysis, and abscess formation. *Klebsiella* species also cause urinary tract infections, wound and soft tissue infections, and bacteremia/sepsis. Recently a particular clone of *K. pneumoniae* has emerged as a cause of community-acquired pyogenic liver abscess that is seen mostly among Asian males worldwide. This particular K1-encapsulated strain phenotypically appears hypermucoviscous when grown in culture. *Klebsiella* species rank among the top 10 bacterial pathogens responsible for hospital-acquired infections. Multilocus sequencing typing has identified global emergence of two particularly important clones. Sequence type 16 has elaborated extended spectrum β -lactamases resulting in resistance to a broad range of penicillins and cephalosporins (but not carbapenem antibiotics). ST 258 is a multidrug-resistant strain called a “carbapenemase producer” because it is resistant to all β -lactam antibiotics including the broad spectrum carbapenem agents. Typically, it is resistant to other antimicrobial agents as a result of acquisition of plasmids that carry multiple resistance genes.

Klebsiella granulomatis (formerly *Calymmatobacterium granulomatis*) causes a chronic genital ulcerative disease, **granuloma inguinale**, and is thought to be a sexually transmitted disease. Granuloma inguinale predominantly occurs in tropical regions (eg, the Caribbean, South America, and South-East Asia) and is a rare disease in the United States. The organism does not grow in standard culture in the laboratory; the diagnosis is based on the visualization of “Donovan bodies” in tissue smears or biopsy specimens (pleomorphic bacilli present in the cytoplasm of macrophages and neutrophils demonstrated by Giemsa or Wright's stain). The recommended treatment regimen is azithromycin 1 g orally once per week (or 500 mg daily) for at least three weeks and until all lesions have completely healed. Alternative antimicrobial treatment

regimens exist, using ciprofloxacin, doxycycline, or trimethoprim-sulfamethoxazole.

Two other *Klebsiella* species are associated with inflammatory conditions of the upper respiratory tract, but are relatively uncommon in the United States: *K. pneumoniae* subspecies *ozaenae* has been isolated from the nasal mucosa and is the cause of ozena (atrophic rhinitis), a fetid, progressive atrophy of mucous membranes. *K. pneumoniae* subspecies *rhinoscleromatis* causes rhinoscleroma, a destructive granulomatous disease of the nasal passages, but can extend to the pharynx, larynx, and even the trachea. Both diseases are more commonly seen in the tropical regions of the world, and appear to be spread by person-to-person transmission.

2. **Enterobacter**—Three species/complexes of *Enterobacter*—*Enterobacter cloacae* complex, *E. aerogenes* complex, and *Enterobacter sakazakii* (now in the genus *Cronobacter*)—cause the majority of *Enterobacter* infections. Many *Enterobacter* species are commonly found in the environment (eg, soil, water, and sewage), and *E. aerogenes* and *E. cloacae* also occur in various foods (eg, meat, dairy products, and vegetables), hospital environments, and the skin and intestinal tract of humans and animals. These bacteria ferment lactose, may contain capsules that produce mucoid colonies, and are motile. These organisms cause a broad range of hospital-acquired infections such as pneumonia, urinary tract infections, and wound and device infections. Most strains possess a chromosomal β -lactamase called *ampC*, which renders them intrinsically resistant to ampicillin and first- and second-generation cephalosporins. Mutants may hyperproduce β -lactamase, conferring resistance to third-generation cephalosporins. Like *K. pneumoniae*, some hospital-acquired strains have plasmids that make them multidrug resistant including the carbapenem class of antimicrobial agents.
3. **Serratia**—*Serratia* species common opportunistic pathogens as well as colonizers in hospitalized patients. *Serratia marcescens* is probably the most frequently isolated *Serratia* species by clinical laboratories. While *Serratia* species are typically transmitted from person to person, transmission via medical devices, intravenous fluids, and indwelling catheters has also been described. In children, the gastrointestinal tract often serves as a reservoir for infection. Some *Serratia* species produce a characteristic red pigment (prodigiosin). In *S. marcescens* pigment production may be an indicator of the strains environmental origin; however, only about 10% of the clinical isolates of *S. marcescens* produce this pigment. Most common sites of infection include the urinary tract, but *S. marcescens* also causes pneumonia, bacteremia, wound infections, bone and soft tissue infections, and endocarditis (the latter frequently in intravenous drug users). Treatment of infections due to *S. marcescens* is often difficult due to resistance to multiple antibiotics; *S. marcescens* is

resistant to penicillin, ampicillin, and first-generation cephalosporins because it harbors an inducible, chromosomal AmpC β -lactamase. Resistance to fluoroquinolones and trimethoprim-sulfamethoxazole has also been described. Because antibiotic susceptibility varies by strain, no empiric guidelines are available for treatment of infections due to *S. marcescens*.

4. **Proteus**—*Proteus* species are widespread in the environment and are normal inhabitants of the human intestinal tract. The two species to most commonly produce infections in humans are *P. mirabilis* and *P. vulgaris*. Both species produce urease, resulting in rapid hydrolysis of urea with liberation of ammonia. Thus, in urinary tract infections with *Proteus* species, the urine becomes alkaline, promoting stone formation and making acidification virtually impossible. In addition, the rapid motility of *Proteus* may also contribute to its invasion of the urinary tract. The spot-indole test is useful for differentiation between the two most common *Proteus* species: *P. vulgaris* is indole positive, whereas *P. mirabilis* is negative. *P. mirabilis* causes urinary tract infections and occasionally other infections, such as bloodstream infection (frequently secondary due to a UTI) and respiratory tract infections. *P. vulgaris* is probably more frequently implicated in wound and soft tissue infections than UTIs.

Strains of *Proteus* vary greatly in antibiotic susceptibility. *P. mirabilis* is resistant to nitrofurantoin but most often susceptible to penicillins (eg, ampicillin and amoxicillin), trimethoprim-sulfamethoxazole, cephalosporins, aminoglycosides, and imipenem; *P. vulgaris* is generally more resistant to various antibiotics (specifically ampicillin, amoxicillin, and piperacillin; the most active antibiotics for *P. vulgaris* and other members of the group are aminoglycosides and broad-spectrum cephalosporins).

5. **Providencia**—*Providencia* species (*P. rettgeri*, *P. alcalifaciens*, and *P. stuartii*) are members of the normal intestinal microbiota. All cause urinary tract infections and occasionally other infections and are often resistant to antimicrobial therapy.
6. **Morganella**—The genus *Morganella* consists of a single species, *M. morganii*. This organism is commonly found in the environment and in the intestinal tract of humans, mammals, and reptiles. It has been described as infrequent cause of nosocomial infections of the urinary tract and wounds; rare cases of bacteremia have also been reported. *M. morganii* is typically resistant to penicillins (eg, ampicillin and amoxicillin), and first- and second-generation cephalosporins; however, it is usually susceptible to broad-spectrum cephalosporins, aminoglycosides, aztreonam, and imipenem.
7. **Citrobacter**—*Citrobacter* species can cause urinary tract infections, sepsis, respiratory tract infections, intra-abdominal infections, and wound infections, principally among immunocompromised and/or debilitated hospitalized patients. In addition, *Citrobacter koseri* has been associated with meningitis in infants less than 2 months of age.

Diagnostic Laboratory Tests

A. Specimens

Specimens include urine, blood, pus, spinal fluid, sputum, or other material, as indicated by the localization of the disease process.

B. Smears

The Enterobacteriaceae resemble each other morphologically. The presence of large capsules is suggestive of *Klebsiella* species.

C. Culture

Specimens are plated on both blood agar and various differential media. With differential media, rapid preliminary identification of Gram-negative enteric bacteria is often possible, and various commercially available phenotyping systems are available for organism identification (see Chapter 47). Alternative methods based on protein profiling or DNA sequence analysis are becoming available to clinical laboratories; MALDI-TOF mass spectrometry (see above) has been shown to be useful for identification of various Enterobacteriaceae.

D. Nucleic Acid Amplification Tests (NAATs)

A variety of multiplex NAATs designed to detect the most common pathogens responsible for particular syndromes are currently available and many more are entering clinical trials. These panel tests detect members of the Enterobacteriaceae in specimens such as positive blood cultures, cerebrospinal fluid, respiratory specimens, and stool. In some of these assays resistance markers are also detected. The reader should consult the literature for the most up to date information on these assays.

Immunity

Specific antibodies develop in systemic infections, but it is uncertain whether significant immunity to the organisms follows.

Treatment

No single specific therapy is available. In general, the sulfonamides, ampicillin, cephalosporins, fluoroquinolones, and aminoglycosides have good to excellent antimicrobial efficacy against many of the enterics; however, variation in susceptibility is great and genus and species dependent (see discussions above). Therefore, laboratory testing for antibiotic susceptibility is essential for defining the appropriate treatment for infections due to the various Enterobacteriaceae. Multidrug resistance is now an increasing problem among many members of the Enterobacteriaceae, since many of the resistances are plasmid-mediated and can be easily transmitted between the various organisms.

Certain conditions predisposing to infection by these organisms require surgical correction, such as relief of urinary tract obstruction, closure of a perforation in an abdominal organ, or resection of a bronchiectatic portion of lung.

Treatment of Gram-negative bacteremia and impending septic shock requires rapid institution of antimicrobial therapy, restoration of fluid and electrolyte balance, and treatment of disseminated intravascular coagulation.

Various means have been proposed for the prevention of traveler's diarrhea, including daily ingestion of bismuth subsalicylate suspension (bismuth subsalicylate can inactivate *E. coli* enterotoxin in vitro) and regular doses of tetracyclines or other antimicrobial drugs for limited periods. Because none of these methods are entirely successful or lacking in adverse effects, it is widely recommended that caution be observed in regard to food and drink in areas where environmental sanitation is poor and that early and brief treatment (eg, with ciprofloxacin or trimethoprim-sulfamethoxazole) be substituted for prophylaxis.

Epidemiology, Prevention, and Control

The enteric bacteria establish themselves in the normal intestinal tract within a few days after birth and from then on constitute a main portion of the normal aerobic (facultative anaerobic) microbial flora. *E. coli* is the prototype. Identifying enterics in water or milk is accepted as proof of fecal contamination from sewage or other sources.

Control measures are not feasible as far as the normal endogenous microbiota is concerned. Enteropathogenic *E. coli* serotypes should be controlled like salmonellae (see below). Some of the enterics constitute a major problem in hospital infection. It is particularly important to recognize that many enteric bacteria are "opportunists" that cause illness when they are introduced into debilitated patients. Within hospitals or other institutions, these bacteria commonly are transmitted by personnel, instruments, or parenteral medications. Their control depends on handwashing, rigorous asepsis, sterilization of equipment, disinfection, restraint in intravenous therapy, and strict precautions in keeping the urinary tract sterile (ie, closed drainage). For control of the multidrug-resistant pathogens, especially carbapenamase producers, surveillance of hospitalized patients with prompt implementation of contact precautions for colonized patients is often employed.

THE SHIGELLAE

The natural habitat of shigellae is limited to the intestinal tracts of humans and other primates, where they produce bacillary dysentery.

Morphology and Identification

A. Typical Organisms

Shigellae are slender, nonmotile Gram-negative rods; coccobacillary forms occur in young cultures.

TABLE 15-2 Pathogenic *Shigella* Species

Present Designation	Group and Type	Mannitol	Ornithine Decarboxylase
<i>Shigella dysenteriae</i>	A	–	–
<i>Shigella flexneri</i>	B	+	–
<i>Shigella boydii</i>	C	+	–
<i>Shigella sonnei</i>	D	+	+

B. Culture

Shigellae are facultative anaerobes but grow best aerobically. Convex, circular, transparent colonies with intact edges reach a diameter of about 2 mm in 24 hours.

C. Growth Characteristics

All strains of *Shigella* species ferment glucose. With the exception of *Shigella sonnei*, they do not ferment lactose. The inability of lactose fermentation distinguishes shigellae on differential media from other, lactose-fermenting members of the *Enterobacteriaceae* (eg, *E. coli*). Shigellae form acid from carbohydrates but rarely produce gas. They may also be divided into those organisms that ferment mannitol and those that do not (Table 15-2).

Antigenic Structure

Shigellae have a complex antigenic pattern. There is great overlapping in the serologic behavior of different species, and most of them share O antigens with other enteric bacilli.

The somatic O antigens of shigellae are lipopolysaccharides. Their serologic specificity depends on the polysaccharide. There are more than 40 serotypes. The classification of shigellae relies on biochemical and antigenic characteristics. The pathogenic species are *S. sonnei*, *S. flexneri*, *S. dysenteriae*, and *S. boydii* (Table 15-2).

Pathogenesis and Pathology

Shigella infections are almost always limited to the gastrointestinal tract; bloodstream invasion is quite rare. Shigellae are highly communicable; the infective dose is low, on the order of 10² organisms (in comparison, the infectious dose for salmonellae and vibrios is usually 10⁵–10⁸). The essential pathologic process is invasion of the mucosal epithelial cells (eg, M cells) by induced phagocytosis, escape from the phagocytic vacuole, multiplication and spread within the epithelial cell cytoplasm, and passage to adjacent cells. Microabscesses in the wall of the large intestine and terminal ileum lead to necrosis of the mucous membrane, superficial ulceration, bleeding, and formation of a “pseudomembrane” on the ulcerated area. This consists of fibrin, leukocytes, cell debris, a necrotic mucous membrane, and bacteria. As the process subsides, granulation tissue fills the ulcers, and scar tissue forms.

Toxins

A. Endotoxin

Upon autolysis, all shigellae release their toxic lipopolysaccharide. This endotoxin probably contributes to the irritation of the bowel wall.

B. *Shigella Dysenteriae* Exotoxin

S. dysenteriae type 1 (Shiga bacillus) produces a heat-labile exotoxin that affects both the gut and the central nervous system. The exotoxin is a protein that is antigenic (stimulating production of antitoxin) and lethal for experimental animals. Acting as an enterotoxin, it produces diarrhea as does the *E. coli* Shiga-like toxin, perhaps by the same mechanism. In humans, the exotoxin also inhibits sugar and amino acid absorption in the small intestine. Acting as a “neurotoxin,” this material may contribute to the extreme severity and fatal nature of *S. dysenteriae* infections and to the central nervous system reactions observed in them (ie, meningismus and coma). Patients with *S. flexneri* or *S. sonnei* infections develop antitoxin that neutralizes *S. dysenteriae* exotoxin in vitro. The toxic activity is distinct from the invasive property of shigellae in dysentery. The two may act in sequence, the toxin producing an early nonbloody, voluminous diarrhea and the invasion of the large intestine, resulting in later dysentery with blood and pus in stools.

Clinical Findings

Members of the genus *Shigella* cause bloody as well as non-bloody diarrhea. After a short incubation period (1–4 days), there is a sudden onset of abdominal pain, fever, and watery diarrhea. A day or so later, as the infection involves the ileum and colon, the number of stools increases; each bowel movement is accompanied by straining and tenesmus (rectal spasms), with resulting lower abdominal pain. In more than half of adult cases, fever and diarrhea subside spontaneously within 2–5 days. However, in children and elderly adults, loss of water and electrolytes may lead to dehydration, acidosis, and even death. The illness caused by *S. dysenteriae* may be particularly severe.

On recovery, most persons shed dysentery bacilli for only a short period. Upon recovery from the infection, most persons develop circulating antibodies to shigellae, but these do not protect against reinfection. Bloodstream infections rarely occur as a complication of shigellosis. Other sequelae of shigellosis include hemolytic uremic syndrome (HUS), typically associated with *S. dysenteriae* type 1, and Reiter’s chronic arthritis syndrome, associated with *S. flexneri*.

Diagnostic Laboratory Tests

A. Specimens

For optimal organism recovery, fecal specimens should be collected during the early stages of the illness. Specimens include fresh stool, mucus flecks, and rectal swabs for culture. While whole stool is usually the preferred specimen for

laboratory workup of diarrhea, rectal swabs with visible fecal staining present may be the preferred specimen for the isolation of shigellae.

B. Culture

The materials are streaked on differential media (eg, MacConkey or EMB agar) and on selective media, such as Hektoen Enteric agar (Figure 15-3A) or xylose-lysine-deoxycholate agar, which suppress other Enterobacteriaceae and Gram-positive organisms. Colorless (lactose-negative) colonies are inoculated into a TSI agar slant. Nonmotile organisms that fail to produce H_2S , that produce acid but not gas in the butt and an alkaline slant in TSI agar medium (Figure 15-3B) should be subjected to slide agglutination by specific *Shigella* antisera. It should be noted that *Shigella* species and *E. coli* cannot be reliably differentiated by MALDI-ToF MS.

C. Serology

Healthy persons often have agglutinins against several *Shigella* species. However, serial determinations of antibody titers may show a rise in specific antibody. Serology is not used to diagnose *Shigella* infections.

D. Nucleic Acid Amplification Tests

There are several commercial NAATs that directly detect shigellae in fecal samples along with some of the other major enteric pathogens.

Immunity

Infection is followed by a type-specific antibody response. Injection of killed shigellae stimulates production of antibodies in serum but fails to protect humans against infection. IgA antibodies in the gut may be important in limiting reinfection; these may be stimulated by live attenuated strains given orally as experimental vaccines. Serum antibodies to somatic *Shigella* antigens are IgM.

Treatment

In general, shigellosis is a self-limited illness, and many patients recover without treatment within 5–7 days. Mortality is generally low in shigellosis, except in malnourished children, infants, and elderly patients. Severe dehydration, febrile seizures, septicemia, and pneumonia are potential complications of severe shigellosis. In general, oral fluid replacement is considered to be sufficient for treatment of

A

B

FIGURE 15-3 **A:** *Shigella* species on Hektoen Enteric (HE) agar. **B:** *Shigella* species on TSI agar slant. *Shigella* spp. do not ferment lactose, salicin, or sucrose, and therefore appear as translucent, colorless colonies on HE agar. *Shigella* spp. ferment glucose, but not lactose and sucrose present in the TSI agar slant. Therefore, they produce an alkaline over acid (K/A) reaction and do not produce H_2S or gas. (Courtesy of S. Riedel.)

uncomplicated shigellosis, but in high-risk patient populations intravenous fluid replacement may be required. Anti-diarrheal medications (eg, loperamide and opioids) should be avoided in *Shigella* dysentery, as such medications may worsen the symptoms of the illness. Antibiotic treatment is recommended for the treatment of severe infections and to prevent secondary spread among people living in closed quarters (eg, family members) or during outbreaks. Because of widespread resistance in the United States, trimethoprim-sulfamethoxazole and ampicillin are no longer recommended as first-line agents for treatment of shigellosis. Ciprofloxacin and ceftriaxone are effective antibiotics of choice; however, in recent years the Centers of Disease Control and Prevention (CDC) have identified emerging strains of *Shigella* species with potentially reduced susceptibility to ciprofloxacin. Ceftriaxone is commonly used for treatment of children with shigellosis. Finally, azithromycin has been shown as a useful antibiotic for treatment of antibiotic-resistant *Shigella* infections in adults and children.

Epidemiology, Prevention, and Control

Humans are the only reservoir for *Shigellae*; the organisms are most commonly transmitted by “food, fingers, feces, and flies” from person to person. Sexual transmission of *Shigella* spp. has also been described among men who have sex with men (MSM). In general, a low infectious dose (10–100 organisms) is capable of causing disease. Shigellosis is a disease that occurs typically in situations where hygiene is compromised. In the United States, an estimated 500,000 cases of shigellosis occur every year, and up to 15% of these cases may be related to international travel. However, in comparison, an estimate 90 million cases occur, worldwide. Most cases of *Shigella* infection occur in children younger than 10 years of age. Shigellosis, caused primarily by *S. sonnei*, accounts for up to 85% of cases in the United States, and has become a common and important problem in daycare centers. *S. flexneri* is the predominant cause of shigellosis in developing countries. *S. dysenteriae* can spread widely and is a common cause of epidemic dysentery, with an associated high morbidity and mortality, particularly in developing countries. Because humans are the main recognized host of pathogenic shigellae, control efforts must be directed at eliminating the organisms from this reservoir by (1) sanitary control of water, food, and milk; sewage disposal and fly control; (2) isolation of patients and disinfection of excreta; (3) detection of subclinical cases and carriers, particularly food handlers; and (4) antibiotic treatment of infected individuals.

THE SALMONELLAE

Salmonellae are both commensal as well as pathogenic for humans and many animals, including mammals, reptiles, birds, and insects. Salmonellae cause clinical disease when acquired by the oral route. They are typically transmitted

via contaminated water or food from animals and animal products to humans; clinically, Salmonellae are the cause of enteritis, systemic infection, and enteric fever; however, asymptomatic colonization may also occur.

Morphology and Identification

Salmonellae are non-spore-forming, facultative anaerobic, Gram-negative bacilli that vary in length. Most isolates are motile with peritrichous flagella. Salmonellae grow readily on simple agar media; they are able to utilize citrate as a sole carbon source and lysine as a nitrogen source, but they almost never ferment lactose or sucrose. Salmonellae do not produce cytochrome oxidase, that is they are oxidase negative. They form acid and sometimes gas from fermentation of glucose and mannose. They usually produce H_2S . They are also capable of surviving freezing in water for long periods. Salmonellae are resistant to certain chemicals (eg, brilliant green, sodium tetrathionate, sodium deoxycholate) that inhibit other enteric bacteria; such compounds are therefore useful for inclusion in agar media to specifically select for isolation of *Salmonella* species from feces.

Classification

The taxonomic classification of salmonellae is complex because the organisms are a continuum rather than a defined species. The members of the genus *Salmonella* were originally classified on the basis of epidemiology; host range; biochemical reactions; and structures of the O, H, and Vi antigens according to the Kauffman-White scheme. The names (eg, *Salmonella* Typhi and *Salmonella typhimurium*) were originally written as if they were genus and species; this form of the nomenclature remains in widespread but incorrect use. DNA–DNA hybridization studies have demonstrated that there are seven evolutionary groups. Currently, the genus *Salmonella* is divided into two species each with multiple subspecies and serotypes. The two species are *Salmonella enterica* and *Salmonella bongori* (formerly subspecies V). Based on the phenotypic profiles, *S. enterica* is further subdivided into six subspecies, which are subspecies *enterica* (subspecies I), subspecies *salamae* (subspecies II), subspecies *arizonae* (subspecies IIIa), subspecies *diarizonae* (subspecies IIIb), subspecies *houtenae* (subspecies IV), and subspecies *indica* (subspecies VI). Most human illness is caused by *S. enterica* subspecies I strains, which are usually found in warm-blooded animals and humans. Rarely human infections may be caused by subspecies IIIa and IIIb or the other subspecies that are frequently found in cold-blooded animals or the environment. Infections due to subspecies IIIa and IIIb are commonly associated with exotic pets such as reptiles.

Furthermore, salmonellae can be classified by their serotype; serotypes are assigned according to antigenically diverse surface structures: somatic O antigens and flagellar H antigens. The 2 species of *Salmonella* and their respective subspecies consist of more than 2500 serotypes (serovars), including

TABLE 15-3 Representative Antigenic Formulas of Salmonellae

O Group	Serotype	Antigenic Formula ^a
D	<i>Salmonella</i> Typhi	9, 12 (Vi):d:—
A	<i>Salmonella</i> Paratyphi A	1, 2, 12:a—
C ₁	<i>Salmonella</i> Choleraesuis	6, 7:c:1,5
B	<i>Salmonella</i> Typhimurium	1, 4, 5, 12:i:1, 2
D	<i>Salmonella</i> Enteritidis	1, 9, 12:g, m:—

^aO antigens: boldface numerals.
(Vi): Vi antigen if present.
Phase 1 H antigen: lowercase letter.
Phase 2 H antigen: numeral.

more than 1400 in DNA hybridization group I. Less than 100 serotypes account for the majority of all human infections, worldwide. The widely accepted nomenclature for classification at the present time is as follows: for example, *S. enterica* subspecies *enterica* serotype Typhimurium, which can be shortened to *Salmonella* Typhimurium with the genus name in italics and the serotype name in roman type. National and international reference laboratories may use the antigenic formulas following the subspecies name because they impart more precise information about the isolates (see Table 15-3).

Based on their serotype, *Salmonella* species (specifically *S. enterica*) are further classified as “typhoidal” and “non-typhoidal”. Typhoidal *Salmonella* refers to those specific serotypes that cause typhoid (“enteric”) fever, and include the serotypes Typhi, Paratyphi A, Paratyphi B, and Paratyphi C. Non-typhoidal *Salmonella* refers to all other serotypes. The non-typhoidal *Salmonella* serotypes Enteritidis and Typhimurium are the two most common serotypes reported in the United States. The more than 1400 other salmonellae that are isolated in clinical laboratories are serogrouped by their O antigens as A, B, C₁, C₂, D, and E; however, some are nontypeable with this set of antisera. These isolates are then sent to reference laboratories for definitive serologic identification. Definitive serologic typing allows public health officials to monitor and assess the epidemiology of *Salmonella* infections on a statewide and nationwide basis.

Variation

Some salmonellae may lose H antigens and become non-motile. Loss of O antigen is associated with a change from smooth to rough colony form. Vi antigen may be lost partially or completely. Antigens may be acquired (or lost) in the process of transduction.

Pathogenesis and Clinical Findings

Typhoidal *Salmonella* serotypes Typhi and Paratyphi are highly adapted to humans and have no other known natural host, and infection with these organisms implies acquisition

from a human source. Non-typhoidal *Salmonella* serotypes are the leading cause of gastroenteritis, worldwide. The Non-typhoidal salmonellae can be acquired from many different animals as well as from the environment. While many animals become infected with salmonellae through their environment, other, different animals may naturally harbor salmonellae in their intestine without obvious disease. Animals known to commonly carry salmonellae include food and farm animals, as well as pets; these include, for example, poultry, pigs, cattle, cats, dogs, rodents, turtles, parrots, and other (exotic) pet animals.

Humans almost always acquire the bacteria via the oral route, usually with contaminated food or drink. The mean infective dose to produce clinical or subclinical infection in humans is 10⁵–10⁸ salmonellae; however, the infectious dose for typhoid fever caused by *Salmonella* Typhi is significantly lower (perhaps ≤10³ organisms). Among the host factors that contribute to “resistance” to *Salmonella* infection are gastric acidity, normal intestinal microbiota, and local intestinal immunity (see later).

Salmonellae produce three main types of disease in humans, but mixed forms may occur (Table 15-4).

A. The “Enteric Fevers” (Typhoid Fever)

Enteric fever is a severe, systemic illness, caused by *Salmonella* Typhi (most common) or *Salmonella* Paratyphi. While the disease is common in many parts of the world, it occurs less frequently in developed countries (eg, United States, Canada, and Western Europe); annually, approximately 300 cases are reported in the United States, with many of these cases being related to foreign travel. After ingestion of contaminated foods or beverages, the salmonellae reach the small intestine, from which they pass through the epithelium via specialized M-cells overlying the Peyer’s patches, and then enter the intestinal lymphatics with subsequent invasion into the bloodstream. Via bloodstream the salmonellae are spread to many other organs (eg, bone marrow). The organisms also multiply within the intestinal lymphoid tissue and are excreted in stools. The principal lesions are hyperplasia and necrosis of lymphoid tissue (eg, Peyer’s patches); hepatitis; focal necrosis of the liver; and inflammation of the gallbladder, periosteum, lungs, and other organs have been also described.

After an incubation period of 10–14 days, fever, malaise, headache, constipation, bradycardia, and myalgia occur. The fever rises to a high plateau (39°C to 40°C), and the spleen and liver become enlarged. Rose spots, 1–4 mm blanching pink macules, are the classic cutaneous manifestation of enteric fever. Rose spots are typically observed on the chest and abdomen; however, they are fairly uncommon (<5%) in patients with uncomplicated typhoid fever. Abdominal symptoms may include diarrhea, constipation, and general abdominal pain; however, invasive diarrhea is typically not observed in typhoid fever. Contrary to the elevated white blood cell counts (WBC) in patients with sepsis, the WBC in

TABLE 15-4 Clinical Diseases Induced by *Salmonellae*

	Enteric Fevers	Septicemias	Enterocolitis
Incubation period	7–20 days	Variable	8–48 hours
Onset	Insidious	Abrupt	Abrupt
Fever	Gradual; then high plateau with “typhoidal” state	Rapid rise; then spiking “septic” temperature	Usually low
Duration of disease	Several weeks	Variable	2–5 days
Gastrointestinal symptoms	Often early constipation; later, bloody diarrhea	Often none	Nausea, vomiting, diarrhea at onset
Blood culture results	Positive in first to second weeks of disease	Positive during high fever	Negative
Stool culture results	Positive from second week on; negative earlier in disease	Infrequently positive	Positive soon after onset

patients with typhoid fever is normal or low. In the preantibiotic era, the chief complications of enteric fever were intestinal hemorrhage and perforation, and the mortality rate was as high as 10–15%. With the advent of successful antibiotic treatment, the mortality rate has decreased to less than 1%.

B. Bacteremia and Other Invasive *Salmonella* Infections

Bacteremia and vascular infection occurs in approximately 8% of patients with non-typhoidal *Salmonella* infections. Cases of meningitis, septic arthritis, and osteomyelitis have been reported as a complication of *Salmonella* bacteremia, but are exceedingly rare events. Bacteremia and vascular infections may occur more frequently with *Salmonella choleraesuis* and *Salmonella* Dublin, but can be caused by any *Salmonella* serotype. Bacteremia is more common among patients with comorbidities (eg, immunosuppression), as well as infants and the elderly. Furthermore, salmonellae have a tendency to cause infections of vascular sites or persistent high-level bacteremia. Endovascular infection complicating *Salmonella* bacteremia usually involves the aorta, often associated with atherosclerotic plaques or aneurysms; people older than 50 years have a higher risk of developing such complications. In general, mortality from *Salmonella* bacteremia in children is less than 10%; however, the risk of death and other complications is higher in adults and patients with underlying conditions. Mortality associated with *Salmonella* bacteremia increases with duration of bacteremia and potential progression to septic shock; rates range from 14% to 60% in patients with concomitant endovascular invasion.

C. Enterocolitis

This is the most common manifestation of *Salmonella* infection. In the United States, *Salmonella typhimurium* and *Salmonella enteritidis* may be most common causes, but enterocolitis can be caused by any of the more than 1400 group I serotypes of salmonellae. Eight to 48 hours after ingestion of contaminated food or water, there is nausea, headache,

vomiting, and profuse diarrhea; however, incubation periods of up to 7 days have been reported as well. Microscopic stool examinations typically show leukocytes, and red cells are less often observed. Inflammatory lesions of the small and large intestine are present. Low-grade fever (38°C to 39°C) and abdominal cramping are very common clinical symptoms. Diarrhea is usually self-limited with a typical duration of 3 to 7 days. Bacteremia is a rare (2–4%) complication, except in immunocompromised patients. Blood culture results are usually negative; however, stool cultures are positive for salmonellae and may remain positive for several weeks after clinical recovery. The mean duration for carriage of organisms after resolution of the infection is 4–5 weeks; antibiotic therapy may increase the duration of carriage.

Diagnostic Laboratory Tests

A. Specimens

Freshly passed stool is the preferred specimen for the diagnosis of non-typhoidal *Salmonella*; specimens collected during the early stages of the enteric illness have the highest yield for recovery of the causative organism. Collection of multiple stool specimens may enhance the recovery rate of *Salmonella*, as well as other enteric pathogens (eg, *Shigella*).

For the definitive diagnosis of enteric fever, *Salmonella* Typhi or *Salmonella* Paratyphi must be isolated in culture; appropriate specimens are blood, bone marrow, other sterile sites, urine, or intestinal secretions. While blood cultures are the most commonly used method of diagnosis, blood must often be taken repeatedly in order to increase the yield of recovering the organism. In enteric fevers and septicemias, blood culture results are often positive in the first week of the disease. The addition of stool cultures may increase the overall yield of recovering the causative organism. While bone marrow cultures have the highest sensitivity (80% to 95%), they are clinically less practical for patients suspected to have enteric fever. Urine culture results may be positive after the second week of the illness. A positive culture of duodenal

drainage establishes the presence of salmonellae in the biliary tract in patients who are carriers of the organisms.

B. Bacteriologic Methods for Isolation of Salmonellae

1. **Differential medium cultures**—EMB, MacConkey, or deoxycholate medium permits rapid detection of lactose nonfermenters (not only salmonellae and shigellae but also *Proteus*, *Pseudomonas*, etc). Gram-positive organisms are somewhat inhibited. Bismuth sulfite medium permits rapid detection of salmonellae, which form black colonies because of H_2S production. Most salmonellae produce H_2S (Figure 15-4A).
2. **Selective medium cultures**—The specimen may also be plated on salmonella-shigella (SS) agar, Hektoen enteric (HE) agar (Figure 15-4B), xylose-lysine desoxycholate (XLD) agar, or desoxycholate-citrate agar, all of which favor growth of salmonellae and shigellae over other Enterobacteriaceae. Chromogenic agars specifically for salmonella recovery are also available.
3. **Enrichment cultures**—The specimen (usually stool) can also be placed into selenite F or tetrathionate broth, both of which inhibit replication of normal intestinal bacteria

and permit multiplication of salmonellae. After incubation for 1–2 days, an aliquot from this broth is plated on differential and selective media.

4. **Final identification**—Suspect colonies from solid media are identified by biochemical reaction patterns and slide agglutination tests with specific sera.

C. Serologic Methods

Serologic techniques are used to identify unknown cultures with known sera (see later discussion) and may also be used to determine antibody titers in patients with unknown illness, although the latter is not very useful in the diagnosis of *Salmonella* infections.

1. **Agglutination test**—In this test, known sera and unknown culture are mixed on a slide. Clumping, when it occurs, can be observed within a few minutes. This test is particularly useful for rapid preliminary identification of cultures. There are commercial kits available to agglutinate and serogroup salmonellae by their O antigens: A, B, C_1 , C_2 , D, and E.
2. **Tube dilution agglutination test (Widal test)**—Serum agglutinins rise sharply during the second and third weeks

A

B

FIGURE 15-4 **A:** *Salmonella* species on TSI agar slant. **B:** *Salmonella* species on HE agar. *Salmonella* spp. do not ferment the carbohydrates present in the HE agar; however, the organism produces H_2S , and the ferric ammonium citrate in the HE agar result in the *Salmonella* colonies to appear black. On TSI agar slant, *Salmonella* spp. ferment glucose, but not lactose; they produce H_2S and gas [$K/A, G, H_2S^+$]. (Courtesy of S. Riedel.)

of S serotype Typhi infection. The Widal test to detect these antibodies against the O and H antigens has been in use for decades. At least two serum specimens, obtained at intervals of 7–10 days, are needed to prove a rise in antibody titer. Serial dilutions of unknown sera are tested against antigens from representative salmonellae. False-positive and false-negative results occur. The interpretive criteria when single serum specimens are tested vary, but a titer against the O antigen of greater than 1:320 and against the H antigen of greater than 1:640 is considered positive. High titer of antibody to the Vi antigen occurs in some carriers. Alternatives to the Widal test include rapid colorimetric and EIA methods. There are conflicting reports in the literature regarding superiority of these methods to the Widal test. Results of serologic tests for *Salmonella* infection cannot be relied upon to establish a definitive diagnosis of typhoid fever and are most often used in resource poor areas of the world where blood cultures are not readily available.

D. Nucleic Acid Amplification Tests

As mentioned above for the shigellae, several commercial NAATs are available for direct detection of salmonellae in fecal samples of patients with acute diarrhea. Since these assays are new, performance characteristics of the assays and their impact on public health surveillance are still under investigation.

Immunity

Infections with *Salmonella* Typhi or *Salmonella* Paratyphi usually confer a certain degree of immunity. While reinfection may occur, it is often milder than the initial infection. Circulating antibodies to O and Vi are related to resistance to infection and disease. However, relapses may occur in 2–3 weeks after recovery despite antibodies. Secretory IgA antibodies may prevent attachment of salmonellae to intestinal epithelium.

Patients, specifically children, with sickle cell disease or sickle cell trait are exceedingly more susceptible to *Salmonella* infections and particularly to *Salmonella* bacteremia and its complications (eg, osteomyelitis) when compared to people with normal hemoglobin.

Treatment

Early diagnosis and prompt initiation of appropriate antibiotic therapy prevents complications of enteric fever and *Salmonella* bacteremia/sepsis. As mentioned above, prompt and appropriate antibiotic treatment results in a significant decrease of the mortality rate (<1%); the mortality rate in untreated cases of enteric fever is greater than 10%. Uncomplicated enteric fever can be managed in the outpatient setting with oral azithromycin (1 g once, followed by 500 mg daily for 7 days); patients with complications should be hospitalized, and treatment with a parenteral third-generation cephalosporin or fluoroquinolone for at least 10 days is

recommended. Non-typhoidal *Salmonella* bacteremia should be empirically treated with a third-generation cephalosporin (eg, ceftriaxone) and a fluoroquinolone, until results from antimicrobial susceptibility testing (AST) are available. In cases of documented (or suspected) endovascular infection (eg, infected aneurysm), patients should be treated with intravenous ceftriaxone, or ampicillin, or a fluoroquinolone for 6 weeks, followed by oral therapy. Early surgical resection of the infected aneurysm is also recommended.

Since non-typhoidal *Salmonella* gastroenteritis is typically a self-limited illness, antimicrobial therapy is usually not necessary and not recommended. In fact, clinical symptoms and excretion of the salmonellae may be prolonged by antimicrobial therapy. In cases with severe diarrhea, replacement of fluids and electrolytes is essential. However, antimicrobial treatment of *Salmonella* gastroenteritis should be considered in neonates as well as patients with immunosuppression (eg, chemotherapy, HIV), and those older than 50 years with suspected or confirmed atherosclerosis, cardiac valvular, and endovascular disease.

For susceptible organisms, oral therapy with amoxicillin, trimethoprim–sulfamethoxazole, or a fluoroquinolone is appropriate. For immunocompromised patients, treatment may be as long as 7–14 days. Plasmid-mediated multiple drug resistance has been increasingly noted among *Salmonella* isolates, and specifically in *Salmonella* Typhi. Antimicrobial susceptibility testing is an important laboratory test, specifically for *Salmonella* isolates from extraintestinal specimens, in order to select the most appropriate antibiotic for therapy.

In most patients who are carriers, the organisms persist in the gallbladder (particularly if gallstones are present) and in the biliary tract. Some chronic carriers have been cured by ampicillin alone, but in most cases cholecystectomy must be combined with antibiotic treatment.

Epidemiology

The incidence and mortality of enteric (typhoid) fever due to *Salmonella* Typhi and Paratyphi vary significantly by region; rates are lowest in developed countries such as the United States, Canada, and Western Europe. Since S. Typhi and S. Paratyphi are pathogens restricted to humans only, transmission occurs from either a carrier or an infected person to others; in addition, fecally contaminated food and water are an important source for the infection, and the organisms can persist for weeks after passage in water and on environmental surfaces and food stuff.

While the incidence of non-typhoidal *Salmonella* human infection has significantly increased over the past decades in many countries, worldwide, the incidence of non-typhoidal salmonellosis in the United States has not changed significantly during the past 15 years; in fact, the CDC reported a slight decrease during the years 2012 and 2013. According to the CDC, an estimated 1.2 million cases of foodborne salmonellosis occur annually in the United States. Unlike *Salmonella* Typhi and S. Paratyphi, the many non-typhoidal

Salmonella can be acquired from various reservoirs, humans, animals, or a contaminated environmental source. The feces of people who have unsuspected subclinical disease or who are carriers are a more important source of contamination than frank clinical cases that are usually isolated promptly after recognition; carriers “shedding” organisms, who are working as food handlers (eg, commercial food preparation industry), are a major source of larger outbreaks of salmonellosis. In addition, many animals, including cattle, rodents, and fowl, are naturally infected with a variety of salmonellae and have the bacteria in their tissues (meat), excreta, or eggs. The high incidence of salmonellae in commercially prepared chickens has been widely publicized. This problem is furthermore aggravated by the widespread use of animal feeds containing antimicrobial drugs that in turn favor the proliferation of drug-resistant salmonellae and their potential transmission to humans. Finally, human salmonellosis associated with exposure to pet animals is a recurring public health problem in the United States, and individual cases or even small outbreaks have been reported.

A. Carriers

After manifest or subclinical infection, some individuals continue to harbor salmonellae in their tissues for variable lengths of time (i.e., convalescent carriers or healthy permanent carriers). Three percent of survivors of typhoid fever become permanent carriers, harboring the organisms in the gallbladder, biliary tract, or, rarely, the intestine or urinary tract.

B. Sources of Infection

The sources of infection are food and drink that have been contaminated with salmonellae. The following sources are important:

1. **Water**—Contamination with feces often results in explosive epidemics
2. **Milk and other dairy products (ice cream, cheese, custard)**—Contamination with feces and inadequate pasteurization or improper handling; some outbreaks are traceable to the source of supply
3. **Shellfish**—From contaminated water
4. **Dried or frozen eggs**—From infected fowl or contaminated during processing
5. **Meats and meat products**—From infected animals (poultry) or contamination with feces by rodents or humans
6. **“Recreational” drugs**—Marijuana and other drugs
7. **Animal dyes**—Dyes (eg, carmine) used in drugs, foods, and cosmetics
8. **Household pets**—Dogs, cats, hedgehogs, birds, and exotic pets such as reptiles (eg, turtles, iguanas, snakes)

Prevention and Control

Sanitary measures must be taken to prevent contamination of food and water by rodents or other animals that excrete

salmonellae. Infected poultry, meats, and eggs must be thoroughly cooked. Carriers must not be allowed to work as food handlers or in food preparation areas, and should observe strict personal hygienic precautions.

Two typhoid vaccines are currently available in the United States: an oral live, attenuated vaccine (Ty21a) and a parenteral Vi capsular polysaccharide vaccine (Vi CPS) for intramuscular use. Vaccination is recommended for travelers to endemic regions, especially if the traveler visits rural areas or small villages where food choices are limited. Both vaccines have an efficacy of 50–80%. The time required for primary vaccination and age limits for each vaccine varies, and individuals should consult the Centers for Disease Control and Prevention’s website or obtain advice from a travel clinic regarding the latest vaccine information.

CHAPTER SUMMARY

- Members of the Enterobacteriaceae are short Gram-negative rods that grow rapidly on standard laboratory media.
- Members of this group are catalase positive; nitrate positive and, with the exception of *Plesiomonas*, are cytochrome oxidase negative. Organisms can be identified readily by the ability to ferment lactose on MacConkey and by other biochemical reactions or newer technologies such as MALDI-TOF MS.
- Enterobacteriaceae express a variety of antigens that include somatic or O antigens (cell wall lipopolysaccharide), capsular or K antigens, and H or flagellar antigens. *Salmonella* express the Vi antigens. These antigens are virulence factors and can be used to serotype those organisms that possess them.
- Enterobacteriaceae cause a variety of human infections that can be broadly classified as either enteric diseases or extraintestinal infections such as urinary tract infections, bacteremia, and meningitis.
- Genera associated with enteric illnesses include *Salmonella*, *Shigella*, and diarrheagenic *E. coli*, of which there are six types based on the mechanism of disease (eg, toxigenic or invasive or both).
- The most common extraintestinal infections caused by these organisms are urinary tract infections. *E. coli* predominates, but the urea-positive organisms such as *Proteus* species can cause bladder and kidney stones.
- Enterobacteriaceae acquired in the hospital environment are often resistant to many antimicrobial agents usually mediated by plasmid-encoded resistance determinants.

REVIEW QUESTIONS

1. A 20-year-old college student goes to the student health center because of dysuria, frequency, and urgency on urination for 24 hours. She has recently become sexually active. On urinalysis,

many polymorphonuclear cells are seen. The most likely organism responsible for these symptoms and signs is

- (A) *Staphylococcus aureus*
 - (B) *Streptococcus agalactiae*
 - (C) *Gardnerella vaginalis*
 - (D) *Lactobacillus* species
 - (E) *E. coli*
2. A 27-year-old woman is admitted to the hospital because of fever, with increasing anorexia, headache, weakness, and altered mental status of 2 days' duration. She works for an airline as a cabin attendant, flying between the Indian subcontinent and other places in Southeast Asia and the West Coast of the United States. Ten days before admission, she had a diarrheal illness that lasted for about 36 hours. She has been constipated for the past 3 days. Her temperature is 39°C, heart rate is 68 beats/min, blood pressure is 120/80 mm Hg, and respirations are 18 breaths/min. She knows who she is and where she is but does not know the date. She is picking at the bedclothes. Rose spots are seen on her trunk. The remainder of the physical examination is normal. Blood cultures are done, and an intravenous line is placed. The most likely cause of her illness is
 - (A) Enterotoxigenic *E. coli* (ETEC)
 - (B) *S. sonnei*
 - (C) *S. enterica* subspecies *enterica* serotype Typhimurium (*Salmonella* Typhimurium)
 - (D) *S. enterica* subspecies *enterica* serotype Typhi (*Salmonella* Typhi)
 - (E) Enteroinvasive *E. coli* (EIEC)
 3. Blood cultures from the patient in Question 2 grow a non-lactose-fermenting Gram-negative bacillus. Which of the following is likely to be a constituent of this organism?
 - (A) O antigen 157, H antigen 7 (O157:H7)
 - (B) Vi antigen (capsule; virulence antigen)
 - (C) O antigen 139 (O139)
 - (D) Urease
 - (E) K1 (capsular type 1)
 4. A 37-year-old woman with a history of urinary tract infections comes to the emergency department with burning on urination along with frequency and urgency. She says her urine smells like ammonia. The cause of her urinary tract infection is likely to be
 - (A) *E. aerogenes*
 - (B) *Proteus mirabilis*
 - (C) *Citrobacter freundii*
 - (D) *E. coli*
 - (E) *S. marcescens*
 5. An 18-year-old student has abdominal cramps and diarrhea. A selective agar plate is inoculated and grows suspicious Gram-negative rods. Triple sugar iron agar is used to identify the isolates as salmonellae or shigellae. A result suggesting one of these two pathogens would be
 - (A) Production of urease
 - (B) Motility in the medium
 - (C) Inability to ferment lactose and sucrose
 - (D) Fermentation of glucose
 - (E) Production of gas in the medium
 6. An uncommon serotype of *S. enterica* subspecies *enterica* was found by laboratories in the health departments of adjacent states. The isolates were all from a small geographic area on either side of the border between the states, suggesting a common source for the isolates. (All of the isolates were from otherwise healthy young adults who smoked marijuana; the same *Salmonella* was isolated from a specimen of the marijuana.) By what method did the public health laboratories determine that these isolates were the same?
 - (A) Capsular (K antigen) typing
 - (B) O antigen and H antigen typing
 - (C) DNA sequencing
 - (D) Sugar fermentation pattern determination
 - (E) Decarboxylase reaction pattern determination
 7. A 43-year-old man with diabetes has a 4-cm nonhealing foot ulcer. Culture of the ulcer yields *S. aureus*, *Bacteroides fragilis*, and a Gram-negative bacillus that swarms across the blood agar plate covering the entire surface of the agar after 36 hours. The Gram-negative bacillus is a member of the genus
 - (A) *Escherichia*
 - (B) *Enterobacter*
 - (C) *Serratia*
 - (D) *Salmonella*
 - (E) *Proteus*
 8. A 4-year-old boy from Kansas City who recently started attending preschool and after-school daycare is brought to his pediatrician for a diarrheal illness characterized by fever to 38.2°C, severe lower abdominal pain, and initially watery diarrhea. His mother became concerned because the stools are now blood tinged 24 hours into the illness, and the child appears quite ill. The mother reports that two other children who attend the same after-school daycare have recently had diarrheal disease, one of whom likewise had bloody stools. Which of the following is the most likely pathogen causing the illness in these children?
 - (A) An enterotoxigenic strain of *E. coli*
 - (B) *S. enterica* subspecies *enterica* serotype Typhi (*Salmonella* Typhi)
 - (C) *S. sonnei*
 - (D) *Edwardsiella tarda*
 - (E) *Klebsiella oxytoca*
 9. A 5-year-old girl attended a birthday party at a local fast food restaurant. About 48 hours later, she developed cramping abdominal pain and a low-grade fever and had five episodes of loose, bloody stools. She is taken to a local emergency department the next evening because the diarrhea has continued, and she now appears pale and lethargic. On presentation, she has a temperature of 38°C, and she is hypotensive and tachycardic. The abdominal examination reveals tenderness in the lower quadrants. Laboratory work is remarkable for a serum creatinine of 2.0 mg/dL, a serum hemoglobin of 8.0 mg/dL, thrombocytopenia, and evidence of hemolysis. What is the most likely pathogen causing this child's illness?
 - (A) *E. coli* O157:H7
 - (B) *S. enterica* subspecies *enterica* serotype Typhimurium
 - (C) Enteropathogenic *E. coli*
 - (D) *Edwardsiella tarda*
 - (E) *P. shigelloides*
 10. A 55-year-old homeless man with alcoholism presents with severe multilobar pneumonia. He requires intubation and mechanical ventilation. A Gram-stain of his sputum reveals numerous polymorphonuclear leukocytes and Gram-negative rods that appear to have a capsule. The organism is a lactose fermenter on MacConkey agar and is very mucoid. It is nonmotile

and lysine decarboxylase positive. What is the most likely organism causing this man's illness?

- (A) *S. marcescens*
- (B) *E. aerogenes*
- (C) *P. mirabilis*
- (D) *Klebsiella pneumoniae*
- (E) *M. morganii*

11. Which of the following statements regarding O antigens is correct?

- (A) All Enterobacteriaceae possess identical O antigens.
- (B) They are found in the polysaccharide capsules of enteric bacteria.
- (C) They are covalently linked to a polysaccharide core.
- (D) They do not stimulate an immune response in the host.
- (E) They are not important in the pathogenesis of infection caused by enteric bacteria.

12. Which of the following test methods is the least sensitive procedure for diagnosis of colitis caused by Shiga toxin-producing *E. coli*?

- (A) Culture on sorbitol MacConkey agar
- (B) Toxin testing using an enzyme immunoassay
- (C) Cell culture cytotoxin assay using Vero cells
- (D) Polymerase chain reaction for detection of the genes that encode Shiga toxin

13. An HIV-positive man recently traveled to the Caribbean for a 2-week vacation. He developed acute watery diarrhea and abdominal pain without fever during the second week of his vacation. Three weeks later, he is seen in clinic for persistent symptoms, and he is concerned because he is beginning to lose weight. Given this history, you suspect:

- (A) Enteroinvasive *E. coli*
- (B) *Salmonella* Typhi
- (C) Enteropathogenic *E. coli*
- (D) *Shigella flexneri*
- (E) Enterotoxigenic *E. coli*

14. Heat-labile toxin of ETEC acts by which of the following mechanisms?

- (A) Attachment and effacement
- (B) Activation of adenyl cyclase
- (C) Aggregative adherence
- (D) Ribosomal dysfunction
- (E) None of the above

15. A young woman presents with recurrent urinary tract infections caused by the same *Proteus mirabilis* strain. What is the major concern?

- (A) She does not take her medication.
- (B) She is pregnant because pregnant patients are more susceptible to UTIs.
- (C) She has a bladder or kidney stone.
- (D) Her partner is infected.
- (E) She has occult diabetes and should have a glucose tolerance test.

Pseudomonas, Acinetobacter, Burkholderia, and Stenotrophomonas

The *Pseudomonas* and *Acinetobacter* species are widely distributed in soil and in water. *Pseudomonas aeruginosa* sometimes colonizes humans and is the major human pathogen of the pseudomonads. *P. aeruginosa* is invasive and toxigenic, produces infections in patients with abnormal host defenses, and is an important nosocomial pathogen. Of the *Acinetobacter* species, *Acinetobacter baumannii* is responsible for most human infections. It is a significant nosocomial pathogen, especially in critical or intensive care units, and is frequently resistant to multiple antibiotics. *Burkholderia* consists of many species, but only *B. cepacia* complex, *B. pseudomallei*, *B. mallei*, and *B. gladioli* are notable human or animal pathogens. Like pseudomonads, *Burkholderia* are typically environmental organisms and opportunistic pathogens. *Stenotrophomonas maltophilia* is typically not pathogenic for healthy people; however, the organism is a well-known opportunistic and nosocomial pathogen.

THE PSEUDOMONAD GROUP

The pseudomonads are ubiquitous Gram-negative, motile, aerobic rods, some of which produce water-soluble pigments. The pseudomonads inhabit a variety of diverse environments, such as soil, water, plants, and animals. Data from the Human Microbiome Project demonstrated that *P. aeruginosa* is almost completely absent from the skin and nares of healthy humans but some other pseudomonads may be present in small numbers in the normal intestinal flora and oral cavity. Changes in the microbiome, however, can lead to decrease in colonization resistance, and subsequent colonization of specific body sites (eg, skin, mucous membranes, and GI tract) with *P. aeruginosa*. The clinically relevant *Pseudomonas* species can be divided into two distinct groups based on their ability to produce certain fluorescent pigments. The fluorescent group of pseudomonads includes *P. aeruginosa*, *P. fluorescens*, *P. putida*, *P. monteilii*, *P. veronii*, and *P. mosselii*. These organisms produce a water-soluble, yellow-green pigment (pyoverdine) that fluoresces blue-green under UV light. Many of the strains of *P. aeruginosa* also produce pyocyanin,

a blue pigment that, when combined with pyoverdine, results in the bright green color that is characteristic of this organism. The following pseudomonads belong to the non-fluorescent group: *P. stutzeri*, *P. mendocina*, *P. alcaligenes*, *P. pseudoalcaligenes*, *P. luteola*, and *P. oryzae*. While *P. aeruginosa* is considered the major pathogen in the group of pseudomonads, other pseudomonads may be less frequently isolated in clinical laboratories as a cause of disease, as well. The classification of pseudomonads is based on rRNA/DNA homology and common culture characteristics.

PSEUDOMONAS AERUGINOSA

P. aeruginosa is widely distributed in nature and is commonly present in moist environments in hospitals. While not a part of the normal human microbiome, *P. aeruginosa* is capable of colonization of various body sites (eg, mucous membrane, respiratory tract, and GI tract). It is known to cause disease in humans, especially in people with altered and decreased host defenses (eg, neutropenia, chemotherapy, and burn wounds). The acquisition of the organism and subsequent infection can be either endogenous or exogenous. Endogenous infection occurs after colonization (eg, bacteremia after GI tract colonization); exogenous infection typically occurs from an environmental reservoir via a susceptible portal of entry (eg, burn wound infections or hot tub folliculitis).

Morphology and Identification

A. Typical Organisms

P. aeruginosa is motile and rod shaped, measuring about $0.6 \times 2 \mu\text{m}$ (Figure 16-1). It is Gram-negative and occurs as single bacteria, in pairs, and occasionally in short chains.

B. Culture

P. aeruginosa is an obligate aerobe that grows readily on many types of culture media, sometimes producing a sweet or grape-like or corn taco-like odor. Some strains hemolyze blood. *P. aeruginosa* forms smooth round colonies with a

FIGURE 16-1 Gram-stain of *P. aeruginosa*, which are about 0.6 × 2 μm. Original magnification ×1000. (Courtesy of H Reyes.)

fluorescent greenish color. As mentioned above, many strains of *P. aeruginosa* produce a non-fluorescent bluish pigment, **pyocyanin**, which diffuses into the agar. As all fluorescent pseudomonads, *P. aeruginosa* also produces the fluorescent pigment **pyoverdine**, which gives a greenish color to the agar when combined with pyocyanin (Figure 16-2). Some strains

FIGURE 16-2 *P. aeruginosa* on a 10-cm Mueller-Hinton agar plate. Individual colonies are 3–4 mm in diameter. The organism produces pyocyanin, which is blue, and pyoverdine, which is green. Together these pigments produce the blue-green color that is seen in the agar around the pseudomonas growth. (Courtesy of S Lowe.)

may also produce a dark red pigment (**pyorubin**) or a brown-black pigment (**pyomelanin**).

P. aeruginosa in culture can produce multiple colony types (Figure 16-3); isolates from different colony types may also have different biochemical and enzymatic activities and different antimicrobial susceptibility patterns. Sometimes, it may not be clear if the colony types represent different strains of *P. aeruginosa* or are variants of the

FIGURE 16-3 Variation in colony morphology of *P. aeruginosa*. **A:** Green-gray colonies 6–8 mm in diameter on a 10-cm blood agar plate; the blood in the agar around the colonies shows hemolysis. **B:** Silver-toned dry colonies on a similar blood agar plate; no hemolysis is present (the *dark shadow* in the lower part of the picture is from a label on the back of the Petri dish). (Courtesy of H Reyes.)

same strain. Cultures from patients with cystic fibrosis (CF) often yield *P. aeruginosa* organisms that form mucoid colonies as a result of overproduction of alginate, an exopolysaccharide. In CF patients, the exopolysaccharide appears to provide the matrix for the organisms to live in a biofilm (see Chapters 2 and 9).

C. Growth Characteristics

P. aeruginosa grows well at 37°C to 42°C; its growth at 42°C helps differentiate it from other *Pseudomonas* species that produce fluorescent pigments. *P. aeruginosa*, like all pseudomonads, does not ferment carbohydrates, but many strains oxidize glucose; these organisms are therefore oxidase positive. Identification is usually based on colonial morphology, the presence of characteristic pigments, oxidase positivity, and growth at 42°C. Differentiation of *P. aeruginosa* from other pseudomonads on the basis of biochemical activity requires testing with a large battery of substrates.

Antigenic Structure and Toxins

Pseudomonads, and *P. aeruginosa* specifically, produce a variety of virulence factors, including adhesins, enzymes, and toxins. Pili (fimbriae) extend from the cell surface and promote attachment to host epithelial cells. An exopolysaccharide, **alginate**, is responsible for the mucoid colonies seen in cultures from patients with CF. Lipopolysaccharide, which exists in multiple immunotypes, is responsible for many of the endotoxic properties of the organism. *P. aeruginosa* can be typed by lipopolysaccharide immunotype and by pyocin (bacteriocin) susceptibility. Most *P. aeruginosa* isolates from clinical infections produce extracellular enzymes, including elastases, proteases, and two hemolysins (a heat-labile phospholipase C and a heat-stable glycolipid). In addition, pyocyanin produced by *P. aeruginosa* is responsible for the production of hydrogen peroxide and superoxide, and stimulates the release of interleukin (IL)-8. The increased release of IL-8 serves as an attractant for neutrophils. The other pigment, pyoverdine, serves as a siderophore, that is, binds iron.

Many strains of *P. aeruginosa* produce **exotoxin A**, which causes tissue necrosis and is lethal for animals when injected in purified form. The toxin blocks protein synthesis by a mechanism of action identical to that of diphtheria toxin, although the structures of the two toxins are not identical. Antitoxins to exotoxin A are found in some human sera, including those of patients who have recovered from serious *P. aeruginosa* infections.

P. aeruginosa produces four type III-secreted toxins that cause cell death or interfere with the host immune response to infection. **Exoenzyme S** and **exoenzyme T** are bifunctional enzymes with GTPase and ADP-ribosyl transferase activity, **exoenzyme U** is a phospholipase, and **exoenzyme Y** is an adenyl cyclase.

Pathogenesis

P. aeruginosa is pathogenic only when introduced into areas devoid of normal defenses, such as when mucous membranes and skin are disrupted by direct tissue damage as in the case of burn wounds; when intravenous or urinary catheters are used; or when neutropenia is present, as in cancer chemotherapy. The bacterium attaches to and colonizes the mucous membranes or skin, invades locally, and subsequently produces systemic disease (eg, bloodstream infections). These processes are promoted by the pili, enzymes, and toxins described earlier. Lipopolysaccharide plays a direct role in causing fever, shock, oliguria, leukocytosis and leukopenia, disseminated intravascular coagulation, and adult respiratory distress syndrome. The propensity to form biofilms by *P. aeruginosa* in the lumen of catheters and in the lungs of CF patients greatly contributes to the virulence of this organism.

P. aeruginosa and other pseudomonads are resistant to many antimicrobial agents and therefore may become dominant and overgrow the more susceptible bacteria that are part of the normal microbiota and are suppressed.

Clinical Findings

P. aeruginosa produces infection of wounds and burns, often giving rise to blue-green pus; meningitis when introduced by lumbar puncture or during a neurosurgical procedure; and urinary tract infection when introduced by catheters and instruments or in irrigating solutions. Involvement of the respiratory tract, especially from contaminated respirators, results in necrotizing pneumonia. In CF patients, *P. aeruginosa* causes a chronic pneumonia, a significant cause of morbidity and mortality in this population. The bacterium is often found in mild otitis externa in swimmers. It may cause invasive (malignant) otitis externa in patients with diabetes. Infection of the eye, which may lead to rapid destruction of the eye, occurs most commonly after injury or surgical procedures. In infants or debilitated persons, *P. aeruginosa* may invade the bloodstream and result in fatal sepsis; this occurs commonly in patients with leukemia or lymphoma who have received antineoplastic drugs or radiation therapy and in patients with severe burns. In most *P. aeruginosa* infections, the symptoms and signs are nonspecific and are related to the organ involved. Occasionally, verdoglobin (a breakdown product of hemoglobin) or fluorescent pigment can be detected in wounds, burns, or urine by ultraviolet fluorescence. Hemorrhagic necrosis of skin occurs often in sepsis caused by *P. aeruginosa*; the lesions, called **ecthyma gangrenosum**, are surrounded by erythema and often do not contain pus. *P. aeruginosa* can be seen on Gram-stained specimens from ecthyma lesions, and culture results are positive. Ecthyma gangrenosum is uncommon in bacteremia caused by organisms other than *P. aeruginosa*. A form of folliculitis associated with poorly chlorinated hot tubs and swimming pools can be seen in otherwise healthy persons.

Diagnostic Laboratory Tests

A. Specimens

Specimens from skin lesions, pus, urine, blood, spinal fluid, sputum, and other material should be obtained as indicated by the type of infection.

B. Smears

Gram-negative rods are often seen in smears. No specific morphologic characteristics differentiate pseudomonads in specimens from enteric or other Gram-negative rods.

C. Culture

Specimens are plated on blood agar and the differential media commonly used to grow the enteric Gram-negative rods. Pseudomonads grow readily on most of these media, but they may grow more slowly than the enterics. *P. aeruginosa* does not ferment carbohydrates, including lactose, and is easily differentiated from the lactose-fermenting bacteria. Culture is the specific test for diagnosis of *P. aeruginosa* infection. *P. aeruginosa* can be presumptively identified as described above; however, definitive identification, as well as differentiation from and identification of other pseudomonads, requires a battery of biochemical tests. Various manual as well as automated commercial test systems are available. In recent years, MALDI-TOF MS has been shown to reliably identify the various fluorescent and non-fluorescent pseudomonads.

Treatment

Traditionally, treatment of *P. aeruginosa* infections with a single antibiotic has not been recommended; a combination antimicrobial therapy is usually required to successfully treat significant infections. There are two reasons why antimicrobial therapy of serious *P. aeruginosa* infections can be challenging: patients with *P. aeruginosa* infections are typically immunocompromised, and in addition, the organism itself is frequently resistant to multiple different classes of antimicrobial agents. An extended-spectrum penicillin, such as piperacillin active against *P. aeruginosa*, is typically used in combination with an aminoglycoside, usually tobramycin. Other drugs active against *P. aeruginosa* include aztreonam; carbapenems such as imipenem or meropenem; and the fluoroquinolones, including ciprofloxacin. Of the cephalosporins, ceftazidime, cefoperazone, and cefepime are active against *P. aeruginosa*; ceftazidime is often used with an aminoglycoside in primary therapy of *P. aeruginosa* infections, especially in patients with neutropenia.

P. aeruginosa is intrinsically resistant to many antimicrobial agents, and can acquire additional resistance to many other antimicrobial agents via horizontal gene transfer and/or mutations. The mechanisms responsible for intrinsic resistance include various multidrug efflux pumps (eg, affecting β -lactams, fluoroquinolones, macrolides, and other antibiotics), as well as an inducible chromosomal AmpC

β -lactamase (resistance to ampicillin, amoxicillin, amoxicillin-clavulanate, first- and second-generation cephalosporins, as well as ceftriaxone and cefotaxime). The susceptibility/resistance patterns of *P. aeruginosa* vary geographically, and antimicrobial susceptibility testing (AST) should be routinely performed to support the choice of antimicrobial therapy and hospital antibiotic stewardship programs. In addition, multidrug resistance has become a major issue in the management of hospital-acquired infections with *P. aeruginosa* because of acquisition of chromosomal β -lactamases, extended-spectrum β -lactamases, carbapenemases, porin channel mutations, and efflux pumps. The percentage of *P. aeruginosa* isolates that are multidrug resistant varies considerably (<1% to >50%) by region and country.

Epidemiology and Control

P. aeruginosa is primarily a nosocomial, opportunistic pathogen, and the methods for control of infection are similar to those for other nosocomial pathogens. According to data from the National Healthcare Safety Network (NHSN), *P. aeruginosa* is currently the fifth most common pathogen implicated in hospital-acquired infections in the United States. Infection rates are especially high in the ICU setting and in long-term acute care hospitals. Because *Pseudomonas* species thrive in moist environments, special attention should be paid to sinks, water baths, showers, hot tubs, and other wet areas. However, given the organism's ubiquitous presence in the hospital environment, all attempts to eliminate its presence are practically ineffective. Instead, effective infection-control prevention measures should focus on preventing the contamination of medical equipment, potential cross-contamination between patients, and selection of appropriate antibiotic therapy guidelines to prevent emergence of drug resistance. For epidemiologic purposes, strains of *P. aeruginosa* can be typed using molecular typing techniques; these techniques are especially useful during "outbreak" investigations.

BURKHOLDERIA PSEUDOMALLEI AND BURKHOLDERIA MALLEI

Burkholderia pseudomallei is a small, motile, oxidase-positive, aerobic Gram-negative bacillus, which is also indole-negative and resistant to colistin and gentamicin. It grows on standard bacteriologic media (eg, sheep blood agar), forming colonies that are initially (24–48 hours) mucoid and smooth/creamy, but upon further length of incubation change in appearance to rough and wrinkled and in color from cream to orange. The organism grows at 42°C and oxidizes glucose, lactose, and a variety of other carbohydrates. *B. pseudomallei* is the cause of melioidosis (also called Whitmore's disease) that occurs predominantly in Southeast Asia and Northern Australia. In these regions of endemicity, infection is typically seasonal, with highest rates of occurrence during the monsoon wet season. The organism is a natural saprophyte that has been

cultured from soil, fresh water, rice paddies, and vegetable produce. Human infection probably originates from these sources by ingestion or inhalation of contaminated dust or water, and by contact with contaminated soil via skin abrasions. Epizootic *B. pseudomallei* infection occurs in sheep, goats, swine, horses, and other animals, although animals do not appear to be a primary reservoir for the organism. Because the organism has been used as an agent of biowarfare/bioterrorism by some countries in the past, *B. pseudomallei* is currently classified as a Category B agent of bioterrorism by the U.S. Centers for Disease Control and Prevention (CDC); if weaponized, the bacterium would be moderately easy to disseminate (eg, aerosolization), resulting in moderate to severe morbidity, and high mortality if untreated. However, mortality is likely much lower (fewer than 2 out of 10 people according to the CDC's information), if timely and appropriate antibiotic treatment is administered.

Melioidosis may manifest itself as acute, subacute, or chronic infection. The incubation period can be as short as 2–3 days, but latent periods of months to years also occur. A localized suppurative infection can occur at the inoculation site where there is a break in the skin. This localized infection may lead to the acute septicemic form of infection with involvement of many organs. The signs and symptoms depend upon the major sites of involvement. The most common form of melioidosis is pulmonary infection, which may be a primary pneumonitis (*B. pseudomallei* transmitted through the upper airway or nasopharynx) or subsequent to a localized suppurative infection and bacteremia. The patient may have fever and leukocytosis with consolidation of the upper lobes. Subsequently, the patient may become afebrile, while upper lobe cavities develop, yielding an appearance similar to that of tuberculosis on chest films. Some patients develop chronic suppurative infection with abscesses in skin, brain, lung, myocardium, liver, bone, and other sites. Patients with chronic suppurative infections may be afebrile and have indolent disease. Latent infection is sometimes reactivated as a result of immunosuppression.

The diagnosis of melioidosis should be considered for a patient from an endemic area who has fulminant upper lobe pulmonary or unexplained systemic disease. A Gram-stain of an appropriate specimen will show small Gram-negative bacilli; bipolar staining (safety pin appearance) is seen with Wright's stain or methylene blue stain. A positive culture result is diagnostic. A positive serologic test result is diagnostically helpful and constitutes evidence of past infection.

Melioidosis has a high mortality rate if untreated. Surgical drainage of localized infection may be necessary. *B. pseudomallei* is intrinsically resistant to penicillin, ampicillin, first- and second-generation cephalosporins, gentamicin and tobramycin, and macrolides. *B. pseudomallei* is generally susceptible to ceftazidime, imipenem, meropenem, and amoxicillin–clavulanic acid, ceftriaxone, cefotaxime, and trimethoprim–sulfamethoxazole (TMP-SMX); however, antimicrobial susceptibility testing should be performed to determine actual susceptibility patterns for

a specific strain or organism. Resistance to TMP-SMX has been reported in *B. pseudomallei*, and depends on the geographic region where the organisms is endemic (rates vary between 2% and 16%). Depending on the clinical setting, the initial antimicrobial therapy should be for a minimum of 10–14 days with ceftazidime, imipenem, or meropenem; TMP-SMX can be considered in patients with severe allergy to β -lactam antimicrobials. Eradication therapy with TMP-SMX or doxycycline should follow the intensive initial therapy and be continued for a minimum of 3 months. Recurrent disease because of failure of organism eradication can occur for several reasons, including resistance to TMP-SMX or any other of the other antibiotics of choice; however, the most important cause is likely noncompliance with the long-term eradication therapy.

Burkholderia mallei is the cause of glanders, a highly communicable disease, typically affecting livestock (eg, horses). Although rare, it can be transmitted to humans. Since the 1940s, no case of glanders in animals has been reported in the United States; the last human case in the United States was reported in 1934. Along with anthrax, *B. mallei* was used as an agent of biowarfare during World War I; therefore, like *B. pseudomallei*, it is also currently classified as a Category B agent of bioterrorism by the CDC. The organism is a small Gram-negative, oxidase-positive, aerobic bacillus. Unlike *B. pseudomallei*, *B. mallei* is nonmotile and does not persist in the environment. The organism can be isolated from blood, sputum, urine, or skin lesions. Human glanders can be acute or chronic; after inhalation of the organism, an acute febrile illness can occur, with ulcerative necrosis of the upper airways, potentially leading to bronchopneumonia, followed by septicemia and dissemination to other internal organs. Percutaneous exposure causes local suppurative skin lesions with associated regional lymphadenopathy. Recommended treatment for glanders is the same as for melioidosis. With animal quarantine and other control measures, equine glanders has been eradicated in most countries, worldwide, and human cases are exceedingly rare.

BURKHOLDERIA CEPACIA COMPLEX

Burkholderia cepacia and 17 other genomospecies comprise the ***B. cepacia* complex**. The classification of these bacteria is complex; their specific identification is difficult. These are environmental organisms able to grow in water, soil, plants, animals, and decaying vegetable materials. In hospitals, members of the *B. cepacia* complex have been isolated from a variety of water and environmental sources from which they can be transmitted to patients. People with CF and those patients with chronic granulomatous disease are particularly vulnerable to infection with bacteria in the *B. cepacia* complex. It is likely that *B. cepacia* can be transmitted from one CF patient to another by close contact. They may have asymptomatic carriage, progressive deterioration over a period of months, or rapidly progressive deterioration with necrotizing

pneumonia and bacteremia. Although a relatively small percentage of CF patients become infected, the association with progressive disease makes *B. cepacia* complex a major concern for these patients. A diagnosis of *B. cepacia* infection in a CF patient may significantly alter the patient's life because he or she may not be allowed association with other CF patients and may be removed from eligibility for lung transplantation. *B. gladioli*, while primarily a plant pathogen, is known to cause infections in CF patients and people with chronic granulomatous diseases and/or other immunosuppression.

B. cepacia grows on most media used in culturing specimens for Gram-negative bacteria. Selective media containing colistin (eg, *B. cepacia* selective agar) can be used and is recommended when culturing the sputum of patients with CF. *B. cepacia* grows more slowly than enteric Gram-negative rods, and it may take 3 days before colonies are visible. *B. cepacia* are oxidase positive and lysine decarboxylase positive and produce acid from glucose, but differentiating *B. cepacia* from other pseudomonads, including *S. maltophilia*, requires a battery of biochemical tests and can be difficult. Submission of isolates to reference laboratories is recommended because of the prognostic implications of colonization in CF patients. In the United States, the Cystic Fibrosis Foundation (<http://www.cff.org>) supports a reference laboratory that uses phenotypic and genotypic methods to confirm the identity of organisms within the *B. cepacia* complex. Antimicrobial susceptibility testing should be performed on *B. cepacia* complex isolates, although slow growth may make routine testing somewhat difficult. *B. cepacia* complex isolates recovered in clinical laboratories frequently express one or more antibiotic resistances; isolates recovered from CF patients often are multidrug- or pan-resistant. Antimicrobial resistance is typically mediated by efflux pumps, antimicrobial degradation or modifying enzymes, and/or altered membrane functions. Carbapenems (eg, meropenem), TMP-SMX, chloramphenicol, and minocycline are effective treatments. Ceftazidime and ciprofloxacin have demonstrated good activity against *B. cepacia*, especially in its planktonic form or when embedded in a biofilm.

STENOTROPHOMONAS MALTOPHILIA

S. maltophilia is a free-living Gram-negative rod that is widely distributed in the environment, specifically in aquatic and humid environments. On blood agar and other enriched bacteriologic media, colonies may have a lavender-green color; an ammonia-like odor may also be noted. The organism is generally oxidase negative, and positive for lysine decarboxylase, DNase, and oxidation of glucose and maltose; the oxidation of maltose is particularly strong (hence the name "maltophilia").

S. maltophilia is an increasingly important cause of hospital-acquired infections in patients who are receiving broad-spectrum antimicrobial therapy and in immunocompromised patients. It has been isolated from many anatomic

sites, including respiratory tract secretions, urine, wounds, and blood. The isolates are often part of mixed flora present in the specimens. When blood culture results are positive, it is commonly in association with use of indwelling intravenous catheters.

S. maltophilia is usually susceptible to trimethoprim-sulfamethoxazole and ticarcillin-clavulanic acid but resistant to many other commonly used antimicrobials, including cephalosporins, aminoglycosides, imipenem, and the quinolones. In addition, the organism is also resistant to various heavy metals, which makes *S. maltophilia* tolerant to silver-lined catheters. While *S. maltophilia* is often intrinsically resistant to many antibiotics, the organism can also rapidly develop resistance during infection when exposed to other antibiotics and through lateral gene transfer. The widespread use of antimicrobial agents plays an important role in the increased frequency with which *S. maltophilia* causes disease and develops additional resistances.

ACINETOBACTER

Acinetobacter species are aerobic, catalase-positive, oxidase-negative, Gram-negative bacteria that are ubiquitous in nature and widely distributed in soil and water

A. baumannii is the species most commonly isolated in clinical laboratories. Other clinically relevant *Acinetobacter* species that are associated with health care infections include *A. nosocomialis*, *A. pittii*, and *A. ursingii*; *A. lwoffii* and *A. radioresistens* have been described to colonize human skin and cause occasionally infections in immunocompromised patients. All other *Acinetobacter* species, some of which have not yet received species names but are referred to as genomospecies, are typically found in water and soil. *Acinetobacter* are usually coccobacillary or coccoid in appearance, but rod-shaped form may also be seen. *Acinetobacter* may also appear as diplococci on smears and then resemble *Neisseria*; however, the *Neisseria* produces oxidase, and *Acinetobacter* does not. *Acinetobacter* grows well on most types of agar media used to culture specimens from patients. While most acinetobacters grown between 20°C and 35°C, the majority of medically important acinetobacters grow best at 35°C to 37°C; some strains of *A. baumannii* are capable of growing at 44°C. Accurate species-level identification of *Acinetobacter* using conventional biochemical tests and/or commercially available phenotypic identification systems can be challenging at times; newer test methods such as MALDI-TOF mass spectrometry have been shown to reliably identify various *Acinetobacter* species, specifically those that are medically relevant.

Acinetobacters are opportunistic pathogens, known to cause nosocomial infections. *A. baumannii* has been isolated from blood, sputum, skin, pleural fluid, and urine. With increasing frequency, *Acinetobacter* has been isolated from hospitalized patients in the ICU or those requiring mechanical ventilation, leading to increased morbidity, length of stay,

and higher mortality. Differentiation between colonization and true infection (pneumonia) is critically important but may be difficult, when *Acinetobacter* species are recovered from respiratory specimens (eg, sputum). *Acinetobacter* species account for up to 2% of all bloodstream infections, and are commonly associated with intravascular devices. Other clinical settings associated with *Acinetobacter* infections include meningitis following neurosurgical procedures, wound infections (eg, severe trauma and burn wounds), and urinary tract infections (associated with biofilm production on indwelling urinary catheters). The pathogenicity of *Acinetobacter* strains is related to the organism's ability to create biofilms on surfaces and human cells and its increasing antimicrobial resistance. Many of the acinetobacters isolated in the hospital setting are multidrug resistant, and therapy of these infections can be difficult. In many cases, the only active antimicrobial agent may be colistin. Such multidrug-resistant *A. baumannii* strains were a common cause of serious wound infections among servicemen in Iraq who sustained traumatic injuries. Environmental contamination during the injury as well as acquisition during medical care had been proposed as a potential source for these infections. Since then, the global establishment of multidrug-resistant *A. baumannii* as a cause of health care-associated infections has become a significant public health challenge. Antimicrobial susceptibility testing should be performed prior to selection of the most appropriate antimicrobial drugs for therapy. The more susceptible *Acinetobacter* strains respond most commonly to gentamicin, amikacin, or tobramycin and to extended-spectrum penicillins or cephalosporins. Tigecycline has been successfully used to treat infections due to carbapenem-resistant acinetobacters. Combination treatment may be necessary, specifically for more complex infections and multidrug-resistant organisms. Given the ability of *Acinetobacter* species to survive on environmental surfaces for extended periods of time, preventative measures, such as strict environmental and hand hygiene, are important measures for infection control in hospitals to prevent outbreaks or even just the spread of *Acinetobacter* between a few patients.

CHAPTER SUMMARY

- *P. aeruginosa* is an oxidase-positive, frequently pigmented, Gram-negative, glucose-nonfermenting rod that elaborates enzymes, such as elastase, and other virulence factors that promote disease. This organism causes a broad range of infections from superficial skin disease, such as hot tub folliculitis, to Gram-negative sepsis and ecthyma gangrenosum in neutropenic patients.
- *B. pseudomallei* is found in the soil and water of Southeast Asia and Northern Australia. Human infection with *B. pseudomallei* can be acute, subacute, or chronic and involves multiple organ systems. It is also considered a Category B agent of bioterrorism by the CDC.

- *B. cepacia* complex are a group of closely related environmental organisms second only to *P. aeruginosa* as a cause of morbidity and mortality in CF patients.
- *Acinetobacter* species and *S. maltophilia* are two organisms frequently associated with hospital-acquired infections that are very drug resistant. In some cases, the only active agent for multidrug-resistant *Acinetobacter* is colistin.

REVIEW QUESTIONS

1. A sputum culture of a patient with cystic fibrosis grows *P. aeruginosa* that forms very mucoid colonies. The implication of this observation is which one of the following?
 - (A) The *P. aeruginosa* is highly susceptible to the aminoglycoside antimicrobial tobramycin.
 - (B) The *P. aeruginosa* is infected with a pyocin (a bacteriocin).
 - (C) The colonies are mucoid because they have polysaccharide capsule of hyaluronic acid.
 - (D) The exotoxin A gene has been disabled and the *P. aeruginosa* is no longer able to block host cell protein synthesis.
 - (E) The *P. aeruginosa* has formed a biofilm in the patient's airway.
2. An environmental Gram-negative bacillus that is resistant to cephalosporins, aminoglycosides, and quinolones has become a very important nosocomial pathogen largely because it is selected by use of those antibiotics. This Gram-negative bacillus can take 2–3 days to grow and must be differentiated from *B. cepacia*. It is
 - (A) *P. aeruginosa*
 - (B) *A. baumannii*
 - (C) *Alcaligenes xylosoxidans*
 - (D) *Klebsiella pneumoniae*
 - (E) *S. maltophilia*
3. A 17-year-old girl with cystic fibrosis has a slight increase in her frequent cough and production of mucoid sputum. A sputum specimen is obtained and plated on routine culture media. The predominant growths are Gram-negative bacilli that form very mucoid colonies after 48 hours of incubation. These bacilli are oxidase positive, grow at 42°C, and have a grapelike odor. These Gram-negative bacilli are which of the following?
 - (A) *K. pneumoniae*
 - (B) *P. aeruginosa*
 - (C) *Staphylococcus aureus*
 - (D) *Streptococcus pneumoniae*
 - (E) *B. cepacia*
4. The sputum from a 26-year-old patient with cystic fibrosis is plated on a colistin-containing agar. After 72 hours of incubation, the colistin-containing agar grows Gram-negative bacilli that are oxidase positive but are otherwise difficult to identify. This microorganism is of major concern. It is sent to a reference laboratory so that molecular methods can be used to identify or rule out which of the following?
 - (A) *P. aeruginosa*
 - (B) *B. cepacia*
 - (C) *Haemophilus influenzae*
 - (D) *Pseudomonas putida*
 - (E) *B. pseudomallei*

5. *Acinetobacter* species:
 - (A) are only found in a hospital environment
 - (B) May appear as Gram-positive rods
 - (C) Can mimic the morphology of *Haemophilus* species in Gram-stains of endocervical secretions
 - (D) Can be a significant cause of ventilator-associated pneumonia in intensive care unit patients
 - (E) Are susceptible to most antibiotics
6. A 37-year-old firefighter sustains smoke inhalation and is hospitalized for ventilatory support. He has a severe cough and begins to expectorate purulent sputum. Gram-stain of his sputum specimen shows numerous polymorphonuclear cells and numerous Gram-negative rods. Sputum culture grows numerous Gram-negative rods that are oxidase positive. They grow well at 42°C. On clear agar medium, they produce a green color in the agar. The agar where the green color is located fluoresces when exposed to ultraviolet light. The organism causing the patient's infection is
 - (A) *P. aeruginosa*
 - (B) *K. pneumoniae*
 - (C) *Escherichia coli*
 - (D) *B. cepacia*
 - (E) *B. pseudomallei*
7. The mechanism of action of exotoxin A of *P. aeruginosa* is
 - (A) To activate acetylcholine esterase
 - (B) To block elongation factor 2
 - (C) To form pores in white blood cells and increase cation permeability
 - (D) To increase intracellular cyclic adenosine monophosphate
 - (E) To split lecithin into phosphorylcholine and diacylglycerol
8. Patients deficient in these cells are particularly at high risk for developing serious systemic infections with *P. aeruginosa*:
 - (A) Eosinophils
 - (B) Neutrophils
 - (C) Macrophages
 - (D) Natural killer cells
 - (E) CD4+ T cells
9. A marine wounded in Afghanistan returns to her home a paraplegic. Her past medical history included surgery to amputate both her legs below the knee and the placement of a suprapubic tube to repair damage to her bladder. She is now at the VA outpatient clinic with a recurrent urinary tract infection that has not responded to conventional antibiotic regimens for community-acquired cystitis. Her urine is positive for small, plump Gram-negative coccobacilli. When cultured, this organism does not ferment carbohydrates, does not hydrolyze urea, does not reduce nitrates, and does not make hydrogen sulfide. The organism most likely causing this marine's infection is:
 - (A) *Klebsiella oxytoca*
 - (B) *E. coli*

- (C) *Staphylococcus saprophyticus*
- (D) *Proteus mirabilis*
- (E) *Acinetobacter baumannii*

10. A 70-year-old neutropenic patient was diagnosed with ecthyma gangrenosum 3 days after he developed a fever of 39°C. Blood cultures drawn the day his fever started grew out overnight a strictly aerobic, Gram-negative rod that was oxidase positive and did not ferment lactose. Which of the following antibiotic regimens would be most appropriate for treating this patient?
 - (A) Tobramycin + piperacillin/tazobactam
 - (B) Vancomycin + metronidazole
 - (C) Cefazolin
 - (D) Tigecycline
 - (E) Oxacillin

Vibrio, Aeromonas, Campylobacter, and Helicobacter

Vibrio, *Aeromonas*, *Campylobacter*, and *Helicobacter* are Gram-negative rods that are all widely distributed in nature. The vibrios are found in marine and surface waters. Aeromonads are inhabitants of aquatic ecosystems, worldwide, and are found in fresh and brackish waters. The campylobacters are found in many species of animals, including many domesticated animals. Helicobacters are found in the gastrointestinal and hepatobiliary tracts of humans and various other mammals (eg, dogs, cats, cattle, and dolphins), as well as chickens and wild birds. *Vibrio cholerae* produces an enterotoxin that causes cholera, a profuse watery diarrhea that can rapidly lead to dehydration and death. *Campylobacter jejuni* is a common cause of enteritis in humans. *Helicobacter pylori* is associated with gastritis and duodenal ulcer disease.

THE VIBRIOS

Vibrios are among the most common bacteria in marine and estuarine waters, worldwide. They are comma-shaped, curved, and sometimes straight facultatively anaerobic, fermentative rods; they are catalase and oxidase positive, and most species are motile by means of monotrichous or multitrichous polar flagella. Vibrios can grow within a broad temperature range (14–40°C), and all species require sodium chloride (NaCl) for growth; hence the term halophilic (“salt loving”). *V. cholerae* serogroups O1 and O139 cause cholera in humans, and other vibrios, most commonly *V. parahaemolyticus* and *V. vulnificus*, are important human pathogens, causing skin and soft tissue infections, sepsis, or gastroenteritis. The medically important vibrios are listed in Table 17-1.

VIBRIO CHOLERAЕ

The bacterium *V. cholerae* is the cause of cholera. The epidemiology of cholera closely parallels the recognition of *V. cholerae* transmission in water and the development of

sanitary water systems. Cholera is associated with poor sanitation, as well as direct contact with or consumption of contaminated water and/or food (eg, water used for drinking, cooking, bathing, and crop irrigation).

Morphology and Identification

A. Typical Organisms

Upon first isolation, *V. cholerae* is a comma-shaped, curved rod 2–4 µm long (Figure 17-1). It is actively motile by means of a polar flagellum. On prolonged cultivation, organisms may become straight rods that can resemble other Gram-negative enteric bacteria.

B. Culture

V. cholerae produces convex, smooth, round colonies that are opaque and granular in transmitted light. *V. cholerae* and most other vibrios grow well at 37°C on routine agar media to recover enteric bacteria (eg, blood agar and MacConkey agar); however, selective agars for *Vibrio* species, such as **thiosulfate-citrate-bile salts-sucrose (TCBS) agar** and enrichment broth (eg, alkaline peptone broth), can also be used to recover vibrios, especially from specimens (eg, stool) when a mixture of organisms is expected. All vibrios, including *V. cholerae*, grow well on TCBS agar; *V. cholerae* produces yellow colonies (sucrose fermented) on TCBS agar that are readily visible against the dark-green background of the agar (Figure 17-2). Non-sucrose-fermenting vibrios (eg, most strains of *V. parahaemolyticus* and *V. vulnificus*) produce green colonies on TCBS agar. Characteristically, vibrios grow at a very high pH (8.5–9.5) and are rapidly killed by acid. To ensure optimal recovery of vibrios, stool specimens should be collected early in the course of the diarrheal illness; prompt inoculation onto appropriate agar media is necessary. If processing of specimens may be delayed, the stool specimen should be mixed in a Cary-Blair transport medium and refrigerated.

In areas where cholera is endemic, direct cultures of stool on selective media, such as TCBS, and enrichment

TABLE 17-1 The Medically Important Vibrios

Organism	Human Disease
<i>V. cholerae</i> serogroups O1 and O139	Epidemic and pandemic cholera
<i>V. cholerae</i> serogroups non-O1/non-O139	Cholera-like diarrhea; mild diarrhea; rarely, extraintestinal infection
<i>V. parahaemolyticus</i>	Gastroenteritis, wound infections, septicemia
<i>V. vulnificus</i>	Gastroenteritis, wound infections, septicemia

broth cultures (eg, alkaline peptone water with 1% NaCl, pH 8.5) are appropriate. In the United States and other countries where cholera is rare, routine use of TCBS agar for stool cultures in clinical laboratories is generally not necessary or cost effective; exceptions may be made if recovery of other vibrios (eg, *V. parahaemolyticus*) is a frequent and/or seasonal occurrence (eg, coastal U.S. regions with regular and frequent consumption of bivalve mollusks and crustaceans).

C. Growth Characteristics

V. cholerae regularly ferments sucrose and mannose but not arabinose. A positive oxidase test result is a key step in the preliminary identification of *V. cholerae* and other vibrios. While most *Vibrio* species are halophilic, requiring the presence of NaCl (range from < 0.5–4.5%) to grow, *V. cholerae* can grow on most agar media without additional salt.

FIGURE 17-1 Gram-stain of *V. cholerae*. Often they are comma shaped or slightly curved (arrows) and 1 × 2 to 4 μm. Original magnification ×1000.

FIGURE 17-2 Colonies of *V. cholerae* growing on thiosulfate, citrate, bile salts, and sucrose agar. The glistening yellow colonies are 2–3 mm in diameter and are surrounded by a diffuse yellowing of the indicator in the agar up to 1 cm in diameter. The plate is 10 cm in diameter.

Antigenic Structure and Biologic Classification

Many vibrios share a single heat-labile flagellar H antigen. Antibodies to the H antigen are probably not involved in the protection of susceptible hosts.

V. cholerae has O lipopolysaccharides that confer serologic specificity. Based on the O antigen, there are over 200 serogroups; however, only *V. cholerae* strains of serogroup O1 and O139 cause epidemic and pandemic cholera. Occasionally, non-O1/non-O139 *V. cholerae* strains have been described as causes of cholera-like diarrheal disease. Antibodies to the O antigens tend to protect laboratory animals against infections with *V. cholerae*.

The *V. cholerae* serogroup O1 antigen has determinants that make possible further subtyping; these serotypes are Ogawa, Inaba, and Hikojima. Furthermore, two biotypes of epidemic *V. cholerae* have been defined, classic and El Tor. The El Tor biotype produces a hemolysin, gives positive results on the Voges-Proskauer test, and is resistant to polymyxin B. Molecular techniques can also be used to type *V. cholerae*. Typing is used for epidemiologic studies, and tests generally are done only in reference laboratories.

V. cholerae O139 is very similar to *V. cholerae* O1 El Tor biotype. *V. cholerae* O139 does not produce the O1 lipopolysaccharide and does not have all the genes necessary to make this antigen. *V. cholerae* O139 and other non-O1 *V. cholerae* strains, as well as *V. vulnificus* produce acidic polysaccharide capsules; however, *V. cholerae* O1 does not make a capsule.

***Vibrio cholerae* Enterotoxin**

V. cholerae produce a heat-labile enterotoxin with a molecular weight (MW) of about 84,000, consisting of subunits A (MW, 28,000) and B (see Chapter 9). Ganglioside GM₁ serves as the mucosal receptor for subunit B, which promotes entry of subunit A into the cell. Activation of subunit A₁ yields increased levels of intracellular cyclic adenosine monophosphate (cAMP) and results in prolonged hypersecretion of water and electrolytes. There is increased sodium-dependent chloride secretion, and absorption of sodium and chloride by the microvilli is inhibited. Electrolyte-rich diarrhea occurs with as much as 20–30 L/day, resulting in dehydration, shock, acidosis, and death. The genes for *V. cholerae* enterotoxin are located on the bacterial chromosome. Cholera enterotoxin is antigenically related to LT of *Escherichia coli* and can stimulate the production of neutralizing antibodies. However, the precise role of antitoxic and antibacterial antibodies in protection against cholera is not clear.

Pathogenesis and Pathology

While *V. cholerae* is pathogenic only for humans, the organism is not solely dependent on the human host for propagation. *V. cholerae* also grows in brackish and marine waters in close association with copepods and zooplankton; the organism can also survive in water of low salinity when it is warm and sufficient organic substrates are available to support growth. A person with normal gastric acidity may have to ingest as many as 10¹⁰ or more *V. cholerae* to become infected; therefore, contaminated food and water are the all more likely source of infections, rather than person-to-person contact. The infectious dose, however, is significantly lower (10²–10⁴) in a person with achlorhydria or hypochlorhydria. Any medication (eg, proton-pump inhibitors) or condition that decreases stomach acidity makes a person more susceptible to infection with *V. cholerae*.

V. cholerae is a noninvasive mucosal pathogen. The organisms do not reach the bloodstream but remain within the intestinal tract. Virulent *V. cholerae* organisms attach to the microvilli of the brush border of epithelial cells. There they multiply and liberate cholera toxin and perhaps mucinases and endotoxin.

Clinical Findings

The spectrum of disease due to *V. cholerae* ranges from asymptomatic intestinal colonization to mild, moderate, or severe diarrhea. About 50% of infections with classic *V. cholerae* are asymptomatic, as are about 75% of infections with the El Tor biotype. The incubation period after ingestion of a sufficiently high infectious dose of *V. cholerae* is 12 hours to 3 days for persons who develop symptoms, depending largely on the size of the inoculum ingested. There is a sudden onset of nausea and vomiting, followed by profuse diarrhea with abdominal cramps. Stools, which resemble “rice

water,” contain mucus, epithelial cells, and large numbers of vibrios. In cases of severe cholera the volume of diarrheal fluid loss can exceed 1 L/h. The rapid loss of fluid and electrolytes can lead to profound dehydration, painful muscle spasms, metabolic acidosis, hypokalemia, and hypovolemic shock with circulatory collapse, and anuria with associated renal failure. The mortality rate without treatment is between 25% and 50%, and can be as high as 70%. On the contrary, mortality in patients promptly treated with fluid replacement has been reported as low as 1% or less. The diagnosis of a full-blown case of cholera presents no problem in the presence of an epidemic. However, sporadic or mild cases are not readily differentiated from other diarrheal diseases. The *V. cholerae* O1 El Tor biotype tends to cause milder disease than the classic biotype.

Diagnostic Laboratory Tests

A. Specimens

As stated above, stool specimens should be collected early in the course of the diarrheal illness and inoculated within 2–4 hours of collection onto appropriate agar media, to ensure optimal recovery of vibrios. If processing of specimens may be delayed, the stool specimen should be mixed in a Cary-Blair transport medium and refrigerated.

B. Smears

Direct detection of *V. cholerae* on smears made from stool samples is not distinctive of the organism, and therefore not routinely recommended. Dark-field or phase-contrast microscopy can be used to detect *V. cholerae* O1 directly from stool samples or the enrichment broth. Observation of “shooting star” motility is suggestive of *V. cholerae* O1; if the motility is extinguished after mixing the sample with a polyvalent O1 antiserum, the organism is confirmed as *V. cholerae* O1. However, if there is no motility or the type of motility does not change after applying the antiserum, the organism is not *V. cholerae* O1.

C. Culture

Vibrios, including *V. cholerae*, grow well on most agar media (including MacConkey and blood agar) used in clinical laboratories. Some strains of *V. cholerae* may however be inhibited on MacConkey agar. Growth is rapid in alkaline peptone broth or water, containing 1% NaCl with a pH of 8.5, or on TCBS agar; typical colonies can be picked in 18 hours of growth. For enrichment, a few drops of stool can be incubated for 6–8 hours in taurocholate peptone broth (pH, 8.0–9.0); organisms from this culture can then be stained or subcultured onto other appropriate agar media. Accurate identification of vibrios, including *V. cholerae*, using commercial systems and kit assays is quite variable. MALDI-TOF MS is a promising newer methodology for identification of vibrios, and studies have shown rapid and reproducibly accurate identification for *V. parahaemolyticus*.

D. Specific Tests

Other rapid detection methods for *V. cholerae* include immunofluorescence, latex agglutination, and coagulation assays. *V. cholerae* organisms are further identified by slide agglutination tests using anti-O group 1 or group 139 antisera and by biochemical reaction patterns. The diagnosis of cholera under field conditions has been reported to be facilitated by a sensitive and specific immunochromatographic dipstick test.

Immunity

Gastric acid provides some protection against vibrios, including *V. cholerae*.

An attack of cholera is followed by immunity to reinfection, but the duration and degree of immunity are not known. In experimental animals, specific IgA antibodies occur in the lumen of the intestine. Similar antibodies in serum develop after infection but last only a few months. Vibriocidal antibodies in serum (titer $\geq 1:20$) have been associated with protection against colonization and disease. The presence of antitoxin antibodies has not been associated with protection.

Treatment

The most important part of treating cholera patients consists of water and electrolyte replacement to correct the severe dehydration and salt depletion. Several guidelines, including those from the World Health Organization, for effective rehydration have been published and are provided in the list of references at the end of this chapter. Many antimicrobial agents are effective against *V. cholerae*, but these play a secondary role in patient management. Appropriate antimicrobial therapy can also reduce the duration and amount of shedding of *Vibrio* organisms in the stool. The antibiotic choice should be based on the local antimicrobial resistance profiles. Tetracycline has shown to be very effective treatment for cholera, and generally has better efficacy than furazolidone and chloramphenicol. Erythromycin and/or azithromycin are an appropriate choice of antimicrobial therapy in children and in pregnant women; other antimicrobial agents that are effective include trimethoprim-sulfamethoxazole, fluoroquinolones, and doxycycline. Increasing antimicrobial resistance in *V. cholerae* has been noticed, globally. Specifically, in areas where cholera is endemic or epidemic, tetracycline resistance has been reported with increasing frequency; the resistance genes are carried by transmissible plasmids. In addition, another likely risk factor for the emerging antimicrobial resistance is the widespread use of antibiotics, including the mass distribution for prophylaxis in asymptomatic individuals. During previous epidemics, antibiotic resistance emerged in the context of antibiotic prophylaxis for household contacts of cholera patients.

Epidemiology, Prevention, and Control

Cholera and cholera-like illnesses have been mentioned in various writings since antiquity; since 1817, seven cholera

pandemics (worldwide epidemics) have been recorded. Six pandemics of cholera occurred between 1817 and 1923 caused most likely by *V. cholerae* O1 of the classic biotype and largely originating in Asia, particularly the Indian subcontinent. The seventh pandemic began in 1961 in the Celebes Islands, Indonesia, with spread throughout Asia, and the Middle East Europe, and Africa. This pandemic was caused by *V. cholerae* O1 biotype El Tor. Starting in 1991, the seventh pandemic spread to Peru and then to other countries of South America and Central America. Subsequently, variant atypical or hybrid *V. cholerae* O1 El Tor strains have emerged in Africa and in Asia; these strains appear to be more virulent than the original El Tor or the classical strains. In 2011, the WHO reported an estimated occurrence of 600,000 cases of cholera with approximately 8000 deaths, annually among 58 countries. However, it is reasonable to state that these numbers for morbidity and mortality underestimate the global burden of this disease. More recent estimates suggest that approximately 3 million cases with an associated mortality of 95,000 cases occur globally and on an annual basis. In 1992, a new serotype of *V. cholerae*, the strain *V. cholerae* O139 Bengal, emerged in India and in Bangladesh. It is believed that horizontal gene transfer of a novel somatic antigen and capsule from an unknown bacterium onto the El Tor strain caused this new strain to emerge. The clinical disease of this new strain is very similar to cholera caused by the O1 strain; however, adults are more often affected by the O139 strain, since prior infection with the O1 strains does not confer immunity. Some consider the cholera epidemic caused by the serotype O139 strain to be the eighth pandemic that began in the Indian subcontinent in 1992–1993, considering the subsequent spread throughout Southeast Asia. However, to date, no cases of *V. cholerae* O139 have been reported outside of Asia; in 2011, China was the only country reporting cases of cholera due to the O139 strain.

Cholera is endemic in India and in Southeast Asia. From these epicenters, it is carried along shipping lanes, trade routes, and pilgrim migration routes. Between 1996 and 2009, most cases of cholera were reported from countries in Africa; in the Americas, cases were infrequently reported. However, in 2010, Haiti experienced a magnitude 7.0 earthquake that devastated the country's infrastructure, and subsequently a severe cholera epidemic began in Haiti on the Caribbean island of Hispaniola. By 2012, more than 600,000 cases of cholera and 7400 deaths associated to the illness were recorded. Cholera subsequently spread to the Dominican Republic, also located on the island of Hispaniola, and then to Cuba; since then imported cases have been reported in many other countries in the Americas, including the United States. Various epidemiologic investigations provided evidence that United Nations peacekeepers from countries in Southeast Asia, who were invited to Haiti for providing support, may have introduced *V. cholerae* O1, serotype Ogawa, biotype El Tor. These people were likely asymptomatic carriers, and *V. cholerae* O1 was introduced into local waterways that are used by the local populace as a source of water for drinking, cooking, and bathing. This cholera epidemic has been the

worst in recent history; more than 665,000 cases with more than 8000 associated deaths have been reported so far and cholera is now endemic in this Caribbean nation.

Cholera is a disease that is spread by contact involving individuals with mild or early illness and by water, food, and flies. In many instances, only 1–5% of exposed susceptible persons develop disease. The carrier state seldom exceeds 3–4 weeks, and the importance of carriers in transmission is unclear.

V. cholerae has no known animal host aside from humans; however, the organisms is capable of surviving in various aquatic environments for some time. Such aquatic environments are considered the vibrios' natural reservoir, where *V. cholerae* lives in close association with algae, copepods, and crustaceans.

People infected with cholera shed the organisms only during the first few days of the illness; however, there is no long-term carriage in humans. Infection control rests on education and on improvement of sanitation; such measures involve adequate sewage management, water purification systems, and methods to prevent food contamination. Additional measures to prevent spread of cholera during outbreaks include isolation of patients and disinfection and appropriate disposal of their excreta. Antimicrobial therapy may be beneficial as it reduces clinical symptoms and the transmission of vibrios from patients to healthy contacts; similarly chemoprophylaxis with antibiotics given to household contacts of cholera patients can help limit the spread of the organisms. In addition, oral and parenteral vaccines are available; in June 2016, the FDA approved a single-dose, live oral cholera vaccine for use in adults (18–64 years old) who are traveling to areas of cholera endemicity and transmission. Three other, killed oral cholera vaccines are prequalified by the WHO and are currently available outside the United States; the whole-cell *V. cholerae* O1 with recombinant cholera toxin B subunit vaccine is used primarily as a vaccine for traveler's to cholera endemic areas; one whole-cell *V. cholerae* O1 and O139 vaccine is available for use in Vietnam, only, whereas another whole-cell *V. cholerae* O1 and O139 vaccine is available for global market use. While the injectable cholera vaccine made from phenol-inactivated strains of *V. cholerae* is still manufactured in a few countries, this vaccine is no longer recommended by the WHO due to the limited efficacy of this vaccine and its short duration of protection. Because cholera vaccines offer only incomplete protection from disease, vaccination should not replace the other standard prevention and control measures described earlier in this paragraph.

VIBRIO PARAHAEMOLYTICUS AND VIBRIO VULNIFICUS

In addition to *V. cholerae* O1 and O139, several other *Vibrio* species have clearly been associated with infections in humans. Among the non-halophilic vibrios, the non-O1/O139 *V. cholerae* strains are associated with a wide spectrum

of diarrheal illness ranging from severe watery diarrhea to milder traveler's diarrhea. Among the halophilic vibrios, *V. parahaemolyticus* and *V. vulnificus* are probably the most commonly encountered organisms.

V. parahaemolyticus is a halophilic bacterium that causes acute gastroenteritis after ingestion of contaminated seafood such as raw fish or shellfish. After an incubation period of 12–24 hours, nausea and vomiting, abdominal cramps, fever, and an explosive watery diarrhea occur. Except in severe cases, grossly evident blood and/or mucus is not found in stool specimens. Clinically, the enteritis ranges from mild watery diarrhea to a forthright, dysentery-like syndrome, but then tends to subside spontaneously within 1–4 days with no treatment other than restoration of water and electrolyte balance. No enterotoxin has yet been isolated from this organism. Because *V. parahaemolyticus* is ubiquitous in coastal waters, gastroenteritis due to this organism occurs worldwide, with highest incidence in Asia. In the United States, *V. parahaemolyticus* is the most often *Vibrio* species isolated in laboratories in Louisiana and in Florida; overall, in the United States, illnesses due to pathogenic, halophilic *Vibrio* species are more frequently encountered between the months of April and October, likely reflecting seasonal changes associated with shellfish consumption and recreational water activities. *V. parahaemolyticus* is a facultatively anaerobe, Gram-negative rod, and does not grow well on some of the routine differential media used to grow salmonellae and shigellae, but it does grow well on blood agar. The organism grows well on TCBS agar, where it yields green colonies (does not ferment sucrose). The final organism identification is achieved by use of various standard biochemical tests. Usually no specific treatment other than rehydration is required since the gastroenteritis is self-limited. However, antimicrobial therapy could be considered for patients in whom the diarrheal illness does not resolve within 5 days; doxycycline and/or fluoroquinolones are appropriate choice for antibiotic therapy and would shorten the duration of the illness.

Among the various non-cholera vibrios, *V. vulnificus* is a particularly virulent species and is primarily known to cause severe wound and soft tissue infections, as well as bacteremia/sepsis, rather than gastroenteritis. It is a free-living bacterium and part of the normal marine microbiota in association with bivalves and crustaceans. In the United States, *V. vulnificus* is found along the Atlantic and Pacific Coasts, and especially the Gulf Coast. Infections due to *V. vulnificus* have been noticed to increase in the United States, particularly in association with Gulf Coast oyster consumption. The organism's association with oysters has long been noticed, and studies found that almost all oysters harvested during the summer months from the Chesapeake Bay contain this pathogen, as do approximately 10% of the crabs. The two most common clinical presentations of *V. vulnificus* infection are rapidly progressive wound infections due to skin/soft tissue injuries following exposure to contaminated seawater and primary bacteremia/sepsis following the consumption of contaminated raw oysters. Following the consumption

of contaminated food (eg, oysters), *V. vulnificus* can invade the bloodstream without causing gastrointestinal symptoms; the clinical picture of the ensuing sepsis is characterized by abrupt onset of chills, fever, followed by hypotension and the development of “metastatic” cutaneous lesions. Such lesions begin as erythematous discolorations of the skin that rapidly progress to hemorrhagic vesicles and bullae and then necrotic ulcerations. *V. vulnificus* septicemia has a fatality rate of greater 50%. Additional risk factors for developing *V. vulnificus* septicemia other than consumption of contaminated/raw seafood have been described. Such risk factors include cirrhosis, other liver diseases, hemochromatosis, hemolytic anemia, malignancies, immunosuppression, and chronic renal failure. Wound infections due to *V. vulnificus* often develop when a superficial wound comes in contact with contaminated seawater; infections develop and spread rapidly in both healthy as well as immunocompromised patients. Wound infections initially present with erythema and swelling, but quickly develop into an intense cellulitis, with bullous skin lesions, myositis, ulceration, and necrosis; mortality in patients with *V. vulnificus* wound infections ranges from 20% to 30%. Because of the rapid progression of the infection, it is often necessary to treat with appropriate antibiotics before culture confirmation of the etiology can be obtained. Diagnosis is by culturing the organism on standard laboratory media (eg, blood agar and MacConkey agar); TCBS agar is the preferred medium for stool cultures, where most strains produce blue-green (sucrose-negative) colonies. Definitive, species-level organism identification is achieved by use of various biochemical tests.

Wound infections caused by *V. vulnificus* respond well to appropriate antimicrobial agents; fluoroquinolones, third-generation cephalosporins (eg, ceftriaxone), and doxycycline are highly active against *V. vulnificus*; however, in severe cases debridement of all devitalized and/or necrotic tissue or even amputations may be necessary and lifesaving.

Concept Checks

- *Vibrio* species are halophilic, oxidase-positive, motile, curved, Gram-negative rods that are found in marine and estuarine aquatic environments, worldwide.
- Many *Vibrio* species are pathogenic for humans, but *V. cholerae* is the species of most global importance and responsible for pandemics of cholera. Although there are more than 200 serotypes of *V. cholerae*, only serotypes O1 and O139 are associated with epidemic and pandemic cholera.
- *V. cholerae* O1 can be further classified into the classic and El Tor biotypes; classic biotypes have been responsible for most of the major pandemics and are more likely to cause symptomatic infection. El Tor has caused the most recent pandemic.
- *V. cholerae* causes an acute watery diarrhea after ingestion of high numbers of organisms in contaminated water or

food by elaboration of a heat-labile enterotoxin that has the classic A-B toxin structure. The B segment binds to GM₁ ganglioside receptors, and the active A subunit induces cAMP, causing secretion of sodium chloride, while at the same time preventing the reabsorption by the microvilli.

- Definitive diagnosis of cholera is established by culturing stool on selective medium such as TCBS agar or alkaline peptone broth and identifying *V. cholerae*. Treatment involves rehydration and secondarily tetracycline or doxycycline.
- Other important *Vibrio* species include *V. parahaemolyticus*, the most common cause of foodborne gastroenteritis in Asia, and *V. vulnificus*, a cause of wound infections and severe sepsis in patients with cirrhosis.

AEROMONAS

Bacteria belonging to the genus *Aeromonas* are ubiquitous inhabitants of fresh and brackish water. Aeromonads are Gram-negative, facultative anaerobic rods that ferment carbohydrates and may resemble morphologically members of the family of Enterobacteriaceae. However, aeromonads are oxidase-positive, whereas Enterobacteriaceae are oxidase negative. *Aeromonas* grows well on blood agar and various enteric differential and selective agars. On blood agar, *Aeromonas* is usually β -hemolytic. Currently, 24 distinct species of *Aeromonas* have been described; however, *A. hydrophila*, *A. caviae*, and *A. veronii* biovar *sobria* are most commonly associated with human infections. *Aeromonas*, most frequently *A. caviae*, is a cause of gastroenteritis, ranging from watery diarrhea (most common) to dysentery-like illness. Associated symptoms are abdominal pain, fever, nausea, and vomiting. Gastroenteritis typically occurs after ingestion of contaminated food or water; infection rates are the highest during the warm summer months, when the concentration of aeromonads in the water is highest. The infection is usually self-limited, but severe diarrhea with dehydration and infections in children may require hospitalization. Usually, there is no need for antimicrobial therapy for *Aeromonas* gastroenteritis; however, in some cases more rapid clinical improvement has been seen with antimicrobial therapy, particularly when symptoms are more severe.

Aeromonads have also been isolated from various extraintestinal sites. *A. hydrophila* has been described as a cause of wound infections; traumatic soft tissue injuries with subsequent exposure to fresh or brackish water typically precede the infection. Most commonly, uncomplicated cellulitis develops within 48 hours of the injury, but systemic symptoms may also develop. In addition to antimicrobial therapy, the suppurative necrosis surrounding the wound may require surgical debridement. Less frequently, fasciitis, myonecrosis, and/or osteomyelitis may develop as complications. Although rare and unusual, *Aeromonas* soft tissue infection has also been recognized as a complication of the use of medicinal leeches. *Aeromonas* bacteremia is an uncommon clinical

entity, and occurs rarely in healthy people. Most cases of *Aeromonas* sepsis are caused by *A. hydrophila*, and have been described in patients with hematologic malignancies and/or liver disease. The clinically significant aeromonads are uniformly resistant to penicillin and ampicillin, and frequently resistant to cefazolin and ticarcillin. However, aeromonads are usually susceptible to third-generation cephalosporins, aztreonam, and carbapenems, as well as aminoglycosides; however, resistance to tobramycin and gentamycin has been described. Fluoroquinolones are highly active against clinically relevant *Aeromonas* species. Because of emerging antimicrobial resistance, empiric therapy usually includes the use of two or more antibiotic agents, until antimicrobial susceptibility testing results become available.

CAMPYLOBACTER

Campylobacters cause both diarrheal and systemic diseases, and are among the most widespread causes of infection, worldwide. *Campylobacter* infections of wild and domesticated animals, which are also the natural reservoirs for these organisms, are also widespread. *C. jejuni* is the prototype organism in the group and is a very common cause of diarrhea in humans. Other campylobacters, less commonly isolated from humans, include *C. fetus*, *C. coli*, and *C. upsaliensis*.

CAMPYLOBACTER JEJUNI

C. jejuni has emerged as a common human pathogen, causing mainly gastroenteritis and occasionally systemic infections. This organism is the most common cause of bacterial gastroenteritis in the United States; according to the CDC surveillance data, an estimated 2 million cases occur in the United States each year.

Morphology and Identification

A. Typical Organisms

C. jejuni and other campylobacters are curved, comma-, or S-shaped, Gram-negative, non-spore-forming rods; they have also been described as having “sea gull wing” shapes (Figure 17-3). Campylobacters are motile, with a single polar flagellum at one or both ends, but some organisms may lack flagella all together.

B. Culture

Campylobacter species, including *C. jejuni*, multiply at a slower rate when compared to other Gram-negative, enteric bacteria; therefore, selective media, containing various antibiotics (eg, Campy-Blood agar and Skirrow's media) are needed for isolation of campylobacters from stool specimens. *Campylobacter* species require a microaerobic atmosphere, containing reduced O_2 (5–7%) and increased 10% CO_2 for incubation and optimal growth. A relatively simple way to

FIGURE 17-3 Gram-stain of *C. jejuni* showing “comma”- or “gull wing”-shaped Gram-negative bacilli (arrows). Campylobacters stain faintly and can be difficult to visualize. Original magnification $\times 1000$.

produce the incubation atmosphere is to place the plates in an anaerobe incubation jar without the catalyst and to produce the gas with a commercially available gas-generating pack or by gas exchange. Furthermore, most campylobacters grow best at 42°C, although growth can be seen on agar media with incubation between 36°C and 42°C. Incubation of primary plates for isolation of *C. jejuni* should always be at 42°C. Several selective agar media are in widespread use for isolation of campylobacters; Skirrow's medium contains vancomycin, polymyxin B, and trimethoprim to inhibit growth of other bacteria, but this medium may be less sensitive than other commercial products that contain charcoal, other inhibitory compounds, as well as cephalosporin antibiotics. These selective media are suitable for isolation of *C. jejuni* and *C. coli* at 42°C. However, *C. upsaliensis*, while growing at 42°C, is not recovered on selective media, and *C. fetus* shows variable growth at 42°C, and may not be recovered at that temperature. The colonies of *Campylobacter* species may have different appearances; generally, the colonies tend to be colorless or gray. They may be watery and spreading or round and convex, and both colony types may appear on one agar plate. Hemolysis on blood-containing agar media is not observed.

C. Growth Characteristics

Because of the selective media and incubation conditions for growth, an abbreviated set of tests is usually all that is necessary for further identification of campylobacters. *C. jejuni* as well as *C. coli* are positive for both oxidase and catalase. Campylobacters do not oxidize or ferment carbohydrates. Gram-stained smears show typical morphology. Nitrate reduction, hydrogen sulfide production, hippurate hydrolysis tests, and antimicrobial susceptibilities can be used for further

identification of species. A positive hippurate hydrolysis test distinguishes *C. jejuni* from the other *Campylobacter* species.

Antigenic Structure and Toxins

The campylobacters have lipopolysaccharides with endotoxic activity. Cytopathic extracellular toxins and enterotoxins have been found, but the significance of the toxins in human disease is not well defined.

Pathogenesis and Pathology

The infection is acquired by the oral route from food, drink, or contact with infected animals or animal products, especially poultry. *C. jejuni* is susceptible to gastric acid, and ingestion of about 10^4 organisms is usually necessary to produce infection. This inoculum is similar to that required for *Salmonella* and *Shigella* infection but less than that for *Vibrio* infection. The organisms multiply in the small intestine, invade the epithelium, and produce inflammation that results in the appearance of red and white blood cells in the stools. Occasionally, the bloodstream is invaded, and a clinical picture of enteric fever develops. Localized tissue invasion coupled with the toxic activity appears to be responsible for the enteritis.

Clinical Findings

C. jejuni and *C. coli* most commonly cause gastroenteritis, while *C. fetus* causes bacteremia and extraintestinal infections in pregnant women and in immunocompromised patients. Less frequently, *C. upsaliensis*, a thermotolerant *Campylobacter* species, is isolated in humans as the cause of diarrhea and/or bacteremia; the organism is also associated with canine and feline gastroenteritis. Clinical manifestations of *C. jejuni* gastroenteritis are acute onset of crampy abdominal pain, profuse diarrhea that may be grossly bloody, headache, malaise, and fever. Usually, the illness is self-limited to a period of 5–8 days, but occasionally it continues for longer times. *C. jejuni* isolates are usually susceptible to macrolides (eg, erythromycin), and therapy shortens the duration of fecal shedding of bacteria. While most cases resolve without antimicrobial therapy, symptoms may recur in about 5–10% of patients, and antimicrobial therapy may be necessary to resolve the infection. Certain serotypes of *C. jejuni* and *C. upsaliensis* have been associated with postdiarrheal Guillain-Barré syndrome, a form of ascending paralytic disease. Reactive arthritis and Reiter's syndrome may also follow acute *Campylobacter* diarrhea.

Diagnostic Laboratory Tests

A. Specimens

Diarrheal stool is the preferred specimen when attempting to isolate campylobacters in patients with gastrointestinal illness. Rectal swabs may also be acceptable specimens. *C. jejuni* and *C. fetus* may occasionally be recovered from blood cultures usually from immunocompromised or elderly patients.

B. Smears

Gram-stained smears of stool may show the typical “gull wing”-shaped rods. Dark-field or phase-contrast microscopy may show the typical darting motility of the organisms.

C. Culture

Culture on the selective media as described earlier is the definitive test to diagnose *C. jejuni* enteritis. If *C. fetus* or another species of *Campylobacter* is suspected, an agar medium without cephalosporins should be used and incubation at 36–37°C is necessary.

Epidemiology and Control

Campylobacter species are the cause of zoonotic infections, worldwide. These organisms are usually commensal bacteria in the gastrointestinal tracts of various wild or domesticated animals; common reservoir hosts for *C. jejuni* include poultry, cattle, and sheep; *C. coli* is usually found in pigs, sheep, and birds; *C. fetus* has been isolated from sheep, cattle, and poultry; and *C. upsaliensis* is most commonly isolated from domesticated pet dogs. Most human infections result typically from consumption of contaminated food and/or water. Since commercially raised poultry is nearly always colonized with *C. jejuni*, slaughterhouse procedures are known to amplify contamination of chicken and turkey meats that are commonly sold in stores and supermarkets in the United States and other developed countries. Consumption of undercooked (commercial) poultry meats has a strong association with *C. jejuni* gastroenteritis. In some cases, consumption of unpasteurized (raw) milk had been identified as the source of the infection. As with other enteric pathogens, fecal-oral person-to-person transmission of *C. jejuni* has been reported; however, this mode of transmission appears to occur less frequent compared to acquisition of the organism via contaminated food and water. In contrast, *C. upsaliensis* is most commonly acquired by close contact with domesticated (pet) dogs that are either ill with diarrheal disease or may just shed the organisms intermittently.

HELICOBACTER PYLORI

Members of the genus *Helicobacter* are usually spiral, curved, or fusiform rod-shaped Gram-negative bacteria. *Helicobacter* species have been isolated from the gastrointestinal and hepatobiliary tract of many different mammalian hosts, including humans, dogs, cats, pigs, cattle, and other domestic and wild animals. The various helicobacters can be divided into two groups: *Helicobacter* species that primarily colonize the stomach (gastric helicobacters), and those that colonize the intestines (enterohepatic helicobacters). Humans are the primary host-reservoir for *H. pylori*, which is a spiral-shaped, Gram-negative, catalase- and oxidase-positive, and urease-positive rod. *H. pylori* is associated with antral gastritis,

duodenal (peptic) ulcer disease, gastric ulcers, gastric adenocarcinoma, and gastric mucosa-associated lymphoid tissue (MALT) lymphomas.

Morphology and Identification

A. Typical Organisms

Helicobacter species, including *H. pylori*, have many characteristics in common with campylobacters. *Helicobacter* species are motile and have single and/or multiple monopolar flagella that are typically sheathed and can vary greatly in their flagellum morphology.

B. Culture

While *H. pylori* can be readily isolated from gastric biopsy specimens, culture sensitivity may be limited by several factors, including delayed specimen transport and processing, prior antimicrobial therapy, or contamination with other mucosal bacteria. Special transport media (eg, Stuart's transport medium) should be used to maintain the organisms' viability when transport to the laboratory is anticipated to exceed 2 hours. *H. pylori* usually grows within 3–6 days when incubated at 37°C in a microaerophilic and humid atmosphere; however, incubation of up to 14 days may be necessary before resulting the culture as negative. To achieve a higher yield for recovery of the organism, the biopsy specimen may be homogenized prior to streaking onto the agar plate. The agar media for primary isolation include enriched agar media supplemented with blood and/or blood products (eg, chocolate agar) or antibiotic-containing media such as Skirrow's medium, in order to suppress overgrowth by other competing bacterial flora. The colonies have varying appearance on blood agar ranging from gray to translucent and are 1–2 mm in diameter.

C. Growth Characteristics

H. pylori is oxidase positive and catalase positive, and has a characteristic Gram-stain morphology; the organism is motile, and is a strong producer of urease.

Pathogenesis and Pathology

H. pylori is able to survive in the acidic environment of the stomach and ultimately establish lifelong colonization of the gastric mucosa in the absence of antimicrobial treatment. While *H. pylori* grows optimally at a pH of 6.0–7.0, it would be killed or not grow at the pH within the gastric lumen (pH 1–3). Several factors contribute to the organism's ability to overcome the acidic environment of the stomach, contributing to colonization, inflammation, changes in gastric acid production, and tissue destruction. Gastric mucus is relatively impermeable to acid and has a strong buffering capacity. On the lumen side of the mucus, the pH is low (1.0–3.0); on the epithelial side, the pH is about 5.0–7.0. After entering the stomach, *H. pylori* utilizes its urease activity to

neutralize the gastric acid; intracellular urease activity as well as urease located on the bacterial cell surface allow for the breakdown of urea into ammonia and CO₂; NH₃ is converted to ammonium (NH₄⁺) and extruded from the bacterial cell leading to neutralization of the gastric acid. Flagella-mediated motility then allows the organisms, protected from the gastric acid, to move through the gastric mucus toward the epithelium. *H. pylori* is found deep in the mucous layer near the epithelial surface where a near physiologic pH is present. *H. pylori* then colonizes the gastric-type but not intestinal-type epithelial cells, and releases several effector proteins and toxins, including adhesion factors, neutrophil-activating protein A, a heat shock protein, and various cytotoxins. Several outer membrane proteins of *H. pylori* have been identified to facilitate cell adhesion; these proteins include BabA (blood-antigen-binding protein A), which binds to fucosylated Lewis b receptor on gastric epithelial cells, and SabA, which binds to sialyl Lewis X receptors. *H. pylori* does not appear to invade the gastric mucosa, but rather release various toxins that ultimately exert tissue damage; among these are mucinase, phospholipase, neutrophil-activating protein A, heat shock protein 60, cytotoxin-associated gene A protein (CagA), and vacuolating cytotoxin A (VacA). CagA is secreted by *H. pylori* and then translocated into the gastric epithelial cells via a type IV secretion system; it interferes with the epithelial cells' cytoskeletal structure and induces IL-8 production, leading to neutrophil attraction. VacA affects the balance between cell death and proliferation, and also acts as an activator of IL-8 mediated acute inflammation. In addition to these two factors, CagA and VacA, that are responsible for the extensive tissue inflammation and damage, *H. pylori* organisms may also secrete urease, which acts as a chemoattractant and activator of host phagocytic and inflammatory cells. Several studies indicate that CagA is directly associated with acute gastritis, gastric ulcer development, and gastric carcinoma. While the prevalence of CagA-positive *H. pylori* organisms is about 60% in western countries, the prevalence of CagA-positive *H. pylori* in Southeast Asian countries is close to 90%, perhaps accounting for the relatively higher incidence of gastric cancer in this part of the world.

In human volunteers, ingestion of *H. pylori* resulted in development of gastritis and hypochlorhydria. There is a strong association between the presence of *H. pylori* infection and peptic ulcer disease as well as duodenal ulceration. Antimicrobial therapy results in clearing of *H. pylori* and improvement of gastritis and duodenal ulcer disease.

Histologically, gastritis is characterized by acute and chronic inflammation. Polymorphonuclear and mononuclear cell infiltrates are seen within the epithelium and lamina propria. Vacuoles within cells are often pronounced. Destruction of the epithelium is common, and glandular atrophy may occur. Thus, *H. pylori* is a major risk factor for gastric cancer. *H. pylori* infection is a known independent risk factor for the development of atrophic gastritis, gastric ulcer disease, gastric adenocarcinomas, and gastric mucosa-associated lymphoid tissue (MALT) lymphomas.

Clinical Findings

Following acquisition of the *H. pylori*, acute infection typically yields an upper gastrointestinal illness (“food poisoning”) with nausea and pain; vomiting and fever may also be present. The acute symptoms may last for less than 1 week or as long as 2 weeks. After the acquisition of the organisms and the initial acute stage of the infection, colonization with *H. pylori* occurs in many patients. Such colonization persists for years, perhaps decades, or even a lifetime. However, not every exposure to *H. pylori* leads to persistent colonization; lack of the organism’s adaptation to a particular host or incidentally concomitant antibiotic therapy may perhaps prevent persistent colonization. However, in the absence of medication-induced ulceration, approximately 90% of patients with duodenal ulcers have indeed a *H. pylori* infection. Colonization with *H. pylori* has been shown to be present in 50–80% of patients with benign gastric ulceration. Finally, long-lasting *H. pylori* colonization, which is associated with chronic gastritis and subsequent development of intestinal metaplasia and atrophic gastritis, is a well-known risk factor for the development of gastric adenocarcinoma.

Diagnostic Laboratory Tests

A. Specimens

Gastric biopsy specimens can be used for histologic examination or minced in saline and used for culture. Blood is collected for determination of serum antibodies. Stool samples may be collected for *H. pylori* antigen detection. Diagnostic testing methods are summarized in Table 17-2.

B. Smears

The diagnosis of gastritis and *H. pylori* infection can be made histologically; this approach is generally more sensitive than culture. A gastroscopy procedure with biopsy is required. Routine stains (eg, hematoxylin & eosin stain) demonstrate acute/chronic gastritis, and Giemsa or special stains (eg, silver stains or immunohistochemical stains) can show the curved or spiral-shaped organisms.

C. Culture

Since *H. pylori* organisms adhere to the gastric mucosa, the bacteria cannot be recovered from stool specimens like other gastrointestinal pathogens. As described above, culture is usually performed when patients are not responding to treatment, and there is a need to perform antimicrobial susceptibility testing. Tissue for culture is obtained by endoscopy and biopsy of the gastric mucosa.

D. Antibodies

Several assays have been developed to detect serum antibodies specific for *H. pylori*. While testing for IgG serum antibodies against *H. pylori* is useful to confirm the exposure to the organism, either for epidemiologic purposes or for the evaluation of a symptomatic patient, the antibody titers do not typically correlate with the severity of the disease. Furthermore, IgM antibodies disappear rapidly during the initial course of an acute infection, and are of little diagnostic value. The relevance of IgA testing remains controversial, and both IgA and IgG serum antibodies persist even if the *H. pylori*

TABLE 17-2 Diagnostic Testing Methods for *H. pylori*

Testing Modality	Advantages	Disadvantages
Invasive Testing		
Histology	Allows for detection of organism and assessment of the extent of tissue damage (eg, ulceration).	Requires mucosal biopsy and sample processing in Pathology. Requires several days for results.
Urease detection in tissue	Rapid test, with most positive results being obtained within 2 hours.	Requires mucosal biopsy. May give false-positive results with bacterial overgrowth. False-negative tests when patient receives PPI treatment.
Microbiologic culture	Allows for antimicrobial susceptibility testing.	Requires several days for results (slow growth of organisms); requires special and careful specimen processing (false-negative results due to prolonged specimen transport and processing in suboptimal conditions).
Noninvasive Testing		
Serology	Noninvasive; inexpensive; “rapid” turn-around-time for results. Useful for epidemiologic purposes and evaluation of symptomatic patients.	Provides no assessment of extent of tissue damage/pathology. Not suitable to assess completion of antimicrobial therapy. Usually cannot differentiate between acute and past infection.
Urea breath test	Relatively noninvasive and rapid. Valuable for assessment of therapy (eradication of infection).	Requires expensive instrumentation for testing; less convenient than serology. False-negative results when patient receives PPI therapy. Provides no assessment of extent of tissue damage/pathology.
Stool antigen test	Relatively noninvasive, convenient, rapid, and inexpensive. Most valuable for assessment of response to antimicrobial therapy.	Not useful to assess the extent of tissue damage/pathology.

infection is eradicated. The role of antibody testing in differentiating active *H. pylori* infection from past infection and/or completion of therapy is therefore limited.

E. Other, Special Test Methods

Other tests for diagnosis include histologic examination of gastric biopsy specimens, detection of urease production, and detection of *H. pylori* antigen. The latter is performed on stool specimens. Histopathological examination of gastric biopsy specimens is widely used for the diagnosis of *H. pylori* in patients undergoing endoscopy with biopsy for evaluation. While the standard hematoxylin and eosin staining method is insufficient for visualizing the organisms, silver staining methods (eg, Warthin-Starry or GMS) or immunohistochemical stains specifically directed against *H. pylori* antigens are used to detect the organisms. The histological examination of gastric biopsy specimens has a sensitivity and specificity of 95–100% for detection of *H. pylori*. At the present time, nucleic acid amplification tests (PCR) for *H. pylori* and other *Helicobacter* species on various clinical specimens are restricted to research use only. Rapid tests to detect urease activity are widely used for presumptive identification of *H. pylori* in specimens. Gastric biopsy material can be placed onto a urea-containing medium with a color indicator. If *H. pylori* is present, the urease rapidly splits the urea (1–2 hours), and the resulting shift in pH yields a color change in the medium. In addition, the production and activity of urease can also be detected by in vivo tests, such as the urea breath test (UBT). In urea breath tests, ^{13}C - or ^{14}C -labeled urea is ingested by the patient. If *H. pylori* is present, the urease activity generates ^{13}C - or ^{14}C -labeled CO_2 that then can be detected in the patient's exhaled breath. The sensitivity and specificity of the UBT range between 94% and 98%.

Detection of *H. pylori* antigen in stool specimens, using enzyme-linked immunosorbent assay tests, has been shown to have great value in diagnosing active *H. pylori* infection. Furthermore, the stool antigen test is also appropriate as a test of cure for patients with known *H. pylori* infection who have completed their course of antimicrobial therapy.

Immunity

Patients infected with *H. pylori* quickly develop an IgM antibody response to the infection. Subsequently, IgG and IgA are produced, and these persist, both systemically and at the mucosa, in high titer in chronically infected persons, while the IgM antibodies decline and eventually disappear. Early antimicrobial treatment of *H. pylori* infection has shown to blunt the antibody response; such patients are thought to be subject to repeat infection.

Treatment

Triple therapy with a proton-pump inhibitor (PPI; standard dose, twice daily), plus amoxicillin (1 g twice daily), plus

clarithromycin (500 mg twice daily) is the recommended regimen for initial therapy for 7–14 days. Alternatively, a quadruple therapy with a PPI, plus metronidazole (250 mg four times daily), plus tetracycline (500 mg, four times daily), plus bismuth (dose-dependent on preparation) for 10–14 days may be prescribed. Such initial therapy regimens given for 14 days typically eradicate *H. pylori* infection in 70–95% of patients. Proton-pump inhibitors (PPIs) directly inhibit *H. pylori* and appear to be potent urease inhibitors. Tailored antibiotic therapies may be needed based on recurrent or persistent infections due to antimicrobial-resistant strains of *H. pylori*. Finally, various medications given for 4–6 weeks for suppression of gastric acid production and following initial therapy have shown to enhance ulcer healing.

Epidemiology and Control

H. pylori has been isolated from humans, worldwide, and it is likely that humans are the primary, if not sole reservoir for the organism. While the exact mode of transmission from person-to-person remains somewhat unclear, epidemiologic studies provide strong evidence to support oral–oral and/or fecal–oral transmission of the organism. In most populations, *H. pylori* seems to be acquired during early childhood. Once acquired, it is likely that colonization persists throughout life, unless the individual is treated with appropriate antibiotics. The prevalence of *H. pylori* infection differs noticeably between developing and developed countries, and a lower socioeconomic status has been shown to be a risk factor for acquisition of *H. pylori*. The highest prevalence has been reported from developing countries, especially in Southeast Asia, where most children are infected by the age of 10, and prevalence remains high (up to 90%) among adults of all age groups. In developed countries, such as the United States, a significantly lower overall prevalence (approximately 40%) among (older) adults has been observed, likely due to improved hygiene and available treatment for people with active infection. In the United States, when compared to other countries, significantly fewer children and young adults are infected with *H. pylori*; the bacteria are present on the gastric mucosa of fewer than 20% of persons younger than 30 years old, but then increases in prevalence to 40–60% of people age 60 years and older, including people who are asymptomatic. The rationale for oral-to-oral transmission of *H. pylori* has been based on studies that demonstrated the ability of detecting viable organisms in regurgitated gastric content; it seems therefore likely that *H. pylori* can temporarily colonize the oral cavity. Person-to-person transmission of *H. pylori* is furthermore supported by studies describing intrafamilial clustering of infection. Fecal–oral transmission of *H. pylori* appears to be more likely in developing countries, where contaminated lack of sanitation and contaminated water supplies may be a more significant risk factor for acquiring the infection. On rare occasion, transmission of *H. pylori* from person-to-person via improperly cleaned endoscopes has also been described.

CHAPTER SUMMARY

- Campylobacters are oxidase-positive, curved or spiral-shaped organisms that sometimes have a “gull’s wing” appearance. *C. jejuni* is the major pathogen and is associated primarily with febrile diarrhea that may be bloody. Contaminated food, primarily poultry, is the major vehicle for infection.
- *C. jejuni* grows well at 42°C in a microaerophilic environment of 5% oxygen and 10% CO₂. Selective media that contain antibiotics are generally used to recover the organisms from stool.
- *Helicobacter* species are also curved or spiral-shaped pathogens. *H. pylori* is associated with upper gastrointestinal diseases such as gastric and duodenal ulcers, gastric adenocarcinoma, and MALT lymphomas. The organism is urease positive, which protects it against gastric acidity. Diagnosis is made by a variety of methods including biopsy, urea breath tests, and stool antigen. Triple and quadruple antibiotic regimens that include PPIs are necessary for successful treatment.

REVIEW QUESTIONS

1. Long-term carriage and shedding is most likely to occur after gastrointestinal infection with which of the following species?
 - (A) *E. coli* O157:H7
 - (B) *Shigella dysenteriae*
 - (C) *V. cholerae*
 - (D) *C. jejuni*
 - (E) *Salmonella typhi*
2. A 63-year-old man visited his favorite oyster restaurant in a small town on the eastern shore of the Gulf Coast of Texas. He ate two dozen oysters. Two days later, he was admitted to the hospital because of an abrupt onset of chills, fever, and light-headedness when he stood up. (In the emergency department [ED], his blood pressure was 60/40 mm Hg.) While in the ED, he developed erythematous skin lesions. These rapidly evolved into hemorrhagic bullae, which then formed ulcers. The man drank a six-pack of beer and one half-bottle of whisky each day. A microorganism of major concern for this patient is
 - (A) *V. vulnificus*
 - (B) *E. coli*
 - (C) *S. typhi*
 - (D) *Clostridium perfringens*
 - (E) *Streptococcus pyogenes* (group A streptococci)
3. A family of four persons ate a meal that included undercooked chicken. Within 3 days, three members developed an illness characterized by fever, headache, myalgia, and malaise. Two of the patients had concomitant diarrhea and abdominal pain. The third person developed diarrhea after the systemic symptoms had cleared. Stool cultures grew *C. jejuni*. Which of the following culture conditions was most likely used to isolate *C. jejuni*?
 - (A) Thiosulfate-citrate-bile-sucrose medium incubated at 37°C in 5% oxygen and 10% CO₂
 - (B) *Salmonella-Shigella* selective medium incubated at 37°C in ambient air
 - (C) MacConkey agar and Hektoen enteric agar incubated at 42°C in 5% oxygen and 10% CO₂
 - (D) 5% sheep blood agar incubated at 37°C in ambient air
 - (E) A medium containing vancomycin, polymyxin B, and trimethoprim incubated at 42°C in 5% oxygen and 10% CO₂
4. Bacteremia associated with a gastrointestinal infection is most likely to occur with which of the following?
 - (A) *S. typhi*
 - (B) *V. cholerae*
 - (C) *Shigella boydii*
 - (D) *V. parahaemolyticus*
 - (E) *C. jejuni*
5. During the El Niño years in the mid- to late 1990s, the waters of Puget Sound between Washington State and British Columbia warmed considerably. During this time, many people who ate clams and oysters from these waters became ill with a disease characterized by explosive diarrhea and moderately severe abdominal cramps. The diarrhea was usually watery, but in some patients, it was bloody. The diarrhea usually had an onset within 24 hours after eating the shellfish. Stool cultures typically yielded a pathogenic Gram-negative bacillus. The microorganism of concern in this setting is
 - (A) Enterotoxigenic *E. coli*
 - (B) *V. cholerae*
 - (C) Enterohemorrhagic *E. coli*
 - (D) *V. parahaemolyticus*
 - (E) *S. dysenteriae*
6. A patient presents to the emergency department with non-bloody diarrhea for 12 hours. The patient lives in Washington, DC, and has not recently traveled out of the area. Which one of the following is *unlikely* to be the cause of your patient’s diarrhea?
 - (A) *S. typhimurium*
 - (B) *C. jejuni*
 - (C) *Shigella sonnei*
 - (D) *V. cholerae*
 - (E) *E. coli*
7. An 18-year-old woman in rural Bangladesh develops profuse (8 L/d) diarrhea. She has no symptoms other than the diarrhea and the manifestations of the fluid and electrolyte loss caused by the diarrhea. The most likely cause of her diarrhea is
 - (A) *C. jejuni*
 - (B) Enterotoxigenic *E. coli*
 - (C) *S. typhimurium*
 - (D) *V. cholerae*
 - (E) *S. dysenteriae*
8. Age and geography are major factors in the prevalence of colonization by *H. pylori*. In developing countries, the prevalence of colonization may be greater than 80% in adults. In the United States, the prevalence of colonization with this microorganism in adults older than age 60 years is
 - (A) 1–2%
 - (B) 5–10%
 - (C) 15–20%
 - (D) 40–60%
 - (E) 80–95%
9. A 59-year-old man comes to the emergency department in the afternoon because of acute swelling and pain in his right leg. Earlier that morning, he had been working on a small sport

- fishing boat in an estuary on the Gulf Coast of Texas. While walking around the boat in shallow water, he scratched his leg, breaking the skin at the site of the current pain and swelling. He was not wearing boots. About 1 hour after the injury, the scratch became red and painful. Swelling developed. Within 3 hours, the leg below the knee had become markedly swollen. The skin was red and tender. There was serous drainage from the wound, which had ulcerated and was now much enlarged. Near the wound, bullae were forming—the largest approximately 2.5 cm in diameter. The most likely cause of this medical emergency is
- (A) *Staphylococcus aureus*
 - (B) *S. pyogenes*
 - (C) *C. perfringens*
 - (D) *E. coli*
 - (E) *V. vulnificus*
10. The *V. cholerae* factor responsible for diarrhea is a toxin that
- (A) Blocks EF-2
 - (B) Yields increased intracellular levels of cAMP
 - (C) Cleaves SNARE
 - (D) Blocks EF-1-dependent binding of amino-acyl-tRNA to ribosomes
 - (E) Cleaves VAMP
11. In September 1854, a severe epidemic of cholera occurred in the Soho/Golden Square area of London. Dr. John Snow, a father of epidemiology, studied the epidemic and helped stop it by which of the following actions?
- (A) Banning the sale of apples at the local markets
 - (B) Removing the handle of the Broad Street water pump
 - (C) Stopping the sale of shellfish imported from Normandy
 - (D) Pasteurizing milk
 - (E) Promoted washing vegetables that were consumed raw
12. A 45-year-old man develops a gastric ulcer that can be visualized on a contrast medium-enhanced radiograph of his stomach. A biopsy specimen is taken from the gastric mucosa at the site of the ulcer. A presumptive diagnosis can be reached most rapidly by inoculating part of the specimen on which of the following?
- (A) A medium used to detect urease incubated at 37°C
 - (B) A medium containing vancomycin, polymyxin B, and trimethoprim incubated at 42°C
 - (C) MacConkey agar medium incubated at 37°C
 - (D) Thiosulfate-citrate-bile-sucrose medium incubated at 42°C
 - (E) Blood agar medium incubated at 37°C

Haemophilus, Bordetella, Brucella, and Francisella

THE HAEMOPHILUS SPECIES

This is a group of small, Gram-negative, pleomorphic bacteria that require enriched media, usually containing blood or its derivatives, for isolation. *Haemophilus influenzae* is a major human pathogen; *Haemophilus ducreyi*, a sexually transmitted pathogen, causes chancroid; six other *Haemophilus* species are among the normal microbiota of mucous membranes and only occasionally cause human disease. *Haemophilus aphrophilus* and *Haemophilus paraphrophilus* have been combined into a single new species *Aggregatibacter aphrophilus*; likewise, *Haemophilus segnis* is now a member of the *Aggregatibacter* genus (Table 18-1).

HAEMOPHILUS INFLUENZAE

H. influenzae is found on the mucous membranes of the upper respiratory tract in humans. It is an important cause of meningitis in unvaccinated children and causes upper and lower respiratory tract infections in children and in adults.

Morphology and Identification

A. Typical Organisms

In specimens from acute infections, the organisms are short (1.5 μm) coccoid bacilli, sometimes occurring in pairs or short chains. In cultures, the morphology depends both on the length of incubation and on the medium. At 6–8 hours in rich medium, the small coccobacillary forms predominate. Later, there are longer rods and very pleomorphic forms.

Some organisms in young cultures (6–18 hours) on enriched medium express a definite capsule. The capsule is the antigen used for “typing” *H. influenzae* (see later discussion).

B. Culture

On chocolate agar, flat, grayish, translucent colonies with diameters of 1–2 mm are present after 24 hours of incubation. IsoVitaleX in media enhances growth. *H. influenzae* does not grow on sheep blood agar except around colonies of staphylococci (“satellite phenomenon”). *Haemophilus haemolyticus*

and *Haemophilus parahaemolyticus* are hemolytic variants of *H. influenzae* and *Haemophilus parainfluenzae*, respectively.

C. Growth Characteristics

Identification of organisms of the *Haemophilus* group depends partly on demonstrating the need for certain growth factors called X and V. Factor X acts physiologically as hemin; factor V can be replaced by nicotinamide adenine dinucleotide (NAD) or other coenzymes. Colonies of staphylococci on sheep blood agar cause the release of NAD, yielding the satellite growth phenomenon. The requirements for X and V factors of various *Haemophilus* species are listed in Table 18-1. Carbohydrate fermentation is useful in species identification as is the presence or absence of hemolysis.

In addition to serotyping on the basis of capsular polysaccharides (see later discussion), *H. influenzae* and *H. parainfluenzae* can be biotyped on the basis of the production of indole, ornithine decarboxylase, and urease. Most of the invasive infections caused by *H. influenzae* belong to biotypes I and II (there are a total of eight).

Antigenic Structure

Encapsulated *H. influenzae* contains **capsular polysaccharides** (molecular weight > 150,000) of one of six types (a–f). The capsular antigen of type b is a polyribitol ribose phosphate (PRP). Encapsulated *H. influenzae* can be typed by slide agglutination, coagglutination with staphylococci, or agglutination of latex particles coated with type-specific antibodies. A capsule swelling test with specific antiserum is analogous to the quellung test for pneumococci. Typing can also be done by immunofluorescence. Most *H. influenzae* organisms in the normal microbiota of the upper respiratory tract are not encapsulated and are referred to as nontypeable (NTHi).

The somatic antigens of *H. influenzae* consist of outer membrane proteins. Lipooligosaccharides (endotoxins) share many structures with those of neisseriae.

Pathogenesis

H. influenzae produces no exotoxin. The nonencapsulated organism is a regular member of the normal respiratory

^bFormerly *H. segnis*.

microbiota of humans. The capsule is antiphagocytic in the absence of specific anticapsular antibodies. The polyribose phosphate capsule of type b *H. influenzae* is the major virulence factor.

The carrier rate in the upper respiratory tract for *H. influenzae* type b was 2–5% in the prevaccine era and is now less than 1%. The carrier rate for NTHi is 50–80% or higher. Type b *H. influenzae* causes meningitis, pneumonia and empyema, epiglottitis, cellulitis, septic arthritis, and occasionally other forms of invasive infection. NTHi tends to cause chronic bronchitis, otitis media, sinusitis, and conjunctivitis after breakdown of normal host defense mechanisms. The carrier rate for the encapsulated types a and c to f is low (1–2%), and these capsular types rarely cause disease. Although type b can cause chronic bronchitis, otitis media, sinusitis, and conjunctivitis, it does so much less commonly than NTHi. Similarly, NTHi only occasionally causes invasive disease (~5% of cases).

Clinical Findings

H. influenzae type b enters by way of the respiratory tract. There may be local extension with involvement of the sinuses or the middle ear. *H. influenzae*, mostly nontypeable, and pneumococci are two of the most common etiologic agents of bacterial otitis media and acute sinusitis. Lower respiratory tract infections such as bronchitis and pneumonia may be seen in patients with conditions that diminish mucociliary clearance. Examples include smoking, chronic obstructive lung disease, and cystic fibrosis. Encapsulated organisms may reach the bloodstream and be carried to the meninges or, less frequently, may establish themselves in the joints to produce septic arthritis. Before the use of the conjugate vaccine, *H. influenzae* type b was the most common cause of bacterial meningitis in children aged 5 months to 5 years in the

United States. Clinically, it resembles other forms of childhood meningitis, and diagnosis rests on bacteriologic demonstration of the organism.

Occasionally, a fulminating obstructive laryngotracheitis with swollen, cherry-red epiglottis develops in young children and requires prompt tracheostomy or intubation as a lifesaving procedure. Pneumonitis and epiglottitis caused by *H. influenzae* may follow upper respiratory tract infections in small children and old or debilitated people. Adults may have bronchitis or pneumonia caused by *H. influenzae*.

Diagnostic Laboratory Tests

A. Specimens

Specimens consist of expectorated sputum and other types of respiratory specimens, pus, blood, and spinal fluid for smears and cultures depending on the source of the infection.

B. Direct Identification

Commercial kits are available for immunologic detection of *H. influenzae* antigens in spinal fluid. These antigen detection tests generally are not more sensitive than a Gram-stain and therefore are not widely used, especially because the incidence of *H. influenzae* meningitis is so low. Their use is discouraged in all but limited resource settings where disease prevalence remains high. A Gram-stain of *H. influenzae* in sputum is depicted in Figure 18-1. Nucleic acid amplification methods have been developed by some laboratories and may soon be commercially available for direct detection from cerebrospinal fluid and lower respiratory tract infections.

FIGURE 18-1 Gram-stain of *H. influenzae* in sputum. The organisms are very small (0.3 × 1 μm), Gram-negative coccobacilli (small arrows). The large, irregularly shaped objects (large arrow) are the nuclei of polymorphonuclear cells. Mucus is faintly stained pink in the background.

C. Culture

Specimens are grown on IsoVitalX-enriched chocolate agar until typical colonies appear (see above). *H. influenzae* is differentiated from related Gram-negative bacilli by its requirements for X and V factors and by its lack of hemolysis on blood agar (see Table 18-1).

Tests for X (heme) and V (nicotinamide adenine dinucleotide) factor requirements can be done in several ways. The *Haemophilus* species that require V factor grow around paper strips or disks containing V factor placed on the surface of agar that has been autoclaved before the blood was added (V factor is heat labile). Alternatively, a strip containing X factor can be placed in parallel with one containing V factor on agar deficient in these nutrients. Growth of *Haemophilus* in the area between the strips indicates requirement for both factors. A better test for X factor requirement is based on the inability of *H. influenzae* (and a few other *Haemophilus* species) to synthesize heme from δ -aminolevulinic acid. The inoculum is incubated with the δ -aminolevulinic acid. *Haemophilus* organisms that do not require X factor synthesize protoporphyrinogen, porphyrins, protoporphyrin IX, and heme. The presence of red fluorescence under ultraviolet light (~360 nm) indicates the presence of porphyrins and a positive test result. *Haemophilus* species that synthesize porphyrins (and thus heme) are not *H. influenzae* (see Table 18-1).

Immunity

Infants younger than age 3 months may have serum antibodies transmitted from their mothers. During this time, *H. influenzae* infection is rare, but subsequently, the antibodies are lost. Children often acquire *H. influenzae* infections, which are usually asymptomatic but may be in the form of respiratory disease or meningitis. *H. influenzae* was the most common cause of bacterial meningitis in children from 5 months to 5 years of age until the early 1990s when the conjugate vaccines became available (see later discussion). By age 3–5 years, many unimmunized children have naturally acquired anti-PRP antibodies that promote complement-dependent bactericidal killing and phagocytosis. Immunization of children with *H. influenzae* type b conjugate vaccine induces the same antibodies.

There is a correlation between the presence of bactericidal antibodies and resistance to major *H. influenzae* type b infections. However, it is not known whether these antibodies alone account for immunity. Pneumonia or arthritis caused by infection with *H. influenzae* can develop in adults with such antibodies.

Treatment

The mortality rate for individuals with untreated *H. influenzae* meningitis may be up to 90%. Many strains of *H. influenzae* type b are susceptible to ampicillin, but up to 25% produce a β -lactamase under control of a transmissible plasmid and are resistant. Essentially all strains are susceptible to the

third-generation cephalosporins and carbapenems. Cefotaxime given intravenously gives excellent results. Prompt diagnosis and antimicrobial therapy are essential to minimize late neurologic and intellectual impairment. Prominent among late complications of *H. influenzae* type b meningitis is the development of a localized subdural accumulation of fluid that requires surgical drainage. Up to 27% of NTHi in the United States also produce β -lactamases.

Epidemiology, Prevention, and Control

Encapsulated *H. influenzae* type b is transmitted from person to person by the respiratory route. *H. influenzae* type b disease can be prevented by administration of ***Haemophilus b* conjugate vaccine** to children. Currently, there are three PRP polysaccharide-protein monovalent conjugate vaccines (polysaccharide linked to outer membrane protein complex) available for use in the United States: PRP-OMP (PedvaxHIB, Merck and Co., Inc.), PRP-T (ActHIB, Sanofi Pasteur, Inc.), and PRP-T (Hiberix, GlaxoSmithKline). In PRP-OMP, the outer membrane protein complex of *Neisseria meningitidis* serogroup B is the protein conjugate, whereas for PRP-T it is tetanus toxoid. There are also three combination vaccines that contain *H. influenzae* type b conjugate vaccine. These are: PRP-OMP-HepB (Merck and Co., Inc.), DTaP-IPV/PRP-T (diphtheria, acellular pertussis, and inactivated polio are added to PRP-T; Sanofi Pasteur), and MenCY/PRP-T (meningococcal C and Y vaccine added to PRP-T; GlaxoSmithKline). The reader is referred to the reference by Briere for a complete discussion of these vaccines. Beginning at age 2 months, all children should be immunized with one of the conjugate vaccines. Depending on which vaccine product is chosen, the series consists of three doses at 2, 4, and 6 months of age or two doses given at 2 and 4 months of age. An additional booster dose is given sometime between 12 and 18 months of age. Monovalent conjugate vaccines can be given at the time of other vaccine administration such as DTaP (diphtheria, tetanus, and acellular pertussis). Widespread use of *H. influenzae* type b vaccine has reduced the incidence of *H. influenzae* type b meningitis in children by more than 95%. The vaccine reduces the carrier rates for *H. influenzae* type b.

Contact with patients with *H. influenzae* type b clinical infection poses little risk for adults but presents a definite risk for nonimmune siblings and other nonimmune children younger than age 4 years who are close contacts. Prophylaxis with rifampin is recommended for such children.

HAEMOPHILUS AEGYPTIUS

This organism was formerly called the Koch-Weeks bacillus, and it is associated with highly communicable form of conjunctivitis (pinkeye) in children. *H. aegyptius* is closely related to *H. influenzae* biotype III, the causative agent of Brazilian purpuric fever. The latter is a disease of children

characterized by fever, purpura, shock, and death. In the past, these infections were mistakenly attributed to *H. aegyptius*.

AGGREGATIBACTER APHROPHILUS

Organisms belonging to the species *H. aphrophilus* and *H. paraphrophilus* have been combined into the same species, and the name was changed to *A. aphrophilus*. *H. segnis* and *Actinobacillus actinomycetemcomitans* have also been added to the genus *Aggregatibacter*. *A. aphrophilus* isolates are often encountered as causes of infective endocarditis and pneumonia. These organisms are present in the oral cavity as part of the normal respiratory microbiota along with other members of the HACEK (*Haemophilus* species, *Actinobacillus/Aggregatibacter* species, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*) group (see Chapter 16).

HAEMOPHILUS DUCREYI

H. ducreyi causes chancroid (soft chancre), a sexually transmitted disease. Chancroid consists of a ragged ulcer on the genitalia, with marked swelling and tenderness. The regional lymph nodes are enlarged and painful. The disease must be differentiated from syphilis, herpes simplex infection, and lymphogranuloma venereum.

The small, Gram-negative rods occur in strands in the lesions, usually in association with other pyogenic microorganisms. *H. ducreyi* requires X factor but not V factor. It is grown best from scrapings of the ulcer base that are inoculated onto chocolate agar containing 1% IsoVitaleX and vancomycin, 3 µg/mL; the agar is incubated in 10% CO₂ at 33°C. Nucleic acid amplification methods are more sensitive than culture. There is no permanent immunity after chancroid infection. The recommended treatment by the Centers for Disease Control and Prevention is 1 g of azithromycin taken orally. Other treatment regimens include intramuscular ceftriaxone, oral ciprofloxacin, or oral erythromycin; healing results in 2 weeks.

OTHER HAEMOPHILUS SPECIES

H. haemolyticus is the most markedly hemolytic organism of the group in vitro; it occurs both in the normal nasopharynx and in association with rare upper respiratory tract infections of moderate severity in childhood. *H. parainfluenzae* resembles *H. influenzae* and is a normal inhabitant of the human respiratory tract; it has been encountered occasionally in infective endocarditis and in urethritis.

Concept Checks

- *Haemophilus* species are pleomorphic, Gram-negative rods that require either X (hemin) or V (NAD) factors or both for growth. Most of the species in this genus are colonizers of the upper respiratory tract of humans.

- *H. influenzae* is the major pathogen in the group, and strains that are encapsulated, especially serotype b, are more virulent, causing invasive disease, including bacteremia and meningitis in unprotected individuals.
- *H. influenzae* type b, once a significant cause of childhood morbidity and mortality, is now rare in industrialized countries that routinely vaccinate children with one of two available conjugate vaccines.
- *H. aphrophilus* and *H. paraphrophilus* have been combined into a single genus and species, *A. aphrophilus*. Other members of the *Aggregatibacter* genus include *A. actinomycetemcomitans* and *A. segnis*. These organisms are associated with a variety of infections including endocarditis.
- *H. ducreyi* is associated with the sexually transmitted disease chancroid.

THE BORDETELLAE

There are several species of *Bordetella*. *Bordetella pertussis*, a highly communicable and important pathogen of humans, causes whooping cough (pertussis). *Bordetella parapertussis* can cause a similar disease. *Bordetella bronchiseptica* (*Bordetella bronchicanis*) causes diseases in animals, such as kennel cough in dogs and snuffles in rabbits, and only occasionally causes respiratory disease and bacteremia in humans. Newer species and their disease associations include *Bordetella hinzii* (bacteremia, respiratory illness, arthritis), *Bordetella holmesii* (bacteremia among immunosuppressed patients), and *Bordetella trematum* (wound infections and otitis media). *B. pertussis*, *B. parapertussis*, and *B. bronchiseptica* are closely related, with 72–94% DNA homology and very limited differences in multilocus enzyme analysis; the three species might be considered three subspecies within a species.

BORDETELLA PERTUSSIS

Morphology and Identification

A. Typical Organisms

The organisms are minute, Gram-negative coccobacilli resembling *H. influenzae*. A capsule is present.

B. Culture

Primary isolation of *B. pertussis* requires enriched media. Bordet-Gengou medium (potato-blood-glycerol agar) that contains penicillin G, 0.5 µg/mL, can be used; however, a charcoal-containing medium supplemented with horse blood, cephalixin, and amphotericin B (Regan-Lowe) is preferable because of the longer shelf life. The plates are incubated at 35–37°C for 3–7 days aerobically in a moist environment (eg, a sealed plastic bag). The small, faintly staining Gram-negative rods are identified by immunofluorescence staining. *B. pertussis* is nonmotile.

C. Growth Characteristics

The organism is a strict aerobe and it is oxidase and catalase positive but nitrate, citrate, and urea negative, the results of which are useful for differentiating among the other species of *bordetellae*. It does not require X and V factors on subculture.

Antigenic Structure, Pathogenesis, and Pathology

B. pertussis produces a number of factors that are involved in the pathogenesis of disease. One locus on the *B. pertussis* chromosome acts as a central regulator of virulence genes. This locus has two *Bordetella operons*, **bvgA** and **bvgS**. The products of the A and S loci are similar to those of known two-component regulatory systems. *bvgS* responds to environmental signals, and *bvgA* is a transcriptional activator of the virulence genes. **Filamentous hemagglutinin**, a large surface protein, and fimbriae (surface appendages) mediate adhesion to ciliated epithelial cells and are essential for tracheal colonization. **Pertussis toxin** (a classic A/B structure toxin) promotes lymphocytosis, sensitization to histamine, and enhanced insulin secretion by means of adenosine diphosphate-ribosylating activity that disrupts function of signal transduction in many cell types. The filamentous hemagglutinin and pertussis toxin are secreted proteins and are found outside of the *B. pertussis* cells. **Adenylate cyclase toxin (ACT)**, **dermonecrotic toxin (DNT)**, and **hemolysin** also are regulated by the *bvg* system. ACT is an important virulence factor that inhibits phagocyte function but the role of DNT in pertussis is unknown. The **tracheal cytotoxin** is not regulated by *bvg* and kills respiratory epithelial cells in vitro. The lipooligosaccharide in the cell wall may also be important in causing damage to the epithelial cells of the upper respiratory tract.

B. pertussis survives for only brief periods outside the human host. There are no vectors. Transmission is largely by the respiratory route from early cases and possibly via carriers. The organism adheres to and multiplies rapidly on the epithelial surface of the trachea and bronchi and interferes with ciliary action. The blood is not invaded. The bacteria liberate the toxins and substances that irritate surface cells, causing coughing and marked lymphocytosis. Later, there may be necrosis of parts of the epithelium and polymorphonuclear infiltration, with peribronchial inflammation and interstitial pneumonia. Secondary invaders such as staphylococci or *H. influenzae* may give rise to bacterial pneumonia. Obstruction of the smaller bronchioles by mucous plugs results in atelectasis and diminished oxygenation of the blood. This probably contributes to the frequency of convulsions in infants with whooping cough.

Clinical Findings

After an incubation period of about 2 weeks, the “catarrhal stage” develops, with mild coughing and sneezing. During

this stage, large numbers of organisms are sprayed in droplets, and the patient is highly infectious but not very ill. During the “paroxysmal” stage, the cough develops its explosive character and the characteristic “whoop” upon inhalation. This leads to rapid exhaustion and may be associated with vomiting, cyanosis, and convulsions. The “whoop” and major complications occur predominantly in infants; paroxysmal coughing predominates in older children and adults. The white blood count is high (16,000–30,000/ μ L), with an absolute lymphocytosis. Convalescence is slow. *B. pertussis* is a common cause of prolonged (4–6 weeks) cough in adults. Rarely, whooping cough is followed by the serious and potentially fatal neurological complications (seizures and encephalopathy). Several types of adenovirus and *Chlamydia pneumoniae* can produce a clinical picture resembling that caused by *B. pertussis*.

Diagnostic Laboratory Tests

A. Specimens

Nasopharyngeal (NP) swabs or NP aspirates using saline are the preferred specimens. Swabs should be either Dacron or rayon tipped and not calcium alginate, as it inhibits the polymerase chain reaction (PCR), nor cotton, as cotton kills the organisms. For adults, cough droplets expelled directly onto a “cough plate” held in front of the patient’s mouth during a paroxysm is a less desirable method of specimen collection.

B. Direct Fluorescent Antibody Test

The fluorescent antibody (FA) reagent can be used to examine nasopharyngeal swab specimens. However, false-positive and false-negative results may occur; the sensitivity is about 50%. The FA test is most useful in identifying *B. pertussis* after culture on solid media.

C. Culture

NP aspirates or swabs are cultured on solid media (see earlier discussion). The antibiotics in the media tend to inhibit other respiratory microbiota but permit growth of *B. pertussis*. Organisms are identified by immunofluorescence staining or by slide agglutination with specific antiserum.

D. Polymerase Chain Reaction

PCR and other nucleic acid amplification methods are the most sensitive methods to diagnose pertussis. Primers for both *B. pertussis* and *B. parapertussis* should be included. Where available, a nucleic acid amplification test should replace the direct FA tests. Existing primer targets may cross-react with other *Bordetella* species.

E. Serology

Production of IgA, IgG, and IgM antibodies occurs after exposure to *B. pertussis*, and these antibodies can be detected by enzyme immunoassays. Serologic tests on patients are of

little diagnostic help acutely because a rise in agglutinating or precipitating antibodies does not occur until the third week of illness. Serology may be useful in evaluating patients presenting between 2 and 4 weeks of illness. A single serum with high-titer anti-PT IgG may be helpful in diagnosing the cause of a long-term cough, that is, one of greater than 4 weeks' duration.

Immunity

Recovery from whooping cough or immunization is followed by immunity that is not lifelong. Second infections may occur but are usually milder; reinfections occurring years later in adults may be severe. It is probable that the first defense against *B. pertussis* infection is the antibody that prevents attachment of the bacteria to the cilia of the respiratory epithelium. Antibodies to PT are highly immunogenic.

Treatment

B. pertussis is susceptible to several antimicrobial drugs *in vitro*. Administration of erythromycin during the catarrhal stage of disease promotes elimination of the organisms and may have prophylactic value. Treatment after onset of the paroxysmal phase rarely alters the clinical course. Oxygen inhalation and sedation may prevent anoxic damage to the brain.

Prevention

Every infant should receive three injections of pertussis vaccine during the first year of life followed by booster series for a total of five doses. Multiple acellular pertussis vaccines are licensed in the United States and elsewhere. Use of these vaccines is recommended. The acellular vaccines have at least two of the following antigens: inactivated pertussis toxin, filamentous hemagglutinin, fimbrial proteins, and pertactin.

Because different vaccines have different antigens, the same product should be used throughout an immunization series. Pertussis vaccine is usually administered in combination with toxoids of diphtheria and tetanus (DTaP). Five doses of pertussis vaccine are recommended before school entry. The usual schedule is administration of doses at 2, 4, 6, and 15–18 months of age and a booster dose at 4–6 years of age. In 2005, it was recommended by the Advisory Committee on Immunization Practices that all adolescents and adults receive a single booster dose of tetanus, diphtheria, and acellular pertussis (Tdap) to replace the booster dose of tetanus and diphtheria toxoids alone (Td). A strategy to control disease in infants <6 months of age is to vaccinate pregnant women with Tdap. Several acellular pertussis vaccines are available in the United States for use in adolescents and adults.

Prophylactic administration of erythromycin for 5 days may also benefit unimmunized infants or heavily exposed adults.

Epidemiology and Control

Whooping cough is endemic in most densely populated areas worldwide and occurs intermittently in epidemics. The source of infection is usually a patient in the early catarrhal stage of the disease. Communicability is high, ranging from 30% to 90%. Most cases occur in children younger than age 5 years; most deaths occur in the first year of life.

Over the last two decades, the general decline in pertussis cases in the United States began to reverse and by the late 1990s to early 2000s the incidence of disease in adolescents increased significantly. This led to the recommendation in 2005 for Tdap at age 11 and 12 years (see above) and coverage of unvaccinated 13–17-year-olds. Disease among adolescents declined. However, between 2010 and 2012 epidemics of disease in fully vaccinated (DTaP) young children (7–10-year-olds) were observed. There are several hypotheses for this lack of durable response which include waning of protection beginning after 3 years of completed vaccination and possibly changes in *B. pertussis* antigens and genotypic characteristics. More research is required to elucidate these trends.

Despite the above trends, control of whooping cough rests mainly on adequate active immunization of all infants and those children and adults who have close contact with them.

BORDETELLA PARAPERTUSSIS

This organism may produce a disease similar to whooping cough, but it is generally less severe. The infection is often subclinical. *B. parapertussis* grows more rapidly than typical *B. pertussis* and produces larger colonies. It also grows on blood agar. *B. parapertussis* has a silent copy of the pertussis toxin gene.

BORDETELLA BRONCHISEPTICA

B. bronchiseptica is a small, Gram-negative bacillus that inhabits the respiratory tracts of canines, in which it may cause “kennel cough” and pneumonitis. It causes snuffles in rabbits and atrophic rhinitis in swine. It is infrequently responsible for chronic respiratory tract infections in humans, primarily in individuals with underlying diseases. It grows on blood agar medium. *B. bronchiseptica* has a silent copy of the pertussis toxin gene. This organism possesses a β -lactamase that renders it resistant to penicillins and cephalosporins.

Concept Checks

- *Bordetella* species are Gram-negative coccobacilli. The genus includes diverse species that range from the fastidious and virulent pathogen *B. pertussis*, the cause of “whooping” cough, to species found primarily in animals.
- *B. pertussis* elaborates numerous virulence factors that are responsible for pathogenesis—fimbriae and filamentous

hemagglutinin promote adherence; a variety of toxins such as pertussis toxin, tracheal cytotoxin, hemolysin, and DNT mediate the severe respiratory symptoms, the hallmark lymphocytosis, and a prolonged course.

- *B. pertussis* is fastidious and slow growing; specialized media such as Regan-Lowe agar and incubation in ambient conditions at 35–37°C for up to 7 days are required for optimum results.
- Nucleic acid amplification tests combined with culture are the diagnostic methods of choice.
- Pertussis, also known as “whooping cough,” begins with the catarrhal stage followed by the characteristic paroxysmal coughing stage that lasts weeks and ends with the convalescence stage.
- Treatment requires supportive care; erythromycin is given to reduce infectivity, but it does not alter the course of the disease. Disease is preventable by vaccination with an acellular vaccine.
- The other species of *Bordetella* may cause respiratory infections but are not capable of causing classic pertussis.

THE BRUCELLAE

The brucellae are obligate parasites of animals and humans and are characteristically located intracellularly. They are relatively inactive metabolically. *Brucella melitensis* typically infects goats; *Brucella suis*, swine; *Brucella abortus*, cattle; and *Brucella canis*, dogs. Other species are found only in animals. Although named as species, DNA relatedness studies have shown there is only one species in the genus, *B. melitensis*, with multiple biovars. The disease in humans, brucellosis (undulant fever, Malta fever), is characterized by an acute bacteremic phase followed by a chronic stage that may extend over many years and may involve many tissues.

Morphology and Identification

A. Typical Organisms

The appearance in young cultures varies from cocci to rods 1.2 µm in length, with short coccobacillary forms predominating. They are Gram-negative but often stain irregularly, and they are aerobic, nonmotile, and nonspore forming.

B. Culture

Small, convex, smooth colonies appear on enriched media in 2–5 days.

C. Growth Characteristics

Brucellae are adapted to an intracellular habitat, and their nutritional requirements are complex. Some strains have been cultivated on defined media containing amino acids, vitamins, salts, and glucose. Fresh specimens from animal or human sources are usually inoculated on trypticase-soy agar or blood culture media. Whereas *B. abortus* requires 5–10% CO₂ for growth, the other three species grow in air.

Brucellae use carbohydrates but produce neither acid nor gas in amounts sufficient for classification. Catalase and oxidase are produced by the four species that infect humans. Hydrogen sulfide is produced by many strains, and nitrates are reduced to nitrites.

Brucellae are moderately sensitive to heat and acidity. They are killed in milk by pasteurization.

Antigenic Structure

Differentiation among *Brucella* species or biovars is made possible by their characteristic sensitivity to dyes and their production of H₂S. Few laboratories have maintained the procedures for these tests, and the brucellae are seldom placed into the traditional species. Because brucellae are hazardous in the laboratory, tests to classify them should be performed only in reference public health laboratories using appropriate biosafety precautions.

Pathogenesis and Pathology

Although each species of *Brucella* has a preferred host, all can infect a wide range of animals, including humans.

The common routes of infection in humans are the intestinal tract (ingestion of infected milk), mucous membranes (droplets), and skin (contact with infected tissues of animals). Cheese made from unpasteurized goats' milk is a particularly common vehicle. The organisms progress from the portal of entry via lymphatic channels and regional lymph nodes to the thoracic duct and the bloodstream, which distributes them to the parenchymatous organs. Granulomatous nodules that may develop into abscesses form in lymphatic tissue, liver, spleen, bone marrow, and other parts of the reticuloendothelial system. In such lesions, the brucellae are principally intracellular. Osteomyelitis, meningitis, or cholecystitis also occasionally occurs. The main histologic reaction in brucellosis consists of proliferation of mononuclear cells, exudation of fibrin, coagulation necrosis, and fibrosis. The granulomas consist of epithelioid and giant cells, with central necrosis and peripheral fibrosis.

The brucellae that infect humans have apparent differences in pathogenicity. *B. abortus* usually causes mild disease without suppurative complications; noncaseating granulomas of the reticuloendothelial system are found. *B. canis* also causes mild disease. *B. suis* infection tends to be chronic with suppurative lesions; caseating granulomas may be present. *B. melitensis* infection is more acute and severe.

Persons with active brucellosis react more markedly (fever, myalgia) than normal persons to injected *Brucella* endotoxin. Sensitivity to endotoxin thus may play a role in pathogenesis.

Placentas and fetal membranes of cattle, swine, sheep, and goats contain erythritol, a growth factor for brucellae. The proliferation of organisms in pregnant animals leads to placentitis and abortion in these species. There is no erythritol in human placentas, and abortion is not part of *Brucella* infection of humans.

Clinical Findings

The incubation period ranges from 1 to 4 weeks. The onset is insidious, with malaise, fever, weakness, aches, and sweats. The fever usually rises in the afternoon; it falls during the night and is accompanied by drenching sweat. There may be gastrointestinal and nervous symptoms. Lymph nodes enlarge, and the spleen becomes palpable. Hepatitis may be accompanied by jaundice. Deep pain and disturbances of motion, particularly in vertebral bodies, suggest osteomyelitis. These symptoms of generalized *Brucella* infection generally subside in weeks or months, although localized lesions and symptoms may continue.

After the initial infection, a chronic stage may develop, characterized by weakness, aches and pains, low-grade fever, nervousness, and other nonspecific manifestations compatible with psychoneurotic symptoms. Brucellae cannot be isolated from the patient at this stage, but the agglutinin titer may be high. The diagnosis of “chronic brucellosis” is difficult to establish with certainty unless local lesions are present.

Diagnostic Laboratory Tests

A. Specimens

Blood should be taken for culture, biopsy material for culture (lymph nodes, bone, and so on), and serum for serologic tests.

B. Culture

Brucella agar was specifically designed to culture *Brucella* species bacteria. The medium is highly enriched and—in reduced form—is used primarily in cultures for anaerobic bacteria. In oxygenated form, the medium grows *Brucella* species bacteria very well. However, infection with *Brucella* species is often not suspected when cultures of a patient's specimens are set up, and *Brucella* agar incubated aerobically is seldom used. *Brucella* species bacteria grow on commonly used media, including trypticase-soy medium with or without 5% sheep blood, brain–heart infusion medium, and chocolate agar. Blood culture media (see below) readily grow *Brucella* species bacteria. Liquid medium used to culture *Mycobacterium tuberculosis* also supports the growth of at least some strains. All cultures should be incubated in 8–10% CO₂ at 35–37°C and should be observed for 3 weeks before being discarded as being negative; liquid media cultures should be blindly subcultured during this time.

Bone marrow and blood are the specimens from which brucellae are most often isolated. The method of choice for bone marrow is to use pediatric Isolator tubes, which do not require centrifugation, with inoculation of the entire contents of the tube onto solid media. Media used in semiautomated and automated blood culture systems readily grow brucellae, usually within 1 week; however, holding the cultures for 3 weeks is recommended. Negative culture results for *Brucella* do not exclude the disease because brucellae can be cultivated from patients only during the acute phase of the illness or during recurrence of activity.

After a few days of incubation on agar media, the brucellae form colonies in the primary streak that are smaller than 1 mm in diameter. They are nonhemolytic. The observation of tiny Gram-negative coccobacilli that are catalase positive and oxidase positive suggests *Brucella* species. All further work on such a culture should be done in a biologic safety cabinet. A Christensen's urea slant should be inoculated and observed frequently. A positive urease test result is characteristic of *Brucella* species. *B. suis* and some strains of *B. melitensis* can yield a positive test result less than 5 minutes after inoculating the slant; other strains take a few hours to 24 hours. Bacteria that meet these criteria should be quickly submitted to a reference public health laboratory for presumptive identification. *Brucella* species are on the United States' select agent list. Molecular methods have been developed to rapidly differentiate among the various biovars.

C. Serology

Laboratory diagnosis of brucellosis is most frequently accomplished by serologic testing. IgM antibody levels rise during the first week of acute illness, peak at 3 months, and may persist during chronic disease. Even with appropriate antibiotic therapy, high IgM levels may persist for up to 2 years in a small percentage of patients. IgG antibody levels rise about 3 weeks after onset of acute disease, peak at 6–8 weeks, and remain high during chronic disease. IgA levels parallel the IgG levels. The usual serologic tests may fail to detect infection with *B. canis* because antigens used may be *B. abortus* or *B. melitensis*. A combination of serological tests (usually agglutination tests with nonagglutinating assays) is recommended to definitely diagnose brucellosis.

1. Agglutination test—To be reliable, serum agglutination tests must be performed with standardized heat-killed, phenolized, smooth *Brucella* antigens. IgG agglutinin titers above 1:80 indicate active infection. Individuals injected with cholera vaccine may develop agglutination titers to brucellae. If the serum agglutination test result is negative in patients with strong clinical evidence of *Brucella* infection, tests must be made for the presence of “blocking” antibodies. These can be detected by adding antihuman globulin to the antigen–serum mixture. Brucellosis agglutinins are cross-reactive with tularemia agglutinins, and tests for both diseases should be done on positive sera; usually, the titer for one disease will be much higher than that for the other.

2. Blocking antibodies—These are IgA antibodies that interfere with agglutination by IgG and IgM and cause a serologic test result to be negative in low serum dilutions (prozone), although positive in higher dilutions. These antibodies appear during the subacute stage of infection, tend to persist for many years independently of activity of infection, and are detected by the Coombs antiglobulin method.

3. Brucellacapt (Vircell, Granada, Spain)—This is a rapid immunocapture agglutination method based on the

Coombs test that detects nonagglutinating IgG and IgA antibodies. It is easy to perform and has a high sensitivity and specificity. This product is not available in the United States.

4. ELISA assays—IgG, IgA, and IgM antibodies may be detected using enzyme-linked immunosorbent assays (ELISA), which use cytoplasmic proteins as antigens. These assays tend to be more sensitive and specific than the agglutination test especially in the setting of chronic disease.

Immunity

An antibody response occurs with infection, and it is probable that some resistance to subsequent attacks is produced. Immunogenic fractions from *Brucella* cell walls have a high phospholipid content; lysine predominates among eight amino acids; and there is no heptose (thus distinguishing the fractions from endotoxin).

Treatment

Brucellae may be susceptible to tetracyclines, rifampin, trimethoprim-sulfamethoxazole, aminoglycosides, and some quinolones. Symptomatic relief may occur within a few days after treatment with these drugs. However, because of their intracellular location, the organisms are not readily eradicated completely from the host. For best results, treatment must be prolonged. Combined treatment with a tetracycline (eg, doxycycline) and either streptomycin or gentamicin for 2–3 weeks or rifampin for 6–8 weeks is recommended. In patients with endocarditis or evidence of neurological disease, triple therapy with doxycycline, rifampin, and an aminoglycoside is suggested.

Epidemiology, Prevention, and Control

Brucellae are animal pathogens transmitted to humans by accidental contact with infected animal feces, urine, milk, or tissues. The common sources of infection for humans are unpasteurized milk, milk products, and cheese as well as occupational contact (eg, farmers, veterinarians, and slaughterhouse workers) with infected animals.

Cheese made from unpasteurized goat's milk is a particularly common vehicle for transmission of brucellosis. Occasionally, the airborne route may be important. Because of occupational contact, *Brucella* infection is much more frequent in men. The majority of infections remain asymptomatic (latent).

Infection rates vary greatly with different animals and in different countries. Outside the United States, infection is more prevalent. Eradication of brucellosis in cattle can be attempted by test and slaughter, active immunization of heifers with avirulent live strain 19, or combined testing, segregation, and immunization. Cattle are examined by means of agglutination tests.

Active immunization of humans against *Brucella* infection is experimental. Control rests on limitation of spread

and possible eradication of animal infection, pasteurization of milk and milk products, and reduction of occupational hazards wherever possible.

Concept Checks

- *Brucella* species are obligate intracellular pathogens found in animals; the disease in humans, brucellosis, known by a variety of synonyms, such as Malta fever and undulant fever, is caused primarily by contact with animals or animal products, especially unpasteurized milk or cheese.
- The incubation period ranges from 1 to 4 weeks; infection may begin abruptly with fever, chills, sweats, and malaise and progress to involve a multisystem illness with splenomegaly, lymphadenopathy, and osteomyelitis; chronic infection may persist for years.
- Diagnosis may be difficult and in many cases relies on serology because this fastidious organism can be difficult to cultivate even on selective media using prolonged incubation.
- Treatment consists of prolonged antimicrobial agents that are effective against intracellular pathogens such as rifampin, trimethoprim-sulfamethoxazole, fluoroquinolones, aminoglycosides, and tetracyclines.

FRANCISELLA TULARENSIS AND TULAREMIA

Francisella species are widely found in animal reservoirs and aquatic environments. The taxonomy of this genus has undergone numerous changes over the years. There are seven species in the genus, the most important of which is *Francisella tularensis*. There are three recognized subspecies of *F. tularensis*: *tularensis* (type A), *holarctica* (type B), and *mediasiatica*. Subspecies *tularensis* (type A) is the most virulent among this group and the most pathogenic for humans. It is associated with wild rabbits, ticks, and tabanid flies. Subspecies *holarctica* strains cause milder infection and are associated with hares, ticks, mosquitoes, and tabanid flies. *F. tularensis* is transmitted to humans by biting arthropods and flies, direct contact with infected animal tissue, inhalation of aerosols, or ingestion of contaminated food or water. The clinical presentation depends on the route of infection; six major syndromes are described (see Pathogenesis and Clinical Findings).

Two other species of *Francisella*, *Francisella philomiragia* and *Francisella novicida*, have been associated with human disease. *F. philomiragia* has usually been found in situations of near-drowning. These organisms will not be discussed.

Morphology and Identification

A. Typical Organisms

F. tularensis is a small, Gram-negative coccobacillus. It is rarely seen in smears of tissue (Figure 18-2).

FIGURE 18-2 Gram-stain of *F. tularensis*. These bacteria are tiny, Gram-negative coccobacilli approximately $0.2 \times 0.7 \mu\text{m}$. Original magnification $\times 1000$. (Courtesy of CDC Public Health Image Library.)

B. Specimens

Blood is taken for serologic tests. The organism may be recovered in culture from lymph node aspirates, bone marrow, peripheral blood, deep tissue, and ulcer biopsies.

C. Culture

Growth requires enriched media containing cysteine. In the past, glucose-cysteine-blood agar was preferred, but *F. tularensis* grows on commercially available hemin-containing media, such as chocolate agar, modified Thayer-Martin agar, and buffered charcoal yeast extract (BCYE) agar used to grow *Legionella* species. Media should be incubated in CO_2 at $35\text{--}37^\circ\text{C}$ for 2–5 days. **Caution:** To avoid laboratory-acquired infections, biosafety level three (BSL III) practices are required when working with live cultures suspected of containing *F. tularensis*. Clinical specimens require BSL II facilities and work practices.

D. Serology

All isolates are serologically identical, possessing a polysaccharide antigen and one or more protein antigens that cross-react with brucellae. However, there are two major biogroups of strains, called Jellison type A and type B. Type A occurs only in North America, is lethal for rabbits, produces severe illness in humans, ferments glycerol, and contains citrulline ureidase. Type B lacks these biochemical features, is not lethal for rabbits, produces milder disease in humans, and is isolated often from rodents or from water in Europe, Asia, and North America. Other biogroups are of low pathogenicity.

The usual antibody response consists of agglutinins developing 7–10 days after the onset of illness.

Pathogenesis and Clinical Findings

F. tularensis is highly infectious: Penetration of the skin or mucous membranes or inhalation of 50 organisms can result in infection. Most commonly, organisms enter through skin abrasions. In 2–6 days, an inflammatory, ulcerating papule develops. Regional lymph nodes enlarge and may become necrotic, sometimes draining for weeks (ulceroglandular tularemia). Inhalation of an infective aerosol results in peribronchial inflammation and localized pneumonitis (pneumonic tularemia). Oculoglandular tularemia can develop when an infected finger or droplet touches the conjunctiva. Yellowish granulomatous lesions on the eyelids may be accompanied by preauricular adenopathy. The other forms of the disease are glandular tularemia (lymphadenopathy but no ulcers), oropharyngeal tularemia, and typhoidal tularemia (septicemia). All affected individuals have fever, malaise, headache, and pain in the involved region and regional lymph nodes.

Because of the highly infectious nature of *F. tularensis*, this organism is a potential agent of bioterrorism and is currently classified on the select agent list as a Tier 1 agent. Laboratories that recover a suspected *F. tularensis* should notify public health officials and should send the isolate to a reference laboratory capable of performing definitive identification.

Diagnostic Laboratory Tests

F. tularensis may be recovered from the clinical specimens listed earlier and by performance of serologic studies. Agglutination testing either in a tubed format or in microagglutination is the standard form of testing. Paired serum samples collected 2 weeks apart can show a rise in agglutination titer. A single-tubed agglutination serum titer greater than 1:160 or a microagglutination titer of greater than 1:128 are highly suggestive if the history and physical findings are compatible with the diagnosis. Because antibodies reactive in the agglutination test for tularemia also react in the test for brucellosis, both tests should be done for positive sera; the titer for the disease affecting the patient is usually fourfold greater than that for the other disease.

Treatment

Streptomycin or gentamicin therapy for 10 days almost always produces rapid improvement. Tetracycline may be equally effective, but relapses occur more frequently. Fluoroquinolones are other potential agents. *F. tularensis* is resistant to all β -lactam antibiotics as a result of β -lactamase production.

Prevention and Control

Humans acquire tularemia from handling infected rabbits or muskrats or from bites by an infected tick or deer fly. Less often, the source is contaminated water or food or contact with a dog or cat that has caught an infected wild animal.

Avoidance is the key to prevention. The infection in wild animals cannot be controlled.

The live attenuated *F. tularensis* vaccine (LVS) is no longer available to persons at high risk. Newer vaccines are under development.

Concept Checks

- *F. tularensis* is a faintly staining Gram-negative coccobacillus that causes the zoonotic infection tularemia that can be mediated by vectors, such as ticks, through direct contact with animals or rarely through ingestion.
- There are three subspecies of *F. tularensis*; subspecies *tularensis* (type A) is the most virulent and pathogenic for humans.
- There are several clinical manifestations of tularemia depending on the type of exposure; the glandular forms are well localized and associated with less mortality than the septicemic or inhalational forms of the disease.
- Diagnosis of tularemia can be made by recovery of the organism from appropriate clinical material and by serology.
- Agents that have been useful in treatment include streptomycin, gentamicin, tetracyclines, and fluoroquinolones. Because of its virulence, *F. tularensis* is considered a potential agent of bioterrorism.

REVIEW QUESTIONS

1. A 68-year-old woman was seen in the clinic because she had felt feverish and had been experiencing increasing pain and swelling in her left knee during the past 3 weeks. Four years earlier, a prosthetic joint had been placed in her left knee. On examination, the knee was swollen, and fluid could be detected. An aspirate of the fluid was obtained. There were 15,000 polymorphonuclear cells/mL in the fluid. No organisms were seen on Gram-stain. A routine culture was done. On the fourth day of incubation, colorless colonies smaller than 1 mm in diameter were seen on the blood and chocolate agar plates. The organism was a tiny Gram-negative coccobacillus that was catalase positive and oxidase positive. A urea slant was inoculated and was positive for urease activity after overnight incubation. The patient was probably infected with which of the following microorganisms?
 - (A) *H. influenzae*
 - (B) *H. ducreyi*
 - (C) *F. tularensis*
 - (D) *Brucella species*
 - (E) *Staphylococcus aureus*
2. After the culture (Question 1) turned positive, additional history was obtained. Approximately 4 weeks before the onset of her knee pain, the patient had visited relatives in Israel and traveled to other countries in the Mediterranean area. She had a particular fondness for one food product that was the probable vehicle for her infection. The product most likely was
 - (A) Bananas
 - (B) Unpasteurized goat's cheese
 - (C) Rare hamburger
 - (D) Fresh orange juice
 - (E) Green tea
3. A 55-year-old game warden in Vermont found a dead muskrat on the bank of a stream. He picked up the animal, thinking it might have been illegally trapped or shot; it was not, and the game warden buried it. Four days later, he developed a 1.5-cm painful ulcer on the index finger of his right hand, a 1-cm ulcer on his right forehead, and pain in his right axilla. Physical examination also revealed right axillary lymphadenopathy. This patient is most likely infected with
 - (A) *Brucella species*
 - (B) *Rickettsia rickettsii*
 - (C) *Salmonella Typhi*
 - (D) *H. ducreyi*
 - (E) *F. tularensis*
4. An 18-month-old boy has been playing with a child who develops *H. influenzae* meningitis. The boy's parents consult his pediatrician, who says she is comfortable that the child will be fine because he has been fully immunized with the polyribitol ribose phosphate (PRP)-protein conjugate vaccine. For what reason is it necessary to immunize infants of 2 months to 2 years of age with polysaccharide-protein conjugate vaccines?
 - (A) The conjugate protein is diphtheria toxoid, and the goal is for the infant to develop simultaneous immunity to diphtheria.
 - (B) Infants 2 months to 2 years of age do not immunologically respond to polysaccharide vaccines that are not conjugated to a protein.
 - (C) The conjugate vaccine is designed for older children and adults as well as infants.
 - (D) Maternal (transplacental) antibodies against *H. influenzae* are gone from the infant's circulation by 2 months of age.
 - (E) None of the above.
5. An 11-year-old boy from Peru was referred to the Brain Tumor Institute. Three months earlier he had developed headaches and then slowly progressive right-sided weakness. A CT scan showed a mass lesion in the left hemisphere. He was thought to have a brain tumor. A lumbar puncture was not done because of concern about increased intracranial pressure and brain herniation through the tentorium cerebelli. During surgery, a mass lesion in the left hemisphere was found. Frozen sections of the tissue were done while the patient was in the operating room. Microscopy of the sections showed a granulomatous inflammatory reaction. No tumor was seen. Tissue was submitted for culture for *M. tuberculosis*. Middlebrook 7H9 broth medium was used. Six days after the culture was set up, the automated machine detected that the culture result was positive. Results of an acid-fast stain and a Gram-stain were both negative. Subcultures were done. Two days later, very small colonies were seen on the sheep blood agar plate. The organism was a tiny Gram-negative coccobacillus that was catalase positive and oxidase positive. It showed urease activity after 2 hours of incubation on urea-containing medium. This child had infection with
 - (A) *Brucella species*
 - (B) *M. tuberculosis*
 - (C) *F. tularensis*
 - (D) *H. influenzae*
 - (E) *Moraxella catarrhalis*

6. A 3-year-old child develops *H. influenzae* meningitis. Therapy is begun with cefotaxime. Why is this third-generation cephalosporin used rather than ampicillin?
- About 80% of *H. influenzae* organisms have modified penicillin-binding proteins that confer resistance to ampicillin.
 - The drug of choice, trimethoprim-sulfamethoxazole, cannot be used because the child is allergic to sulfonamides.
 - It is easier to administer intravenous cefotaxime than intravenous ampicillin.
 - There is concern that the child will rapidly develop a penicillin (ampicillin) allergy.
 - About 20% of *H. influenzae* organisms have a plasmid that encodes for β -lactamase.
7. A 55-year-old man with severe dental caries presented with 1 month of fever, malaise, and back pain and now presents with moderately severe shortness of breath. The examination reveals a febrile man who appears pale and dyspneic. Other physical findings include conjunctival petechiae, a grade III/VI systolic murmur, and an enlarged spleen. Blood cultures grow a pleomorphic Gram-negative rod that is not hemolytic and that when tested is X and V factor negative. The most likely causative pathogen is
- H. influenzae*
 - H. ducreyi*
 - A. aphrophilus*
 - Actinobacillus hominis*
 - H. parainfluenzae*
8. All of the following statements regarding acellular pertussis vaccines are correct *except*
- All formulations of the vaccine contain at least two antigens.
 - The acellular vaccine has replaced the whole cell vaccine in the childhood vaccine series.
 - All children should receive five doses of the vaccine before school entry.
 - The vaccine is approved only for young children and adolescents.
 - The vaccine is safer than and as immunogenic as whole-cell vaccines.
9. Which of the following subspecies of *F. tularensis* is the most virulent for humans?
- tularensis*
 - holarctica*
 - mediasiatica*
 - novicida*
10. All of the following statements regarding the etiologic agent of chancroid are correct *except*
- The organism is a small Gram-negative rod.
 - The organism requires X factor but not V factor.
 - The organism grows well on standard chocolate agar.
 - On Gram-stain of lesions, the organism occurs in strands.
 - The organism is susceptible to erythromycin.
11. A 3-month-old infant is brought to the pediatric emergency department in severe respiratory distress. The child appears dehydrated, and there is a prominent peripheral lymphocytosis. The chest radiograph reveals perihilar infiltrates. The child's grandmother, who watches the infant now that the mother has returned to work, has had a dry hacking cough for about 2 weeks. The most likely causative agent is
- H. influenzae* type b
 - B. pertussis*
 - Streptococcus agalactiae*
 - C. pneumoniae*
 - B. bronchiseptica*
12. In Question 11, the factor responsible for the profound lymphocytosis is
- A hemagglutinin
 - A polysaccharide capsule
 - An A/B structured toxin
 - A heat-labile toxin
 - A neuraminidase
13. All of the following cause zoonotic infections *except*
- F. tularensis*
 - B. melitensis*
 - B. pertussis*
 - Bacillus anthracis*
 - Leptospira interrogans*
14. Which of the following is not a recognized virulence factor of *B. pertussis*?
- Heat-labile toxin
 - Filamentous hemagglutinin
 - Tracheal cytotoxin
 - Pertussis toxin
 - Dermonecrotic toxin
15. Which of the following pathogens discussed in this chapter is on the select agent list?
- H. influenzae*
 - A. aphrophilus*
 - B. pertussis*
 - F. tularensis*
 - All of the above

Yersinia and *Pasteurella*

The organisms discussed in this chapter are short, pleomorphic Gram-negative rods that often exhibit bipolar staining. They are catalase positive and microaerophilic or facultatively anaerobic. While most of the organisms discussed here have animals as their natural hosts, they are known to cause zoonotic infections and produce at times serious disease in humans.

The genus *Yersinia* includes 17 different species; however, only three species are pathogenic to humans, whereas the other 14 are considered to be environmental species and nonpathogenic. The three human pathogens include *Yersinia pestis*, *Yersinia enterocolitica*, and *Yersinia pseudotuberculosis*. These three *Yersinia* species generally cause disease in domestic and wild animals (eg, pigs, rodents, and birds) and humans are usually considered to be incidental hosts. *Y. pestis* is the cause of plague; *Y. enterocolitica* and *Y. pseudotuberculosis* are zoonotic food-borne pathogens, both typically causing a mild diarrheal disease, following ingestion of contaminated food and/or water. *Pasteurella* species are primarily commensals and/or pathogens in a variety of wild and domestic animals; however, *Pasteurella multocida* can also produce human disease.

YERSINIA PESTIS AND PLAGUE

While the epizootic cycle of plague has not been completely understood, infection with *Y. pestis* is fundamentally a disease of rodents, and plague is found in various endemic foci around the world. Humans are incidental, “dead-end” hosts that become infected when the plague bacillus is transmitted via flea bite or by exposure to fluids and tissues from an infected animal. As a result of such exposure, a serious infection will develop, often with a high mortality (40–100%). Plague has caused at least three major pandemics in previous centuries. The first pandemic occurred during the time of the Byzantine Empire in the 6th century, and the second pandemic, often called the “Black Death,” began in Central Asia and subsequently spread along ancient trade routes and reached Europe in 1346, where it spread quickly between the years 1347 and 1354, killing an estimated one-third of the population. During the 300 years following the “Black Death,” plague caused numerous smaller epidemics in various European countries. The third pandemic began during

the 1850s in China, from where it spread via trade routes and steam ships to many countries, worldwide. While *Y. pestis* is an organism of considerable historic importance and interest, its potential use as an agent of Biowarfare has also been well recognized and documented. The ability of this organism to be easily transmitted by aerosol and the severity and high mortality associated with pneumonic plague make *Y. pestis* quite suitable for being a potential agent of biowarfare.

Morphology and Identification

Y. pestis is a Gram-negative rod that exhibits striking bipolar staining with special stains such as Wright, Giemsa, Wayson, or methylene blue (Figure 19-1). It is nonmotile. It grows as a facultative anaerobe on many bacteriologic media and can be readily isolated when sterile specimens such as blood or lymph node aspirates are plated onto sheep blood agar. Growth is more rapid when agar plates are incubated at 28°C. In cultures on sheep blood agar incubated at 37°C, colonies may be smaller when compared to colonies from agar plates incubated at 28°C. To enhance the recovery of *Y. pestis* from a nonsterile site specimen (eg, sputum), it is recommended to inoculate the specimen onto cefsulodin-irgasan-novobiocin (CIN) agar and incubate agar plates at 25–28°C. Colonies of *Y. pestis* are typically gray to white, sometimes opaque, and are 1–1.5 mm in diameter with irregular edges; the organism does not produce hemolysis.

Antigenic Structure

All yersiniae possess lipopolysaccharides that have endotoxic activity when released. *Y. pestis* and *Y. enterocolitica* also produce antigens and toxins that act as virulence factors. They have type III secretion systems that consist of a membrane-spanning complex that allows the bacteria to inject proteins directly into cytoplasm of the host cells. The virulent yersiniae produce V and W antigens, which are encoded by genes on a plasmid of approximately 70 kb. This is essential for virulence; the V and W antigens yield the requirement for calcium for growth at 37°C. Compared with the other pathogenic yersiniae, *Y. pestis* has gained additional plasmids. pPCP1 is a 9.5-kb plasmid that contains genes that yield plasminogen-activating protease that has temperature-dependent coagulase activity (20–28°C, the temperature of the flea) and fibrinolytic activity

FIGURE 19-1 *Y. pestis* (arrows) in blood, Wright-Giemsa stain. Some of the *Y. pestis* have bipolar staining, which gives them a hairpin-like appearance. Original magnification $\times 1000$. (Courtesy of K Gage, Plague Section, Centers for Disease Control and Prevention, Ft. Collins, CO.)

(35–37°C, the temperature of the host). This factor is involved in dissemination of the organism from the flea bite injection site. The pFra/pMT plasmid (80–101 kb) encodes the capsular protein (fraction F1) that is produced mainly at 37°C and confers antiphagocytic properties. In addition, this plasmid contains genes that encode phospholipase D, which is required for organism survival in the flea midgut.

Y. pestis and *Y. enterocolitica* have a pathogenicity island (PAI) that encodes for an iron-scavenging siderophore (see Chapter 9), yersiniabactin.

Pathogenesis and Pathology

When a flea feeds on a rodent infected with *Y. pestis*, the ingested organisms multiply in the gut of the flea and, helped by the coagulase, block its proventriculus so that no food can pass through. Subsequently, the “blocked” and hungry flea bites ferociously, and the aspirated blood, contaminated with *Y. pestis* from the flea, is regurgitated into the bite wound. The inoculated organisms may be phagocytosed by polymorphonuclear cells and macrophages. The *Y. pestis* organisms are killed by the polymorphonuclear cells but multiply in the macrophages; because the bacteria are multiplying at 37°C, they produce the antiphagocytic protein and subsequently are able to resist phagocytosis. The pathogens rapidly reach the lymphatics, and an intense hemorrhagic inflammation develops in the enlarged lymph nodes, which may undergo necrosis and become fluctuant. Although the invasion may stop there, *Y. pestis* organisms often reach the bloodstream and become widely disseminated. Hemorrhagic and necrotic lesions may develop in all organs; meningitis, pneumonia, and serosanguineous pleuropneumonia are prominent features.

Primary pneumonic plague results from inhalation of infective droplets (usually from a coughing patient), and it is characterized by hemorrhagic consolidation, sepsis, and death.

Clinical Findings

The clinical manifestations of plague depend on the route of exposure, and three forms of the disease have been described: bubonic plague, pneumonic plague, septicemic plague. Bubonic plague is by far the most common clinical presentation of infection with *Y. pestis*. After an incubation period of 2–7 days, there is a sudden onset of high fever and development of painful lymphadenopathy, commonly with greatly enlarged, tender lymph nodes (buboes) in the neck, groin, or axillae. Septicemic plague can occur spontaneously or as a complication of untreated bubonic plague. In this form of the disease, *Y. pestis* multiplies intravascularly and can be seen in blood smears. Patients typically present with a sudden onset of high fever, chills, and weakness, progressing rapidly to septic shock with associated disseminated intravascular coagulation, hypotension (septic shock), altered mental status, and renal and cardiac failure. Bleeding into skin and organs can also occur. Vomiting and diarrhea may develop during the early stages of septicemic plague. Terminally, signs of pneumonia and meningitis can appear. Primary pneumonic plague results from direct inhalation of organisms into the lung. This form of the disease typically occurs through close and direct contact with another patient who has pneumonic plague, and symptoms begin within 1–4 days after the exposure. Patients often have a fulminant course with chest pain, cough, hemoptysis, and severe respiratory distress. Secondary pneumonic plague is a complication in approximately 10% of patients with bubonic plague through hematogenous spread of the organisms from the buboes and often in the setting of delayed or inappropriate antibiotic treatment.

Diagnostic Laboratory Tests

Plague should be suspected in febrile patients who have been exposed to rodents in known endemic areas. Rapid recognition and laboratory confirmation of the disease are essential to institute lifesaving therapy.

A. Specimens

Blood is taken for culture and aspirates of enlarged lymph nodes for smear and culture. Acute and convalescent sera may be examined for antibody levels. In pneumonia, sputum is cultured; in possible meningitis, cerebrospinal fluid is taken for smear and culture.

B. Smears

Y. pestis are small Gram-negative bacilli that appear as single cells or as pairs or short chains in clinical material. Wright, Giemsa, or Wayson stains may be more useful when staining material from a suspected bubo or a positive blood culture result because of the striking bipolar appearance (safety pin shape) of the organism using these stains that is not evident on a

direct Gram-stain. More specific direct staining methods (possibly available through reference laboratories) include the use of fluorescent antibody stains targeting the capsular F1 antigen.

C. Culture

All materials are cultured on blood agar, chocolate, and MacConkey agar plates and in brain–heart infusion broth. Growth on solid media may be slow, requiring more than 48 hours, but blood culture results are often positive in 24 hours. Cultures can be tentatively identified by biochemical reactions. *Y. pestis* produces nonlactose-fermenting colonies on MacConkey agar, and it grows better at 25°C than at 37°C. The organism is catalase positive; indole, oxidase, and urease negative; and nonmotile. The last two reactions are useful in differentiating *Y. pestis* from other pathogenic yersiniae. The use of automated (commercial) identification systems using various biochemical reactions is not recommended for the identification of *Y. pestis*, and an organism with the abovementioned characteristics should be referred to a public health laboratory for more confirmatory testing. Definite identification of cultures is best done by immunofluorescence or by lysis by a specific *Y. pestis* bacteriophage (confirmation available through state health department laboratories and by consultation with the Centers for Disease Control and Prevention [CDC], Plague Branch, Fort Collins, CO).

All cultures are highly infectious and must be handled with extreme caution inside a biological safety cabinet.

D. Serology

In patients who have not been previously vaccinated, a convalescent serum antibody titer of 1:16 or greater is presumptive evidence of *Y. pestis* infection. A titer rise in two sequential specimens confirms the serologic diagnosis.

Treatment

Unless promptly treated, plague may have a mortality rate of nearly 50%; pneumonic plague has a mortality rate of nearly 100%. The drug of choice is streptomycin, but the more readily available aminoglycoside gentamicin has been shown to be as effective. Streptomycin is nephrotoxic and ototoxic and should therefore be cautiously used in elderly patients, pregnant women, and in children. For these patient groups as well as other patients with contraindications to the use of aminoglycosides, doxycycline, or ciprofloxacin (and other fluoroquinolones) are considered alternative drugs for the treatment of plague. These agents can also be given in combination with streptomycin or gentamicin. Antimicrobial drug resistance in *Y. pestis* has never been documented in the United States and has rarely been noted in *Y. pestis* isolates in other parts of the world.

Epidemiology and Control

Plague is an infection of wild rodents (field mice, gerbils, moles, skunks, and other animals) that occurs in many parts of the world. The primary enzootic areas are India, Southeast Asia (especially Vietnam), Africa, and North and

South America. The western states of the United States and Mexico also contain reservoirs of infection. Epizootics with high mortality rates occur intermittently; at such times, the infection can spread to domestic rodents (eg, rats) and other animals (eg, cats), and humans can be infected by flea bites or by contact. The commonest vector of plague is the rat flea (*Xenopsylla cheopis*), but other fleas may also transmit the infection. *Y. pestis* does not form spores and is extremely susceptible to UV radiation (eg, sunlight) and desiccation. Therefore, it is reasonable to expect that the majority of organisms become nonviable within 1 hour following the release into the environment. However, studies have also demonstrated the plague bacilli are capable of surviving in soil for prolonged periods of time. The control of plague requires surveys of infected animals, vectors, and human contacts; in the United States, this is done by county and state agencies with support from the Plague Branch of the CDC and by destruction of plague-infected animals. If a human case is diagnosed, health authorities must be notified promptly. All patients with suspected plague should be isolated, particularly if pulmonary involvement has not been ruled out. All specimens must be treated with extreme caution. Postexposure prophylaxis with either doxycycline or ciprofloxacin is indicated for people who have a known or documented exposure to plague; typical exposures include close contact with a pneumonic plague patient or direct contact with contaminated/infected fluids and/or tissues. Postexposure prophylaxis is usually given for 7 days following the exposure. Mass chemoprophylaxis is considered as a likely public health response following an intentional release of *Y. pestis*, and the CDC and State Public Health Departments have formulated detailed guidelines for the response to such an event. Aside from chemoprophylaxis, disease preventative measures for the risk of an occupational exposure (eg, emergency first responder personnel) include the use of biosafety level 3 personal protective equipment (ie, Tyvek suits, booties, gloves, or HEPA-filtered respirators).

Killed whole-cell vaccines are no longer available in the United States. Because of concern for *Y. pestis* being a potential agent of biowarfare and bioterrorism, numerous vaccines are currently under development.

YERSINIA ENTEROCOLITICA AND YERSINIA PSEUDOTUBERCULOSIS

Y. enterocolitica and *Y. pseudotuberculosis* are zoonotic, food-borne pathogens that spread through the fecal–oral route. *Y. enterocolitica* is a well-known human pathogen but rarely causes disease in animals; on the contrary, *Y. pseudotuberculosis* is a well-known animal pathogen that very infrequently causes disease in humans. Both of the *Yersinia* species are nonlactose-fermenting, pleomorphic Gram-negative rods that are urease positive and oxidase negative. They grow best at 25°C and are motile at 25°C but nonmotile at 37°C. They are found in the intestinal tracts of a variety of animals, in which they may cause disease, and are transmissible to humans, in whom they can produce a variety of clinical syndromes.

Y. enterocolitica exists in more than 70 serotypes; most isolates from human disease belong to serotypes O:3, O:8, and O:9. There are striking geographic differences in the distribution of *Y. enterocolitica* serotypes. *Y. enterocolitica* can produce a heat-stable enterotoxin, but the role of this toxin in diarrhea associated with infection is not well defined.

Y. enterocolitica has been isolated from rodents and domestic animals (eg, sheep, cattle, swine, dogs, and cats) and waters contaminated by them. Transmission to humans probably occurs by contamination of food, drink, or fomites. Person-to-person transmission with this organism is probably rare.

Y. pseudotuberculosis is commonly found in water and soil, as well as in various domesticated and wild animals. The organism is less frequently isolated in the United States, but is more commonly found in northern Europe and Asia. Rodents, rabbits, and wild birds are the main natural reservoir for *Y. pseudotuberculosis*, and humans usually acquire the infection via contaminated food and water.

Pathogenesis and Clinical Findings

An inoculum of 10^8 – 10^9 yersiniae must enter the alimentary tract to produce infection. During the incubation period of 4–7 days, yersiniae multiply in the gut mucosa, particularly the ileum. This leads to inflammation and ulceration, and leukocytes appear in feces. The process may extend to mesenteric lymph nodes and, rarely, to bacteremia.

Y. enterocolitica typically causes enterocolitis and early symptoms include fever, abdominal pain, and diarrhea. Diarrhea ranges from watery to bloody and may be caused by an enterotoxin or due to invasion of the mucosa. Some patients may present with a mesenteric adenitis or terminal ileitis, and at times, the abdominal pain can be severe and located in the right lower quadrant, clinically suggesting appendicitis. One to 2 weeks after onset of diarrhea, some patients with histocompatibility antigen HLA-B 27 may develop arthralgia, arthritis, and erythema nodosum, suggesting an immunologic reaction to the infection. Other, rarer immunologic complications include ankylosing spondylitis and acute reactive arthritis (formerly known as Reiter's syndrome, with arthritis, urethritis, and conjunctivitis). Very rarely, *Y. enterocolitica* infection produces pneumonia, meningitis, or sepsis; in most cases, the majority of gastrointestinal infections are self-limited.

Y. enterocolitica has also been associated with transfusion-related infections caused by contaminated red blood cells. This is a consequence of the ability of the organism, transmitted by an asymptomatic donor, to multiply at refrigeration temperatures.

Y. pseudotuberculosis usually affects children and young adults and presents clinically as mesenteric adenitis, an acute appendicitis-like syndrome. When an exploratory laparotomy or appendectomy are performed, the appendix has usually a normal appearance, but enlarged mesenteric lymph nodes and an inflammation of the terminal ileum can often be appreciated. The infection is usually self-limited, and antibiotic therapy is probably not necessary for patients with mesenteric adenitis.

Diagnostic Laboratory Tests

A. Specimens

Specimens may be stool, blood, or material obtained at surgical exploration. Stained smears are not contributory.

B. Culture

The number of yersiniae in stool may be small and can be increased by "cold enrichment": a small amount of feces or a rectal swab is placed in buffered saline with a pH of 7.6 and kept at 4°C for 2–4 weeks; many fecal organisms do not survive, but *Y. enterocolitica* multiplies. Subcultures made at intervals on MacConkey agar may yield yersiniae. Alternatively, most clinical laboratories use a *Yersinia*-selective agar such as cefsulodin-irgasan-novobiocin (CIN) agar incubated at room temperature for several days. *Y. enterocolitica* colonies have a bull's eye appearance with a red center on CIN agar. *Y. pseudotuberculosis* can be differentiated from other non-pestis *Yersinia* species by various biochemical test characteristics.

C. Serology

In paired serum specimens taken 2 or more weeks apart, a rise in agglutinating antibodies can be shown; however, cross-reactions between yersiniae and other organisms (vibrios, salmonellae, and brucellae) may confuse the results.

Treatment

Infections due to *Y. enterocolitica* or *Y. pseudotuberculosis* cause a mild diarrhea that is usually self-limited, and the possible benefits of antimicrobial therapy are unknown. *Y. enterocolitica* is generally susceptible to aminoglycosides, chloramphenicol, tetracycline, trimethoprim-sulfamethoxazole, piperacillin, third-generation cephalosporins, and fluoroquinolones; it is typically resistant to ampicillin and to first-generation cephalosporins. *Y. pseudotuberculosis* is usually susceptible to ampicillin, tetracycline, chloramphenicol, cephalosporins, and aminoglycosides. Sepsis and meningitis due to *Y. enterocolitica* and also *Y. pseudotuberculosis* carry a high mortality rate, but deaths occur mainly in immunocompromised patients. Sepsis due to non-pestis *Yersinia* species can be successfully treated with third-generation cephalosporins (possibly in combination with an aminoglycoside) or a fluoroquinolone (possibly in combination with another anti-microbial); however, sepsis due to *Y. pseudotuberculosis* has a high mortality rate even when appropriate antibiotic therapy is given. In cases in which clinical manifestations strongly point to either appendicitis or mesenteric adenitis, surgical exploration has been the rule unless several simultaneous cases indicate that *Yersinia* infection is likely.

Prevention and Control

Contact with farm and domestic animals, their feces, or materials contaminated by them probably accounts for most human infections. Contaminated meat (especially pork and pork

products) and occasionally dairy products have been indicated as sources of infections, and group outbreaks have frequently been traced to contaminated food or drink. Conventional sanitary precautions are probably helpful, and consumption of raw or undercooked meats should be avoided. In addition, public health measures focusing on safe food handling and processing practices can be helpful to decrease the risk of contamination of food and dairy products. In blood banks and blood donor centers, volunteers are asked about recent fever, abdominal pain, or diarrhea prior to blood donation, in order to decrease the risk of collecting potentially contaminated blood products.

PASTEURELLA MULTOCIDA

Pasteurellae are nonmotile, Gram-negative coccobacilli with a bipolar appearance on stained smears. They are aerobes or facultative anaerobes that grow readily on ordinary bacteriologic media at 37°C. They are all oxidase positive and catalase positive but diverge in other biochemical reactions.

P. multocida occurs worldwide in the respiratory and gastrointestinal tracts of many domestic and wild animals. It is perhaps the most common organism in human wounds inflicted by bites from cats and dogs. It is one of the common causes of hemorrhagic septicemia in a variety of animals, including rabbits, rats, horses, sheep, fowl, cats, and swine. It can also produce human infections in many systems and may at times be part of normal human microbiota.

Clinical Findings

The most common presentation is a history of animal bite followed within hours by an acute onset of redness, swelling, and pain. Regional lymphadenopathy is variable, and fever is often low grade. *Pasteurella* infections sometimes present as bacteremia or chronic respiratory infection without an evident connection with animals.

P. multocida is susceptible to most antibiotics. Penicillin G is considered the drug of choice for *P. multocida* infections resulting from animal bites. Tetracyclines and fluoroquinolones are alternative drugs.

CHAPTER SUMMARY

- *Yersinia* species are zoonotic pathogens that cause disease in humans ranging from mild gastrointestinal infections to serious diseases with high mortality such as plague.
- *Y. pestis* is transmitted to humans usually through the bite of an infected flea, although inhalation is another potential route. *Y. pestis* possesses virulence factors transmitted by plasmids that allow it to survive in the gut of the flea and that contribute to severe clinical manifestations in humans.
- A bubo (an enlarged suppurative lymph node) forms close to the bite wound accompanied by fever and is the most common form of plague. From the localized lesion, the infection may disseminate causing the septicemic form of the disease.

- Treatment consists of supportive care and antibiotic treatment with streptomycin, gentamicin, doxycycline, or a fluoroquinolone antibiotic.
- *Y. enterocolitica* causes gastroenteritis or mesenteric lymphadenitis after ingestion of contaminated food or water.
- *Y. enterocolitica* can be recovered from the stool of infected patients using selective media called CIN agar incubated at room temperature.
- Treatment for gastroenteritis caused by *Y. enterocolitica* consists of trimethoprim–sulfamethoxazole, doxycycline, or a fluoroquinolone antibiotic.
- *Pasteurella multocida* occurs worldwide in the respiratory and gastrointestinal tracts of many domestic and wild animals.
- In humans, *P. multocida* typically causes wound infections and associated lymphadenopathy following animal bites, specifically cat and dog bites.
- *P. multocida* is nonmotile, Gram-negative with bipolar staining pattern, with a coccobacillary appearance. It grows readily on ordinary bacteriologic media at 37°C and is oxidase and catalase positive.
- *P. multocida* is susceptible to most antibiotics; Penicillin G is considered the drug of choice.

REVIEW QUESTIONS

1. An 18-year-old male resident of Arizona came to the emergency department (ED) complaining of fever, pain in his left groin, and diarrhea for the past 2 days. On examination, he was afebrile, had a pulse rate of 126 beats/min, a respiratory rate of 20 breaths/min, and a blood pressure of 130/80 mm Hg. Left groin swelling and tenderness were noted. A groin muscle strain was diagnosed, attributed to a fall 2 days earlier. He was treated with nonsteroidal anti-inflammatory drugs and released. The next day, the patient reported feeling weak, had difficulty breathing, and collapsed while taking a shower. He was transported to a hospital ED and pronounced dead shortly after arrival. Cultures of blood samples obtained in the ED were positive for *Y. pestis*. An epidemiologic investigation indicated that the patient most likely became infected as a result of bites by *Y. pestis*-infected fleas while walking through a prairie dog colony (see Chapter 48). Which of the following statements about the pathogenesis of plague is correct?
 - (A) *Y. pestis* produces a coagulase when incubated at 28°C.
 - (B) There is no risk for pneumonia caused by person-to-person transmission of *Y. pestis*.
 - (C) *Y. pestis* organisms multiply in polymorphonuclear cells.
 - (D) After the bite of an infected flea, *Y. pestis* infection seldom, if ever, disseminates beyond the site of the flea bite and the regional lymph nodes.
 - (E) *Y. pestis* is transmitted to animals (and humans) in flea feces excreted when the flea is feeding.
2. The drug of choice to treat the patient in Question 1 would have been
 - (A) Ampicillin
 - (B) Cefotaxime
 - (C) Levofloxacin
 - (D) Erythromycin
 - (E) Streptomycin

3. *Y. pestis* entered North America through San Francisco in the 1890s, carried by rats on ships that had sailed from Hong Kong, where a plague epidemic occurred. The current reservoir for *Y. pestis* in the United States is/are
 - (A) Urban feral cats
 - (B) Urban rats
 - (C) Domestic cows
 - (D) Coyotes
 - (E) Rural wild rodents
4. Which of the following is generally *not* considered a potential agent of bioterrorism and biologic warfare?
 - (A) *Y. pestis*
 - (B) Botulinum toxin
 - (C) *Streptococcus pyogenes*
 - (D) *Brucella* species
 - (E) *Bacillus anthracis*
5. An 8-year-old boy was bitten by a stray cat. Two days later, the wound was red and swollen and drained purulent fluid. *P. multocida* was cultured from the wound. The drug of choice to treat this infection is
 - (A) Amikacin
 - (B) Erythromycin
 - (C) Gentamicin
 - (D) Penicillin G
 - (E) Clindamycin
6. Intimate contacts of patients with suspected plague pneumonia should receive which of the following agents as chemoprophylaxis?
 - (A) Gentamicin
 - (B) Cefazolin
 - (C) Rifampin
 - (D) Penicillin
 - (E) Doxycycline
7. In a patient who has the bubonic form of plague, all of the following specimens are acceptable for diagnosis *except*
 - (A) Stool culture on hektoen enteric agar
 - (B) Blood culture using routine laboratory media
 - (C) Culture of a lymph node aspirate on blood and MacConkey agars
 - (D) Acute and convalescent serology
 - (E) Immunohistochemical staining of lymph node tissue
8. All of the following statements regarding the pFra/pMT plasmid of *Y. pestis* are true *except*
 - (A) It encodes the capsular protein (fraction FI) that confers antiphagocytic properties.
 - (B) It contains genes that yield plasminogen-activating protease that has temperature-dependent coagulase activity.
 - (C) It contains genes that encode phospholipase D, which is required for organism survival in the flea midgut.
 - (D) It is unique to *Y. pestis*.
 - (E) It encodes factors that are important for survival in both the flea and the human.
9. All of the following statements regarding the epidemiology of infections caused by *Y. enterocolitica* are correct *except*
 - (A) Most human infections are caused by serotype O:1.
 - (B) Humans acquire the infection from ingestion of food or drinks contaminated by animals or animal products.
 - (C) Person-to-person spread is quite common.
 - (D) A large inoculum is required to cause infection.
 - (E) Infection is more prevalent in persons with histocompatibility antigen HLA-B27.
10. Optimum recovery of *Y. enterocolitica* from the stools of patients with gastroenteritis requires which of the following specialized media?
 - (A) Cefsulodin-irgasan-novobiocin agar
 - (B) Xylose-lysine decarboxylase agar
 - (C) Hektoen-enteric agar
 - (D) Regan-Lowe medium
 - (E) MacConkey agar
11. An organism suspected of being *Y. pestis* is recovered from a patient with sepsis. The isolate has bipolar staining and is catalase positive but is oxidase and urease negative and is nonmotile. At this point, what should be done?
 - (A) Nothing; the laboratory has confirmed the diagnosis.
 - (B) Inoculate the isolate to an identification kit or automated system for confirmation.
 - (C) Call the police because there is a possible bioterrorism event.
 - (D) Send the isolate to the nearest public health laboratory for confirmation.
 - (E) Send the isolate to the hospital across town for sequencing.

The Neisseriae

The family Neisseriaceae includes the genera *Neisseria*, *Kingella*, *Eikenella*, and 32 other genera. The *Neisseria* species are Gram-negative cocci that usually occur in pairs (diplococci). *Neisseria gonorrhoeae* (gonococci) and *Neisseria meningitidis* (meningococci) are exclusively pathogenic for humans and typically are found associated with or inside polymorphonuclear cells (PMNs). Many other *Neisseria* species are normal inhabitants of the human respiratory tract, rarely if ever cause disease, and occur extracellularly. Members of the group are listed in Table 20-1.

Gonococci and meningococci are closely related, with 70% DNA homology, and are differentiated by a few laboratory tests and specific characteristics. Meningococci have polysaccharide capsules but gonococci do not, and meningococci rarely have plasmids but most gonococci do. Most importantly, the two species are differentiated by the usual clinical presentations of the diseases they cause: Meningococci typically are found in the upper respiratory tract and cause meningitis, but gonococci cause genital infections. However, the clinical spectra of the diseases caused by gonococci and meningococci do overlap.

Morphology and Identification

A. Typical Organisms

The typical *Neisseria* is an aerobic, Gram-negative, nonmotile diplococcus, approximately 0.8 μm in diameter (Figures 20-1 and 20-2). Individual cocci are kidney bean shaped; when the organisms occur in pairs, the flat or concave sides are adjacent.

B. Culture

The various pathogenic and nonpathogenic *Neisseria* species can be differentiated by their ability to grow on sheep blood agar, chocolate agar, and selective agar media (eg, modified Thayer-Martin agar, Martin-Lewis agar, GC-Lect agar, and New York City medium; see also Table 20-1). While *N. meningitidis* grows on sheep blood agar as well as selective media, *N. gonorrhoeae* requires enriched chocolate agar and/or selective media for optimal growth. Because chocolate agar supports the growth of other commensal bacteria, cultivation of *N. gonorrhoeae* from mucosal and otherwise nonsterile body sites requires the use of selective media

(eg, Thayer-Martin agar, etc). The selective media contain vancomycin (suppression of Gram-positive bacteria), colistin (suppression of Gram-negative bacteria), and other inhibitory substances to suppress the growth of many of the commensal microorganisms from these clinical sites. *N. gonorrhoeae*, *N. meningitidis*, and *N. lactamica* are colistin-resistant, and are therefore able to grow on these selective media. When grown on suitable agar media, gonococci and meningococci form convex, glistening, elevated, mucoid colonies 1–5 mm in diameter. Colonies are transparent or opaque, nonpigmented, and nonhemolytic. *Neisseria flavescens*, *Neisseria cinerea*, *Neisseria subflava*, and *Neisseria lactamica* may have yellow pigmentation. *Neisseria sicca* produces opaque, brittle, wrinkled colonies. *Moraxella catarrhalis* produces nonpigmented or pinkish gray opaque colonies.

C. Growth Characteristics

The neisseriae grow best under aerobic conditions; however, some *Neisseria* species (eg, *N. gonorrhoeae*) are capable of growing under anaerobic conditions as well. The neisseriae produce acid but not gas by oxidation of various carbohydrates (not by fermentation!); the oxidase test is hence a key test for identifying neisseriae. When organisms are spotted on a filter paper soaked with tetramethyl-*p*-phenylenediamine hydrochloride (oxidase), the neisseriae rapidly turn dark purple. Furthermore, all *Neisseria* species, with the exception of *N. elongata*, are catalase positive. The patterns by which the different *Neisseria* species oxidize carbohydrates are a useful means of distinguishing them (see Table 20-1).

While most *Neisseria* species are not nutritionally demanding, meningococci and gonococci grow best on media containing complex organic substances, such as heated blood, hemin, and animal proteins, and in an atmosphere containing 5% CO_2 . These two organisms are also rapidly killed by drying, prolonged exposure to sunlight, moist heat, and many disinfectants. They produce autolytic enzymes that result in rapid swelling and lysis in vitro at 25°C and at an alkaline pH.

NEISSERIA GONORRHOEAE

Gonococci oxidize only glucose and differ antigenically from the other neisseriae. Gonococci usually produce smaller

colonies than those of the other neisseriae. Gonococci that require arginine, hypoxanthine, and uracil (Arg[–], Hyx[–], and Ura[–] auxotype) tend to grow most slowly on primary culture. Gonococci isolated from clinical specimens or maintained

by selective subculture have typical small colonies containing piliated bacteria. On nonselective subculture agar media, larger colonies containing nonpiliated gonococci are also formed. Opaque and transparent variants of both the small and large colony types also occur; the opaque colonies are associated with the presence of a surface-exposed protein, Opa.

Antigenic Structure

N. gonorrhoeae is antigenically heterogeneous and capable of changing its surface structures in vitro—and presumably in vivo—to avoid host defenses. Surface structures include the following.

FIGURE 20-1 Gram-stain of a urethral exudate of a patient with gonorrhea. Nuclei of many polymorphonuclear cells are seen (large arrows). Intracellular Gram-negative diplococci (*N. gonorrhoeae*) in one polymorphonuclear cell are marked by the small arrow.

FIGURE 20-2 Collage and drawing of *N. gonorrhoeae* showing pili and the three layers of the cell envelop.

A. Pili (Fimbriae)

Pili are the hairlike appendages that extend up to several micrometers from the gonococcal surface. They enhance attachment to host cells and resistance to phagocytosis. They are made up of stacked pilin proteins (molecular weight [MW], 17–21 kDa). The amino terminal of the pilin molecule, which contains a high percentage of hydrophobic amino acids, is conserved. The amino acid sequence near the midportion of the molecule also is conserved; this portion of the molecule serves in attachment to host cells and is less prominent in the immune response. The amino acid sequence near the carboxyl terminal is highly variable; this portion of the molecule is most prominent in the immune response. The pilins of almost all strains of *N. gonorrhoeae* are antigenically different, and a single strain can make many antigenically distinct forms of pilin.

B. Por

Por protein extends through the gonococcal cell membrane. It forms pores in the surface through which some nutrients enter the cell. Por proteins may impact intracellular killing of gonococci within neutrophils by preventing phagosome–lysosome fusion. In addition, variable resistance of gonococci to killing by normal human serum depends on whether Por protein selectively binds to complement components C3b and C4b. The MW of Por varies from 32 to 36 kDa. Each strain of gonococcus expresses only one of two types of Por, but the Por of different strains is antigenically different. Serologic typing of Por by agglutination reactions with monoclonal antibodies was a useful method for studying the epidemiology of *N. gonorrhoeae*. However, this method has been replaced by genotypic methods such as pulsed-field gel electrophoresis, Opa typing, and DNA sequencing.

C. Opa Proteins

These proteins function in adhesion of gonococci within colonies and in attachment of gonococci to host cell receptors such as heparin-related compounds and CD66 or carcinoembryonic antigen-related cell adhesion molecules. One portion of the Opa molecule is in the gonococcal outer membrane, and the rest is exposed on the surface. The MW of Opa ranges from 20 to 28 kDa. A strain of gonococcus can express no, one, two, or occasionally three types of Opa, but each strain has 11–12 genes for different Opas. PCR of the *opa* genes followed by restriction endonuclease digestion, and analysis of subsequent fragments by gel electrophoresis is a useful method of strain typing performed by reference laboratories.

D. Rmp (Protein III)

This protein (MW, 30–31 kDa) is antigenically conserved in all gonococci. It is a reduction-modifiable protein (Rmp) and changes its apparent MW when in a reduced state. It associates with Por in the formation of pores in the cell surface.

E. Lipooligosaccharide

In contrast to the enteric Gram-negative rods (see Chapters 2 and 15), gonococcal lipopolysaccharide (LPS) does not have long O-antigen side chains and is called a lipooligosaccharide (LOS). Its MW is 3–7 kDa. Gonococci can express more than one antigenically different LOS chain simultaneously. Toxicity in gonococcal infections is largely attributable to the endotoxic effects of LOS. Specifically, in the fallopian tube explant model, LOS causes ciliary loss and mucosal cell death.

In a form of molecular mimicry, gonococci make LOS molecules that structurally resemble human cell membrane glycosphingolipids. A structure is depicted in Figure 20-3. The gonococcal LOS and the human glycosphingolipid of the same structural class react with the same monoclonal antibody, indicating the molecular mimicry. The presence on the gonococcal surface of the same surface structures as human cells helps gonococci evade immune recognition.

The terminal galactose of human glycosphingolipids is often conjugated with sialic acid. Sialic acid is a nine-carbon, 5-*N*-acetylated ketulosonic acid also called *N*-acetylneuraminic acid (NANA). Gonococci do not make sialic acid but do make a sialyltransferase that functions to take NANA from the human nucleotide sugar cytidine-5'-monophospho-*N*-acetylneuraminic acid (CMPNANA) and place the NANA on the terminal galactose of a gonococcal acceptor LOS. This sialylation affects the pathogenesis of gonococcal infection. It makes the gonococci resistant to killing by the human antibody–complement system and interferes with gonococcal binding to receptors on phagocytic cells.

N. meningitidis and *Haemophilus influenzae* make many but not all of the same LOS structures as *N. gonorrhoeae*. The biology of the LOS for the three species and for some of the nonpathogenic *Neisseria* species is similar. Four of the various serogroups of *N. meningitidis* make different sialic acid capsules (see later discussion), indicating that they also have biosynthetic pathways different from those of gonococci. These four serogroups sialylate their LOS using sialic acid from their endogenous pools.

F. Other Proteins

Several antigenically constant proteins of gonococci have poorly defined roles in pathogenesis. **Lip (H8)** is a surface-exposed protein that is heat modifiable like Opa. The **Fbp (ferric-binding protein)**, similar in MW to Por, is expressed when the available iron supply is limited, such as in human infection. Gonococci elaborate an **IgA1 protease** that splits and inactivates IgA1, a major mucosal immunoglobulin of humans. *N. meningitidis*, *H. influenzae*, and *Streptococcus pneumoniae* elaborate similar IgA1 proteases.

Genetics and Antigenic Heterogeneity

Gonococci have evolved mechanisms for frequently switching from one antigenic form (pilin, Opa, or LPS) to another antigenic form of the same molecule. This switching takes

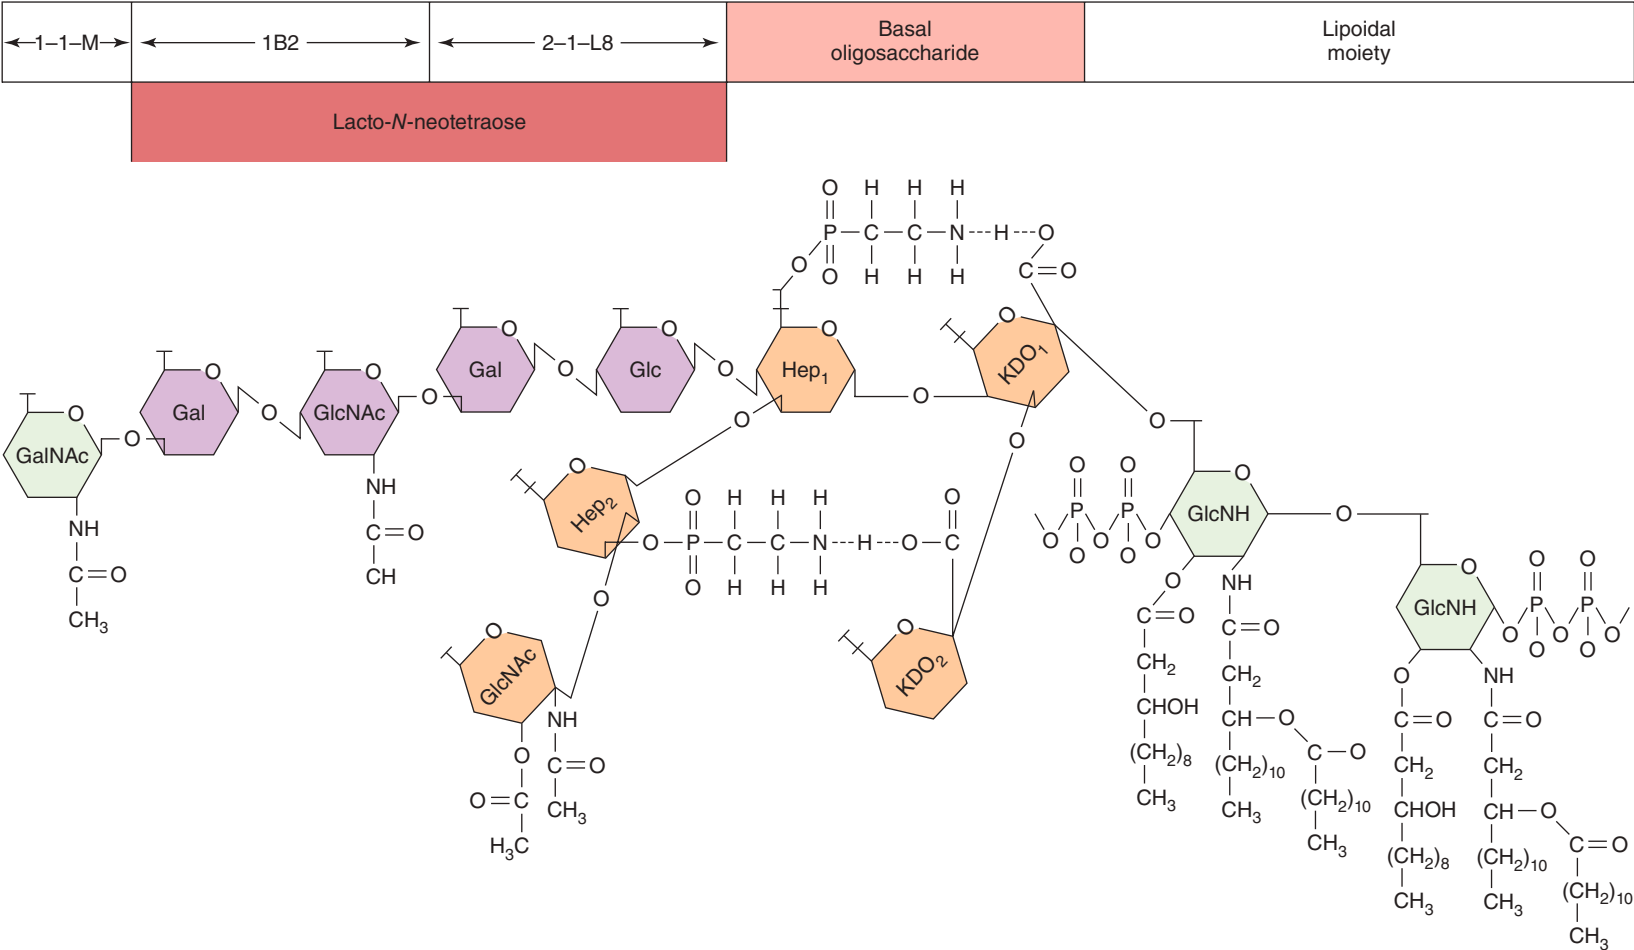

FIGURE 20-3 Structure of gonococcal lipooligosaccharide, which has lacto-*N*-neotetraose and a terminal galactosamine in a structure similar to the human ganglioside glycosphingolipid series. The basal oligosaccharide is in *light red*, and the lacto-*N*-neotetraose is in *dark red*. (Courtesy of JM Griffiss.)

place in one in every $10^{2.5}$ – 10^3 gonococci, an extremely rapid rate of change for bacteria. Because pilin, Opa, and LPS are surface-exposed antigens on gonococci, they are important in the immune response to infection. The molecules' rapid switching from one antigenic form to another helps the gonococci elude the host immune system.

The switching mechanism for pilin, which has been the most thoroughly studied, is different from the mechanism for Opa.

Gonococci have multiple genes that code for pilin, but only one gene is inserted into the expression site. Gonococci can remove all or part of this pilin gene and replace it with all or part of another pilin gene. This mechanism allows gonococci to express many antigenically different pilin molecules over time.

The switching mechanism of Opa involves, at least in part, the addition or removal from the DNA of one or more of the pentameric coding repeats preceding the sequence that codes for the structural Opa gene. The switching mechanism of LPS is unknown.

Gonococci contain several plasmids; 95% of strains have a small, "cryptic" plasmid (MW, 2.6 mDa) of unknown function. Two other plasmids (MW, 3.4 and 4.7 mDa) contain genes that code for TEM-1 type (penicillinases) β -lactamases, which cause resistance to penicillin. These plasmids are transmissible by conjugation among gonococci; they are similar to a plasmid found in penicillinase-producing *Haemophilus* species and may have been acquired from *Haemophilus* or other Gram-negative organisms. About 5–20% of gonococci contain a plasmid (MW, 24.5×10^6 kDa) with the genes that code for conjugation; the incidence is highest in geographic areas where penicillinase-producing gonococci are most common. High-level tetracycline resistance (minimum inhibitory concentrations [MICs] ≥ 16 mg/L) has developed in gonococci by the insertion of a streptococcal gene *tetM* coding for tetracycline resistance into the conjugative plasmid.

Pathogenesis, Pathology, and Clinical Findings

Gonococci exhibit several morphologic types of colonies (see earlier discussion), but only piliated bacteria appear to be virulent. Opa protein expression varies depending on the type of infection. Gonococci that form opaque colonies are isolated from men with symptomatic urethritis and from uterine cervical cultures at midcycle. Gonococci that form transparent colonies are frequently isolated from men with asymptomatic urethral infection, from menstruating women, and from patients with invasive forms of gonorrhea, including salpingitis and disseminated infection. Antigenic variation of surface proteins during infection allows the organism to circumvent host immune response.

Gonococci attack mucous membranes of the genitourinary tract, eye, rectum, and throat, producing acute suppurative that may lead to tissue invasion; this is followed

by chronic inflammation and fibrosis. Men usually have urethritis, with yellow, creamy pus and painful urination. The process may extend to the epididymis. As suppuration subsides in untreated infection, fibrosis occurs, sometimes leading to urethral strictures. Urethral infection in men can be asymptomatic. In women, the primary infection is in the endocervix and extends to the urethra and vagina, giving rise to mucopurulent discharge. It may then progress to the uterine tubes, causing salpingitis, fibrosis, and obliteration of the tubes. Infertility occurs in 20% of women with gonococcal salpingitis. Chronic gonococcal cervicitis and proctitis are often asymptomatic.

Gonococcal bacteremia leads to skin lesions (especially hemorrhagic papules and pustules) on the hands, forearms, feet, and legs and to tenosynovitis and suppurative arthritis, usually of the knees, ankles, and wrists. Gonococci can be cultured from blood or joint fluid of only 30% of patients with gonococcal arthritis. Gonococcal endocarditis is an uncommon but severe infection. Gonococci sometimes cause meningitis and eye infections in adults; these have manifestations similar to those caused by meningococci. Complement deficiency is frequently found in patients with gonococcal bacteremia. Patients with bacteremia, especially if recurrent, should be tested for total hemolytic complement activity.

Gonococcal ophthalmia neonatorum, an infection of the eye in newborns, is acquired during passage through an infected birth canal. The initial conjunctivitis rapidly progresses and, if untreated, results in blindness. To prevent gonococcal ophthalmia neonatorum, instillation of erythromycin ointment into the conjunctival sac of newborns is compulsory in the United States.

Gonococci that produce localized infection are often serum sensitive (ie, killed by antibody and complement).

Diagnostic Laboratory Tests

A. Specimens

Pus and secretions are taken from the urethra, cervix, rectum, conjunctiva, throat, or synovial fluid for culture and smear. Blood culture is necessary in systemic illness, but a special culture system is helpful because gonococci (and meningococci) may be susceptible to the polyanethol sulfonate present in standard blood culture media. Proprietary swabs may be required for diagnostic molecular assays. Clinicians should check with clinical laboratories regarding the appropriate collection devices for the assays used in a particular institution.

B. Smears

Gram-stained smears of urethral or endocervical exudates typically reveal many diplococci within PMNs, therefore providing a presumptive diagnosis. Stained smears of the urethral exudate from men have a sensitivity of about 90% and a specificity of 99%. Stained smears of endocervical exudates have a sensitivity of about 50% and a specificity of about 95%

when examined by an experienced microscopist. Additional diagnostic testing of urethral exudates from men may not be necessary when the Gram-stain result is positive; however, nucleic acid amplification tests (NAATs) or cultures should be done for women. Stained smears of conjunctival exudates can also be of diagnostic value; however, Gram-stains of specimens from the throat or rectum are generally not helpful for the identification of pathogenic *Neisseria* species, considering that these sites are frequently colonized by commensal, nonpathogenic neisseriae.

C. Culture

Immediately after collection, pus or mucus is streaked on enriched selective medium (eg, modified Thayer-Martin medium [MTM]) and incubated in an atmosphere containing 5% CO₂ at 37°C. To avoid overgrowth by contaminants, selective media contain antimicrobial drugs (eg, vancomycin, colistin, nystatin, and trimethoprim). If immediate incubation is not possible, the specimen should be placed in a CO₂-containing transport-culture system. Forty-eight hours after culture, identified presumptive identification can be achieved by the organisms' appearance on a Gram-stained smear and by a positive oxidase test. The definitive species level of the subcultured bacteria may be determined by their ability to produce acid from certain carbohydrates by oxidation; the only carbohydrate used by *N. gonorrhoeae* is glucose (see Table 20-1). Other laboratory tests for definitive identification of *N. gonorrhoeae* include chromogenic enzyme substrate tests and immunologic test methods (eg, coagglutination assays). Matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF MS) has potential to provide rapid (same-day) identification of cultured isolates. The gonococcal isolates from anatomic sites other than the genital tract or from children should be identified as to species level, using two different confirmatory tests because of the legal and social implications of a positive culture result. Most laboratories have abandoned culture in favor of NAATs. Because of this change in preferred diagnostic methodology, it may be difficult to routinely monitor for increasing multidrug resistance in *N. gonorrhoeae* (see discussion below). Culture should be considered in a patient who appears to have failed initial standard treatment for the infection.

D. Nucleic Acid Amplification Tests

Several Food and Drug Administration–cleared nucleic acid amplification assays are available for direct detection of *N. gonorrhoeae* in genitourinary specimens, and these are the preferred tests from these sources. In general, these assays have excellent sensitivity and specificity in symptomatic, high-prevalence populations. Advantages include better detection, more rapid results, and the ability to use urine as a specimen source. Disadvantages include poor specificity of some assays because of cross-reactivity with nongonococcal *Neisseria* species. Some of these assays are not approved for use in the diagnosis of extragenital gonococcal infections or

for infection in children. NAATs are not recommended as tests of cure because nucleic acid may persist in patient specimens for up to 3 weeks after successful treatment. Patients who are believed to have failed treatment are best reevaluated using culture so that the organism can be tested for antimicrobial resistance (see discussion below under Treatment).

E. Serology

Serum and genital fluid contain IgG and IgA antibodies against gonococcal pili, outer membrane proteins, and LPS. Some IgM of human sera is bactericidal for gonococci in vitro.

In infected individuals, antibodies to gonococcal pili and outer membrane proteins can be detected by immunoblotting, radioimmunoassay, and enzyme-linked immunosorbent assay (ELISA) tests. However, these tests are not useful as diagnostic aids for several reasons, including gonococcal antigenic heterogeneity, the delay in development of antibodies in acute infection, and a high background level of antibodies in the sexually active population.

Immunity

Repeated gonococcal infections are common. Protective immunity to reinfection does not appear to develop as part of the disease process, because of the antigenic variety of gonococci. Although antibodies can be demonstrated, including the IgA and IgG on mucosal surfaces, they either are highly strain specific or have little protective ability.

Treatment

Since the development and widespread use of penicillin, gonococcal resistance to penicillin has gradually risen, owing to the selection of chromosomal mutants and to increased prevalence of penicillinase-producing *N. gonorrhoeae* (PPNG) (see earlier discussion). Since 1989, the Centers for Disease Control and Prevention (CDC) no longer recommends penicillin for treatment of gonococcal infections. Tetracyclines were discovered in the 1940s and initially used as an alternate treatment for gonorrhea, particularly in patients who were allergic to penicillin. However, the tetracycline MICs increased over time, and chromosomally mediated resistance to tetracycline (MIC ≥ 2 µg/mL) is now very common. In addition, high-level, plasmid-mediated resistance to tetracycline (MIC ≥ 32 µg/mL) also occurs. Spectinomycin resistance as well as resistance to fluoroquinolones has been noted. Single-dose fluoroquinolone treatment was recommended for treatment of gonococcal infections from 1993 until 2006. During the 2000s, the prevalence of fluoroquinolone-resistant *N. gonorrhoeae* increased steadily, with close to 20% of isolates tested in the CDC's Gonococcal Isolate Surveillance Project (GISP) in 2014 being resistant; resistance rates in isolates from men who have sex with men (MSM) were found to be as high as

30%. Since 2007, the CDC no longer recommends to use of fluoroquinolones for treatment of gonorrhea. Fluoroquinolones act by inhibition of the organism's DNA gyrase and topoisomerase IV. Resistance is due to mutations in the *gyrA* and *gyrB* genes, resulting in decreased binding affinity of the DNA gyrase to fluoroquinolones. Spectinomycin was used initially as an alternate treatment for PPNG; however, after the emergence of high-level and low-level resistance, spectinomycin was ultimately abandoned in the late 1980s as a monotherapy against *N. gonorrhoeae*. Since 2005, spectinomycin is no longer available in the United States for treatment of gonorrhea. Because of these problems with antimicrobial resistance in *N. gonorrhoeae*, the CDC recommended that patients with uncomplicated genital or rectal infections be treated with ceftriaxone (250 mg) given intramuscularly as a single dose, and azithromycin (1 g) given orally as a single dose, both drugs administered together on the same day. Based on the experience with other bacteria that developed antimicrobial resistance, the CDC's recommendations for dual antimicrobial therapy are based on the theoretical concept, that such approach will likely improve treatment efficacy and perhaps slow the emergence of antimicrobial resistance. In addition, people infected with *N. gonorrhoeae* are frequently coinfecting with *Chlamydia trachomatis*, and the dual therapy regimen is effective in treating the chlamydial coinfection at the same time. In the case of an azithromycin allergy, the patient may be treated with doxycycline (100 mg orally, twice daily for 7 days) as an alternative to azithromycin. However, because of the higher rates of resistance to tetracyclines in *N. gonorrhoeae*, the use of azithromycin as a secondary drug to a cephalosporin is preferred. A 400 mg single dose of cefixime given orally together with azithromycin (1 g, orally, single dose) can also be administered as an alternative regimen; however, Unfortunately, new data from the CDC's GISP have noted an increase in the percentage of isolates exhibiting elevated MICs to both oral cefixime and ceftriaxone. This observation, combined with reports of cefixime treatment failures in other countries, has resulted in revised treatment guidelines. Since ceftriaxone is more potent than cefixime, the CDC no longer recommends cefixime as an effective treatment. Injectable ceftriaxone 250 mg IM once plus either azithromycin or doxycycline as written above is recommended for treatment of uncomplicated urethritis, cervicitis, and proctitis. While azithromycin has been found to be safe and effective in pregnant women, doxycycline is contraindicated. Modifications of this basic treatment regimen are recommended for treatment of other types of *N. gonorrhoeae* infection. These modified treatment regimens for *N. gonorrhoeae* infections of other body sites or for disseminated gonococcal infections are available at the CDC's website and the 2015 Sexually Transmitted Diseases Treatment Guidelines (<https://www.cdc.gov/std/tg2015/tg-2015-print.pdf>).

Because other sexually transmitted diseases may have been acquired at the same time as gonorrhea, steps must also

be taken to diagnose and treat these diseases (see discussions of chlamydiae, syphilis).

Epidemiology, Prevention, and Control

Gonorrhea is worldwide in distribution. In the United States, gonorrhea is a nationally notifiable disease; its incidence rose steadily from 1955 until the late 1970s, when the incidence was between 400 and 500 cases per 100,000 population. Between 1975 and 1997, there was a 74% decline in the rate of reported gonococcal infections. Thereafter, the rates plateaued for 10 years and decreased from 2006 to 2009, but since 2009 rates have once again increased slightly each year. Gonorrhea is exclusively transmitted by sexual contact, often by women and men with asymptomatic infections. The infectivity of the organism is such that the chance of acquiring infection from a single exposure to an infected sexual partner is 20–30% for men and even greater for women. The infection rate can be reduced by avoiding multiple sexual partners, rapidly eradicating gonococci from infected individuals by means of early diagnosis and treatment, and finding cases and contacts through education and screening of populations at high risk. Mechanical prophylaxis (condoms) provides partial protection. Chemoprophylaxis is of limited value because of the rise in antibiotic resistance of the gonococcus.

Gonococcal ophthalmia neonatorum is prevented by local application of 0.5% erythromycin ophthalmic ointment or 1% tetracycline ointment to the conjunctiva of newborns. Although instillation of silver nitrate solution is also effective and is the classic method for preventing ophthalmia neonatorum, silver nitrate is difficult to store and causes conjunctival irritation; its use has largely been replaced by use of erythromycin or tetracycline ointment.

NEISSERIA MENINGITIDIS

Antigenic Structure

At least 13 serogroups of meningococci have been identified by immunologic specificity of capsular polysaccharides. The six most important serogroups associated with disease in humans, worldwide, are A, B, C, X, Y, and W-135. In contrast to the other capsular serogroups in which the capsule is composed of sialic acid moieties, the group A polysaccharide is a polymer of *N*-acetyl-mannosamine-1-phosphate. Incorporation of human sialic acid derivatives such as NANA into the meningococcal capsules allows the organism to be overlooked by the host immune system (often referred to as "molecular mimicry"). Meningococcal antigens are found in blood and cerebrospinal fluid of patients with active disease.

The outer membrane of *N. meningitidis* consists of proteins and LPS that play major roles in organism virulence. There are two porin proteins (Por A and Por B) that are important in controlling nutrient diffusion into the organism and also interact with host cells. These porins have been targets of interest in vaccine development. The opacity proteins

(Opa) are comparable to Opa of the gonococci and play a role in attachment. Meningococci are piliated and these structures initiate binding to nasopharyngeal epithelial cells and other host cells such as endothelium and erythrocytes. The lipid A disaccharide of meningococcal LPS is responsible for many of the toxic effects found in meningococcal disease. The highest levels of endotoxin measured in sepsis have been found in patients with meningococcemia (50- to 100-fold greater than with other Gram-negative infections). Collectively, these structures and proteins are responsible for the devastating clinical features so characteristic of meningococcal infections.

Pathogenesis, Pathology, and Clinical Findings

Humans are the only natural hosts for whom meningococci are pathogenic. The nasopharynx is the portal of entry. There, the organisms attach to epithelial cells with the aid of pili; they may form part of the transient microbiota without producing symptoms and/or disease. Invasive meningococcal disease (IMD) occurs in only a small number of individuals who acquired the organism and are transient carriers; infants and adolescents have the highest incidence of IMD in developed countries. From the nasopharynx, organisms may reach the bloodstream, producing meningococcal bacteremia; the initial symptoms during this stage of the actual infection may be similar to those of an upper respiratory tract, “flu-like” infection, but IMD quickly ensues. IMD typically presents as meningitis, sepsis (ie, meningococcemia), or as a combination of both. Meningitis is the most common complication of meningococcal bacteremia. It usually begins suddenly with an intense headache, vomiting, photophobia, confusion, and stiff neck; it may progress to coma within a few hours. Fulminant meningococcemia is more severe, presenting with a high fever and a hemorrhagic rash; the patient may also develop disseminated intravascular coagulation and ultimate circulatory collapse with bilateral hemorrhagic necrosis of the adrenal glands with subsequent adrenal failure (Waterhouse-Friderichsen syndrome).

During meningococcemia, there is thrombosis of many small blood vessels in many organs, with perivascular infiltration and petechial hemorrhages. There may be interstitial myocarditis, arthritis, and skin lesions. In meningitis, the meninges are acutely inflamed, with thrombosis of blood vessels and exudation of polymorphonuclear leukocytes, so that the surface of the brain is covered with a thick purulent exudate.

The exact mechanisms that transform an asymptomatic colonization of the nasopharynx into meningococcal bacteremia, subsequently leading to meningococcemia and meningitis, are not very well understood; however, the invasion of the bloodstream can be prevented by specific bactericidal serum antibodies against the infecting serotype. *Neisseria* bacteremia is favored by the absence of bactericidal antibody (IgM and IgG), inhibition of serum bactericidal action by a blocking IgA antibody, or a complement component deficiency (C5, C6, C7, or C8). Meningococci are readily phagocytosed in the presence of a specific opsonin.

Diagnostic Laboratory Tests

A. Specimens

The typical specimens for isolation of *N. meningitidis* include blood for culture and cerebrospinal fluid (CSF) for smear and culture. Puncture material or biopsies from petechiae may be taken for smear and culture. Nasopharyngeal swab cultures are suitable for carrier surveys.

B. Smears

Gram-stained smears of the sediment of centrifuged spinal fluid or of petechial aspirate often show typical neisseriae within polymorphonuclear leukocytes or extracellularly.

C. Culture

Although neisseriae are inhibited by certain toxic factors present in media and polyanethole sulfonate (anticoagulant) present in commercial blood culture broths, this seems to be of a lesser problem for the ability to recover *N. meningitis* from blood cultures, compared to *N. gonorrhoeae*. CSF specimens are plated on sheep blood agar and chocolate agar and then incubated at 37°C in an atmosphere of 5% CO₂. A MTM agar favors the growth of neisseriae, inhibits many other bacteria, and is used for nasopharyngeal cultures. Colonies of *N. meningitidis* are gray, convex, and glistening, with entire edges; a positive oxidase test together with a Gram-stain showing Gram-negative diplococci provides presumptive organism identification. Spinal fluid and blood generally typically yield pure cultures that can be further identified by carbohydrate oxidative reactions (see Table 20-1) and subsequent agglutination with type-specific or polyvalent serum.

D. Serology

Antibodies to meningococcal polysaccharides can be measured by latex agglutination or hemagglutination tests or by their bactericidal activity. These tests are only performed in reference laboratories.

Immunity

Immunity to meningococcal infection is associated with the presence of specific, complement-dependent, bactericidal antibodies in the serum. These antibodies develop after subclinical infections with different strains or injection of antigens and are group specific, type specific, or both. The immunizing antigens for groups A, C, Y, and W-135 are the capsular polysaccharides. For group B, two vaccines, 4CMenB (Bexsero®) and Trumenba are licensed by the US FDA for use in the United States. Currently, there are three vaccines against serogroups A, C, Y, and W-135 and one that contains only C and Y available in the United States. A polysaccharide tetra-valent vaccine (Menomune®, Sanofi Pasteur) in which each dose consists of four purified bacterial capsular polysaccharides is poorly immunogenic in children younger than age 18 months, does not confer long-lasting immunity, and does

not cause a sustainable reduction in nasopharyngeal carriage. This is approved as a single dose for individuals ≥ 2 years. A tetravalent conjugate vaccine approved in 2005 (Menactra™, Sanofi Pasteur) is licensed for use in persons 9 months to 55 years of age. It contains capsular polysaccharide conjugated to diphtheria toxoid. In children aged 9–23 months, two doses are required. Menveo (Novartis) is another tetravalent conjugate vaccine in which A, C, Y, and W135 oligosaccharide is conjugated to diphtheria CRM197. This vaccine is approved for use in individuals 2–55 years of age. The Hib-MenCy-TT conjugate vaccine (GlaxoSmithKline) is a four-dose series vaccine approved for children 6 weeks to 18 months old. A quadrivalent meningococcal vaccine in which tetanus toxoid is the conjugate protein (MenACWY-tt; Nimenrix®) is available in Europe. The advantage of the conjugate vaccines is that a T cell-dependent response to vaccine is induced. This enhances primary response among infants and substantially reduces asymptomatic carriage.

Routine vaccination of all young adolescents (ages 11–12 years) before high school with a booster dose at age 16 years using an approved conjugate vaccine is now recommended. Vaccination is also recommended for persons 2 months of age or older who are among the following at-risk groups: persons with functional or surgical asplenia, and persons with complement deficiencies. Persons aged 9 months or older who are travelers to or residents of highly endemic areas (eg, sub-Saharan Africa), “closed populations” such as college freshman living in dorms and military personnel, populations experiencing a community outbreak, and clinical laboratory workers (microbiologists) are other at-risk groups who should routinely be vaccinated.

Treatment

Penicillin G is the drug of choice for treating patients with meningococcal disease. Either chloramphenicol or a third-generation cephalosporin such as cefotaxime or ceftriaxone is used in persons who are allergic to penicillins.

Epidemiology, Prevention, and Control

Meningococcal meningitis occurs in epidemic waves (eg, in military encampments, in religious pilgrims, and in sub-Saharan Africa, the so-called “meningitis belt”); and a smaller number of sporadic interepidemic cases. Outbreaks and sporadic cases in the Western hemisphere in the past decade have been caused mainly by groups B, C, W-135, and Y; outbreaks in southern Finland and São Paulo, Brazil, were caused by groups B and C; outbreaks in New Zealand have been caused by a particular B strain; and those in Africa were mainly caused by group A. Group C and, especially, group A are associated with epidemic disease.

Serogroup A is responsible for the majority of outbreaks in sub-Saharan Africa, whereas serogroup B is most often the cause of sporadic infections. About 5–30% of the normal population may harbor meningococci (often nontypeable

isolates) in the nasopharynx during interepidemic periods. During epidemics, the carrier rate goes up to 70–80%. A rise in the number of cases is preceded by an increased number of respiratory carriers. Treatment with penicillin or other antibiotics does not eradicate the carrier state. Chemoprophylaxis for household and other close contacts following exposure to an index case is recommended, using rifampin, 600 mg orally for adults, 5 mg/kg for children <1 month, or 10 mg/kg for children 1 month or older twice daily for 2 days. Ciprofloxacin in adults, 500 mg as a single dose, and ceftriaxone in children <15 years, 125 mg IM as a single dose, are alternative agents. While clinical cases of meningitis present only a negligible source of infection, and isolation of individual patients therefore has only limited usefulness; however, droplet and standard precautions for the first 24 hours of antimicrobial therapy are recommended by the CDC. Prevention of meningococcal disease has focused on enhancing immunity through administration of vaccines in an at risk population as discussed; another approach is the reduction of personal contacts in a population with a high carrier rate. This can be accomplished by avoidance of crowding.

OTHER NEISSERIAE

N. lactamica very rarely causes disease but is important because it grows on selective agar media (eg, modified MTM) used for cultures of gonococci and meningococci from clinical specimens. *N. lactamica* can be cultured from the nasopharynx of 3–40% of persons and most often is found as a commensal of the upper respiratory tract in infants and children. Unlike the other *Neisseria* species, it acidifies lactose, in addition to glucose and maltose.

N. sicca, *N. subflava*, *N. cinerea*, *N. mucosa*, and *N. flavescens* are also members of the normal microbiota of the respiratory tract, particularly the nasopharynx, and very rarely produce disease. *N. cinerea* sometimes resembles *N. gonorrhoeae* because of its morphology and positive hydroxyprolyl aminopeptidase reaction.

M. catarrhalis is a strictly aerobic, oxidase-positive, Gram-negative diplococcus, occurring predominantly in pairs, or sometimes in short chains. The organism was previously named *Branhamella catarrhalis* and before that *Neisseria catarrhalis*. It is a member of the normal microbiota in 40–50% of healthy school children. *M. catarrhalis* causes bronchitis, pneumonia, sinusitis, otitis media, and conjunctivitis. It is also of concern as a cause of infection in immunocompromised patients. *M. catarrhalis* grows well on sheep blood agar, chocolate agar, and even selective agar media such as MTM. *M. catarrhalis* can be differentiated from the *Neisseria* species by its lack of acidification of carbohydrates and by its production of DNase. The organism also produces butyrate esterase, which forms the basis for rapid fluorometric tests for identification. Most strains of *M. catarrhalis* from clinically significant infections produce β -lactamases and are resistant to penicillins. However, the majority of these clinical isolates remain susceptible to many other antibiotics,

including cephalosporins, macrolides, tetracyclines, and the combination of β -lactams with a β -lactamase inhibitor (eg, amoxicillin–clavulanic acid).

CHAPTER SUMMARY

- The genus *Neisseria* consists of two major human pathogens, *N. gonorrhoeae* and *N. meningitidis*; both of them have elaborated factors that facilitate disease in otherwise healthy people. The remaining species constitute part of the normal human microbiota of the respiratory tract and other mucosal membranes, and may play a role in localized infections.
 - Members of the genus *Neisseria* are Gram-negative diplococci that vary in their growth requirements. *N. gonorrhoeae* is fastidious; selective, enriched media containing antibiotics, amino acids, and other supplements to support growth are used to recover the organism from primary clinical specimens. The other *Neisseria* species are less fastidious and grow on routine laboratory media.
 - *N. gonorrhoeae* causes the sexually transmitted disease gonorrhea, which is characterized by purulent cervicitis in women and purulent urethral discharge in men. Infants born to women infected at the time of delivery may develop purulent conjunctivitis.
 - Diagnosis is made primarily by NAATs; treatment consists of intramuscular ceftriaxone plus an agent such as azithromycin or doxycycline to treat concomitant *Chlamydia* infections.
 - *N. meningitidis* is the cause of endemic and epidemic meningitis. Its major virulence factor is the thick polysaccharide capsule. There are approximately 13 capsular types, of which the most common causes of disease are A, B, C, X, Y, and W-135.
 - Meningococcal meningitis is a serious infection that carries a high morbidity and is often associated with sepsis because of its potent LOS. Penicillin is the drug of choice for treatment.
 - Diagnosis is made by culturing the cerebrospinal fluid on chocolate agar incubated at 37°C in CO₂.
 - Prevention consists of immunization with one of two conjugate vaccines (routinely recommended for children 11–12 years of age) or the polysaccharide vaccine.
2. A 9-year-old boy presented to the clinic with a urethral discharge for the past 24 hours. *N. gonorrhoeae* was cultured from the specimen and found to be β -lactamase positive and resistant to high levels (≥ 32 $\mu\text{g/mL}$) of tetracycline. Which of the following statements about these antimicrobial resistance factors is correct?
 - (A) β -Lactamase production and high-level resistance to tetracycline are both mediated by genes on plasmids.
 - (B) Whereas β -lactamase production is mediated by a gene on the bacterial chromosome, high-level tetracycline resistance is mediated by a gene on a plasmid.
 - (C) Whereas β -lactamase production is mediated by a gene on a plasmid, high-level tetracycline resistance is mediated by a gene on the bacterial chromosome.
 - (D) β -Lactamase production and high-level resistance to tetracycline are both mediated by genes on the bacterial chromosome.
 3. A 6-year-old boy develops a fever and headache. He is taken to the emergency department, where he is noted to have a stiff neck, suggesting meningeal irritation. A lumbar puncture is done, and culture of the cerebrospinal fluid grows *N. meningitidis* serogroup B. Which of the following should be considered for his family (household) members?
 - (A) No prophylaxis or other steps are necessary.
 - (B) They should be given *N. meningitidis* pilin vaccine.
 - (C) They should be given *N. meningitidis* serogroup B polysaccharide capsule vaccine.
 - (D) They should be given rifampin prophylaxis.
 - (E) They should be given sulfonamide prophylaxis.
 4. An 18-year-old woman who reports unprotected sex with a new partner 2 weeks previously develops fever and left lower quadrant abdominal pain with onset in association with her menstrual period. On pelvic examination in the emergency department, she has bilateral tenderness when the uterus is palpated. A mass 2–3 cm in diameter is felt on the left, suggestive of tubo-ovarian abscess. Subsequently, *N. gonorrhoeae* is cultured from her endocervix. The diagnosis is gonococcal pelvic inflammatory disease. A common sequela of this infection is
 - (A) Cancer of the cervix
 - (B) Urethral stricture
 - (C) Uterine fibroid tumors
 - (D) Infertility
 - (E) Vaginal-rectal fistula
 5. A 38-year-old vice squad police officer comes to the emergency department with a chief complaint expressed as follows: “I have disseminated gonococcal infection again.” He is correct. Cultures of his urethra and knee fluid yield *N. gonorrhoeae*. He has previously had five episodes of disseminated gonococcal infection. The patient should be evaluated for
 - (A) Selective IgA deficiency
 - (B) A polymorphonuclear cell chemotactic defect
 - (C) Deficiency of a late-acting complement component C5, C6, C7, or C8
 - (D) Absent lymphocyte adenosine deaminase activity
 - (E) Myeloperoxidase deficiency
 6. Which of the following individuals should routinely receive vaccination with the conjugate meningococcal vaccine?
 - (A) A healthy young adolescent entering high school
 - (B) A healthy child entering kindergarten
 - (C) A 60-year-old man with insulin-dependent diabetes

REVIEW QUESTIONS

1. The inhabitants of a group of small villages in rural sub-Saharan Africa experienced an epidemic of meningitis. Ten percent of the people died, most of them younger than the age of 15 years. The microorganism that most likely caused this epidemic was
 - (A) *Streptococcus agalactiae* (group B)
 - (B) *Escherichia coli* K1 (capsular type 1)
 - (C) *H. influenzae* serotype b
 - (D) *N. meningitidis* serogroup A
 - (E) West Nile virus

- (D) A healthy 40-year-old technician who works in a cancer research laboratory
- (E) A 65-year-old woman with coronary artery disease
7. A 25-year-old sexually active woman presents with purulent vaginal discharge and dysuria 7 days after having unprotected sexual intercourse with a new partner. Of the choices below, what is the most sensitive diagnostic method for determining the likely etiologic agent?
- (A) Gram-stain
- (B) An enzyme immunoassay
- (C) Bacterial culture on selective media
- (D) A nucleic acid amplification test
- (E) Serology
8. What is the currently recommended treatment for gonococcal urethritis in men who have sex with men in the United States?
- (A) Single dose of an oral fluoroquinolone
- (B) Seven days of oral doxycycline
- (C) Ceftriaxone given intramuscularly as a single dose
- (D) Spectinomycin given intramuscularly as a single dose
- (E) Seven days of oral amoxicillin
9. Which of the following cell components produced by *N. gonorrhoeae* is responsible for attachment to host cells?
- (A) Lipooligosaccharide
- (B) Pili (fimbriae)
- (C) IgA1 protease
- (D) Outer membrane porin protein
- (E) Iron-binding protein
10. A 60-year-old man with severe chronic lung disease presents with fever, cough productive of purulent sputum, and worsening hypoxemia. A sputum sample is collected, and the specimen is sent promptly to the laboratory. Microscopic examination of a Gram-stain reveals numerous polymorphonuclear leukocytes and predominately Gram-negative diplococci that are both intracellular and extracellular. The organism grows well on 5% SBA and chocolate agar and is positive for butyrate esterase. What is the most likely organism causing this man's illness?
- (A) *N. gonorrhoeae*
- (B) *N. lactamica*
- (C) *M. catarrhalis*
- (D) *H. influenzae*
- (E) *N. meningitidis*
11. One major advantage of the conjugate meningococcal vaccines compared with the polysaccharide vaccine is
- (A) Stimulation of mucosal secretory IgA
- (B) Fewer side effects
- (C) A T cell-dependent response to vaccine is induced
- (D) Inclusion of serogroup B
12. A 25-year-old woman presents with septic arthritis of the knee. The fluid aspirate grows a Gram-negative diplococcus on chocolate agar after 48 hours of incubation. The isolate is oxidase positive and oxidizes glucose but not maltose, lactose, or sucrose. You suspect infection with
- (A) *N. meningitidis*
- (B) *N. lactamica*
- (C) *M. catarrhalis*
- (D) *N. gonorrhoeae*
- (E) None of the above
13. A useful test to differentiate *M. catarrhalis* from saprophytic neisseriae in respiratory samples is
- (A) Butyrate esterase
- (B) Gram-stain
- (C) Growth on 5% sheep blood agar
- (D) PYR
- (E) Oxidase

Infections Caused by Anaerobic Bacteria

Medically important infections caused by anaerobic bacteria are common. The infections are often polymicrobial—that is, the anaerobic bacteria are found in mixed infections with other anaerobes, facultative anaerobes, and aerobes (see the glossary of definitions). Anaerobic bacteria are found throughout the human body—on the skin, on mucosal surfaces, and in high concentrations in the mouth and in gastrointestinal tract—as part of the normal microbiota (see Chapter 10). Infection results when anaerobes and other bacteria of the normal microbiota contaminate normally sterile body sites.

Several important diseases are caused by anaerobic *Clostridium* species from the environment or from normal flora: botulism, tetanus, gas gangrene, food poisoning, and pseudomembranous colitis. These diseases are discussed in Chapters 9 and 11.

GLOSSARY

Aerobic bacteria: Bacteria that require oxygen as a terminal electron acceptor and will not grow under anaerobic conditions (ie, in the absence of O_2). Some *Bacillus* species and *Mycobacterium tuberculosis* are obligate aerobes (ie, they must have oxygen to survive).

Anaerobic bacteria: Bacteria that do not use oxygen for growth and metabolism but obtain their energy from fermentation reactions. A functional definition of anaerobes is that they require reduced oxygen tension for growth and fail to grow on the surface of solid medium in 10% CO_2 in ambient air. *Bacteroides* and *Clostridium* species are the examples of anaerobes.

Facultative anaerobes: Bacteria that can grow either oxidatively, using oxygen as a terminal electron acceptor, or anaerobically, using fermentation reactions to obtain energy. Such bacteria are common pathogens. *Streptococcus* species and the Enterobacteriaceae (eg, *Escherichia coli*) are among the many facultative anaerobes that cause disease. Often, bacteria that are facultative anaerobes are called “aerobes.”

PHYSIOLOGY AND GROWTH CONDITIONS FOR ANAEROBES

Anaerobic bacteria do not grow in the presence of oxygen and are killed by oxygen or toxic oxygen radicals (see later discussion); pH and oxidation–reduction potential (E_h) are also important in establishing conditions that favor growth of anaerobes. Anaerobes grow at a low or negative E_h .

Aerobes and facultative anaerobes often have the metabolic systems listed below, but anaerobic bacteria frequently do not.

1. Cytochrome systems for the metabolism of O_2
2. Superoxide dismutase (SOD), which catalyzes the following reaction:

3. Catalase, which catalyzes the following reaction:

Anaerobic bacteria do not have cytochrome systems for oxygen metabolism. Less fastidious anaerobes may have low levels of SOD and may or may not have catalase. Most bacteria of the *Bacteroides fragilis* group have small amounts of both catalase and SOD. There appear to be multiple mechanisms for oxygen toxicity. Presumably, when anaerobes have SOD or catalase (or both), they are able to negate the toxic effects of oxygen radicals and hydrogen peroxide and thus tolerate oxygen. **Obligate anaerobes** usually lack SOD and catalase and are susceptible to the lethal effects of oxygen; such strict obligate anaerobes are infrequently isolated from human infections, and most anaerobic infections of humans are caused by “moderately obligate anaerobes.”

The ability of anaerobes to tolerate oxygen or grow in its presence varies from species to species. Similarly, there is strain-to-strain variation within a given species (eg, one strain of *Prevotella melaninogenica* can grow at an O_2 concentration of 0.1% but not of 1%; another can grow at a concentration of 2% but not of 4%). Also, in the absence of oxygen, some anaerobic bacteria grow at a more positive E_h .

Facultative anaerobes grow as well or better under anaerobic conditions than they do under aerobic conditions. Bacteria that are facultative anaerobes are often termed *aerobes*. When a facultative anaerobe such as *E. coli* is present at the site of an infection (eg, abdominal abscess), it can rapidly consume all available oxygen and change to anaerobic metabolism, producing an anaerobic environment and low E_h and thus allow the anaerobic bacteria that are present to grow and produce disease.

ANAEROBIC BACTERIA FOUND IN HUMAN INFECTIONS

Since the 1990s, the taxonomic classification of the anaerobic bacteria has changed significantly due to the application of molecular sequencing and DNA–DNA hybridization technologies. The nomenclature used in this chapter refers to genera of anaerobes frequently found in human infections and to certain species recognized as important pathogens of humans. Anaerobes commonly found in human infections are listed in Table 21-1.

Gram-Negative Anaerobes

A. Gram-Negative Bacilli

1. *Bacteroides*—The *Bacteroides* species are very important anaerobes that cause human infection. They are a large group of bile-resistant, non–spore-forming, slender Gram-negative rods that may appear as coccobacilli. Many species previously included in the genus *Bacteroides* have been reclassified

into the genus *Prevotella* or the genus *Porphyromonas*. Those species retained in the *Bacteroides* genus are members of the *B. fragilis* group (~20 species).

Bacteroides species are normal inhabitants of the bowel and other sites. Normal stools contain 10^{11} *B. fragilis* organisms per gram (compared with 10^8 /g for facultative anaerobes). Other commonly isolated members of the *B. fragilis* group include *Bacteroides ovatus*, *Bacteroides distasonis*, *Bacteroides vulgatus*, and *Bacteroides thetaiotaomicron*. *Bacteroides* species are most often implicated in intra-abdominal infections, usually under circumstances of disruption of the intestinal wall as occurs in perforations related to surgery or trauma, acute appendicitis, and diverticulitis. These infections are often polymicrobial. Both *B. fragilis* and *B. thetaiotaomicron* are implicated in serious intrapelvic infections, such as pelvic inflammatory disease and ovarian abscesses. *B. fragilis* group species are the most common species recovered in some series of anaerobic bacteremia, and these organisms are associated with a very high mortality rate. As discussed later in the chapter, *B. fragilis* is capable of elaborating numerous virulence factors, which contribute to its pathogenicity and mortality in the host.

2. *Prevotella*—*Prevotella* species are Gram-negative bacilli and may appear as slender rods or coccobacilli. Most commonly isolated are *P. melaninogenica*, *Prevotella bivia*, and *Prevotella disiens*. *P. melaninogenica* and similar species are found in infections associated with the upper respiratory tract. *P. bivia* and *P. disiens* occur in the female genital tract. *Prevotella* species are found in brain and lung abscesses, in empyema, and in pelvic inflammatory disease and tubo-ovarian abscesses.

In these infections, the *Prevotella* species are often associated with other anaerobic organisms that are part of the normal microbiota—particularly peptostreptococci, anaerobic Gram-positive rods, and *Fusobacterium* species—as well as Gram-positive and Gram-negative facultative anaerobes that are part of the normal microbiota.

3. *Porphyromonas*—The *Porphyromonas* species also are Gram-negative bacilli that are part of the normal oral microbiota and occur at other anatomic sites as well. *Porphyromonas* species can be cultured from gingival and periapical tooth infections and, more commonly, breast, axillary, perianal, and male genital infections.

4. *Fusobacteria*—There are approximately 13 *Fusobacterium* species, but most human infections are caused by *Fusobacterium necrophorum* and *Fusobacterium nucleatum*. Both species differ in morphology and habitat as well as the range of associated infections. *F. necrophorum* is a very pleomorphic, long rod with round ends and tends to make bizarre forms. It is not a component of the healthy oral cavity. *F. necrophorum* is quite virulent, causing severe infections of the head and neck that can progress to a complicated infection called Lemierre’s disease. The latter is characterized by acute jugular vein septic thrombophlebitis that progresses to sepsis with metastatic abscesses of the lungs, mediastinum, pleural space, and liver. Lemierre’s disease is most common among older children and

**Cutibacterium acnes* was formerly termed *Propionibacterium acnes* (see reference: Scholz CFP, Kilian M. The natural history of cutaneous propionibacteria and reclassification of selected species within the genus *Propionibacterium* to the proposed novel genera *Acidipropionibacterium* gen. nov., *Cutibacterium* gen. nov. and *Pseudopropionibacterium* gen. nov. *Int J Syst Evol Microbiol* 2016; 66 (11):4422–4432).

young adults and often occurs in association with infectious mononucleosis. *F. necrophorum* is also seen in polymicrobial, intra-abdominal infections. *F. nucleatum* is a thin rod with tapered ends (needle-shaped morphology) and is a significant component of the gingival microbiota as well as the genital, gastrointestinal, and upper respiratory tracts. As such, it is frequently encountered in a variety of clinical infections such as pleuropulmonary infections, obstetric infections, significantly chorioamnionitis, and occasionally brain abscesses complicating periodontal disease. Rarely does it cause bacteremia in neutropenic patients.

BACTERIA THAT CAUSE VAGINOSIS

Bacterial vaginosis is a common vaginal condition of women of reproductive age. It is associated with premature rupture of membranes and preterm labor and birth. Bacterial vaginosis has a complex microbiology; one organism, *Gardnerella vaginalis*, has been most specifically associated with the disease process.

GARDNERELLA VAGINALIS

G. vaginalis is a serologically distinct organism isolated from the normal female genitourinary tract and also associated with vaginosis, so named because inflammatory cells are not present. In wet smears, this “nonspecific” vaginitis, or **bacterial vaginosis**, yields “clue cells,” which are vaginal epithelial cells covered with many Gram-variable bacilli, and there is an absence of other common causes of vaginitis such as trichomonads or yeasts. Vaginal discharge often has a distinct “fishy” odor and contains many anaerobes in addition to *G. vaginalis*. The pH of the vaginal secretions is greater than 4.5 (normal pH is <4.5). The vaginosis attributed to this organism is suppressed by metronidazole, suggesting an association with anaerobes. Oral metronidazole is generally curative.

Gram-Positive Anaerobes

A. Gram-Positive Bacilli

1. Actinomyces—The *Actinomyces* group includes several species that cause actinomycosis, of which *Actinomyces israelii* and *Actinomyces gerencseriae* are the ones most commonly encountered. Several new, recently described species that are not associated with actinomycosis have been associated with infections of the groin, urogenital area, breast, and axilla and postoperative infections of the mandible, eye, and head and neck. Some species have also been implicated in cases of endocarditis, particularly among substance abusers. These newly described species are aerotolerant and form small, nondescript colonies that are probably frequently overlooked as contaminants. On Gram-stain, they vary considerably in length; they may be short and club shaped or long, thin, beaded filaments. They may be branched or unbranched. Because they often grow slowly, prolonged incubation of the culture may be necessary before laboratory confirmation of the clinical diagnosis of actinomycosis can be made.

Some strains produce colonies on agar that resemble molar teeth. Some *Actinomyces* species are oxygen tolerant (aerotolerant) and grow in the presence of air; these strains may be confused with *Corynebacterium* species (diphtheroids; see Chapter 12). Actinomycosis is a chronic suppurative and granulomatous infection that produces pyogenic lesions with interconnecting sinus tracts that contain granules composed of microcolonies of the bacteria embedded in tissue elements (Figure 21-1). Infection is initiated by trauma that introduces these endogenous bacteria into the mucosa. The organisms grow in an anaerobic niche, induce a mixed inflammatory response, and spread with the formation of sinuses, which contain the granules and may drain to the surface. The infection causes swelling and may spread to neighboring organs, including the bones.

Based on the site of involvement, the three common forms are cervicofacial, thoracic, and abdominal actinomycosis. Cervicofacial disease presents as a swollen, erythematous process in the jaw area (known as “lumpy jaw”). With progression, the mass becomes fluctuant, producing draining fistulas. The disease will extend to contiguous tissue, bone, and lymph nodes of the head and neck. The symptoms of thoracic actinomycosis resemble those of a subacute pulmonary infection and include a mild fever, cough, and purulent sputum. Eventually, lung tissue is destroyed, sinus tracts may erupt through to the chest wall, and invasion of the ribs may occur. Abdominal actinomycosis often follows a ruptured appendix or an ulcer. In the peritoneal cavity, the pathology is the same, but any of several organs may be involved. Genital actinomycosis is a rare occurrence in women that results from colonization of an intrauterine device with subsequent invasion.

Diagnosis can be made by examining pus from draining sinuses, sputum, or specimens of tissue for the presence of sulfur granules. The granules are hard, lobulated, and composed of tissue and bacterial filaments, which are club shaped at the periphery. Specimens should be cultured anaerobically on appropriate media. Treatment requires prolonged administration of penicillin (6–12 months). Clindamycin or erythromycin is effective in penicillin-allergic patients. Surgical excision and drainage may be required.

2. Cutibacterium—*Cutibacterium* species (formerly termed *Propionibacterium* species) are members of the normal microbiota of the skin, oral cavity, large intestine, conjunctiva, and external ear canal. Their metabolic products include propionic acid, from which the genus name derives. On Gram-stain, they are highly pleomorphic, showing curved, clubbed, or pointed ends; long forms with beaded uneven staining; and occasionally coccoid or spherical forms. *Cutibacterium acnes* (formerly *Propionibacterium acnes*), often considered an opportunistic pathogen, causes the disease acne vulgaris and is associated with a variety of inflammatory conditions. It causes acne by producing lipases that split free fatty acids off from skin lipids. These fatty acids can produce tissue inflammation that contributes to acne formation. In addition, *C. acnes* is frequently a cause of postsurgical wound infections, particularly those that involve insertion of devices, such as prosthetic joint infections, particularly of the shoulder, central nervous system shunt infections,

C

FIGURE 21-1 *Actinomyces* species. **A:** Colony of *Actinomyces* species after 72 hours growth on brain–heart infusion agar, which usually yields colonies about 2 mm in diameter; they are often termed “molar tooth” colonies. (Courtesy of CDC Public Health Image Library, L Georg.) **B:** Granule of *Actinomyces* species in tissue with Brown and Breen stain. Original magnification $\times 400$. Filaments of the branching bacilli are visible at the periphery of the granule. Such granules are commonly called “sulfur granules” because of their unstained gross yellow color. (Courtesy of CDC Public Health Image Library.) **C:** *Actinomyces naeslundii* in a brain abscess stained with methylene blue. Branching bacilli are visible. Original magnification $\times 1000$. (Courtesy of CDC Public Health Image Library, L Georg.)

osteomyelitis, endocarditis, and endophthalmitis. Because it is part of the normal skin microbiota, *C. acnes* sometimes contaminates blood or cerebrospinal fluid cultures that are obtained by penetrating the skin. It is therefore important (but often difficult) to differentiate a contaminated culture from one that is positive and indicates infection.

3. *Clostridium*—Clostridia are Gram-positive, spore-forming bacilli (see Chapter 11).

B. Gram-Positive Cocci

The group of anaerobic Gram-positive cocci has undergone significant taxonomic expansion. Many species within the genus *Peptostreptococcus* have been reassigned to new genera such as *Anaerococcus*, *Fingoldia*, and *Peptoniphilus*. The species contained within these genera, as well as *Peptococcus niger*, are important members of the normal microbiota of the skin, oral cavity, upper respiratory tract, gastrointestinal tract, and female genitourinary system. The members of this group are opportunistic pathogens and are most frequently found in mixed infections particularly from specimens that have not been carefully procured. However, these organisms have been associated with serious infections, such as brain abscesses, pleuropulmonary infections, necrotizing fasciitis, and other deep skin and soft tissue infections, intra-abdominal infections, and infections of the female genital tract.

PATHOGENESIS OF ANAEROBIC INFECTIONS

Infections caused by anaerobes commonly are caused by combinations of bacteria that function in synergistic pathogenicity. Although studies of the pathogenesis of anaerobic infections have often focused on a single species, it is important to recognize that the anaerobic infections most often are caused by several species of anaerobes acting together to cause infection.

B. fragilis is a very important pathogen among the anaerobes that are part of the normal microbiota. The pathogenesis of anaerobic infection has been most extensively studied with *B. fragilis* using a rat model of intra-abdominal infection, which in many ways mimics human disease. A characteristic sequence occurs after colon contents (including *B. fragilis* and a facultative anaerobe such as *E. coli*) are placed via needle, gelatin capsule, or other means into the abdomens of rats. A high percentage of the study animals die of sepsis caused by the facultative anaerobe. However, if the animals are first treated with gentamicin, a drug effective against the facultative anaerobe but not *Bacteroides* species, few of the animals die, and after a few days, the surviving animals develop intra-abdominal abscesses from the *Bacteroides* infection. Treatment of the animals with both gentamicin and clindamycin, a drug effective against *Bacteroides* species, prevents both the initial sepsis and the later development of abdominal abscesses.

The capsular polysaccharides of *Bacteroides* are important virulence factors. A unique feature of infections with *B. fragilis* is the ability of the organism to induce abscess formation as the sole infecting organism. When injected into rats' abdomens, purified capsular polysaccharides from *B. fragilis* cause abscess formation, but those from other bacteria (eg, *Streptococcus pneumoniae* and *E. coli*) do not. The mechanism by which the *B. fragilis* capsule induces abscess formation is not well understood.

Bacteroides species have lipopolysaccharides (endotoxins; see Chapter 9) but lack the lipopolysaccharide structures with endotoxic activity (including β -hydroxymyristic acid). The lipopolysaccharides of *B. fragilis* are much less toxic than those of other Gram-negative bacteria. Thus, infection caused by *Bacteroides* does not directly produce the clinical signs of sepsis (eg, fever and shock) so important in infections caused by other Gram-negative bacteria. When these clinical signs appear in *Bacteroides* infection, they are a result of the inflammatory immune response to the infection.

B. fragilis elaborates a number of enzymes important in disease. In addition to proteases and neuraminidases, production of two cytolysins acts together to cause hemolysis of erythrocytes. An enterotoxin capable of causing diarrhea and whose gene is contained on a pathogenicity island is found in the majority of isolates that are recovered from blood cultures.

B. fragilis produces an SOD and can survive in the presence of oxygen for days. When a facultative anaerobe such as *E. coli* is present at the site of infection, it can consume all available oxygen and thereby produce an environment in which *Bacteroides* species and other anaerobes can grow (see earlier).

F. necrophorum likewise possesses important virulence factors that enable it to cause Lemierre's syndrome and other seriously invasive infections. One of these factors is a leukotoxin likely responsible for the necrosis seen with these infections. Other factors include a hemagglutinin, a hemolysin, and lipopolysaccharide (endotoxin). In addition, *F. necrophorum* is capable of causing platelet aggregation. The exact pathogenic interplay, if any, among these factors in the pathogenesis of human infections remains to be elucidated.

Many anaerobic bacteria produce heparinase, collagenase, and other enzymes that damage or destroy tissue. It is likely that enzymes play a part in the pathogenesis of mixed anaerobic infections, although laboratory experiments have not been able to define specific roles.

THE POLYMICROBIAL NATURE OF ANAEROBIC INFECTIONS

Most anaerobic infections are associated with contamination of tissue by normal microbiota of the mucosa of the mouth, pharynx, gastrointestinal tract, or genital tract. Typically, multiple species (five or six species or more when standard culture conditions are used) are found, including both anaerobes and facultative anaerobes. Oropharyngeal, pleuropulmonary, abdominal, and female pelvic infections associated with

**Cutibacterium acnes* was formerly termed *Propionibacterium acnes* (see reference: Scholz CFP, Kilian M. The natural history of cutaneous propionibacteria and reclassification of selected species within the genus *Propionibacterium* to the proposed novel genera *Acidipropionibacterium* gen. nov., *Cutibacterium* gen. nov. and *Pseudopropionibacterium* gen. nov. *Int J Syst Evol Microbiol* 2016;66 (11):4422–4432).

contamination by normal mucosal microbiota have a relatively equal distribution of anaerobes and facultative anaerobes as causative agents; about 25% have anaerobes alone, about 25% have facultative anaerobes alone, and about 50% have both anaerobes and facultative anaerobes. Aerobic bacteria may also be present, but obligate aerobes are much less common than anaerobes and facultative anaerobes. Anaerobic bacteria and associated representative infections are listed in Table 21-2.

DIAGNOSIS OF ANAEROBIC INFECTIONS

Clinical signs suggesting possible infection with anaerobes include the following:

1. Foul-smelling discharge (caused by short-chain fatty-acid products of anaerobic metabolism)
2. Infection in proximity to a mucosal surface (anaerobes are part of the normal microbiota)

3. Gas in tissues (production of CO₂ and H₂)
4. Negative aerobic culture results

Diagnosis of anaerobic infection is made by anaerobic culture of properly obtained and transported specimens (see Chapter 47). Anaerobes grow most readily on complex media such as trypticase soy agar base, Schaedler's blood agar, brucella agar, brain–heart infusion agar, and others—each highly supplemented (eg, with hemin, vitamin K₁, and blood). A selective complex medium containing kanamycin is used in parallel. Kanamycin (similar to all aminoglycosides) does not inhibit the growth of obligate anaerobes; thus, it permits them to proliferate without being overshadowed by rapidly growing facultative anaerobes. Cultures are incubated at 35–37°C in an anaerobic atmosphere containing CO₂.

Colony morphology, pigmentation, and fluorescence are helpful in identifying anaerobes. Biochemical activities and production of short-chain fatty acids as measured by gas-liquid chromatography are used for laboratory confirmation.

TREATMENT OF ANAEROBIC INFECTIONS

Treatment of mixed anaerobic infections is by surgical drainage (under most circumstances) plus antimicrobial therapy.

The *B. fragilis* group of organisms found in abdominal and other infections universally produces β-lactamase, as do many of the *P. bivia* and *P. disiens* strains found in genital tract infections in women. Fortunately, these β-lactamases are inhibited by β-lactam–β-lactamase inhibitor combinations such as ampicillin–sulbactam. Therapy with antimicrobials (other than penicillin G) is necessary to treat infections with these organisms. At least two-thirds of the *P. melaninogenica* strains from pulmonary and oropharyngeal infections also produce β-lactamase.

The most active drugs for treatment of anaerobic infections are clindamycin and metronidazole, although clindamycin resistance among the *B. fragilis* group has increased in the past decade. Clindamycin is preferred for infections above the diaphragm. Relatively few anaerobes are resistant to clindamycin (*B. fragilis* group excepted) and few, if any, are resistant to metronidazole. Alternative drugs include cefoxitin, cefotetan, some of the other newer cephalosporins, and piperacillin, but these drugs are not as active as clindamycin and metronidazole. The carbapenem antibiotics, ertapenem, imipenem, meropenem, and doripenem, have good activity against many anaerobes, and resistance is still uncommon. Tigecycline has good in vitro activity against a variety of anaerobe species, including the *B. fragilis* group. Penicillin G remains the drug of choice for treatment of anaerobic infections that do not involve β-lactamase-producing *Bacteroides* and *Prevotella* species.

CHAPTER SUMMARY

- Anaerobic bacteria are organisms that do not grow in the presence of oxygen and require special handling to recover them from clinical material.
- Anaerobes constitute a substantial component of the normal human microbiota, yet some produce potent exotoxins that cause serious, life-threatening infections.
- Anaerobes are often implicated in mixed bacterial infections when an important mucosal barrier has been compromised such as in the case of trauma.
- *B. fragilis* is one of the most frequently isolated Gram-negative anaerobes from clinical material; it possesses a capsule capable of causing abscess formation.
- Treatment of anaerobic infections requires drainage of abscesses and antibiotics, such as penicillin (for non-β-lactamase producers), clindamycin, cefoxitin, metronidazole, and the carbapenems.

REVIEW QUESTIONS

1. A 55-year-old man visits his physician complaining of a severe cough and production of purulent sputum. His breath has a very unpleasant fetid odor. Chest radiography shows a large amount of fluid in the left pleural space and a 5-cm lung cavity with an air-fluid level. A needle is inserted through the chest wall, and some of the fluid in the pleural space is removed; it is thick, yellow-gray in color, and malodorous. Which of the following organisms or sets of organisms are most likely to be cultured from the pleural fluid?
 - (A) *B. fragilis*, *E. coli*, and enterococci
 - (B) *P. bivia*, peptostreptococci, and *Staphylococcus epidermidis*
 - (C) *P. melaninogenica*, *Fusobacterium* species, and viridans streptococci
 - (D) *Propionibacterium* species, peptostreptococci, and *Staphylococcus aureus*
 - (E) *S. pneumoniae*
2. An 18-year-old man develops fever with pain in the right lower quadrant of his abdomen. After initial evaluation, he is taken to the operating room. During surgery, a ruptured appendix with an abscess is found. *B. fragilis* is cultured from the abscess fluid. Which of the following factors promote abscess formation by *B. fragilis*?
 - (A) Lipopolysaccharide
 - (B) Capsule
 - (C) Superoxide dismutase
 - (D) Pili
 - (E) Leukocidin toxin
3. Infections caused by *Bacteroides* species can be treated with all of the following antibiotics *except*
 - (A) Ampicillin–sulbactam
 - (B) Clindamycin
 - (C) Metronidazole
 - (D) Penicillin
 - (E) Cefoxitin
4. A 17-year-old high school senior develops infectious mononucleosis. About 2 weeks later, he develops a significantly higher fever, a worsening sore throat, an inability to swallow, and severe neck and

chest pain. Upon admission, he has signs of sepsis and respiratory distress. What is the most likely organism causing this complication?

- (A) *F. necrophorum*
 - (B) *B. ovatus*
 - (C) *P. melaninogenica*
 - (D) *Clostridium tetani*
 - (E) *A. israelii*
5. The drug of choice for treatment of infections caused by *Actinomyces* species is
 - (A) Tigecycline
 - (B) Cefoxitin
 - (C) Metronidazole
 - (D) Imipenem
 - (E) Penicillin
 6. All of the following statements regarding anaerobes are true *except*
 - (A) They possess the enzyme cytochrome oxidase.
 - (B) Many species are part of the normal human microbiota.
 - (C) They are often found along with aerobes in complicated infections.
 - (D) Special techniques are required to ensure their recovery from clinical specimens.
 - (E) Some species are more tolerant of exposure to oxygen than others.
 7. Lemierre's disease is a serious infection of the head and neck associated with which of the following anaerobes?
 - (A) *P. melaninogenica*
 - (B) *Bacteroides thetaiotamicron*
 - (C) *Porphyromonas gingivalis*
 - (D) *P. niger*
 - (E) *F. necrophorum*
 8. Definitive identification of an anaerobe is likely best accomplished by
 - (A) Colony morphology on anaerobic media
 - (B) The presence of pigment
 - (C) Susceptibility to a variety of antimicrobial disks
 - (D) Cell wall fatty acid analysis using gas liquid chromatography
 - (E) Gram-stain morphology
 9. A patient who has not maintained good dentition presents with induration and swelling of the mandibular area. On examination, you note purulent material draining from a small opening. The material appears yellowish, and there are some visible granules. You perform a Gram-stain, and pleomorphic Gram-positive rods with short branches are noted along with cells suggestive of acute and chronic inflammation. You suspect which of the following organisms?
 - (A) *B. fragilis*
 - (B) *Lactobacillus acidophilus*
 - (C) *Clostridium perfringens*
 - (D) *A. israelii*
 - (E) *S. aureus*

Legionella, Bartonella, and Unusual Bacterial Pathogens

LEGIONELLA PNEUMOPHILA AND OTHER LEGIONELLAE

A widely publicized outbreak of pneumonia in persons attending an American Legion convention in Philadelphia in 1976 prompted investigations that defined *L. pneumophila* and the legionellae. Other outbreaks of respiratory illness caused by related organisms since 1947 have been diagnosed retrospectively. Several dozen species of *Legionella* exist, some with multiple serogroups. *L. pneumophila* is the major cause of disease in humans; *Legionella micdadei* and a few other species sometimes cause pneumonia. The other legionellae are rarely isolated from patients or have been isolated only from the environment.

Morphology and Identification

L. pneumophila is the prototype bacterium of the group. Legionellae of primary medical importance are listed in Table 22-1.

A. Typical Organisms

Legionellae are fastidious, aerobic Gram-negative bacteria that are 0.5–1 μm wide and 2–50 μm long (Figure 22-1). They often stain poorly by Gram's method and are not easily seen in stains of clinical specimens. Gram-stained smears should be made for suspect *Legionella* growth on agar media. Basic fuchsin (0.1%) should be used as the counterstain because safranin stains the bacteria very poorly. Silver stains, such as Warthin-Starry and Dieterle, can be used to detect legionellae in embedded tissues. Of note, *L. micdadei* may be acid-fast stain positive.

B. Culture and Growth Characteristics

Legionellae can be grown on complex media such as buffered charcoal yeast extract (BCYE) agar with α -ketoglutarate, L-cysteine, and iron at a pH of 6.9, temperature of 35°C, and 90% humidity. Antibiotics can be added to make the medium selective for *Legionella* species. The charcoal acts as a detoxifying agent. Legionellae grow slowly; visible colonies are usually present after 3 days of incubation. Colonies that appear after overnight incubation are not *Legionella* species. Colonies are round or flat with entire edges. They vary in color

from colorless to iridescent pink or blue and are translucent or speckled. Variation in colony morphology is common, and the colonies may rapidly lose their color and speckles. Many other genera of bacteria grow on BCYE medium and must be differentiated from *Legionella* by Gram-staining and other tests.

Suspicious colonies require definitive identification by methods other than biochemical assessment since legionellae are biochemically inert. Confirmatory tests include direct fluorescent antibody tests, 16SrRNA gene sequencing, and the use of matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS).

The legionellae are catalase positive. *L. pneumophila* is oxidase positive; the other legionellae are variable in oxidase activity. *L. pneumophila* hydrolyzes hippurate; the other legionellae do not. Most legionellae produce gelatinase and β -lactamase; *L. micdadei* produces neither gelatinase nor β -lactamase.

Antigens and Cell Products

Antigenic specificity of *L. pneumophila* is thought to be attributable to complex antigenic structures. There are at least 16 serogroups of *L. pneumophila*; serogroup 1 was the cause of the 1976 outbreak of Legionnaires' disease and remains the most common serogroup isolated from humans. *Legionella* species cannot be identified by serogrouping alone because there is cross-reactive antigenicity among different species. Occasionally, other Gram-negative bacteria may also cross-react with *L. pneumophila* antisera.

The legionellae produce distinctive 14- to 17-carbon branched-chain fatty acids. Gas-liquid chromatography can be used to help characterize and determine the species of legionellae.

The legionellae make proteases, phosphatase, lipase, DNase, and RNase. A major secretory protein, a metalloprotease, has hemolytic and cytotoxic activity; however, this protein has not been shown to be a required virulence factor.

Pathology and Pathogenesis

Legionellae are ubiquitous in warm, moist environments. They are found in lakes, streams, and other bodies of water.

TABLE 22-1 *Legionella* Species Isolated from Humans

Species	Pneumonia	Pontiac Fever
<i>Legionella pneumophila</i>	+	Serogroups 1 and 6
<i>Legionella micdadei</i>	+	
<i>Legionella gormanii</i>	+	
<i>Legionella dumoffii</i>	+	
<i>Legionella bozemanæ</i>	+	
<i>Legionella longbeachæ</i>	+	
<i>Legionella wadsworthii</i>	+	
<i>Legionella jordanis</i>	+	
<i>Legionella feeleyi</i>	+	+
<i>Legionella oakridgensis</i>	+	
<i>Legionella birminghamensis</i>	+

<i>Legionella parisiensis</i>	+	
<i>Legionella saintelensis</i>	+	
<i>Legionella tusconensis</i>	+	

They can multiply in free-living amoebas and can coexist with them in biofilms (see Epidemiology and Control). Infection of debilitated or immunocompromised humans commonly follows inhalation of the bacteria from aerosols generated from contaminated air-conditioning systems, shower heads, and similar water sources. *L. pneumophila* usually produces a lobar, segmental, or patchy pulmonary infiltration. Histologically, the appearance is similar to that produced by many other bacterial pathogens. Acute pneumonia involving the alveoli is present with a dense intra-alveolar exudate of macrophages, polymorphonuclear leukocytes, red blood cells, and proteinaceous material. Most of the legionellae in the lesions are within phagocytic cells. There is little interstitial infiltration and little or no inflammation of the bronchioles and upper airways.

Knowledge of the pathogenesis of *L. pneumophila* infection comes from study of isolated cells from humans and from study of susceptible animals such as guinea pigs.

L. pneumophila readily enters and grows within human alveolar macrophages and monocytes and is not effectively killed by polymorphonuclear leukocytes. *Legionella* species do not require opsonization by C3b or antibody to enter macrophages. A virulence factor important for macrophage invasion is the Mip protein, which promotes adherence and phagocytosis. Inside the cell, the individual bacteria are contained within phagosomal vacuoles (Legionella-containing vacuole, LCV), but the defense mechanisms of the macrophages stop at that point. Instead, the LCV fails to fuse with

A

(Courtesy CDC Public Health Image Library.) **B:** Direct fluorescent antibody stain of *Legionella* of mixed species using antibodies against legionellae genus antigens conjugated with fluorescein. Original magnification $\times 1000$. (Courtesy R Nadarajah.)

lysosomal granules. The phagocyte oxidative metabolic burst is reduced. The LCV does not acidify as much as phagosomes containing other ingested particles. Ribosomes, mitochondria, and small vesicles accumulate around LCVs, preventing recognition by the cellular immune system. In addition to this process, phagosome survival and organism replication are facilitated by elaboration of a type IV secretion system call Dot/Icm, which is essential for *L. pneumophila* virulence. The bacteria multiply within the vacuoles until they are numerous, the cells are destroyed, the bacteria are released, and infection of other macrophages then occurs. The presence of iron (transferrin iron) is also essential for the process of intracellular growth of the bacteria.

Clinical Findings

Asymptomatic infection is common in all age groups, as shown by elevated titers of specific antibodies. The incidence of clinically significant disease is highest in men after age 55 years. Disease in children has been reported but remains rare. Factors associated with high risk include smoking, alcohol misuse, diabetes mellitus, chronic bronchitis and emphysema or cardiovascular disease, steroid and other immunosuppressive treatment (as in renal transplantation), cancer chemotherapy, and, more recently, as a complication of antitumor necrosis factor (TNF)- α therapy, especially infliximab or adalimumab. When pneumonia occurs in patients with these risk factors, *Legionella* should be investigated as the cause.

Infection may result in nondescript febrile illness of short duration or in a severe, rapidly progressive illness with high fever, chills, malaise, nonproductive cough, hypoxia, diarrhea, and delirium. Chest radiography reveals patchy, often multilobar consolidation. Immunocompromised patients may develop cavitory pneumonia and pleural effusions. There may be leukocytosis, hyponatremia, hematuria (and even renal failure), or abnormal liver function. During some outbreaks, the mortality rate has reached 10%. The diagnosis is based on the clinical picture and exclusion of other causes of pneumonia by laboratory tests. Demonstration of *Legionella* species in clinical specimens can rapidly yield a specific diagnosis. The *Legionella* urinary antigen test may be used early in the course of infection with *L. pneumophila* serogroup 1 and is very helpful when the result is positive. The diagnosis can also be made by culture for *Legionella* species or by serologic tests, but results of these tests are often delayed beyond the time when specific therapy must be started.

L. pneumophila also produces a disease called “Pontiac fever” after the clinical syndrome that occurred in an outbreak in Michigan. The syndrome is characterized by fever and chills, myalgia, malaise, and headache that develop over 6–12 hours and persist for 2–5 days. Dizziness, photophobia, neck stiffness, and confusion also occur. Respiratory symptoms are much less prominent in patients with Pontiac fever than in those with Legionnaires’ disease and include mild cough and sore throat. This illness is self-limited and does not require treatment with antibiotics.

Diagnostic Laboratory Tests

A. Specimens

In human infections, the organisms can be recovered from expectorated sputum (when available), bronchial washings, pleural fluid, lung biopsy specimens, or (rarely) blood. Isolation of *Legionella* species from sputum is more difficult because of the predominance of bacteria of the normal microbiota and because often the cough is dry. *Legionella* species are rarely recovered from other anatomic sites.

B. Smears

Legionellae are not demonstrable in Gram-stained smears of clinical specimens. Direct fluorescent antibody tests of

specimens can be diagnostic, but the test has low sensitivity compared with culture and is rarely done directly on clinical specimens. Silver stains are sometimes used on tissue specimens.

C. Culture

Specimens are cultured on BCYE agar with and without antibiotics (see earlier discussion). Cultured organisms can be rapidly identified by immunofluorescence staining. MALDI-TOF MS has the potential to provide rapid diagnosis of culture isolates.

D. Specific Tests

Sometimes *Legionella* antigens can be demonstrated in the patient’s urine by immunologic methods. The urine antigen test is specific for *L. pneumophila* serogroup 1. Thus, the *Legionella* urine antigen test is not useful to diagnose 20–70% of *Legionella* species infections, depending on geographic location, and should not be relied on as the sole test to rule out *Legionella* infections. Molecular assays, such as polymerase chain reaction (PCR), that amplify genes such as *mip* and 16SrRNA, among others, have been used by laboratories capable of developing and verifying their own assays. However, specificity has been an issue related to contamination of reagents with *Legionella* DNA found in water sources. In the United States, there are no FDA-cleared assays that are available for *Legionella* detection.

E. Serologic Tests

Levels of antibodies to legionellae rise slowly during the illness. Serologic tests have a sensitivity of 60–80% and a specificity of 95–99%. Serologic tests are most useful in obtaining a retrospective diagnosis in outbreaks of *Legionella* infections.

Immunity

Infected patients make antibodies against *Legionella* species, but the peak antibody response may not occur until 4–8 weeks after infection. The roles of antibodies and cell-mediated responses in protective immunity in humans have not been defined. Animals challenged with sublethal doses of virulent *L. pneumophila*, avirulent *L. pneumophila*, or a major secretory protein vaccine are immune to subsequent lethal doses of *L. pneumophila*. Both humoral and cell-mediated immune responses occur. The cell-mediated response is important in protective immunity because of the intracellular infection and growth of *Legionella*.

Treatment

L. pneumophila are intracellular parasites of macrophages, other phagocytic cells, and probably of other human cells as well. Other *Legionella* species may also show significant growth within human macrophages. Thus, antimicrobials useful for treatment of *Legionella* infections must enter the

phagocytes and have biological activity there. Macrolides (erythromycin, azithromycin, telithromycin, and clarithromycin), quinolones (ciprofloxacin and levofloxacin), and tetracyclines (doxycycline) are effective. β -Lactams, monobactams, and aminoglycosides are not effective; in addition, many legionellae make β -lactamases. Prolonged therapy, up to 3 weeks, may be required depending on the clinical situation. Therapy should not be discontinued until the patient has been afebrile for 48–72 hours.

Epidemiology and Control

Peak season for *Legionella* infections is late summer to autumn. Travel, particularly on cruise ships, may be a risk factor. Transmission is usually the result of inhalation or ingestion followed by aspiration of aerosols from contaminated water systems. The natural habitats for legionellae are lakes, streams, rivers, and especially thermally heated bodies of water and soil. Legionellae grow best in warm water in the presence of amebas and water bacteria. They proliferate in amebas much as they do in pulmonary macrophages in the lung. When harsh environmental conditions occur and the amebas encyst, the amebas and legionellae both survive until better growth conditions occur, allowing excystment. The legionellae, amebas, and other microorganisms exist in biofilms; the legionellae go into a sessile state. The legionellae survive water treatment processes, and small numbers enter the water distribution systems, where they proliferate.

Cooling towers and evaporative condensers can be heavily contaminated with *L. pneumophila*. Presumably, aerosols exiting such towers or condensers spread the organisms to susceptible persons. Similarly, there are links between contamination of residential water systems and community-acquired Legionnaires' disease and between contamination of hospital water systems and nosocomial *L. pneumophila* infection. Hyperchlorination and superheating of water can help control the multiplication of legionellae in water and in air-conditioning systems. More effective measures include point of use filters, copper–silver ionization, and possibly chlorine dioxide or monochloramine (see Lin et al, 2011).

Concept Checks

- *Legionella* species are ubiquitous, poorly staining Gram-negative bacteria that inhabit fresh water and a variety of potable water systems, where they survive within amebas and biofilms. Humans acquire infections from inhalation of contaminated water.
- There are more than 50 species of *Legionella*, but most infections are caused by *L. pneumophila* serogroup 1. Patients at risk for infection include those who are immunocompromised, such as bone marrow and solid organ transplant recipients; patients who smoke or have chronic lung disease; and patients with diabetes mellitus.
- Legionnaire's disease is a multisystem infection that includes pneumonia, gastrointestinal symptoms, delirium,

and a variety of laboratory abnormalities. *Legionella* pneumonia is indistinguishable from other bacterial causes of lower respiratory tract infections.

- Diagnosis rests on a strong clinical specimen and the use of *Legionella* urinary antigen testing and culture. Serology is largely retrospective and insensitive. Molecular diagnostic tests are not widely available and may lack specificity.
- *Legionella* species are intracellular pathogens, and hence only antibiotics capable of intracellular penetration such as macrolides and fluoroquinolones should be used for treatment.
- Hospitals that care for immunocompromised patients should monitor potable water systems for the presence of *Legionella* species and treat the water if they are found. Local public health authorities and the Centers for Disease Control and Prevention can provide guidance for testing and treatment.

BARTONELLA

The three most prevalent species of medical importance in the genus *Bartonella* are *Bartonella bacilliformis*, the cause of Oroya fever and verruga peruana; *Bartonella quintana*, the cause of trench fever and some cases of bacillary angiomatosis; and *Bartonella henselae*, which causes cat-scratch disease and has also been associated with bacillary angiomatosis. These diseases have many common characteristics. There is an additional small set of *Bartonella* species and subspecies that have rarely been associated with human disease, primarily endocarditis, and these are *Bartonella elizabethae*, *Bartonella vinsonii* subsp. *berkhoffi*, *B. vinsonii* subsp. *arupensis*, *Bartonella koehlerae*, and *Bartonella alsatica*. There is a larger set associated with animals, and transmission to humans from these animal reservoirs has not yet been described.

The *Bartonella* species are intracellular, Gram-negative rods that are pleomorphic, slow growing, and difficult to isolate in the laboratory. They can be seen in infected tissues stained with the Warthin-Starry silver impregnation stain.

Bartonella Bacilliformis

There are two stages of *B. bacilliformis* infection. The initial stage is **Oroya fever**, a serious infectious anemia. The second is the eruptive stage, **verruca peruana**, which commonly begins 2–8 weeks later, although verruga may also occur in the absence of Oroya fever.

Oroya fever is characterized by the rapid development of severe anemia caused by the red blood cell destruction, enlargement of the spleen and liver, and hemorrhage into the lymph nodes. Masses of bartonellae fill the cytoplasm of cells lining the blood vessels, and endothelial swelling may lead to vascular occlusion and thrombosis. The mortality rate of untreated Oroya fever can be as high as 85%. The diagnosis is made by examining stained blood smears and blood cultures in semisolid medium.

Weeks to months following acute infection, a second stage of infection called verruga peruana, characterized by vascular nodular skin lesions that occur in successive crops, appears. This infection lasts for about 1 year and produces little systemic reaction and no fatalities. Mucosal and internal lesions have been described. *Bartonellae* can be seen in the granulomas; blood culture results are often positive, but there is no anemia.

B. bacilliformis produces an extracellular protein called deformin that promotes deformity (indentation) of red blood cell membranes, and flagella provide the organisms with the mechanical force to invade red blood cells. Replication of the organism occurs within an endocytic vacuole facilitated by outer membrane proteins and erythrocyte membrane fragments created at the time of attachment and membrane deformity. *B. bacilliformis* also invades endothelial cells and other types of human cells in vitro.

Bartonellosis is limited to the mountainous areas of the American Andes in tropical Peru, Colombia, and Ecuador, and is transmitted by sandflies of the genus *Lutzomyia*.

B. bacilliformis grows in semisolid nutrient agar containing 10% rabbit serum and 0.5% hemoglobin. After 10 days or more of incubation at 28°C, turbidity develops in the medium, and rod-shaped and granular organisms can be seen in Giemsa-stained smears.

Ciprofloxacin, doxycycline, macrolides, or sulfamethoxazole–trimethoprim given for at least 10 days has been used to successfully treat patients. Parenteral therapy can be used if the patient is unable to absorb oral medication. Chloramphenicol for 14 days has been used to effectively treat *B. bacilliformis* infections particularly in South America. Coupled with blood transfusions, when indicated, antimicrobial therapy greatly reduces the mortality rate. Control of the disease depends on elimination of the sandfly vectors; insecticides, insect repellents, and elimination of sandfly breeding areas are of value. Prevention with antibiotics may be useful.

Bartonella henselae* and *Bartonella quintana

A. Cat-Scratch Disease

Cat-scratch disease is usually a benign, self-limited illness manifested by fever and lymphadenopathy that develop 1–3 weeks after contact with a cat (usually a scratch, lick, bite, or perhaps a flea bite). A primary skin lesion (papule or pustule) develops at the site. The patient usually appears well but may have low-grade fever and occasionally headache, malaise, and sore throat. The regional lymph nodes (axillary, epitrochlear, or cervical most commonly) are markedly enlarged and sometimes tender, and they may not subside for several weeks or even months. They may suppurate and discharge pus. Atypical cases (5–10%) may be characterized by preauricular lymphadenopathy and conjunctivitis (Parinaud's oculoglandular syndrome). More serious systemic features, such as meningitis, encephalopathy, bone lesions, and

retinitis, have been described. More than 22,000 cases a year are thought to occur in the United States.

The diagnosis of cat-scratch disease is based on (1) a suggestive history and physical findings; (2) aspiration of pus from lymph nodes that contain no bacteria culturable by routine methods; and (3) characteristic histopathologic findings with granulomatous lesions, which may include bacteria seen on silver-impregnated stains. A positive skin test result has also been included as a criterion, but is of historical interest only. A titer of 1:64 or greater in a single serum in the indirect fluorescent antibody (IFA) test strongly supports the diagnosis, but development of a diagnostic titer may be delayed or may not occur in immunocompromised patients. Enzyme immunoassays are available but may be less sensitive than IFA.

Cat-scratch disease is caused by *B. henselae*, a small, pleomorphic, Gram-negative rod present mainly in the walls of capillaries near follicular hyperplasia or within microabscesses. The organisms are seen best in tissue sections stained with Warthin-Starry silver impregnation stain; they may also be detected by immunofluorescent stains. Culture of *B. henselae* is generally not recommended for this relatively benign disease.

The reservoir for *B. henselae* is domestic cats, and one-third of cats or more (and possibly their fleas) may be infected. Contact with infected cats through skin lesions is thought to transmit the infection.

Cat-scratch disease occurs commonly in immunocompetent people and is usually self-limited. Treatment is mainly supportive: reassurance; hot, moist soaks; and analgesics. Aspiration of pus or surgical removal of an excessively large lymph node may ameliorate symptoms. While anecdotal reports demonstrate that tetracycline, azithromycin, trimethoprim–sulfamethoxazole, rifampin, gentamicin, or fluoroquinolone therapy may be helpful, more recent analyses do not support treatment with antibiotics.

B. Bacillary Angiomatosis

Bacillary angiomatosis is a disease predominantly of immunosuppressed individuals, particularly individuals with AIDS. Rare cases occur in immunocompetent persons. Bacillary angiomatosis is characterized histopathologically as circumscribed lesions with lobular capillary proliferation and round, open vessels with cuboidal endothelial cells protruding into the vascular lumen. A prominent finding is epithelioid histiocytes surrounded by a loose fibromyxoid matrix. The pleomorphic bacilli can be seen in the subendothelial tissue when stained with the Warthin-Starry silver impregnation stain. The lesions may be infiltrated by polymorphonuclear leukocytes.

In its common form, bacillary angiomatosis presents as an enlarging red (cranberry-like) papule, often with surrounding scale and erythema. The lesions enlarge and may become several centimeters in diameter and ulcerate. There may be single or many lesions. The clinical appearance is often similar to that of Kaposi sarcoma in AIDS patients, but the two diseases are different histologically. Bacillary angiomatosis occurs in virtually every organ. Involvement of the liver (and spleen)

is characterized by a proliferation of cystic blood-filled spaces surrounded by a fibromyxoid matrix containing the bacteria; this form of the disease is called **peliosis hepatis** and is usually accompanied by fever, weight loss, and abdominal pain. A bacteremic form of infection with the nonspecific signs of malaise, fever, and weight loss also occurs.

The diagnosis is confirmed by the characteristic histopathologic findings and demonstration of the pleomorphic bacilli on silver-stained sections. *B. henselae* and *B. quintana* can be isolated by direct culture of biopsies of involved tissue carefully obtained so that no contaminating skin bacteria are present. The biopsy specimens are homogenized in supplemented tissue culture medium and inoculated onto fresh chocolate agar and heart infusion agar with 5% rabbit blood. Cultures of blood obtained by the lysis centrifugation method can be inoculated onto the same media. The cultures should be incubated in 5% CO₂ at 36°C for a minimum of 3 weeks. Specimens can also be cultured on eukaryotic tissue culture monolayers. Biochemically, *B. henselae* and *B. quintana* are relatively inert, including negative catalase and oxidase reactions and negative carbohydrate utilization tests. Enzyme activity can be seen with amino acid substrates by methods to test for preformed enzymes. Definitive identification is obtained by sequencing all or part of the 16S ribosomal RNA gene amplified by the PCR. Because of the difficulty in recovering *Bartonella* species from clinical material and the insensitivity to date of molecular methods, serologic testing is still considered by many to be the best option. IFA tests are the most frequently used.

Bacillary angiomatosis is treated with oral erythromycin (drug of first choice) or doxycycline (plus gentamicin for very ill patients) for a minimum of 2 months. The often rapid response of skin lesions to erythromycin is believed to be due to its anti-inflammatory and anti-angiogenic effects. Relapses are common but can be treated by the same initial drug regimen.

C. Trench Fever

Trench fever (also known as quintan fever) is characterized by sudden onset of fever accompanied by headache, malaise, restlessness, and shin pain. Symptoms coincide with release of *B. quintana* in blood every 3–5 days with each episode lasting 5 days. A prominent affliction seen during World War I, *B. quintana* is now more frequently seen as a cause of culture-negative endocarditis and bacteremia in homeless individuals.

The reservoir for *B. henselae* usually is the domestic cat, and patients with this organism as the etiology of bacillary angiomatosis often have contact with cats or histories of cat flea bites. The only known reservoirs for *B. quintana* are humans and the body louse.

Concept Checks

- *Bartonella* species are small Gram-negative rods that are found among animals, humans, and their vectors.
- The human pathogens include *B. bacilliformis*, which causes acute Oroya fever and chronic verruga peruana primarily among populations in the Andes, and *B. quintana*,

which is responsible for trench fever, endocarditis, and bacillary angiomatosis. *B. henselae* can cause endocarditis, cat-scratch disease, and bacillary angiomatosis. Infection is acquired by the bite or scratch from a cat or perhaps a bite from cat fleas.

- Diagnosis of *B. henselae* infections may be difficult because they are slow growing and grow best on media containing rabbit blood or chocolate agar. Demonstration of organisms in tissue using Warthin-Starry stains is possible. Serologic diagnosis is the mainstay.
- Treatment of *Bartonella* infections includes azithromycin or other macrolides, fluoroquinolones, and doxycycline.

STREPTOBACILLUS MONILIFORMIS

Streptobacillus moniliformis is an aerobic, Gram-negative, highly pleomorphic organism that forms irregular chains of bacilli interspersed with fusiform enlargements and large round bodies. It grows best at 37°C in media containing serum protein, egg yolk, or starch, but ceases to grow at 22°C. L forms can easily be demonstrated in most cultures of the organism. Subculture of pure colonies of L forms in liquid media often yields the streptobacilli again. Previously believed to be the only species in the genus, recently it has been joined by a novel species officially named *Streptobacillus hongkongensis* sp. nov. *S. moniliformis* is a normal inhabitant of the throats of rats, and humans can be infected by rat bites. The human disease (**rat-bite fever**) is characterized by septic fever, blotchy and petechial rashes, and very painful polyarthritides. Other types of presentations include bacteremia, endocarditis, and abscesses. Diagnosis rests on cultures of blood, joint fluid, or pus; on mouse inoculation (not done in clinical laboratories); and on serum agglutination tests. This organism can also produce infection after being ingested in milk. The disease is called Haverhill fever and has occurred in epidemics.

The reservoir for *S. hongkongensis* is unknown. This organism has been recovered from a peritonsillar abscess and a septic elbow from separate patients in Hong Kong.

Penicillin, third-generation cephalosporins, and some fluoroquinolones all have activity against *S. moniliformis* and *S. hongkongensis*.

Rat-bite fever of somewhat different clinical appearance (sodoku) is caused by *Spirillum minus* (see Chapter 24).

WHIPPLE DISEASE

Whipple disease is characterized by fever, abdominal pain, diarrhea, weight loss, and migratory polyarthralgia most commonly in middle-aged men. The primary site of involvement is the small intestine and mesenteric lymph nodes, but any organ can be affected; most notably, musculoskeletal, neurologic, cardiac, and ophthalmic manifestations are described. Histologically, there is a prominent macrophage infiltration and glycoprotein deposition. Characteristic

vacuoles within the macrophage that stain with periodic acid–Schiff (PAS) stain (foamy macrophages) are pathognomonic of the disease. The intracellular and extracellular PAS-positive materials are bacilli. Historically, routine cultures of clinical specimens have been negative, but more recently the organism has been cultured in association with eukaryotic cells (human fibroblasts, deactivated peripheral blood monocytes). Before the organism was successfully cultured, PCR amplification of bacterial 16S ribosomal RNA allowed identification of a unique sequence from the bacteria in the lesions. Phylogenetic analysis has shown the organism is a Gram-positive actinomycete not closely related to any known genus. The organism has been named *Tropheryma whippelii*. The diagnosis of Whipple disease is by PCR amplification of an appropriate specimen (bowel biopsy, brain biopsy, etc) for *T. whippelii*.

REVIEW QUESTIONS

- Humans become infected with *L. pneumophila* by
 - Kissing a person who is a legionella carrier
 - Breathing aerosols from environmental water sources
 - Receiving a mosquito bite
 - Consuming undercooked pork
- An 11-year-old girl developed an acute onset of fever, chills, headache, vomiting, and severe migratory arthralgias (joint pain) and myalgias (muscle pain). Two days later, she developed a maculopapular rash over her palms, soles, and extremities. At the same time, her left knee became extremely painful and swollen. On examination, fluid was demonstrated in the knee. Further history disclosed that the patient had a pet rat. Culture of the fluid from her knee on 5% sheep blood agar showed 2-mm colonies after 3 days of incubation. Broth culture showed small puffball-like growth. Gram-staining showed a Gram-negative bacillus 0.5 μm wide and 1–4 μm long. Some extremely long forms (up to 150 μm) with beadlike chains, fusiform swellings, and large round bodies were seen. The microbiologist who observed the Gram-stained smear immediately knew the cause of the girl's infection to be
 - Pasteurella multocida*
 - Streptobacillus moniliformis*
 - Francisella tularensis*
 - B. bacilliformis*
 - Yersinia pestis*
- A 70-year-old man presents with bilateral pneumonia. His *Legionella* urinary antigen test result is positive. Which of the following is the likely cause of his pneumonia?
 - L. pneumophila* serogroup 1
 - L. micdadei* serogroup 4
 - Legionella bozemanii* serogroup 2
 - L. longbeachae* serogroup 2
 - All of the above because the urinary antigen test is genus specific and not species or serotype specific.
- A 65-year-old man comes to the emergency department feeling feverish and "really tired." He has a chronic cigarette cough, but this has dramatically increased in the past week and he has been producing whitish sputum. The previous day he had a temperature of 38°C and watery diarrhea. Physical examination reveals inspiratory and expiratory wheezes and rales over the right lower lung field. Chest radiography shows a patchy right lower lobe infiltrate. The differential diagnosis of this patient's disease is
 - Streptococcus pneumoniae* pneumonia
 - L. pneumophila* pneumonia
 - Haemophilus influenzae* pneumonia
 - Mycoplasma pneumoniae* pneumonia
 - All of the above
- Routine sputum cultures for the patient in Question 4 grow normal microbiota. Treatment with ampicillin for 2 days yields no improvement. A diagnosis of Legionnaires' disease is considered, and bronchoscopy is done to obtain bronchial alveolar lavage fluid and deep airway specimens. Which of the following would suggest a diagnosis of disease caused by *L. pneumophila* serotype 1?
 - Legionella urinary antigen assay
 - Direct fluorescent antibody on the bronchial alveolar lavage fluid
 - Culture of the bronchial alveolar lavage on charcoal yeast extract medium with antibiotics
 - Antibody assay on paired (acute phase and convalescent phase) sera
 - All of the above
- Charcoal is present in buffered charcoal yeast extract agar used to isolate *L. pneumophila* to
 - Provide the growth factors ordinarily provided by free-living amebas present in environmental water
 - Serve as a carbon source for the growth of *L. pneumophila*
 - Prevent hemolysis of the red blood cells in the medium
 - Provide a dark background
 - Act as a detoxifying agent
- A 23-year-old, otherwise healthy woman presents with a 3-day history of low-grade fever and headache. Examination reveals enlarged and slightly tender lymph nodes near her left elbow and in the left axilla. Approximately 2 weeks earlier, she had visited a friend whose cat had scratched her on the left arm; the site later developed a reddish papule. Which of the following statements about this disease is correct?
 - Characteristic histopathology in response to infection is acute, neutrophilic inflammation.
 - The diagnosis is based on a suggestive history and physical examination.
 - β -Lactam/ β -lactamase inhibitor combinations are the agents of choice for treatment.
 - The diagnosis is based on negative routine bacterial cultures of pus aspirated from involved lymph nodes.
 - The disease rapidly leads to sepsis even in immunocompetent people.
- Which of the following statements about bacillary angiomatosis is most correct?
 - It is caused by *B. bacilliformis*.
 - It is typically confined to the skin.
 - The major differential diagnosis is Kaposi sarcoma.
 - The etiologic agent can be grown in 1–2 days in routine culture on sheep blood agar.
 - Dogs are the reservoir for the etiologic agent.
- An important factor in the pathogenesis of Legionnaires' disease is that
 - L. pneumophila* kills polymorphonuclear cells.
 - Alveolar macrophages phagocytose *L. pneumophila* using coiled pseudopods.

- (C) *L. pneumophila* invades pulmonary capillaries, leading to dissemination and systemic illness.
- (D) *L. pneumophila* induces alveolar macrophage phagosomes to fuse with lysosomes.
- (E) *L. pneumophila* outer surface protein A (OspA) is important for invasion of alveolar macrophages.
10. True statements regarding *T. whippelii* include all of the following *except*
- (A) It is easy to cultivate on chocolate agar after 3 days of incubation.
- (B) It is a Gram-positive actinomycete.
- (C) It causes fever, abdominal pain, diarrhea, weight loss, and migratory polyarthralgia.
- (D) It stains with PAS.
11. All of the statements below regarding infections with *Legionella* are correct *except*
- (A) Hospitals that care for patients at risk for *Legionella* infections should know if their potable water systems contain *Legionella*.
- (B) Human-to-human transmission is the major mechanism of transmission of *Legionella* infection.
- (C) *Legionella* species can be visualized with Gram-stain if carbolfuchsin is used for the counter stain.
- (D) The chest radiograph of a patient who has *Legionella* pneumonia is indistinguishable from that of patients with pneumonia caused by other pathogens.
- (E) A macrolide or quinolone are the drugs of first choice for treatment of *Legionella* infections.
12. Which of the following best represents the role of the Mip protein in *Legionella* pathogenesis?
- (A) It prevents phagosome–lysosome fusion.
- (B) It acts as a siderophore to capture iron.
- (C) It prevents phagocytosis.
- (D) It facilitates adherence to the macrophage and stimulates cellular invasion.
- (E) None of the above.
13. Pontiac fever is a severe form of pneumonia caused by *L. pneumophila* serotypes 1 and 6.
- (A) True
- (B) False
14. All of the following statements regarding *S. moniliformis* are correct *except*
- (A) It is susceptible to penicillin.
- (B) It causes the disease rat-bite fever.
- (C) It causes Haverhill fever from ingestion of contaminated food.
- (D) The morphology of the organism is spiral shaped.

15. The diagnosis of Whipple's disease is best made by
- (A) Paired serum obtained 8 weeks apart
- (B) Prolonged culture on mycobacterial media
- (C) Nucleic acid amplification testing performed on tissue
- (D) Histopathology
- (E) None of the above

Mycobacteria

The mycobacteria are rod-shaped, aerobic bacteria that do not form spores. The cell wall contains peptidoglycolipids, mycolic acids, and other fatty acids and waxes; many of these compounds are responsible for the various characteristics of mycobacteria (eg, slow growth, acid fastness, resistance to detergents, and common antibiotics). Because of their high lipid content in their cell walls, mycobacteria do not stain well with common aniline dyes, including the regular Gram-stain method. Special staining procedures, using phenol-based, arylmethane dyes (eg, carbolfuchsin), are used instead to stain mycobacteria. Due to the high content of mycolic acids in their cell wall, mycobacteria retain these dyes even after exposure to strong alcohol-acid or mineral-acid solutions. Therefore, mycobacteria are described as “acid-fast” organisms. There are more than 200 *Mycobacterium* species, including many that are saprophytes. The mycobacteria that infect humans are listed in Table 23-1. By far the most common mycobacterial human pathogens, worldwide, are *M. tuberculosis*, *M. leprae*, and *M. ulcerans*. *Mycobacterium tuberculosis* causes tuberculosis and is a very important pathogen of humans. *Mycobacterium leprae* causes leprosy (Hansen’s disease), which is a chronic granulomatous and debilitating disease. *Mycobacterium ulcerans* causes necrotizing skin and soft tissue infections, which are characterized by formation of ulcers that progressively enlarge over time, if left untreated. In Africa, the disease is known as Buruli ulcer, whereas in Australia, the disease is called Bairnsdale ulcer. *Mycobacterium avium-intracellulare* (*M. avium* complex, or MAC) and other nontuberculous mycobacteria (NTM) frequently infect patients with AIDS are opportunistic pathogens in other immunocompromised persons, and occasionally cause disease in patients with normal immune systems.

MYCOBACTERIUM TUBERCULOSIS

Morphology and Identification

A. Typical Organisms

In tissue, *M. tuberculosis* and other mycobacteria are thin, straight rods measuring about $0.4 \times 3 \mu\text{m}$ (Figure 23-1). On artificial media, coccoid and filamentous forms are seen with

variable morphology from one species to another. Because of their high lipid content in their cell walls, mycobacteria do not stain well with common aniline dyes, including the regular Gram-stain method. The organisms typically appear as “Gram-invisible” or appear as clear zones (“ghosts”). Some mycobacteria, specifically some of the rapid growers, may appear as beaded Gram-positive rods, but branching may not be observed. The extent of acid fastness depends on the integrity and amount of the mycolic acids within the organisms’ cell wall. Aside from mycobacteria, some other bacteria also express the acid-fast staining characteristic; these bacterial organisms include the genus *Nocardia*, *Rhodococcus*, *Gordonia*, and *Tsukamurella*. The **Ziehl-Neelsen technique** of staining is used for identification of acid-fast bacteria. The method is detailed in Chapter 47. In smears of sputum or sections of tissue, mycobacteria can be demonstrated by yellow-orange fluorescence after staining with fluorochrome stains (eg, auramine and rhodamine). The ease with which acid-fast bacteria can be visualized with fluorochrome stains makes them the preferred stains for clinical specimens (Figure 23-1B). The availability of ultrabright light-emitting diode microscopes, some of which do not require electricity, has advanced fluorescence microscopy in resource-limited countries.

B. Culture

The media for primary culture of mycobacteria should include a nonselective medium and a selective medium. Selective media contain antibiotics to prevent the overgrowth of contaminating bacteria and fungi. There are three general formulations that can be used for both the nonselective and selective media. Agar-based (solid) media are useful for observing colony morphology, for detection of mixed cultures, for antimicrobial susceptibility testing, and can also provide some indication of the quantity of organisms in a particular specimen.

1. Semisynthetic agar media—These media (eg, Middlebrook 7H10 and 7H11) contain defined salts, vitamins, cofactors, oleic acid, albumin, catalase, and glycerol; the 7H11 medium also contains casein hydrolysate. The albumin neutralizes the toxic and inhibitory effects of fatty acids in the

TABLE 23-1 Mycobacteria That Infect Humans

Species	Reservoir	Common Clinical Manifestations; Comment
SPECIES ALWAYS CONSIDERED PATHOGENS		
<i>Mycobacterium tuberculosis</i>	Humans	Pulmonary and disseminated tuberculosis; millions of cases annually in the world
<i>Mycobacterium leprae</i>	Humans	Leprosy
<i>Mycobacterium bovis</i>	Humans, cattle	Tuberculosis-like disease; rare in North America; <i>M. bovis</i> is closely related to <i>M. tuberculosis</i>
SPECIES POTENTIALLY PATHOGENIC IN HUMANS		
Common causes of disease		
<i>Mycobacterium avium</i> complex	Soil, water, birds, fowl, swine, cattle, environment	Disseminated, pulmonary; very common in untreated AIDS patients; occurs in other immunosuppressed patients; uncommon in patients with normal immune systems
<i>Mycobacterium kansasii</i>	Water, cattle	Pulmonary, other sites
<i>Mycobacterium ulcerans</i>	Humans, environment	Subcutaneous nodules and ulcers; may be severe; <i>M. ulcerans</i> is closely related to <i>M. marinum</i> ; the organism takes 6–12 weeks to grow on agar media; growth at 33°C suggests an environmental source for the infection; the global disease burden has long been underestimated, and today <i>M. ulcerans</i> disease is the third most common mycobacterial disease after <i>M. tuberculosis</i> and <i>M. leprae</i>
Uncommon to very rare causes of disease		
<i>Mycobacterium africanum</i>	Humans, monkeys	Pulmonary cultures; resembles <i>M. tuberculosis</i> ; rare
<i>Mycobacterium genavense</i>	Humans, pet birds	Blood in AIDS patients; grows in liquid medium (BACTEC) and on solid medium supplemented with mycobactin J; grows in 2–8 weeks
<i>Mycobacterium haemophilum</i>	Unknown	Subcutaneous nodules and ulcers primarily in AIDS patients; requires hemoglobin or hemin; grows at 28–32°C; rare
<i>Mycobacterium malmøense</i>	Unknown, environment	Pulmonary, tuberculosis-like (adults), lymph nodes (children); most reported cases are from Sweden, but organism may be much more widespread; <i>M. malmøense</i> is closely related to <i>M. avium-intracellulare</i> ; takes 8–12 weeks to grow
<i>Mycobacterium marinum</i>	Fish, water	Subcutaneous nodules and abscesses, skin ulcers
<i>Mycobacterium scrofulaceum</i>	Soil, water, moist foods	Cervical lymphadenitis; usually cured by incision, drainage, and removal of involved lymph nodes
<i>Mycobacterium nonchromogenicum</i>	Environment	The primary pathogen in the <i>M. terrae</i> complex. Causes tenosynovitis of the hand
<i>Mycobacterium simiae</i> (new members of <i>M. simiae</i> complex include <i>M. lentiflavum</i> , <i>M. triplex</i> , and <i>M. europaeum</i>)	Monkeys, water	Pulmonary, disseminated in AIDS patients; rare
<i>Mycobacterium szulgai</i>	Unknown	Pulmonary, tuberculosis-like; rare
<i>Mycobacterium xenopi</i>	Water, birds	Pulmonary, tuberculosis-like with preexisting lung disease; rare
Rapid growers		
<i>Mycobacterium abscessus</i>	Soil, water, animals	Most frequently isolated rapid grower from pulmonary infections; skin and soft tissue infections; frequently multidrug resistant
<i>Mycobacterium chelonae</i>	Soil, water, animals, marine life	Cutaneous lesions most common, subcutaneous abscesses, disseminated infections in immunocompromised patients
<i>Mycobacterium fortuitum</i>	Soil, water, animals	Consists of a complex of organisms that can only be differentiated by molecular methods; associated with nail salon furunculosis; pulmonary infections similar to <i>M. abscessus</i>
<i>Mycobacterium immunogenum</i>	Environment	Associated with pseudo-outbreaks linked to contaminated equipment in hospitals; isolates have been associated with joint disease, skin ulcers, catheter infections, and some pulmonary disease; closely related to <i>M. chelonae-abscessus</i>
<i>Mycobacterium mucogenicum</i>	Unknown	CVC-associated infections are the most important infections associated with this organism; name reflects its mucoid appearance in culture

(Continued)

TABLE 23-1 Mycobacteria That Infect Humans (Continued)

Species	Reservoir	Common Clinical Manifestations; Comment
SAPROPHYTIC SPECIES THAT VERY RARELY CAUSE DISEASE IN HUMANS		
<i>Mycobacterium gordonae</i>	Water	These saprophytic <i>Mycobacterium</i> species are very uncommon causes of disease in humans; positive culture results for these mycobacteria usually represent environmental contamination of specimens and not disease; many of the saprophytic mycobacteria grow best at temperatures <33°C; there are many other saprophytic <i>Mycobacterium</i> species not listed here that seldom, if ever, appear in cultures of patients' specimens
<i>Mycobacterium flavescens</i>	Soil, water	
<i>Mycobacterium fallax</i>	Soil, water	
<i>Mycobacterium gastri</i>	Gastric washings	
<i>Mycobacterium smegmatis</i>	Soil, water	
<i>Mycobacterium terrae complex</i>	Soil, water	

CVC, central venous catheter.

specimen or medium. Large inocula yield growth on these media in several weeks. Because large inocula may be necessary, these media may be less sensitive than other media for primary isolation of mycobacteria.

2. Inspissated egg media—These media (eg, Löwenstein-Jensen) contain defined salts, glycerol, and complex organic substances (eg, fresh eggs or egg yolks, potato flour, and other ingredients in various combinations). Malachite green is included to inhibit other bacteria. Small inocula in specimens from patients will grow on these media in 3–6 weeks. These media with added antibiotics (Gruft and Mycobactosel) are used as selective media.

3. Broth media—Broth media (eg, Middlebrook 7H9 and 7H12) support the proliferation of small inocula. Ordinarily, mycobacteria grow in clumps or masses because of the hydrophobic character of the cell surface. If tweens (water-soluble

esters of fatty acids) are added, they wet the surface and thus permit dispersed growth in liquid media. Growth is often more rapid than on complex media. There are several commercial sources of these media that are used in many clinical and reference laboratories. These include the MGIT system (Becton Dickinson, Sparks, MD), VersaTREK® Culture System (ThermoFisher Scientific, Houston, TX), and MB Redox (Heipha Diagnostica Biotest, Eppelheim, Germany).

C. Growth Characteristics

Mycobacteria are obligate aerobes and derive energy from the oxidation of many simple carbon compounds. Increased CO₂ tension enhances growth. Biochemical activities are not characteristic, and the growth rate is much slower than that of most bacteria. The doubling time of tubercle bacilli is about 18 hours. Saprophytic forms tend to grow more rapidly, to proliferate well at 22–33°C, to produce more pigment, and to be less acid fast than pathogenic forms.

FIGURE 23-1 **A:** *M. tuberculosis* (arrows) in a processed sputum specimen stained by Ziehl-Neelsen stain. The *M. tuberculosis* is red against a blue background. **B:** The fluorescent dye Auramine O was used to stain a sputum sample. It shows two fluorescent *M. tuberculosis*. Original magnification ×1000. (Courtesy of G Cunningham.)

D. Reaction to Physical and Chemical Agents

Mycobacteria tend to be more resistant to chemical agents than other bacteria because of the hydrophobic nature of the cell surface and their clumped growth. Dyes (eg, malachite green) or antibacterial agents (eg, penicillin) that are bacteriostatic to other bacteria can be incorporated into media without inhibiting the growth of tubercle bacilli. Acids and alkalis permit the survival of some exposed tubercle bacilli and are used to help eliminate contaminating organisms and for “concentration” of clinical specimens. Tubercle bacilli are resistant to drying and survive for long periods in dried sputum.

E. Variation

Variation can occur in colony appearance, pigmentation, virulence, optimal growth temperature, and many other cellular or growth characteristics.

F. Pathogenicity of Mycobacteria

There are marked differences in the ability of different mycobacteria to cause lesions in various host species. Humans and guinea pigs are highly susceptible to *M. tuberculosis* infection, but fowl and cattle are resistant. *M. tuberculosis* and *Mycobacterium bovis* are equally pathogenic for humans. The route of infection (respiratory vs intestinal) determines the pattern of lesions. In developed countries, *M. bovis* has become very rare. Some “atypical” mycobacteria, now designated as NTM (eg, *Mycobacterium kansasii*), produce human disease indistinguishable from tuberculosis; others (eg, *Mycobacterium fortuitum*) cause only surface lesions or act as opportunists.

Constituents of Tubercle Bacilli

The constituents listed as follows are found mainly in cell walls. Mycobacterial cell walls can induce delayed hypersensitivity and some resistance to infection and can replace whole mycobacterial cells in Freund’s adjuvant. Mycobacterial cell contents only elicit delayed hypersensitivity reactions in previously sensitized animals.

A. Lipids

Mycobacteria are rich in lipids. These include mycolic acids (long-chain fatty acids C78–C90), waxes, and phosphatides. In the cell, the lipids are largely bound to proteins and polysaccharides. Muramyl dipeptide (from peptidoglycan) complexed with mycolic acids can cause granuloma formation; phospholipids induce caseous necrosis. Lipids are to some extent responsible for acid fastness. Their removal with hot acid destroys acid fastness, which depends on both the integrity of the cell wall and the presence of certain lipids. Acid fastness is also lost after sonication of mycobacterial cells. Analysis of lipids by gas chromatography reveals patterns that aid in classification of different species.

Virulent strains of tubercle bacilli form microscopic “serpentine cords” in which acid-fast bacilli are arranged in parallel chains. Cord formation is correlated with virulence. A “cord factor” (trehalose-6,6’-dimycolate) has been extracted from virulent bacilli with petroleum ether. It inhibits migration of leukocytes, causes chronic granulomas, and can serve as an immunologic “adjuvant.”

B. Proteins

Each type of *Mycobacterium* contains several proteins that elicit the tuberculin reaction. Proteins bound to a wax fraction can, upon injection, induce tuberculin sensitivity. They can also elicit the formation of a variety of antibodies.

C. Polysaccharides

Mycobacteria contain a variety of polysaccharides. Their role in the pathogenesis of disease is uncertain. They can induce the immediate type of hypersensitivity and can serve as antigens in reactions with sera of infected persons.

Pathogenesis

Mycobacteria are emitted in droplets smaller than 25 μm in diameter when infected persons cough, sneeze, or speak. The droplets evaporate, leaving organisms that are small enough, when inhaled, to be deposited in alveoli. Inside the alveoli, the host’s immune system responds by release of cytokines and lymphokines that stimulate monocytes and macrophages. Mycobacteria begin to multiply within macrophages. Some of the macrophages develop an enhanced ability to kill the organism, but others may be killed by the bacilli. Pathogenic lesions associated with infection appear in the lung 1–2 months after exposure. Two types of lesions as described later under Pathology may develop. Resistance and hypersensitivity of the host greatly influence development of disease and the type of lesions that are seen.

Pathology

The production and development of lesions and their healing or progression are determined chiefly by (1) the number of mycobacteria in the inoculum and their subsequent multiplication and (2) the type of host and immune response.

A. Two Principal Lesions

1. Exudative type—This type consists of an acute inflammatory reaction with edema fluid; polymorphonuclear leukocytes; and, later, monocytes around the tubercle bacilli. This type is seen particularly in lung tissue, where it resembles bacterial pneumonia. It may heal by resolution so that the entire exudate becomes absorbed; it may lead to massive necrosis of tissue or may develop into the second (productive) type of lesion. During the exudative phase, the tuberculin test result becomes positive.

2. Productive (proliferative) type—When fully developed, this lesion type, a chronic granuloma, consists of three

zones: (1) a central area of large, multinucleated giant cells containing tubercle bacilli; (2) a mid zone of pale epithelioid cells, often arranged radially; and (3) a peripheral zone of fibroblasts, lymphocytes, and monocytes. Later, peripheral fibrous tissue develops, and the central area undergoes caseation necrosis. Such a lesion is called a *tubercle*. A caseous tubercle may break into a bronchus, empty its contents there, and form a cavity. It may subsequently heal by fibrosis or calcification.

B. Spread of Organisms in the Host

Tubercle bacilli spread in the host by direct extension, through the lymphatic channels and bloodstream, and via the bronchi and gastrointestinal tract.

In the first infection, tubercle bacilli always spread from the initial site via the lymphatics to the regional lymph nodes. The bacilli may spread farther and reach the bloodstream, which in turn distributes bacilli to all organs (miliary distribution). The bloodstream can be invaded also by erosion of a vein by a caseating tubercle or lymph node. If a caseating lesion discharges its contents into a bronchus, they are aspirated and distributed to other parts of the lungs or are swallowed and passed into the stomach and intestines.

C. Intracellular Site of Growth

When mycobacteria establish themselves in tissue, they reside principally intracellularly in monocytes, reticuloendothelial cells, and giant cells. The intracellular location is one of the features that makes chemotherapy difficult and favors microbial persistence. Within the cells of immune animals, multiplication of tubercle bacilli is greatly inhibited.

Primary Infection and Reactivation Types of Tuberculosis

When a host has first contact with tubercle bacilli, the following features are usually observed: (1) An acute exudative lesion develops and rapidly spreads to the lymphatics and regional lymph nodes. The exudative lesion in tissue often heals rapidly. (2) The lymph node undergoes massive caseation, which usually calcifies (Ghon lesion). (3) The tuberculin test result becomes positive.

As described in the early 20th century, primary infection type occurred usually in childhood, and involved any part of the lung but most often the mid-lung fields or the base. Enlarged hilar and mediastinal lymph nodes are frequently observed.

The reactivation type is usually caused by tubercle bacilli that have survived in the primary lesion. Reactivation tuberculosis is characterized by chronic tissue lesions, the formation of tubercles, caseation, and fibrosis. Regional lymph nodes are only slightly involved, and they do not caseate. The reactivation type almost always begins at the apex of the lung, where the oxygen tension (PO_2) is highest.

These differences between primary infection and reinfection or reactivation are attributed to (1) resistance and (2)

hypersensitivity induced by the first infection. It is not clear to what extent each of these components participates in the modified response in reactivation tuberculosis.

Immunity and Hypersensitivity

During the first infection with tubercle bacilli, a certain resistance is acquired, and there is an increased capacity to localize tubercle bacilli, retard their multiplication, limit their spread, and reduce lymphatic dissemination. This can be attributed to the development of cellular immunity, with evident ability of mononuclear phagocytes to limit the multiplication of ingested organisms and even to destroy them.

In the course of primary infection, the host also acquires hypersensitivity to the tubercle bacilli. This is made evident by the development of a positive tuberculin reaction (see later discussion). Tuberculin sensitivity can be induced by whole tubercle bacilli or by tuberculo-protein in combination with the chloroform-soluble wax D of the tubercle bacillus but not by tuberculo-protein alone. Hypersensitivity and resistance appear to be distinct aspects of related cell-mediated reactions.

Tuberculin Test

A. Material

Old tuberculin is a concentrated filtrate of broth in which tubercle bacilli have grown for 6 weeks. In addition to the reactive tuberculo-proteins, this material contains a variety of other constituents of tubercle bacilli and of growth medium. A purified protein derivative (PPD) is obtained by chemical fractionation of old tuberculin. PPD is standardized in terms of its biologic reactivity as tuberculin units (TU). By international agreement, the TU is defined as the activity contained in a specified weight of Siebert's PPD Lot No. 49608 in a specified buffer. This is PPD-S, the standard for tuberculin against which the potency of all products must be established by biologic assay (ie, by reaction size in humans). First-strength tuberculin has 1 TU, intermediate-strength has 5 TU, and second-strength has 250 TU. Bioequivalency of PPD products is not based on the weight of the material but on comparative activity.

B. Dose of Tuberculin

A large amount of tuberculin injected into a hypersensitive host may give rise to severe local reactions and a flare-up of inflammation and necrosis at the main sites of infection (focal reactions). For this reason, tuberculin tests in surveys use 5 TU in 0.1 mL solution; in persons suspected of extreme hypersensitivity, skin testing is begun with 1 TU. The volume is usually 0.1 mL injected intracutaneously, usually on the volar aspect of the forearm. The PPD preparation must be stabilized with polysorbate 80 to prevent adsorption to glass.

C. Reactions to Tuberculin

After the tuberculin skin test is placed, the area is examined for the presence of induration no later than 72 hours after

placement. It is imperative that a person trained in the accurate reading of these tests examine the area in question. Erythema alone should not be interpreted as a reactive test result. The Centers for Disease Control and Prevention (CDC) has established three different cut points defining a positive test result, considering both the sensitivity and specificity of the test and the prevalence of tuberculosis in various populations. For patients at the highest risk of developing active disease (eg, HIV-infected persons and people who have had exposure to persons with active tuberculosis), 5 mm or larger of induration is considered positive; larger than 10 mm is considered positive for persons with increased probability of recent infection. This category might include individuals such as recent immigrants from high-prevalence countries, injection drug users, and health care workers with exposure to tuberculosis. For persons at low risk for tuberculosis, 15 mm or larger of induration is considered a positive test result. In an individual who has not had contact with mycobacteria, there is generally no reaction to PPD-S. Positive test results tend to persist for several days. Weak reactions may disappear more rapidly.

The tuberculin test result becomes positive within 4–6 weeks after infection (or injection of avirulent bacilli). It may be negative in the presence of tuberculous infection when “anergy” develops because of overwhelming tuberculosis, measles, Hodgkin disease, sarcoidosis, AIDS, or immunosuppression. A positive tuberculin test result may occasionally revert to negative upon isoniazid (INH) treatment of a recent converter. After *Bacillus Calmette-Guérin* (BCG) vaccination, people convert to a positive test result, but this may last for only 3–7 years. Only the elimination of viable tubercle bacilli results in reversion of the tuberculin test result to negative. However, persons who were PPD positive years ago and are healthy may fail to give a positive skin test result. When such persons are retested 2 weeks later, their PPD skin test result—“boosted” by the recent antigen injection—will give a positive size of induration again.

A positive tuberculin test result indicates that an individual has been infected in the past. It does not imply that active disease or immunity to disease is present. Tuberculin-positive persons are at risk of developing disease from reactivation of the primary infection, but tuberculin-negative persons who have never been infected are not subject to that risk, although they may become infected from an external source.

D. Interferon-Gamma Release Assays for Detection of Tuberculosis

Sometimes the results of the tuberculin skin test are equivocal, particularly in persons who have been vaccinated with BCG or who live in areas where NTM are highly prevalent in the environment. In an effort to improve diagnostic accuracy, whole-blood interferon- γ release assays (IGRAs) have been commercially developed. These assays are based on the host's immune responses to specific *M. tuberculosis* antigens ESAT-6 (early secretory antigenic target-6), CFP-10

(culture filtrate protein-10), and TB7.7, which are absent from most NTM and BCG. The tests detect interferon- γ that is released by sensitized CD4 T cells in response to these antigens. Currently, two commercial assays are available in the United States. The QuantiFERON-Gold In-Tube test (QFT-GIT) (Cellestis Limited, Carnegie, Victoria, Australia) is an enzyme-linked immunosorbent assay (ELISA) that detects interferon- γ in whole blood. The T-SPOT-TB (Oxford Immunotec, Oxford, UK) is an ELISA ImmunoSpot assay that uses purified peripheral blood mononuclear cells. Results for both tests are reported as positive, negative, or indeterminate. These assays are still undergoing extensive evaluation. They are susceptible to biological variation in the immune response. However, multiple studies have shown that these assays are comparable to the tuberculin skin test in evaluating latent infection, particularly in persons who have received BCG. However, they should not be used in severely immunocompromised hosts or in very young children (<5 years of age). The CDC has drafted updated guidelines summarizing recommendations on the use of the IGRAs (see Mazurek et al, 2010).

Patients that who have newly converted from having a negative to a positive result by skin test or IGRA as well as others who have had a positive test result and meet certain criteria for increased risk of active disease if infected are usually given prophylaxis with INH daily for 9 months. Recently, the CDC has published new recommendations for treatment of latent tuberculosis that significantly shorten the length of therapy to 12 weeks. The new regimen consists of once-weekly treatment with INH and rifapentine by directly observed therapy. The new regimen was shown to be equivalent to the old treatment in three randomized controlled trials.

Clinical Findings

Because the tubercle bacillus can involve every organ system, its clinical manifestations are protean. Fatigue, weakness, weight loss, fever, and night sweats may be signs of tuberculous disease. Pulmonary involvement giving rise to chronic cough and spitting of blood usually is associated with far-advanced lesions. Meningitis or urinary tract involvement can occur in the absence of other signs of tuberculosis. Bloodstream dissemination leads to miliary tuberculosis with lesions in many organs and a high mortality rate.

Diagnostic Laboratory Tests

A positive tuberculin test result does not prove the presence of active disease caused by tubercle bacilli. Isolation of tubercle bacilli provides such proof.

A. Specimens

Specimens consist of fresh sputum, gastric washings, urine, pleural fluid, cerebrospinal fluid, joint fluid, biopsy material, blood, or other suspected material.

B. Decontamination and Concentration of Specimens

Specimens from sputum and other nonsterile sites should be liquefied with *N*-acetyl-L-cysteine decontaminated with NaOH (kills many other bacteria and fungi), neutralized with buffer, and concentrated by centrifugation. Specimens processed in this way can be used for acid-fast stains and for culture. Specimens from sterile sites, such as cerebrospinal fluid, do not need the decontamination procedure but can be directly centrifuged, examined, and cultured.

C. Smears

Sputum, exudate, or other material is examined for acid-fast bacilli by staining. Stains of gastric washings and urine generally are not recommended because saprophytic mycobacteria may be present and yield a positive stain. Fluorescence microscopy with auramine–rhodamine stain is more sensitive than traditional acid-fast stains, such as Ziehl-Neelsen, and is the preferred method for clinical material. If acid-fast organisms are found in an appropriate specimen, this is presumptive evidence of mycobacterial infection.

D. Culture, Identification, and Susceptibility Testing

Processed specimens from nonsterile sites and centrifuged specimens from sterile sites can be cultured directly onto selective and nonselective media (see earlier discussion). The selective broth culture often is the most sensitive method and provides results most rapidly. A selective agar media (eg, Löwenstein-Jensen or Middlebrook 7H10/7H11 biplate with antibiotics) should be inoculated in parallel with broth media cultures. Incubation is at 35–37°C in 5–10% CO₂ for up to 8 weeks. If culture results are negative in the setting of a positive acid-fast stain or if slowly growing NTM (see later) are suspected, then a set of inoculated media should be incubated at a lower temperature (eg, 24–33°C) and both sets incubated for 12 weeks.

Blood for culture of mycobacteria (usually MAC) should be anticoagulated and processed by one of two methods: (1) commercially available lysis centrifugation system or (2) inoculation into commercially available broth media specifically designed for blood cultures. It is medically important to characterize and separate *M. tuberculosis* complex from all the other species of mycobacteria. Isolated mycobacteria should be identified as to species. Conventional methods for identification of mycobacteria include observation of rate of growth, colony morphology, pigmentation, and biochemical profiles. The conventional methods often require 6–8 weeks for identification and are rapidly becoming of historical interest because they are inadequate to identify the expanding numbers of clinically relevant species. Most laboratories have abandoned reliance on these biochemical tests. Growth rate separates the rapid growers (growth in ≤7 days) from other mycobacteria (Table 23-2). **Photochromogens** produce pigment in light but not in darkness, **scotochromogens** develop

TABLE 23-2 Traditional Runyon Classification of Mycobacteria

Classification	Organism

pigment when growing in the dark, and **nonchromogens** (nonphotochromogens) are nonpigmented or have light tan or buff-colored colonies. Molecular probe methods are available for four species (see later) and are much faster than the conventional methods. The probes can be used on mycobacterial growth from solid media or from broth cultures. DNA probes specific for ribosomal RNA (rRNA) sequences of the test organism are used in a hybridization procedure. There are approximately 10,000 copies of the rRNA per mycobacterial cell, providing a natural amplification system, enhancing detection. Double-stranded hybrids are separated from unhybridized single-stranded probes. The DNA probes are linked with chemicals that are activated in the hybrids and detected by chemiluminescence. Probes for the *M. tuberculosis* complex (*M. tuberculosis*, *M. bovis*, *M. africanum*, *M. caprae*, *M. microti*, *M. canettii*, and *M. pinnipedii*), MAC (*M. avium*, *M. intracellulare*, and

closely related mycobacteria), *M. kansasii*, and *Mycobacterium gordonae* are available. The use of these probes has shortened the time to identification of clinically important mycobacteria from several weeks to as little as 1 day.

In the United States, these four groups (*M. tuberculosis* complex, *M. avium* complex, *M. kansasii*, and *M. gordonae*) make up 95% or more of clinical isolates of mycobacteria.

For species that cannot be identified by DNA probes, many laboratories with molecular capabilities have implemented 16S rRNA gene sequencing to rapidly identify probe-negative species or send such organisms to a reference laboratory with sequencing capability.

High-performance liquid chromatography (HPLC) has been applied to the identification of mycobacteria. The method is based on development of profiles of mycolic acids, which vary from one species to another. HPLC is available in reference laboratories to achieve species-level identification for most mycobacteria.

Other methods for species-level identification of mycobacteria recovered from culture include pyrosequencing and matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS). Susceptibility testing of mycobacteria is an important adjunct in selecting drugs for effective therapy. A standardized broth culture technique can be used to test for susceptibility to first-line drugs. The complex and more arduous conventional agar-based technique usually is performed in reference laboratories; first- and second-line drugs can be tested by this method. A modification of liquid broth cultures involves inoculating mycobacteria on a multi-well plate with and without addition of antibiotics (Microscopic Observation Drug Susceptibility, MODS assay) and examining for cording that is characteristic of *M. tuberculosis* complex. This method is largely used outside the United States.

E. Nucleic Acid Amplification Tests (NAATs)

NAATs are available for the rapid and direct detection of *M. tuberculosis* in clinical specimens. An advance over the in-lab-developed PCR tests and the existing FDA-cleared commercial assays is the GeneXpert MTB/RIF test (Cepheid, Sunnyvale, CA), a real-time multiplex PCR method that both identifies the Mtb complex and also detects genes that encode rifampin resistance. One of the earlier publications on this method (see reference Boehme) reported a sensitivity for smear positive respiratory specimens of 98.2% and for smear negative samples, 72.5%. Overall specificity was 99.2%. In terms of the detection of rifampin resistance, the assay does detect the common mutations, but discrepancies between phenotypic test results and genotypic results still challenge complete reliance on this component of the test. This assay is not yet widely available in the United States but is available in other countries.

The characterization of specific strains of *M. tuberculosis* can be important for clinical and epidemiologic purposes. It facilitates tracking transmission, analysis of outbreaks of

tuberculosis, and demonstration of reactivation versus reinfection in individual patients. DNA fingerprinting is done using a standardized protocol based on restriction fragment length polymorphism. Many copies of the insertion sequence 6110 (IS6110) are present in the chromosome of most strains of *M. tuberculosis*, and these are located at variable positions. DNA fragments are generated by restriction endonuclease digestion and separated by electrophoresis. A probe against IS6110 is used to determine the genotypes. Other useful methods for strain characterization include spoligotyping, a PCR-based technique that targets the direct repeat locus of *M. tuberculosis* and mycobacterial interspersed repetitive units-variable number of tandem repeats (MIRU-VNTR) analysis. The latter method is slowly replacing IS6110 typing. Genotyping is done at the CDC, at some state health department laboratories, and in research laboratories.

Treatment

The primary treatment for mycobacterial infection is specific chemotherapy. The drugs for treatment of mycobacterial infection are discussed in Chapter 28. Two cases of tuberculosis are presented in Chapter 48.

Between one in 10^6 and one in 10^8 tubercle bacilli are spontaneous mutants resistant to first-line antituberculosis drugs. When the drugs are used singly, the resistant tubercle bacilli emerge rapidly and multiply. Therefore, treatment regimens use drugs in combination to yield cure rates of greater than 95%.

The two major drugs used to treat tuberculosis are **INH** and **RMP**. The other first-line drugs are **pyrazinamide (PZA)** and **ethambutol (EMB)**. Second-line drugs are more toxic or less effective (or both), and they should be used in therapy only under extenuating circumstances (eg, treatment failure and multiple drug resistance). Second-line drugs include kanamycin, capreomycin, ethionamide, cycloserine, ofloxacin, and ciprofloxacin.

A four-drug regimen of INH, RMP, PZA, and EMB is recommended for persons in the United States who have a slight to moderate risk for being infected with drug-resistant tubercle bacilli. The risk factors include recent emigration from Latin America or Asia, persons with HIV infections or who are at risk for HIV infection and live in an area with a low prevalence of multidrug-resistant tubercle bacilli, and persons who were previously treated with a regimen that did not include RMP. These four drugs are continued for 2 months. If the isolate is susceptible to INH and RMP, PZA and EMB can be discontinued, and the remaining treatment with INH and RMP is continued to complete a 6-month course. In patients with cavitary disease or in whom the sputum culture results are still positive after 2 months of treatment, an additional 3 months of therapy (total course duration of 9 months) should be given to prevent relapse. In noncompliant patients, directly observed therapy is important.

Drug resistance in *M. tuberculosis* is a worldwide problem. Mechanisms explaining the resistance phenomenon for

many, but not all, of the resistant strains have been defined. INH resistance has been associated with deletions or mutations in the catalase-peroxidase gene (*katG*); these isolates become catalase negative or have decreased catalase activity. INH resistance has also been associated with alterations in the *inhA* gene, which encodes an enzyme that functions in mycolic acid synthesis. Streptomycin resistance has been associated with mutations in genes encoding the ribosomal S12 protein and 16S rRNA, *rpsL* and *rrs*, respectively. RMP resistance has been associated with alterations in the B subunit of RNA polymerase, the *rpoB* gene. Mutations in the DNA gyrase gene *gyrA* have been associated with resistance to fluoroquinolones. The possibility that drug resistance is present in a patient's *M. tuberculosis* isolate must be taken into account when selecting therapy.

Multidrug-resistant *M. tuberculosis* (resistant to both INH and RMP) is a major problem in tuberculosis treatment and control. Such strains are prevalent in certain geographic areas and certain populations (eg, hospitals and prisons). There have been many outbreaks of tuberculosis with multidrug-resistant strains. They are particularly important in persons with HIV infections in resource-poor countries. Persons infected with multidrug-resistant organisms or who are at high risk for such infections, including exposure to another person with such an infection, should be treated according to susceptibility test results for the infecting strain. If susceptibility results are not available, the drugs should be selected according to the known pattern of susceptibility in the community and modified when the susceptibility test results are available. Therapy should include a minimum of three and preferably more than three drugs to which the organisms have demonstrated susceptibility.

Extensively drug-resistant (XDR) strains are now globally recognized. These are defined by the World Health Organization (WHO) as isolates of *M. tuberculosis* with resistance to INH and RMP; any fluoroquinolone; and at least one of three injectable second-line drugs such as amikacin, capreomycin, or kanamycin. The true prevalence of XDR tuberculosis is underestimated in resource-limited countries because of the lack of available diagnostic and susceptibility tests. Factors that have contributed to the global epidemic include ineffective tuberculosis treatment; lack of proper diagnostic testing; and most importantly, poor infection control practices. Persons infected with XDR tuberculosis have a poorer clinical outcome and are 64% more likely to die during treatment than persons infected with susceptible strains. In 2006, the WHO Global Task Force on XDR-TB issued multifaceted and comprehensive recommendations to address the XDR-TB epidemic (available at http://www.who.int/tb/features_archive/global_taskforce_report/en/).

Epidemiology

The most frequent source of infection is humans who excrete, particularly from the respiratory tract, large numbers of tubercle bacilli. Close contact (eg, in the family) and massive

exposure (eg, in medical personnel) make transmission by droplet nuclei most likely.

Susceptibility to tuberculosis is a function of the risk of acquiring the infection and the risk of clinical disease after infection has occurred. For tuberculin-negative people, the risk of acquiring tubercle bacilli depends on exposure to sources of infectious bacilli, principally sputum-positive patients. This risk is proportionate to the rate of active infection in the population, crowding, socioeconomic disadvantage, and inadequacy of medical care.

The development of clinical disease after infection may have a genetic component (proven in animals and suggested in humans by a higher incidence of disease in those with HLA-Bw15 histocompatibility antigen). It is influenced by age (high risk in infancy and in elderly adults); by undernutrition; and by immunologic status, coexisting diseases (eg, silicosis, diabetes), and other individual host resistance factors.

Infection occurs at an earlier age in urban than in rural populations. Disease occurs only in a small proportion of infected individuals. In the United States at present, active disease has several epidemiologic patterns in which individuals are at increased risk, including minorities, predominantly African Americans and Hispanics; immigrants from countries of high endemicity; HIV-infected patients; homeless persons; and very young and very old individuals. The incidence of tuberculosis is especially high in minority persons with HIV infections. Primary infection can occur in any person exposed to an infectious source. Patients who have had tuberculosis can be infected exogenously a second time. Endogenous reactivation tuberculosis occurs most commonly among persons with AIDS immunosuppression and elderly malnourished or alcoholic destitute men.

Prevention and Control

1. Prompt and effective treatment of patients with active tuberculosis and careful follow-up of their contacts with tuberculin tests, radiographs, and appropriate treatment are the mainstays of public health tuberculosis control.
2. Drug treatment of asymptomatic tuberculin-positive persons in the age groups most prone to develop complications (eg, children) and in tuberculin-positive persons who must receive immunosuppressive drugs greatly reduces reactivation of infection.
3. Nonspecific factors may reduce host resistance, thus favoring the conversion of asymptomatic infection into disease. Such factors include starvation, gastrectomy, and suppression of cellular immunity by drugs (eg, corticosteroids) or infection. HIV infection is a major risk factor for tuberculosis.
4. Various living avirulent tubercle bacilli, particularly BCG (an attenuated bovine organism), have been used to induce a certain amount of resistance in those heavily exposed to infection. Vaccination with these organisms is a substitute for primary infection with virulent tubercle bacilli without

the danger inherent in the latter. The available vaccines are inadequate from many technical and biologic standpoints. Nevertheless, BCG is given to children in many countries. Statistical evidence indicates that an increased resistance for a limited period follows BCG vaccination.

5. Eradication of tuberculosis in cattle and pasteurization of milk have greatly reduced *M. bovis* infections.

Concept Checks

- Mycobacteria are rod-shaped, aerobic organisms that are “acid-fast” positive because of the complex nature of their cell walls that include mycolic acids.
- Mycobacteria grow more slowly than other bacteria. Both nonselective and selective media in solid and liquid forms are used to recover organisms from clinical material.
- Although there are more than 200 species of Mycobacteria, the slow-growing *M. tuberculosis* complex is of most importance to humans and public health.
- The hallmark of infections with *M. tuberculosis* is granulomas. Granulomas have a concentric structure that consists of a central necrotic center (caseous necrosis) surrounded by a zone of multinucleated giant cells, monocytes, and histiocytes and an outer ring of fibrosis.
- Humans acquire tuberculosis from inhalation of infected droplet nuclei.
- The tuberculin skin test or the IGRAs can be used to screen persons for latent tuberculosis infection.
- Diagnosis of tuberculosis requires acid-fast smear and culture; nucleic acid amplification tests when performed on smear-positive specimens can be very helpful.
- The mainstay of therapy is an initial four-drug regimen of INH, RMP, PZA, and EMB followed by 4 months of INH and RMP. Acceptable alternative regimens are also available. Multidrug-resistant and XDR tuberculosis have become a global health care crisis.

OTHER MYCOBACTERIA

In addition to the organisms in the *M. tuberculosis* complex, other mycobacteria of varying degrees of pathogenicity have been isolated from human sources in past decades. These nontuberculous mycobacteria were initially grouped according to speed of growth at various temperatures and production of pigments (see earlier discussion). Several are now identified using DNA probes or by DNA sequencing. Most of the nontuberculous mycobacteria occur in the environment (eg, soil, water, plants, and animals), are not readily transmitted from person to person, and are typically opportunistic pathogens (see Table 23-1).

Species or complexes that are significant causes of disease are outlined.

Mycobacterium avium Complex

The *M. avium* complex is often called the MAC or MAI (*M. avium-intracellulare*) complex. These organisms grow

optimally at 41°C and produce smooth, soft, nonpigmented colonies. They are ubiquitous in the environment and have been cultured from water, soil, food, and animals, including birds.

MAC organisms infrequently cause disease in immunocompetent humans. However, in the United States, disseminated MAC infection is one of the most common opportunistic infections of bacterial origin in patients with AIDS. The risk of developing disseminated MAC infection in HIV-infected persons is greatly increased when the CD4-positive lymphocyte count declines to below 100/μL. (See Case 17 in Chapter 48.) Gender, race, ethnic group, and individual risk factors for HIV infection do not influence the development of disseminated MAC infection, but prior *Pneumocystis jirovecii* infection, severe anemia, and interruption of antiretroviral therapy may increase the risk.

During the first 15 years of the AIDS epidemic, approximately 25% and perhaps as high as 50% of HIV-infected patients developed MAC bacteremia and disseminated infection during the course of AIDS. Subsequently, the use of highly active antiretroviral therapy (HAART) and the use of azithromycin or clarithromycin prophylaxis have greatly decreased the incidence of disseminated MAC infection in AIDS patients.

Other patients at risk include those with cystic fibrosis and pulmonary alveolar proteinosis. Pulmonary MAC disease has also been described in middle-aged to elderly women in the absence of chronic lung disease and has been referred to as “Lady Windermere” syndrome. This form of the disease is indolent and over time is characterized by nodules in the middle lobes and lingula that progress to cavitation. Cervical lymphadenitis is the most common presentation in young children (<5 years of age). The major manifestation is unilateral, firm adenopathy; fever is generally absent.

Environmental exposure can lead to MAC colonization of either the respiratory or gastrointestinal tract. Transient bacteremia occurs followed by invasion of tissues. Persistent bacteremia and extensive infiltration of tissues result in organ dysfunction. Any organ can be involved. In the lung, nodules, diffuse infiltrates, cavities, and endobronchial lesions are common. Other manifestations include pericarditis, soft tissue abscesses, skin lesions, lymph node involvement, bone infection, and central nervous system lesions. The patients often present with nonspecific symptoms of fever, night sweats, abdominal pain, diarrhea, and weight loss. The diagnosis is made by culturing MAC organisms from blood or tissue.

MAC organisms routinely are resistant to first-line anti-tuberculosis drugs. Treatment with either clarithromycin or azithromycin plus EMB is a preferred initial therapy. Other drugs that may be useful are rifabutin (Ansamycin), clofazimine, and fluoroquinolones. Amikacin and streptomycin have activity but are less desirable because of toxicity. Multiple drugs often are used in combination. Therapy should be continued for life. Therapy results in decreasing counts of MAC organisms in blood and amelioration of clinical symptoms.

Mycobacterium kansasii

M. kansasii is second to MAC as a cause of nontuberculous mycobacterial lung disease in the United States and many other countries. *M. kansasii* produces a pulmonary disease indistinguishable from tuberculosis; extrapulmonary infections have also been described and include cervical lymphadenitis in children, skin and soft tissue infections, and pericarditis. *M. kansasii* rarely causes a disseminated disease, except in patients with impaired immune responses (eg, AIDS and solid organ transplants). *M. kansasii* is a photochromogen that requires complex media for growth at 37°C. The organism is usually susceptible to RMP, and infections are often treated with the combination of RMP, EMB, and INH with a good clinical response. Tap water has been identified as the major environmental reservoir for *M. kansasii*, which is a presumed source of the infection in humans. However, there has been no evidence for person-to-person transmission of *M. kansasii*, to date.

Mycobacterium scrofulaceum

This is a scotochromogen occasionally found in water and as a saprophyte in adults with chronic lung disease. It causes chronic cervical lymphadenitis in children and, rarely, other granulomatous disease. Surgical excision of involved cervical lymph nodes may be curative, and resistance to antituberculosis drugs is common. (*M. szulgai* and *M. xenopi* are similar.)

Mycobacterium marinum

Mycobacterium marinum causes granulomatous skin and soft tissue infections following a trauma to the skin with subsequent exposure to water contaminated with the organism. *M. marinum* is associated with fresh and saltwater fish, and infections in humans often follow an exposure to contaminated fresh water fish tanks ("fish tank granuloma") or salt water. In the United States, the disease more commonly occurs in the Southern coastal regions. The typical clinical presentation is that of a single, small violet papule or nodule confined to one extremity (eg, finger, toe, elbow, or knee) developing some 2–3 weeks after the trauma/exposure. Over time, these lesions may become verrucous or ulcerated; occasionally, the infection may even ascend more proximally along the lymphatics, resembling cutaneous sporotrichosis. Other complications, albeit rare, may also occur, including tenosynovitis, bursitis, and osteomyelitis. *M. marinum* is a photochromogen and grows best at 28–30°C. No specific antimicrobial treatment regimen has been established; however, in addition to surgical excision, combination treatment with RMP and EMB has been proven successful. Monotherapy with doxycycline, or minocycline, or clarithromycin, or trimethoprim–sulfamethoxazole, given for a 3-months' duration, has also been shown to be effective.

Mycobacterium ulcerans

Infection due to *M. ulcerans* has long been underestimated; however, today, it is globally the third most common mycobacterial infection in humans, following tuberculosis and leprosy. The organism causes necrotizing skin and soft tissue infections, which are characterized by formation of ulcers that progressively enlarge over time, if left untreated. The disease can also manifest as a subcutaneous nodule, plaque, or as an aggressive edematous infection of the soft tissue. *M. ulcerans* is closely associated with tropical wetlands, and it has been proposed that transmission to humans is likely to occur via mosquitoes and aquatic biting arthropods. *M. ulcerans* is fastidious and extremely slow growing; the optimum temperature for incubation is 30°C. Molecular techniques (PCR) for organism identification have been developed and can expedite the diagnosis. As per WHO recommendations, antimicrobial therapy for treatment of *M. ulcerans* infection is a combination antibiotic regimen with rifampicin plus streptomycin, rifampicin plus clarithromycin, or rifampicin plus moxifloxacin. These different combination treatments are usually given for 8 weeks; complementary treatment modalities include surgical debridement, skin grafting, and wound care.

***Mycobacterium fortuitum* Complex**

These are saprophytes found in soil and water that grow rapidly (3–6 days) in culture and produce no pigment. They can cause superficial and systemic disease in humans on rare occasions. The organisms are often resistant to antimycobacterial drugs but may respond to amikacin, doxycycline, cefoxitin, erythromycin, or RMP.

Mycobacterium chelonae-abscessus

These rapid growers should be differentiated because the types and severity of disease are different and because therapy for *M. chelonae* is easier as it is more susceptible to antimicrobial agents. Both species are capable of causing skin, soft tissue, and bone infections after trauma or surgery, which can disseminate in immunocompromised patients. *M. abscessus* is also frequently recovered from patients with respiratory disease in the United States, especially in southeastern regions. The individuals most commonly infected are elderly, white, female nonsmokers. Patients with cystic fibrosis are also at risk and may succumb to a fulminant, rapidly progressive form of the disease. *M. chelonae* is typically susceptible to tobramycin, clarithromycin, linezolid, and imipenem. Clarithromycin, amikacin, and cefoxitin are usually used for treatment of *M. abscessus*, although drug resistance is a major problem with this organism.

Other *Mycobacterium* Species

The high risk for mycobacterial infection in patients with AIDS has resulted in increased awareness of mycobacterial

infections in general. Species previously considered to be curiosities and extremely uncommon have been more widely recognized (see Table 23-1). *M. malmoeense* has been reported mostly from Northern Europe. It causes a pulmonary tuberculosis-like disease in adults and lymphadenitis in children. *M. haemophilum* and *M. genavense* cause disease in patients with AIDS. The importance of these two species is not fully understood.

MYCOBACTERIUM LEPRAE

Leprosy, also known as Hansen's disease, is caused by *M. leprae*, and has been known since antiquity. Although this organism was first described by Hansen in 1873 (9 years before Koch's discovery of the tubercle bacillus), efforts to grow the organism *in vitro* on agar and other bacteriologic media have remained unsuccessful. Leprosy occurs in one of two clinical presentations: lepromatous (multibacillary) leprosy or tuberculoid (paucibacillary) leprosy. Since the 1940s when dapsone was recognized as an effective antimicrobial therapy, the global disease burden has been significantly reduced, due to the successful use of antimicrobial therapy and the start of the WHO's campaign efforts to eliminate leprosy in 1991. According to the WHO database, 136 countries reported new cases of leprosy in 2015. Globally, the majority of cases occur in India (60%), Brazil (13%), and Indonesia (9%). In the United States, leprosy is a rare disease; in 2015, 178 new cases were reported, with most of these cases being reported in the following States: Arkansas, California, Florida, Hawaii, Louisiana, New York, and Texas. The epidemiology of leprosy in the United States closely reflects immigration patterns, and the majority of patients (approx. 60%) were born outside the United States. Detailed data are available from the CDC, the U.S. National Hansen's Disease Program, and the WHO.

Typical acid-fast bacilli—singly, in parallel bundles, or in globular masses—are regularly found in scrapings from skin or mucous membranes (particularly the nasal septum) in patients with lepromatous leprosy. The bacilli are often found within the endothelial cells of blood vessels or in mononuclear cells. When bacilli from human leprosy (ground tissue nasal scrapings) are inoculated into the footpads of mice, local granulomatous lesions develop with limited multiplication of bacilli. Inoculated armadillos develop extensive lepromatous leprosy, and armadillos naturally infected with leprosy have been found in Texas and Mexico. *M. leprae* from armadillo or human tissue contains a unique *o*-diphenoloxidase, perhaps an enzyme characteristic of leprosy bacilli.

Clinical Findings

The onset of leprosy is insidious. The lesions involve the cooler tissue of the body, including the skin, superficial nerves, nose, pharynx, larynx, eyes, and testicles. The skin lesions may occur as pale, anesthetic macular lesions 1–10 cm in diameter; diffuse or discrete erythematous, infiltrated

nodules 1–5 cm in diameter; or a diffuse skin infiltration. Neurologic disturbances are manifested by nerve infiltration and thickening, with resultant anesthesia, neuritis, paresthesia, trophic ulcers, and bone resorption and shortening of the digits. The disfigurement caused by the skin infiltration and nerve involvement in untreated cases may be extreme.

The disease is divided into two major types: lepromatous and tuberculoid, with several intermediate stages (see the Ridley-Jopling classification system). In the lepromatous type, the course is progressive and malignant, with nodular skin lesions; slow, symmetric nerve involvement; abundant acid-fast bacilli in the skin lesions; continuous bacteremia; and a negative lepromin (extract of lepromatous tissue) skin test result. In lepromatous leprosy, cell-mediated immunity is markedly deficient, and the skin is infiltrated with suppressor T cells. In the tuberculoid type, the course is benign and nonprogressive, with a small number of macular skin lesions containing few bacilli, severe asymmetric nerve involvement of sudden onset, and a positive lepromin skin test result. In tuberculoid leprosy, cell-mediated immunity is intact, and the skin is infiltrated with helper T cells.

Systemic manifestations of anemia and lymphadenopathy may also occur. Eye involvement is common. Amyloidosis may develop.

Diagnosis

Scrapings with a scalpel blade from skin or nasal mucosa or from a biopsy of earlobe skin are smeared on a slide and stained by the Ziehl-Neelsen technique. Biopsy of skin or of a thickened nerve gives a typical histologic picture. No serologic tests are of value. Nontreponemal serologic tests for syphilis frequently yield false-positive results in patients with leprosy.

Treatment

Sulfones such as dapsone (see Chapter 28) are first-line therapy for both tuberculoid and lepromatous leprosy. RMP and/or clofazimine generally are included in the initial treatment regimens. Other drugs active against *M. leprae* include minocycline, clarithromycin, and some fluoroquinolones. Regimens recommended by the WHO are practical. Several years of therapy may be necessary to adequately treat leprosy.

Epidemiology

While it is currently not exactly known how *M. leprae* spreads among people, transmission of leprosy is most likely to occur via respiratory droplets (eg, cough and sneezing) from an infected individual to a healthy person. Prolonged and close contact with infected individuals is necessary for effective transmission of the organism; nasal secretions are the most likely infectious material for family contacts. Casual contact (eg, shaking hands) with a person who has leprosy does not pose a risk for transmission of the organism. The incubation

period for leprosy is probably 2–10 years. Without prophylaxis, about 10% of exposed children may acquire the disease. Treatment tends to reduce and abolish the infectivity of patients. In the southern United States (eg, Texas) and Mexico, some armadillos are found to be naturally infected with *M. leprae*. Recent studies suggest that armadillos may be a source of human infection in the southern United States; however, the risk of transmission to human appears to be low, specifically when appropriate precautions are used when handling potentially infected animals.

Prevention and Control

In the United States, the current recommendations for prevention of leprosy include a thorough examination of household contacts and close relatives. This should include a complete skin examination and an examination of the peripheral nervous system. The U.S. Public Health Service National Hansen's Disease Program does not recommend routine dapsone prophylaxis. A therapeutic trial may be indicated for patients whose signs and symptoms are suggestive of leprosy but who do not have a definitive diagnosis.

BCG does provide some protection against leprosy especially among household contacts of cases.

Concept Checks

- The NTM are a diverse group of organisms commonly found in the environment, and the group includes both saprophytes and human pathogens.
- The NTM can be further classified into the rapid growers (grow in <7 days) and slow growers. Each group can be subdivided on the basis of pigment production.
- Members of MAC are among the most frequently isolated NTM. They are responsible for significant disease in patients with AIDS and others with chronic lung disease.
- *M. kansasii* causes pulmonary infections that mimic tuberculosis. It responds to therapy with INH, RIF, and EMB.
- The rapid growers are diverse. *M. fortuitum* complex, *M. chelonae*, and *M. abscessus* are the most prevalent. *M. abscessus* causes the most severe disease and is often multidrug resistant.
- *M. leprae* causes the disease leprosy. The organism is not cultivatable, so diagnosis is difficult. Treatment with dapsone, RMP, and clofazimine is often prolonged for many years.

REVIEW QUESTIONS

1. A 60-year-old man has a 5-month history of progressive weakness and a weight loss of 13 kg along with intermittent fever, chills, and a chronic cough productive of yellow sputum, occasionally streaked with blood. A sputum specimen is obtained, and numerous acid-fast bacteria are seen on the smear. Culture of the sputum is positive for *M. tuberculosis*. Which treatment regimen is most appropriate for initial therapy?
 - (A) Isoniazid and rifampin
 - (B) Sulfamethoxazole–trimethoprim and streptomycin
 - (C) Isoniazid, rifampin, pyrazinamide, and ethambutol
 - (D) Isoniazid, cycloserine, and ciprofloxacin
 - (E) Rifampin and streptomycin
2. If the patient's *M. tuberculosis* isolate (Question 1) proves to be resistant to isoniazid, the likely mechanism for resistance is
 - (A) β -Lactamase
 - (B) Mutations in the catalase-peroxidase gene
 - (C) Alterations in the β subunit of RNA polymerase
 - (D) Mutations in the DNA gyrase gene
 - (E) Mutations in the genes encoding the S12 protein and 16S rRNA
3. A 47-year-old woman presents with a 3-month history of progressive cough, weight loss, and fever. Chest radiography shows bilateral cavitary disease suggestive of tuberculosis. Sputum culture grows an acid-fast bacillus that is a photochromogen (makes an orange pigment when exposed to light). The organism most likely is
 - (A) *M. tuberculosis*
 - (B) *M. kansasii*
 - (C) *M. gordonae*
 - (D) *M. avium* complex
 - (E) *M. fortuitum*
4. A 31-year-old Asian woman is admitted to the hospital with a 7-week history of increasing malaise, myalgia, nonproductive cough, and shortness of breath. She has daily fevers of 38–39°C and a recent 5-kg weight loss. She had a negative chest radiograph when she entered the United States 7 years ago. The patient's grandmother died of tuberculosis when the patient was an infant. A current chest radiograph is normal; results of other tests show a decreased hematocrit and liver function test abnormalities. Liver and bone marrow biopsies show granulomas with giant cells and acid-fast bacilli. She is probably infected with
 - (A) *M. leprae*
 - (B) *M. fortuitum*
 - (C) *M. ulcerans*
 - (D) *M. gordonae*
 - (E) *M. tuberculosis*
5. It is very important that the patient in Question 4 also be evaluated for
 - (A) HIV/AIDS
 - (B) Typhoid fever
 - (C) Liver abscess
 - (D) Lymphoma
 - (E) Malaria
6. Of concern regarding the patient in Question 4 is that she could be infected with a *Mycobacterium* that is
 - (A) Susceptible only to isoniazid
 - (B) Resistant to streptomycin
 - (C) Resistant to clarithromycin
 - (D) Susceptible only to ciprofloxacin
 - (E) Resistant to isoniazid and rifampin
7. You observe a 40-year-old man begging on a street in a town in India. He has clawing of the fourth and fifth digits with loss of distal parts of the digits of both hands, strongly suggesting leprosy. The causative agent of this disease
 - (A) Is susceptible to isoniazid and rifampin
 - (B) Grows in parts of the body that are cooler than 37°C

- (C) Can be cultured in the laboratory using Middlebrook 7H11 medium
- (D) Is seen in high numbers in biopsies of tuberculoid leprosy lesions
- (E) Commonly infects people in Texas because armadillos are hosts of *M. leprae*
8. Which of the following statements about the purified protein derivative (PPD) and the tuberculin skin test is most correct?
- (A) It is strongly recommended that medical and other health science students have PPD skin tests every 5 years.
- (B) Persons immunized with BCG rarely, if ever, convert to positive PPD skin test results.
- (C) The intradermal skin test is usually read 4 hours after being applied.
- (D) A positive tuberculin test result indicates that an individual has been infected with *M. tuberculosis* in the past and may continue to carry viable mycobacteria.
- (E) A positive PPD skin test result implies that a person is immune to active tuberculosis.
9. A 72-year-old woman has an artificial hip joint placed because of degenerative joint disease. One week after the procedure, she has fever and joint pain. The hip is aspirated, and the fluid is submitted for routine culture and for culture for acid-fast organisms. After 2 days of incubation, there is no growth on any of the media. After 4 days, however, bacilli are seen growing on the sheep blood agar plate, and similar-appearing acid-fast bacilli are growing on the culture for acid-fast bacteria. The patient is most likely infected with
- (A) *M. tuberculosis*
- (B) *M. chelonae*
- (C) *M. leprae*
- (D) *M. kansasii*
- (E) *M. avium* complex
10. A 10-year-old child has a primary pulmonary *M. tuberculosis* infection. Which of the following features of tuberculosis is most correct?
- (A) In primary tuberculosis, an active exudative lesion develops and rapidly spreads to lymphatics and regional lymph nodes.
- (B) The exudative lesion of primary tuberculosis often heals slowly.
- (C) If tuberculosis develops years later, it is a result of another exposure to *M. tuberculosis*.
- (D) In primary tuberculosis, all of the infecting *M. tuberculosis* organisms are killed by the patient's immune response.
- (E) In primary tuberculosis, the immune system is primed, but the PPD skin test result remains negative until there is a second exposure to *M. tuberculosis*.
11. Which of the following statements regarding interferon- γ release assays (IGRAs) is correct?
- (A) They are useful for evaluating immunocompromised patients for active tuberculosis.
- (B) They detect antigens present in all *Mycobacterium* species.
- (C) They are not available yet for testing in the United States.
- (D) They are performed using molecular probes that detect organism DNA.
- (E) They are used as alternatives to the tuberculin skin test to evaluate for latent tuberculosis.
12. *M. abscessus* most often causes pulmonary disease among which group of individuals?
- (A) Young children exposed to dirt
- (B) African American smokers
- (C) Elderly, nonsmoking white females
- (D) Hispanic men who work outdoors
- (E) Persons living in the Northwestern United States
13. A newly characterized rapidly growing *Mycobacterium* that has emerged as an important cause of central venous catheter associated infections is
- (A) *M. phlei*
- (B) *M. mucogenicum*
- (C) *M. xenopi*
- (D) *M. smegmatis*
- (E) *M. terrae*
14. The definition of extensively drug-resistant (XDR) tuberculosis includes
- (A) Resistance to isoniazid
- (B) Resistance to a fluoroquinolone
- (C) Resistance to capreomycin, amikacin, or kanamycin
- (D) Resistance to rifampin
- (E) All of the above

Spirochetes: *Treponema*, *Borrelia*, and *Leptospira*

The spirochetes are a large, heterogeneous group of spiral, motile bacteria. One family (Spirochaetaceae) of the order Spirochaetales consists of two genera whose members are human pathogens: *Borrelia* and *Treponema*. The other family (Leptospiraceae) includes one genus of medical importance: *Leptospira*.

The spirochetes have many structural characteristics in common, as typified by *Treponema pallidum* (Figure 24-1). They are long, slender, helically coiled, spiral, or corkscrew-shaped bacilli. *T. pallidum* has an **outer sheath** or glycosaminoglycan coating. Inside the sheath is the outer membrane, which contains peptidoglycan and maintains the structural integrity of the organisms. **Endoflagella** (axial filaments) are the flagella-like organelles in the periplasmic space encased by the outer membrane. The endoflagella begin at each end of the organism and wind around it, extending to and overlapping at the midpoint. Inside the endoflagella is the inner membrane (cytoplasmic membrane) that provides osmotic stability and covers the protoplasmic cylinder. A series of cytoplasmic tubules (body fibrils) are inside the cell near the inner membrane. Treponemes reproduce by transverse fission.

TREPONEMA PALLIDUM AND SYPHILIS

Morphology and Identification

A. Typical Organisms

T. pallidum are slender spirals measuring about 0.2 μm in width and 5–15 μm in length. The spiral coils are regularly spaced at a distance of 1 μm from one another. The organisms are actively motile, rotating steadily around their endoflagella even after attaching to cells by their tapered ends. The long axis of the spiral is ordinarily straight but may sometimes bend so that the organism forms a complete circle for moments at a time, returning then to its normal straight position.

The spirals are so thin that they are not readily seen unless immunofluorescent stain or dark-field illumination is used. They do not stain well with aniline dyes, but they can be seen in tissues when stained by a silver impregnation method.

B. Culture

Pathogenic *T. pallidum* has never been cultured continuously on artificial media, in fertile eggs, or in tissue culture.

In proper suspending fluids and in the presence of reducing substances, *T. pallidum* may remain motile for 3–6 days at 25°C. In whole blood or plasma stored at 4°C, organisms remain viable for at least 24 hours, which is of potential importance in blood transfusions.

D. Reactions to Physical and Chemical Agents

Drying kills the spirochete rapidly, as does elevation of the temperature to 42°C. Treponemes are rapidly immobilized and killed by trivalent arsenical, mercury, and bismuth (contained in drugs of historical interest in the treatment of syphilis). Penicillin is treponemicidal in minute concentrations, but the rate of killing is slow, presumably because of the metabolic inactivity and slow multiplication rate of *T. pallidum* (estimated division time is 30 hours). Resistance to penicillin has not been demonstrated in syphilis.

E. Genome

The *T. pallidum* genome is a circular chromosome of approximately 1,138,000 base pairs, which is small for bacteria. Most pathogenic bacteria have transposable elements, but *T. pallidum* does not, which suggests that the genome is highly conserved and may explain its continued susceptibility to penicillin. There are few genes involved in energy production and synthesis of nutrients, indicating that *T. pallidum* obtains these from the host.

Antigenic Structure

The fact that *T. pallidum* cannot be cultured in vitro has markedly limited the characterization of its antigens. The outer membrane surrounds the periplasmic space and the peptidoglycan–cytoplasmic membrane complex. Membrane proteins are present that contain covalently bound lipids at their amino terminals. The lipids appear to anchor the proteins to the cytoplasmic or outer membranes and keep the proteins inaccessible to antibodies. The endoflagella are in the periplasmic space. *T. pallidum* has hyaluronidase that breaks down the hyaluronic acid in the ground substance of tissue and presumably enhances the invasiveness of the organism. The endoflagella are composed of three core proteins that are homologous to other bacterial flagellin

FIGURE 24-1 Electron micrograph of whole-mounted *T. pallidum* subspecies *pallidum*. The endoflagella are clearly visible. **Inset:** Electron micrograph of thin-sectioned *T. pallidum*. Note the position of the endoflagella (EF) in the periplasmic space between the inner membrane (IM) and the outer membrane (OM). (Courtesy of EM Walker.)

proteins plus an unrelated sheath protein. Cardiolipin is an important component of the treponemal antigens.

Humans with syphilis develop antibodies capable of staining *T. pallidum* by indirect immunofluorescence, immobilizing and killing live motile *T. pallidum*, and fixing complement in the presence of a suspension of *T. pallidum* or related spirochetes. The spirochetes also cause the development of a distinct antibody-like substance, reagin, which gives positive complement fixation (CF) and flocculation test results with aqueous suspensions of cardiolipin extracted from normal mammalian tissues. Both reagin and antitreponemal antibody can be used for the serologic diagnosis of syphilis.

Pathogenesis, Pathology, and Clinical Findings

A. Acquired Syphilis

Natural infection with *T. pallidum* is limited to the human host. Human infection is usually transmitted by sexual contact, and the infectious lesion is on the skin or mucous membranes of genitalia. In 10–20% of cases, however, the primary lesion is intrarectal, perianal, or oral. It may be anywhere on the body. *T. pallidum* can probably penetrate intact mucous membranes, or the organisms may enter through a break in the epidermis. Based on experiments in rabbits, as few as four to eight spirochetes may cause infection.

Spirochetes multiply locally at the site of entry, and some spread to nearby lymph nodes and then reach the bloodstream. Within 2–10 weeks after infection, a papule develops at the site of infection and breaks down to form an ulcer with a clean, hard base (“hard chancre”). The inflammation is characterized by a predominance of lymphocytes and plasma cells. This “primary lesion” always heals spontaneously, but 2–10 weeks later, the “secondary” lesions appear. These consist of a red maculopapular rash anywhere on the body, including the hands and feet, and moist, pale papules (condylomas) in the anogenital region, axillae, and mouth. The patient may also have syphilitic meningitis, chorioretinitis, hepatitis, nephritis (immune complex type), or periostitis. The secondary lesions also subside spontaneously. Both primary and secondary lesions are rich in spirochetes and are highly infectious. Contagious lesions may recur within 3–5 years after infection, but thereafter the individual is not infectious. Syphilitic infection may remain subclinical, and the patient may pass through the primary or secondary stage (or both) without symptoms or signs yet develop tertiary lesions.

In about 30% of cases, early syphilitic infection progresses spontaneously to complete cure without treatment. In another 30%, the untreated infection remains latent (principally evident by positive serologic test results). In the remainder, the disease progresses to the “tertiary stage” characterized by the development of granulomatous lesions (gummas) in the skin, bones, and liver; degenerative changes in the central nervous system (meningovascular syphilis, paresis, tabes); or cardiovascular lesions (aortitis, aortic aneurysm, aortic valve insufficiency). In all tertiary lesions, treponemes are very rare, and the exaggerated tissue response must be attributed to hypersensitivity to the organisms. However, treponemes can occasionally be found in the eye or central nervous system in late syphilis.

B. Congenital Syphilis

A pregnant woman with syphilis can transmit *T. pallidum* to the fetus through the placenta beginning in the 10th–15th weeks of gestation. Some of the infected fetuses die, and miscarriages result; others are stillborn at term. Others are born live but develop the signs of congenital syphilis in childhood, including interstitial keratitis, Hutchinson’s teeth, saddle nose, periostitis, and a variety of central nervous system anomalies. Adequate treatment of the mother during pregnancy prevents congenital syphilis. The reagin titer in the blood of the child rises with active infection but falls with time if antibody was passively transmitted from the mother. In congenital infection, the child makes IgM antitreponemal antibody.

Diagnostic Laboratory Tests

A. Specimens

Specimens include tissue fluid expressed from early surface lesions for demonstration of spirochetes by either dark-field

microscopy or immunofluorescence; such specimens can also be tested by nucleic acid amplification. Blood can be obtained for serologic tests; cerebrospinal fluid (CSF) is useful for Venereal Disease Research Laboratory (VDRL) testing (see later discussion).

B. Dark-Field Examination

A drop of tissue fluid or exudate is placed on a slide, and a coverslip is pressed over it to make a thin layer. The preparation is then examined under oil immersion within 20 minutes of collection with dark-field illumination for typical motile spirochetes. Dark-field microscopy should not be performed on lesions within the oral cavity because it is not possible to differentiate pathogenic from commensal spirochetes.

Treponemes disappear from lesions within a few hours after the beginning of antibiotic treatment.

C. Immunofluorescence

Tissue fluid or exudate is spread on a glass slide, air-dried, and sent to the laboratory. It is fixed, stained with a fluorescein-labeled antitreponeme antibody and examined by means of immunofluorescence microscopy for typical fluorescent spirochetes.

D. Serologic Tests for Syphilis

These tests use either nontreponemal or treponemal antigens.

1. Nontreponemal tests—The nontreponemal tests are universally used as screening tests for syphilis. The tests are widely available, lend themselves to automation with ease of performance in large numbers, and have a low cost. In addition to their function as screening tests, they can be used to follow the efficacy of therapy. The drawbacks to the nontreponemal tests are that they are not very sensitive in early syphilis, and the results may not turn positive until a few weeks after initial infection; false-positive results can occur with many other diseases; and there may be a prozone phenomenon, particularly in secondary syphilis (antibody excess produces a negative result at low serum dilutions but positive results at higher dilutions). The antigens in these tests contain measured amounts of cardiolipin, cholesterol, and purified lecithin in quantities sufficient to yield a standardized amount of reactivity. Historically, the cardiolipin was extracted from beef heart or liver with added lecithin and cholesterol to enhance reaction with syphilitic “reagin” antibodies. Regain is a mixture of IgM and IgG antibodies reactive with the cardiolipin-cholesterol-lecithin complex. All of the tests are based on the fact that the particles of the lipid antigen remain dispersed in normal serum but flocculate when combining with regain. The **VDRL** and **unheated serum regain (USR)** tests require microscopic examination to detect flocculation. The **rapid plasma regain (RPR)** test and **toluidine red unheated serum test (TRUST)** have colored particles that become caught in the mesh of the antigen-antibody complex, allowing the tests to be read without

microscopic magnification. Results develop within a few minutes, particularly if the suspension is agitated.

The nontreponemal tests can give quantitative results using serial twofold dilutions. An estimate of the amount of regain present in serum can be expressed as the titer or as the highest dilution giving a positive result. Quantitative results are valuable in establishing a diagnosis and in evaluating the effect of treatment. Positive nontreponemal test results develop after 2–3 weeks of untreated syphilis and are positive in high titer in secondary syphilis. Positive nontreponemal test results typically revert to negative, often in 6–18 months and generally by 3 years after effective treatment of syphilis. A positive nontreponemal test result late after treatment for syphilis suggests ineffective treatment or reinfection.

The VDRL test is standardized for use on CSF, and the result becomes positive in patients with neurosyphilis. Regain antibodies generally do not reach the CSF from the bloodstream but are probably formed in the central nervous system in response to syphilitic infection. The serologic diagnosis of **neurosyphilis** is complex.

2. Treponemal antibody tests—The treponemal tests measure antibodies against *T. pallidum* antigens. The tests are used to determine if a positive result from a nontreponemal test is truly positive or falsely positive. A positive result of a treponemal test on a serum specimen that is also positive on a nontreponemal test is a strong indication of *T. pallidum* infection. The traditional treponemal tests are less useful as screening tests because once positive after initial syphilitic infection the tests remain positive for life independent of therapy for syphilis. Serial dilutions of serum are not done in the treponemal tests, and results are reported as reactive or nonreactive (or occasionally inconclusive). The treponemal antibody tests tend to be more costly than the nontreponemal test, which is important when large groups of people (eg, blood donors) are being screened.

The *T. pallidum*-particle agglutination (TP-PA) test is perhaps the most widely used treponemal test in the United States. Gelatin particles sensitized with *T. pallidum* subspecies *pallidum* antigens are added to a standard dilution of serum. When anti-*T. pallidum* antibodies (IgG, IgM, or both) react with the sensitized particles, a mat of agglutinated particles forms in the well of the microdilution tray. Gelatin particles that are not sensitized are tested with diluted serum to exclude nonspecific agglutination.

The *T. pallidum* hemagglutination (TPHA) and the microhemagglutination *T. pallidum* (MHA-TP) are based on the same principles as the TP-PA but use sheep erythrocytes rather than gelatin particles and may be more prone to nonspecific agglutination.

The **fluorescent treponemal antibody absorbed (FTA-ABS)** test is the treponemal antibody test used for many years. Because it is difficult to perform, the test is used only in selected circumstances. The test uses indirect immunofluorescence to detect reactive antibodies, including killed *T. pallidum* and the patient's serum absorbed with sonicated

saprophytic Reiter spirochetes plus antihuman γ -globulin labeled with a fluorescent compound. The presence of IgM FTA in the blood of newborns is a good evidence of in utero infection (ie, congenital syphilis). A negative FTA-ABS result on CSF tends to exclude neurosyphilis, but a positive FTA-ABS result on CSF can occur by transfer of antibodies from serum and is not helpful in the diagnosis of neurosyphilis.

Multiple relatively similar treponemal antibody tests using enzyme immunoassay (EIA) or chemiluminescence (CIA) formats for *T. pallidum* are available. These tests use antigens obtained by sonication of *T. pallidum* or recombinant antigens. An aliquot of serum at a standard dilution is added to a sensitized well of a microdilution plate. After washing, addition of an enzyme-labeled conjugate, and further washing, a precursor substrate is added. A color change or CIA indicates a reactive serum. Because some of these assays are available as high-throughput automated tests, many laboratories have now reversed the traditional algorithm for screening. Instead of screening with the nontreponemal test and verifying with a treponemal assay, the high throughput allows screening with a more sensitive treponemal test. The advantage to this approach is that patients with early disease or untreated latent disease are more likely to be detected (see earlier discussion).

There are some concerns about variability in assay performance among these tests that result in more false positives when testing low-prevalence populations. Because of this, the Centers for Disease Control and Prevention (CDC) has recommended an algorithm for confirming a positive EIA or CIA test result with a quantitative RPR or other nontreponemal test. If the RPR result is positive, a current or past infection with syphilis is likely. If the RPR result is negative, then additional testing with a traditional treponemal test such as the TP-PA is recommended. If the TP-PA result is positive, syphilis is likely; if it is negative, syphilis is unlikely.

Immunity

A person with active or latent syphilis appears to be resistant to superinfection with *T. pallidum*. However, if early syphilis is treated adequately and the infection is eradicated, the individual again becomes fully susceptible. The various immune responses usually fail to eradicate the infection or arrest its progression.

Treatment

Penicillin in concentrations of 0.003 U/mL has definite treponemocidal activity, and penicillin is the treatment of choice. Syphilis of less than 1 year duration is treated by a single injection of benzathine penicillin G 2.4 million units intramuscularly. In older or latent syphilis, benzathine penicillin G intramuscularly is given three times at weekly intervals. In neurosyphilis, the same therapy is acceptable, but larger amounts of intravenous penicillin are sometimes recommended. Other antibiotics (eg, tetracyclines or erythromycin) can occasionally be substituted. Treatment of gonorrhea is thought to cure

incubating syphilis. Prolonged follow-up is essential. In neurosyphilis, treponemes occasionally survive such treatment. Severe neurologic relapses of treated syphilis have occurred in patients with AIDS who are infected with both HIV and *T. pallidum*. A typical Jarisch-Herxheimer reaction may occur within hours after treatment is begun. It is caused by the release of toxic products from dying or killed spirochetes.

Epidemiology, Prevention, and Control

With the exceptions of congenital syphilis and the rare occupational exposure of medical personnel, syphilis is acquired through sexual exposure. Reinfection in treated persons is common. An infected person may remain contagious for 3–5 years during “early” syphilis. “Late” syphilis, of more than 5 years’ duration, is usually not contagious. Consequently, control measures depend on (1) prompt and adequate treatment of all discovered cases, (2) follow-up on sources of infection and contacts so that they can be treated, and (3) safe sex with condoms. Several sexually transmitted diseases can be transmitted simultaneously. Therefore, it is important to consider the possibility of syphilis when any one sexually transmitted disease has been found.

Concept Checks

- *T. pallidum* cannot be cultivated on artificial media; therefore, they are detected directly in tissues or exudates using dark-field microscopy, immunofluorescence, or molecular tests.
- Infections with *T. pallidum* are limited to humans and are acquired by direct sexual contact and less commonly transplacentally (congenital disease) or through occupational exposure.
- The primary lesion at the site of inoculation is the painless “hard chancre,” a type of genital ulcer.
- Untreated primary infection can lead to secondary disease with spread of the spirochetes systemically; latent disease is characterized by the absence of symptoms but with a positive serologic test result. The tertiary stage involves serious disease with central nervous system or cardiac manifestations.
- In addition to direct detection in clinical specimens, most often the diagnosis is made by serologic testing. The traditional testing algorithm involves screening using a nontreponemal test followed by confirmation with a treponemal test such as the TP-PA.
- The availability of high-throughput EIA or CIA tests has resulted in the reversal of this sequence of testing with many laboratories offering screening with one of these treponemal tests followed by confirmation with the nontreponemal test. Concern for false-positive test results has prompted the CDC to recommend an algorithm that confirms a negative nontreponemal test result with one of the traditional treponemal tests.
- Penicillin is the drug of choice for treatment of all stages of syphilis.

BORRELIA

BORRELIA SPECIES AND RELAPSING FEVER

Relapsing fever in epidemic form is caused by *Borrelia recurrentis*, which is transmitted by the human body louse; it does not occur in the United States. Endemic relapsing fever is caused by borreliae transmitted by ticks of the genus *Ornithodoros*. The species name of the *Borrelia* genus is often the same as that of the tick. *Borrelia hermsii*, the cause of relapsing fever in the western United States, is transmitted by *Ornithodoros hermsi*. In recent years, *Borrelia miyamotoi*, a relapsing fever spirochete, has been recognized in the United States as the cause of an acute febrile, Lyme disease-like illness. *B. miyamotoi* is transmitted by the same hard-bodied ticks, namely *Ixodes scapularis*, that transmit *B. burgdorferi* and other *Borrelia* species that cause Lyme disease (see discussion below).

Morphology and Identification

A. Typical Organisms

The borreliae form irregular spirals 10–30 μm long and 0.3 μm wide. The distance between turns varies from 2 to 4 μm . The organisms are highly flexible and move both by rotation and by twisting. Borreliae stain readily with bacteriologic dyes as well as with blood stains such as Giemsa stain or Wright stain (Figure 24-2).

B. Culture

The organism can be cultured in fluid media containing blood, serum, or tissue, but it rapidly loses its pathogenicity for animals when transferred repeatedly in vitro. Multiplication

is rapid in chick embryos when blood from patients is inoculated onto the chorioallantoic membrane.

C. Growth Characteristics

Little is known of the metabolic requirements or activity of borreliae. At 4°C, the organisms survive for several months in infected blood or in culture. In some ticks (but not in lice), spirochetes are passed from generation to generation.

D. Variation

The only significant variation of *Borrelia* species is with respect to its antigenic structure.

Antigenic Structure

Antibodies develop in high titer after infection with borreliae. The antigenic structure of the organisms changes in the course of a single infection. The antibodies produced initially act as a selective factor that permits the survival only of antigenically distinct variants. The relapsing course of the disease appears to be caused by the multiplication of such antigenic variants, against which the host must then develop new antibodies. Ultimate recovery (after 3–10 relapses) is associated with the presence of antibodies against several antigenic variants.

Pathology

Fatal cases show spirochetes in great numbers in the spleen and liver, necrotic foci in other parenchymatous organs, and hemorrhagic lesions in the kidneys and the gastrointestinal tract. Spirochetes have occasionally been demonstrated in the spinal fluid and brain of persons who have had meningitis. In experimental animals (guinea pigs, rats), the brain may serve as a reservoir of borreliae after they have disappeared from the blood.

Pathogenesis and Clinical Findings

The incubation period is 3–10 days. The onset is sudden, with chills and an abrupt rise of temperature. During this time, spirochetes abound in the blood. The fever persists for 3–5 days and then declines, leaving the patient weak but not ill. The afebrile period lasts 4–10 days and is followed by a second attack of chills, fever, intense headache, and malaise. There are 3–10 such recurrences, generally of diminishing severity. During the febrile stages (especially when the temperature is rising), organisms are present in the blood; during the afebrile periods, they are absent.

Antibodies against the spirochetes appear during the febrile stage, and the attack is probably terminated by their agglutinating and lytic effects. These antibodies may select out antigenically distinct variants that multiply and cause a relapse. Several distinct antigenic varieties of borreliae may be isolated from a single patient's sequential relapses

FIGURE 24-2 *Borrelia* (arrow) in a peripheral blood smear of a patient with relapsing fever. Original magnification $\times 1000$.

even after experimental inoculation with a single organism. Infection with the recently emerging pathogen *B. miyamotoi* typically presents as a febrile illness, with high fever ($\geq 40^{\circ}\text{C}$), fatigue, headache, myalgia, arthralgia, and nausea. In some patients, leukopenia, thrombocytopenia, and elevated transaminases have also been reported. In contrast to Lyme disease, the typical skin lesions (erythema migrans) are absent with *B. miyamotoi* infection. Symptoms of infection usually resolve within 1 week of starting antibiotic therapy. In severely immunocompromised patients, meningoencephalitis has been described as a complication of *B. miyamotoi* infection. Infection with *B. miyamotoi* should be considered in patients with an acute febrile illness following the exposure to *Ixodes* ticks in areas where Lyme disease is also present.

Diagnostic Laboratory Tests

A. Specimens

Blood specimens are obtained during the rise in fever for smears and animal inoculation.

B. Smears

Thin or thick blood smears stained with Wright or Giemsa stain reveal large, loosely coiled spirochetes among the red cells.

C. Animal Inoculation

White mice or young rats are inoculated intraperitoneally with blood. Stained films of tail blood are examined for spirochetes 2–4 days later.

D. Serology

Spirochetes grown in culture can serve as antigens for CF tests, but the preparation of satisfactory antigens is difficult. Patients with epidemic (louse-borne) relapsing fever may develop a positive VDRL test result.

E. Other tests

There are currently no FDA-approved tests for the diagnosis of *B. miyamotoi* infection. No serologic tests are currently available, and in some cases cross-reactivity with serologic tests for *B. burgdorferi* has been reported. However, several PCR tests have been described for the detection of *B. miyamotoi* from whole blood, plasma, CSF, and tissue.

Immunity

Immunity following infection is usually of short duration.

Treatment

The great variability of the spontaneous remissions of relapsing fever makes evaluation of chemotherapeutic effectiveness difficult. Tetracyclines, erythromycin, and penicillin are all

believed to be effective. Treatment for a single day may be sufficient to terminate an individual attack.

Epidemiology, Prevention, and Control

Relapsing fever is endemic in many parts of the world. Its main reservoir is the rodent population, which serves as a source of infection for ticks of the genus *Ornithodoros*. The distribution of endemic foci and the seasonal incidence of the disease are largely determined by the ecology of the ticks in different areas. In the United States, infected ticks are found throughout the West, especially in mountainous areas, but clinical cases are rare. In the tick, *Borrelia* species may be transmitted transovarially from generation to generation.

Spirochetes are present in all tissues of the tick and may be transmitted by the bite or by crushing the tick. The tick-borne disease is not epidemic. However, when an infected individual harbors lice, the lice become infected by sucking blood; 4–5 days later, they may serve as a source of infection for other individuals. The infection of the lice is not transmitted to the next generation, and the disease is the result of rubbing crushed lice into bite wounds. Severe epidemics may occur in louse-infected populations, and transmission is favored by crowding, malnutrition, and cold climate.

In endemic areas, human infection may occasionally result from contact with the blood and tissues of infected rodents. The mortality rate of the endemic disease is low, but in epidemics, it may reach 30%.

Prevention is based on avoidance of exposure to ticks and lice and on delousing (cleanliness, insecticides).

BORRELIA BURGDORFERI AND LYME DISEASE

Lyme disease is named after the town of Lyme, Connecticut, where clusters of cases in children were identified. Since 1992, three species of *Borrelia* have been associated with Lyme disease: *Borrelia burgdorferi* sensu stricto, *Borrelia afzelii*, and *Borrelia garinii*. All three species cause disease in Europe, but only *B. burgdorferi* is responsible for disease in North America. The spirochete *B. burgdorferi* is transmitted to humans by the bite of a small *Ixodes* tick. The disease has early manifestations with a characteristic skin lesion, **erythema migrans**, along with flulike symptoms, and late manifestations often with arthralgia and arthritis.

Morphology and Identification

A. Typical Organisms

B. burgdorferi is a spiral organism 20–30 μm long and 0.2–0.3 μm wide. The distance between turns varies from 2 to 4 μm . The organisms have variable numbers (7–11) of endoflagella and are highly motile. *B. burgdorferi* stains readily with acid and aniline dyes and by silver impregnation techniques.

B. Culture and Growth Characteristics

B. burgdorferi grows most readily in a complex liquid medium, Barbour-Stoenner-Kelly medium (BSK II). Rifampin, fosfomycin (phosphonomycin), and amphotericin B can be added to BSK II to reduce the rate of culture contamination by other bacteria and fungi. *B. burgdorferi* has been most easily isolated from erythema migrans skin lesions; isolation of the organism from other sites has been difficult. The organism can also be cultured from ticks. Because culture of the organism is a complex and specialized procedure with a low diagnostic yield, it is seldom used.

Antigenic Structure and Variation

B. burgdorferi has a morphologic appearance similar to that of other spirochetes. The entire genome of *B. burgdorferi* has been sequenced, allowing prediction of many antigenic structures. There is an unusual linear chromosome of about 950 kb and multiple circular and linear plasmids. There are a large number of sequences for lipoproteins, including outer surface proteins OspA to F. Differential expression of these proteins is thought to help *B. burgdorferi* live in the very different tick and mammalian hosts. OspA and OspB along with lipoprotein 6.6 are expressed primarily in ticks. Other outer surface proteins are upregulated during tick feeding when the organisms migrate from the tick's midgut to the salivary gland. This may explain why the tick must feed for 24–48 hours before transmission of *B. burgdorferi* occurs.

Pathogenesis and Clinical Findings

The transmission of *B. burgdorferi* to humans is by injection of the organism in tick saliva or by regurgitation of the tick's midgut contents. The organism adheres to proteoglycans on host cells; this is mediated by a borrelial glycosaminoglycan receptor. After injection by the tick, the organism migrates out from the site, producing the characteristic skin lesion. Dissemination occurs by lymphatics or blood to other skin and musculoskeletal sites and to many other organs.

Lyme disease, similar to other spirochetal diseases, occurs in stages with early and late manifestations. A unique skin lesion that begins 3 days to 4 weeks after a tick bite often marks stage 1. The lesion, erythema migrans, begins as a flat reddened area near the tick bite and slowly expands, with central clearing. With the skin lesion, there is often a flulike illness with fever, chills, myalgia, and headache. Stage 2 occurs weeks to months later and includes arthralgia and arthritis; neurologic manifestations with meningitis, facial nerve palsy, and painful radiculopathy; and cardiac disease with conduction defects and myopericarditis. Stage 3 begins months to years later with chronic skin, nervous system, or joint involvement. Spirochetes have been isolated from all of these sites, and it is likely that some of the late manifestations are caused by deposition of antigen-antibody complexes.

Diagnostic Laboratory Tests

In some symptomatic patients, the diagnosis of early Lyme disease can be established clinically by observing the unique skin lesion. When this skin lesion is not present and at later stages of the disease, which must be differentiated from many other diseases, it is necessary to perform diagnostic laboratory tests. There is, however, no one test that is both sensitive and specific.

A. Specimens

Blood is obtained for serologic tests. CSF or joint fluid can be obtained, but culture usually is not recommended. These specimens and others can be used to detect *B. burgdorferi* DNA by PCR.

B. Smears

B. burgdorferi has been found in sections of biopsy specimens, but examination of stained smears is an insensitive method for diagnosis of Lyme disease. *B. burgdorferi* in tissue sections can sometimes be identified using antibodies and immunohistochemical methods.

C. Culture

Culture is generally not performed because it takes 6–8 weeks to complete and lacks sensitivity.

D. Nucleic Acid Amplification Methods

The PCR assay has been applied to detection of *B. burgdorferi* DNA in many body fluids. It is rapid, sensitive, and specific, but it does not differentiate between DNA from live *B. burgdorferi* in active disease and DNA from dead *B. burgdorferi* in treated or inactive disease. It has about 85% sensitivity when applied to synovial fluid samples, but the sensitivity is much lower when it is applied to CSF samples from patients with neuroborreliosis.

E. Serology

Serology has been the mainstay for the diagnosis of Lyme disease, but 3–5% of normal people and persons with other diseases (eg, rheumatoid arthritis, many infectious diseases) may be seropositive by initial EIA or indirect fluorescent antibody (IFA) assay. When the prevalence of Lyme disease is low as it is in many geographic areas, there is a much greater likelihood that a positive test result is from a person who does not have Lyme disease than from a person who does have the disease (a positive predictive value of <10%). Thus, serology for Lyme disease should only be done when there are highly suggestive clinical findings. A diagnosis of Lyme disease should not be based on a positive EIA or IFA test result in the absence of suggestive clinical findings. A two-stage approach to the serodiagnosis is strongly recommended that includes EIA or IFA followed by an immunoblot assay for reactivity with specific *B. burgdorferi* antigens.

The EIA and IFA are the most widely used initial tests for Lyme disease. Multiple variations of these assays using

different antigen preparations, techniques, and end points have been marketed. Results of the initial tests are generally reported as positive, negative, or indeterminate.

The immunoblot assay is generally performed to confirm results obtained by the EIA tests. Recombinant *B. burgdorferi* antigens or antigens from whole-cell lysates are electrophoretically separated, transferred to a nitrocellulose membrane, and reacted with a patient's serum. Interpretation of the immunoblot is based on the number and molecular size of antibody reactions with the *B. burgdorferi* proteins. Blots can be analyzed for IgG or IgM. The antigen–antibody band patterns on the immunoblots should be interpreted with knowledge of known results from patients at various stages of Lyme borreliosis, and caution should be used to avoid overinterpretation of minimally reactive blots.

Immunity

The immunologic response to *B. burgdorferi* develops slowly. Sera obtained in stage 1 are positive in 20–50% of patients. Sera obtained during stage 2 are positive in 70–90% with reactive IgG and IgM; IgG predominates in longstanding infection. In stage 3, nearly 100% of patients have IgG reactive with *B. burgdorferi*. The antibody response can expand from months to years and appears to be directed sequentially against a series of *B. burgdorferi* proteins. Early antimicrobial treatment decreases the antibody response. Antibody titers fall slowly after treatment, but most patients with later manifestation of Lyme disease remain seropositive for years.

Treatment

Early infection, either local or disseminated, should be treated with doxycycline, amoxicillin, or cefuroxime axetil for 14–21 days. Treatment relieves early symptoms and promotes resolution of skin lesions. Doxycycline may be more effective than amoxicillin in preventing late manifestations. Established arthritis may respond to prolonged therapy with doxycycline or amoxicillin orally or penicillin G or ceftriaxone intravenously. In refractory cases, ceftriaxone has been effective. Nearly 50% of patients treated with doxycycline or amoxicillin early in the course of Lyme disease develop minor late complications (eg, headache and joint pains).

Epidemiology, Prevention, and Control

B. burgdorferi is transmitted by a small tick of the genus *Ixodes*. The vector is *I. scapularis* (also called *Ixodes dammini*) in the Northeast and Midwest and *Ixodes pacificus* on the West Coast of the United States. In Europe, the vector is *Ixodes ricinus*, and other tick vectors appear to be important in other areas of the world. The *Ixodes* ticks are quite small and often are not noticed when feeding on the skin. The larvae are about 1 mm; the nymphs about the size of a poppy seed or piece of cracked pepper (~2 mm), and the adult female 3–4 mm. All stages are smaller by one-half or more than comparable stages of the dog

tick *Dermacentor variabilis*. Depending on the developmental stage and the *Ixodes* species, the ticks must feed for 2–4 days to obtain a blood meal. Transmission of *B. burgdorferi* occurs late in the feeding process. Mice and deer constitute the main animal reservoirs of *B. burgdorferi*, but other rodents and birds may also be infected. In the eastern part of the United States, 10–50% of ticks are infected; in the western states, the infection rate in ticks is much lower, about 2%.

Most exposures are in May through July, when the nymphal stage of the ticks is most active; however, the larval stage (August and September) and adult stage (spring and fall) also feed on humans and can transmit *B. burgdorferi*.

Prevention is based on avoidance of exposure to ticks. Wearing long sleeves and long pants tucked into socks is recommended. Careful examination of the skin for ticks after being outdoors can locate ticks for removal before they transmit *B. burgdorferi*.

Environmental control of ticks using application of insecticides has provided modest success in reducing the number of nymphal ticks for a season.

Concept Checks

- A variety of *Borrelia* species cause disease, usually after the bite of an arthropod or other vector.
- *B. recurrentis*, transmitted by the human body louse, causes epidemic relapsing fever; endemic disease is usually transmitted by ticks of the genus *Ornithodoros*. *B. hermsii* is the cause of relapsing fever in the western United States.
- Relapsing fever is characterized by abrupt rise in temperature that persists for 3–5 days. After a brief afebrile hiatus, a second attack occurs, usually related to antigenic variants.
- Diagnosis of relapsing fever is best done by obtaining thick and thin blood smears and staining them with Wright or Giemsa stain.
- Treatment requires penicillin, tetracycline, or erythromycin.
- *B. burgdorferi* is responsible for Lyme disease and is most often transmitted by the nymphal stage of the *Ixodes* tick.
- Lyme disease occurs in stages. The hallmark of stage 1 is erythema migrans at the site of the tick bite. Stages 2 and 3 are characterized by arthritis and cardiac and neurologic manifestations.
- Diagnosis rests on a two-stage serologic approach beginning with an EIA or IFA test followed by an immunoblot assay for reactivity to specific antigens if the screening test result is positive.
- Treatment depends on the stage of the disease; penicillin, doxycycline, cefuroxime, and parenteral ceftriaxone have all been effective.

LEPTOSPIRA AND LEPTOSPIROSIS

Leptospirosis is a zoonosis of worldwide distribution. It is caused by spirochetes of the genus *Leptospira*. There is one

pathogenic species, *Leptospira interrogans*, but more than 200 serovars of *L. interrogans*. These serovars are further organized into over two dozen serogroups. The serogroups are based on shared antigenicity and are primarily for laboratory use.

Morphology and Identification

A. Typical Organisms

Leptospirae are tightly coiled, thin, flexible spirochetes 5–15 μm long, with very fine spirals 0.1–0.2 μm wide; one end is often bent, forming a hook. They are actively motile, which is best seen using a dark-field microscope. Electron micrographs show a thin axial filament and a delicate membrane. The spirochete is so delicate that in the dark-field view, it may appear only as a chain of minute cocci. It does not stain readily but can be impregnated with silver.

B. Culture

Leptospirae grow best under aerobic conditions at 28–30°C in semisolid medium (eg, Ellinghausen-McCullough-Johnson-Harris, EMJH) in 10 mL test tubes with 0.1% agar and 5-fluorouracil (see also Diagnostic Laboratory Tests). After 1–2 weeks, the leptospirae produce a diffuse zone of growth near the top of the tube and later a ring of growth at a level in the tube corresponding to the level of the optimal oxygen tension for the organisms.

C. Growth Requirements

Leptospirae derive energy from oxidation of long-chain fatty acids and cannot use amino acids or carbohydrates as major energy sources. Ammonium salts are a main source of nitrogen. Leptospirae can survive for weeks in water, particularly at alkaline pH.

Antigenic Structure

The main strains (“serovars”) of *L. interrogans* are all serologically related and exhibit cross-reactivity in serologic tests. This indicates considerable overlapping in antigenic structure, and quantitative tests and antibody absorption studies are necessary for a specific serologic diagnosis. The outer envelope contains large amounts of lipopolysaccharide of antigenic structure that is variable from one strain to another. This variation forms the basis for the serologic classification of the *Leptospira* species. It also determines the specificity of the human immune response to leptospirae.

Pathogenesis and Clinical Findings

Human infection usually results from leptospirae, often in bodies of water, entering the body through breaks in the skin (cuts and abrasions) and mucous membranes (mouth, nose, conjunctivae). Ingestion is considered to be less important. After an incubation period of 1–2 weeks, there is a variable febrile onset during which spirochetes are present in the

bloodstream. They then establish themselves in the parenchymatous organs (particularly liver and kidneys), producing hemorrhage and necrosis of tissue and resulting in dysfunction of those organs (jaundice, hemorrhage, nitrogen retention). The illness is often biphasic. After initial improvement, the second phase develops when the IgM antibody titer rises. It manifests itself often as “aseptic meningitis” with an intense headache, stiff neck, and pleocytosis of the CSF. Nephritis and hepatitis may also recur, and there may be skin, muscle, and eye lesions. The degree and distribution of organ involvement vary in the different diseases produced by different leptospirae in various parts of the world. Many infections are mild or subclinical. Hepatitis is frequent in patients with leptospirosis.

Kidney involvement in many animal species is chronic and results in the shedding of large numbers of leptospirae in the urine; this is probably the main source of environmental contamination resulting in infection of humans. Human urine also may contain spirochetes in the second and third weeks of disease.

Agglutinating, complement-fixing, and lytic antibodies develop during the infection. Serum from convalescent patients protects experimental animals against an otherwise fatal infection. The immunity resulting from infection in humans and animals appears to be serovar specific.

Diagnostic Laboratory Tests

A. Specimens

Specimens consist of aseptically collected blood in a heparin tube, CSF, or tissues for microscopic examination and culture. Urine should be collected using great care to avoid contamination. Serum is collected for agglutination tests.

B. Microscopic Examination

Dark-field examination or thick smears stained by the Giemsa technique occasionally show leptospirae in fresh blood from early infections. Results of dark-field examination of centrifuged urine may also be positive. Fluorescein-conjugated antibodies or other immunohistochemical techniques can be used also.

C. Culture

Whole fresh blood or urine can be cultured in a semisolid medium. Because of inhibitory substances in blood, only one or two drops should be placed in each of five tubes containing 5 or 10 mL of medium. Up to 0.5 mL of CSF can be used. One drop of undiluted urine can be used followed by one drop each of tenfold serially diluted urine for a total of four tubes. Tissue approximately 5 mm in diameter should be crushed and used as the inoculum. Growth is slow, and cultures should be kept for at least 8 weeks.

D. Serology

The diagnosis of leptospirosis in most cases is confirmed serologically. Agglutinating antibodies first appear 5–7 days after infection and develop slowly, reaching a peak at 5–8 weeks.

Very high titers may be attained ($>1:10,000$). The reference laboratory standard for detection of leptospiral antibody uses microscopic agglutination of live organisms, which can be hazardous. The test is highly sensitive, but it is difficult to standardize; the end point is 50% agglutination, which is difficult to determine. Agglutination of the live suspensions is most specific for the serovar of the infecting leptospire. Agglutination tests are generally performed only in reference laboratories. Paired sera that show a significant change in titer or a single serum with high-titer agglutinins plus a compatible clinical illness can be diagnostic. Because of the difficulty in performing the definitive agglutination tests, a variety of other tests have been developed for use primarily as screening tests.

Immunity

Serovar-specific immunity follows infection, but reinfection with different serovars may occur.

Treatment

Treatment of mild leptospirosis should be with oral doxycycline, ampicillin, or amoxicillin. Treatment of moderate or severe disease should be with intravenous penicillin, ampicillin, or ceftriaxone.

Epidemiology, Prevention, and Control

The leptospiroses are essentially animal infections; human infection is only accidental, occurring after contact with water or other materials contaminated with the excreta of animal hosts. Rats, mice, wild rodents, dogs, swine, and cattle are the principal sources of human infection. They excrete leptospirae in urine both during the active illness and during the asymptomatic carrier state. Leptospirae remain viable in stagnant water for several weeks; drinking, swimming, bathing, or food contamination may lead to human infection. Persons most likely to come in contact with water contaminated by rats (eg, miners, sewer workers, farmers, and fishermen) run the greatest risk of infection. Children acquire the infection from dogs more frequently than adults do. Control consists of preventing exposure to potentially contaminated water and reducing contamination by rodent control. Doxycycline, 200 mg orally once weekly during heavy exposure, is effective prophylaxis. Dogs can receive distemper–hepatitis–leptospirosis vaccinations.

CONCEPT CHECKS

- Leptospirosis is a zoonosis with worldwide distribution, caused by spirochetes in the genus *Leptospira* interrogans; *Leptospira* are maintained in nature via chronic renal infection of carrier animals, specifically rodents.
- The main serovars of *L. interrogans* are all serologically related and exhibit cross-reactivity.
- Infections usually occur following the occupational or recreational exposure to soil and/or water contaminated with rodent urine.
- *Leptospira* can penetrate intact mucous membranes or skin through small cuts and abrasions.
- In humans, infections with *Leptospira* can present as a sub-clinical illness, as a mild influenza-like febrile illness, or as a severe systemic illness with renal and hepatic failure, vasculitis, and myocarditis.
- Clinical diagnosis requires a high index of suspicion; laboratory diagnosis is based on serology, but serologic tests may have poor sensitivity during the first week of the illness.
- Treatment requires penicillin, amoxicillin, ampicillin, or doxycycline.
- Prevention of the illness rests on reduction of the risk of exposure to soil and/or water contaminated with rodent urine.

REVIEW QUESTIONS

1. A 28-year-old woman who is 10 weeks pregnant presents to the obstetrics clinic for prenatal care. She has a history of treatment for syphilis 7 years previously. The results of serologic tests for syphilis are as follows: nontreponemal test, RPR, nonreactive; treponemal test (TP-PA), reactive. Which of the following statements is most correct?
 - (A) The mother's previous treatment for syphilis was effective.
 - (B) The baby is at high risk for congenital syphilis.
 - (C) The mother needs to be treated again for syphilis.
 - (D) The mother needs a lumbar puncture and a VDRL test of her CSF for neurosyphilis.
2. A 12-year-old Boy Scout went to summer camp for 2 weeks in late August at a site located just outside Mystic, Connecticut. When he returned home, his mother noticed a bull's-eye-shaped rash on the back of her son's left calf. Shortly after Labor Day, the boy developed a flulike illness that resolved after 4 days of bed rest. Three weeks later, the boy complained to his mother that his body hurt all over whenever he moved. This prompted a visit to the pediatrician, who ordered an infectious disease workup. What is the most likely source of the boy's infection?
 - (A) Respiratory transmission from another sick camper
 - (B) Ingestion of urine-contaminated water from a stream
 - (C) The bite of a mosquito harboring a parasite
 - (D) Ingestion of fecally contaminated food
 - (E) The bite of a spirochete-infected tick
3. Nontreponemal serological tests:
 - (A) Are useful in definitively identifying a *T. pallidum* infection.
 - (B) Measure antibodies against *T. pallidum*.
 - (C) Can be used to monitor antibiotic treatment of primary or secondary syphilis.
 - (D) Measure antibodies against lipids released from damaged cells.
 - (E) Are useful in diagnosing a disseminated gonococcal infection.
4. A 42-year-old woman went camping in the Sierra Nevada Mountains, where she slept for two nights in an abandoned log

- cabin. After the second night, a tick was found on her shoulder. Six days later, she developed fever to 38°C, which lasted for 4 days. Ten days later, she had another similar episode of fever. Examination of a blood smear stained with Wright stain showed spirochetes suggestive of *Borrelia* species. Which of the following statements about relapsing fever is correct?
- Each relapse is associated with an antigenically distinct variant.
 - Blood smears should be made when the patient is afebrile.
 - Borreliae* do not pass transovarially from one generation to the next in ticks.
 - The main reservoir for the *Borrelia* is deer.
 - Borrelia* is resistant to penicillin and tetracycline.
- A 23-year-old man presented with a maculopapular rash over much of his trunk but not in his mouth or on his palms. Because secondary syphilis was considered in the differential diagnosis, a RPR test was done, and the result was positive at a 1:2 dilution. However, the TP-PA test result was negative. Which of the following diseases can be ruled out?
 - Secondary syphilis
 - Atypical measles
 - Coxsackie virus infection
 - Acute HIV 1 infection
 - Allergic drug reaction
 - Which of the following animals is the source of *L. interrogans*?
 - Alligators
 - Ducks
 - Frogs
 - Catfish
 - Swine
 - A 27-year-old medical resident was admitted to the hospital because of sudden onset of fever to 39°C and headache. Two weeks previously, he had vacationed in rural Oregon, where he had frequently gone swimming in an irrigation canal that bordered land where cows were pastured. Blood tests done shortly after admission indicated renal function abnormality and elevated bilirubin and other liver function test results. Routine blood, urine, and CSF culture results were negative. Leptospirosis is suspected. Which of the following would be most likely to confirm this diagnosis?
 - Testing acute and convalescent phase sera using the RPR test
 - Culture of urine on human diploid fibroblast cells
 - Testing serum by dark-field examination for the presence of leptospires
 - Testing acute and convalescent phase sera for antileptospiral antibodies
 - Culture of CSF on blood and chocolate agar
 - Gram-stain of CSF and blood
 - A 47-year-old man presents with slowly progressive arthritis in his knees. He enjoys hiking in the coastal areas of Northern California, where the prevalence of *B. burgdorferi* in the *Ixodes* ticks is known to be 1–3% (considered low). The patient is concerned about Lyme disease. He never noticed a tick on his body and did not see an expanding red rash. The result of an EIA for Lyme borreliosis is positive. What should be done now?
 - A biopsy specimen of the synovium of a knee joint should be examined for *B. burgdorferi*.
 - The patient should be given an antibiotic to treat Lyme disease.
 - PCR on the patient's plasma should be done to detect *B. burgdorferi*.
 - A serum specimen should be submitted for immunoblot assay to detect antibodies reactive with *B. burgdorferi* antigens.
 - Culture of synovial fluid on blood and chocolate agar.
 - Which of the following organisms principally infects the liver and kidneys?
 - L. interrogans*
 - Staphylococcus aureus*
 - Escherichia coli*
 - Enterococcus faecalis*
 - T. pallidum*
 - All of the following statements regarding relapsing fever are correct *except*
 - Epidemic disease carries a higher mortality rate than endemic disease.
 - Endemic disease in North America is caused by *B. recurrentis*.
 - The recurrent febrile episodes are caused by antigenic variation among the spirochetes.
 - Penicillin is the drug of choice.
 - Crushing a tick could transmit the spirochetes.

Mycoplasmas and Cell Wall-Defective Bacteria

MYCOPLASMAS

There are more than 200 known species in the class of Mollicutes (cell wall-free bacteria). At least 16 of these species are thought to be of human origin; others have been isolated from animals and plants. In humans, four species are of primary importance: *Mycoplasma pneumoniae* causes pneumonia and has been associated with joint and other infections. *M. hominis* sometimes causes postpartum fever and has been found with other bacteria in uterine tube infections. *Ureaplasma urealyticum* is a cause of nongonococcal urethritis in men and is associated with lung disease in premature infants of low birth weight. *Mycoplasma genitalium* is closely related to *M. pneumoniae* and has been associated with urethral and other urogenital infections. Other members of the genus *Mycoplasma* are pathogens of the respiratory and urogenital tracts and joints of humans and animals.

The smallest genome of known mycoplasmas, *M. genitalium*, is little more than twice the genome size of certain large viruses. Mycoplasmas are the smallest organisms that can be free living in nature and self-replicating on laboratory media. They have the following characteristics: (1) the smallest mycoplasmas are 125–250 nm in size; (2) they are highly pleomorphic because they lack a rigid cell wall and instead are bounded by a triple-layered “unit membrane” that contains a sterol (mycoplasmas require the addition of serum or cholesterol to the medium to produce sterols for growth); (3) mycoplasmas are completely resistant to penicillin because they lack the cell wall structures at which penicillin acts, but they are inhibited by tetracycline or erythromycin; (4) mycoplasmas can reproduce in cell-free media; on agar, the center of the whole colony is characteristically embedded beneath the surface; (5) growth of mycoplasmas is inhibited by specific antibody; and (6) mycoplasmas have an affinity for mammalian cell membranes.

Morphology and Identification

A. Typical Organisms

Mycoplasmas cannot be studied by the usual bacteriologic methods because of the small size of their colonies and the plasticity and delicacy of their individual cells. Growth in fluid media gives rise to many different forms. Growth on

solid media consists principally of protoplasmic masses of indefinite shape that are easily distorted. These structures vary greatly in size, ranging from 50 to 300 nm in diameter. The morphology appears different according to the method of examination (eg, dark field, immunofluorescence, Giemsa-stained films from solid or liquid media, and agar fixation).

B. Culture

Culture of mycoplasmas that cause disease in humans requires media with serum, a metabolic substrate such as glucose or urea, and growth factors such as yeast extract. There is no one medium that is optimal for all the species because of different properties and substrate requirements. After incubation at 37°C for 48–96 hours, there may be no turbidity in broth cultures; however, Giemsa stains of the centrifuged sediment show the characteristic pleomorphic structures, and subculture on appropriate solid media yields minute colonies.

After 2–6 days on biphasic (broth over agar) and agar medium incubated in a Petri dish that has been sealed to prevent evaporation, isolated colonies of the more rapidly growing mycoplasmas measuring 20–500 µm can be detected with a hand lens. These colonies are round, with a granular surface and a dark center typically buried in the agar. They can be subcultured by cutting out a small square of agar containing one or more colonies and streaking this material on a fresh plate or dropping it into liquid medium.

C. Growth Characteristics

Mycoplasmas are unique in microbiology because of their (1) lack of a cell wall; (2) extremely small size; and (3) growth on complex but cell-free media.

Mycoplasmas pass through filters with 450-nm pore size and thus are comparable to Chlamydiae or large viruses. However, parasitic mycoplasmas grow on cell-free media that contain lipoprotein and sterol. This sterol requirement for growth and membrane synthesis is unique.

Many mycoplasmas use glucose as a source of energy; ureaplasmas require urea.

Some human mycoplasmas produce peroxides and hemolyze red blood cells. In cell cultures and in vivo, mycoplasmas are observed predominantly at cell surfaces. Many established animal and human cell culture lines carry

mycoplasmas as contaminants; often the mycoplasmas are intracellular as well.

D. Variation

The extreme pleomorphism of mycoplasmas is one of their principal characteristics.

Antigenic Structure

At least 16 antigenically distinct species can be identified from humans, including *M. hominis*, *M. pneumoniae*, *M. genitalium*, and *U. urealyticum*. Most *Mycoplasma* species have high evolved systems for variation of outer membrane antigens presumably for evading the host immune response during infection.

The species are classified by biochemical and serologic features. The complement fixation (CF) antigens of mycoplasmas are glycolipids. Antigens for enzyme-linked immunoassay (ELISA) tests are proteins. Some species have more than one serotype.

Pathogenesis

Many pathogenic mycoplasmas have flasklike or filamentous shapes and have specialized polar tip structures that mediate adherence to host cells. These structures are a complex group of interactive proteins, adhesins (eg, the P1 adhesin of *M. pneumoniae* and the MgPa adhesin of *M. genitalium*), and adherence-accessory proteins. The proteins are proline rich, which influence the protein folding and binding and are important in the adherence to cells. The mycoplasmas attach to the surfaces of ciliated and nonciliated cells, probably through the mucosal cell sialoglycoconjugates and sulfated glycolipids. Some mycoplasmas lack the distinct tip structures but use adhesin proteins or have alternative mechanisms to adhere to host cells. The subsequent events in infection are less well understood but may include several factors as follows: direct cytotoxicity through generation of hydrogen peroxide and superoxide radicals, cytolysis mediated by antigen–antibody reactions or by chemotaxis and action of mononuclear cells, and competition for and depletion of nutrients.

Mycoplasma Infection

Mycoplasmas have been cultivated from human mucous membranes and tissues, particularly from the genital, urinary, and respiratory tracts. Mycoplasmas are part of the normal microbiota of the mouth and can be grown from normal saliva, oral mucous membranes, sputum, or tonsillar tissue. *M. hominis* is found in the oropharynx of fewer than 5% of adults. *M. pneumoniae* in the oropharynx is generally associated with disease (see next).

Some mycoplasmas are inhabitants of the genitourinary tract, particularly in women. In both men and women, genital carriage of mycoplasmas is directly related to the number of lifetime sex partners. *M. hominis* can be cultured from 1% to 5%

of asymptomatic men and 30–70% of asymptomatic women; the rates increase to 20% and more than 90% positive for men and women, respectively, in sexually transmitted disease clinics. *U. urealyticum* is found in the genital tracts of 5–20% of sexually active men and 40–80% of sexually active women. Approximately 10% of women attending sexually transmitted disease clinics have *M. genitalium* in their lower genital tracts. The presence of *M. genitalium* in the male urethra is typically associated with disease, a syndrome termed nongonococcal urethritis. Other mycoplasmas also occur in the lower genital tract.

Diagnostic Laboratory Tests

A. Specimens

Specimens consist of throat swabs; sputum; inflammatory exudates; and respiratory, urethral, or genital secretions.

B. Microscopic Examination

Direct examination of a specimen for mycoplasmas is useless. Cultures are examined as described earlier.

C. Cultures

The material is inoculated into broth and onto special solid media depending on the organism sought. Agar media are best incubated at 37°C with 5–10% CO₂ (under microaerophilic conditions or even anaerobic conditions). Broths require incubation at 37°C under atmospheric (aerobic) conditions. The duration of incubation varies from 2 to 4 days for organisms such as *M. hominis* and *U. urealyticum* to up to 4 weeks for *M. pneumoniae*.

One or two transfers of media may be necessary before growth appears that is suitable for microscopic examination by staining or immunofluorescence. Colonies of *M. hominis* may have a typical “fried egg” appearance on agar, but those of *M. pneumoniae* and *M. genitalium* are smaller and may lack the typical appearance.

Specimens submitted for diagnosis of *Ureaplasma* species are usually inoculated to broth or agar media (eg, A8 agar) containing urea. Growth is signaled by a color change indicating hydrolysis of urea.

D. Serology

Antibodies develop in humans infected with mycoplasmas and can be demonstrated by several methods. CF tests can be performed with glycolipid antigens extracted with chloroform–methanol from cultured mycoplasmas. *M. pneumoniae* and *M. genitalium* are serologically cross-reactive using CF tests. HI tests can be applied to tanned red blood cells with adsorbed *Mycoplasma* antigens. Indirect immunofluorescence may be used. The test that measures growth inhibition by antibody is quite specific. Enzyme immunoassays (EIAs) are available in most laboratories, but sensitivity and specificity are quite variable depending on the assay. In general, EIAs are considered better than CF. With all of these serologic techniques, there is adequate specificity for different human

Mycoplasma species, but a rising antibody titer is required for diagnostic significance because of the high incidence of positive serologic test results in normal individuals.

E. Nucleic Acid Amplification Tests

Molecular methods for the detection of the human mycoplasmas and ureaplasma are available in many reference laboratories, and a variety of primers and probes have been published. Very few assays are cleared by the U.S. Food and Drug Administration, although many platforms are in development and this situation will likely improve. Nucleic acid amplification tests (NAATs) are particularly useful for those organisms that are difficult to cultivate such as *M. pneumoniae* and *M. genitalium* and less useful for the more rapidly growing organisms. The difficulty arises when these test results are positive in the absence of corroborating clinical or other positive diagnostic test results. At this time, these assays are best used in combination with other traditional diagnostic methods such as serology until more clinical data become available.

Treatment

Many strains of mycoplasmas are inhibited by a variety of antimicrobial drugs, but most strains are resistant to penicillins, cephalosporins, and vancomycin. Tetracyclines and erythromycins are effective both in vitro and in vivo and are, at present, the drugs of choice in mycoplasmal pneumonia. Some ureaplasmas are resistant to tetracycline. Treatment of *M. genitalium* urethritis in men is typically through a single dose of azithromycin administered in the clinic. This ensures compliance and reduces the likelihood of sexual transmission to other partners.

Epidemiology, Prevention, and Control

M. pneumoniae behaves like a communicable viral respiratory pathogen (see later discussion) and is capable of causing both endemic and epidemic infections. The genital mycoplasmas and ureaplasma are spread by genital or oral–genital contact and may be transmitted along with other sexually acquired pathogens. Safe sexual practices should reduce spread. No vaccines are available to protect against any of these organisms.

MYCOPLASMA PNEUMONIAE AND ATYPICAL PNEUMONIAS

M. pneumoniae is a prominent cause of pneumonia, especially in persons 5–20 years of age.

Pathogenesis

M. pneumoniae is transmitted from person to person by means of infected respiratory secretions. Infection is initiated by attachment of the organism's tip to a receptor on the surface of respiratory epithelial cells (Figure 25-1). Attachment

FIGURE 25-1 Electron micrograph of *M. pneumoniae* attached to ciliated respiratory epithelial cells in a sputum sample from a patient with culture-proved *M. pneumoniae* pneumonia. The organisms (M) are seen on the luminal border attached between cilia (C). (Courtesy AM Collier, Department of Pediatrics, University of North Carolina.)

is mediated by a specific adhesin protein on the differentiated terminal structure of the organism. During infection, the organisms remain extracellular.

Clinical Findings

Mycoplasma pneumoniae is generally a mild disease. The clinical spectrum of *M. pneumoniae* infection ranges from asymptomatic infection to serious pneumonitis, with occasional neurologic and hematologic (ie, hemolytic anemia) involvement and a variety of possible skin lesions. Bullous myringitis occurs in spontaneous cases and in experimentally inoculated volunteers.

The incubation period varies from 1 to 3 weeks. The onset is usually insidious, with malaise, fever, headache, sore throat, and cough. Initially, the cough is nonproductive, but it is occasionally paroxysmal. Later, there may be blood-streaked sputum and chest pain. Early in the course, the patient appears only moderately ill, and physical signs of pulmonary consolidation are often negligible compared with the striking consolidation seen on radiographs. Later, when the infiltration is at a peak, the illness may be severe. Resolution of pulmonary infiltration and clinical improvement occur slowly over 1–4 weeks. Although the course of the illness is exceedingly variable, death is very rare and is usually attributable to cardiac failure. Complications are uncommon, but hemolytic anemia may occur. The most common pathologic findings in complicated cases are interstitial with peribronchial pneumonitis and necrotizing bronchiolitis. Other diseases less commonly related to *M. pneumoniae* include erythema multiforme; central nervous system involvement, including meningitis, meningoencephalitis, and mono- and polyneuritis; myocarditis; pericarditis; arthritis; and pancreatitis.

Common causes of community-acquired bacterial pneumonia, in addition to *M. pneumoniae*, include *Streptococcus pneumoniae*, *Legionella pneumophila*, *Chlamydia pneumoniae*, and *Haemophilus influenzae*. The clinical presentations of these infections can be very similar, and recognition of the subtleties of signs and symptoms is important. The causative organisms must be determined by sputum examination and culture, blood culture, and other tests.

Laboratory Tests

The diagnosis of *M. pneumoniae* pneumonia is largely made by the clinical recognition of the syndrome. Laboratory tests are of secondary value. The white blood cell count may be slightly elevated. A sputum Gram-stain is of value only to identify a non-mycoplasma bacterial pathogen (eg, *S. pneumoniae*). The causative mycoplasmas can be recovered by culture from the pharynx and from sputum, but culture is a highly specialized test and is almost never done to diagnose *M. pneumoniae* infection. Cold hemagglutinins for group O human erythrocytes appear in about 50% of untreated patients, in rising titer, with the maximum reached in the third or fourth week after onset. A titer of 1:64 or more supports the diagnosis of *M. pneumoniae* infection. There is a rise in specific antibodies to *M. pneumoniae* that is demonstrable by CF tests; acute and convalescent phase sera are necessary to demonstrate a fourfold rise in the CF antibodies. EIA to detect immunoglobulin M (IgM) and IgG antibodies can be highly sensitive and specific and are considered more sensitive than CF tests. Polymerase chain reaction (PCR) assays of specimens from throat swabs or other clinical material can be diagnostic (see earlier discussion).

Treatment

Tetracyclines, macrolides, or fluoroquinolones can produce clinical improvement but do not always eradicate *M. pneumoniae*, possibly because of their ability to reside intracellularly as well as extracellularly.

Epidemiology, Prevention, and Control

M. pneumoniae infections are endemic all over the world. In populations of children and young adults, where close contact prevails, and in families, the infection rate may be high (50–90%), but the incidence of pneumonitis is variable (3–30%). For every case of frank pneumonitis, there exist several cases of milder respiratory illness. *M. pneumoniae* is apparently transmitted mainly by direct contact involving respiratory secretions. Second attacks are infrequent. The presence of antibodies to *M. pneumoniae* has been associated with resistance to infection but may not be responsible for it. Cell-mediated immune reactions occur. The pneumonic process may be attributed in part to an immunologic response rather than only to infection.

MYCOPLASMA HOMINIS

M. hominis has been associated with a variety of diseases but is a demonstrated cause in only a few of them. The evidence for a causal relationship in disease is from culture and serologic studies. *M. hominis* can be cultured from the upper urinary tract in about 10% of patients with pyelonephritis. *M. hominis* is strongly associated with infection of the uterine tubes (salpingitis) and tubo-ovarian abscesses; the organism can be isolated from the uterine tubes of about 10% of patients with salpingitis but not from women with no signs of disease. Women with salpingitis more commonly have antibodies against *M. hominis* than women with no disease. *M. hominis* has been isolated from the blood of about 10% of women who have postabortal or postpartum fever and occasionally from joint fluid cultures of patients with arthritis.

UREAPLASMA UREALYTICUM

U. urealyticum, like *M. hominis*, has been associated with a variety of diseases but is a demonstrated cause in only a few of them. *U. urealyticum*, which requires 10% urea for growth, causes nongonococcal, nonchlamydial urethritis in men. Recent data show that urethritis is associated with biovar 2 and not biovar 1 (*Ureaplasma parvum*). *U. urealyticum* is common in the female genital tract, where the association with disease is weak. *U. urealyticum* has been associated with lung disease in premature low-birth-weight infants who acquired the organism during birth, but a causal effect has not been clearly demonstrated. However, in a symptomatic neonate with radiographic abnormalities in the lung and the absence of another discernible cause for the pneumonia, treatment for *Ureaplasma* species and *M. hominis* seems warranted. The evidence that *U. urealyticum* is associated with involuntary infertility is at best marginal.

MYCOPLASMA GENITALIUM

M. genitalium was originally isolated from urethral cultures of two men with nongonococcal urethritis, but culture of *M. genitalium* is difficult, and subsequent observations have been based on data obtained by using NAATs and serologic data. The data suggest that *M. genitalium* in men is associated with some cases of acute as well as chronic nongonococcal urethritis. In women, *M. genitalium* has been associated with a variety of infections such as cervicitis, endometritis, salpingitis, and infertility.

CHAPTER SUMMARY

- The major pathogens of medical importance include *M. pneumoniae*, the cause of endemic and epidemic respiratory infections, and the urogenital mycoplasmas, *M. hominis*, *M. genitalium*, and *U. urealyticum*.
- *M. hominis* and *U. urealyticum* are easily cultivatable because of rapid growth and less stringent requirements;

M. genitalium and *M. pneumoniae* require a much longer incubation.

- *M. pneumoniae* is an important cause of community-acquired pneumonia. Infection is insidious and often protracted. Diagnosis is best made clinically and confirmed by serology (fourfold rise in IgG or IgM) or by NAATs or both.
- The urogenital mycoplasmas have been associated with nonchlamydial, nongonococcal urethritis in men (*U. urealyticum*). Both *M. hominis* and *U. urealyticum* may cause postpartum fever and respiratory infections in premature infants. *M. hominis* is more prevalent in women with bacterial vaginosis than in healthy women.
- *Mycoplasma* and *Ureaplasma* infections do not respond to β -lactam antibiotics. Tetracyclines, macrolides, and quinolones are the agents of choice.

REVIEW QUESTIONS

1. *U. urealyticum* is so named because
 - (A) It thrives in the upper urinary tract.
 - (B) It requires urea as a growth substrate.
 - (C) It is a frequent cause of symptomatic urinary bladder infections in young women.
 - (D) It causes chronic urinary tract infections in premature babies born to mothers with ureaplasmas as part of the genital flora.
2. An 18-year-old sexually active woman develops left lower quadrant pain and fever. On pelvic examination, she has tenderness in the left adnexa, and a mass suggestive of a uterine tube abscess is palpated. The patient is diagnosed with pelvic inflammatory disease. Which of the following bacteria is considered to be a common cause of pelvic inflammatory disease?
 - (A) *Bacillus cereus*
 - (B) *H. influenzae*
 - (C) *Neisseria subflava*
 - (D) *M. pneumoniae*
 - (E) *Chlamydia trachomatis*
3. Which of the following is important in the pathogenesis of mycoplasmal infections?
 - (A) The peptidoglycan in the mycoplasmal cell wall
 - (B) The presence of lacto-*N*-neotetraose with a terminal galactosamine as the host cell receptor
 - (C) The structures and the interactive proteins that mediate adhesion to host cells
 - (D) The absence of cilia on the surface of the host cells
 - (E) Growth in an anatomic site where anaerobic organisms thrive
4. A 25-year-old woman is referred to the sexually transmitted diseases clinic because of contact with a male partner with gonorrhea. The woman has had 15 male sex partners since becoming sexually active. The likelihood that she also has genital *M. hominis* infection is
 - (A) 1%
 - (B) 5%
 - (C) 15%
 - (D) 40%
 - (E) 90%
5. A 25-year-old medical student has contact with a patient who has pneumonia with fever and cough. Four days later, the medical student develops fever and cough, and chest radiographs show consolidation of the right lower lobe. Routine bacterial sputum culture results are negative. Pneumonia caused by *M. pneumoniae* is considered. All of the following are methods to confirm the clinical suspicion except
 - (A) PCR amplification of *M. pneumoniae* DNA in sputum
 - (B) Culture of sputum for *M. pneumoniae*
 - (C) Gram-stain of sputum smear
 - (D) Culture of a lung aspirate for *M. pneumoniae*
 - (E) Enzyme immunoassay test of acute and convalescent sera
6. Which type of test is most readily used to obtain laboratory confirmation of *M. pneumoniae* infection?
 - (A) Culture in broth containing serum, glucose, and a penicillin (to inhibit other flora)
 - (B) PCR
 - (C) Electron microscopy
 - (D) EIA tests on acute and convalescent phase sera
7. A 13-year-old boy develops infection with *M. pneumoniae*. What is the risk for infection in other members of his household?
 - (A) None; it is sexually transmitted
 - (B) 1–3%
 - (C) 10–15%
 - (D) 20–40%
 - (E) 50–90%
8. A 19-year-old man develops cough and fever. A chest radiograph shows consolidation of the left lower lobe. A diagnosis of pneumonia is made. Which of the following bacteria is a frequent cause of community-acquired pneumonia?
 - (A) *L. pneumophila*
 - (B) *C. pneumoniae*
 - (C) *S. pneumoniae*
 - (D) *Mycoplasma pneumoniae*
 - (E) *Klebsiella pneumoniae*
9. Initiation of infection by *M. pneumoniae* begins with
 - (A) Elaboration of a polysaccharide capsule that inhibits phagocytosis
 - (B) Secretion of a potent exotoxin
 - (C) Endocytosis by ciliated respiratory epithelial cells
 - (D) Adherence to respiratory epithelial cells mediated by P1 adhesin
 - (E) Phagocytic uptake by alveolar macrophages
10. Infection with *M. genitalium*:
 - (A) is not restricted to the genitourinary tract.
 - (B) results in inflammation causing urethritis in males and cervicitis in females.
 - (C) is best treated with a first-generation cephalosporin.
 - (D) is associated only with nongonococcal urethritis in males.
 - (E) is asymptomatic unless a co-infection with *Chlamydia trachomatis* is present.

Rickettsia and Related Genera

GENERAL

The human pathogens in the family Rickettsiaceae are small bacteria of the genera *Rickettsia* and *Orientia*. They are closely related to members of the family Anaplasmataceae that includes the genera *Ehrlichia* and *Anaplasma*. These organisms are obligate intracellular parasites that are transmitted to humans by arthropods. Many rickettsiae are transmitted transovarially in the arthropod, which serves as both vector and reservoir. Rickettsial infections, but not the ehrlichioses, typically are manifested by fever, rashes, and vasculitis. They are grouped on the basis of their clinical features, epidemiologic aspects, and immunologic characteristics (Table 26-1). *Coxiella burnetii* resides in the family Coxiellaceae and is more closely related to the genus *Legionella*; for convenience, it is discussed at the end of this chapter.

RICKETTSIA AND ORIENTIA

Properties of Rickettsiae

Rickettsiae are pleomorphic coccobacilli, appearing either as short rods ($0.3 \times 1\text{--}2\ \mu\text{m}$) or as cocci ($0.3\ \mu\text{m}$ in diameter). They do not stain well with Gram-stain but are readily visible under the light microscope when stained with Giemsa stain, Gimenez stain, acridine orange, or other stains. However, immunohistochemical or immunofluorescence stains performed at a laboratory skilled in rickettsial diagnostics are the most useful methods for confirming a diagnosis of rickettsial infections.

Rickettsiae grow readily in yolk sacs of embryonated eggs. Pure preparations of rickettsiae for use in laboratory testing can be obtained by differential centrifugation of yolk sac suspensions. Many strains of rickettsiae also grow in cell culture, where the generation time is 8–10 hours at 34°C . Cell culture has replaced animal inoculation (except for *Orientia* species) and yolk sac cultivation for isolation of these organisms. For reasons of biosafety, isolation of rickettsiae should be done only in reference laboratories.

Rickettsiae have Gram-negative cell wall structures that include peptidoglycan-containing muramic acid and diaminopimelic acid. The genus is divided into several groups.

The typhus group, the spotted fever group, and the transitional group have species that are pathogenic to humans. Rickettsiae contain lipopolysaccharide, and the cell wall proteins include the surface proteins OmpA and OmpB. These surface proteins are important in adherence to host cells and in the humoral immune response and also provide the basis for serotyping.

Rickettsiae grow in different parts of the cell. Those of the typhus group are usually found in the cytoplasm, and those of the spotted fever group are usually found in the nucleus. Rickettsial growth is enhanced in the presence of sulfonamides, and rickettsial diseases are made more severe by these drugs. Tetracyclines and chloramphenicol inhibit the growth of rickettsiae and can be therapeutically effective.

Most rickettsiae survive only for short times outside of the vector or host. Rickettsiae are quickly destroyed by heat, drying, and bactericidal chemicals. Dried feces of infected lice may contain infectious *Rickettsia prowazekii* for months at room temperature.

Rickettsial Antigens and Serology

The direct immunofluorescent antibody test can be used to detect rickettsiae in ticks and sections of tissues. The test has been most useful to detect *Rickettsia rickettsii* in skin biopsy specimens to aid in the diagnosis of Rocky Mountain spotted fever (RMSF); however, the test is performed in only a few reference laboratories.

Serologic evidence of infection occurs no earlier than the second week of illness for any of the rickettsial diseases. Thus, serologic tests are useful only to confirm the diagnosis, which is based on clinical findings (eg, fever, headache, and rash) and epidemiologic information (eg, tick bite). Therapy for potentially severe diseases, such as RMSF and typhus, should be instituted before seroconversion occurs.

A variety of serologic tests have been used to diagnose rickettsial diseases. Most of these tests are performed only in reference laboratories. Antigens for the **indirect immunofluorescence**, latex agglutination, indirect immunoperoxidase tests, and enzyme immunoassay for RMSF are commercially available. Reagents for other tests are prepared only in public health or other reference laboratories. The indirect

TABLE 26-1 Rickettsial, Ehrlichial Diseases, and Q Fever

Group	Organism	Disease	Geographic Distribution	Vector	Mammalian Reservoir	Clinical Features	Diagnostic Tests ^a
Typhus group	<i>Rickettsia prowazekii</i>	Epidemic typhus (louse-borne typhus), Brill-Zinsser disease	Worldwide: South America, Africa, Asia, North America	Louse	Humans	Fever, chills, myalgia, headache, rash (no eschar); severe illness if untreated	Serology
	<i>Rickettsia typhi</i>	Murine typhus, endemic typhus, flea-borne typhus	Worldwide (small foci)	Flea	Rodents	Fever, headache, myalgia, rash (no eschar); milder illness than epidemic typhus	Serology
Scrub typhus group	<i>Orientia tsutsugamushi</i>	Scrub typhus	Asia, South Pacific, northern Australia	Mite	Rodents	Fever, headache, rash (50% have eschar), lymphadenopathy, atypical lymphocytes	
Spotted fever group ^b	<i>Rickettsia rickettsii</i>	Rocky Mountain spotted fever	Western Hemisphere (United States, South America)	Tick ^c	Rodents, dogs	Fever, headache, rash (no eschar); many systemic manifestations	Direct FA of rickettsiae in tissue; serology; PCR
	<i>Rickettsia conorii</i>	Fièvre boutonneuse, Mediterranean spotted fever, Israeli spotted fever, South African tick fever, African (Kenya) tick typhus, Indian tick typhus	Mediterranean countries, Africa, Middle East, India	Tick ^c	Rodents, dogs	Fever, headache, rash, “tache noire” (eschar)	Direct FA of rickettsiae in tissue not sensitive; serology
	<i>Rickettsia sibirica</i>	Siberian tick typhus (North Asian tick typhus)	Siberia, Mongolia	Tick ^c	Rodents	Fever, rash (eschar)	Serology
Transitional group	<i>Rickettsia akari</i>	Rickettsial pox	United States; Russia; Korea; South Africa	Mite ^c	Mice	Mild illness, fever, headache, vesicular rash (eschar)	Serology
	<i>Rickettsia australis</i>	Queensland tick typhus	Australia	Tick ^c	Rodents, marsupials	Fever, rash of trunk and limbs (eschar)	Serology
Q fever	<i>Coxiella burnetii</i>	Q fever	Worldwide	Airborne fomites tick	Sheep, cattle, goats, others	Headache, fever, fatigue, pneumonia (no rash); can have major complications	Positive CF to phase I, II antigens
Ehrlichiae	<i>Ehrlichia chaffeensis</i>	Human monocyte ehrlichiosis	South-central, southeastern, and western United States	Tick	Deer, dogs, humans	Fever, headache, atypical white blood cells	Inclusions in circulating monocytes; indirect FA for antibodies
	<i>Anaplasma phagocytophilum</i>	Human granulocyte anaplasmosis	Upper midwestern, northwestern, and West Coast United States and Europe	Tick	Mice, other mammals	Fever, headache, myalgia	Inclusions in granulocytes; indirect FA for antibodies
	<i>Ehrlichia ewingii</i>	Ewingii ehrlichiosis	Midwestern United States	Tick	Dogs	Fever, headache, myalgia	Inclusions in granulocytes; indirect FA for antibodies

^aEIAs; latex agglutination among others depending on the genus and species.
^bOther *Rickettsia* species in the spotted fever group that infect humans include *Rickettsia africae*, *Rickettsia japonica*, *Rickettsia honei*, and *Rickettsia slovaca*.
^cAlso serves as arthropod reservoir by maintaining the rickettsiae through transovarian transmission.
FA, immunofluorescent antibody test; PCR, polymerase chain reaction.

fluorescent antibody technique may be the most widely used method because of the availability of reagents and the ease with which it can be performed. The test is relatively sensitive, requires little antigen, and can be used to detect immunoglobulin M (IgM) and IgG. *Rickettsiae* partially purified from infected yolk sac material are tested with dilutions of a patient's serum. Reactive antibody is detected with a fluorescein-labeled antihuman globulin. The results indicate the presence of partly species-specific antibodies, but cross-reactions are observed.

Pathology

Rickettsiae multiply in endothelial cells of small blood vessels and produce vasculitis characterized by lymphocytes that surround the blood vessels. The cells become swollen and necrotic; there is thrombosis of the vessel, leading to rupture and necrosis. Vascular lesions are prominent in the skin, but vasculitis occurs in many organs and appears to be the basis of hemostatic disturbances. Disseminated intravascular coagulation and vascular occlusion may develop. In the brain, aggregations of lymphocytes, polymorphonuclear leukocytes, and macrophages are associated with the blood vessels of the gray matter; these are called "typhus nodules." The heart shows similar lesions of the small blood vessels. Other organs may also be involved.

Immunity

In cell cultures of macrophages, *rickettsiae* are phagocytosed and replicate intracellularly even in the presence of antibody. The addition of lymphocytes from immune animals stops this multiplication *in vitro*. Infection in humans is followed by partial immunity to reinfection from external sources, but relapses occur (see the discussion of Brill-Zinsser disease).

Clinical Findings

Rickettsial infections are characterized by fever, headache, malaise, prostration, skin rash, and enlargement of the spleen and liver.

A. Typhus Group

1. Epidemic typhus (*R. prowazekii*)—Disease is transmitted by the body louse in a human–louse cycle. In epidemic typhus, systemic infection and prostration are severe, and fever lasts for about 2 weeks. The disease is more severe and more often fatal in patients older than 40 years of age. During epidemics, the case fatality rate has been 6–30%.

2. Endemic typhus or murine typhus (*Rickettsia typhi*)—Infected flea feces rubbed into the bite wound is the method of transmission. The clinical picture of endemic typhus has many features in common with that of epidemic typhus, but the disease is milder and is rarely fatal except in elderly patients.

B. Spotted Fever Group

The spotted fever group resembles typhus clinically; however, unlike the rash in other rickettsial diseases, the rash of the spotted fever group usually appears after 3–5 days of illness, first on the extremities, then moves centripetally, and involves the palms and soles. Some, such as Brazilian spotted fever and RMSF, may produce severe infections possibly due to infection of endothelial cells that leads to vascular permeability and consequently complications such as pulmonary edema and hemorrhages; others, such as Mediterranean spotted fever, are mild. The case fatality rate varies greatly. RMSF is life-threatening for all age groups but mortality is usually much greater in elderly persons (up to 50%) than in young adults or children.

C. Transitional Group

Rickettsialpox (*Rickettsia akari*) is a mild disease with a vesicular rash resembling that of varicella. About 1 week before onset of fever, a firm red papule appears at the site of the mite bite and develops into a deep-seated vesicle that in turn forms a black eschar (see later discussion).

D. Scrub Typhus

Scrub typhus (*Orientia tsutsugamushi*)—This disease resembles epidemic typhus clinically. One feature is the eschar, the punched-out ulcer covered with a blackened scab that indicates the location of the mite bite. Generalized lymphadenopathy and lymphocytosis are common. Illness can be severe with associated cardiac and cerebral involvement leading to death in about 30% of patients.

Laboratory Findings

Isolation of *rickettsiae* is technically difficult and is of only limited usefulness in diagnosis. It is also hazardous and must be performed in a biosafety level 3 laboratory. Animal inoculation has been replaced by cell culture methods for cultivation of most of the *rickettsiae*. Appropriate specimens include heparinized plasma, buffy coat, and skin lesions. Organisms can be detected in cell cultures by molecular methods or by immunofluorescence staining.

In RMSF, some other rickettsial infections, and scrub typhus, skin biopsies taken from patients between the fourth and eighth days of illness may reveal *rickettsiae* by immunohistochemical stains that are available in a specialized laboratory at the Centers for Disease Control and Prevention.

The polymerase chain reaction (PCR) has been used to help diagnose RMSF, other diseases of the spotted fever group, murine typhus, and scrub typhus. Real-time PCR methods have enhanced sensitivity and allow for diagnosis before a serologic response. Appropriate specimens include tissues, plasma, peripheral blood, and buffy coat specimens. Molecular techniques have also been applied to detection of *rickettsiae* in the vectors as well. These assays are available on a limited basis primarily in reference laboratories.

Serology is the main method available to clinical laboratories for the diagnosis of rickettsial infections. The most widely used serologic tests are indirect immunofluorescence and enzyme immunoassays (see earlier discussion). Complement fixation is no longer used in most laboratories. An antibody rise should be demonstrated during the course of the illness. In RMSF, the antibody response may not occur until after the second week of illness.

Treatment

Tetracyclines, preferably doxycycline, are effective, provided treatment is started early. Doxycycline is given daily orally and continued for 3–4 days after defervescence. In severely ill patients, the initial doses can be given intravenously. Chloramphenicol also can be effective.

Sulfonamides enhance the disease and are contraindicated. There is limited clinical experience with the fluoroquinolones, although they have been shown to have *in vitro* activity.

Epidemiology

A variety of arthropods, especially ticks and mites, harbor rickettsia-like organisms in the cells that line the alimentary tract. Many such organisms are not evidently pathogenic for humans.

The life cycles of different rickettsiae vary. *R. prowazekii* has a life cycle in humans and the human louse (*Pediculus humanus corporis* and *Pediculus humanus capitis*). The louse obtains the organism by biting infected human beings and transmits the agent by fecal excretion on the surface of the skin of another person. Whenever a louse bites, it defecates at the same time. Scratching the area of the bite allows the rickettsiae excreted in the feces to penetrate the skin. As a result of the infection, the louse dies, but the organisms remain viable for some time in its dried feces. Rickettsiae are not transmitted from one generation of lice to another. Delousing large proportions of the population with insecticides has controlled typhus epidemics.

Brill-Zinsser disease is a recrudescence of an old typhus infection. The rickettsiae can persist for many years in the lymph nodes of an individual without any symptoms being manifest. The rickettsiae isolated from such cases behave like classic *R. prowazekii*; this suggests that humans themselves are the reservoir of the rickettsiae of epidemic typhus. Typhus epidemics have been associated with war and the lowering of standards of personal hygiene, which in turn have increased the opportunities for human lice to flourish. If this occurs at the time of recrudescence of an old typhus infection, an epidemic may be set off. Brill-Zinsser disease occurs in local populations of typhus areas as well as in persons who migrate from such areas to places where the disease does not exist. Serologic characteristics readily distinguish Brill disease from primary epidemic typhus. Antibodies arise earlier and are IgG rather than the IgM detected after primary infection.

They reach a maximum by the 10th day of disease. This early IgG antibody response and the mild course of the disease suggest that partial immunity is still present from the primary infection.

In the United States, *R. prowazekii* has an extrahuman reservoir in the southern flying squirrel, *Glaucomys volans*. In areas where southern flying squirrels are indigenous (southern Maine to Florida to the center of the United States), human infections have occurred after bites by ectoparasites of this rodent. Infection between humans occurs by the human body louse *Pediculus humanus corporis*. Recent reports indicate that epidemic typhus may be increasing in some areas; *R. prowazekii* is considered a biothreat agent.

R. typhi has its reservoir in the rat, in which the infection is inapparent and long lasting. Rat fleas carry the rickettsiae from rat to rat and sometimes from rats to humans, who develop endemic typhus. Cat fleas can serve as vectors. In endemic typhus, the flea cannot transmit the rickettsiae transovarially.

O. tsutsugamushi has its true reservoir in the mites that infest rodents. Rickettsiae can persist in rats for more than 1 year after infection. Mites transmit the infection transovarially. Occasionally, infected mites or rat fleas bite humans, and scrub typhus results. The rickettsiae persist in the mite–rat–mite cycle in the scrub or secondary jungle vegetation that has replaced virgin jungle in areas of partial cultivation. Such areas may become infested with rats and trombiculid mites.

R. rickettsii may be found in healthy wood ticks (*Dermacentor andersoni*) and is passed transovarially. Infected ticks in the western United States occasionally bite vertebrates such as rodents, deer, and humans. To be infectious, the tick carrying the rickettsiae must be engorged with blood because this increases the number of rickettsiae in the tick. Thus, there is a delay of 45–90 minutes between the time of the attachment of the tick and its becoming infective. In the eastern United States, the dog tick *Dermacentor variabilis* and *Rhipicephalus sanguineus* ticks transmit RMSF. Dogs are hosts to these ticks and may serve as a reservoir for tick infection. Small rodents are another reservoir. Most cases of RMSF in the United States now occur in the eastern and southeastern regions.

R. akari has its vector in bloodsucking mites of the species *Liponyssoides sanguineus*. These mites may be found on the mice (*Mus musculus*) trapped in apartment houses in the United States where rickettsialpox has occurred. Transovarial transmission of the rickettsiae occurs in the mite. Thus, the mite may act as a true reservoir as well as a vector. *R. akari* has also been isolated in eastern Europe, South Africa, and Korea.

Geographic Occurrence

A. Epidemic Typhus

This potentially worldwide infection has disappeared from the United States, Britain, and Scandinavia. It is still present in the Balkans, Asia, Africa, Mexico, and the Andes

mountains of South America. In view of its long duration in humans as a latent infection (Brill-Zinsser disease), it can emerge and flourish quickly under proper environmental conditions, as it did in Europe during World War II because of the deterioration of community hygiene.

B. Endemic Murine Typhus

Disease exists worldwide, especially in areas of high rat infestation. It may exist in the same areas as—and may be confused with—epidemic typhus or scrub typhus.

C. Scrub Typhus

Infection is seen in the Far East, especially Myanmar (Burma), India, Sri Lanka, New Guinea, Japan, western Australia, eastern Russia, China, and Taiwan. The larval stage (chigger) of various trombiculid mites serves both as a reservoir, through transovarian transmission, and as a vector for infecting humans and rodents.

D. Spotted Fever Group

These infections occur around the globe, exhibiting as a rule some epidemiologic and immunologic differences in different areas. Transmission by a tick of the Ixodidae family is common to the group. The diseases that are grouped together include RMSF and Colombian, Brazilian, and Mexican spotted fevers; Mediterranean (boutonneuse), South African tick, and Kenya fevers; North Queensland tick typhus; and North Asian tickborne rickettsioses.

E. Rickettsialpox

The human disease has been found among inhabitants of apartment houses in the northern United States. However, the infection also occurs in Russia, Africa, and Korea.

Seasonal Occurrence

Epidemic typhus is more common in cool climates, reaching its peak in winter and waning in the spring. This is probably a reflection of crowding, lack of fuel, and low standards of personal hygiene, which favor louse infestation.

Rickettsial infections that must be transmitted to the human host by vector reach their peak incidence at the time the vector is most prevalent—the summer and fall months.

Control

Control must rely on breaking the infection chain, treating patients with antibiotics, and immunizing when possible. Patients with rickettsial disease who are free from ectoparasites are not contagious and do not transmit the infection.

A. Prevention of Transmission by Breaking the Chain of Infection

1. Epidemic typhus—Delousing with insecticide.

2. Murine typhus—Rat proofing buildings and using rat poisons.

3. Scrub typhus—Clearing from campsites the secondary jungle vegetation in which rats and mites live.

4. Spotted fever—Similar measures for the spotted fevers may be used, including clearing of infested land, personal prophylaxis in the form of protective clothing such as high boots and socks worn over trousers, tick repellents, and frequent removal of attached ticks.

5. Rickettsialpox—Elimination of rodents and their parasites from human domiciles.

Concept Checks

- *Rickettsia* are pleomorphic coccobacilli that are obligate intracellular pathogens similar to Gram-negative bacteria but they do not stain with Gram-stain.
- *Rickettsia* can be cultivated in cell culture lines and yolk sacs, but immunohistochemical or immunofluorescent stains, serology, or molecular methods are usually used for their detection in clinical material.
- The hallmark of infection with *Rickettsia* is vasculitis.
- *Rickettsia* can be divided into the typhus, spotted fever, and transitional groups; *O. tsutsugamushi* causes scrub typhus. Vectors, clinical manifestations, and geographic distributions vary by group.
- Disease may be mild as in the case of *Rickettsialpox* or severe as in RMSF.
- Doxycycline is the drug of choice.

EHRlichia AND ANAPlasma

The ehrlichiae that cause disease in humans have been classified in a limited number of species based in large part on sequence analysis of rRNA genes. The pathogens are as follows: *Ehrlichia chaffeensis*, which causes human monocytic ehrlichiosis (HME); *Ehrlichia ewingii*, which causes *E. ewingii* ehrlichiosis; and *Anaplasma phagocytophilum*, which causes human granulocyte anaplasmosis (HGE). The same genera contain additional species that infect animals but apparently not humans. The human pathogens in the group have animal reservoirs and can cause disease in animals as well.

The *Ehrlichia* group organisms are obligate intracellular bacteria that are taxonomically grouped with the rickettsiae. They have tick vectors (see Table 26-1).

Properties of Ehrlichiae

Ehrlichiae and *Anaplasma* are small (0.5 μm), obligate intracellular, Gram-negative bacteria. They infect circulating leukocytes, erythrocytes, and platelets, where they multiply within phagocytic vacuoles, forming clusters with inclusion-like appearance. These clusters of ehrlichiae are called

morulae, which is derived from the Latin word for mulberry. The ehrlichiae and chlamydiae (see Chapter 27) resemble each other in that both are found in intracellular vacuoles. The ehrlichiae, however, are similar to the rickettsiae in that they are able to synthesize adenosine triphosphate (ATP); the chlamydiae are not able to synthesize ATP.

Clinical Findings

The incubation periods after a tick bite for both HME and HGE can range from 5 to 21 days. The clinical manifestations of ehrlichiosis in humans are nonspecific and include fever, chills, headache, myalgia, nausea or vomiting, anorexia, and weight loss. These manifestations are very similar to those of RMSF without the rash. *E. chaffeensis* frequently and *A. phagocytophilum* less often cause severe or fatal illness. Complications with HME include meningoencephalitis; renal failure; myocarditis; and respiratory failure, among other life-threatening syndromes, including shock. Seroprevalence studies suggest that subclinical ehrlichiosis occurs frequently.

Laboratory Findings

Laboratory abnormalities with HME and HGE include leukopenia, lymphopenia, thrombocytopenia, and elevated hepatic enzymes. The diagnosis is confirmed by observing typical morulae in white blood cells (granulocytes in HGA or *E. ewingii* and mononuclear cells in the case of HME). The sensitivity of microscopic examination for morulae is greatest during the first week of infection and ranges from 25% to 75%.

The indirect fluorescent antibody test can also be used to confirm the diagnosis. Antibodies are measured against *E. chaffeensis* and *A. phagocytophilum*. *E. chaffeensis* is also used as the substrate for *E. ewingii* because the two species share antigens. Seroconversion from less than 1:64–1:128 or greater or a fourfold or greater rise in titer makes a confirmed serologic diagnosis of HME in a patient with a clinically compatible illness.

Multiple methods have been described for PCR detection of ehrlichiae in EDTA (ethylenediaminetetraacetic acid)-anticoagulated blood. Culture using a variety of tissue culture cell lines also can be used. PCR and culture are performed in experienced reference laboratories and in a small number of commercial laboratories.

Treatment

Tetracycline, commonly in the form of doxycycline, is the drug of choice for ehrlichiae and is the treatment of choice. Therapy is administered for 5–14 days. Rifamycins also are ehrlichicidal. Limited data suggest that fluoroquinolones and chloramphenicol are not useful.

Epidemiology and Prevention

The incidence of human ehrlichiosis is not well defined. *E. chaffeensis* has been found in ticks in at least 14 states in the

southeastern, south central, and mid-Atlantic regions of the United States, but cases of HME have been reported in more than 30 states. This area corresponds to the area of distribution of the Lone Star tick, *Amblyomma americanum*. Cases of human monocytotropic ehrlichiosis in the western United States and in Europe and Africa suggest other tick vectors such as *D. variabilis*. In Oklahoma, which has the highest incidence of RMSF, human monocytotropic ehrlichiosis is at least as common. More than 90% of cases occur between mid April and October, and more than 80% of cases are in men. Most patients give histories of tick exposure in the month before onset of illness.

Cases of human granulocytotropic ehrlichiosis occur in the upper Midwest and East Coast states and in West Coast states. These areas correspond to the distribution of the tick vectors *Ixodes scapularis* and *Ixodes pacificus*, respectively.

Concept Checks

- The pathogens that cause the human ehrlichioses include *E. chaffeensis*, the cause of HME; *E. ewingii*, the cause of Ewingii ehrlichiosis; and *Anaplasma phagocytophilum*, the cause of HGE.
- The *Ehrlichia* group consists of obligate intracellular bacteria transmitted by tick vectors.
- *Ehrlichia* and *Anaplasma* species infect circulating leukocytes in which they multiply within phagocytic vacuoles and form morulae.
- The clinical manifestations of ehrlichiosis in humans are nonspecific and include fever, chills, headache, myalgias, nausea or vomiting, anorexia, and weight loss.
- Diagnosis is made by demonstration of morula within the respective leukocytes (relatively insensitive) and by serology or PCR.
- Doxycycline is the drug of choice for treatment.

COXIELLA BURNETII

Properties

C. burnetii is a small obligate organism that has a membrane similar to Gram-negative bacteria. However, it does not stain with the Gram-stain but does stain with Gimenez. *C. burnetii*, which causes Q fever, is resistant to drying. This organism may survive pasteurization at 60°C for 30 minutes and can survive for months in dried feces or milk. This may be because of the formation of endospore-like structures by *C. burnetii*. Coxiellae grow only in cytoplasmic vacuoles.

Antigens and Antigenic Variation

When grown in cell culture, *C. burnetii* exhibits various phases. These phases are associated with differences in virulence. Phase I is the virulent form that is found in humans with Q fever and in infected vertebrate animals. It is the

infectious form of the organism and the lipopolysaccharide expressed during this phase appears to be a key virulence factor. Phase II forms are not infectious and occur only by serial passage in cell cultures. Patients with clinical illness mount antibodies to both phase I and phase II antigens.

Epidemiology

C. burnetii is found in ticks, which transmit the agent to sheep, goats, and cattle, but transmission by ticks to humans is uncommon. Workers in slaughterhouses and in plants that process wool and cattle hides have contracted the disease as a result of handling infected animal tissues. *C. burnetii* is transmitted by the respiratory pathway rather than through the skin. There may be a chronic infection of the udder of the cow or goat. In such cases, the rickettsiae are excreted in the milk and rarely may be transmitted to humans by ingestion of unpasteurized milk.

Infected sheep may excrete *C. burnetii* in the feces and urine and heavily contaminate their skin and woolen coat. The placentas of infected cows, sheep, goats, and cats contain the organism, and parturition creates infectious aerosols. The soil may be heavily contaminated from one of the above sources, and the inhalation of infected dust leads to infection of humans and livestock. It has been proposed that endospores formed by *C. burnetii* contribute to its persistence and dissemination. *Coxiella* infection is now widespread among sheep and cattle in the United States. *Coxiella* can cause endocarditis (with a rise in the titer of antibodies to *C. burnetii*, phase I) in addition to pneumonitis and hepatitis.

Clinical Findings

A. Q Fever

This disease is recognized around the world and occurs mainly in persons associated with goats, sheep, dairy cattle, or parturient cats. It has attracted attention because of outbreaks in veterinary and medical centers where large numbers of people were exposed to animals shedding *Coxiella* species.

Infections may be acute or chronic. Acute disease resembles influenza, nonbacterial (atypical) pneumonia, and hepatitis. There is a rise in the titer of specific antibodies to *C. burnetii*, phase II. Transmission results from inhalation of dust contaminated with the organism from placenta, dried feces, urine, or milk or from aerosols in slaughterhouses.

Chronic Q fever is infection that lasts more than 6 months. Infective endocarditis is the most common form of disease in this phase. Blood cultures for bacteria are negative, and there is a high titer of antibodies to *C. burnetii*, phase I. Virtually all patients have preexisting valve abnormalities or have some form of immune compromise.

Laboratory Findings

C. burnetii can be cultivated in cell cultures, but this should only be done in experienced biosafety level 3 laboratories.

Serology is the diagnostic method of choice, and indirect immunofluorescence is considered the best method. PCR has been useful in diagnosing culture-negative endocarditis caused by *C. burnetii*.

Treatment

Doxycycline is the drug of choice for the treatment of acute Q fever. The newer macrolides have also been shown to be effective in the treatment of acute pneumonia. Chronic Q fever requires prolonged treatment for 18 months or longer with a combination of doxycycline and hydroxychloroquine. Duration of treatment is long as mentioned earlier and should be determined by decrease in phase I antibody titers. In endocarditis, combination therapy is necessary to prevent relapse; occasionally, valve replacement is required and can prolong survival.

Prevention

The presently recommended conditions of “high-temperature, short-time” pasteurization at 71.5°C for 15 seconds are adequate to destroy viable *Coxiella* species.

For *C. burnetii*, an investigational vaccine made from infected egg yolk sacs is available. This vaccine has been used for laboratory workers who handle live *C. burnetii* but currently is only commercially available in Australia.

Concept Checks

- *C. burnetii* is a small obligate organism that has a membrane similar to Gram-negative bacteria, does not stain with Gram-stain, multiplies within vacuoles, and causes the disease Q fever.
- *C. burnetii* exists in two antigenic forms called phase I and phase II. Phase I is the virulent form that is found in humans with Q fever and infected vertebrate animals, and it is the infectious form. Phase II is the avirulent form.
- *C. burnetii* is found in sheep, goats, cattle, and a variety of other animals, which are usually asymptomatic. Transmission to humans is by inhalation of contaminated dirt from animal feces, products of conception, or dust from animal products such as contaminated hides.
- Q fever is characterized by acute and chronic infections. Acute pneumonia and hepatitis are associated with antibodies to phase II antigens; endocarditis is the most common form of chronic infection and is associated with antibodies to phase I antigens.
- Diagnosis is clinically suspected and confirmed largely by serology or PCR performed in reference laboratories that have developed and verified their own assays.
- Doxycycline is the drug of choice in both acute and chronic infections. In chronic infections, it is combined with hydroxychloroquine.

REVIEW QUESTIONS

- Morulae (intracellular inclusions in leukocytes) are characteristic of which of the following diseases?
 - Malaria caused by *Plasmodium falciparum* infection but not *Plasmodium malariae* infection
 - Dengue
 - Babesia infection
 - Ehrlichiae infection
 - Loa loa
- Which of the following statements about epidemic typhus (*R. prowazekii* disease) is most correct?
 - The disease occurs primarily in sub-Saharan Africa.
 - It is transmitted by ticks.
 - Mice are the reservoir.
 - Historically, the disease occurs in times of prosperity.
 - Recrudescence can occur many years after the initial infection.
- The most useful drug to treat ehrlichiosis is
 - Doxycycline
 - Penicillin G
 - Trimethoprim-sulfamethoxazole
 - Gentamicin
 - Nitrofurantoin
- A disease characterized by malaise, headache, rigors, and fever developed in members of several families living in an unheated war-damaged house in an Eastern European country. Erythematous 2–6 mm macular red rashes appeared on the peoples' trunks and later on their extremities. Some of the people had coughs. One elderly person, although sick, was much less sick than other adults. The people huddled together to keep warm; body lice were common. Which of the following statements is most correct?
 - The disease that these people had is common in the Rocky Mountain states.
 - The elderly person may have had acute epidemic typhus many years ago and recrudescence typhus now.
 - Fleas from rodents in the house were spreading *R. typhi*.
 - The primary host of the body louse infecting the people is the rat.
 - Epidemic typhus can be prevented by a vaccine.
- Which of the following statements about Ehrlichiae and ehrlichiosis is most correct?
 - Dogs and mice are reservoirs.
 - Mosquitoes are the vectors.
 - Ampicillin is the treatment of choice.
 - Culture is a good method to confirm the diagnosis.
 - Ehrlichiae are typically found in lymphocytes.
- A group of urban teenagers visited a sheep ranch in a large Western state for a 2-week experience. While they were there, many of the pregnant ewes delivered lambs to the delight of the closely observing teenagers. About 10 days later, three of the teenagers developed flulike illnesses characterized by malaise, cough, and fever. One had an infiltrate on chest radiography, indicating pneumonia. The three teenagers had different doctors, but the physicians each drew a blood specimen and submitted it to the city health department for serologic testing. All three specimens were positive for Q fever. Public health investigators determined that all of the teenagers had been to the sheep ranch. When the investigators contacted the ranch, they were told that there was no Q fever there and that no one who lived at the ranch had been sick. The most likely explanation for the teenagers' illnesses and the lack of illness at the ranch is
 - There was no Q fever at the ranch, and it was acquired elsewhere.
 - The people at the ranch had been previously immunized against Q fever.
 - The teenagers acquired Q fever at the ranch, and the people who lived there had all previously had Q fever and were now immune to it.
 - The teenagers had other illnesses, and the positive Q fever serology result was unrelated.
 - The public health laboratory had errors in the Q fever serologic tests.
- A middle-aged sportsman, a resident of Oklahoma, took a hike through a rural wooded and brushy area near his home. The next morning, he noticed and removed a large (>1 cm) tick from his upper arm. About 1 week later, he experienced a gradual onset of fever and malaise. He now seeks medical attention because he is concerned about a possible infection transmitted by the tick. Which of the following diseases is most likely to be acquired from a tick?
 - Dengue
 - Rocky Mountain spotted fever
 - Typhus
 - Yellow fever
 - Malaria
- Which of the following drugs should *not* be used to treat Rocky Mountain spotted fever (*R. rickettsii* infection)?
 - Trimethoprim-sulfamethoxazole
 - Chloramphenicol
 - Doxycycline
- Which of the following should be used to prevent Rocky Mountain spotted fever (*R. rickettsii* infection)?
 - Attenuated *R. rickettsii* vaccine
 - Prophylactic doxycycline
 - Preventing tick bites by wearing protective clothing
 - Delousing with insecticide
- One week after deer hunting in a wooded area, a 33-year-old man developed fever to 39°C with headache and malaise. Over the subsequent 24 hours, he developed nausea, vomiting, abdominal pain, and diarrhea. On day 4, he developed a rash, initially around the wrists and ankles, which then progressively evolved, involving the arms, trunk, palms, and soles. Initially the rash was macular, but it quickly evolved into maculopapules, some with central petechiae. Rocky Mountain spotted fever caused by *R. rickettsii* was diagnosed. Which of the following statements about Rocky Mountain spotted fever is correct?
 - The vectors of *R. rickettsii* are ticks of the genus *Ixodes*.
 - A rash consistently appears by day 4 of illness.
 - R. rickettsii* forms inclusions in monocytes.
 - The patient's antibody response may not occur until after the second week of illness.
 - The highest incidence of this disease is in the Rocky Mountain states.
- The recommended treatment for Q-fever endocarditis is
 - Emergent surgery; antibiotics are not effective
 - Levofloxacin monotherapy for 6 weeks

- (C) 18 months of combination therapy with doxycycline and hydroxychloroquine
 (D) Penicillin and gentamicin combination therapy using IgG titers to determine duration
12. *C. burnetii* can be transmitted by milk when animals such as goats and cows are infected. The presently recommended conditions of “high-temperature, short-time” pasteurization are adequate to destroy viable *Coxiella* organisms.
 (A) True
 (B) False
13. The histopathological hallmark of infection caused by *R. rickettsii* is
 (A) Morulae within granulocytes
 (B) Morulae within monocytes
 (C) Granulomatous inflammation
 (D) Intracellular vacuoles
 (E) Perivascular lymphocytes
14. All of the following statements regarding Rickettsialpox are correct except
 (A) The cause of the disease is *R. akari*.
 (B) Ticks of the genus *Amblyomma* are responsible for transmission.
 (C) The disease is mild.
 (D) Disease is more common in urban than rural areas.
15. Reasons why *C. burnetii* could be a potential agent of bioterrorism include
 (A) It is acquired by the inhalation.
 (B) It is highly infectious.
 (C) It can be difficult to treat depending on the phase of infection.
 (D) Pneumonia may be severe.
 (E) All of the above.

Chlamydia spp.

Chlamydiae that infect humans are divided into three species, *Chlamydia trachomatis*, *Chlamydia pneumoniae*, and *Chlamydia psittaci*, on the basis of antigenic composition, intracellular inclusions, sulfadiazine susceptibility, and disease production. The separation of the genus *Chlamydia* into the genera *Chlamydia* and *Chlamydophila* remains controversial; in this chapter, the three chlamydiae that are pathogens of humans are considered to be in the genus *Chlamydia* in keeping with publications that do not support the new taxonomy. Other chlamydiae infect animals but rarely if ever infect humans. All chlamydiae exhibit similar morphologic features, share a common group antigen, and multiply in the cytoplasm of their host cells by a distinctive developmental cycle. The chlamydiae can be viewed as Gram-negative bacteria that lack mechanisms for the production of metabolic energy and cannot synthesize adenosine triphosphate (ATP). This restricts them to an intracellular existence, where the host cell furnishes energy-rich intermediates. Thus, chlamydiae are **obligate intracellular pathogens**.

Developmental Cycle

All chlamydiae share a common and unique biphasic developmental cycle. The environmentally stable infectious particle (transmissible form) is a small cell called the **elementary body (EB)**. These are about 0.3 μm in diameter (Figure 27-1) with an electron-dense nucleoid. The EB membrane proteins have highly cross-linked membrane proteins. The EBs have a high affinity for host epithelial cells and rapidly enter them. The first step in entry involves interaction between outer membrane proteins of the EB and heparin sulfate proteoglycan of the host cells. The second step involves additional and irreversible binding to a variety of other host cell receptors. There appear to be multiple adhesins, such as OmcB, the major outer membrane protein (**MOMP**), glycosylated MOMP, and other surface proteins. Following adherence, the mechanisms thought to mediate entry into the host cell also vary and involve cytoskeletal rearrangements and activation of type III secretion systems and other effectors. EBs are usually seen attached near the base of microvilli, where they are subsequently engulfed by the host cell. More than one mechanism appears to be

functional: receptor-mediated endocytosis into clathrin-coated pits and pinocytosis via noncoated pits. Lysosomal fusion is inhibited, creating a protected membrane-bound environment around the chlamydiae. Shortly after entry into the host cell, the disulfide bonds of the EB membrane proteins are reduced (no longer cross-linked), and the EB is reorganized into a larger structure called a **reticulate body (RB)** [**replicative form**] measuring about 0.5–1 μm (see Figure 27-1) and devoid of an electron-dense nucleoid. Within the membrane-bound vacuole, the RB grows in size and divides repeatedly by binary fission. Eventually, the entire vacuole becomes filled with EBs derived from the RBs to form a cytoplasmic **inclusion**. The newly formed EBs may be liberated from the host cell to infect new cells. The developmental cycle takes 48–72 hours.

Structure and Chemical Composition

In chlamydiae, the outer **cell wall** resembles the cell wall of Gram-negative bacteria. It has a relatively high lipid content including lipopolysaccharide of low endotoxic activity. It is rigid but does not contain a typical bacterial peptidoglycan. As mentioned above, another important structural component is the MOMP encoded by *ompA*. MOMP antigenic variants of *C. trachomatis* are associated with different clinical syndromes. Penicillin-binding proteins occur in chlamydiae, and chlamydial cell wall formation is inhibited by penicillins and other drugs that inhibit transpeptidation of bacterial peptidoglycan. Lysozyme has no effect on chlamydial cell walls. *N*-acetylmuramic acid appears to be absent from chlamydial cell walls. Both DNA and RNA are present in EBs and RBs. The RBs contain about four times as much RNA as DNA, whereas the EBs contain about equal amounts of RNA and DNA. In EBs, most DNA is concentrated in the electron-dense central nucleoid. Most RNA exists in ribosomes. The circular genome of chlamydiae is 1.04 megabases in length, encodes 900 genes, and is one of the smallest bacterial genomes.

Multiple chlamydial genomes have been sequenced, providing insight into the basic biology of the organisms. For example, chlamydiae have a type III secretion system, which may allow them to inject effector proteins into host cells as

A

B

C

FIGURE 27-1 Chlamydiae. **A:** Thin section electron micrograph of chlamydiae in various stages of development. EB, elementary body particles with cell walls (*inset*); RB, reticulate body. **B:** *C. trachomatis* grown in McCoy cells and stained with iodine. The McCoy cells stain a faint yellow in the background. The glycogen-rich intracytoplasmic inclusions of *C. trachomatis* stain a dark brown. **C:** Similar growth of *C. trachomatis* in McCoy cells stained with a fluorescein-labeled antibody against a *C. trachomatis* species antigen. The intracytoplasmic inclusions of *C. trachomatis* stain bright yellow-green. Faint outlines of the McCoy cells are visible. (Courtesy of J Schachter.)

part of the infectious process (see discussion above under Developmental Cycle).

Staining Properties

Chlamydiae have distinctive staining properties (similar to those of rickettsiae). Elementary bodies stain purple with Giemsa stain—in contrast to the blue of host cell cytoplasm. The larger, noninfective RBs stain blue with Giemsa stain. The Gram reaction of chlamydiae is negative or variable and is not useful in identification of the agents. Chlamydial particles and inclusions stain brightly by immunofluorescence, with group-specific, species-specific, or serovar-specific antibodies.

Fully formed, mature intracellular inclusions of *C. trachomatis* are compact masses near the nucleus that are dark purple when stained with Giemsa stain because of the densely packed mature particles. If stained with dilute Lugol's iodine solution, some of the inclusions of *C. trachomatis* (but not *C. pneumoniae* or *C. psittaci*) appear brown because of the glycogen matrix that surrounds the particles (see Figure 27-1). In contrast, inclusions of *C. psittaci* appear as diffuse intracytoplasmic aggregates.

Antigens

Chlamydiae possess **shared group (genus)-specific antigens**. These are heat-stable lipopolysaccharides with

2-keto-3-deoxy-octanoic acid as an immunodominant component. Antibody to these genus-specific antigens can be detected by **complement fixation** (CF) and immunofluorescence. **Species-specific** or **serovar-specific** antigens are mainly outer membrane proteins. Specific antigens can best be detected by **immunofluorescence**, particularly using monoclonal antibodies. Specific antigens are shared by only a limited number of chlamydiae, but a given organism may contain several specific antigens. There are at least 15 **serovars** of *C. trachomatis* that are separated into two biovariants that cause different clinical syndromes. The trachoma biovar includes serovars A, B, Ba, and C as well as the genital tract serovars D–K. The lymphogranuloma venereum (LGV) biovar includes serovars L1, L2, and L3. Several serovars of *C. psittaci* can be demonstrated by CF and **microimmunofluorescence** (MIF) tests. Only one serovar of *C. pneumoniae* has been described.

Growth and Metabolism

Chlamydiae require an intracellular habitat because of the small genome size, which make them dependent upon host cells for their development and for energy requirements. Chlamydiae grow in cultures of a variety of eukaryotic cells lines. McCoy cells treated with cycloheximide commonly are used to isolate chlamydiae; *C. pneumoniae* grows better in HL or HEp-2 cells. All types of chlamydiae proliferate in embryonated eggs, particularly in the yolk sac.

Some chlamydiae have an endogenous metabolism similar to other bacteria. They can liberate CO₂ from glucose, pyruvate, and glutamate; they also contain dehydrogenases. Nevertheless, they require energy-rich intermediates from the host cell to carry out their biosynthetic activities.

The replication of chlamydiae can be inhibited by many antibacterial drugs. Cell wall inhibitors such as penicillins and cephalosporins result in the production of morphologically defective forms but are not effective in treatment of clinical

diseases. Inhibitors of protein synthesis (tetracyclines, macrolides) are effective in most clinical infections. *C. trachomatis* strains synthesize folates and are susceptible to inhibition by sulfonamides. Aminoglycosides are noninhibitory.

Characteristics of Host–Parasite Relationship

The outstanding biologic feature of infection by chlamydiae is the balance that is often reached between host and parasite, resulting in prolonged persistence of infection. Subclinical infection is the rule—and overt disease the exception—in the natural hosts of these agents. Spread from one species to another (eg, birds to humans, as in psittacosis) more frequently leads to disease. Antibodies to several antigens of chlamydiae are regularly produced by the infected host. These antibodies have little protective effect against reinfection. The infectious agent commonly persists in the presence of high antibody titers. Treatment with effective antimicrobial drugs (eg, tetracyclines) for prolonged periods may eliminate the chlamydiae from the infected host. Very early, intensive treatment may suppress antibody formation. Late treatment with antimicrobial drugs in moderate doses may suppress disease but permit persistence of the infecting agent in tissues.

The immunization of humans has been singularly unsuccessful in protecting against reinfection. Prior infection or immunization at most tends to result in milder disease upon reinfection, but at times, the accompanying hypersensitization aggravates inflammation and scarring (eg, in trachoma).

Classification

Chlamydiae are classified according to their pathogenic potential, host range, antigenic differences, and other methods. Three species that infect humans have been characterized (Table 27-1).

TABLE 27-1 Characteristics of the Chlamydiae

	<i>Chlamydia trachomatis</i>	<i>Chlamydia pneumoniae</i>	<i>Chlamydia psittaci</i>
Inclusion morphology	Round, vacuolar	Round, dense	Large, variable shape, dense
Glycogen in inclusions	Yes	No	No
Elementary body morphology	Round	Pear shaped, round	Round
Susceptible to sulfonamides	Yes	No	No
Plasmid	Yes	No	Yes
Serovars	15	1	≥4
Natural host	Humans	Humans, animals	Birds
Mode of transmission	Person to person, mother to infant	Airborne person to person	Airborne bird excreta to humans
Major diseases	Trachoma, STDs, infant pneumonia, LGV	Pneumonia, bronchitis, pharyngitis, sinusitis	Psittacosis, pneumonia, fever of unexplained origin

STD, sexually transmitted disease; LGV, lymphogranuloma venereum.

A. *Chlamydia trachomatis*

This species produces compact intracytoplasmic inclusions that contain glycogen; it is usually inhibited by sulfonamides. It includes agents of human disorders such as trachoma, inclusion conjunctivitis, nongonococcal urethritis, salpingitis, cervicitis, pneumonitis of infants, and LGV.

B. *Chlamydia pneumoniae*

This species produces intracytoplasmic inclusions that lack glycogen; it is usually resistant to sulfonamides. It causes respiratory tract infections in humans.

C. *Chlamydia psittaci*

This species produces diffuse intracytoplasmic inclusions that lack glycogen; it is usually resistant to sulfonamides. It includes agents of psittacosis in humans, ornithosis in birds, feline pneumonitis, and other animal diseases.

CHLAMYDIA TRACHOMATIS OCULAR, GENITAL, AND RESPIRATORY INFECTIONS

Humans are the natural host for *C. trachomatis*. Monkeys and chimpanzees can be infected in the eye and genital tract. *C. trachomatis* also replicates in cells in tissue culture. *C. trachomatis* of different serovars replicates differently. Isolates from trachoma do not grow as well as those from LGV or genital infections. Intracytoplasmic replication results in the formation of compact inclusions with a glycogen matrix in which EBs are embedded.

TRACHOMA

Trachoma is an ancient eye disease, well described in the Ebers Papyrus, which was written in Egypt 3800 years ago. It is a chronic keratoconjunctivitis that begins with acute inflammatory changes in the conjunctiva and cornea and progresses to scarring and blindness. The *C. trachomatis* serovars A, B, Ba, and C are associated with clinical trachoma.

Clinical Findings

The incubation period for chlamydial conjunctival infection is 3–10 days. In endemic areas, initial infection occurs in early childhood, and the onset of the long-term consequence, trachoma, is insidious. Chlamydial infection is often mixed with bacterial conjunctivitis in endemic areas, and the two together produce the clinical picture. The earliest symptoms of trachoma are lacrimation, mucopurulent discharge, conjunctival hyperemia, and follicular hypertrophy. Microscopic examination of the cornea reveals epithelial keratitis, subepithelial infiltrates, and extension of limbal vessels into the cornea (pannus). As the pannus extends downward across the

cornea, there are scarring of the conjunctiva, eyelid deformities (entropion, trichiasis), and an added insult caused by eyelashes sweeping across the cornea (trichiasis). With secondary bacterial infection, loss of vision progresses over a period of years. There are, however, no systemic symptoms or signs of infection. The World Health Organization has a grading scheme for assessment of trachoma (see reference by Batteiger and Tan).

Laboratory Diagnosis

The laboratory diagnosis of chlamydial infections is also discussed in Chapter 47.

A. Culture

Typical cytoplasmic inclusions are found in epithelial cells of conjunctival scrapings stained with fluorescent antibody or by the Giemsa method. These occur most frequently in the early stages of the disease and on the upper tarsal conjunctiva.

Inoculation of conjunctival scrapings into cycloheximide-treated McCoy cell cultures permits growth of *C. trachomatis* if the number of viable infectious particles is sufficiently large. Centrifugation of the inoculum into the cells increases the sensitivity of the method. The diagnosis can sometimes be made in the first passage after 2–3 days of incubation by looking for inclusions by immunofluorescence or staining with iodine or Giemsa stain.

B. Serology

Infected individuals often develop both group antibodies and serovar-specific antibodies in serum and in eye secretions. Immunofluorescence is the most sensitive method for their detection. Neither ocular nor serum antibodies confer significant resistance to reinfection.

C. Molecular Methods

Developing countries, where trachoma is endemic, generally do not have the resources to apply polymerase chain reaction (PCR) or other molecular methods to the diagnosis of *C. trachomatis* infections of the eye. Developed countries have relatively little trachoma and little need for such tests. Thus, the molecular methods have been developed for the diagnosis of genital infections. Only research projects have used PCR in studies of trachoma.

Treatment

Clinical trials in villages with endemic trachoma using mass azithromycin treatment show that infection and clinical disease are greatly decreased at 6 and 12 months after therapy; this is true even with single-dose therapy. Thus, azithromycin has replaced erythromycin and doxycycline in the mass treatment of endemic trachoma. Topical therapy is of little value.

Epidemiology and Control

It is believed that more than 400 million people throughout the world have trachoma and that 20 million are blinded by it. The disease is most prevalent in sub-Saharan Africa, Asia, and the Mediterranean basin, where hygienic conditions are poor and water is scarce. In such hyperendemic areas, childhood infection may be universal, and severe blinding disease (resulting from frequent bacterial superinfection) is common. In the United States, trachoma occurs sporadically in some areas, and endemic foci persist.

The World Health Organization has initiated the S-A-F-E program to eliminate blinding trachoma and at least markedly reduce clinically active disease. The S-A-F-E program is as follows: surgery for deformed eyelids, periodic azithromycin therapy, face washing and hygiene, and environmental improvement such as building latrines and decreasing the number of flies that feed on conjunctival exudates. It is clear that improved socioeconomic conditions enhance the disappearance of endemic trachoma.

CHLAMYDIA TRACHOMATIS GENITAL INFECTIONS AND INCLUSION CONJUNCTIVITIS

C. trachomatis serovars D–K cause sexually transmitted diseases, especially in developed countries, and may also produce infection of the eye (inclusion conjunctivitis). In sexually active men, *C. trachomatis* causes **nongonococcal urethritis** and, occasionally, **epididymitis**. In women, *C. trachomatis* causes **urethritis**, **cervicitis**, and **pelvic inflammatory disease**, which can lead to **sterility** and predispose to **ectopic pregnancy**. Proctitis and proctocolitis may occur in men and women, although these infections appear to be most common in men who have sex with men. Any of these anatomic sites of infection may give rise to symptoms and signs, or the infection may remain asymptomatic but communicable to sex partners. Up to 50% of nongonococcal urethritis (men) or the urethral syndrome (women) is attributed to chlamydiae and produces dysuria, nonpurulent discharge, and frequency of urination. Genital secretions of infected adults can be self-inoculated into the conjunctiva, resulting in inclusion conjunctivitis, an ocular infection that closely resembles acute trachoma.

The newborn acquires the infection during passage through an infected birth canal. Probably 30–50% of infants of infected mothers acquire the infection, with 15–20% of infected infants manifesting eye symptoms and 10–40% manifesting respiratory tract involvement. **Inclusion conjunctivitis of the newborn** begins as a mucopurulent conjunctivitis 5–12 days after delivery. It tends to subside with erythromycin or tetracycline treatment or spontaneously after weeks or months. Occasionally, inclusion conjunctivitis persists as a chronic chlamydial infection with a clinical picture indistinguishable from

that of subacute or chronic childhood trachoma in non-endemic areas and usually not associated with bacterial conjunctivitis.

Laboratory Diagnosis

A. Specimen Collection

Proper specimen collection is the key to the laboratory diagnosis of chlamydia infection. Because the chlamydiae are obligate intracellular bacteria, it is important that the specimens contain infected human cells as well as the extracellular material where they might also be present. Endocervical specimens should be collected after removal of discharge and secretions from the cervix. A swab or cytology brush is used to scrape epithelial cells from 1 to 2 cm deep into the endocervix. Dacron, cotton, or rayon on a plastic shaft should be used to collect the specimen; some other swab materials (calcium alginate) and wooden shafts are toxic to chlamydiae. A similar method is used to collect specimens from the vagina, urethra, or conjunctiva. The commercial diagnostic nonculture tests for chlamydia do not require viable organisms. In general, these proprietary tests include the specimen collection swabs and transport tubes that have been demonstrated to be suitable for the specific tests. For culture, the swab specimens should be placed in a chlamydiae transport medium, such as 2-sucrose phosphate supplemented with bovine serum and antibiotics that inhibit normal microbiota, and kept at refrigerator temperature before transport to the laboratory.

Urine can be tested for the presence of chlamydial nucleic acid. Only the first 20 mL of the void should be collected because a larger volume of bladder urine would dilute the initial urine that passes through the urethra; this could result in a negative test result because of the dilution.

B. Nucleic Acid Detection

Nucleic acid amplification tests (NAATs) are the tests of choice for the diagnosis of genital *C. trachomatis* infections. There are at least five U.S. Food and Drug Administration (FDA)-cleared assays in the United States. They use a variety of molecular methods that target the *C. trachomatis* cryptic plasmid or 23SrRNA, including PCR, strand displacement, and transcription-mediated amplification. These tests have become widely used and have replaced most of the nonamplification methods. Although they are highly sensitive and specific, they are not perfect.

Specimen types that are appropriate for testing by NAATs include first void urine from males and females and vaginal, cervical, and urethral swabs. Some of the commercial companies that market these platforms are in the process of validating or have validated extragenital sources such as conjunctival, oropharyngeal, and rectal samples. The nucleic acid detection tests have been adapted to simultaneously detect *Neisseria gonorrhoeae*.

C. Direct Cytologic Examination (Direct Fluorescent Antibody) and Enzyme-Linked Immunoassay

Commercially available direct fluorescent antibody (DFA) and enzyme-linked immunoassay (EIA) assays to detect *C. trachomatis* continue to be marketed. The DFA uses monoclonal antibodies directed against a species-specific antigen on the chlamydial MOMP. The EIA detects the presence of genus-specific antigens extracted from EBs in the specimen. DFA remains useful for detection of chlamydiae in extragenital samples, such as conjunctival swabs. Because of their very low sensitivity and the widespread availability of the more sensitive NAATs, EIAs are being phased out as acceptable methods for screening for both chlamydia and gonorrhea.

D. Culture

Culture of *C. trachomatis* has historically been used to diagnose chlamydia infections. Culture, however, is costly and arduous. Results are delayed compared with the timeliness of NAATs and other tests. Culture is generally much less sensitive than NAATs; the degree of lower sensitivity is largely dependent on the culture method used. Culture is now done in a limited number of reference laboratories. A number of susceptible cell lines can be used, most often McCoy, HeLa 229, or HEp-2. The cells are grown in monolayers on coverslips in dram or shell vials. Some laboratories use flat-bottomed microdilution trays, but cultures by this method are not as sensitive as those achieved with the shell vial method. The cells are treated with cycloheximide to inhibit metabolism and increase the sensitivity of isolation of the chlamydiae. The inoculum from the swab specimen is centrifuged onto the monolayer and incubated at 35–37°C for 48–72 hours. A second monolayer can be inoculated, and after incubation, it can be sonicated and passaged to another monolayer to enhance sensitivity. The monolayers are examined by direct immunofluorescence to visualize the cytoplasmic inclusions. Chlamydial cultures by this method are about 80% sensitive but 100% specific.

E. Serology

Because of the relatively great antigenic mass of chlamydiae in genital tract infections, serum antibodies occur much more commonly than in trachoma and are of higher titer. A titer rise occurs during and after acute chlamydial infection. Because of the high prevalence of chlamydial genital tract infections in some societies, there is a high background of antichlamydial antibodies in the population; serologic tests to diagnose genital tract chlamydial infections generally are not useful.

In genital secretions (eg, cervical), antibody can be detected during active infection and is directed against the infecting immunotype (serovar).

Treatment

It is essential that chlamydial infections be treated simultaneously in both sex partners and in offspring to prevent reinfection. Tetracyclines (eg, doxycycline) are commonly used

in nongonococcal urethritis and in nonpregnant infected women. Azithromycin is effective and can be given to pregnant women. Topical tetracycline or erythromycin is used for neonatal *N. gonorrhoeae* infections but may not effectively prevent neonatal *C. trachomatis* infection. Systemic therapy should be used for inclusion conjunctivitis because topical therapy may not cure the eye infections or prevent respiratory disease.

Epidemiology and Control

Genital chlamydial infection and inclusion conjunctivitis are sexually transmitted diseases that are spread by contact with infected sex partners. Neonatal inclusion conjunctivitis originates in the mother's infected genital tract. Prevention of neonatal eye disease depends on diagnosis and treatment of the pregnant woman and her sex partner. As in all sexually transmitted diseases, the presence of multiple etiologic agents (eg, gonococci, treponemes, trichomonads, and herpes simplex viruses) must be considered. Instillation of erythromycin or tetracycline into the newborn's eyes does not prevent development of chlamydial conjunctivitis. The ultimate control of this—and all—sexually transmitted disease depends on safe sex practices and on early diagnosis and treatment of infected persons. To accomplish the latter, the Centers for Disease Control and Prevention recommends annual screening of all sexually active women ages 25 years and younger.

CHLAMYDIA TRACHOMATIS AND NEONATAL PNEUMONIA

Of newborns infected by the mother, 10–20% may develop respiratory tract involvement 2–12 weeks after birth, culminating in pneumonia. Affected newborns have nasal obstruction or discharge, striking tachypnea, a characteristic paroxysmal staccato cough, an absence of fever, and eosinophilia. Interstitial infiltrates and hyperinflation can be seen on radiographs. The diagnosis should be suspected if pneumonitis develops in a newborn who has inclusion conjunctivitis and can be established by isolation of *C. trachomatis* from respiratory secretions. In such neonatal pneumonia, an immunoglobulin M (IgM) antibody titer to *C. trachomatis* of 1:32 or more is considered diagnostic. Oral azithromycin for 5 days is recommended; systemic azithromycin is effective treatment in severe cases.

LYMPHOGRANULOMA VENEREUM

LGV is a sexually transmitted disease caused by *C. trachomatis* and is characterized by suppurative inguinal adenitis; it is most common in tropical climates.

Properties of the Agent

The particles contain CF heat-stable chlamydial group antigens that are shared with all other chlamydiae. They also

contain one of three serovar antigens (L1–L3), which can be defined by immunofluorescence.

Clinical Findings

Several days to several weeks after exposure, a small, evanescent papule or vesicle develops on any part of the external genitalia, anus, rectum, or elsewhere. The lesion may ulcerate, but usually it remains unnoticed and heals in a few days. Days to weeks later, the regional lymph nodes enlarge and tend to become matted and painful. In men, inguinal nodes are most commonly involved both above and below Poupart's ligament and the overlying skin often turns purplish as the nodes suppurate (bubo formation) and eventually discharge pus through multiple sinus tracts. In women and in homosexual men, the perirectal nodes are prominently involved, with proctitis and a bloody mucopurulent anal discharge. During the stage of active lymphadenitis, there are often marked systemic symptoms, including fever, headaches, meningismus, conjunctivitis, skin rashes, nausea and vomiting, and arthralgias. Meningitis, arthritis, and pericarditis occur rarely. Unless effective antimicrobial drug treatment is given at that stage, the chronic inflammatory process progresses to fibrosis, lymphatic obstruction, and rectal strictures. The lymphatic obstruction may lead to elephantiasis of the penis, scrotum, or vulva. The chronic proctitis of women or homosexual men may lead to progressive rectal strictures, rectosigmoid obstruction, and fistula formation.

Laboratory Diagnosis

A. Smears

Pus, buboes, or biopsy material may be stained, but particles are rarely recognized.

B. Nucleic Acid Amplification Tests

All of the commercial NAATs detect all of the LGV serovars but cannot differentiate them from other *C. trachomatis* serovars.

C. Culture

Suspected material is inoculated into McCoy cell cultures. The inoculum can be treated with an aminoglycoside (but not with penicillin) to lessen bacterial contamination. The agent is identified by morphology and serologic tests.

D. Serology

Antibodies are commonly demonstrated by the CF reaction. The test becomes positive 2–4 weeks after onset of illness. In a clinically compatible case, a rising antibody level or a single titer of more than 1:64 is good evidence of active infection. If treatment has eradicated the LGV infection, the CF titer falls. Serologic diagnosis of LGV can use immunofluorescence, but the antibody is broadly reactive with many chlamydial antigens.

Immunity

Untreated infections tend to be chronic, with persistence of the agent for many years. Little is known about active immunity. The coexistence of latent infection, antibodies, and cell-mediated reactions is typical of many chlamydial infections.

Treatment

Oral doxycycline and erythromycin for 21 days are effective therapies. Some drug-treated persons have a marked decline in complement-fixing antibodies, which may indicate that the infective agent has been eliminated from the body. Late stages require surgery.

Epidemiology and Control

Although the highest incidence of LGV has been reported from subtropical and tropical areas, the infection occurs all over the world. The disease is most often spread by sexual contact but not exclusively so. The portal of entry may sometimes be the eye (conjunctivitis with an oculoglandular syndrome). The genital tracts and rectums of chronically infected (but at times asymptomatic) persons serve as reservoirs of infection. Laboratory personnel exposed to aerosols of *C. trachomatis* serovars L1–L3 can develop a chlamydial pneumonitis with mediastinal and hilar adenopathy. If the infection is recognized, treatment with doxycycline or erythromycin is effective.

The measures used for the control of other sexually transmitted diseases also apply to the control of LGV. Case finding and early treatment and control of infected persons are essential.

CHLAMYDIA PNEUMONIAE AND RESPIRATORY INFECTIONS

The first *C. pneumoniae* strain was obtained in the 1960s in chick embryo yolk sac culture. After the development of cell culture methods, this initial strain was thought to be a member of the species *C. psittaci*. Subsequently, *C. pneumoniae* was firmly established as a new species that causes respiratory disease in humans and nonhuman species.

Properties of the Agent

C. pneumoniae produces round, dense, glycogen-negative inclusions that are sulfonamide resistant, similar to *C. psittaci* (see Table 27-1). The EBs sometimes have a pear-shaped appearance. The genetic relatedness of *C. pneumoniae* isolates is greater than 95%. Only one serovar has been demonstrated.

Clinical Findings

Most infections with *C. pneumoniae* are asymptomatic or associated with mild illness, but severe disease has been reported.

There are no signs or symptoms that specifically differentiate *C. pneumoniae* infections from those caused by many other agents. Both upper and lower airway diseases occur. Pharyngitis is common. Sinusitis and otitis media may occur and be accompanied by lower airway disease. An atypical pneumonia similar to that caused by *Mycoplasma pneumoniae* is the primary recognized illness. The proportion of cases of community-acquired pneumonia caused by *C. pneumoniae* varies in the literature from 0% to 40%, but seems to be lower in more recent series (<5%).

Laboratory Diagnosis

A. Smears

Direct detection of EBs in clinical specimens using fluorescent antibody techniques is insensitive. Other stains do not effectively demonstrate the organism.

B. Culture

Swab specimens of the pharynx should be put into a chlamydiae transport medium and placed at 4°C; *C. pneumoniae* is rapidly inactivated at room temperature. It grows poorly in cell culture, forming inclusions smaller than those formed by the other chlamydiae. *C. pneumoniae* grows better in HL and HEp-2 cells than in HeLa 229 or McCoy cells; the McCoy cells are widely used to culture *C. trachomatis*. The sensitivity of the culture is increased by incorporation of cycloheximide into the cell culture medium to inhibit the eukaryotic cell metabolism and by centrifugation of the inoculum onto the cell layer. Growth is better at 35°C than 37°C. After 3 days' incubation, the cells are fixed and inclusions detected by fluorescent antibody staining with genus- or species-specific antibody or, preferably, with a *C. pneumoniae*-specific monoclonal antibody conjugated with fluorescein. Giemsa staining is insensitive, and the glycogen-negative inclusions do not stain with iodine. It is moderately difficult to grow *C. pneumoniae*—as evidenced by the number of isolates described compared with the incidence of infection.

C. Serology

Serology using the MIF test is the most sensitive method for diagnosis of *C. pneumoniae* infection. The test is species specific and can detect IgG or IgM antibodies by using the appropriate reagents. Primary infection yields IgM antibody after about 3 weeks followed by IgG antibody at 6–8 weeks. In reinfection, the IgM response may be absent or minimal, and the IgG response occurs in 1–2 weeks. The following criteria have been suggested for the serologic diagnosis of *C. pneumoniae* infection: a single IgM titer of 1:16 or greater, a single IgG titer of 1:512 or greater, and a fourfold rise in either the IgM or IgG titers.

The CF test can be used, but it is group reacting, does not differentiate *C. pneumoniae* infection from psittacosis or LGV, and is less sensitive than the MIF test.

D. Nucleic Acid Amplification Methods

Many research and reference laboratories have attempted to develop molecular assays targeting genes such as the 16SrRNA gene and the *ompA* gene but progress has been hampered by the lack of a reliable gold standard. However, BioFire Diagnostics, Inc. (Salt Lake City, UT) offers a nested multiplex PCR in a closed “lab-in-a-pouch” format for testing nasopharyngeal specimens. Such tests are needed so that the true contribution of *C. pneumoniae* to clinical disease can be fully determined.

Immunity

Little is known about active or potentially protective immunity. Prolonged infections can occur with *C. pneumoniae*, and asymptomatic carriage may be common.

Treatment

C. pneumoniae is susceptible to the macrolides and tetracyclines and to some fluoroquinolones. Treatment with doxycycline, azithromycin, or clarithromycin, levofloxacin or moxifloxacin, appears to significantly benefit patients with *C. pneumoniae* infection, but there are only limited data on the efficacy of antibiotic treatment. Reports indicate that the symptoms may continue or recur after routine courses of therapy with erythromycin, doxycycline, or tetracycline, and these drugs should be given for 10- to 14-day courses.

Epidemiology

Infection with *C. pneumoniae* is common. Worldwide, 30–50% of people have antibody to *C. pneumoniae*. Few young children have antibody, but after the age of 6–8 years, the prevalence of antibody increases through young adulthood. Infection is both endemic and epidemic, with multiple outbreaks attributed to *C. pneumoniae*. There is no known animal reservoir, and transmission is presumed to be from person to person, predominantly by the airborne route.

Lines of evidence suggesting that *C. pneumoniae* is associated with atherosclerotic coronary artery and cerebrovascular disease consist of seroepidemiologic studies, detection of *C. pneumoniae* in atherosclerotic tissues, cell culture studies, animal models, and trials of prevention using antibiotic agents. However, other studies have shown no association. The possible link between *C. pneumoniae* infection and coronary artery disease remains controversial.

CHLAMYDIA PSITTACI AND PSITTACOSIS

The term *psittacosis* is applied to the human *C. psittaci* disease acquired from contact with birds and also the infection of psittacine birds (eg, parrots, parakeets, and cockatoos). The term *ornithosis* is applied to infection with similar agents

in all types of domestic birds (eg, pigeons, chickens, ducks, geese, and turkeys) and free-living birds (eg, gulls, egrets, and petrels). In humans, *C. psittaci* produces a spectrum of clinical manifestations ranging from severe pneumonia and sepsis with a high mortality rate to a mild inapparent infection.

Properties of the Agent

C. psittaci can be propagated in embryonated eggs, in mice and other animals, and in some cell cultures. The heat-stable group-reactive CF antigen resists proteolytic enzymes and appears to be a lipopolysaccharide. Treatment of *C. psittaci* infection with deoxycholate and trypsin yields extracts that contain group-reactive CF antigens, but the cell walls retain the species-specific antigen. Antibodies to the species-specific antigen are able to neutralize toxicity and infectivity. Specific serovars characteristic for certain mammalian and avian species may be demonstrated by immunofluorescence typing. Neutralization of infectivity of the agent by specific antibody or cross-protection of immunized animals can also be used for serotyping, and the results parallel those of immunofluorescence typing.

Pathogenesis and Pathology

The agent enters through the respiratory tract, is found in the blood during the first 2 weeks of the disease, and may be found in the sputum at the time the lung is involved.

Psittacosis causes a patchy inflammation of the lungs in which consolidated areas are sharply demarcated. The exudates are predominantly mononuclear. Only minor changes occur in the large bronchioles and bronchi. The lesions are similar to those found in pneumonitis caused by some viruses and mycoplasmas. The liver, spleen, heart, and kidney are often enlarged and congested.

Clinical Findings

A sudden onset of illness taking the form of influenza or non-bacterial pneumonia in a person exposed to birds is suggestive of psittacosis. The incubation period averages 10 days. The onset is usually sudden, but can be insidious, with malaise, fever, anorexia, sore throat, photophobia, and severe headache. The disease may progress no further, and the patient may improve in a few days. In severe cases, the signs and symptoms of bronchial pneumonia appear at the end of the first week of the disease. The clinical picture often resembles that of influenza, nonbacterial pneumonia, or typhoid fever. The mortality rate may be as high as 20% in untreated cases, especially in elderly adults.

Laboratory Diagnosis

A. Culture

Culture of *C. psittaci* can be dangerous, and detection of the organism using immunoassays or PCR is preferred.

If necessary, *C. psittaci* can be cultured from blood or sputum or from lung tissue by culture in tissue culture cells, embryonated eggs, or mice in an appropriate biosafety level-3 laboratory. Isolation of *C. psittaci* is confirmed by the serial transmission, its microscopic demonstration, and serologic identification.

B. Antigen Detection of *Chlamydia psittaci*

Antigen detection by DFA staining or by immunoassay or molecular diagnosis by PCR is done in reference or research laboratories.

C. Serology

A diagnosis of psittacosis is usually confirmed by demonstrating complement-fixing or microimmunofluorescent antibodies in serum specimens. A confirmed case is one with a positive culture result or associated with a compatible clinical illness plus a fourfold or greater change in antibody titer to at least 1:32 or a single MIF IgM titer of at least 1:16. A probable case is one associated with a compatible illness linked epidemiologically with a confirmed case or a titer of at least 1:32 in a single specimen. The CF test is cross-reactive with *C. trachomatis* and *C. pneumoniae*. The MIF test is more sensitive and specific than the CF test, but cross-reactions do occur. MIF allows detection of IgM and IgG. Although antibodies usually develop within 10 days, the use of antibiotics may delay their development for 20–40 days or suppress it altogether.

In live birds, infection is suggested by a positive CF test result and an enlarged spleen or liver. This can be confirmed by demonstration of particles in smears or sections of organs and by passage of the agent in mice and eggs.

D. Molecular Methods

Multiple PCR assays have been developed to detect *C. psittaci* in respiratory tract specimens, vascular tissues, serum, and mononuclear cells from peripheral blood. These tests are done in reference or research laboratories.

Immunity

Immunity in animals and humans is incomplete. A carrier state in humans can persist for 10 years after recovery. During this period, the agent may continue to be excreted in the sputum.

Live or inactivated vaccines induce only partial resistance in animals. They have not been used in humans.

Treatment

Because of the difficulty in obtaining laboratory confirmation of *C. psittaci* infection, most infections are treated based only on the clinical diagnosis. Information on therapeutic efficacy comes from several clinical trials. Doxycycline and tetracycline are the preferred agents for treatment; macrolides and fluoroquinolones may be alternatives.

Epidemiology and Control

Outbreaks of human disease can occur whenever there is close and continued contact between humans and infected birds that excrete or shed large amounts of infectious agent. Birds often acquire infection as fledglings in the nest, may develop diarrheal illness or no illness, and often carry the infectious agent for their normal lifespan. When subjected to stress (eg, malnutrition or shipping), birds may become sick and die. The agent is present in tissues (eg, the spleen) and is often excreted in feces by healthy birds. The inhalation of infected dried bird feces is a common method of human infection. Another source of infection is the handling of infected tissues (eg, in poultry rendering plants) and inhalation of an infected aerosol.

Birds kept as pets have been an important source of human infection. Foremost among these were the many imported psittacine birds. Latent infections often flared up in these birds during transport and crowding, and sick birds excreted exceedingly large quantities of infectious agent. Control of bird shipment, quarantine, testing of imported birds for psittacosis infection, and prophylactic tetracyclines in bird feed have helped to control this source. Pigeons kept for racing or as pets or raised for squab meat have been important sources of infection. Pigeons populating buildings and thoroughfares in many cities, if infected, shed relatively small quantities of agent.

CHAPTER SUMMARY

- *Chlamydiae* are small organisms that multiply in the cytoplasm of their host cells using unique biphasic developmental cycles.
- The EB is the infectious particle that is environmentally stable. The RB is the metabolically active form that divides by binary fission within a membrane-bound vacuole.
- There are three species of *Chlamydia* that cause disease in humans: *C. trachomatis*, *C. pneumoniae*, and *C. psittaci*.
- *C. trachomatis* is responsible for sexually transmitted diseases that include cervicitis, pelvic inflammatory disease, urethritis, epididymitis, LGV, and proctitis, and when transmitted to infants of infected pregnant women, infant inclusion conjunctivitis and eosinophilic pneumonia.
- Diagnosis of *C. trachomatis* urogenital infections is made most readily by NAATs; culture or DFA is required to diagnose pediatric syndromes. Treatment of infections caused by *C. trachomatis* requires doxycycline or azithromycin.
- *C. pneumoniae* causes a variety of upper and lower respiratory infections. Pharyngitis is common, and atypical pneumonia resembling that of *M. pneumoniae* is responsible for approximately 5% of cases of community-acquired pneumonia.
- Serology using MIF is the most sensitive means of diagnosing *C. pneumoniae*. NAATs are available in research and reference laboratories but vary in their performance. There is one FDA-approved commercial assay that detects *C. pneumoniae*.
- *C. psittaci* is acquired from contact with birds such as parrots, pigeons, and various domestic poultry.
- The disease psittacosis may be inapparent or mild, but severe pneumonia and sepsis associated with a high mortality rate have also been described.
- Diagnosis is made serologically; doxycycline is used for treatment.

REVIEW QUESTIONS

1. Which of the following statements about chlamydial antigens is correct?
 - (A) Chlamydiae have shared group or genus-specific antigens.
 - (B) There is no cross-reaction between *C. trachomatis* and *C. pneumoniae* antigens.
 - (C) All five serovars of *C. pneumoniae* cross-react with *C. psittaci*.
 - (D) One serovar of *C. trachomatis* causes eye infections, and the second serovar causes genital infections.
 - (E) Chlamydiae frequently vary the epitopes of their antigens to avoid immune clearance.
2. As part of the control of *C. psittaci* and psittacosis in birds:
 - (A) All psittacine birds imported into the United States are first vaccinated.
 - (B) Psittacine birds hatched in the United States are preferred as pets.
 - (C) All birds are tested for *C. psittaci* infection.
 - (D) The shipment of all birds between states is highly regulated.
 - (E) Psittacine birds are fed penicillin G prophylactically.
3. Perinatal *C. trachomatis* infections frequently manifest as:
 - (A) urogenital disease.
 - (B) necrotic pneumonia.
 - (C) inclusion conjunctivitis.
 - (D) a pustular rash.
 - (E) endophthalmitis.
4. An adolescent girl came to the clinic because of a vaginal discharge. She had recently become sexually active and had two new partners during the previous month. On pelvic examination, a purulent discharge was seen at the opening of her endocervical canal. Which of the following statements about this patient is most correct?
 - (A) A serologic test for syphilis is not indicated because her symptoms are not those of syphilis.
 - (B) A Gram-stain of her endocervical specimen would show *C. trachomatis* inside polymorphonuclear cells.
 - (C) The differential diagnosis includes infection with *N. gonorrhoeae*, *C. trachomatis*, or both.
 - (D) The endocervical specimen should be analyzed for herpes simplex.
 - (E) Initial treatment is with ampicillin.
5. Which of following statements about trachoma is most accurate?
 - (A) It follows an acute eye infection with *C. trachomatis*.
 - (B) Millions of people in the United States have trachoma.
 - (C) There is no chlamydial vaccine to prevent trachoma.
 - (D) Progression of trachoma is accelerated by intermittent treatment with azithromycin.
 - (E) Trachoma involves direct damage to corneal epithelium.

6. Which of the following is not effective in the elimination of blinding trachoma?
 - (A) Periodic administration of azithromycin
 - (B) Face washing and hygiene
 - (C) Periodic culture screening of conjunctiva swab specimens for *C. trachomatis*
 - (D) Environment improvements to sewage systems to decrease the number of flies
 - (E) Surgery on deformed eyelids
7. Which one of the following statements about *C. pneumoniae* is most correct?
 - (A) Transmission from person to person is by the airborne route.
 - (B) It makes glycogen-rich inclusions that stain with iodine.
 - (C) There are multiple serovars, including three that cause a systemic illness.
 - (D) They are resistant to macrolides.
 - (E) The reservoir is house cats.
8. The serovars of *C. trachomatis* generally can be divided into groups representing their clinical infections and anatomic site infected. Which of the following statements about the *C. trachomatis* serovars is most correct?
 - (A) There is no immunologic cross-reaction between *C. trachomatis* serovars A, B, Ba, and D and the *C. pneumoniae* serovar.
 - (B) Serovars L1, L2, and L3 are associated with lymphogranuloma venereum.
 - (C) The same *C. trachomatis* serovars are associated with blinding trachoma and sexually transmitted infections.
 - (D) The antibody titer rise seen beginning around 6–8 years follows infections with *C. trachomatis* serovars D–K.
9. In the United States, it has long been known that the positive seroprevalence for *C. trachomatis* infection increases greatly during the primary school years (ages 6–10 years). A likely reason for this is
 - (A) Frequent adenovirus infections
 - (B) Increased incidence of infections with *C. trachomatis*
 - (C) Cross-reactive antibodies with M protein of group A streptococci (*Streptococcus pyogenes*)
 - (D) Children often have psittacosis
 - (E) Frequent infections with *C. pneumoniae*
10. Which of the following statements about lymphogranuloma venereum (LGV) is most accurate?
 - (A) Chronic LGV proctitis can lead to rectal prolapse.
 - (B) The disease is more common in tropical climates.
 - (C) There are few systemic symptoms of infection.
 - (D) Acute inflammation with LGV will lead to lymphatic obstruction.
 - (E) Inguinal lymph nodes are unaffected.
11. Which of the following methods are considered the diagnostic tests of choice for urogenital infections caused by *C. trachomatis*?
 - (A) Serology using complement fixation
 - (B) Cell culture using cycloheximide containing McCoy cells
 - (C) Direct fluorescent antibody testing on urethral and cervical specimens
 - (D) Nucleic acid amplification methods
 - (E) Enzyme immunoassays performed on genital tract specimens
12. Which of the following specimens is not acceptable for nucleic acid amplification testing for the diagnosis of chlamydial infections?
 - (A) Self-collected vaginal swabs in women
 - (B) First void urine samples obtained from men
 - (C) Rectal swabs obtained from children 12 years of age or younger
 - (D) Urethral swab samples obtained from adult men
 - (E) Cervical swab samples obtained from adolescent girls
13. *C. pneumoniae* pneumonia most resembles infection caused which of the following organisms?
 - (A) *Streptococcus pneumoniae*
 - (B) *Mycoplasma pneumoniae*
 - (C) *Haemophilus influenzae*
 - (D) *C. trachomatis*
 - (E) Rhinovirus
14. Inclusion conjunctivitis of the newborn
 - (A) Is a mucopurulent conjunctivitis that occurs 7–12 days after delivery
 - (B) Is caused by *C. psittaci*
 - (C) Is a result of exposure to pet birds in the home
 - (D) Is treated with systemic penicillin because it may progress to pneumonia
 - (E) None of the above
15. The diagnostic method of choice for *C. trachomatis* pneumonia in the newborn is
 - (A) A nucleic acid amplification test that targets the *ompA* gene
 - (B) Culture of respiratory secretions in McCoy cells or other cell lines
 - (C) Enzyme immunoassay testing of respiratory secretions
 - (D) IgG antibodies detected by complement fixation

Antimicrobial Chemotherapy

Drugs have been used for the treatment of infectious diseases since the 17th century (eg, quinine for malaria and emetine for amebiasis); however, chemotherapy as a science began in the first decade of the 20th century with understanding of the principles of selective toxicity, the specific chemical relationships between microbial pathogens and drugs, the development of drug resistance, and the role of combined therapy. Experiments by the German physician and scientist Paul Erlich led to the arsphenamines for syphilis, the first planned chemotherapeutic regimen.

The current era of antimicrobial chemotherapy began in 1935 with the discovery of the sulfonamides by German physician and scientist Gerhard Domagk. In 1940, it was demonstrated that penicillin, discovered in 1929 by Scottish physician and scientist Sir Alexander Fleming, could be an effective therapeutic substance. During the next 25 years, research on chemotherapeutic agents focused largely on substances of microbial origin called antibiotics. The isolation, concentration, purification, and mass production of penicillin were followed by the development of streptomycin, tetracyclines, chloramphenicol, and many other agents. These substances were originally isolated from filtrates of media in which their respective molds and filamentous bacteria had grown. Synthetic modification of previously described drugs has been prominent in the development of new antimicrobial agents.

Antimicrobial agents commonly used in the treatment of patients with bacterial infections are presented in this chapter. The chemotherapy of viruses, fungi, and parasites is discussed in Chapters 30, 45, and 46, respectively. Additional comments on antimicrobial susceptibility testing for bacteria are found in Chapter 47.

MECHANISMS OF ACTION OF ANTIMICROBIAL DRUGS

Antimicrobial drugs act in one of several ways: by selective toxicity, by inhibition of cell membrane synthesis and function, by inhibition of protein synthesis, or by inhibition of nucleic acid synthesis.

SELECTIVE TOXICITY

An ideal antimicrobial agent exhibits selective toxicity, which means that the drug is harmful to a pathogen without being harmful to the host. Often, selective toxicity is relative rather than absolute; this implies that a drug in a concentration tolerated by the host may damage an infecting microorganism.

Selective toxicity may be a function of a specific receptor required for drug attachment, or it may depend on the inhibition of biochemical events essential to the pathogen but not to the host. The mechanisms of action of antimicrobial drugs can be discussed under four headings:

1. Inhibition of cell wall synthesis
2. Inhibition of cell membrane function
3. Inhibition of protein synthesis (ie, inhibition of translation and transcription of genetic material)
4. Inhibition of nucleic acid synthesis

INHIBITION OF CELL WALL SYNTHESIS

Bacteria have a rigid outer layer, the cell wall. The cell wall maintains the shape and size of the microorganism, which has a high internal osmotic pressure. Injury to the cell wall (eg, by lysozyme) or inhibition of its formation may lead to lysis of the cell. In a hypertonic environment (eg, 20% sucrose), damaged cell wall formation leads to formation of spherical bacterial “protoplasts” from Gram-positive organisms or “spheroplasts” from Gram-negative organisms; these forms are limited by the fragile cytoplasmic membrane. If such **protoplasts** or **spheroplasts** are placed in an environment of ordinary tonicity, they take up fluid rapidly, swell, and may burst. Specimens from patients being treated with cell wall-active antibiotics often show swollen or misshapen bacteria.

The cell wall contains a chemically distinct complex polymer “mucopolysaccharide” (“peptidoglycan”) consisting of polysaccharides and a highly cross-linked polypeptide. The polysaccharides regularly contain the amino sugars *N*-acetylglucosamine and *N*-acetylmuramic acid. The latter is found only in bacteria. To the amino sugars are attached

short peptide chains. The final rigidity of the cell wall is imparted by cross-linking of the peptide chains (eg, through pentaglycine bonds) as a result of transpeptidation reactions carried out by several enzymes. The peptidoglycan layer is much thicker in the cell wall of Gram-positive than of Gram-negative bacteria.

All β -lactam drugs are selective inhibitors of bacterial cell wall synthesis and therefore active against growing bacteria. This inhibition is only one of several different activities of these drugs, but it is the best understood. The initial step in drug action consists of binding of the drug to cell receptors (**penicillin-binding proteins [PBPs]**). There are at least six different PBPs (molecular weight [MW], 40–120 kilodaltons [kD]), some of which are transpeptidation enzymes. Different receptors have different affinities for a drug, and each may mediate a different effect. For example, attachment of penicillin to one PBP may result chiefly in abnormal elongation of the cell, but attachment to another PBP may lead to a defect in the periphery of the cell wall with resulting cell lysis. PBPs are under chromosomal control, and mutations may alter their number or their affinity for β -lactam drugs.

After a β -lactam drug has attached to one or more receptors, the transpeptidation reaction is inhibited, and peptidoglycan synthesis is blocked. The next step probably involves removal or inactivation of an inhibitor of autolytic enzymes in the cell wall. This activates the lytic enzyme and results in lysis if the environment is isotonic. In a markedly hypertonic environment, the microbes change to protoplasts or spheroplasts, covered only by the fragile cell membrane. In such cells, synthesis of proteins and nucleic acids may continue for some time.

The inhibition of the transpeptidation enzymes by penicillins and cephalosporins may be attributable to a structural similarity of these drugs to acyl-D-alanyl-D-alanine. The transpeptidation reaction involves loss of a D-alanine from the pentapeptide.

The remarkable lack of toxicity of β -lactam drugs to mammalian cells must be attributed to the absence in animal cells of a bacterial type cell wall with its peptidoglycan. The difference in susceptibility of Gram-positive and Gram-negative bacteria to various penicillins or cephalosporins probably depends on structural differences in their cell walls (eg, amount of peptidoglycan, presence of receptors and lipids, nature of cross-linking, and activity of autolytic enzymes) that determine penetration, binding, and activity of the drugs.

Resistance to penicillins may be determined by the organism's production of penicillin-destroying enzymes (β -lactamases). The α -**lactamases** open the β -lactam ring of penicillins and cephalosporins and abolish their antimicrobial activity. β -Lactamases have been described for many species of Gram-positive and Gram-negative bacteria. Some β -lactamases are plasmid mediated (eg, penicillinase of *Staphylococcus aureus*), and others are chromosomally mediated (eg, many species of Gram-negative bacteria). All of the plasmid-mediated β -lactamases are produced

constitutively and have a high propensity to move from one species of bacteria to another (eg, β -lactamase-producing *Neisseria gonorrhoeae*, *Haemophilus influenzae*, and enterococci). Chromosomally mediated β -lactamases may be constitutively produced (eg, *Bacteroides* and *Acinetobacter* species), or they may be inducible (eg, *Enterobacter*, *Citrobacter*, and *Pseudomonas* species).

There is one group of β -lactamases that is occasionally found in certain species of Gram-negative bacilli such as, *Klebsiella pneumoniae*. These enzymes are termed **extended-spectrum α -lactamases (ESBLs)** because they confer upon the bacteria the additional ability to hydrolyze the β -lactam rings of cefotaxime, ceftazidime, or aztreonam.

The classification of β -lactamases is complex, based on the genetics, biochemical properties, and substrate affinity for a β -lactamase inhibitor (clavulanic acid) (Table 28-1 has the two major classification systems). Clavulanic acid, sulbactam, and tazobactam are β -lactamase inhibitors that have a high affinity for and irreversibly bind some β -lactamases (eg, penicillinase of *S. aureus*) but are not hydrolyzed by the β -lactamase. These inhibitors protect simultaneously present hydrolyzable penicillins (eg, ampicillin, amoxicillin, and piperacillin) from destruction. Certain penicillins (eg, cloxacillin) also have a high affinity for β -lactamases.

Shortly after their first description almost 3 decades ago, the most common ESBLs were of the class A TEM and SHV plasmid-mediated types (see Table 28-1). Currently throughout much of the world, the **CTX-M enzymes** have become more prevalent. These enzymes are more active against cefotaxime and ceftriaxone than ceftazidime and seem to be inhibited more readily by tazobactam than the other β -lactamase inhibitors. Of most concern is the emergence of *K. pneumoniae* **carbapenemases (KPC)**, which are ESBL-type enzymes that confer resistance to third- and fourth-generation cephalosporins and carbapenems. This resistance mechanism is plasmid mediated and has spread nosocomially among many hospitals throughout the United States and other countries.

Although they were discovered in the mid-1960s, global spread of genes encoding metallo- β -lactamases has facilitated spread of these broad-range, inhibitor-resistant enzymes among many Gram-negative pathogens. This has ushered in an era of widespread dissemination of carbapenem-resistant Enterobacteriaceae possessing the VIM-type (Verona integron-encoded metallo- β -lactamase) and NDM-type (New Delhi metallo- β -lactamase) of these enzymes. VIM-type enzymes first appeared in *Pseudomonas aeruginosa* and *Acinetobacter baumannii*, but have spread to Enterobacteriaceae. There are more than 20 types, and they are most prevalent in Europe, the Middle East, and Asia. NDM-1 was described first in a *K. pneumoniae* strain in Sweden from a patient who had traveled to India. In addition to spread to other Enterobacteriaceae, NDM-1 producing *A. baumannii* have appeared. Because these organisms often contain genes that encode resistance to other classes of antimicrobials, such as fluoroquinolones and aminoglycosides, options for

TABLE 28-1 Classification of β -Lactamases

Bush-Jacoby-Medeiros System Group	Enzyme Type	Inhibition by Clavulanate	Ambler System	Main Attributes
1	Cephalosporinase	No	C	Chromosomal; AMP-C-type enzymes; resistant to all β -lactams except carbapenems
2a	Penicillinase	Yes	A (serine)	Staphylococcal penicillinase; <i>Bacillus cereus</i>
2b	Broad-spectrum	Yes	A	TEM-1, TEM-2, SHV-1
2be	Extended-spectrum	Yes	A (serine)	TEM- and SHV variants; CTX-M-derived; GES-1, 2; VEB-1, 2
2br	Inhibitor resistant	Diminished	A	Inhibitor-resistant TEM-30
2c	Carbenicillinase	Yes	A	Carbenicillin hydrolyzing
2d	Cloxacillinase	Yes	D* or A	Oxacillin hydrolyzing (OXA)
2e	Cephalosporinase	Yes	A	Cephalosporinases
2f	Carbapenemase	Yes	A	Carbapenemases inhibited by clavulanate (eg, IMI, KPC, SME-1)
3	Metalloenzymes	No	B (Zn ²⁺)	Zinc-dependent carbapenemases (eg, IMP, VIM, NDM-1, GIM, SPM, SIM)
4	Penicillinase	No	Not classified	Misc enzymes

AMP, ampicillin; CTX, cefotaxime; GES, Guyana; GIM, German imipenemase; IMI, imipenem; IMP, imipenem; KPC, *Klebsiella pneumoniae* carbapenemase; OXA, oxacillin; SIM, Seoul imipenemase; SHV, sulfhydryl variable; SME, *Serratia marcescens* extended-spectrum β -lactamase; SPM, Sao Paulo metallo- β -lactamase; TEM, TEMoniera; VEB, Verona integron-encoded metallo- β -lactamase; VIM, Verona-integron-encoded.

*Includes the broad-spectrum OXA-family in *Pseudomonas aeruginosa*, the OXA-derived carbapenemases found in *Acinetobacter* and the extended-spectrum OXA-derived enzymes produced by *P. aeruginosa*.

treatment are very limited to agents such colistin. Therefore, such patients are often placed on maximum infection control precautions to prevent spread to other patients within hospital environments.

A troubling concern has been the emergence and global spread of **mobilized colistin resistance determinants (*mcr*)**. MCR confers resistance to colistin and polymyxin B by reducing the net negative charge of the Lipid A moiety of LPS. First discovered in Southern China in late 2015, Enterobacteriaceae harboring plasmids carrying *mcr-1* have spread to over 40 countries covering five of seven continents. It is just a matter of time before there will be infections caused by β -lactamase producing Enterobacteriaceae that are essentially untreatable.

There are two other types of resistance mechanisms. One is caused by the absence of some PBPs and occurs as a result of chromosomal mutation; the other results from failure of the β -lactam drug to activate the autolytic enzymes in the cell wall. As a result, the organism is inhibited but not killed. Such **tolerance** has been observed especially with staphylococci and certain streptococci.

Examples of agents acting by inhibition of cell wall synthesis are β -lactam drugs such as the penicillins, the cephalosporins, the carbapenems; the monobactam aztreonam; glycopeptide antibiotics such as vancomycin and teicoplanin; and lipoglycopeptides such as oritavancin, telavancin, and dalbavancin. Several other drugs, including fosfomycin,

bacitracin, cycloserine, and novobiocin, inhibit early steps in the biosynthesis of the peptidoglycan. Because the early stages of synthesis take place inside the cytoplasmic membrane, these drugs must penetrate the membrane to be effective.

INHIBITION/ALTERATION OF CELL MEMBRANE FUNCTION

The cytoplasm of all living cells are bounded by the cytoplasmic membrane, which serves as a selective permeability barrier and carries out active transport functions and thus controls the internal composition of the cell. If the functional integrity of the cytoplasmic membrane is disrupted, macromolecules and ions escape from the cell, and cell damage or death ensues. The cytoplasmic membrane of bacteria and fungi has a structure different from that of animal cells and can be more readily disrupted by certain agents. Consequently, selective chemotherapy is possible.

Detergents, which contain lipophilic and hydrophilic groups, disrupt cytoplasmic membranes and kill the cell (see Chapter 4). One class of antibiotics, the polymyxins, consists of detergent-like cyclic peptides that selectively damage membranes containing phosphatidylethanolamine, a major component of bacterial membranes. Daptomycin is a cyclic 13-member lipopeptide antibiotic that is rapidly bactericidal

by binding to the cell membrane in a calcium ion-dependent manner, causing depolarization of bacterial membrane potential. This leads to intracellular potassium release that causes cell death. Currently, this agent is approved for use in the treatment of *S. aureus* bloodstream infections and skin and soft tissue infections caused by Gram-positive bacteria, particularly organisms that are highly resistant to β -lactam agents and vancomycin.

INHIBITION OF PROTEIN SYNTHESIS

It is established that macrolides, lincosamides, tetracyclines, glycylicyclines, aminoglycosides, and chloramphenicol can inhibit protein synthesis in bacteria. The precise mechanisms of action differ among these classes of drugs.

Whereas bacteria have 70S ribosomes, mammalian cells have 80S ribosomes. The subunits of each type of ribosome, their chemical composition, and their functional specificities are sufficiently different to explain why antimicrobial drugs can inhibit protein synthesis in bacterial ribosomes without having a major effect on mammalian ribosomes.

In normal microbial protein synthesis, the mRNA message is simultaneously “read” by several ribosomes that are strung out along the mRNA strand. These are called **polysomes**.

Aminoglycosides

The mode of action of streptomycin has been studied far more intensively than that of other aminoglycosides, but all act similarly. The first step is the attachment of the aminoglycoside to a specific receptor protein (P 12 in the case of streptomycin) on the 30S subunit of the microbial ribosome. Second, the aminoglycoside blocks the normal activity of the “initiation complex” of peptide formation (mRNA + formyl methionine + tRNA). Third, the mRNA message is misread on the “recognition region” of the ribosome; consequently, the wrong amino acid is inserted into the peptide, resulting in a nonfunctional protein. Fourth, aminoglycoside attachment results in the breakup of polysomes and their separation into **monosomes** incapable of protein synthesis. These activities occur more or less simultaneously, and the overall effect is usually an irreversible event—killing of the bacterium.

Chromosomal resistance of microbes to aminoglycosides principally depends on the lack of a specific protein receptor (modification of the target site caused by mutations) on the 30S subunit of the ribosome. Plasmid-dependent resistance to aminoglycosides depends on the production by the microorganism of adenylating, phosphorylating, or acetylating enzymes that destroy the drugs (most common mechanism). A third type of resistance consists of a “permeability defect,” an outer membrane change that reduces active transport of the aminoglycoside into the cell so the drug cannot reach the ribosome. Often this is plasmid mediated.

Macrolides and Ketolides

These drugs (erythromycin, azithromycin, clarithromycin, fidaxomicin, and the ketolide telithromycin) bind to the 50S subunit of the ribosome, and the binding site is domain V of the 23S rRNA. They may interfere with formation of initiation complexes for peptide chain synthesis or may interfere with aminoacyl translocation reactions. Some macrolide-resistant bacteria lack the proper receptor on the ribosome (through methylation of the 23S rRNA target site). The *erm* (erythromycin ribosome methylation) genes that encode this mechanism may be under plasmid or chromosomal control. They may be expressed constitutively or may be induced by subinhibitory concentrations of macrolides. Other less common mechanisms of resistance include production of inactivating enzymes or *mef*- and *msr*-encoded efflux. Efflux-mediated resistance does not affect susceptibility to ketolides.

Lincosamides

Clindamycin and lincomycin bind to the 50S subunit of the microbial ribosome and resemble macrolides in binding site, antibacterial activity, and mode of action. Chromosomal mutants are resistant because they lack the proper binding site on the 50S subunit.

Tetracyclines

Tetracyclines bind reversibly to the 30S subunit of microbial ribosomes. They inhibit protein synthesis by blocking the attachment of charged aminoacyl-tRNA. Thus, they prevent introduction of new amino acids to the nascent peptide chain. The action is usually inhibitory and reversible upon withdrawal of the drug. Resistance to tetracyclines occurs by multiple mechanisms—efflux, ribosomal protection proteins, and chemical modification, among others.

The first two are the most important and occur as follows: Efflux pumps, located in the bacterial cell cytoplasmic membrane, are responsible for pumping the drug out of the cell. *Tet* gene products are responsible for protecting the ribosome, likely through mechanisms that induce conformational changes. These conformational changes either prevent binding of the tetracyclines or cause their dissociation from the ribosome. This is often plasmid controlled. Mammalian cells do not actively concentrate tetracyclines.

Glycylicyclines

The glycylicyclines are synthetic analogues of the tetracyclines. The agent that is available for use in the United States and Europe is tigecycline, a derivative of minocycline. The glycylicyclines inhibit protein synthesis in a manner similar to the tetracyclines but they demonstrate more avid binding to the ribosome. Tigecycline is active against a broad range of Gram-positive and Gram-negative bacteria, including

strains resistant to the typical tetracyclines. This drug has approved indications for treatment of skin and skin structure infections, in intra-abdominal infections and for the treatment of community-acquired pneumonia, particularly those caused by bacterial pathogens resistant to a variety of other antimicrobial agents. In addition, use of this drug for treatment of multidrug-resistant health care-associated infections (except *P. aeruginosa*) has substantially increased. In 2013, the FDA issued a warning based upon an analysis of 13 clinical trials that demonstrated an increased risk of death with tigecycline (https://www.accessdata.fda.gov/drugsatfda_docs/label/2013/021821s026s031lbl.pdf). It is suggested that this drug be reserved for situations where other agents are not available or cannot be used because of resistance.

Chloramphenicol

Chloramphenicol binds to the 50S subunit of the 70S bacterial ribosome. It interferes with the binding of new amino acids to the nascent peptide chain, largely because chloramphenicol inhibits peptidyl transferase. Chloramphenicol is mainly bacteriostatic, and growth of microorganisms resumes when the drug is withdrawn. Microorganisms resistant to chloramphenicol usually produce the chloramphenicol acetyltransferases, which destroys drug activity. The production of this enzyme is usually under the control of plasmid-mediated resistance genes called *cat* genes. Other mechanisms of resistance include efflux pumps and decreased membrane permeability.

Streptogramins

Quinupristin–dalfopristin is a combination of two pristina-mycin derivatives. These two agents act synergistically to achieve bactericidal activity against Gram-positive bacteria not seen with either agent alone. The mechanism of action appears to be irreversible binding to different sites on the 50S subunits of the 70S bacterial ribosomes. Resistance may occur from conformational changes in the target, efflux, and enzymatic inactivation.

Oxazolidinones

The oxazolidinones possess a unique mechanism of inhibition of protein synthesis primarily in Gram-positive bacteria. These compounds interfere with translation by inhibiting the formation of *N*-formyl-methionyl-tRNA, the initiation complex at the 23S ribosome. Linezolid was the first agent to become commercially available and it has seen widespread usage in the treatment of a variety of serious Gram-positive infections including those caused by vancomycin-resistant enterococci and even mycobacterial infections. The second oxazolidone to become available is tedizolid phosphate, tedizolid is similar in spectrum of activity, mechanism of action, and pharmacology to linezolid.

INHIBITION OF NUCLEIC ACID SYNTHESIS

Examples of drugs acting by inhibition of nucleic acid synthesis are the quinolones, pyrimethamine, rifampin, sulfonamides, trimethoprim, and trimetrexate. Rifampin inhibits bacterial growth by binding strongly to the DNA-dependent RNA polymerase of bacteria. Thus, it inhibits bacterial RNA synthesis. Rifampin resistance results from a change in RNA polymerase because of a chromosomal mutation that occurs with high frequency.

All quinolones and fluoroquinolones inhibit microbial DNA synthesis by blocking DNA gyrases, topoisomerase enzymes that play key roles in DNA replication and repair.

For many microorganisms, *p*-aminobenzoic acid (PABA) is an essential metabolite. The specific mode of action of PABA involves an adenosine triphosphate (ATP)-dependent condensation of a pteridine with PABA to yield dihydropteroic acid, which is subsequently converted to folic acid. PABA is involved in the synthesis of folic acid, an important precursor to the synthesis of nucleic acids. Sulfonamides are structural analogs of PABA and inhibit dihydropteroate synthetase.

Sulfonamides can enter into the reaction in place of PABA and compete for the active center of the enzyme. As a result, nonfunctional analogs of folic acid are formed, preventing further growth of the bacterial cell. The inhibiting action of sulfonamides on bacterial growth can be counteracted by an excess of PABA in the environment (competitive inhibition). Animal cells cannot synthesize folic acid and must depend on exogenous sources. Some bacteria, similar to animal cells, are not inhibited by sulfonamides. Many other bacteria, however, synthesize folic acid, as mentioned earlier, and consequently are susceptible to action by sulfonamides.

Trimethoprim (3,4,5-trimethoxybenzylpyrimidine) inhibits dihydrofolic acid reductase 50,000 times more efficiently in bacteria than in mammalian cells. This enzyme reduces dihydrofolic to tetrahydrofolic acid, a stage in the sequence leading to the synthesis of purines and ultimately of DNA. Sulfonamides and trimethoprim each can be used alone to inhibit bacterial growth. If used together, they produce sequential blocking, resulting in a marked enhancement (synergism) of activity. Such mixtures of sulfonamide (five parts) plus trimethoprim (one part) have been used in the treatment of pneumocystis pneumonia, malaria, shigella

enteritis, systemic salmonella infections, urinary tract infections, and many others.

Pyrimethamine also inhibits dihydrofolate reductase, but it is more active against the enzyme in mammalian cells and therefore is more toxic than trimethoprim. Pyrimethamine plus sulfonamide or clindamycin is the current treatment of choice in toxoplasmosis and some other protozoal infections.

RESISTANCE TO ANTIMICROBIAL DRUGS

There are many different mechanisms by which microorganisms might exhibit resistance to drugs.

1. Microorganisms produce enzymes that destroy the active drug. **Examples:** Staphylococci resistant to penicillin G produce a β -lactamase that destroys the drug. Other β -lactamases are produced by Gram-negative rods (see Table 28-1). Gram-negative bacteria resistant to aminoglycosides (by virtue of a plasmid) produce adenylating, phosphorylating, or acetylating enzymes that destroy the drug.
2. Microorganisms change their permeability to the drug. **Examples:** Tetracyclines accumulate in susceptible bacteria but not in resistant bacteria. Resistance to polymyxins is also associated with a change in permeability to the drugs. Streptococci have a natural permeability barrier to aminoglycosides. This can be partly overcome by the simultaneous presence of a cell wall-active drug such as a penicillin. Resistance to amikacin and to some other aminoglycosides may depend on a lack of permeability to the drugs caused by an outer membrane change that impairs active transport into the cell.
3. Microorganisms develop an altered structural target for the drug (see also 5). **Examples:** Erythromycin-resistant organisms have an altered receptor on the 50S subunit of the ribosome, resulting from methylation of a 23S ribosomal RNA. Resistance to some penicillins and cephalosporins may be a function of the loss or alteration of PBPs. Penicillin resistance in *Streptococcus pneumoniae* and enterococci is attributable to altered PBPs.
4. Microorganisms develop an altered metabolic pathway that bypasses the reaction inhibited by the drug. **Example:** Some sulfonamide-resistant bacteria do not require extracellular PABA but, similar to mammalian cells, can use preformed folic acid.
5. Microorganisms develop an altered enzyme that can still perform its metabolic function but is much less affected by the drug. **Example:** In trimethoprim-resistant bacteria, the dihydrofolic acid reductase is inhibited far less efficiently than in trimethoprim-susceptible bacteria.
6. Microorganisms can develop efflux pumps that transport the antibiotics out of the cell. Many Gram-positive and

especially Gram-negative organisms have developed this mechanism for tetracyclines (common), macrolides, fluoroquinolones, and even β -lactam agents.

ORIGIN OF DRUG RESISTANCE

Nongenetic Origin of Drug Resistance

Active replication of bacteria is required for most antibacterial drug actions. Consequently, microorganisms that are metabolically inactive (nonmultiplying) may be phenotypically resistant to drugs. However, their offspring are fully susceptible. **Example:** *Mycobacteria* often survive in tissues for many years after infection yet are restrained by the host's defenses and do not multiply. Such "persisting" organisms are resistant to treatment and cannot be eradicated by drugs. Yet if they start to multiply (eg, after suppression of cellular immunity in the patient), they are fully susceptible to the same drugs.

Microorganisms may lose the specific target structure for a drug for several generations and thus be resistant. **Example:** Penicillin-susceptible organisms may change to cell wall-deficient L forms during penicillin administration. Lacking cell walls, they are resistant to cell wall-inhibitor drugs (penicillins, cephalosporins) and may remain so for several generations. When these organisms revert to their bacterial parent forms by resuming cell wall production, they are again susceptible to penicillin.

Microorganisms may infect the host at sites where antimicrobials are excluded or are not active. **Examples:** Aminoglycosides such as gentamicin are not effective in treating *Salmonella* enteric fevers because the salmonellae are intracellular and the aminoglycosides do not enter the cells. Similarly, only drugs that enter cells are effective in treating Legionnaires' disease because of the intracellular location of *Legionella pneumophila*.

Genetic Origin of Drug Resistance

Most drug-resistant microbes emerge as a result of genetic change and subsequent selection processes by antimicrobial drugs.

A. Chromosomal Resistance

This develops as a result of spontaneous mutation in a locus that controls susceptibility to a given antimicrobial drug. The presence of the antimicrobial drug serves as a selecting mechanism to suppress susceptible organisms and favor the growth of drug-resistant mutants. Spontaneous mutation occurs with a frequency of 10^{-12} – 10^{-7} and thus is an infrequent cause of the emergence of clinical drug resistance in a given patient. However, chromosomal mutants resistant to rifampin occur with high frequency ($\sim 10^{-7}$ – 10^{-5}). Consequently, treatment of bacterial infections with rifampin as the sole drug often fails. Chromosomal mutants are most commonly resistant by virtue of a change in a structural receptor for a drug. Thus,

the P 12 protein on the 30S subunit of the bacterial ribosome serves as a receptor for streptomycin attachment. Mutation in the gene controlling that structural protein results in streptomycin resistance. Mutation can also result in the loss of PBPs, making such mutants resistant to β -lactam drugs.

B. Extrachromosomal Resistance

Bacteria often contain extrachromosomal genetic elements called plasmids. Their features are described in Chapter 7.

Some plasmids carry genes for resistance to one—and often several—antimicrobial drugs. Plasmid genes for antimicrobial resistance often control the formation of enzymes capable of destroying the antimicrobial drugs. Thus, plasmids determine resistance to penicillins and cephalosporins by carrying genes for the formation of β -. Plasmids code for enzymes that acetylate, adenylate, or phosphorylate various aminoglycosides; for enzymes that determine the active transport of tetracyclines across the cell membrane; and for others.

Genetic material and plasmids can be transferred by transduction, transformation, and conjugation. These processes are discussed in Chapter 7.

CROSS-RESISTANCE

Microorganisms resistant to a certain drug may also be resistant to other drugs that share a mechanism of action. Such relationships exist mainly between agents that are closely related chemically (eg, different aminoglycosides) or that have a similar mode of binding or action (eg, macrolides and lincosamides). In certain classes of drugs, the active nucleus of the chemical is so similar among many congeners (eg, tetracyclines) that extensive cross-resistance is to be expected.

LIMITATION OF DRUG RESISTANCE

Emergence of drug resistance in infections may be minimized in the following ways: (1) by maintaining sufficiently high levels of the drug in the tissues to inhibit both the original population and first-step mutants; (2) by simultaneously administering two drugs that do not give cross-resistance, each of which delays the emergence of mutants resistant to the other drug (eg, rifampin and isoniazid [INH] in the treatment of tuberculosis); and (3) by avoiding exposure of microorganisms to a particularly valuable drug by limiting its use, especially in hospitals.

CLINICAL IMPLICATIONS OF DRUG RESISTANCE

A few examples will illustrate the impact of the emergence of drug-resistant organisms and their selection by the widespread use of antimicrobial drugs.

Gonococci

When sulfonamides were first used in the late 1930s for the treatment of gonorrhea, virtually all isolates of gonococci were susceptible, and most infections were cured. A few years later, most strains had become resistant to sulfonamides, and gonorrhea was rarely curable by these drugs. Most gonococci were still highly susceptible to penicillin. Over the next decades, there was a gradual increase in resistance to penicillin, but large doses of that drug were still curative. In the 1970s, β -lactamase-producing gonococci appeared, first in the Philippines and in West Africa, and then spread to form endemic foci worldwide. Such infections could not be treated effectively by penicillin but were treated with spectinomycin. Resistance to spectinomycin has appeared. Third-generation cephalosporins or quinolones were recommended to treat gonorrhea. However, the emergence of quinolone resistance in some geographic locations has subsequently limited their use, and they are no longer recommended as first-line treatment. Of more concern are the recent observations regarding treatment failures with oral third-generation cephalosporins due to rising MICs among *N. gonorrhoeae*. Parenteral third-generation cephalosporins remain the agents of choice for gonorrhea. However, in cases of apparent relapse, cultures for *N. gonorrhoeae* followed by susceptibility testing are recommended to monitor the trend of emerging cephalosporin resistance.

Meningococci

Until 1962, meningococci were uniformly susceptible to sulfonamides, and these drugs were effective for both prophylaxis and therapy. Subsequently, sulfonamide-resistant meningococci spread widely, and the sulfonamides have now lost their usefulness against meningococcal infections. Penicillins remain effective for therapy, and until recently, rifampin was used for prophylaxis. However, rifampin-resistant meningococci have emerged (as high as 27% of isolates), which may cause invasive infections. Fluoroquinolones have largely replaced rifampin for prophylaxis.

Staphylococci

In 1944, most staphylococci were susceptible to penicillin G, although a few resistant strains had been observed. After massive use of penicillin, 65–85% of staphylococci isolated from hospitals in 1948 were β -lactamase producers and thus resistant to penicillin G. The advent of β -lactamase-resistant penicillins (eg, nafcillin, methicillin, and oxacillin) provided a temporary respite, but infections caused by methicillin-resistant *S. aureus* (MRSA) are common. Presently, penicillin-resistant staphylococci include not only those acquired in hospitals but also 80–90% of those isolated in the community. These organisms also tend to be resistant to other drugs (eg, tetracyclines). Likewise, MRSA are common in both

community-onset infections caused by circulating clones such as USA 300 and in hospital-acquired infections. Health care-associated infections may be caused by either the more susceptible community strains or the typical multidrug-resistant nosocomially acquired clones. Vancomycin has been the major drug used for treatment of MRSA infections, but recovery of isolates with intermediate resistance and the reports of several cases of high-level resistance to vancomycin have spurred the search for newer agents. Some of the newer agents with activity against MRSA include daptomycin; linezolid; quinupristin–dalfopristin; and a novel cephalosporin agent, ceftaroline.

Pneumococci

S. pneumoniae was uniformly susceptible to penicillin G until 1963, when relatively penicillin-resistant strains were found in New Guinea. Penicillin-resistant pneumococci subsequently were found in South Africa, Japan, Spain, and later worldwide. In the United States, approximately 10% of pneumococci are resistant to penicillin G (minimum inhibitory concentrations [MICs] $> 2 \mu\text{g/mL}$), and approximately 18% are intermediate (MICs, $0.1\text{--}1 \mu\text{g/mL}$). The penicillin resistance is attributable to altered PBPs. Penicillin resistance in pneumococci tends to be clonal. Pneumococci also are frequently resistant to trimethoprim–sulfamethoxazole, erythromycin, and tetracycline. Quinolone resistance is also beginning to emerge because of increased usage and is caused by mutations in DNA topoisomerase IV or GyrA or GyrB of DNA gyrase.

Enterococci

The enterococci have intrinsic resistance to multiple antimicrobials, including penicillin G and ampicillin with high MICs, cephalosporins with very high MICs, low-level resistance to aminoglycosides, and resistance to trimethoprim–sulfamethoxazole in vivo. The enterococci also have shown acquired resistance to almost all other antimicrobials as follows: altered PBPs and resistance to β -lactams; high-level resistance to aminoglycosides; and resistance to fluoroquinolones, macrolides, azalides, and tetracyclines. Some enterococci have acquired a plasmid that encodes for β -lactamase that renders them fully resistant to penicillin and ampicillin. Of greatest importance is the development of resistance to vancomycin, which has become common in Europe and North America, although there is geographic variation in the percentages of enterococci that are vancomycin resistant. *Enterococcus faecium* is the species that is most commonly vancomycin resistant. In outbreaks of infections caused by vancomycin-resistant enterococci (VRE), the isolates may be clonal or genetically diverse. Resistance to the streptogramins (quinupristin–dalfopristin) also occurs in enterococci. Increasing resistance to active drugs for VRE treatment such as linezolid is of major concern.

Gram-Negative Enteric Bacteria

Most drug resistance in enteric bacteria is attributable to the widespread transmission of resistance plasmids among different genera. About half the strains of *Shigella* species in many parts of the world are now resistant to multiple drugs.

Salmonellae carried by animals have also developed resistance, particularly to drugs (especially tetracyclines) incorporated into animal feeds. The practice of incorporating drugs into animal feeds causes farm animals to grow more rapidly but is associated with an increase in drug-resistant enteric organisms in the fecal microbiota of farm workers. A concomitant rise in drug-resistant *Salmonella* infections in Britain led to a restriction on antibiotic supplements in animal feeds. Continued use of tetracycline supplements in animal feeds in the United States may contribute to the spread of resistance plasmids and drug-resistant salmonellae. In the late 1990s, a clone of *Salmonella* serotype Typhimurium phage type DT104 emerged and spread globally. This particular strain is resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline.

Plasmids carrying drug resistance genes occur in many Gram-negative bacteria of the normal gut microbiota. The abundant use of antimicrobial drugs—particularly in hospitalized patients—leads to the suppression of drug-susceptible organisms in the gut microbiota and favors the persistence and growth of drug-resistant bacteria, including *Enterobacter*, *Klebsiella*, *Proteus*, *Pseudomonas*, and *Serratia* species and fungi. Such organisms present particularly difficult problems in granulocytopenic and immunocompromised patients. The closed environments of hospitals favor transmission of such resistant organisms through personnel and fomites as well as by direct contact.

Mycobacterium tuberculosis

Primary drug resistance in *M. tuberculosis* occurs in about 10% of isolates and most commonly is to INH or streptomycin. Resistance to rifampin or ethambutol is less common. INH and rifampin are the primary drugs used in most standard treatment regimens; other first-line drugs are pyrazinamide and ethambutol. Resistance to INH and rifampin is considered multiple drug resistance. In the United States, multiple drug resistance of *M. tuberculosis* (MDR-TB) has significantly decreased. Worldwide, the highest rates of MDR-TB have been reported from Eastern European countries, particularly among countries of the former Soviet Union. Poor compliance with drug treatment is a major factor in the development of drug resistance during therapy. Control of MDR-TB is a significant worldwide problem. More recently, emergence of extensively drug-resistant TB (XDR-TB) presents a significant challenge to global tuberculosis control. In addition to resistance to INH and rifampin, these organisms are also resistant to quinolones and injectable drugs, such as aminoglycosides or capreomycin (second-line agents).

ANTIMICROBIAL ACTIVITY IN VITRO

Antimicrobial activity is measured in vitro to determine: (1) the potency of an antibacterial agent in solution, (2) its concentration in body fluids or tissues, and (3) the susceptibility of a given microorganism to known concentrations of the drug.

FACTORS AFFECTING ANTIMICROBIAL ACTIVITY

Among the many factors that affect antimicrobial activity in vitro, the following must be considered because they significantly influence the results of tests.

pH of Environment

Some drugs are more active at an acid pH (eg, nitrofurantoin); others are more active at an alkaline pH (eg, aminoglycosides and sulfonamides).

Components of Medium

Sodium polyanethol sulfonate (in blood culture media) and other anionic detergents inhibit aminoglycosides. PABA in tissue extracts antagonizes sulfonamides. Serum proteins bind penicillins in varying degrees, ranging from 40% for methicillin to 98% for dicloxacillin. Addition of NaCl to the medium enhances the detection of methicillin resistance in *S. aureus*.

Stability of Drug

At incubator temperature, several antimicrobial agents lose their activity. Penicillins are inactivated slowly, but aminoglycosides and ciprofloxacin are quite stable for long periods.

Size of Inoculum

In general, the larger the bacterial inoculum, the lower the apparent “susceptibility” of the organism. Large bacterial populations are less promptly and completely inhibited than small ones. In addition, a resistant mutant is much more likely to emerge in large populations.

Length of Incubation

In many instances, microorganisms are not killed but only inhibited upon short exposure to antimicrobial agents. The longer incubation continues, the greater the chance for resistant mutants to emerge or for the least susceptible members of the antimicrobial population to begin multiplying as the drug deteriorates.

Metabolic Activity of Microorganisms

In general, actively and rapidly growing organisms are more susceptible to drug action than those in the resting phase. Metabolically inactive organisms that survive long exposure to a drug may have offspring that are fully susceptible to the same drug.

MEASUREMENT OF ANTIMICROBIAL ACTIVITY

Determination of the susceptibility of a bacterial pathogen to antimicrobial drugs can be done by one of the two principal methods: dilution or diffusion. It is important to use a standardized method that controls for all the factors that affect antimicrobial activity. In the United States, the tests are performed according to the methods of the Clinical and Laboratory Standards Institute (CLSI). These tests also are discussed in Chapter 47.

Using an appropriate standard test organism and a known sample of drug for comparison, these methods can be used to estimate either the potency of antibiotic in the sample or the susceptibility of the microorganism.

Dilution Method

Graded amounts of antimicrobial substances are incorporated into liquid or solid bacteriologic media. Commonly, twofold (\log_2) dilutions of the antimicrobial agents are used. The media are subsequently inoculated with test bacteria and incubated. The end point is taken as that amount of antimicrobial substance required to inhibit the growth of—or to kill—the test bacteria. Agar dilution susceptibility tests are time consuming, and their use is limited to special circumstances. Broth dilution tests were cumbersome and little used when dilutions had to be made in test tubes; however, the advent of prepared broth dilution panels for many different drugs in manual or automated microdilution plates (eg, Vitek 2 instrument and bioMérieux, Inc.) has greatly enhanced and simplified the method. The advantage of microbroth dilution tests is that they permit a quantitative result to be reported, indicating the amount of a given drug necessary to inhibit (minimum inhibitory concentration, MIC) or kill (minimum bactericidal concentration, MBC) the microorganisms tested.

Diffusion Method

A widely used method in smaller laboratories is the disk diffusion test. A filter paper disk containing a measured quantity of a drug is placed on the surface of a solid medium that has been inoculated on the surface with the test organism. After incubation, the diameter of the clear zone of inhibition surrounding the disk is taken as a measure of the inhibitory power of the drug against the particular test organism. This method is subject to many physical and chemical factors in addition to the simple interaction of drug and organisms

(eg, the nature of the medium and diffusibility, molecular size, and the stability of the drug). Nevertheless, standardization of conditions permits determination of the susceptibility of the organism.

Interpretation of the results of diffusion tests must be based on comparisons between dilution and diffusion methods. Such comparisons have led to the establishment of reference standards. Linear regression lines can express the relationship between log of minimum inhibitory concentration in dilution tests and diameter of inhibition zones in diffusion tests.

Use of a single disk for each antibiotic with careful standardization of the test conditions permits the report of susceptible or resistant for a microorganism by comparing the size of the inhibition zone with a standard of the same drug. Inhibition around a disk containing a certain amount of antimicrobial drug does not imply susceptibility to that same concentration of drug per milliliter of medium, blood, or urine.

An alternative to using disks are plastic strips with a predefined gradient of antibiotic covering a continuous concentration range. Printed on the strip is a scale with values that correspond to the concentration of antibiotic forming the gradient. When placed on an agar dish inoculated with a lawn of test bacteria, the antibiotic diffuses out in a concentration-dependent fashion from the plastic strip and growth is inhibited. Rather than producing a circular zone of inhibition, an ellipse is formed, hence the name of the test, an **Epsilometer test** (or Etest). The MIC value is read from the scale in terms of $\mu\text{g/mL}$ where the ellipse edge intersects the strip.

ANTIMICROBIAL ACTIVITY IN VIVO

Analysis of the activity of antimicrobial agents in vivo is much more complex than the circumstances in vitro. The activity involves not only the drug and organism but also a third factor, the host. Drug–pathogen and host–pathogen relationships are discussed in the following paragraphs. Host–drug relationships (absorption, excretion, distribution, metabolism, and toxicity) are dealt with mainly in pharmacology texts.

DRUG–PATHOGEN RELATIONSHIPS

Several important interactions between drug and pathogen have been discussed in the preceding pages. The following are the additional important in vivo factors.

Environment

In the host, varying environmental influences affect microorganisms located in different tissues and in different parts of the body—in contrast to the test tube or Petri dish, where the

environment is constant for all members of a microbial population. Therefore, the response of the microbial population is much less uniform within the host than in the test tube.

A. State of Metabolic Activity

In the body, the state of metabolic activity is diverse—undoubtedly, many organisms exist at a low level of biosynthetic activity and are thus relatively insusceptible to drug action. These “dormant” microorganisms often survive exposure to high concentrations of drugs and subsequently may produce a clinical relapse of the infection. Bacteria that form biofilms frequently become metabolically less active (or dormant) when embedded in a biofilm matrix thus making them harder to eradicate with antibiotics than planktonic organisms.

B. Distribution of Drug

In the body, the antimicrobial agent is unequally distributed in tissues and fluids. Many drugs do not reach the central nervous system (CNS) or bone effectively. The concentration in urine is often much greater than the concentration in blood or other tissue. The tissue response induced by the microorganism may protect it from the drug. Necrotic tissue or pus may adsorb the drug and thus prevent its contact with bacteria.

C. Location of Organisms

In the body, microorganisms often are located within tissue cells. Drugs enter tissue cells at different rates. Some (eg, tetracyclines) reach about the same concentration inside monocytes as in the extracellular fluid. With others (eg, gentamicin), the drug probably does not enter host cells at all. This is in contrast to the test tube, where microorganisms come into direct contact with the drug.

D. Interfering Substances

The biochemical environment of microorganisms in the body is very complex and results in significant interference with drug action. The drug may be bound by blood and tissue proteins or phospholipids; it may also react with nucleic acids in pus and may be physically adsorbed onto exudates, cells, and necrotic debris. In necrotic tissue, the pH may be highly acid and thus unfavorable for drug action (eg, aminoglycosides).

Concentration

In the body, microorganisms are not exposed to a constant concentration of drug; in the test tube, they are.

A. Absorption

The absorption of drugs from the intestinal tract (if taken by mouth) or from tissues (if injected) is irregular. There is also a continuous excretion as well as inactivation of the

drug. Consequently, the levels of drug in body compartments fluctuate continually, and the microorganisms are exposed to varying concentrations of the antimicrobial agent.

B. Distribution

The distribution of drugs varies greatly with different tissues. Some drugs penetrate certain tissues poorly (eg, CNS, prostate, and bone). Drug concentrations after systemic administration may therefore be inadequate for effective treatment. On surface wounds or mucous membranes such as the conjunctivae, local (topical) application of poorly absorbed drugs permits highly effective local concentrations without toxic side effects. Alternatively, some drugs applied topically on surface wounds are well absorbed. Drug concentrations in urine are often much higher than in blood.

C. Variability of Concentration

It is critical to maintain an effective concentration of a drug where the infecting microorganisms proliferate. This concentration must be maintained for a sufficient length of time to eradicate the microorganisms. Because the drug is administered intermittently and is absorbed and excreted irregularly, the levels constantly fluctuate at the site of infection. To maintain sufficient drug concentrations for a sufficient time, the time–dose relationship must be considered. The larger each individual drug dose, the longer the permissible interval between doses. The smaller the individual dose, the shorter the interval that will ensure adequate drug levels.

D. Postantibiotic Effect

The postantibiotic effect is the delayed regrowth of bacteria after exposure to antimicrobial agents. It is a property of most antimicrobials except that most β -lactams do not show the postantibiotic effect with Gram-negative bacilli. The carbapenems do have a postantibiotic effect with the Gram-negative bacilli. Aminoglycosides and fluoroquinolones have prolonged (up to several hours) in vitro postantibiotic effects against Gram-negative bacilli.

HOST–PATHOGEN RELATIONSHIPS

Host–pathogen relationships may be altered by antimicrobial drugs in several ways.

Alteration of Tissue Response

The inflammatory response of the tissue to infections may be altered if the drug suppresses the multiplication of microorganisms but does not eliminate them from the body. An acute process may in this way be transformed into a chronic one. Conversely, the suppression of inflammatory reactions in tissues by impairment of cell-mediated immunity in recipients of tissue transplants or antineoplastic therapy or by

immunocompromise as a result of disease (eg, AIDS) causes enhanced susceptibility to infection and impaired responsiveness to antimicrobial drugs.

Alteration of Immune Response

If an infection is modified by an antimicrobial drug, the immune response of the host may also be altered. One example illustrates this phenomenon: Pharyngeal infection with β -hemolytic group A streptococci is followed frequently by the development of antistreptococcal antibodies, and if there is a hyperimmune response, the infection may be followed by rheumatic fever. If the infective process can be interrupted early and completely with antimicrobial drugs, the development of an immune response and of rheumatic fever can be prevented (presumably by rapid elimination of the antigen). Drugs and dosages that rapidly eradicate the infecting streptococci (eg, penicillin) are more effective in preventing rheumatic fever than those that merely suppress the microorganisms temporarily (eg, tetracycline).

Alteration of Normal Microbiota

Antimicrobial drugs affect not only the microorganisms causing disease but also susceptible members of the normal microbiota. An imbalance is thus created that in itself may lead to disease. A few examples are of interest.

1. In hospitalized patients who receive antimicrobials, the normal microbiota is suppressed. This creates a partial void that is filled by the organisms most prevalent in the environment, particularly drug-resistant Gram-negative aerobic bacteria (eg, pseudomonads, staphylococci). Such superinfecting organisms subsequently may produce serious drug-resistant infections.
2. In women taking antibiotics by mouth, the normal vaginal microbiota may be suppressed, permitting marked overgrowth of *Candida*. This leads to unpleasant local inflammation (vulvovaginitis) and itching that are difficult to control.
3. In the presence of urinary tract obstruction, the tendency to bladder infection is great. When such urinary tract infection due to a susceptible microorganism (eg, *E. coli*) is treated with an appropriate drug, the organism may be eradicated. However, it often happens that reinfection caused by another drug-resistant Gram-negative bacillus occurs after the drug-susceptible microorganisms are eliminated. A similar process accounts for respiratory tract superinfections in patients given antimicrobials for chronic bronchitis.
4. In persons receiving antimicrobial drugs for several days, parts of the normal intestinal microbiota may be suppressed. Drug-resistant organisms may establish themselves in the bowel in great numbers and may precipitate serious enterocolitis (eg, antibiotic-associated diarrhea caused by *Clostridium difficile*).

CLINICAL USE OF ANTIBIOTICS

SELECTION OF ANTIBIOTICS

The rational selection of antimicrobial drugs depends on the following considerations.

Diagnosis

The “best guess” of a causative organism is based on the following considerations, among others: (1) the site of infection (eg, pneumonia or urinary tract infection), (2) the age of the patient (eg, meningitis: neonatal, young child, adult), (3) the place where the infection was acquired (hospital versus community), (4) mechanical predisposing factors (indwelling vascular catheter, urinary catheter, ventilator, exposure to vector), and (5) predisposing host factors (immunodeficiency, corticosteroids, transplant, cancer chemotherapy).

In most infections, the relationship between causative agent and clinical picture is not constant. It is therefore important to obtain proper specimens for bacteriologic identification of the causative agent. As soon as such specimens have been secured, empiric antibiotic therapy can be started on the basis of the “best guess.” In general, empiric antibiotic therapy consists of a broad spectrum drug that will cover the most likely organisms causing the infection. To assist in making correct, evidence-based decisions on which antibiotic to choose, hospitals and other health care organizations will publish antibiograms, tables of frequently encountered pathogens (> 10 isolates from different patients) with the percentage of isolates seen by the clinical microbiology laboratory which are susceptible to a given antibiotic. Some antibiograms will go further and offer suggestions for treatment regimens based on past successes, cost and what is available in the hospital’s formulary. After the causative agent has been identified, the laboratory will provide a susceptibility profile, and the broad spectrum empiric therapy should then be tailored to a more defined antibiotic regimen with agents of a narrower spectrum.

Susceptibility Tests

Laboratory tests for antibiotic susceptibility are indicated in the following circumstances: (1) when the microorganism recovered is of a type that is often resistant to antimicrobial drugs (eg, Gram-negative enteric bacteria); (2) when an infectious process is likely to be fatal unless treated specifically (eg, meningitis or septicemia); and (3) in certain infections where eradication of the infectious organisms requires the use of drugs that are rapidly bactericidal, not merely bacteriostatic (eg, infective endocarditis). The basic principles of antimicrobial susceptibility testing are presented earlier in this chapter. Additional laboratory aspects of antimicrobial susceptibility testing are discussed in Chapter 47.

DANGERS OF INDISCRIMINATE USE

The indications for administration of antibiotics must sometimes be qualified by the following concerns:

1. Widespread sensitization of the population, with resulting hypersensitivity, anaphylaxis, rashes, fever, blood disorders, cholestatic hepatitis, and perhaps collagen-vascular diseases.
2. Changes in the normal microbiota of the body, with disease resulting from “superinfection” caused by overgrowth of drug-resistant organisms.
3. Masking serious infection without eradicating it (eg, the clinical manifestations of an abscess may be suppressed, while the infectious process continues).
4. Direct drug toxicity (eg, granulocytopenia or thrombocytopenia with cephalosporins and penicillins and renal damage or auditory nerve damage from aminoglycosides).
5. Development of drug resistance in microbial populations, chiefly through the elimination of drug-susceptible microorganisms from antibiotic-saturated environments (eg, hospitals) and their replacement by drug-resistant microorganisms.

ANTIMICROBIAL DRUGS USED IN COMBINATION

Indications

Possible reasons for using two or more antimicrobials simultaneously instead of a single drug are as follows:

1. To give prompt treatment in desperately ill patients suspected of having serious microbial infections. A good guess, usually based on available antibiogram data, about the most probable two or three pathogens, is made, and drugs are aimed at those organisms. Before such treatment is started, it is essential that adequate specimens be obtained for identifying the etiologic agent in the laboratory. Suspected Gram-negative or staphylococcal sepsis in immunocompromised patients and bacterial meningitis in children are the foremost indications in this category.
2. To delay the emergence of microbial mutants resistant to one drug in chronic infections by the use of a second or third non-cross-reacting drug. The most prominent example is treatment for active tuberculosis.
3. To treat mixed infections, particularly those after massive trauma or those involving vascular structures. Each drug is aimed at an important pathogenic microorganism.
4. To achieve bactericidal synergism or to provide bactericidal action (see later discussion). In a few infections, such as enterococcal sepsis, a combination of drugs is more likely to eradicate the infection than either drug used alone. Such synergism is only partially predictable, and a given drug pair may be synergistic for only a single microbial strain. Occasionally, simultaneous use of two

drugs permits significant reduction in dose and thus avoids toxicity but still provides satisfactory antimicrobial action.

Disadvantages

The following disadvantages of using antimicrobial drugs in combinations must always be considered:

1. The physician may believe that because several drugs are already being given, everything possible has been done for the patient, leading to relaxation of the effort to establish a specific diagnosis. It may also give a false sense of security.
2. The more drugs that are administered, the greater the chance for drug reactions to occur or for the patient to become sensitized to drugs.
3. The cost is unnecessarily high.
4. Antimicrobial combinations usually accomplish no more than an effective single drug.
5. Very rarely, one drug may antagonize a second drug given simultaneously (see later).

Mechanisms

When two antimicrobial agents act simultaneously on a homogeneous microbial population, the effect may be one of the following: (1) indifference (ie, the combined action is no greater than that of the more effective agent when used alone), (2) additive (ie, the combined action is equivalent to the sum of the actions of each drug when used alone), (3) synergism (ie, the combined action is significantly greater than the sum of both effects), or (4) antagonism (ie, the combined action is less than that of the more effective agent when used alone). All these effects may be observed in vitro (particularly in terms of bactericidal rate) and in vivo.

The effects that can be achieved with combinations of antimicrobial drugs vary with different combinations and are specific for each strain of microorganism. Thus, no combination is uniformly synergistic.

Combined therapy should not be used indiscriminately; every effort should be made to use the single antibiotic of choice. In resistant infections, detailed laboratory study can at times define synergistic drug combinations that may be essential to eradicate the microorganisms.

Antimicrobial synergism can occur in several types of situations.

1. Two drugs may sequentially block a microbial metabolic pathway. Sulfonamides inhibit the use of extracellular PABA by some microbes for the synthesis of folic acid. Trimethoprim or pyrimethamine inhibits the next metabolic step, the reduction of dihydro- to tetrahydrofolic acid. The simultaneous use of a sulfonamide plus trimethoprim is effective in some bacterial (shigellosis, salmonellosis,

Serratia species) and some other infections (pneumocystosis, malaria). Pyrimethamine plus a sulfonamide or clindamycin is used in toxoplasmosis.

2. A drug such as a cell wall inhibitor (a penicillin or cephalosporin) may enhance the entry of an aminoglycoside into bacteria and thus produce synergistic effects. Penicillins enhance the uptake of gentamicin or streptomycin by enterococci. Thus, ampicillin plus gentamicin may be essential for the eradication of *Enterococcus faecalis*, particularly in endocarditis. Similarly, piperacillin plus tobramycin may be synergistic against some strains of *Pseudomonas* species.
3. One drug may affect the cell membrane and facilitate the entry of the second drug. The combined effect may then be greater than the sum of its parts. For example, amphotericin has been synergistic with flucytosine against certain fungi (eg, *Cryptococcus* and *Candida* species).
4. One drug may prevent the inactivation of a second drug by microbial enzymes. Thus, inhibitors of β -lactamase (eg, clavulanic acid, sulbactam, and tazobactam) can protect amoxicillin, piperacillin, and other β -lactam agents from inactivation by β -lactamases. In such circumstances, a form of synergism takes place.

Antimicrobial antagonism is sharply limited by time-dose relationships and is therefore a rare event in clinical antimicrobial therapy. Antagonism resulting in higher morbidity and mortality rates has been most clearly demonstrated in bacterial meningitis. It occurred when a bacteriostatic drug (which inhibited protein synthesis in bacteria) such as chloramphenicol or tetracycline was given with a bactericidal drug such as a penicillin or an aminoglycoside. Antagonism occurred mainly if the bacteriostatic drug reached the site of infection before the bactericidal drug, if the killing of bacteria was essential for cure, and if only minimal effective doses of either drug in the pair were present. Another example is combining β -lactam drugs in treatment of *P. aeruginosa* infections (eg, imipenem and piperacillin because imipenem is a potent β -lactamase inducer and the β -lactamase breaks down the less stable piperacillin).

ANTIMICROBIAL CHEMOPROPHYLAXIS

Anti-infective chemoprophylaxis implies the administration of antimicrobial drugs to prevent infection. In a broader sense, it also includes the use of antimicrobial drugs soon after the acquisition of pathogenic microorganisms (eg, after compound fracture) but before the development of signs of infection.

Useful chemoprophylaxis is limited to the action of a specific drug on a specific organism. An effort to prevent all types of microorganisms in the environment from establishing themselves only selects the most drug-resistant organisms as the cause of a subsequent infection. In all proposed uses of prophylactic antimicrobials, the risk of the patient's

acquiring an infection must be weighed against the toxicity, cost, inconvenience, and enhanced risk of superinfection resulting from the prophylactic drug.

Prophylaxis in Persons of Normal Susceptibility Exposed to a Specific Pathogen

In this category, a specific drug is administered to prevent one specific infection. Particular examples are the injection of benzathine penicillin G intramuscularly once every 3 to 4 weeks to prevent reinfection with group A hemolytic streptococci in rheumatic patients; prevention of meningitis by eradicating the meningococcal carrier state with rifampin or ciprofloxacin; prevention of syphilis by the injection of benzathine penicillin G; prevention of plague pneumonia by oral administration of tetracycline in persons exposed to infectious droplets; prevention of leptospirosis with oral administration of doxycycline in a hyperendemic environment; and prevention of malaria in travelers to endemic areas of the world with various agents such as Malarone.

Early treatment of an asymptomatic infection is sometimes called *prophylaxis*. Thus, administration of INH, 6–10 mg/kg/day (maximum, 300 mg/day) orally for 6 months, to an asymptomatic person who converts from a negative to a positive tuberculin skin test result may prevent later clinically active tuberculosis.

Prophylaxis in Persons of Increased Susceptibility

Certain anatomic or functional abnormalities predispose to serious infections. It may be feasible to prevent or abort such infections by giving a specific drug for short periods. Some important examples are listed here.

A. Heart Disease

Persons with heart valve abnormalities or with prosthetic heart valves are unusually susceptible to implantation of microorganisms circulating in the bloodstream. Thus, infective endocarditis can sometimes be prevented if the proper drug can be used during periods of bacteremia. Large numbers of viridans streptococci are pushed into the circulation during dental procedures and operations on the mouth or throat. At such times, the increased risk warrants the use of a prophylactic antimicrobial drug aimed at viridans streptococci. For example, amoxicillin taken orally before the procedure and 2 hours later can be effective. Persons allergic to penicillin can take a macrolide or clindamycin orally. Recommendations for prophylaxis following non-dental procedures vary depending upon the type of valvular abnormality. For example, prophylaxis is no longer recommended following gastrointestinal or genitourinary procedures in patients with rheumatic valvular disease but may still be indicated in patients with congenital heart disease or those patients

with prosthetic material. The reader is referred to the latest American Heart Association guidelines (www.heart.org) for the most current recommendations.

B. Respiratory Tract Disease

Trimethoprim–sulfamethoxazole orally or pentamidine by aerosol is used for prophylaxis for pneumocystis pneumonia in AIDS patients.

C. Recurrent Urinary Tract Infection

For certain women who are subject to frequently recurring urinary tract infections, the oral intake either daily or three times weekly of nitrofurantoin or trimethoprim–sulfamethoxazole can markedly reduce the frequency of symptomatic recurrences over long periods.

Certain women tend to develop symptoms of cystitis after sexual intercourse. The ingestion of a single dose of antimicrobial drug (eg, nitrofurantoin or trimethoprim–sulfamethoxazole) can prevent postcoital cystitis by early inhibition of growth of bacteria moved from the introitus into the proximal urethra or bladder during intercourse.

D. Opportunistic Infections in Severe Granulocytopenia

Immunocompromised patients receiving organ transplants or antineoplastic chemotherapy often develop profound leukopenia. When the neutrophil count falls below 1000/ μ L, they become unusually susceptible to opportunistic infections, most often Gram-negative sepsis. Such persons are sometimes given a fluoroquinolone, a cephalosporin, or a drug combination (eg, vancomycin, gentamicin, and cephalosporin) directed at the most prevalent opportunists at the earliest sign—or even without clinical evidence—of infection. This is continued for several days until the granulocyte count rises again. Several studies suggest that there is benefit from empiric therapy. Two clinical cases—liver and bone marrow transplants—presented in Chapter 48 illustrate the infections that occur in these patients and the antimicrobials used for prophylaxis and treatment.

Prophylaxis in Surgery

A major portion of all antimicrobial drugs used in hospitals is used on surgical services with the stated intent of prophylaxis.

Several general features of surgical prophylaxis merit consideration:

1. The benefit of prophylactic antimicrobial agents for clean surgery has been established.
2. The type of antimicrobial agent that is chosen depends upon several factors: type of surgery and the knowledge of the endogenous microbiota; types of pathogens causing wound infections and their resistance patterns in a particular institution; patient allergies; penetration of the agent at the surgical site; cost and other considerations.

- 3. Cephalosporins, most commonly cefazolin, are the preferred agents.
- 4. The goal with administration of prophylactic agents is to ensure adequate tissue levels of the drug during the entire operative procedure. This may require redosing during long procedures (see list of recommendations for agents and dosing schedules in Bratzler et al).
- 5. The initial dose of systemic prophylactic antibiotic should be given within 60 minutes of the incision or within 120 minutes if vancomycin or a fluoroquinolone is used.
- 6. Prolonged administration of antimicrobial drugs tends to alter the normal microbiota of organ systems, suppressing the susceptible microorganisms and favoring the implantation of drug-resistant ones. Thus, antimicrobial prophylaxis should usually continue for no more than 24 hours after the procedure and ideally should be given only intraoperatively.
- 7. Systemic levels of antimicrobial drugs usually do not prevent wound infection, pneumonia, or urinary tract infection if physiologic abnormalities or foreign bodies are present.

Topical antimicrobials for prophylaxis (eg, intravenous catheter site, closed urinary drainage, within a surgical wound, and acrylic bone cement) have limited usefulness.

Studies have demonstrated increased morbidity and mortality with *S. aureus* postsurgical wound infections, particularly if the infection is caused by MRSA. Many hospitals perform presurgical nares surveillance screening for MRSA using either culture or nucleic acid amplification. Patients who are found to be colonized are treated with mupirocin ointment to the nares for 3–5 days along with chlorhexidine for bathing in an attempt to eliminate colonization before the procedure. Some investigators advocate the addition of vancomycin to a cephalosporin for intraoperative prophylaxis in patients known to be MRSA carriers.

Disinfectants

Disinfectants and antiseptics differ from systemically active antimicrobials in that they possess little selective toxicity. They are toxic not only for microbial pathogens but for host cells as well. Therefore, they can be used only to inactivate microorganisms in the inanimate environment or, to a limited extent, on skin surfaces. They cannot be administered systemically.

The antimicrobial action of disinfectants is determined by concentration, time, and temperature, and the evaluation of their effect may be complex. A few examples of disinfectants that are used in medicine or public health are listed in Table 28-2.

ANTIMICROBIAL DRUGS FOR SYSTEMIC ADMINISTRATION

Refer to Table 28-3 for a list of infecting organisms and their respective primary and alternative drug choices.

TABLE 28-2 Chemical Disinfectants, Antiseptics, and Topical Antimicrobial Agents

Disinfection of the inanimate environment	
Tabletops, instruments	Lysol or other phenolic compound Formaldehyde Aqueous glutaraldehyde Quaternary ammonium compounds
Excreta, bandages, bedpans	Sodium hypochlorite Lysol or other phenolic compound
Air	Propylene glycol mist or aerosol Formaldehyde vapor
Heat-sensitive instruments	Ethylene oxide gas (alkylates nucleic acids; residual gas must be removed by aeration)
Antisepsis of skin or wounds	
	Washing with soap and water Soaps or detergents containing hexachlorophene or trichlorocarbanilide or chlorhexidine Tincture of iodine Ethyl alcohol; isopropyl alcohol Povidone–iodine (water soluble) Peracids (hydrogen peroxide, peracetic acid) Nitrofurazone jelly or solution
Topical drugs to skin or mucous membranes	
In candidiasis	Nystatin cream Candididin ointment Miconazole creams
In burns	Mafenide acetate cream Silver sulfadiazine
In dermatophytosis	Undecylenic acid powder or cream Tolnaftate cream Azole cream
In pyoderma	Bacitracin–neomycin–polymyxin ointment Potassium permanganate
In pediculosis	Malathion or permethrin lotion
In nasal decolonization	Mupirocin
Topical application of drugs to eyes	
For gonorrhea prophylaxis	Erythromycin or tetracycline ointment
For bacterial conjunctivitis	Sulfacetamide ointment Gentamicin or tobramycin ointment Ciprofloxacin ointment Moxifloxacin ophthalmic solution Gatifloxacin solution Levofloxacin solution

PENICILLINS

The penicillins are derived from molds of the genus *Penicillium* (eg, *Penicillium notatum*). The most widely used natural penicillin is penicillin G. From fermentation brews of *Penicillium*, 6-aminopenicillanic acid has been isolated on

TABLE 28-3 Drugs of Choice for Suspected or Proved Microbial Pathogens

Suspected or Proved Etiologic Agent	Drug(s) of First Choice	Alternative Drug(s)
Gram-negative cocci		
<i>Moraxella catarrhalis</i>	Cefuroxime, a fluoroquinolone ^a	TMP-SMZ, ^b cefotaxime, ceftizoxime, cefpodoxime, an erythromycin, ^c doxycycline, ^d azithromycin, amoxicillin–clavulanic acid, clarithromycin
<i>Neisseria gonorrhoeae</i> (gonococcus)	Ceftriaxone plus azithromycin or doxycycline	Cefixime plus azithromycin or doxycycline
<i>Neisseria meningitides</i> (meningococcus)	Penicillin G ^e	Cefotaxime, ceftizoxime, ceftriaxone, chloramphenicol, a fluoroquinolone
Gram-positive cocci		
<i>Streptococcus pneumoniae</i> (pneumococcus) ^g	Penicillin G ^e or V; amoxicillin	An erythromycin, ^c a cephalosporin, ^f vancomycin, TMP-SMZ, ^b clindamycin, azithromycin, clarithromycin, a tetracycline, ^d imipenem, meropenem, doripenem, or ertapenem, quinupristin–dalfopristin, certain fluoroquinolones, ^a linezolid, telavancin
<i>Streptococcus</i> , hemolytic, groups A, B, C, G	Penicillin G ^e or V; ampicillin	An erythromycin, ^c a cephalosporin, ^f vancomycin, clindamycin, azithromycin, clarithromycin, linezolid, daptomycin, telavancin
Viridans streptococci	Penicillin G ^e ± gentamicin	A cephalosporin, ^f vancomycin, telavancin
<i>Staphylococcus</i> , methicillin-resistant	Vancomycin ± gentamicin ± rifampin	TMP-SMZ, ^b doxycycline, a fluoroquinolone, ^a linezolid, quinupristin–dalfopristin, daptomycin, tigecycline, ceftaroline, newer lipoglycopeptides
<i>Staphylococcus</i> , non–penicillinase-producing	Penicillin ^e	A cephalosporin, ^g vancomycin, imipenem, meropenem, a fluoroquinolone, ^a clindamycin
<i>Staphylococcus</i> , penicillinase producing, methicillin susceptible	Penicillinase-resistant penicillin ^h	Vancomycin, a cephalosporin, ^f clindamycin, amoxicillin–clavulanic acid, ampicillin–sulbactam, piperacillin–tazobactam, imipenem, meropenem, a fluoroquinolone, ^a TMP-SMZ, ^b daptomycin, linezolid, telavancin
<i>Enterococcus faecalis</i>	Ampicillin + gentamicin ⁱ	Vancomycin + gentamicin or streptomycin; linezolid, daptomycin, quinupristin–dalfopristin, telavancin, tigecycline, newer lipoglycopeptides
<i>Enterococcus faecium</i> (vancomycin susceptible)	Vancomycin + gentamicin ⁱ	Quinupristin–dalfopristin, linezolid; daptomycin
<i>Enterococcus faecium</i> (vancomycin resistant)	Linezolid or quinupristin–dalfopristin	Daptomycin + aminoglycoside; doxycycline
Gram-negative rods		
<i>Acinetobacter</i> species	Imipenem or meropenem	Doxycycline, TMP-SMZ, ^b doxycycline, aminoglycosides, ^j ceftazidime, ciprofloxacin, ^a piperacillin–tazobactam, sulbactam, colistin, tigecycline
<i>Prevotella</i> , oropharyngeal strains	Clindamycin	Penicillin, ^e metronidazole, ceftiofur, cefotetan
<i>Bacteroides</i> species	Metronidazole	Imipenem, meropenem, ertapenem, ampicillin–sulbactam, piperacillin–tazobactam; amoxicillin–clavulanate
<i>Brucella</i> species	Tetracycline + rifampin ^d	TMP-SMZ ^b ± gentamicin; chloramphenicol ± gentamicin; doxycycline + gentamicin; ciprofloxacin + rifampin
<i>Campylobacter jejuni</i>	Erythromycin ^c or azithromycin	A fluoroquinolone, ^a tetracycline ^d
<i>Enterobacter</i> species	Imipenem, meropenem, or cefepime	Aminoglycoside, ciprofloxacin, piperacillin–tazobactam, TMP-SMZ, ^b aztreonam, third-generation cephalosporin, tigecycline, aztreonam
<i>Escherichia coli</i> (sepsis)	Cefotaxime, ceftriaxone, ceftazidime, cefepime	Imipenem, meropenem, doripenem, or ertapenem, aminoglycosides, ^j a fluoroquinolone, ^a piperacillin–tazobactam
<i>E. coli</i> (uncomplicated urinary infection)	TMP-SMZ, ^b nitrofurantoin	Fluoroquinolones ^a oral cephalosporin, fosfomycin

(Continued)

TABLE 28-3 Drugs of Choice for Suspected or Proved Microbial Pathogens (Continued)

Suspected or Proved Etiologic Agent	Drug(s) of First Choice	Alternative Drug(s)
Gram-negative rods (Continued)		
<i>Haemophilus</i> (meningitis and other serious infections)	Cefotaxime, ceftriaxone	Chloramphenicol, meropenem
<i>Haemophilus</i> (respiratory infections, otitis)	Amoxicillin–clavulanate	Ampicillin, amoxicillin, doxycycline, azithromycin, clarithromycin, cefotaxime, ceftizoxime, ceftriaxone, cefuroxime, cefuroxime axetil, a fluoroquinolone, a tetracycline, TMP-SMZ ^b
<i>Helicobacter pylori</i>	Proton-pump inhibitor + clarithromycin + either amoxicillin or metronidazole	Bismuth subsalicylate + metronidazole + tetracycline HCl + proton-pump inhibitor or H ₂ -blocker
<i>Klebsiella pneumoniae</i>	Cefotaxime, ceftriaxone, cefepime, or ceftazidime	TMP-SMZ, ^b aminoglycoside, ^j imipenem, meropenem, doripenem, or ertapenem, a fluoroquinolone, ^a piperacillin–tazobactam, aztreonam, tigecycline
<i>Legionella</i> species (pneumonia)	Azithromycin, or fluoroquinolones ^a ± rifampin	TMP-SMZ, ^b doxycycline ± rifampin, erythromycin
<i>Proteus mirabilis</i>	Ampicillin	An aminoglycoside, ^j TMP-SMZ, ^b a fluoroquinolone, ^d a cephalosporin, ^f imipenem, meropenem, doripenem, or ertapenem, piperacillin–tazobactam; chloramphenicol
<i>Proteus vulgaris</i> and other species (<i>Morganella</i> , <i>Providencia</i>)	Cefotaxime, ceftriaxone, ceftazidime, cefepime	Aminoglycoside, ^j TMP-SMZ, ^b a fluoroquinolone, ^a imipenem, meropenem, doripenem, ertapenem, aztreonam, piperacillin–tazobactam, ampicillin–sulbactam, amoxicillin–clavulanate
<i>Pseudomonas aeruginosa</i>	Aminoglycoside ^j + an antipseudomonal penicillin ^k	Ceftazidime ± aminoglycoside; imipenem, meropenem, or doripenem ± aminoglycoside; aztreonam ± aminoglycoside; ciprofloxacin; cefepime
<i>Burkholderia pseudomallei</i> (melioidosis)	Ceftazidime, imipenem	Chloramphenicol + tetracycline, ^d TMP-SMZ, ^b amoxicillin–clavulanic acid, meropenem
<i>Burkholderia mallei</i> (glanders)	Streptomycin + a tetracycline ^d	Chloramphenicol + streptomycin; imipenem
<i>Salmonella</i> (bacteremia)	Cefotaxime, ceftriaxone, or a fluoroquinolone ^a	TMP-SMZ, ^b ampicillin, chloramphenicol
<i>Serratia</i> species	Imipenem or meropenem	TMP-SMZ, ^b aminoglycosides, ^j a fluoroquinolone, ^a ceftriaxone, cefotaxime, ceftizoxime, ceftazidime, cefepime
<i>Shigella</i>	A fluoroquinolone ^a	Ampicillin, TMP-SMZ, ^b ceftriaxone, azithromycin
<i>Vibrio</i> (cholera, sepsis)	Azithromycin or erythromycin, Tetracycline ^d	TMP-SMZ, ^b a fluoroquinolone ^a
<i>Yersinia enterocolitica</i>	Tetracycline, TMP-SMX	A fluoroquinolone, an aminoglycoside, cefotaxime
<i>Yersinia pestis</i> (plague)	Streptomycin or gentamicin ± doxycycline	Tetracycline, Chloramphenicol, TMP-SMZ, ^b ciprofloxacin, levofloxacin
Gram-positive rods		
<i>Actinomyces</i>	Penicillin ^e	Doxycycline, ^d clindamycin, erythromycin
<i>Bacillus</i> (including anthrax)	Penicillin ^e (ciprofloxacin or doxycycline for anthrax)	Erythromycin, ^c tetracycline, ^d a fluoroquinolone ^a
<i>Bacillus anthracis</i>	Ciprofloxacin, a tetracycline	Penicillin G, amoxicillin, erythromycin, imipenem, clindamycin, levofloxacin
<i>Bacillus cereus</i> (<i>subtilis</i>)	Vancomycin	Imipenem or meropenem, clindamycin
<i>Clostridium</i> (eg, gas gangrene, tetanus)	Penicillin G, ^e clindamycin	Metronidazole, chloramphenicol, imipenem, meropenem, doripenem, or ertapenem
<i>Corynebacterium diphtheriae</i>	Erythromycin ^c	Penicillin G ^e
<i>Corynebacterium jeikeium</i>	Vancomycin	Penicillin G + gentamicin, erythromycin
<i>Listeria monocytogenes</i>	Ampicillin ± aminoglycoside ^j	TMP-SMZ ^b

(Continued)

TABLE 28-3 Drugs of Choice for Suspected or Proved Microbial Pathogens (Continued)

Suspected or Proved Etiologic Agent	Drug(s) of First Choice	Alternative Drug(s)
Acid-fast rods		
<i>Mycobacterium tuberculosis</i> ¹	INH + rifampin + pyrazinamide ± ethambutol	A fluoroquinolone; cycloserine; capreomycin or kanamycin or amikacin; ethionamide; PAS
<i>Mycobacterium leprae</i>	Dapsone + rifampin ± clofazimine	Minocycline; ofloxacin; clarithromycin
<i>Mycobacterium kansasii</i>	INH + rifampin ± ethambutol	Ethionamide; cycloserine; clarithromycin, or azithromycin
<i>Mycobacterium avium</i> complex	Clarithromycin or azithromycin + one or more of the following: ethambutol ± rifabutin	Amikacin, ciprofloxacin
<i>Mycobacterium fortuitum–cheloniae</i>	Amikacin + clarithromycin	Cefoxitin, sulfonamide, doxycycline, linezolid, rifampin, ethambutol
<i>Nocardia</i>	TMP-SMZ ²	Imipenem or meropenem, sulfisoxazole, linezolid, a tetracycline, amikacin; ceftriaxone; cycloserine
Spirochetes		
<i>Borrelia burgdorferi</i> (Lyme disease)	Doxycycline, amoxicillin, cefuroxime axetil	Ceftriaxone, cefotaxime, penicillin G, azithromycin, clarithromycin
<i>Borrelia recurrentis</i> (relapsing fever)	Doxycycline ⁴ or other tetracycline	Penicillin G, ^e erythromycin
<i>Leptospira</i>	Penicillin G ^e	Doxycycline, ^d ceftriaxone
<i>Treponema pallidum</i> (syphilis)	Penicillin G ^e	Doxycycline, ceftriaxone
<i>Treponema pertenue</i> (yaws)	Penicillin G ^e	Doxycycline ^d
Mycoplasmas	Erythromycin ^c or doxycycline; clarithromycin; azithromycin	A fluoroquinolone ^a
Chlamydiae		
<i>Chlamydia psittaci</i>	A tetracycline	Chloramphenicol
<i>Chlamydia trachomatis</i> (urethritis or pelvic inflammatory disease)	Doxycycline or azithromycin	Levofloxacin; erythromycin; amoxicillin
<i>C. trachomatis</i> (LGV)	Doxycycline	Erythromycin
<i>Chlamydia pneumoniae</i>	A tetracycline, erythromycin, ^c clarithromycin, azithromycin	A fluoroquinolone ^{a,m}
Rickettsiae	Doxycycline	Chloramphenicol, a fluoroquinolone ^a

INH, isoniazid; PAS, para-aminosalicylic acid; TMP-SMZ, trimethoprim–sulfamethoxazole.

^aThe fluoroquinolones include ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin, and others (see text). Gemifloxacin, levofloxacin, and moxifloxacin have the best activity against Gram-positive organisms, including penicillin-resistant *S. pneumoniae* and methicillin-susceptible *S. aureus*. Activity against enterococci and *S. epidermidis* is variable. Ciprofloxacin has the best activity against *P. aeruginosa*.

^bTMP-SMZ is a mixture of 1 part trimethoprim and 5 parts sulfamethoxazole.

^cErythromycin estolate is best absorbed orally but carries the highest risk of hepatitis; erythromycin stearate and erythromycin ethylsuccinate are also available.

^dAll tetracyclines have similar activity against most microorganisms. Minocycline (and its derivative, tigecycline) and doxycycline have increased activity against *S. aureus*. The dosage is determined by rates of absorption and excretion of various preparations. These drugs are not recommended for pregnant women or children younger than 8 years old.

^ePenicillin G is preferred for parenteral injection; penicillin V for oral administration—to be used only in treating infections caused by highly susceptible organisms.

^fMost intravenous cephalosporins (with the exception of ceftazidime) have good activity against Gram-positive cocci.

^gIntermediate- and high-level resistances to penicillin have been described. Infections caused by strains with intermediate resistance may respond to high doses of penicillin, cefotaxime, or ceftriaxone. Infections caused by highly resistant strains should be treated with vancomycin ± rifampin or linezolid, quinupristin–dalbopristin, or telavancin. Many strains of penicillin-resistant pneumococci are resistant to erythromycin, macrolides, TMP-SMZ, and chloramphenicol.

^hParenteral nafcillin or oxacillin; oral dicloxacillin, cloxacillin, or oxacillin.

ⁱAddition of gentamicin indicated only for severe enterococcal infections (eg, endocarditis, meningitis).

^jAminoglycosides—gentamicin, tobramycin, amikacin, netilmicin—should be chosen on the basis of local patterns of susceptibility.

^kAntipseudomonal penicillins: piperacillin.

^lResistance may be a problem, and susceptibility testing should be done.

^mCiprofloxacin has inferior antichlamydial activity compared with newer fluoroquinolones.

a large scale. This makes it possible to synthesize an almost unlimited variety of penicillin compounds by coupling the free amino group of the penicillanic acid to free carboxyl groups of different radicals.

All penicillins share the same basic structure (see 6-aminopenicillanic acid in Figure 28-1). A thiazolidine ring is attached to a β -lactam ring that carries a free amino group. The acidic radicals attached to the amino group can be split off by bacterial and other amidases. The structural integrity of the 6-aminopenicillanic acid nucleus is essential to the biologic activity of the compounds. If the β -lactam ring is enzymatically cleaved by β -lactamases (penicillinases), the

resulting product, penicilloic acid, is devoid of antibacterial activity. However, it carries an antigenic determinant of the penicillins and acts as a sensitizing hapten when attached to carrier proteins.

The different side chains attached to the aminopenicillanic acid determine the essential pharmacologic properties of the resulting drugs. The clinically important penicillins fall into five principal groups: (1) highest activity against Gram-positive organisms, spirochetes, and some others, natural penicillins are susceptible to hydrolysis by β -lactamases and are acid labile (eg, penicillin G); (2) relative resistance to β -lactamases but lower activity against Gram-positive

6-Aminopenicillanic acid

The following structures can each be substituted at the R to produce a new penicillin.

Penicillin G (benzylpenicillin):

High activity against Gram-positive bacteria.
Low activity against Gram-negative bacteria.
Acid-labile. Destroyed by β -lactamase.
60% protein-bound.

Oxacillin (no Cl atoms); cloxacillin (one Cl in structure); dicloxacillin (2 Cls in structure); flucloxacillin (one Cl and one F in structure) (isoxazolyl penicillins):

Similar to methicillin in β -lactamase resistance, but acid-stable. Can be taken orally. Highly protein-bound (95–98%).

Nafcillin (ethoxynaphthamido penicillin):

Similar to isoxazolyl penicillins. Less strongly protein-bound (90%). Can be given by mouth or by vein. Resistant to staphylococcal β -lactamase.

Ampicillin (alpha-aminobenzylpenicillin):

Similar to penicillin G (destroyed by β -lactamase) but acid-stable and more active against Gram-negative bacteria. Carbenicillin has $-\text{COONa}$ instead of $-\text{NH}_2$ group.

Ticarcillin:

Similar to carbenicillin but gives higher blood levels. Piperacillin, azlocillin, and mezlocillin resemble ticarcillin in action against Gram-negative aerobes.

Amoxicillin:

Similar to ampicillin but better absorbed, gives higher blood levels.

FIGURE 28-1 Structures of some penicillins. R, side chain.

organisms and inactivity against Gram-negative organisms (eg, nafcillin, methicillin, and oxacillin); (3) aminopenicillins have relatively high activity against both Gram-positive and Gram-negative organisms but are destroyed by β -lactamases (eg, ampicillin and amoxicillin); (4) ureidopenicillins possess activity against *Pseudomonas* species and other resistant Gram-negative rods (piperacillin); and (5) carboxypenicillins, which are no longer available in the United States (eg, carbenicillin and ticarcillin). Most penicillins are dispensed as sodium or potassium salts of the free acid. Potassium penicillin G contains about 1.7 mEq of K^+ per million units (2.8 mEq/g). Procaine salts and benzathine salts of penicillin provide repository forms for intramuscular injection. In dry form, penicillins are stable, but solutions rapidly lose their activity and must be prepared fresh for administration.

Antimicrobial Activity

The initial step in penicillin action is binding of the drug to cell receptors. These receptors are PBPs, at least some of which are enzymes involved in transpeptidation reactions. From three to six (or more) PBPs per cell can be present. After penicillin molecules have attached to the receptors, peptidoglycan synthesis is inhibited as final transpeptidation is blocked. A final bactericidal event is the removal or inactivation of an inhibitor of autolytic enzymes in the cell wall. This activates the autolytic enzymes and results in cell lysis. Organisms with defective autolysin function are inhibited but not killed by β -lactam drugs, and they are said to be “tolerant.”

Because active cell wall synthesis is required for penicillin action, metabolically inactive microorganisms are not susceptible.

Penicillin G and penicillin V are often measured in units (1 million units = 0.6 g), but the semisynthetic penicillins are measured in grams. Whereas 0.002–1 μ g/mL of penicillin G is lethal for a majority of susceptible Gram-positive organisms, 10–100 times more is required to kill Gram-negative bacteria (except neisseriae).

Resistance

Resistance to penicillins falls into several categories:

1. Production of β -lactamases by staphylococci, Gram-negative bacteria, *Haemophilus* sp., gonococci, and others. More than 50 different β -lactamases are known, most of them produced under the control of bacterial plasmids. Some β -lactamases are inducible by the newer cephalosporins.
2. Lack of PBPs or altered PBPs (eg, pneumococci and enterococci) or inaccessibility of PBPs because of permeability barriers of bacterial outer membranes (more common in Gram-negative bacteria). These are often under chromosomal control.
3. Efflux of drug out of the cell. Genes that encode these pumps are common in Gram-negative bacteria (eg, *OprD* in *P. aeruginosa*).

4. Failure to synthesize peptidoglycans, such as in mycoplasmas, L forms, or metabolically inactive bacteria.

Absorption, Distribution, and Excretion

After intramuscular or intravenous administration, absorption of most penicillins is rapid and complete. After oral administration, absorption is variable and ranges from 15% to 80% depending on acid stability, binding to foods, presence of buffers, and so on. Amoxicillin is well absorbed. After absorption, penicillins are widely distributed in tissues and body fluids.

Special dosage forms have been designed for delayed absorption to yield drug levels for long periods. After a single intramuscular dose of benzathine penicillin, 1.5 g (2.4 million units), serum levels of 0.03 unit/mL are maintained for 10 days and levels of 0.005 unit/mL for 3 weeks. Procaine penicillin given intramuscularly yields therapeutic levels for 24 hours.

In many tissues, penicillin concentrations are similar to those in serum. Lower levels occur in the eyes, the prostate, and the CNS. However, in meningitis, penetration is enhanced, and levels of 0.5–5 μ g/mL occur in the cerebrospinal fluid (CSF) with a daily parenteral dose of 12 g.

Most of the penicillins are rapidly excreted by the kidneys. About 10% of renal excretion is by glomerular filtration and 90% by tubular secretion. The latter can be partially blocked by probenecid to achieve higher systemic and CSF levels. In newborns and in persons with renal failure, penicillin excretion is reduced and systemic levels remain elevated longer. Some penicillins (eg, nafcillin) are eliminated mainly by nonrenal mechanisms.

Clinical Uses

Penicillins are the most widely used antibiotics, particularly in the following areas.

Penicillin G is the drug of choice in most infections caused by streptococci, susceptible pneumococci, meningococci, spirochetes, clostridia, aerobic Gram-positive rods, non-penicillinase-producing staphylococci, and actinomycetes.

Penicillin G is inhibitory for enterococci (*E. faecalis*), but for bactericidal effects (eg, in enterococcal endocarditis), an aminoglycoside must be added. Penicillin G in ordinary doses is excreted into the urine in sufficiently high concentrations to inhibit some Gram-negative organisms unless they produce a large amount of β -lactamases.

Benzathine penicillin G is a salt of very low solubility given intramuscularly for low but prolonged drug levels. A single injection of 1.2 million units (0.7 g) is satisfactory treatment for group A streptococcal pharyngitis and primary syphilis. The same injection once every 3–4 weeks is satisfactory prophylaxis against group A streptococcal reinfection in patients with rheumatic fever.

Infection with β -lactamase-producing staphylococci is the only indication for the use of penicillinase-resistant

penicillins (eg, nafcillin and oxacillin). Cloxacillin or dicloxacillin by mouth can be given for milder staphylococcal infections. Staphylococci resistant to oxacillin and nafcillin have the *mecA* gene and make a low-affinity penicillin-binding protein, 2a (see Table 28-1).

Oral amoxicillin is better absorbed than ampicillin and yields higher levels. Amoxicillin given together with clavulanic acid is active against β -lactamase-producing *H. influenzae*. Piperacillin is more effective against aerobic Gram-negative rods, especially pseudomonads. Piperacillin combined with the β -lactamase inhibitor tazobactam has increased activity against some β -lactamase-producing Gram-negative rods. The piperacillin-tazobactam combination, however, is no more active against *P. aeruginosa* than piperacillin alone.

Side Effects

Penicillins possess less direct toxicity than most of the other antimicrobial drugs. Most serious side effects are caused by hypersensitivity.

All penicillins are cross-sensitizing and cross-reacting. Any material (including milk or cosmetics) containing penicillin may induce sensitization. The responsible antigens are degradation products (eg, penicilloic acid) bound to host protein. Skin tests with penicilloyl-polylysine, with alkaline hydrolysis products, and with undegraded penicillin identify many hypersensitive persons. Among positive reactors to skin tests, the incidence of major immediate allergic reactions is high. Such reactions are associated with cell-bound immunoglobulin E (IgE) antibodies. IgG antibodies to penicillin are common and are not associated with allergic reactions other than rare cases of hemolytic anemia. A history of a penicillin reaction in the past is not reliable, but the drug must be administered with caution to such persons, or a substitute drug should be chosen.

Allergic reactions may occur as typical anaphylactic shock; typical serum sickness-type reactions (urticaria, joint swelling, angioneurotic edema, pruritus, respiratory embarrassment within 7–12 days of penicillin dosage); and as a variety of skin rashes, fever, nephritis, eosinophilia, vasculitis, and so on. The incidence of hypersensitivity to penicillin is negligible in children but may be 1–5% among adults in the United States. Acute anaphylactic life-threatening reactions are very rare (0.5%). Corticosteroids can sometimes suppress allergic manifestations to penicillins.

Very high doses may produce CNS concentrations that are irritating. In patients with renal failure, smaller doses may produce encephalopathy, delirium, and seizures. With such doses, direct cation toxicity (K^+) may also occur. Nafcillin occasionally causes granulocytopenia. Oral penicillins can cause diarrhea. High doses of penicillins may cause a bleeding tendency. Some penicillins have become obsolete because of their enhanced toxicities. Methicillin too frequently causes interstitial nephritis. Carbenicillin too frequently decreases normal platelet aggregation, which can lead to clinically significant bleeding.

7-Aminocephalosporanic acid nucleus. The following structures can each be substituted at R_1 and R_2 to produce the named derivatives.

FIGURE 28-2 Basic structure of the cephalosporins. R, side chain. Various structures can be added at R_1 and R_2 to create the named derivatives.

CEPHALOSPORINS

Some cephalosporium fungi yield antimicrobial substances called cephalosporins. These are β -lactam compounds with a nucleus of 7-aminocephalosporanic acid (Figure 28-2) instead of the penicillins' 6-aminopenicillanic acid. Natural cephalosporins have low antibacterial activity, but the attachment of various R side groups has resulted in the proliferation of an enormous array of drugs with varying pharmacologic properties and antimicrobial spectra and activity. Cephamycins are similar to cephalosporins but are derived from actinomycetes.

The mechanism of action of cephalosporins is analogous to that of penicillins: (1) binding to specific PBPs that serve as drug receptors on bacteria, (2) inhibiting cell wall synthesis by blocking the transpeptidation of peptidoglycan, and (3) activating autolytic enzymes in the cell wall that can produce lesions resulting in bacterial death. Resistance to cephalosporins can be attributed to (1) poor permeation of bacteria by the drug; (2) lack of PBP for a specific drug or alteration of a PBP that decreases affinity for the drug; (3) degradation of drug by β -lactamases, many of which exist; and (4) efflux mechanisms. Certain second- and third-generation cephalosporins can induce special β -lactamases in Gram-negative bacteria. In general, however, cephalosporins tend to be resistant to the β -lactamases produced by staphylococci and common Gram-negative bacteria that hydrolyze and inactivate many penicillins.

For ease of reference, cephalosporins have been arranged into major groups, or "generations," discussed in the paragraphs that follow (Table 28-4). Many cephalosporins are excreted mainly by the kidney and may accumulate and induce toxicity in patients with renal insufficiency.

First-Generation Cephalosporins

The first-generation cephalosporins are very active against Gram-positive cocci—except enterococci and MRSA—and are moderately active against some Gram-negative rods, primarily *E. coli*, *Proteus*, and *Klebsiella*. Anaerobic cocci are often sensitive, but *Bacteroides fragilis* is not.

Cephalexin, cefadroxil, and cephadrine (no longer available in the United States) are absorbed from the gut to a variable extent and can be used to treat uncomplicated urinary tract infections and streptococcal pharyngitis. Other

^aOral agents.

^bThese are cephamycins, and they have enhanced anaerobe activity but otherwise are similar in spectrum to the second-generation cephalosporins.

Modified with permission from Craig WA, Andes DR: Cephalosporins. In Bennett JE, Dolin R, Blaser MJ (editors). *Mandel, Douglas and Bennett's Principles and Practice of Infectious Diseases*, 8th ed, Elsevier, 2015, p. 280. Copyright Elsevier.

first-generation cephalosporins must be injected to give adequate levels in blood and tissues. Cefazolin is a choice for surgical prophylaxis because it gives the highest (90–120 µg/mL) levels with every 8-hour dosing. Cephalothin, cephapirin, and cephradine (these agents are no longer available in the United States) in the same dose give lower levels. None of the first-generation drugs penetrate the CNS, and they are not drugs of first choice for any infection.

Second-Generation Cephalosporins

The second-generation cephalosporins are a heterogeneous group. All are active against organisms covered by first-generation drugs but have extended coverage against Gram-negative rods, including *Klebsiella* and *Proteus* but not *P. aeruginosa*.

Some (not all) oral second-generation cephalosporins can be used to treat sinusitis and otitis media caused by *H. influenzae*, including β-lactamase-producing strains. Cefoxitin and cefotetan used in mixed anaerobic infections, including peritonitis and pelvic inflammatory disease. However, resistance to these agents among the *B. fragilis* group has increased substantially.

Third-Generation Cephalosporins

The third-generation cephalosporins have decreased activity against Gram-positive cocci except for *S. pneumoniae*; enterococci are intrinsically resistant to cephalosporins and often produce superinfections during their use. Most third-generation cephalosporins are active against methicillin-susceptible staphylococci, but ceftazidime is only weakly active. A major advantage of third-generation drugs is their enhanced activity against Gram-negative rods. When second-generation drugs tend to fail against *P. aeruginosa*, ceftazidime or cefoperazone may succeed. Thus, third-generation drugs are very useful in the management of hospital-acquired Gram-negative bacteremia. Ceftazidime may also be lifesaving in severe melioidosis (*Burkholderia pseudomallei* infection).

Another important distinguishing feature of several third-generation drugs—except cefoperazone—is the ability to reach the CNS and to appear in the spinal fluid in sufficient concentrations to treat meningitis caused by Gram-negative rods. Cefotaxime, ceftriaxone, or ceftizoxime given intravenously may be used for management of Gram-negative bacterial sepsis and meningitis.

Fourth-Generation Cephalosporins

Cefepime is the only fourth-generation cephalosporin now in clinical use in the United States. It has enhanced activity against *Enterobacter* and *Citrobacter* species that are resistant to third-generation cephalosporins. Cefepime has activity comparable to that of ceftazidime against *P. aeruginosa*. The activity against streptococci and methicillin-susceptible staphylococci is greater than that of ceftazidime and comparable with that of the other third-generation compounds. Cefpirome is a fourth-generation cephalosporin available outside of the United States.

Several new agents have recently been approved in the United States. Cefditoren is an oral third-generation cephalosporin with excellent activity against many Gram-positive and Gram-negative species. This agent has bactericidal activity and stability against many β-lactamase enzymes. Cefditoren is the most potent orally administered cephalosporin against *S. pneumoniae*. Two agents—ceftaroline and ceftobiprole—have activity against MRSA. Ceftaroline has enhanced anti-Gram-positive activity, including MRSA, ampicillin-susceptible *E. faecalis*, and penicillin-nonsusceptible pneumococci. It is indicated for the treatment of acute bacterial skin and skin structure infections as well as community-acquired pneumonia. There are anecdotal reports of its successful use

in more serious infections such as bacterial infections caused by MRSA. Ceftobiprole has a spectrum of activity similar to that of other cephalosporins but, in addition, is active against MRSA, ampicillin-susceptible *E. faecalis*, and penicillin-resistant *S. pneumoniae*. It is not currently marketed in the United States. These latter two agents have been referred to as “MRSA-active cephalosporins.” However, it is important to note that these agents do not have good activity against *P. aeruginosa*, *Acinetobacter* species, or ESBL-producing Enterobacteriaceae.

Because of the growing numbers of β -lactamases, some cephalosporins are being combined with β -lactamase inhibitors. The most promising ones to date include ceftazidime and ceftaroline combined with avibactam, a novel β -lactamase inhibitor. These combinations have a spectrum of activity similar to the carbapenems. A novel cephalosporin with enhanced activity against *P. aeruginosa* ceftolozane has been combined with tazobactam in clinical trials to treat AmpC-hyperproducing *Enterobacter* and KPCs. Both ceftazidime-avibactam and ceftolozane-tazobactam have been cleared by the FDA.

Adverse Effects of Cephalosporins

The cephalosporins are sensitizing and can elicit a variety of hypersensitivity reactions, including anaphylaxis, fever, skin rashes, nephritis, granulocytopenia, and hemolytic anemia. The frequency of cross-allergy between cephalosporins and penicillins is approximately 5%. Patients with minor penicillin allergy can often tolerate cephalosporins, but those with a history of anaphylaxis cannot.

Thrombophlebitis can occur after intravenous injection. Hypoprothrombinemia is frequent with cephalosporins that have a methylthiotetrazole group (eg, cefamandole, cefmetazole, cefotetan, and cefoperazone). Oral administration of vitamin K (10 mg twice weekly) can prevent this complication. These same drugs can also cause severe disulfiram reactions, and use of alcohol must be avoided.

Gastrointestinal side effects, mostly diarrhea, occur infrequently. Reversible biliary pseudolithiasis has been described with high-dose ceftriaxone administration.

Because many second-, third-, and fourth-generation cephalosporins have little activity against Gram-positive organisms, particularly enterococci, superinfection with these organisms and with fungi may occur.

OTHER β -LACTAM DRUGS

Monobactams

Monobactams have a monocyclic β -lactam ring and are resistant to β -lactamases. They are active against Gram-negative rods primarily through binding to PBP3 but not against Gram-positive bacteria or anaerobes. The first such drug to become available was aztreonam, which resembles aminoglycosides in activity and is given intravenously or

intramuscularly every 8 or 12 hours. Patients with IgE-mediated penicillin allergy can tolerate it without reaction, and apart from skin rashes and minor aminotransferase disturbances, no major toxicity has been reported. Superinfections with staphylococci and enterococci can occur.

Carbapenems

These drugs are structurally related to the β -lactam antibiotics. Imipenem, the first drug of this type, has good activity against many Gram-negative rods, Gram-positive organisms, and anaerobes. It is resistant to β -lactamases but is inactivated by dehydropeptidases in renal tubules. Consequently, it is administered together with a peptidase inhibitor, cilastatin.

Imipenem penetrates body tissues and fluids well, including CSF. The drug is given intravenously every 6–8 hours and in reduced dosage in renal insufficiency. Imipenem may be indicated for infections caused by organisms resistant to other drugs. Compared to the other carbapenems, imipenem may have better Gram-positive coverage. Meropenem and doripenem have better Gram-negative coverage.

Adverse effects of imipenem include vomiting, diarrhea, skin rashes, and reactions at infusion sites. Excessive levels in patients with renal failure may lead to seizures. Patients who are allergic to penicillins may be allergic to imipenem as well.

Meropenem is similar to imipenem in pharmacology and antimicrobial spectrum of activity. However, it is not inactivated by dipeptidases and is less likely to cause seizures than imipenem.

Ertapenem has a long half-life suitable for once-daily administration. It is useful for treatment of complicated infections not involving hospital pathogens. It has poor activity against *Enterococcus* species and *P. aeruginosa* and other glucose-nonfermenting Gram-negative rods.

Doripenem is the most recent carbapenem to be approved for use in the United States. The sulfamoylaminoethylpyrrolidinylthio group in its side chain at position 2 enhances its activity against glucose-nonfermenting Gram-negative rods. This drug has been reported to have strong affinity for PBPs that are species specific. For example, doripenem has affinity for PBP3 in *P. aeruginosa*. It is reported that doripenem is more active against *P. aeruginosa* than imipenem but equal in activity to meropenem. None of the carbapenems have activity against *Stenotrophomonas maltophilia*.

TETRACYCLINES

The tetracyclines are a group of drugs that differ in physical and pharmacologic characteristics but have virtually identical antimicrobial properties and give complete cross-resistance. All tetracyclines are readily absorbed from the intestinal tract and distributed widely in tissues but penetrate into the CSF poorly (except doxycycline). Some can also be administered intramuscularly or intravenously. They are excreted in stool and into bile and urine at varying rates. With doses of

tetracycline hydrochloride, 2 g/day orally, blood levels reach 8 µg/mL. Minocycline and doxycycline are excreted more slowly and therefore are administered at longer intervals.

The tetracyclines have the basic structure shown below.

Antimicrobial Activity

Tetracyclines are concentrated by susceptible bacteria and inhibit protein synthesis by inhibiting the binding of aminoacyl-tRNA to the 30S unit of bacterial ribosomes. Resistant bacteria fail to concentrate the drug. This resistance is under the control of transmissible plasmids.

The tetracyclines are principally bacteriostatic agents. They inhibit the growth of susceptible Gram-positive and Gram-negative bacteria (inhibited by 0.1–10 µg/mL) and are drugs of choice in infections caused by rickettsiae, *Anaplasma*, *Bartonella*, chlamydiae, and *Mycoplasma pneumoniae*. Tetracyclines are used in cholera to shorten excretion of vibrios. Tetracycline hydrochloride or doxycycline orally for 7 days is effective against chlamydial genital infection. Tetracyclines are sometimes used in combination with streptomycin to treat *Brucella*, *Yersinia*, and *Francisella* infections. Minocycline is often active against *Nocardia* infections and can eradicate the meningococcal carrier state. Low doses of tetracycline for many months are given for acne to suppress both skin bacteria and their lipases, which promote inflammatory changes.

Tetracyclines do not inhibit fungi. They temporarily suppress parts of the normal bowel microbiota, but superinfections may occur, particularly with tetracycline-resistant pseudomonads, staphylococci, and yeasts.

Side Effects

The tetracyclines produce varying degrees of gastrointestinal upset (nausea, vomiting, diarrhea), skin rashes, mucous membrane lesions, and fever in many patients, particularly when administration is prolonged and dosage high. Photosensitivity resulting in a rash in sun-exposed areas is also common. Replacement of bacterial microbiota (see earlier) occurs commonly. Overgrowth of yeasts on anal and vaginal mucous membranes during tetracycline administration leads to inflammation and pruritus. Overgrowth of organisms in the intestine may lead to enterocolitis.

Tetracyclines are deposited in bony structures and teeth, particularly in fetuses and during the first 6 years of life. Discoloration and fluorescence of the teeth occur in newborns if tetracyclines are taken for prolonged periods by pregnant women. Hepatic damage may also occur. Minocycline can cause marked vestibular disturbances.

Bacteriologic Examination

Organisms that are susceptible to tetracycline are also considered susceptible to doxycycline and minocycline. However, resistance to tetracycline cannot be used to predict resistance to the other agents.

GLYCYLCYCLINES

The glycylicyclines are synthetic analogs of the tetracyclines. Only one agent, tigecycline, is currently available for use. Tigecycline is the 9-*tert*-butyl-glycylamido derivative of minocycline. Tigecycline shares the same binding site on the ribosome as the tetracyclines. It binds more avidly to the ribosome, and this stronger binding is likely responsible for the enhanced activity against tetracycline-resistant organisms. Tigecycline is active against a broad spectrum of Gram-positive and Gram-negative pathogens. Compared with the tetracyclines, it is more active against MRSA and *S. epidermidis*, drug-susceptible and drug-resistant *S. pneumoniae*, and enterococci. In terms of the Gram-negative aerobes, in addition to the spectrum of the other tetracyclines, tigecycline has enhanced activity against several Enterobacteriaceae, including *Salmonella* and *Shigella* species, and *Acinetobacter* species. It does not have good activity against *P. aeruginosa*, *S. maltophilia*, or *Burkholderia cepacia*. Tigecycline also has good activity against many anaerobic bacteria, including *B. fragilis*.

Tigecycline is currently available only as a parenteral agent because of poor bioavailability. The drug has extensive and rapid distribution in tissues. Protein binding ranges from 73% to 79%. Tigecycline is not metabolized to pharmacologically active metabolites. The half-life is long, approximately 40 hours. The major route of elimination is via the biliary tract and through the feces; renal clearance is a secondary route of elimination. Currently, tigecycline is approved in the United States for treatment of complicated skin and soft tissue infections, complicated intra-abdominal infections, and community-acquired pneumonia. In 2013, the FDA issued a warning regarding the increased risk of death in patients taking this drug compared to other antimicrobial agents. It is suggested that this drug be reserved for situations where other agents are not available or cannot be used because of resistance.

CHLORAMPHENICOL

Chloramphenicol is a substance produced originally from cultures of *Streptomyces venezuelae* but is now manufactured synthetically.

Crystalline chloramphenicol is a stable compound that is rapidly absorbed from the gastrointestinal tract and widely distributed into tissues and body fluids, including the CNS and CSF; it penetrates cells well. Most of the drug is inactivated in the liver by conjugation with glucuronic acid or by reduction to inactive arylamines. Excretion is mainly in the urine, 90% in an inactive form. Although chloramphenicol is usually administered orally, the succinate can be injected intravenously in similar dosage.

Chloramphenicol is a potent inhibitor of protein synthesis in microorganisms. It blocks the attachment of amino acids to the nascent peptide chain on the 50S unit of ribosomes by interfering with the action of peptidyl transferase. Chloramphenicol is principally bacteriostatic, and its spectrum, dosage, and blood levels are similar to those of the tetracyclines. Chloramphenicol has been used to treat many types of infection (eg, from salmonellae, meningococci, and *H. influenzae*), but it is no longer the drug of choice for any infection.

Chloramphenicol resistance is caused by destruction of the drug by an enzyme (chloramphenicol acetyltransferase) that is under plasmid control.

Chloramphenicol infrequently causes gastrointestinal upsets. However, administration of more than 3 g/day regularly induces disturbances in red blood cell maturation, elevation of serum iron, and anemia. These changes are reversible upon discontinuance of the drug. Very rarely, individuals exhibit an apparent idiosyncrasy to chloramphenicol and develop severe or fatal aplastic anemia that is distinct from the dose-related reversible effect described earlier. For these reasons, the use of chloramphenicol is generally restricted to infections in which it is clearly the most effective drug by laboratory test or experience.

In premature and newborn infants, chloramphenicol can induce collapse ("gray syndrome") because the normal mechanism of detoxification (glucuronide conjugation in the liver) is not yet developed.

MACROLIDES

Erythromycin is obtained from *Streptomyces erythreus* and has the chemical formula $C_{37}H_{67}NO_{13}$. Drugs related to erythromycin are clarithromycin, azithromycin, and others. Macrolides attach to a receptor (a 23S rRNA) on the 50S subunit of the bacterial ribosome. They inhibit protein synthesis by interfering with translocation reactions

and the formation of initiation complexes. Resistance to macrolides results from an alteration (methylation) of the rRNA receptor. This is under the control of a transmissible plasmid. Other mechanisms include inactivating enzymes and active efflux of drug encoded by *mef* and *msr* genes. The activity of erythromycins is greatly enhanced at alkaline pH.

Macrolides in concentrations of 0.1–2 µg/mL are active against Gram-positive bacteria, including pneumococci, streptococci, and corynebacteria. *M. pneumoniae*, *Chlamydia trachomatis*, *L. pneumophila*, and *Campylobacter jejuni* are also susceptible. Resistant variants occur in susceptible microbial populations and tend to emerge during treatment, especially in staphylococcal infections.

Erythromycins may be drugs of choice in infections caused by the organisms listed and are substitutes for penicillins in persons hypersensitive to the latter. Erythromycin stearate, succinate, or estolate orally four times a day yields serum levels of 0.5–2 µg/mL. Other forms are given intravenously.

Undesirable side effects are drug fever, mild gastrointestinal upsets, and cholestatic hepatitis as a hypersensitivity reaction, especially to the estolate. Hepatotoxicity may be increased during pregnancy. Cardiac arrhythmias specifically ventricular tachycardia with QT prolongation has been described with both oral and intravenous erythromycin. Coadministration of CYP3A-inhibitors markedly increases the risk of this occurring. Erythromycin tends to increase the levels of simultaneously administered anticoagulants, cyclosporine, and a variety of other drugs by depressing microsomal enzymes.

Clarithromycin and azithromycin are azalides that are chemically related to erythromycin. Similar to erythromycin, both clarithromycin and azithromycin are active against staphylococci and streptococci. Clarithromycin has enhanced activity against *L. pneumophila*, *Helicobacter pylori*, *Moraxella catarrhalis*, *C. trachomatis*, and *Borrelia burgdorferi*. Azithromycin has enhanced activity against *C. jejuni*, *H. influenzae*, *M. pneumoniae*, *M. catarrhalis*, *N. gonorrhoeae*, and *B. burgdorferi*. Both drugs are active against *Mycobacterium avium* complex, and both drugs inhibit most strains of *Mycobacterium chelonae* and *Mycobacterium fortuitum*. Bacteria resistant to erythromycin are also resistant to clarithromycin and azithromycin. The chemical modifications prevent the metabolism of clarithromycin and azithromycin to inactive forms, and the drugs are given twice daily (clarithromycin) or once daily (azithromycin). Both drugs are associated with a much lower incidence of gastrointestinal side effects than erythromycin.

The ketolides are semisynthetic derivatives of erythromycin. They are more active than the macrolides, particularly against some macrolide-resistant bacteria, and have improved pharmacokinetics. Telithromycin is the agent currently approved for use in the United States. It is administered orally for the treatment of acute upper and lower respiratory tract infections. Its mechanism of action and side-effect

profile are similar to those of the macrolides. Rare reports of severe hepatotoxicity have limited its use in the United States.

CLINDAMYCIN AND LINCOMYCIN

Lincomycin (derived from *Streptomyces lincolnensis*) and clindamycin (a chlorine-substituted derivative) resemble erythromycins in mode of action, antibacterial spectrum, and ribosomal receptor site but are chemically distinct. Clindamycin is active against *Bacteroides* species and other anaerobes, although resistance among the *B. fragilis* group has increased.

The drugs are acid stable and can be given by mouth or intravenously. They are widely distributed in tissues except the CNS. Excretion is mainly through the liver, bile, and urine.

Probably the most important indication for intravenous clindamycin is the treatment of patients with severe anaerobic infections. Successful treatment of staphylococcal infections of bone with lincomycins has been recorded. Clindamycin has been used extensively more recently in the treatment of skin and skin-structure infections caused by community-associated MRSA. Lincomycins should not be used in meningitis. Clindamycin has been prominent as a cause of antibiotic-associated colitis caused by *C. difficile*; however, most antimicrobials have been associated with *C. difficile* colitis.

GLYCOPEPTIDES, LIPOPEPTIDES, LIPOGLYCOPEPTIDES

Vancomycin

Vancomycin is produced by *Streptomyces orientalis*. It is poorly absorbed from the intestine.

Vancomycin is markedly bactericidal for staphylococci, some clostridia, and some bacilli. The drug inhibits early stages in cell wall peptidoglycan synthesis. Drug-resistant

strains do not emerge rapidly. Vancomycin is given intravenously for serious systemic staphylococcal infections, including endocarditis, especially if resistant to nafcillin. For enterococcal sepsis or endocarditis, vancomycin can be effective if combined with an aminoglycoside. Oral vancomycin is indicated in antibiotic-associated pseudomembranous colitis.

The development of vancomycin resistance in enterococci has had a major impact on the treatment of severe multidrug-resistant enterococcal infections. See the section Clinical Implications of Drug Resistance earlier in this chapter and Chapter 14.

S. aureus of intermediate susceptibility to vancomycin in vitro has been isolated from patients in several countries, including the United States. These patients have tended to have complex illnesses that included long-term therapy with vancomycin. In some cases, the infections appeared to have failed vancomycin therapy.

High-level vancomycin resistance in *S. aureus* is of major international concern. The mechanism is the same as or similar to the transposon-mediated vancomycin resistance in enterococci (acquisition of *vanA* genes [see Chapter 14]). Such isolates have been cultured from several patients and may occur in more patients in the future.

Undesirable side effects are thrombophlebitis, skin rashes, nerve deafness, leukopenia, and perhaps kidney damage when used in combination with an aminoglycoside.

Teicoplanin

Teicoplanin has a structure similar to that of vancomycin. It is active against staphylococci (including methicillin-resistant strains), streptococci, enterococci, and many other Gram-positive bacteria. Enterococci with *VanA* resistance to vancomycin are also resistant to teicoplanin, but enterococci with *VanB* vancomycin resistance are susceptible to teicoplanin. The drug has a long half-life and is administered once a day. Adverse effects include localized irritation at injection sites, hypersensitivity, and the potential for ototoxicity and nephrotoxicity. Teicoplanin is available in Europe and Asia, but not in the United States.

Daptomycin

Daptomycin is a naturally occurring cyclic lipopeptide produced by *Streptomyces roseosporus*. Structurally, it has a 10-member amino acid ring, a 10-carbon decanoic acid attached to a terminal L-tryptophan. It is bactericidal by causing depolarization of the bacterial membrane in a calcium-dependent manner. It is available in a parenteral form administered once daily. It is highly protein bound and excreted in the kidneys as parent drug. Dosage adjustment is required in patients with creatinine clearance below 30 mL/min.

A major adverse effect of daptomycin is reversible myopathy. This side effect appears to occur more often with the higher dose (6 mg/kg/day) used to treat *S. aureus* bacteremia. Weekly monitoring of creatine phosphokinase (CPK)

is recommended, and the drug should be discontinued when levels reach five times normal. Currently, daptomycin is approved for use in the United States for treatment of skin and soft tissue infections caused by susceptible and resistant Gram-positive cocci and for *S. aureus* bacteremia. In vitro synergy is seen when daptomycin is combined with gentamicin and combination therapy with other agents such as rifampin and β -lactam antibiotics is being explored.

Telavancin, Dalbavancin, and Oritavancin

Some newer lipoglycopeptides with hydrophobic substituents have dual mechanisms of action. The lipophilic side chain among this group of agents prolongs the half-life. They inhibit the transglycosylation of cell wall peptidoglycan synthesis by forming a complex with the D-alanyl-D-alanine residues, and they also depolarize the bacterial cell membrane. Telavancin, the first agent of this group to get approval in the United States for acute bacterial skin and skin structure infections as well as for the treatment of refractory *S. aureus* nosocomial pneumonia, has a prolonged half-life of 7–9 hours and has good penetration into tissues. It is excreted mainly by the kidneys.

Dalbavancin was recently FDA approved and its half-life of 8.5 days allows for once weekly administration. Its indication is similar to that of telavancin. Oritavancin was approved in the summer of 2014.

These lipoglycopeptides are more active against a broad range of Gram-positive pathogens, including MRSA, vancomycin-intermediate *S. aureus* (VISA), and vancomycin-resistant *S. aureus* (VRSA) strains than vancomycin. They have activity against some Gram-positive organisms that may be resistant to linezolid and daptomycin. Common adverse reactions include taste disturbance, nausea, vomiting, and reversible renal dysfunction.

STREPTOGRAMINS

Quinupristin–dalfopristin is an injectable streptogramin antibiotic consisting of a 30:70 mixture of two semisynthetic derivatives of pristinamycin (a group B streptogramin) and dalfopristin (a group A streptogramin). The two components act synergistically to inhibit a wide spectrum of Gram-positive bacteria, including methicillin-resistant staphylococci, VRE, and penicillin-resistant pneumococci. Quinupristin–dalfopristin is active against some anaerobes and certain Gram-negative bacteria (eg, *N. gonorrhoeae* and *H. influenzae*) but not against Enterobacteriaceae, *P. aeruginosa*, or *Acinetobacter* species. VRE that are resistant also to quinupristin–dalfopristin occur but are uncommon. Major adverse events include phlebitis and arthralgias and myalgias.

OXAZOLIDINONES

Oxazolidinones are a class of synthetic antimicrobials discovered in 1987. Linezolid was the first only commercially

available agent. The antimicrobial spectrum is similar to that of the glycopeptides. The mechanism of action of linezolid is seen early in protein synthesis—interference with translation by inhibiting the formation of N-formylmethionyl-tRNA, the initiation complex at the 30S ribosome. Linezolid is 100% bioavailable and is superior to vancomycin in that it has excellent penetration into respiratory secretions. It also diffuses well into bone, fat, and urine. Linezolid is most frequently used to treat pneumonia, bacteremia, and skin and soft tissue infections caused by glycopeptide-resistant staphylococci and enterococci. Its major side effect is reversible thrombocytopenia. Tedizolid was approved in the summer of 2014 for treatment of acute bacterial skin and skin structure infections caused by susceptible Gram-positive organisms. Tedizolid is available as an intravenous or oral medication administered once daily. Its spectrum of activity is similar to that of linezolid although some linezolid-resistant Gram-positive cocci may be susceptible to tedizolid. Major adverse events are gastrointestinal and include nausea, vomiting, and diarrhea; headache and dizziness may also occur. Thrombocytopenia may be less than what is seen with linezolid.

BACITRACIN

Bacitracin is a polypeptide obtained from a strain (Tracy strain) of *Bacillus subtilis*. It is stable and poorly absorbed from the intestinal tract. Its only use is for topical application to skin, wounds, or mucous membranes.

Bacitracin is mainly bactericidal for Gram-positive bacteria, including penicillin-resistant staphylococci. For topical use, concentrations of 500–2000 units/mL of solution or Gram of ointment are used. In combination with polymyxin B or neomycin, bacitracin is useful for the suppression of mixed bacterial flora in surface lesions.

Bacitracin is toxic for the kidneys, causing proteinuria, hematuria, and nitrogen retention. For this reason, it has no place in systemic therapy. Bacitracin is said not to readily induce hypersensitivity.

POLYMYXINS

The polymyxins are basic cationic polypeptides that are nephrotoxic and neurotoxic. The polymyxins can be bactericidal for many Gram-negative aerobic rods—including pseudomonads and serratae—by binding to cell membranes rich in phosphatidylethanolamine and destroying membrane functions of active transport and permeability barrier. Until recently, because of their toxicity and poor distribution to tissues, the polymyxins were used primarily topically and rarely for systemic infections. Polymyxin E (colistin), available parenterally as colistimethate sodium, has undergone renewed interest and increasing utilization as an alternative agent for treatment of multidrug-resistant *A. baumannii* and *P. aeruginosa* and as salvage therapy for carbapenemase-resistant *Klebsiella* infections. Colistin is bactericidal against

these Gram-negative organisms. When used wisely, observed toxicity has been less than previously described.

AMINOGLYCOSIDES

The aminoglycosides are a group of drugs sharing chemical, antimicrobial, pharmacologic, and toxic characteristics. At present, the group includes streptomycin, neomycin, kanamycin, amikacin, gentamicin, tobramycin, sisomicin, netilmicin, arbekacin, and dibekacin. Sisomicin, arbekacin, and dibekacin are available outside of the United States. All inhibit protein synthesis of bacteria by attaching to and inhibiting the function of the 30S subunit of the bacterial ribosome. Resistance is based on (1) a deficiency of the ribosomal receptor (mutation or methylation of 16S rRNA-binding site), (2) enzymatic destruction of the drug (plasmid-mediated transmissible resistance of clinical importance), or (3) lack of permeability to the drug molecule and lack of active transport into the cell or active efflux pumps. Anaerobic bacteria are often resistant to aminoglycosides because transport through the cell membrane is an energy-requiring process that is oxygen dependent.

All aminoglycosides are more active at alkaline pH than at acid pH. All are potentially ototoxic and nephrotoxic, although to different degrees. All can accumulate in renal failure; therefore, marked dosage adjustments must be made when nitrogen retention occurs. Aminoglycosides are used most widely against Gram-negative enteric bacteria or when there is suspicion of sepsis. In the treatment of bacteremia or endocarditis caused by streptococci, enterococci, or some Gram-negative bacteria, the aminoglycoside is given together with a penicillin that facilitates the entry of the aminoglycoside. Aminoglycosides are selected according to recent susceptibility patterns in a given area or hospitals until susceptibility tests become available on a specific isolate. The clinical usefulness of aminoglycosides has declined with the advent of cephalosporins and quinolones, but they continue to be used in combinations (eg, with cephalosporins for multidrug-resistant Gram-negative bacteremias). All positively charged aminoglycosides are inhibited in blood cultures by sodium polyanetholsulfonate and other polyanionic detergents. Some aminoglycosides (especially streptomycin) are useful as antimycobacterial drugs.

Neomycin and Kanamycin

Kanamycin is a close relative of neomycin with similar activity and complete cross-resistance. Paromomycin is also closely related and is used in amebiasis. These drugs are stable and poorly absorbed from the intestinal tract and other surfaces. Neither drug is used systemically because of ototoxicity and neurotoxicity. Oral doses of both neomycin and kanamycin are used for reduction of intestinal microbiota before large bowel surgery, often in combination with erythromycin. Otherwise, these drugs are mainly limited to topical application on infected surfaces (skin and wounds).

Amikacin

Amikacin is a semisynthetic derivative of kanamycin. It is relatively resistant to several of the enzymes that inactivate gentamicin and tobramycin and therefore can be used against some microorganisms resistant to the latter drugs. However, bacterial resistance caused by impermeability to amikacin is slowly increasing. Many Gram-negative enteric bacteria are inhibited by amikacin in concentrations obtained after injection. CNS infections require intrathecal or intraventricular injection.

Similar to all aminoglycosides, amikacin is nephrotoxic and ototoxic (particularly for the auditory portion of the eighth nerve). Its level should be monitored in patients with renal failure.

Gentamicin

In concentrations of 0.5–5 µg/mL, gentamicin is bactericidal for many Gram-positive and Gram-negative bacteria, including many strains of *Proteus*, *Serratia*, and *Pseudomonas*. Gentamicin is ineffective against streptococci and *Bacteroides* species.

Gentamicin has been used in serious infections caused by Gram-negative bacteria resistant to other drugs. Penicillins may precipitate gentamicin in vitro (and thus must not be mixed), but in vivo, they may facilitate the aminoglycoside entrance into streptococci and Gram-negative rods and result in bactericidal synergism, which is beneficial in sepsis and endocarditis.

Gentamicin is toxic, particularly in the presence of impaired renal function. Gentamicin sulfate, 0.1%, has been used topically in creams or solutions for infected burns or skin lesions. Such creams tend to select gentamicin-resistant bacteria.

Tobramycin

This aminoglycoside closely resembles gentamicin, and there is some cross-resistance between them. Separate susceptibility tests are desirable. Tobramycin has slightly enhanced activity against *P. aeruginosa* when compared with gentamicin. Inhaled formulations of the drug have been used to treat chronic pseudomonas infections in patients with cystic fibrosis.

The pharmacologic properties of tobramycin are virtually identical to those of gentamicin. Most of the drug is excreted by glomerular filtration. In renal failure, the drug dosage must be reduced, and monitoring of blood levels is desirable.

Similar to other aminoglycosides, tobramycin is ototoxic but perhaps less nephrotoxic than gentamicin. It should not be used concurrently with other drugs having similar adverse effects or with diuretics, which tend to enhance aminoglycoside tissue concentrations.

Netilmicin

Netilmicin shares many characteristics with gentamicin and tobramycin, but it is not inactivated by some bacteria that are resistant to the other drugs.

The principal indication for netilmicin may be iatrogenic infections in immunocompromised and severely ill patients at very high risk for Gram-negative bacterial sepsis in the hospital setting.

Netilmicin may be somewhat less ototoxic and nephrotoxic than the other aminoglycosides.

Streptomycin

Streptomycin was the first aminoglycoside—it was discovered in the 1940s as a product of *Streptomyces griseus*. It was studied in great detail and became the prototype of this class of drugs. For this reason, its properties are listed here, although widespread resistance among microorganisms has greatly reduced its clinical usefulness.

After intramuscular injection, streptomycin is rapidly absorbed and widely distributed in tissues except the CNS. Only 5% of the extracellular concentration of streptomycin reaches the interior of the cell. Absorbed streptomycin is excreted by glomerular filtration into the urine. After oral administration, it is poorly absorbed from the gut; most of it is excreted in feces.

Streptomycin may be bactericidal for enterococci (eg, in endocarditis) when combined with a penicillin. In tularemia and plague, it may be given with a tetracycline. In tuberculosis, it is used in combination with other antituberculous drugs (INH, rifampin). Streptomycin should not be used alone to treat any infection.

The therapeutic effectiveness of streptomycin is limited by the rapid emergence of resistant mutants. All microbial strains produce streptomycin-resistant chromosomal mutants with relatively high frequency. Chromosomal mutants have an alteration in the P 12 receptor on the 30S ribosomal subunit. Plasmid-mediated resistance results in enzymatic destruction of the drug. Enterococci resistant to high levels of streptomycin (2000 µg/mL) or gentamicin (500 µg/mL) are resistant to the synergistic actions of these drugs with penicillin.

Fever, skin rashes, and other allergic manifestations may result from hypersensitivity to streptomycin. These occur most frequently upon prolonged contact with the drug, in patients receiving a protracted course of treatment (eg, for tuberculosis), or in personnel preparing and handling the drug. (Personnel preparing solutions should wear gloves.)

Streptomycin is markedly toxic for the vestibular portion of the eighth cranial nerve, causing tinnitus, vertigo, and ataxia, which are often irreversible. It is moderately nephrotoxic.

Spectinomycin

Spectinomycin is an aminocyclitol antibiotic (related to aminoglycosides) for intramuscular administration. Its sole application was in the single-dose treatment of gonorrhea caused by β -lactamase-producing gonococci or occurring in individuals hypersensitive to penicillin. About 5–10% of gonococci are probably resistant. There is usually pain at the injection site, and the patient may have nausea and fever. However, nephrotoxicity and ototoxicity do not occur. This drug is no longer available in the United States.

QUINOLONES

The quinolones are synthetic analogs of nalidixic acid. The mode of action of all quinolones involves inhibition of bacterial DNA synthesis by blocking of DNA gyrase and topoisomerase IV.

The earlier quinolones (nalidixic acid, oxolinic acid, and cinoxacin) did not achieve systemic antibacterial levels after oral intake and thus were useful only as urinary antiseptics (see later discussion). The fluorinated derivatives (eg, ciprofloxacin, norfloxacin, and others; see Figure 28-3) have greater antibacterial activity and low toxicity and achieve clinically useful levels in blood and tissues.

FIGURE 28-3 Structures of some fluoroquinolones.

Antimicrobial Activity

The fluoroquinolones inhibit many types of bacteria, but the spectrum of activity varies from one drug to another. The drugs are highly active against Enterobacteriaceae, including those resistant to third-generation cephalosporins, *Haemophilus* species, neisseriae, chlamydiae, and others. *P. aeruginosa* and legionellae are inhibited by somewhat larger amounts of these drugs. The quinolones vary in their activity against Gram-positive pathogens. Some are active against multidrug-resistant *S. pneumoniae*. They may be active against methicillin-susceptible staphylococci and *E. faecalis*. VRE are usually resistant to the quinolones. Newer fluoroquinolones have increased activity against anaerobic bacteria, allowing them to be used as monotherapy in the treatment of mixed aerobic and anaerobic infections.

The fluoroquinolones may also have activity against *M. tuberculosis*, *M. fortuitum*, *Mycobacterium kansasii*, and sometimes *M. chelonae*.

During fluoroquinolone therapy, the emergence of resistance of pseudomonads, staphylococci, and other pathogens has been observed. At least two major mechanisms of quinolone resistance have been described. Chromosomal resistance develops by mutation and involves either an alteration in the A or B subunit of the target enzyme, DNA gyrase, or mutations in ParC or ParE of topoisomerase IV. A change in outer membrane permeability results in decreased drug accumulation in the bacterium. Finally, plasmid-encoded efflux pumps such as QepA and OqxAB have also been described.

Absorption and Excretion

After oral administration, representative fluoroquinolones are well absorbed and widely distributed in body fluids and tissues to varying degrees, but they do not reach the CNS to a significant extent. The serum half-life is variable (3–8 hours) and can be prolonged in renal failure depending on the specific drug used.

The fluoroquinolones are mainly excreted into the urine via the kidneys, but some of the dose may be metabolized in the liver.

Clinical Uses

Fluoroquinolones are generally effective in urinary tract infections, and several of them benefit patients with prostatitis. Some fluoroquinolones are valuable in the treatment of sexually transmitted diseases caused by *N. gonorrhoeae* and *C. trachomatis* but have no effect on *Treponema pallidum*. Developing resistance, however, precludes their use as first-line treatment for gonorrhea. These drugs can control lower respiratory infections caused by infection with *H. influenzae* (but may not be drugs of choice) and enteritis caused by salmonellae, shigellae, or campylobacters. Fluoroquinolones may be suitable for the treatment of major gynecologic and soft tissue bacterial infections and for osteomyelitis of

Gram-negative origin. Although they can benefit some exacerbations of cystic fibrosis caused by pseudomonads, about one-third of such mucoid organisms are drug resistant. Fluoroquinolones have increased in use for the treatment of mycobacterial infections, including multi-drug-resistant *M. tuberculosis*.

Side Effects

The most prominent adverse effects are nausea, insomnia, headache, and dizziness. Occasionally, other gastrointestinal disturbances, impaired liver function, skin rashes, and superinfections occur, particularly with enterococci and staphylococci. In puppies, prolonged administration of fluoroquinolones produces joint damage, and for that reason, the fluoroquinolones have been seldom prescribed for children but are used as needed in cystic fibrosis patients. The FDA issued a drug safety warning regarding the occurrence of tendinitis in adults resulting in tendon rupture, most frequently of the Achilles tendon. Other more serious adverse events include prolongation of the QTc interval. Disturbances of blood glucose leading to significant hypoglycemia have been reported with newer agents, such as gatifloxacin, causing its discontinued use in the United States. Extensive fluoroquinolone use is believed to be responsible for the global increase in *C. difficile* colitis.

SULFONAMIDES AND TRIMETHOPRIM

The sulfonamides are a group of compounds with the basic formula shown earlier in this chapter. By substituting various R-radicals, a series of compounds is obtained with somewhat varying physical, pharmacologic, and antibacterial properties. The basic mechanism of action of all these compounds is the competitive inhibition of PABA utilization. The simultaneous use of sulfonamides with trimethoprim results in the inhibition of sequential metabolic steps and possible antibacterial synergism.

The sulfonamides are bacteriostatic for some Gram-negative and Gram-positive bacteria, chlamydiae, nocardiae, and protozoa.

The “soluble” sulfonamides (eg, trisulfapyrimidines and sulfisoxazole) are readily absorbed from the intestinal tract after oral administration and are distributed in all tissues and body fluids. Most sulfonamides are excreted rapidly in the urine. Some (eg, sulfamethoxypyridazine) are excreted very slowly and thus tend to be toxic. At present, sulfonamides are particularly useful in the treatment of nocardiosis and first attacks of urinary tract infections caused by coliform bacteria. By contrast, many meningococci, shigellae, group A streptococci, and organisms causing recurrent urinary tract infections are now resistant. A mixture of five parts sulfamethoxazole plus one part trimethoprim is widely used in urinary tract infections, shigellosis, and salmonellosis and infections with other Gram-negative bacterial infections and in pneumocystis pneumonia.

Trimethoprim alone can be effective treatment for uncomplicated urinary tract infections.

Resistance

Microorganisms that do not use extracellular PABA, but similar to mammalian cells, can use preformed folic acid, are resistant to sulfonamides. In some sulfonamide-resistant mutants, the tetrahydropteroic acid synthetase has a much higher affinity for PABA than for sulfonamides. The opposite is true for sulfonamide-susceptible organisms.

Side Effects

The soluble sulfonamides may produce side effects that fall into two categories: allergy and toxicity. Many individuals develop hypersensitivity to sulfonamides after initial contact with these drugs and, on reexposure, may develop fever, hives, skin rashes, and chronic vascular diseases such as polyarteritis nodosa. Toxic effects are manifested by fever, skin rashes, gastrointestinal disturbances, depression of the bone marrow leading to anemia or agranulocytosis, hemolytic anemia, and liver and kidney function abnormalities. Toxicity is especially frequent in patients with AIDS.

OTHER DRUGS WITH SPECIALIZED USES

Trimetrexate

Trimetrexate is a folinic acid analog whose mechanism of action is inhibition of dihydrofolate reductase. The primary use of trimetrexate is in the treatment of *Pneumocystis jirovecii* infections in AIDS patients who are intolerant of or refractory to trimethoprim-sulfamethoxazole and pentamidine isethionate. Because trimetrexate is lipophilic, it passively diffuses across host cell membranes with associated toxicity, primarily bone marrow suppression. Therefore, it must be coadministered with leucovorin calcium, a reduced folate coenzyme, which is transported into and protects the host cells but not *P. jirovecii*.

Dapsone

Dapsone is a sulfone closely related to the sulfonamides. Combined therapy with dapsone and rifampin is often given in the initial therapy of leprosy. Dapsone may also be used to treat pneumocystis pneumonia in AIDS patients. Dapsone is well absorbed from the gastrointestinal tract and is widely distributed in tissues. Side effects are common, including hemolytic anemia, gastrointestinal intolerance, fever, itching, and rashes.

Metronidazole

Metronidazole is an antiprotozoal drug used in treating trichomonas, *Giardia*, and amebic infections. It also has striking effects in anaerobic bacterial infections, such as those caused by *Bacteroides* species, and in bacterial vaginosis. It appears to be effective for the preoperative preparation of the colon and in antibiotic-associated diarrhea caused by toxigenic *C. difficile*. Adverse effects include stomatitis, diarrhea, and nausea.

Urinary Antiseptics

These are drugs with antibacterial effects limited to the urine. They fail to produce significant levels in tissues and thus have no effect on systemic infections. However, they effectively lower bacteria counts in the urine and thus greatly diminish the symptoms of lower urinary tract infection. They are used only in the management of urinary tract infections.

The following are commonly used urinary antiseptics: nitrofurantoin, fosfomycin, nalidixic acid, methenamine mandelate, and methenamine hippurate. Nitrofurantoin is active against many bacteria but may cause gastrointestinal distress. Fosfomycin is a derivative of phosphonic acid and is used primarily in the United States as single-dose therapy for urinary tract infections caused by *E. coli* and other Enterobacteriaceae and enterococci. Nalidixic acid, a quinolone, is effective only in urine, but resistant bacteria may rapidly emerge in the urine. Both methenamine mandelate and methenamine hippurate acidify the urine and liberate formaldehyde there. Other substances that acidify urine (eg, methionine and cranberry juice) may result in bacteriostasis in urine.

Systemically absorbed oral drugs that are excreted in high concentrations in urine are usually preferred in acute urinary tract infections. These include ampicillin, amoxicillin, sulfonamides, quinolones, and others.

DRUGS USED PRIMARILY TO TREAT MYCOBACTERIAL INFECTIONS

Isoniazid

Isoniazid has little effect on most bacteria but is strikingly active against mycobacteria, especially *M. tuberculosis*. Most tubercle bacilli are inhibited and killed in vitro by 0.1–1 µg/mL of INH, but large populations of tubercle bacilli usually contain some INH-resistant organisms. For this reason, the drug is used in combination with other antimycobacterial agents (especially ethambutol or rifampin) to reduce the emergence of resistant tubercle bacilli. INH acts on mycobacteria by inhibiting the synthesis of mycolic acids and also by inhibiting the catalase-peroxidase enzyme. INH and pyridoxine are structural analogs. Patients receiving INH excrete pyridoxine in excessive amounts, which results in peripheral neuritis. This can be prevented by the coadministration of

pyridoxine, which does not interfere with the antituberculous action of INH.

Isoniazid is rapidly and completely absorbed from the gastrointestinal tract and is in part acetylated and in part excreted in the urine. With usual doses, toxic manifestations (eg, hepatitis) are infrequent. INH freely diffuses into tissue fluids, including the CSF.

In converters from negative to positive tuberculin skin tests who have no evidence of disease, INH may be used as prophylaxis.

Ethambutol

Ethambutol is a synthetic water-soluble, heat-stable D isomer of the structure shown below.

Many strains of *M. tuberculosis* and of "atypical" mycobacteria are inhibited in vitro by 1–5 µg/mL of ethambutol.

Ethambutol is well absorbed from the gut. About 20% of the drug is excreted in feces and 50% in urine in unchanged form. Excretion is delayed in renal failure. In meningitis, ethambutol appears in the CSF.

Resistance to ethambutol emerges fairly rapidly among mycobacteria when the drug is used alone. Therefore, ethambutol is always given in combination with other antituberculous drugs.

Ethambutol is usually given as a single oral daily dose. Hypersensitivity to ethambutol occurs infrequently. The most common side effects are visual disturbances, but these are rare at standard dosages: Reduction in visual acuity, optic neuritis, and perhaps retinal damage occur in some patients given high doses for several months. Most of these changes apparently regress when ethambutol is

discontinued. However, periodic visual acuity testing is mandatory during treatment. With low doses, visual disturbances are very rare.

Rifamycins

Rifampin is a semisynthetic derivative of rifamycin, an antibiotic produced by *Streptomyces mediterranei*. It is active in vitro against some Gram-positive and Gram-negative cocci, some enteric bacteria, mycobacteria, chlamydiae, and poxviruses. Although many meningococci and mycobacteria are inhibited by less than 1 µg/mL, highly resistant mutants occur in all microbial populations in a frequency of 10^{-6} – 10^{-5} . The prolonged administration of rifampin as a single drug permits the emergence of these highly resistant mutants. There is no cross-resistance to other antimicrobial drugs.

Rifampin binds strongly to DNA-dependent RNA polymerase and thus inhibits RNA synthesis in bacteria. It blocks a late stage in the assembly of poxviruses. Rifampin penetrates phagocytic cells well and can kill intracellular organisms. Rifampin-resistant mutants exhibit an altered RNA polymerase.

Rifampin is well absorbed after oral administration, widely distributed in tissues, and excreted mainly through the liver and to a lesser extent into the urine.

In tuberculosis, a single oral dose is administered together with ethambutol, INH, or another antituberculous drug to delay the emergence of rifampin-resistant mycobacteria. A similar regimen may apply to non-tuberculous mycobacteria. In short-term treatment schedules for tuberculosis, rifampin is given orally, at first daily (together with INH), and then two or three times weekly for 6–9 months. However, no less than two doses weekly should be given to avoid a "flu syndrome" and anemia. Rifampin used in conjunction with a sulfone is effective in leprosy.

Oral rifampin can eliminate a majority of meningococci from carriers. Unfortunately, some highly resistant meningococcal strains are selected out by this procedure. Close contacts of children with *H. influenzae* infections (eg, in the family or in daycare centers) can receive rifampin as prophylaxis. In urinary tract infections and chronic bronchitis, rifampin is not useful because resistance emerges promptly.

Rifampin imparts a harmless orange color to urine, sweat, and contact lenses. Occasional adverse effects include rashes, thrombocytopenia, light-chain proteinuria, and impairment of liver function. Rifampin induces microsomal enzymes (eg, cytochrome P450).

Rifabutin is a related antimycobacterial drug that is active in the prevention of infection caused by *M. avium* complex.

Rifaximin is a derivative of rifampin that possesses an additional pyridoimidazole ring. It is a nonabsorbed oral agent useful in the treatment of traveler's diarrhea and as salvage therapy for recurrent *C. difficile* disease.

Rifapentine is used for the treatment of tuberculosis and because it is longer acting it is useful in regimens that

are administered once or twice per week. Food increases the absorption.

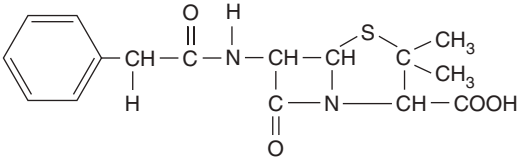

Pyrazinamide

Pyrazinamide is related to nicotinamide. It is readily absorbed from the gastrointestinal tract and widely distributed in tissues. *M. tuberculosis* readily develops resistance to pyrazinamide, but there is no cross-resistance with INH or other antituberculous drugs. The major adverse effects of pyrazinamide are hepatotoxicity (1–5%), nausea, vomiting, hypersensitivity, and hyperuricemia.

Pyrazinamide (PZA)

REVIEW QUESTIONS

- The antimicrobial agent whose structure is shown below is considered the drug of choice to treat infections caused by which one of the following microorganisms?
 
 - Bacteroides fragilis*
 - P. aeruginosa*
 - Herpes simplex virus
 - Streptococcus pyogenes* (group A streptococci)
 - Mycobacterium tuberculosis*
- Resistance of *Staphylococcus aureus* to the drug shown in Question 1 is caused by
 - The action of acetyltransferase
 - The action of β -lactamase
 - Substitution of the D-Ala-D-Ala dipeptide with the D-Ala-D-Lac dipeptide in the cell wall peptidoglycan
 - Decreased permeability of the bacterial cell wall to the drug
 - S. aureus* being an intracellular pathogen
- S. pneumoniae* resistance to the drug shown in Question 1 is caused by
 - The action of acetyltransferase
 - The action of β -lactamase
 - Substitution of the D-Ala-D-Ala dipeptide with D-Ala-D-Lac dipeptide in the cell wall peptidoglycan
 - Decreased permeability of the bacterial cell wall
 - Genetically modified binding proteins in the bacterial cell wall
- All of the following statements about antimicrobial resistance of enterococci are correct *except*
 - Enterococci are resistant to sulfamethoxazole-trimethoprim in vivo.
 - Cephalosporins are not active against enterococci.
 - Resistance to the streptogramins (quinupristin-dalfopristin) has emerged.
 - Vancomycin-resistant enterococci are rare in Europe and in the United States.
 - Vancomycin-resistant enterococci once consistently clonal are now heterogeneous.
- A 20-year-old Asian woman, a recent immigrant to the United States, develops fever and a cough productive of blood-streaked sputum. She has lost 6 kg of body weight in the past 6 weeks. Her chest radiograph shows bilateral upper lobe infiltrates with cavities. Given the history and chest radiography findings, which of the following drug regimens would be the best appropriate initial therapy while awaiting culture results?
 - Isoniazid, rifampin, pyrazinamide, and ethambutol
 - Penicillin G and rifampin
 - Cefotaxime, clindamycin, and trimethoprim-sulfamethoxazole
 - Ampicillin-sulbactam
 - Vancomycin, gentamicin, and clindamycin
- Aminoglycoside antibiotics typically cause which of the following adverse events?
 - They cause aplastic anemia.
 - They cause nonspecific stimulation of B cells.
 - They cause ototoxicity and nephrotoxicity.
 - They cause photosensitivity.
- Which one of the following groups of antimicrobial agents acts on microorganisms by inhibiting protein synthesis?
 - Fluoroquinolones
 - Aminoglycosides
 - Penicillins
 - Glycopeptides (eg, vancomycin)
 - Polymyxins
- There are many bacterial-antimicrobial resistance combinations. Which one of the following is of major international concern?
 - Sulfonamide resistance in *Neisseria meningitidis*
 - Penicillin G resistance in *N. gonorrhoeae*
 - Ampicillin resistance in *H. influenzae*
 - Erythromycin resistance in *S. pyogenes* (group A streptococci)
 - Vancomycin resistance in *S. aureus*
- Which of the following factors is not generally considered when selecting initial antimicrobial therapy for an infection?
 - Age of the patient
 - Anatomic site of the infection (eg, meningitis or urinary tract infection)
 - Whether or not the patient is immunocompromised
 - Whether or not the patient has implanted devices in place (eg, artificial hip joint, artificial heart valve, and urinary catheter)
 - Waiting for culture and susceptibility test results
- All of the following agents have good activity against Gram-positive organisms *except*
 - Daptomycin
 - Vancomycin
 - Aztreonam
 - Quinupristin-dalfopristin
 - Tigecycline

11. Tigecycline, a new glycylcycline antibiotic with good activity against a variety of pathogens, is best used for treatment of which of the following infections?
 - (A) Meningitis
 - (B) Intra-abdominal infections caused by mixed aerobic and anaerobic bacteria
 - (C) Neonatal sepsis
 - (D) Urethritis caused by *C. trachomatis*
 - (E) As monotherapy for bacteremia caused by *A. baumannii*
12. Which of the following carbapenem antibiotics has no activity against *P. aeruginosa*?
 - (A) Imipenem
 - (B) Meropenem
 - (C) Doripenem
 - (D) Ertapenem
13. Which of the following agents would not be expected to demonstrate postantibiotic effect against Gram-negative bacilli?
 - (A) Imipenem
 - (B) Ciprofloxacin
 - (C) Gentamicin
 - (D) Ampicillin
14. All of the following are common mechanisms of resistance to the penicillins *except*
 - (A) Production of β -lactamases
 - (B) Alterations in target receptors (PBPs)
 - (C) Inability to activate autolytic enzymes
 - (D) Failure to synthesize peptidoglycans
 - (E) Methylation of ribosomal RNA
15. The drug of first choice for the treatment of serious anaerobic infections caused by *B. fragilis* is
 - (A) Clindamycin
 - (B) Ampicillin
 - (C) Cefoxitin
 - (D) Metronidazole
 - (E) Amoxicillin-clavulanate

SECTION IV VIROLOGY

General Properties of Viruses

C H A P T E R

29

Viruses are the smallest infectious agents (ranging from about 20 to 300 nm in diameter) and contain only one kind of nucleic acid (RNA or DNA) as their genome. The nucleic acid is encased in a protein shell, which may be surrounded by a lipid-containing membrane. The entire infectious unit is termed a *virion*. Viruses are parasites at the genetic level, replicating only in living cells and are inert in the extracellular environment. The viral nucleic acid contains information necessary to cause the infected host cell to synthesize virus-specific macromolecules required for the production of viral progeny. During the replicative cycle, numerous copies of viral nucleic acid and coat proteins are produced. The coat proteins assemble together to form the capsid, which encases and stabilizes the viral nucleic acid against the extracellular environment and facilitates the attachment and penetration by the virus upon contact with new susceptible cells. The virus infection may have little or no effect on the host cell or may result in cell damage or death.

The spectrum of viruses is rich in diversity. Viruses vary greatly in structure, genome organization and expression, and strategies of replication and transmission. The host range for a given virus may be broad or extremely limited. Viruses are known to infect unicellular organisms, such as mycoplasmas, bacteria, and algae, and all higher plants and animals. General effects of viral infection on the host are considered in Chapter 30.

Much information on virus–host relationships has been obtained from studies on bacteriophages, the viruses that attack bacteria. This subject is discussed in Chapter 7. Properties of individual viruses are discussed in Chapters 31–44.

TERMS AND DEFINITIONS IN VIROLOGY

Schematic diagrams of viruses with icosahedral and helical symmetry are shown in Figure 29-1. Indicated viral components are described below.

Capsid: The protein shell, or coat, that encloses the nucleic acid genome.

Capsomeres: Morphologic units seen in the electron microscope on the surface of icosahedral virus particles. Capsomeres represent clusters of polypeptides, but the morphologic units do not necessarily correspond to the chemically defined structural units.

Defective virus: A virus particle that is functionally deficient in some aspect of replication.

Envelope: A lipid-containing membrane that surrounds some virus particles. It is acquired during viral maturation by a budding process through a cellular membrane (see Figure 29-3). Virus-encoded glycoproteins are exposed on the surface of the envelope. These projections are called **peplomers**.

Nucleocapsid: The protein–nucleic acid complex representing the packaged form of the viral genome. The term is commonly used in cases in which the nucleocapsid is a substructure of a more complex virus particle.

Structural units: The basic protein building blocks of the coat. They are usually a collection of more than one non-identical protein subunit. The structural unit is often referred to as a **protomer**.

Subunit: A single folded viral polypeptide chain.

Virion: The complete virus particle. In some instances (eg, papillomaviruses and picornaviruses), the virion is

FIGURE 29-1 Schematic diagram illustrating the components of the complete virus particle (the virion). **A:** Enveloped virus with icosahedral symmetry. Not all icosahedral viruses have envelopes. **B:** Virus with helical symmetry.

identical with the nucleocapsid. In more complex virions (herpesviruses, orthomyxoviruses), this includes the nucleocapsid plus a surrounding envelope. This structure, the virion, serves to transfer the viral nucleic acid from one cell to another.

EVOLUTIONARY ORIGIN OF VIRUSES

The origin of viruses is not known. There are profound differences among the DNA viruses, the RNA viruses, and viruses that use both DNA and RNA as their genetic material during different stages of their life cycle. It is possible that different types of agents are of different origins. Two theories of viral origin can be summarized as follows:

1. Viruses may be derived from DNA or RNA nucleic acid components of host cells that became able to replicate autonomously and evolve independently. They resemble genes that have acquired the capacity to exist independently of the cell. Some viral sequences are related to portions of cellular genes encoding protein functional domains. It seems likely that at least some viruses evolved in this fashion.
2. Viruses may be degenerate forms of intracellular parasites. There is no evidence that viruses evolved from bacteria, although other obligately intracellular organisms (eg, rickettsiae and chlamydiae) presumably did so. However, poxviruses are so large and complex that they might represent evolutionary products of some cellular ancestor.

CLASSIFICATION OF VIRUSES

Basis of Classification

The following properties have been used as a basis for the classification of viruses. The amount of information available in each category is not the same for all viruses. Genome sequencing is now often performed early in virus identification, and comparisons with databases provide detailed information on the viral classification, predicted protein composition, and taxonomic relatedness to other viruses.

1. Virion morphology, including size, shape, type of symmetry, presence or absence of peplomers, and presence or absence of membranes.
2. Virus genome properties, including type of nucleic acid (DNA or RNA), size of the genome, strandedness (single or double), whether linear or circular, sense (positive, negative, ambisense), segments (number, size), nucleotide sequence, percent GC content, and presence of special features (repetitive elements, isomerization, 5'-terminal cap, 5'-terminal covalently linked protein, 3'-terminal poly(A) tract).
3. Genome organization and replication, including gene order, number and position of open reading frames, strategy of replication (patterns of transcription, translation), and cellular sites (accumulation of proteins, virion assembly, virion release).
4. Virus protein properties, including number, size, amino acid sequence, modifications (glycosylation, phosphorylation, myristoylation), and functional activities of structural and nonstructural proteins (transcriptase, reverse transcriptase, neuraminidase, fusion activities).
5. Antigenic properties, particularly reactions to various antisera.
6. Physicochemical properties of the virion, including molecular mass, buoyant density, pH stability, thermal stability, and susceptibility to physical and chemical agents, especially solubilizing agents and detergents.
7. Biologic properties, including natural host range, mode of transmission, vector relationships, pathogenicity, tissue tropisms, and pathology.

Universal System of Virus Taxonomy

A system has been established in which viruses are separated into major groupings—called **families**—on the basis of virion morphology, genome structure, and strategies of replication. Virus family names have the suffix **-viridae**. Table 29-1 sets forth a convenient scheme used for classification. Diagrams of animal virus families are shown in Figure 29-2.

Within each family, subdivisions called **genera** are usually based on biological, genomic, physicochemical, or serologic differences. Criteria used to define genera vary from family to family. Genus names carry the suffix **-virus**. In several families (Herpesviridae, Paramyxoviridae, Parvoviridae, Poxviridae,

^aDiameter, or diameter × length.
^bds, double stranded; ss, single stranded.
^cThe negative-sense strand has a constant length of 3.2 kb; the other varies in length, leaving a large single-stranded gap.
^dThe genus *Orthopoxvirus*, which includes the better-studied poxviruses (eg, vaccinia), is ether resistant; some of the poxviruses belonging to other genera are ether sensitive.
^eSize of monomer.
^fFilamentous forms vary greatly in length.

Reoviridae, Retroviridae), a larger grouping called **subfamilies** has been defined, reflecting the complexity of relationships among member viruses. Virus orders may be used to group virus families that share common characteristics. For example, order Mononegavirales encompasses the Bornaviridae, Filoviridae, Paramyxoviridae, and Rhabdoviridae families. As

of 2017, the International Committee on Taxonomy of Viruses had organized more than 4400 virus species into 122 families and 735 genera.

Properties of the major families of animal viruses that contain members important in human disease are summarized in Table 29-1. They are discussed briefly below in the

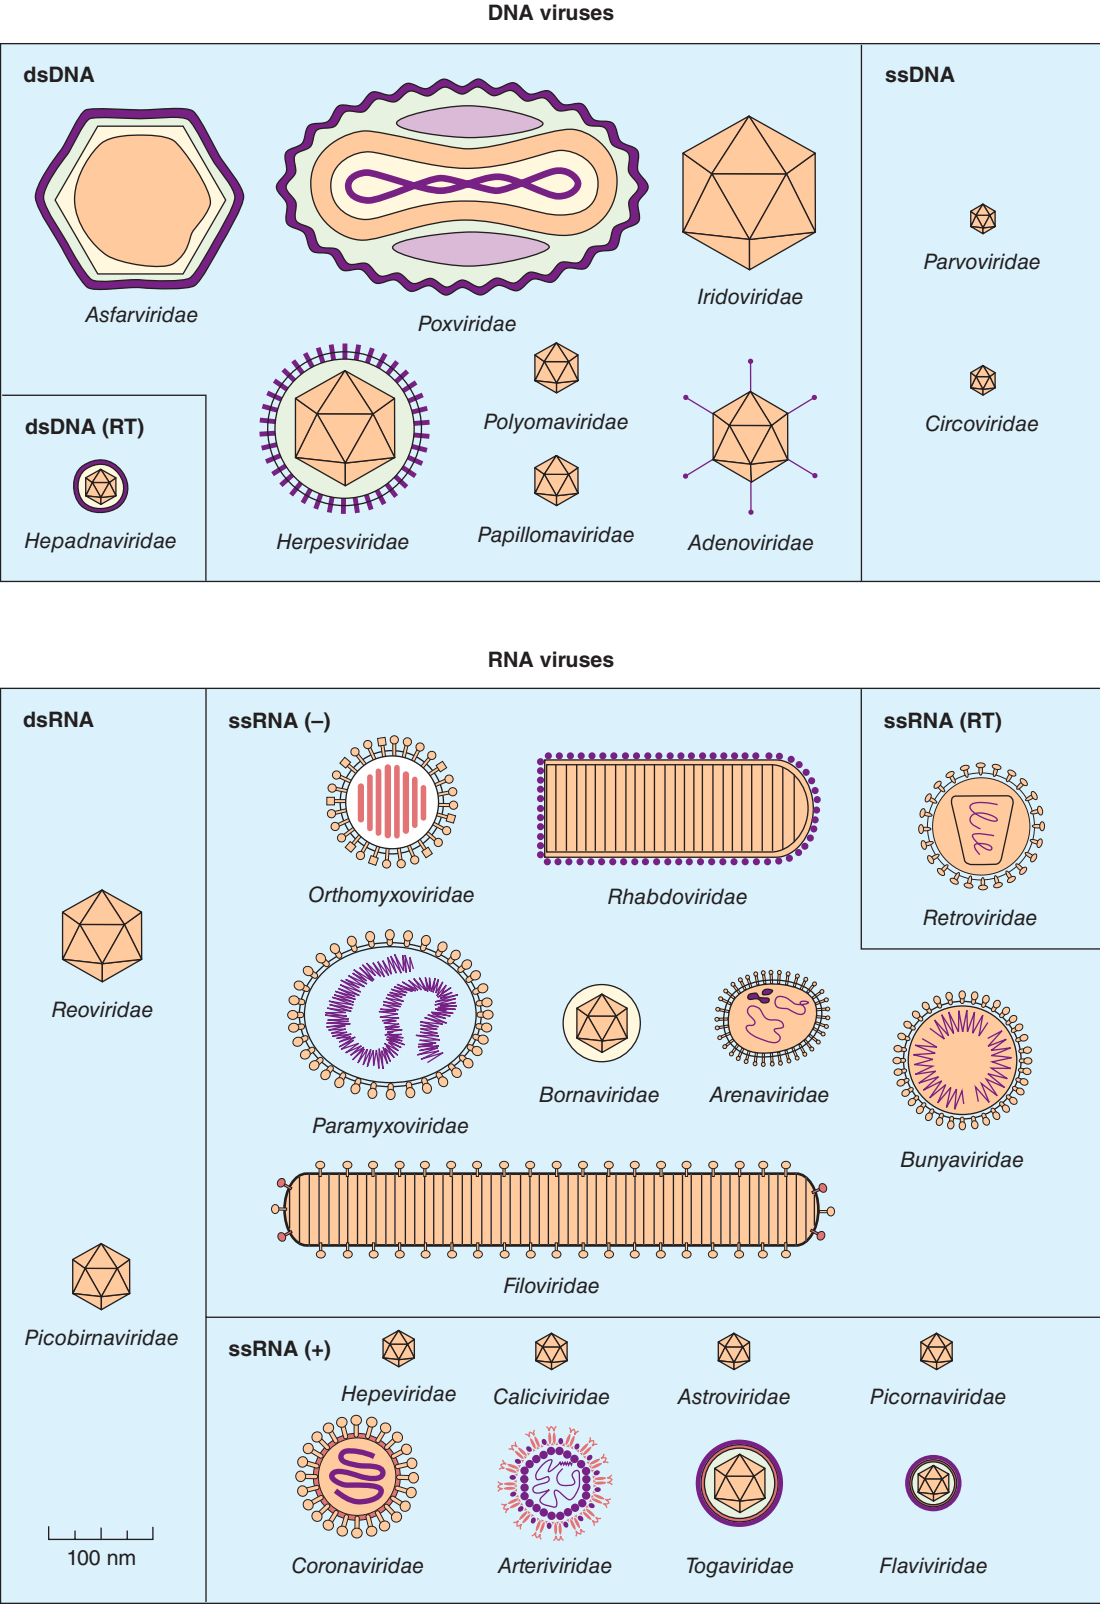

FIGURE 29-2 Shapes and relative sizes of animal viruses of families that infect vertebrates. In some diagrams, certain internal structures of the particles are represented. Only those families that include human pathogens are listed in Table 29-1 and described in the text. (Reproduced with permission from van Regenmortel MHV, Fauquet CM, Bishop DHL, et al [editors]: *Virus Taxonomy: Classification and Nomenclature of Viruses. Seventh Report of the International Committee on Taxonomy of Viruses*. Academic Press, 2000.)

order shown in Table 29-1 and are considered in greater detail in the chapters that follow.

Survey of DNA-Containing Virus Families

A. Parvoviridae

Parvoviruses (from Latin *parvus* meaning small) are very small viruses with a particle size of about 18–26 nm. The particles have cubic symmetry, with 32 capsomeres, but they have no envelope. The genome is linear, single-stranded DNA, averaging 5 kb in size. Replication occurs only in actively dividing cells; capsid assembly takes place in the nucleus of the infected cell. Human parvovirus B19 replicates in immature erythroid cells and causes several adverse consequences, including aplastic crisis, fifth disease, and fetal death (see Chapter 31).

B. Anelloviridae

Anelloviruses (from Latin *anello* meaning ring) are small (~30 nm in diameter), icosahedral virions that lack an envelope. The viral genome is negative sense, circular, single-stranded DNA, 2–4 kb in size. Anelloviruses include the torque teno viruses, and are globally distributed in the human population and many animal species. No specific disease associations have been proven.

C. Polyomaviridae

Polyomaviruses are small (45 nm), nonenveloped, heat-stable, solubilization-resistant viruses exhibiting cubic symmetry, with 72 capsomeres. The name derives from Greek *poly-* (many) and *-oma* (tumor) and refers to the ability of some of these viruses to produce tumors in infected hosts. The genome is circular, double-stranded DNA, about 5 kb in size. These agents have a slow growth cycle, stimulate cell DNA synthesis, and replicate within the nucleus. The most well-known human polyomaviruses are JC virus, the causative agent of progressive multifocal leukoencephalopathy; BK virus, associated with nephropathy in transplant recipients; and Merkel cell virus, found associated with the majority of Merkel cell skin carcinomas. SV40, a primate virus, can also infect humans. Most animal species harbor chronic infections with one or more polyomaviruses (see Chapter 43).

D. Papillomaviridae

Papillomaviruses are similar to polyomaviruses in some respects but with a larger genome (8 kb) and particle size (55–60 nm). The name refers to Latin *papilla* (nipple) and Greek *-oma* (tumor) and describes wart-like lesions produced by these viral infections. There are many types of human papillomaviruses, and certain high-risk types are causative agents of genital cancers in humans (see Chapter 43).

E. Adenoviridae

Adenoviruses (from Latin *adenos* meaning gland) are medium-sized (70–90 nm), nonenveloped viruses exhibiting

cubic symmetry, with fiber spikes protruding from capsomers that aid in host attachment. The genome is linear, double-stranded DNA, 26–48 kb in size. Replication occurs in the nucleus. Complex splicing patterns produce mRNAs. At least 67 types infect humans, especially in mucous membranes, and some types can persist in lymphoid tissue. Adenoviruses can cause acute respiratory diseases, conjunctivitis, and gastroenteritis. Some human adenoviruses can induce tumors in newborn hamsters. Many serotypes infect animals (see Chapters 32 and 43).

F. Hepadnaviridae

Hepadnaviruses (from Latin *hepa* meaning liver) are small (40–48 nm), enveloped viruses containing circular, partially double-stranded DNA molecules that are about 3.2 kbp in size. Replication involves repair of the single-stranded gap in the DNA, transcription of RNA, and reverse transcription of the RNA to make genomic DNA. The virus consists of a 27-nm icosahedral nucleocapsid core within a closely adherent envelope that contains lipid and the viral surface antigen. The surface protein is characteristically overproduced during replication of the virus, which takes place in the liver, and is shed into the bloodstream. Hepadnaviruses such as Hepatitis B virus can cause acute and chronic hepatitis; persistent infections are associated with a high risk of developing liver cancer. Viral types are known that infect mammals and ducks (see Chapter 35).

G. Herpesviridae

Herpesviruses are family of large viruses 150–200 nm in diameter. The name refers to Latin *herpes* (creep), describing the spreading nature of skin lesions caused by these viruses. The nucleocapsid is 100 nm in diameter, with cubic symmetry and 162 capsomeres, surrounded by a lipid-containing envelope. The genome is linear, double-stranded DNA, 120–240 kb in size. Latent infections may last for the life span of the host, usually in ganglial or lymphoblastoid cells. Human herpesviruses include herpes simplex types 1 and 2 (oral and genital lesions), varicella-zoster virus (chickenpox and shingles), cytomegalovirus, Epstein-Barr virus (infectious mononucleosis and association with human neoplasms), human herpesviruses 6 and 7 (T cell lymphotropic), and human herpesvirus 8 (associated with Kaposi sarcoma). Other herpesviruses occur in many animals (see Chapters 33 and 43).

H. Poxviridae

Poxviruses are large brick-shaped or ovoid viruses 220–450 nm long × 140–260 nm wide × 140–260 nm thick. The particle structure is complex, with a lipid-containing envelope. The name derives from Anglo-Saxon *pokkes* meaning pouch, referring to their characteristic vesicular skin lesions. The genome is linear, covalently closed, double-stranded DNA, 130–375 kb in size. Poxvirus particles contain about 100 proteins, including many with enzymatic

activities, such as a DNA-dependent RNA polymerase. Replication occurs entirely within the cell cytoplasm. Some are pathogenic for humans (smallpox, vaccinia, molluscum contagiosum); others that are pathogenic for animals can infect humans (cowpox, monkeypox) (see Chapter 34).

Survey of RNA-Containing Viruses

A. Picornaviridae

Picornaviruses are small (28–30 nm), ether-resistant viruses exhibiting cubic symmetry. The RNA genome is single stranded and positive sense (ie, it can serve as an mRNA) and is 7.2–8.4 kb in size. The groups infecting humans are enteroviruses (polioviruses, coxsackieviruses, echoviruses, parechoviruses, and rhinoviruses [more than 100 serotypes causing common colds]) and hepatovirus (hepatitis A). Rhinoviruses are acid labile and have a high density; other enteroviruses are generally acid stable and have a lower density. Picornaviruses infecting animals include foot-and-mouth disease of cattle and encephalomyocarditis of rodents (see Chapter 36).

B. Astroviridae

Astroviruses are similar in size to picornaviruses (28–30 nm), but particles display a distinctive star-shaped outline on their surfaces. The genome is linear, positive-sense, single-stranded RNA, 6.8–7.0 kb in size. These agents are associated with gastroenteritis in humans and neurological disease in some animals (see Chapter 37).

C. Caliciviridae

Caliciviruses are similar to picornaviruses but slightly larger (27–40 nm). The particles appear to have cup-shaped depressions on their surfaces. The genome is single-stranded, positive-sense RNA, 7.3–8.3 kb in size; the virion has no envelope. Important human pathogens are the noroviruses (eg, Norwalk virus), the cause of epidemic acute gastroenteritis. Other agents infect cats and sea lions as well as primates (see Chapter 37).

D. Hepeviridae

Hepeviruses are similar to caliciviruses. The particles are small (32–34 nm) and ether resistant. The genome is single-stranded, positive-sense RNA, 7.2 kb in size. It lacks a genome-linked protein (VPg). Human hepatitis E virus belongs to this group (see Chapter 35).

E. Picobirnaviridae

Picobirnaviruses are small (35–40 nm) nonenveloped viruses with icosahedral structure. The genome is linear, double-stranded, segmented (bipartite) RNA (two segments), totaling about 4 kb. Human disease associations remain unclear.

F. Reoviridae

Reoviruses are medium-sized (60–80 nm), ether-resistant, nonenveloped viruses having icosahedral symmetry. Particles

have two or three protein shells with channels extending from the surface to the core; short spikes extend from the virion surface. The genome is linear, double-stranded, segmented RNA (10–12 segments), totaling 18–30 kbp in size. Individual RNA segments range in size from 200 to 3000 bp. Replication occurs in the cytoplasm; genome segment reassortment occurs readily. Reoviruses of humans include rotaviruses, which have a distinctive wheel-shaped appearance and cause gastroenteritis. Antigenically similar reoviruses infect many animals. The genus *Coltivirus* includes Colorado tick fever virus of humans. (See Chapter 37.)

G. Arboviruses and Rodent-Borne Viruses

Arboviruses and rodent-borne viruses are ecologic groupings (not a virus family) of viruses with diverse physical and chemical properties. The arboviruses (there are more than 350 of them) have a complex cycle involving arthropods as vectors that transmit the viruses to vertebrate hosts by their bite. Viral replication does not seem to harm the infected arthropod. Arboviruses infect humans, mammals, birds, and reptiles and use mosquitoes and ticks as vectors. Human pathogens include dengue, yellow fever, West Nile fever, and encephalitis viruses. Rodent-borne viruses establish persistent infections in rodents and are transmitted without an arthropod vector. Human diseases include hantavirus infections and Lassa fever. The viruses in these ecologic groupings belong to several virus families, including arenaviridae, bunyaviridae, flaviviridae, reoviridae, rhabdoviridae, and togaviridae (see Chapter 38).

H. Togaviridae

Many arboviruses that are major human pathogens, called **alphaviruses**—as well as rubella virus—belong to this group. They have a lipid-containing envelope and are ether sensitive, and their genome is single-stranded, positive-sense RNA, 9.7–11.8 kb in size. The enveloped virion measures 65–70 nm. The virus particles mature by budding from host cell membranes. An example is eastern equine encephalitis virus. Rubella virus has no arthropod vector (see Chapters 38 and 40).

I. Flaviviridae

Flaviviruses are enveloped viruses, 40–60 nm in diameter, containing single-stranded, positive-sense RNA. Genome sizes vary from 9.5 to 12 kb. Mature virions accumulate within cisternae of the endoplasmic reticulum. This group of arboviruses includes yellow fever virus and dengue viruses. Most members are transmitted by blood-sucking arthropods. Hepatitis C virus is a flavivirus with no known vector (see Chapters 35 and 38).

J. Arenaviridae

Arenaviruses are pleomorphic, enveloped viruses ranging in size from 60 to 300 nm (mean, 110–130 nm). The genome

is segmented, circular, single-stranded RNA that is negative sense and ambisense, 10–14 kb in total size. Replication occurs in the cytoplasm with assembly via budding on the plasma membrane. The virions incorporate host cell ribosomes during maturation, which gives the particles a “sandy” appearance. Most members of this family are unique to tropical America (ie, the Tacaribe complex). Arenaviruses pathogenic for humans cause chronic infections in rodents. Lassa fever virus of Africa is one example. These viruses require maximum containment conditions in the laboratory (see Chapter 38).

K. Coronaviridae

Coronaviruses are enveloped 120- to 160-nm particles containing an unsegmented genome of positive-sense, single-stranded RNA, 27–32 kb in size. Coronaviruses resemble orthomyxoviruses but have petal-shaped surface projections arranged in a fringe, similar to a solar corona. Coronavirus nucleocapsids develop in the cytoplasm and mature by budding into cytoplasmic vesicles. These viruses have narrow host ranges. Classically, human coronaviruses cause mild acute upper respiratory tract illnesses—“colds”—but more recently discovered coronaviruses cause severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS). Toroviruses, which cause gastroenteritis, form a distinct genus. Coronaviruses of animals readily establish persistent infections and include mouse hepatitis virus and avian infectious bronchitis virus (see Chapter 41).

L. Retroviridae

Retroviruses are spherical, enveloped viruses (80–110 nm in diameter) whose genome contains two copies of linear, positive-sense, single-stranded RNA. Each monomer RNA is 7–11 kb in size. Particles contain a helical nucleocapsid within an icosahedral capsid. Replication is unique; the virion contains a reverse transcriptase enzyme that produces a DNA copy of the RNA genome. This DNA becomes circularized and integrated into host chromosomal DNA. The virus is then replicated from the integrated “provirus” DNA copy. Virion assembly occurs by budding from plasma membranes. Hosts remain chronically infected. Retroviruses are widely distributed; there are also endogenous proviruses resulting from ancient infections of germ cells transmitted as inherited genes in most species. Leukemia and sarcoma viruses of animals and humans (see Chapter 43), foamy viruses of primates, and lentiviruses (human immunodeficiency viruses; visna of sheep) (see Chapters 42 and 44) are included in this group. Retroviruses cause acquired immunodeficiency syndrome (AIDS) (see Chapter 44) and make possible the identification of cellular oncogenes (see Chapter 43).

M. Orthomyxoviridae

Orthomyxoviruses are medium-sized, 80- to 120-nm enveloped viruses exhibiting helical symmetry. Particles are either round or filamentous, with surface projections that contain

hemagglutinin or neuraminidase activity. The genome is linear, segmented, negative-sense, single-stranded RNA, totaling 10–13.6 kb in size. Segments range from 890 to 2350 nucleotides each. The virus matures by budding at the cell membrane. Orthomyxoviruses include influenza viruses that infect humans or animals. The segmented nature of the viral genome permits ready genetic reassortment when two influenza viruses infect the same cell, presumably fostering the high rate of natural variation among influenza viruses. Viral reassortment and transmission from other species is thought to explain the emergence of new human pandemic strains of influenza A viruses (see Chapter 39).

N. Bunyaviridae

Bunyaviruses are spherical or pleomorphic, 80- to 120-nm enveloped particles. The genome is made up of a triple-segmented, single-stranded, negative-sense or ambisense RNA, 11–19 kb in overall size. Virion particles contain three circular, helically symmetric nucleocapsids about 2.5 nm in diameter and 200–3000 nm in length. Replication occurs in the cytoplasm, and an envelope is acquired by budding into the Golgi. The majority of these viruses are transmitted to vertebrates by arthropods (arboviruses). Hantaviruses are transmitted not by arthropods but by persistently infected rodents via aerosols of contaminated excreta. They cause hemorrhagic fevers and nephropathy as well as a severe pulmonary syndrome (see Chapter 38).

O. Bornaviridae

Bornaviruses are enveloped, spherical (70–130 nm) viruses. The genome is linear, single-stranded, nonsegmented, negative-sense RNA, 8.5–10.5 kb in size. Unique among nonsegmented, negative-sense RNA viruses, replication and transcription of the viral genome occur in the nucleus. Borna disease virus is neurotropic in animals; a postulated association with neuropsychiatric disorders of humans is unproven (see Chapter 42).

P. Rhabdoviridae

Rhabdoviruses are enveloped virions resembling a bullet, flat at one end and round at the other, measuring about 75×180 nm. The envelope has 10-nm spikes. The genome is linear, single-stranded, nonsegmented, negative-sense RNA, 11–15 kb in size. Particles are formed by budding from the cell membrane. Viruses have broad host ranges. Rabies virus is a member of this group (see Chapter 42).

Q. Paramyxoviridae

Paramyxoviruses are similar to but larger (150–300 nm) than orthomyxoviruses. Particles are pleomorphic. The internal nucleocapsid measures 13–18 nm, and the linear, single-stranded, nonsegmented, negative-sense RNA is 16–20 kb in size. Both the nucleocapsid and the hemagglutinin are formed in the cytoplasm. Those infecting humans include

mumps, measles, parainfluenza, metapneumovirus, and respiratory syncytial viruses. These viruses have narrow host ranges. In contrast to influenza viruses, paramyxoviruses are genetically stable (see Chapter 40).

R. Filoviridae

Filoviruses are enveloped, pleomorphic viruses that may appear very long and threadlike. They typically are 80 nm wide and about 1000 nm long. The envelope contains large peplomers. The genome is linear, negative-sense, single-stranded RNA, 18–19 kb in size. Marburg and Ebola viruses cause severe hemorrhagic fever in Africa. These viruses require maximum containment conditions (Biosafety Level 4) for handling (see Chapter 38).

S. Emerging Viruses

Novel viruses are being discovered with increasing frequency; most belong to existing families but rarely agents are not classifiable. Some of these are associated with human disease, while many affect other species (see Chapter 48).

T. Viroids

Viroids are small infectious agents that cause diseases of plants. Viroids are agents that do not fit the definition of classic viruses. They are nucleic acid molecules without a protein coat. Plant viroids are single-stranded, covalently closed circular RNA molecules consisting of about 360 nucleotides and with a highly base-paired rodlike structure. Viroids replicate by an entirely novel mechanism. Viroid RNA does not encode any protein products; the devastating plant diseases induced by viroids occur by an unknown mechanism. Hepatitis D virus in humans has properties similar to viroids.

U. Prions

Prions are infectious particles composed solely of protein with no detectable nucleic acid. They are highly resistant to inactivation by heat, formaldehyde, and ultraviolet light that inactivate viruses. The infectious prion protein is misfolded and able to change the conformation of the native prion protein which is encoded by a single cellular gene. Prion diseases, called “transmissible spongiform encephalopathies,” include scrapie in sheep, mad cow disease in cattle, and kuru and Creutzfeldt-Jakob disease in humans (see Chapter 42).

PRINCIPLES OF VIRUS STRUCTURE

Viruses come in many shapes and sizes. Structural information is necessary for virus classification and for establishing structure–function relationships of viral proteins. The particular structural features of each virus family are determined by the functions of the virion: morphogenesis and release from infected cells; transmission to new hosts; and attachment, penetration, and uncoating in newly infected cells. Knowledge of virus structure furthers our understanding of

the mechanisms of certain processes such as the interaction of virus particles with cell surface receptors and neutralizing antibodies. It may lead also to the rational design of antiviral drugs capable of blocking viral attachment, uncoating, or assembly in susceptible cells.

Types of Symmetry of Virus Particles

Electron microscopy, cryoelectron microscopy, and x-ray diffraction techniques have made it possible to resolve fine differences in the basic morphology of viruses. The study of viral symmetry by standard electron microscopy requires the use of heavy metal stains (eg, potassium phosphotungstate) to emphasize surface structure. The heavy metal adsorbs to virus particles and brings out the surface structure of viruses by virtue of “negative staining.” The typical level of resolution is 3–4 nm. (The size of a DNA double helix is 2 nm.) However, conventional methods of sample preparation often cause distortions and changes in particle morphology. Cryoelectron microscopy uses virus samples quickly frozen in vitreous ice; fine structural features are preserved, and the use of negative stains is avoided. Three-dimensional structural information can be obtained by the use of computer image processing procedures. Examples of image reconstructions of virus particles are shown in following chapters (see Chapters 32 and 37).

X-ray crystallography can provide atomic resolution information, generally at a level of 0.2–0.3 nm. The specimen must be crystalline, and this has only been achieved with small, nonenveloped viruses. However, it is possible to obtain high-resolution structural data on well-defined substructures prepared from the more complex viruses.

Genetic economy requires that a viral structure be made from many identical molecules of one or a few proteins. Viral architecture can be grouped into three types based on the arrangement of morphologic subunits: (1) cubic symmetry (eg, adenoviruses), (2) helical symmetry (eg, orthomyxoviruses), and (3) complex structures (eg, poxviruses).

A. Cubic Symmetry

All cubic symmetry observed with animal viruses is of the icosahedral pattern, the most efficient arrangement for subunits in a closed shell. The icosahedron has 20 faces (each an equilateral triangle), 12 vertices, and fivefold, threefold, and twofold axes of rotational symmetry. The vertex units have five neighbors (pentavalent), and all others have six (hexavalent).

There are 60 identical subunits on the surface of an icosahedron. To build a particle size adequate to encapsidate viral genomes, viral shells are often composed of multiples of 60 structural units. Larger capsid structures are formed in some cases to accommodate the size of the viral genome with the association of additional protein subunits.

Most viruses that have icosahedral symmetry do not have an icosahedral shape—rather, the physical appearance of the particle is spherical.

The viral nucleic acid is condensed within the isometric particles; virus-encoded core proteins—or, in the case of polyomaviruses and papillomaviruses, cellular histones—are involved in condensation of the nucleic acid into a form suitable for packaging. “Packaging sequences” on viral nucleic acid are involved in assembly into virus particles. There are size constraints on the nucleic acid molecules that can be packaged into a given icosahedral capsid. Icosahedral capsids are formed independently of nucleic acid. Most preparations of isometric viruses contain some “empty” particles devoid of viral nucleic acid. Expression of capsid proteins from cloned genes often results in self-assembly and formation of empty “virus-like particles.” Both DNA and RNA viral groups exhibit examples of cubic symmetry.

B. Helical Symmetry

In cases of helical symmetry, protein subunits are bound in a periodic way to the viral nucleic acid, winding it into a helix. The filamentous viral nucleic acid–protein complex (nucleocapsid) is then coiled inside a lipid-containing envelope. Thus, as is not the case with icosahedral structures, there is a regular, periodic interaction between capsid protein and nucleic acid in viruses with helical symmetry. It is not possible for “empty” helical particles to form.

All known examples of animal viruses with helical symmetry contain RNA genomes and, with the exception of rhabdoviruses, have flexible nucleocapsids that are wound into a ball inside envelopes (see Figures 29-1B, 29-2, and 42-1).

C. Complex Structures

Some virus particles do not exhibit simple cubic or helical symmetry but are more complicated in structure. For example, poxviruses are brick shaped, with ridges on the external surface and a core and lateral bodies inside (see Figures 29-2 and 34-1).

Measuring the Sizes of Viruses

Small size and the ability to pass through filters that hold back bacteria are classic attributes of viruses. However, because some bacteria may be smaller than the largest viruses, filterability is not regarded as a unique feature of viruses.

Direct observation in the electron microscope is the most widely used method for estimating particle size. Viruses can be visualized in preparations from tissue extracts and in ultrathin sections of infected cells. Another method that can be used is sedimentation in the ultracentrifuge. The relationship between the size and shape of a particle and its rate of sedimentation permits determination of particle density.

A. Comparative Measurements

Viruses range in diameter from about 20 to 300 nm (see Table 29-1). For purposes of comparison, the following data should be recalled: (1) *Staphylococcus* species have a diameter of about 1000 nm (1 μm). (2) Bacterial viruses (bacteriophages)

vary in size (10–100 nm). Some are spherical or hexagonal and have short or long tails. (3) Representative protein molecules range in diameter from serum albumin (5 nm) and globulin (7 nm) to certain hemocyanins (23 nm). (4) Eukaryotic ribosomes are about 25–30 nm in size, with mitochondria being much larger (1–10 μm). (5) Red blood cells are about 6–8 μm in diameter. (6) The width of a human hair is about 100 μm.

The relative sizes and morphology of various virus families are shown in Figure 29-2. Particles with a twofold difference in diameter have an eightfold difference in volume. Thus, the mass of a poxvirus is about 1000 times greater than that of the poliovirus particle, and the mass of a small bacterium is 50,000 times greater.

CHEMICAL COMPOSITION OF VIRUSES

Viral Protein

The structural proteins of viruses have several important functions. Their major purpose is to facilitate transfer of the viral nucleic acid from one host cell to another. They serve to protect the viral genome against inactivation by nucleases, participate in the attachment of the virus particle to a susceptible cell, and provide the structural symmetry of the virus particle.

The proteins determine the antigenic characteristics of the virus. The host’s protective immune response is directed against antigenic determinants of proteins or glycoproteins exposed on the surface of the virus particle. Some surface proteins may also exhibit specific activities (eg, influenza virus hemagglutinin agglutinates red blood cells).

Some viruses carry protein enzymes inside the virions. The enzymes are present in very small amounts and are probably not important in the structure of the virus particles; however, they are essential for the initiation of the viral replicative cycle when the virion enters a host cell. Examples include an RNA polymerase carried by viruses with negative-sense RNA genomes (eg, orthomyxoviruses and rhabdoviruses) that is needed to copy the first mRNAs, and reverse transcriptase, an enzyme in retroviruses that makes a DNA copy of the viral RNA, an essential step in replication and transformation. At the extreme in this respect are the poxviruses, the cores of which contain a transcriptional system; many different enzymes are packaged in poxvirus particles.

Viral Nucleic Acid

Viruses contain a single kind of nucleic acid—either DNA or RNA—that encodes the genetic information necessary for replication of the virus. The genome may be single or double stranded, circular or linear, and segmented or nonsegmented. The type of nucleic acid, its polarity, and its size are major characteristics used for classifying viruses into families (see Table 29-1).

The size of the viral DNA genome ranges from 3.2 kbp (hepadnaviruses) to 375 kbp (poxviruses). The size of the

viral RNA genome ranges from about 4 kb (picobirnaviruses) to 32 kb (coronaviruses).

All major DNA viral groups in Table 29-1 have genomes that are single molecules of DNA and have a linear or circular configuration.

Viral RNAs exist in several forms. The RNA may be a single linear molecule (eg, picornaviruses). For other viruses (eg, orthomyxoviruses), the genome consists of several segments of RNA that may be loosely associated within the virion. The isolated RNA of viruses with positive-sense genomes (ie, picornaviruses, togaviruses) is infectious, and the molecule functions as an mRNA within the infected cell. The isolated RNA of the negative-sense RNA viruses, such as rhabdoviruses and orthomyxoviruses, is not infectious. For these viral families, the virions carry an RNA polymerase that in the cell transcribes the genomic RNA molecules into several complementary RNA molecules, each of which may serve as an mRNA template.

The sequence and composition of nucleotides of each viral nucleic acid are distinctive. Many viral genomes have been sequenced. The sequences can reveal genetic relationships among isolates, including unexpected relationships between viruses not thought to be closely related. The number of genes in a virus can be estimated from the open reading frames deduced from the nucleic acid sequence.

Molecular techniques such as polymerase chain reaction assays and nucleic acid sequencing permit the study of transcription of the viral genome within the infected cell as well as comparison of the relatedness of different viruses. Viral nucleic acid may be characterized by its GC content, profile based on use of restriction endonucleases, enzymes that cleave DNA at specific nucleotide sequences, and genome sequence. Comparison to nucleic acid or protein sequence databases can be used to classify viral agents.

Viral Lipid Envelopes

A number of different viruses contain lipid envelopes as part of their structure. The lipid is acquired when the viral nucleocapsid buds through a cellular membrane during maturation. Budding occurs only at sites where virus-specific proteins have been inserted into the host cell membrane. The budding process varies markedly depending on the replication strategy of the virus and the structure of the nucleocapsid. Budding by influenza virus is illustrated in Figure 29-3.

The phospholipid composition of a virion envelope is determined by the specific type of cell membrane involved in the budding process. For example, herpesviruses bud through the nuclear membrane of the host cell, and the phospholipid composition of the purified virus reflects the lipids of the nuclear membrane. The acquisition of a lipid-containing membrane is an integral step in virion morphogenesis in some viral groups (see Replication of Viruses).

Lipid-containing viruses are sensitive to treatment with ether and other organic solvents (see Table 29-1), indicating that disruption or loss of lipid results in loss of infectivity.

FIGURE 29-3 Release of influenza virus by plasma membrane budding. First, viral envelope proteins (hemagglutinin and neuraminidase) are inserted into the host plasma membrane. Then the nucleocapsid approaches the inner surface of the membrane and binds to it. At the same time, viral proteins collect at the site, and host membrane proteins are excluded. Finally, the plasma membrane buds to simultaneously form the viral envelope and release the mature virion. (Reproduced with permission from Willey JM, Sherwood LM, Woolverton CJ: *Prescott, Harley, and Klein's Microbiology*, 7th ed. McGraw-Hill, 2008. © McGraw-Hill Education.)

Nonlipid-containing viruses are generally resistant to ether and detergents.

Viral Glycoproteins

Viral envelopes contain glycoproteins. In contrast to the lipids in viral membranes, which are derived from the host cell, the envelope glycoproteins are virus encoded. However, the sugars added to viral glycoproteins typically reflect the host cell in which the virus is grown.

The surface glycoproteins of an enveloped virus attach the virus particle to a target cell by interacting with a cellular receptor. They are also often involved in the membrane fusion step of infection. The glycoproteins are also important viral antigens. As a result of their position at the outer surface of the virion, they are frequently involved in the interaction of the virus particle with neutralizing antibody. Extensive glycosylation of viral surface proteins may prevent effective

neutralization of a virus particle by specific antibody. The three-dimensional structures of the externally exposed regions of some viral glycoproteins have been determined by x-ray crystallography (see Figure 39-2). Such studies provide insights into the antigenic structure and functional activities of viral glycoproteins.

CULTIVATION AND DETECTION OF VIRUSES

Cultivation of Viruses

Many viruses can be grown in cell cultures or in fertile eggs under strictly controlled conditions. Virus growth in animals is still used for the primary isolation of certain viruses and for studies of the pathogenesis of viral diseases and of viral oncogenesis. Diagnostic laboratories may attempt to recover viruses from clinical samples to establish disease causes (see Chapter 47). Research laboratories cultivate viruses as the basis for detailed analyses of viral replication and protein function.

Cells grown *in vitro* are central to the cultivation and characterization of viruses. There are three basic types of cell cultures. Primary cultures are made by dispersing cells (usually with trypsin) from freshly removed host tissues. In general, they are unable to grow for more than a few passages in culture. Diploid cell lines are secondary cultures that have undergone a change that allows their limited culture (up to 50 passages) but that retain their normal chromosome pattern. Continuous cell lines are cultures capable of more prolonged—perhaps indefinite—growth that have been derived from diploid cell lines or from malignant tissues. These have altered and irregular numbers of chromosomes. The type of cell culture used for viral cultivation depends on the sensitivity of the cells to a particular virus.

A. Detection of Virus-Infected Cells

Multiplication of a virus can be monitored in a variety of ways:

1. Development of cytopathic effects (ie, morphologic changes in the cells). Types of virus-induced cytopathic effects include cell lysis or necrosis, inclusion body formation, giant cell formation, and cytoplasmic vacuolization (Figure 29-4A, B, and C).
2. Appearance of a virus-encoded protein, such as the hemagglutinin of influenza virus. Specific antisera can be used to detect the synthesis of viral proteins in infected cells.
3. Detection of virus-specific nucleic acid. Molecular-based assays such as polymerase chain reaction provide rapid, sensitive, and specific methods of detection.
4. Adsorption of erythrocytes to infected cells, called **hemadsorption**, caused by the presence of virus-encoded hemagglutinin (parainfluenza, influenza) in cellular membranes. This reaction becomes positive before cytopathic changes

FIGURE 29-4 Cytopathic effects produced in monolayers of cultured cells by different viruses. The cultures are shown as they would normally be viewed in the laboratory, unfixed and unstained (60×). **A:** Enterovirus—rapid rounding of cells progressing to complete cell destruction. **B:** Herpesvirus—focal areas of swollen, rounded cells. **C:** Paramyxovirus—focal areas of fused cells (syncytia). **D:** Hemadsorption. Erythrocytes adhere to those cells in the monolayer that are infected by a virus that causes a hemagglutinin to be incorporated into the plasma membrane. Many enveloped viruses that mature by budding from cytoplasmic membranes produce hemadsorption. (Courtesy of I Jack.)

are visible and in some cases occurs in the absence of cytopathic effects (Figure 29-4D).

5. Viral growth in an embryonated chick egg may result in death of the embryo (eg, encephalitis viruses), production of pocks or plaques on the chorioallantoic membrane (eg, herpes, smallpox, and vaccinia), or development of hemagglutinins in the embryonic fluids or tissues (eg, influenza).

B. Inclusion Body Formation

In the course of viral multiplication within cells, virus-specific structures called **inclusion bodies** may be produced. They become far larger than the individual virus particle and often have an affinity for acid dyes (eg, eosin). They may be situated in the nucleus (herpesvirus; see Figure 33-3), in the

cytoplasm (poxvirus, rabies virus), or in both (measles virus; see Figure 40-5). In many viral infections, the inclusion bodies are the site of development of the virions (the viral factories). Variations in the appearance of inclusion material depend on the tissue fixative and stain used.

Quantitation of Viruses

A. Physical Methods

Quantitative nucleic acid-based assays such as the polymerase chain reaction can determine the number of viral genome copies in a sample. Both infectious and noninfectious genomes are detected. Virus sequence variation may reduce virus detection and quantitation by this method.

A variety of serologic tests such as radioimmunoassays and enzyme-linked immunosorbent assays (see Chapter 47) can be standardized to quantitate the amount of virus in a sample. These tests do not distinguish infectious from noninfectious particles and sometimes detect viral proteins not assembled into particles.

Certain viruses contain a protein (hemagglutinin) that has the ability to agglutinate red blood cells of humans or some animal. Hemagglutination assays provide a method for quantitating the infective and noninfective particles of these types of viruses (see Chapter 47).

Virus particles can be counted directly in the electron microscope by comparison with a standard suspension of latex particles of similar small size. However, a relatively concentrated preparation of virus is necessary for this procedure, and infectious virus particles cannot be distinguished from noninfectious ones.

B. Biologic Methods

End point biologic assays depend on the measurement of animal death, animal infection, or cytopathic effects in tissue culture at a series of dilutions of the virus being tested. The titer is expressed as the 50% infectious dose (ID_{50}), which is the reciprocal of the dilution of virus that produces infection in 50% of the cells or animals inoculated. The ratio of the number of infectious particles to the total number of virus particles varies widely, from near unity to less than one per 1000, but often is one per several hundred. Precise assays require the use of a large number of replicates.

A widely used assay for infectious virus is the plaque assay, although it can only be used for viruses that grow well in tissue culture. Monolayers of host cells are inoculated with suitable dilutions of virus and after adsorption are overlaid with medium containing agar or carboxymethylcellulose to prevent virus spreading throughout the culture. After several days, the cells initially infected have produced virus that spreads only to surrounding cells. Multiple cycles of replication and cell killing produce a small area of infection, or plaque. The length of time from infection to when plaques can be visualized for counting depends on the replication cycle of the virus and can range from a few days

(eg, poliovirus) to 2 weeks or more (eg, SV40). Under controlled conditions, a single plaque can arise from a single clonal infectious virus particle, termed a plaque-forming unit. The cytopathic effect of infected cells within the plaque can be distinguished from uninfected cells of the monolayer. A more rapid method of assay is based on determination of the number of infected cells producing a viral antigen, such as by immunofluorescence.

Certain viruses (eg, herpes and vaccinia) form pocks when inoculated onto the chorioallantoic membrane of an embryonated egg. Such viruses can be quantitated by relating the number of pocks counted to the viral dilution inoculated.

PURIFICATION AND IDENTIFICATION OF VIRUSES

Purification of Virus Particles

Pure virus must be available in order for certain types of studies on the properties and molecular biology of the agent to be carried out. For purification studies, the starting material is usually large volumes of tissue culture medium, body fluids, or infected cells. The first step frequently involves concentration of the virus particles by precipitation with ammonium sulfate, ethanol, or polyethylene glycol or by ultrafiltration. Hemagglutination and elution can be used to concentrate orthomyxoviruses (see Chapter 39). After concentration, virus can be separated from host materials by differential centrifugation, density gradient centrifugation, column chromatography, and electrophoresis.

More than one step is usually necessary to achieve adequate purification. A preliminary purification will remove most nonviral material. This first step may include centrifugation; the final purification step almost always involves density gradient centrifugation. In rate-zonal centrifugation, a sample of concentrated virus is layered onto a preformed linear density gradient of sucrose or glycerol, and during centrifugation the virus sediments as a band at a rate determined primarily by the density of the virus particle.

Viruses can also be purified by high-speed centrifugation in density gradients of cesium chloride, potassium tartrate, potassium citrate, or sucrose. The gradient material of choice is the one that is least toxic to the virus. Virus particles migrate to an equilibrium position where the density of the solution is equal to their buoyant density and form a visible band.

Additional methods for purification are based on the chemical properties of the viral surface. In column chromatography, virus is bound to a substance such as diethylaminoethyl or phosphocellulose and then eluted by changes in pH or salt concentration. Zone electrophoresis permits separation of virus particles from contaminants on the basis of charge. Specific antisera also can be used to remove virus particles from host materials.

Icosahedral viruses are easier to purify than enveloped viruses. Because the latter usually contain variable amounts

of envelope per particle, the viral population is heterogeneous in both size and density.

It is very difficult to achieve complete purity of viruses. Small amounts of cellular material tend to adsorb to particles and copurify. The minimal criteria for purity are a homogeneous appearance in electron micrographs and the failure of additional purification procedures to remove “contaminants” without reducing infectivity.

Identification of a Particle as a Virus

When a characteristic physical particle has been obtained, it should fulfill the following criteria before it is identified as a virus particle:

1. The particle can be obtained only from infected cells or tissues.
2. Particles obtained from various sources are identical regardless of the cellular origin in which the virus is grown.
3. Particles contain nucleic acid (DNA or RNA), the sequence of which is not the same as the species of host cells from which the particles were obtained.
4. The degree of infective activity of the preparation varies directly with the number of particles present.
5. Destruction of the physical particle by chemical or physical means is associated with a loss of viral activity.
6. Certain properties of the particles and infectivity must be shown to be identical (eg, their sedimentation behavior in the ultracentrifuge and their pH stability curves).
7. Antisera prepared against the infectious virus should react with the characteristic particle and vice versa. Direct observation of an unknown virus can be accomplished by electron microscopic examination of aggregate formation in a mixture of antisera and crude viral suspension.
8. The particles should be able to induce the characteristic disease in vivo (if such experiments are feasible).
9. Passage of the particles in tissue culture should result in the production of progeny with biologic and antigenic properties of the virus.

LABORATORY SAFETY

Many viruses are human pathogens, and laboratory-acquired infections can occur. Laboratory procedures are often potentially hazardous if proper technique is not followed. Among the common hazards that might expose laboratory personnel to the risk of infection are the following: (1) aerosols—generated by homogenization of infected tissues, centrifugation, ultrasonic vibration, or broken glassware; (2) ingestion—from mouth pipetting, eating or smoking in the laboratory, or inadequate washing of hands; (3) skin penetration—from needle sticks, broken glassware, hand contamination by leaking containers, handling of infected tissues, or animal bites; and (4) splashes into the eye or mucous membranes.

Good biosafety practices include the following: (1) training in and use of aseptic techniques; (2) no eating, drinking, mouth pipetting, or smoking in the laboratory; (3) use of personal protective equipment (eg, coats, gloves, or masks) not to be worn outside the laboratory; (4) sterilization of experimental wastes; (5) use of biosafety hoods; and (6) immunization if relevant vaccines are available. Additional precautions and special containment facilities (Biosafety Level 4) are necessary when personnel are performing research with high-risk agents such as the filoviruses (see Chapter 38) and rabies virus (see Chapter 42).

REACTION TO PHYSICAL AND CHEMICAL AGENTS

Heat and Cold

There is great variability in the heat stability of different viruses. Icosahedral viruses tend to be stable, losing little infectivity after several hours at 37°C. Enveloped viruses are much more heat labile, rapidly dropping in titer at 37°C. Viral infectivity is generally destroyed by heating at 50–60°C for 30 minutes, although there are some notable exceptions (eg, hepatitis B virus and polyomaviruses).

Viruses can be preserved by storage at subfreezing temperatures, and some may withstand lyophilization and can thus be preserved in the dry state at 4°C or even at room temperature. Enveloped viruses tend to lose infectivity after prolonged storage even at –80°C and are particularly sensitive to repeated freezing and thawing.

Stabilization of Viruses by Salts

Many viruses can be stabilized by salts in order to resist heat inactivation, which is important in the preparation of vaccines. The ordinary nonstabilized oral polio vaccine must be stored at freezing temperatures to preserve its potency. However, with the addition of salts for stabilization of the virus, potency can be maintained for weeks at ambient temperatures even in the high temperatures of the tropics.

pH

Viruses are usually stable between pH values of 5.0 and 9.0. Some viruses (eg, enteroviruses) are resistant to acidic conditions. All viruses are destroyed by alkaline conditions. Hemagglutination reactions can be quite sensitive to changes in pH.

Radiation

Ultraviolet, x-ray, and high-energy particles inactivate viruses. The dose varies for different viruses. Infectivity is the most radiosensitive property because replication requires expression of the entire genetic contents. Irradiated particles

that are unable to replicate may still be able to express some specific functions in host cells.

Ether Susceptibility

Ether susceptibility can be used to distinguish viruses that possess an envelope from those that do not. Ether sensitivity of different virus groups is shown in Table 29-1.

Detergents

Nonionic detergents (eg, Nonidet P40 and Triton X-100) solubilize lipid constituents of viral membranes. The viral proteins in the envelope are released (undenatured). Anionic detergents (eg, sodium dodecyl sulfate) also solubilize viral envelopes; in addition, they disrupt capsids into separated polypeptides.

Formaldehyde

Formaldehyde destroys viral infectivity by reacting with nucleic acid. Viruses with single-stranded genomes are inactivated much more readily than those with double-stranded genomes. Formaldehyde has minimal adverse effects on the antigenicity of proteins and therefore has been used frequently in the production of inactivated viral vaccines.

Photodynamic Inactivation

Viruses are penetrable to a varying degree by vital dyes such as toluidine blue, neutral red, and proflavine. These dyes bind to the viral nucleic acid, and the virus then becomes susceptible to inactivation by visible light.

Antibiotics and Other Antibacterial Agents

Antibacterial antibiotics and sulfonamides have no effect on viruses. Some antiviral drugs are available, however (see Chapter 30).

Certain disinfectants, such as quaternary ammonium and organic iodine compounds, are not effective against viruses. Larger concentrations of chlorine are required to destroy viruses than to kill bacteria, especially in the presence of extraneous proteins. For example, the chlorine treatment of stools adequate to inactivate typhoid bacilli is inadequate to destroy poliomyelitis virus present in feces. Alcohols, such as isopropanol and ethanol, are relatively ineffective against certain viruses, especially picornaviruses.

Common Methods of Inactivating Viruses for Various Purposes

Viruses may be inactivated for various reasons, such as to sterilize laboratory supplies and equipment, disinfect surfaces or skin, make drinking water safe, and produce inactivated virus vaccines. Different methods and chemicals are used for these purposes.

Sterilization may be accomplished by steam under pressure, dry heat, ethylene oxide, and γ -irradiation. Surface disinfectants include sodium hypochlorite, glutaraldehyde, formaldehyde, and peracetic acid. Skin disinfectants include chlorhexidine, 70% ethanol, and iodophors. Vaccine production may involve the use of formaldehyde, β -propiolactone, psoralen + ultraviolet irradiation, or detergents (subunit vaccines) to inactivate the vaccine virus.

REPLICATION OF VIRUSES: AN OVERVIEW

Viruses multiply only in living cells. The host cell provides the energy and synthetic machinery and the low-molecular-weight precursors for the synthesis of viral proteins and nucleic acids. The viral nucleic acid carries the genetic specificity to code for all of the virus-specific macromolecules in a highly organized fashion.

For a virus to replicate, viral proteins must be synthesized by the host cell protein-synthesizing machinery. Therefore, the virus genome must be able to produce a functional mRNA. Various mechanisms have been identified that allow viral RNAs to compete successfully with cellular mRNAs to produce adequate amounts of viral proteins.

The unique feature of viral multiplication is that soon after interaction with a host cell the infecting virion is disrupted and its measurable infectivity is lost. This phase of the growth cycle is called the **eclipse period**; its duration varies depending on both the particular virus and the host cell, and it is followed by an interval of rapid accumulation of infectious progeny virus particles. The eclipse period is actually one of intense synthetic activity as the cell is redirected toward fulfilling the needs of the viral parasite. In some cases, as soon as the viral nucleic acid enters the host cell, the cellular metabolism is redirected exclusively toward the synthesis of new virus particles and the cell is destroyed. In other cases, the metabolic processes of the host cell are not altered significantly, although the cell synthesizes viral proteins and nucleic acids, and the cell is not killed.

After the synthesis of viral nucleic acid and viral proteins, the components assemble to form new infectious virions. The yield of infectious virus per cell ranges widely, from modest numbers to more than 100,000 particles. The duration of the virus replication cycle also varies widely, from 6 to 8 hours (picornaviruses) to more than 40 hours (some herpesviruses).

Not all infections lead to new progeny virus. **Productive** infections occur in **permissive** cells and result in the production of infectious virus. **Abortive** infections fail to produce infectious progeny, either because the cell may be **nonpermissive** and unable to support the expression of all viral genes or because the infecting virus may be **defective**, lacking some functional viral gene. A **latent** infection may ensue, with the persistence of viral genomes, the expression of no or a few viral genes, and the survival of the infected cell. The pattern of replication may vary for a given virus, depending on the type of host cell infected.

General Steps in Viral Replication Cycles

A variety of different viral strategies have evolved for accomplishing multiplication in parasitized host cells. Although the details vary from group to group, the general outline of the replication cycles is similar. The growth cycles of a double-stranded DNA virus and a positive-sense, single-stranded

RNA virus are shown in Figure 29-5. Details are included in the following chapters devoted to specific virus groups.

A. Attachment, Penetration, and Uncoating

The first step in viral infection is **attachment**, interaction of a virion with a specific receptor site on the surface of a cell.

FIGURE 29-5 Example of viral growth cycles. **A:** The growth cycle of a nonenveloped, double-stranded DNA virus. In this example multiple steps in the replication cycle take place in the nucleus. (1) After penetrating the host cell, viral DNA is uncoated and enters the nucleus. (2) Viral genes are transcribed. (3) The mRNAs are translated in the cytoplasm. Newly synthesized proteins enter the nucleus. (4) Viral DNA is replicated in the nucleus, sometimes with the help of newly synthesized viral replication proteins. (5) Viral DNA and viral structural proteins assemble in the nucleus to produce new progeny virions. (6) On rare occasions, viral DNA may be incorporated into cellular DNA as a side effect of infection. **B:** The growth cycle of a positive-sense, single-stranded RNA virus. In this example, the replication cycle occurs in the cytoplasm. (1) The virus enters the cell and the viral RNA genome is uncoated. (2) As a positive-sense, single-stranded genome, the RNA is directly translated, producing viral proteins. (3) A negative-sense RNA copy of the positive template is synthesized. (4) It is used to produce many positive-sense copies. (5) The newly synthesized positive-sense RNA molecules are assembled with viral structural proteins to produce new progeny virions. (Reproduced with permission from Talaro KP: *Foundations in Microbiology: Basic Principles*, 6th ed. McGraw-Hill, 2008. © McGraw-Hill Education.)

Receptor molecules differ for different viruses but are generally glycoproteins. In some cases, the virus binds protein sequences (eg, picornaviruses) and in others oligosaccharides (eg, orthomyxoviruses and paramyxoviruses). The presence or absence of receptors plays an important determining role in cell tropism and viral pathogenesis. Not all cells in a susceptible host will express the necessary receptors; for example, poliovirus is able to attach only to cells in the central nervous system and intestinal tract of primates. Each susceptible cell may contain up to 100,000 receptor sites for a given virus.

After binding, the virus particle is taken up inside the cell. This step is referred to as **penetration** or engulfment. In some systems, this is accomplished by receptor-mediated endocytosis, with uptake of the ingested virus particles within endosomes. There are also examples of direct penetration of virus particles across the plasma membrane. In other cases, there is fusion of the virion envelope with the plasma membrane of the cell. Those systems involve the interaction of a viral fusion protein with a second cellular receptor or coreceptor.

Uncoating occurs concomitantly with or shortly after penetration. Uncoating is the physical separation of the viral nucleic acid from the outer structural components of the virion so that it can function. The genome may be released as free nucleic acid (picornaviruses) or as a nucleocapsid (reoviruses). The nucleocapsids usually contain polymerases. Uncoating may require acidic pH in the endosome. The infectivity of the parental virus is lost at the uncoating stage. Viruses are the only infectious agents for which dissolution of the infecting agent is an obligatory step in the replicative pathway.

B. Expression of Viral Genomes and Synthesis of Viral Components

The synthetic phase of the viral replicative cycle ensues after uncoating of the viral genome. The essential theme in viral

replication is that specific mRNAs must be transcribed from the viral nucleic acid for successful expression and duplication of genetic information. After this is accomplished, viruses use cell components to translate the mRNA. Various classes of viruses use different pathways to synthesize the mRNAs depending on the structure of the viral nucleic acid. Table 29-2 summarizes various pathways of transcription (but not necessarily those of replication) of the nucleic acids of different classes of viruses. Some viruses (eg, rhabdoviruses) carry RNA polymerases to synthesize mRNAs. RNA viruses of this type are called **negative-strand (negative-sense) viruses** because their single-strand RNA genome is complementary to mRNA, which is conventionally designated positive strand (positive sense). The negative-strand viruses must supply their own RNA polymerase because eukaryotic cells lack enzymes able to synthesize mRNA from an RNA template.

In the course of viral replication, all of the virus-specified macromolecules are synthesized in a highly organized sequence. In some viral infections, notably those involving double-stranded DNA-containing viruses, early viral proteins are synthesized soon after infection and late proteins are made only late in infection after viral DNA synthesis begins. Early genes may or may not be shut off when late products are made. In contrast, most, if not all, of the genetic information of RNA-containing viruses is expressed at the same time. In addition to these temporal controls, quantitative controls also exist because not all viral proteins are made in the same amounts. Viral microRNAs or virus-specific proteins may regulate the extent of transcription of the genome or the translation of viral mRNA.

Small animal viruses and bacteriophages are good models for studies of gene expression. The total nucleotide sequences of many viruses have been elucidated. This led to the discovery of overlapping genes in which some sequences

TABLE 29-2 Pathways of Nucleic Acid Transcription for Various Virus Classes

Type of Viral Nucleic Acid	Intermediates	Type of mRNA	Example	Comments
± ds DNA	None	+ mRNA	Most DNA viruses (eg, herpesvirus and adenovirus)	
+ ss DNA	± ds DNA	+ mRNA	Parvoviruses	
± ds RNA	None	+ mRNA	Reoviruses	Virion contains RNA polymerase that transcribes each segment to mRNA.
+ ss RNA	± ds RNA	+ mRNA	Picornaviruses, togaviruses, flaviviruses	Viral nucleic acid is infectious and serves as mRNA. For togaviruses, smaller + mRNA is also formed for certain proteins.
– ss RNA	None	+ mRNA	Rhabdoviruses, paramyxoviruses, orthomyxoviruses	Viral nucleic acid is not infectious; virion contains RNA polymerase, which forms + mRNAs smaller than the genome. For orthomyxoviruses, + mRNAs are transcribed from each segment.
+ ss RNA	– DNA, ± DNA	+ mRNA	Retroviruses	Virion contains reverse transcriptase; viral RNA is not infectious, but complementary DNA from transformed cell is.

–, negative strand; +, positive strand; ±, a helix containing a positive and a negative strand; ds, double stranded; ss, single stranded.

in DNA are used in the synthesis of two different polypeptides, either by the use of two different reading frames or by two mRNA molecules using the same reading frame but different starting points. A viral system (adenovirus) first revealed the mRNA processing phenomenon called “splicing,” whereby the mRNA sequences that code for a given protein are generated from separated sequences in the template, with noncoding intervening sequences spliced out of the transcript. Recently, several DNA viruses (herpesviruses, polyomaviruses) were found to encode microRNAs; these small (~22 nucleotide) RNAs function at a new level of posttranscriptional gene regulation, either by mediating degradation of target mRNAs or by inducing inhibition of translation of those mRNAs.

The widest variation in strategies of gene expression is found among RNA-containing viruses (Table 29-3). Some virions carry polymerases (orthomyxoviruses, reoviruses); some systems use subgenomic messages, sometimes generated by splicing (orthomyxoviruses, retroviruses); and some viruses synthesize large polypeptide precursors that are processed and cleaved to generate the final gene products (picornaviruses, retroviruses). In HIV, the viral protease is required for this function, enabling it to be targeted by protease inhibitor drugs.

The extent to which virus-specific enzymes are involved in these processes varies from group to group. DNA viruses that replicate in the nucleus generally use host cell DNA and RNA polymerases and processing enzymes. The larger viruses (herpesviruses, poxviruses) are more independent of cellular functions than are the smaller viruses. This is one reason the larger viruses are more susceptible to antiviral chemotherapy (see Chapter 30)—because more virus-specific processes are available as targets for drug action.

The intracellular sites where the different events in viral replication take place vary from group to group (Table 29-4). A few generalizations are possible. Viral protein is synthesized in the cytoplasm on polyribosomes composed of virus-specific mRNA and host cell ribosomes. Many viral proteins undergo modifications (glycosylation, acylation, cleavages, etc). Viral DNA is usually replicated in the nucleus. Viral genomic RNA is generally duplicated in the cell cytoplasm, although there are exceptions.

C. Morphogenesis and Release

Newly synthesized viral genomes and capsid polypeptides assemble together to form progeny viruses. Whereas icosahedral capsids can condense in the absence of nucleic acid,

TABLE 29-3 Comparison of Replication Strategies of Several Important RNA Virus Families

Characteristic	Grouping Based on Genomic RNA ^a					
	Positive-Strand Viruses			Negative-Strand Viruses		Double-Stranded Viruses
	Picornaviridae	Togaviridae	Retroviridae	Orthomyxoviridae	Paramyxoviridae and Rhabdoviridae	Reoviridae
Structure of genomic RNA	ss	ss	ss	ss	ss	ds
Sense of genomic RNA	Positive	Positive	Positive	Negative	Negative	
Segmented genome	0	0	0 ^b	+	0	+
Genomic RNA infectious	+	+	0	0	0	0
Genomic RNA acts as messenger	+	+	+	0	0	0
Virion-associated polymerase	0	0	+ ^c	+	+	+
Subgenomic messages	0	+	+	+	+	+
Polypeptide precursors	+	+	+	0	0	0

^a+, indicated property applies to that virus family; 0, indicated property does not apply to that virus family; ds, double stranded; negative, complementary to mRNA; positive, same sense as mRNA; ss, single stranded.

^bRetroviruses contain a diploid genome (two copies of nonsegmented genomic RNA).

^cRetroviruses contain a reverse transcriptase (RNA-dependent DNA polymerase).

TABLE 29-4 Summary of Replication Cycles of Major Virus Families

Virus Family	Presence of Virion Envelope	Intracellular Location			Multiplication Cycle (Hours) ^b
		Replication of Genome	Formation of Nucleocapsid ^a	Virion Maturation	
DNA viruses					
Parvoviridae	0	N	N	N	24
Polyomaviridae	0	N	N	N	48
Adenoviridae	0	N	N	N	25
Hepadnaviridae	+	N	C	M-E	12-24
Herpesviridae	+	N	N	M	15-72
Poxviridae	0	C	C	C	20
RNA viruses					
Picornaviridae	0	C	C	C	6-8

Orthomyxoviridae	+	N	N	M-P	15-30
Paramyxoviridae	+	C	C	M-P	10-48
Rhabdoviridae	+	C	C	M-P	6-10

C, cytoplasm; M, membranes; M-E, endoplasmic reticulum membranes; M-G, Golgi membranes; M-P, plasma membranes; N, nucleus.

^aThe synthesis of viral proteins always occurs in the cytoplasm.

^bThe values shown for duration of the multiplication cycle are approximate; ranges indicate that various members within a given family replicate with different kinetics. Different host cell types also influence the kinetics of viral replication.

nucleocapsids of viruses with helical symmetry cannot form without viral RNA. In general, nonenveloped viruses accumulate in infected cells, and the cells eventually lyse and release the virus particles.

Enveloped viruses mature by a budding process. Virus-specific envelope glycoproteins are inserted into cellular membranes; viral nucleocapsids then bud through the membrane at these modified sites and in so doing acquire an envelope. Budding frequently occurs at the plasma membrane but may involve other membranes in the cell. Enveloped viruses are not infectious until they have acquired their envelopes. Therefore, infectious progeny virions typically do not accumulate within the infected cell.

Viral maturation is sometimes an inefficient process. Excess amounts of viral components may accumulate and be involved in the formation of inclusion bodies in the cell. As a result of the profound deleterious effects of viral replication, cellular cytopathic effects eventually develop and the cell dies. However, there are instances in which the cell is not damaged by the virus and long-term, persistent infections evolve (see Chapter 30). Virus-induced mechanisms may regulate apoptosis, a genetically programmed event that makes

cells undergo self-destruction. Some virus infections delay early apoptosis, which allows time for the production of high yields of progeny virus. Additionally, some viruses actively induce apoptosis at late stages, which facilitates spread of progeny virus to new cells.

GENETICS OF ANIMAL VIRUSES

Genetic analysis is a powerful approach toward understanding the structure and function of the viral genome, its gene products, and their roles in infection and disease. Viral variants can arise naturally, with changes in biologic properties caused by genetic mutations. Variation in viral properties is of great importance for human medicine. Viruses that have stable antigens on their surfaces (poliovirus, measles virus) can be controlled by vaccination. Other viruses that exist as many antigenic types (rhinoviruses) or change frequently (influenza virus A) are difficult to control by vaccination; viral genetics may help develop more effective vaccines. Some types of viral infections recur repetitively (parainfluenza viruses) or persist (retroviruses) in the presence of

antibody and may be better controlled by antiviral drugs. Genetic analysis will help identify virus-specific processes that may be appropriate targets for the development of antiviral therapy.

The following terms are basic to a discussion of genetics:

Genotype refers to the genetic constitution of an organism. **Phenotype** refers to the observable properties of an organism, which are produced by the genotype in cooperation with the environment. A **mutation** is a heritable change in the genotype. The **genome** is the sum of the genes of an organism. **Wild-type virus** denotes the original virus from which mutants are derived and with which the mutants are compared; the term may not accurately characterize the virus as it is isolated in nature. Fresh virus isolates from the natural host are referred to as **field isolates** or **primary isolates**.

Mapping of Viral Genomes

The rapid and precise techniques of molecular biology have facilitated the identification of viral gene products and the mapping of these on the viral genome. Biochemical, genetic, and physical mapping can be done using classic techniques. Sequence analysis and comparison with known viruses is often used for mapping viral genomes, comparative phylogeny, and predication of active properties.

Restriction endonucleases can be used for identification of specific strains of DNA viruses. Viral DNA is isolated and incubated with a specific endonuclease until DNA sequences susceptible to the nuclease are cleaved. The fragments are then resolved on the basis of size by gel electrophoresis. The large fragments are most retarded by the sieving effect of the gel, so that an inverse relationship between size and migration is observed.

Physical maps can be correlated with genetic maps. This allows viral gene products to be mapped to individual regions of the genome defined by the restriction enzyme fragments. Transcription of mRNAs throughout the replication cycle can be assigned to specific DNA fragments. Using mutagenesis, mutations can be introduced into defined sites of the genome for functional studies.

Types of Virus Mutants

Conditional-lethal mutants are mutants that are lethal (in that no infectious virus is produced) under one set of conditions—termed **nonpermissive conditions**—but that yield normal infectious progeny under other conditions—termed **permissive conditions**. Temperature-sensitive mutants grow at low (permissive) temperatures but not at high (nonpermissive) temperatures. Host-range mutants are able to grow in one kind of cell (permissive cell), but abortive infection occurs in another type (nonpermissive cell). Mixed infection studies with pairs of mutants under permissive and nonpermissive conditions can yield information concerning gene functions and mechanisms of viral replication at the molecular level.

Defective Viruses

A defective virus is one that lacks one or more functional genes required for viral replication. Defective viruses require helper activity from another virus for some step in replication or maturation.

One type of defective virus lacks a portion of its genome (ie, deletion mutant). The extent of loss by deletion may vary from a short base sequence to a large amount of the genome. Spontaneous deletion mutants may interfere with the replication of homologous virus and are called **defective interfering virus particles**. Defective interfering particles have lost essential segments of genome but contain normal capsid proteins; they require infectious homologous virus as helper for replication, and they interfere with the multiplication of that homologous virus.

Another category of defective virus requires an unrelated replication-competent virus as helper. Examples include the adeno-associated satellite viruses and hepatitis D virus (delta agent), which replicate only in the presence of coinfecting human adenovirus or hepatitis B virus, respectively.

Pseudovirions, a different type of defective particle, contain host cell DNA rather than the viral genome. During viral replication, the capsid sometimes encloses random pieces of host nucleic acid rather than viral nucleic acid. Such particles look like ordinary virus particles when observed by electron microscopy, but they are not able to replicate. Pseudovirions theoretically might be able to transduce cellular nucleic acid from one cell to another.

The transforming retroviruses are usually defective. A portion of the viral genome has been deleted and replaced with a piece of DNA of cellular origin that encodes a transforming protein. These viruses allowed the identification of cellular oncogenes (see Chapter 43). Another retrovirus is required as helper for the transforming virus to replicate.

Interactions Among Viruses

When two or more virus particles infect the same host cell, they may interact in a variety of ways. They must be sufficiently closely related, usually within the same viral family, for most types of interactions to occur. Genetic interaction results in some progeny that are heritably (genetically) different from either parent. Progeny produced as a consequence of nongenetic interaction are similar to the parental viruses.

A. Recombination

Recombination results in the production of progeny virus (recombinant) that carries traits not found together in either parent. The classic mechanism is that the nucleic acid strands break, and part of the genome of one parent is joined to part of the genome of the second parent. The recombinant virus is genetically stable, yielding progeny similar to itself upon replication. Viruses vary widely in the frequency with which they undergo recombination. In the case of viruses with segmented genomes (eg, influenza virus), the formation of recombinants

is caused by **reassortment** of individual genome fragments in multiply infected cells rather than by an actual crossover event, and it occurs with ease (see Chapter 39).

B. Complementation

This refers to the interaction of viral gene products in cells infected with two viruses, one or both of which may be defective. It results in the replication of one or both under conditions in which replication would not ordinarily occur. The basis for complementation is that one virus provides a gene product in which the second is defective, allowing the second virus to grow. The genotypes of the two viruses remain unchanged.

C. Phenotypic Mixing

A special case of complementation is phenotypic mixing, or the association of a genotype with a heterologous phenotype. This occurs when the genome of one virus becomes randomly incorporated within capsid proteins specified by a different virus or a capsid consisting of components of both viruses. If the genome is encased in a completely heterologous protein coat, this extreme example of phenotypic mixing may be called “phenotypic masking” or “transcapsidation.” Such mixing is not a stable genetic change because, upon replication, the phenotypically mixed parent will yield progeny with capsids derived from its genome.

Phenotypic mixing usually occurs between different members of the same virus family; the intermixed capsid proteins must be able to interact correctly to form a structurally intact capsid. However, phenotypic mixing also can occur between enveloped viruses, and in this case, the viruses do not have to be closely related. The nucleocapsid of one virus becomes encased within an envelope specified by another, a phenomenon designated “pseudotype formation.” There are many examples of pseudotype formation among the RNA tumor viruses (see Chapter 43). The nucleocapsid of vesicular stomatitis virus, a rhabdovirus, has an unusual propensity for being involved in pseudotype formation with unrelated envelope material.

D. Interference

Infection of either cell cultures or whole animals with two viruses often leads to an inhibition of multiplication of one of the viruses, an effect called **interference**. Interference in animals is distinct from specific immunity. Furthermore, interference does not occur with all viral combinations; two viruses may infect and multiply within the same cell as efficiently as in single infections.

Several mechanisms have been elucidated as causes of interference: (1) One virus may inhibit the ability of the second to adsorb to the cell, either by blocking its receptors (retroviruses, enteroviruses) or by destroying its receptors (orthomyxoviruses). (2) One virus may compete with the second for components of the replication apparatus (eg, polymerase, translation initiation factor). (3) The first virus may cause the infected cell to produce an inhibitor (interferon; see Chapter 30) that prevents replication of the second virus.

Viral Vectors

Recombinant DNA technology has revolutionized the production of biologic materials, hormones, vaccines, interferon, and other gene products. Viral genomes have been engineered to serve as replication and expression vectors for both viral and cellular genes. Almost any virus can be converted to a vector if enough is known about its replication functions, transcription controls, and packaging signals. Viral vector technology is based on both DNA viruses (eg, SV40, parvovirus, bovine papillomavirus, adenovirus, herpesviruses, and vaccinia virus) and RNA viruses (eg, poliovirus, Sindbis virus, and retroviruses). Each system has distinct advantages and disadvantages.

Typical eukaryotic expression vectors contain viral regulatory elements (promoters or enhancers) that control transcription of the desired cloned gene placed adjacent, signals for efficient termination and polyadenylation of transcripts, and an intronic sequence bounded by splice donor and acceptor sites. There may be sequences that enhance translation or affect expression in a particular cell type. The principles of recombinant DNA technology are described and illustrated in Chapter 7. This approach offers the possibility of producing large amounts of a pure antigen for structural studies or for vaccine purposes.

NATURAL HISTORY (ECOLOGY) AND MODES OF TRANSMISSION OF VIRUSES

Ecology is the study of interactions between living organisms and their environment. Different viruses have evolved ingenious and often complicated mechanisms for survival in nature and transmission from one host to the next. The mode of transmission used by a given virus depends on the nature of the interaction between the virus and the host.

Viruses may be transmitted in the following ways:

1. Direct transmission from person to person by contact. The major means of transmission include droplet or aerosol infection (eg, influenza, rhinovirus, measles, and smallpox); by sexual contact (eg, papillomavirus, hepatitis B, herpes simplex type 2, and human immunodeficiency virus); by hand–mouth, hand–eye, or mouth–mouth contact (eg, herpes simplex and Epstein-Barr virus); or by exchange of contaminated blood (eg, hepatitis B, hepatitis C, and human immunodeficiency virus).
2. Indirect transmission by the fecal–oral route (eg, enteroviruses, rotaviruses, and hepatitis A) or by fomites (eg, Norwalk virus and rhinovirus).
3. Transmission from animal to animal, with humans an accidental host. Spread may be by bite (rabies) or by droplet or aerosol infection from rodent-contaminated quarters (eg, arenaviruses and hantaviruses).
4. Transmission by means of an arthropod vector (eg, arboviruses, now classified primarily as togaviruses, flaviviruses, and bunyaviruses).

At least three different transmission patterns have been recognized among the arthropod-borne viruses:

- 1. **Human–arthropod cycle: Examples**—Urban yellow fever, dengue. This occurs in densely populated areas infested with competent vectors.

- 2. **Lower vertebrate–arthropod cycle with tangential infection of humans: Examples**—Jungle yellow fever, St. Louis encephalitis. This is a more common mechanism with humans as an accidental “dead end” host.

- 3. **Arthropod–arthropod cycle with occasional infection of humans and lower vertebrates: Examples**—Colorado tick fever, La Crosse encephalitis.

In this cycle, the virus may be transmitted from the adult arthropod to its offspring through the egg (transovarian passage); thus, the cycle may continue with or without intervention of a viremic vertebrate host.

In vertebrates, the invasion of most viruses evokes a violent reaction, usually of short duration. The result is decisive. Either the host succumbs or it lives until the production of antibodies that neutralize the virus. The period of the active virus is usually short, although persistent or latent infections that last for months to years may occur (hepatitis B, herpes simplex, cytomegalovirus, retroviruses). In arthropod vectors of the virus, the relationship is usually quite different. The viruses produce little or no ill effect and remain active in the arthropod throughout the latter’s natural life. Thus, arthropods, in contrast to vertebrates, act as permanent hosts and reservoirs.

Emerging Viral Diseases

Owing to wide-reaching changes in societal structures, technology, and the environment—plus the decreased effectiveness of previous approaches to disease control—the spectrum of infectious diseases is expanding today. New agents appear,

and diseases once thought to be under control are increasing in incidence as pathogens evolve and spread. The term “emerging infectious diseases” denotes these phenomena.

Viral diseases emerge following one of three general patterns: recognition of a new agent, abrupt increase in illnesses caused by an endemic agent, and invasion of a new host population.

Combinations of factors contribute to disease emergence. Some factors increase human exposure to once-obscure pathogens, others provide for dissemination of once-localized infections, and still others force changes in viral properties or host responses to infection. Factors include: (1) environmental changes (deforestation, damming or other changes in water ecosystems, flood or drought, famine); (2) human behavior (sexual behavior, drug use, outdoor recreation); (3) socioeconomic and demographic phenomena (war, poverty, population growth and migration, urban decay); (4) travel and commerce (highways, international air travel); (5) food production (globalization of food supplies, changes in methods of food processing and packaging); (6) health care (new medical devices, blood transfusions, organ and tissue transplantation, drugs causing immunosuppression, widespread use of antibiotics comorbid conditions); (7) microbial adaptation (new viral strains arising through mutation, recombination or reassortment resulting in changes in transmissibility, virulence, or development of drug resistance); and (8) public health measures (inadequate sanitation and vector control measures, curtailment of prevention programs, lack of trained personnel in sufficient numbers).

Examples of emerging viral agents in different regions of the world include Zika, chikungunya, Ebola, avian influenza, Nipah, hantavirus, human immunodeficiency virus, dengue, West Nile, Rift Valley fever, and bovine spongiform encephalopathy (the latter a prion disease).

Of potential concern also is the possible use of animal organs as xenografts in humans. Because the numbers of available human donor organs cannot meet the needs of all waiting patients, xenotransplantation of nonhuman primate and porcine organs is considered an alternative. Concerns exist about the potential accidental introduction of new viral pathogens from the donor species into humans.

Bioterrorism Agents

Bioterrorism agents are microorganisms (or toxins) that could be used to produce death and disease in humans, animals, or plants for terrorist purposes. Such microorganisms could be genetically modified to increase their virulence, make them resistant to drugs or vaccines, or enhance their ability to be disseminated in the environment.

Potential bioterrorism agents are classified into risk categories based on the ease of dissemination or transmission from person to person, mortality rates, ability to cause public panic, and requirement for public health preparedness. Viral agents in the highest risk category are smallpox and the viral hemorrhagic fevers; highest risk bacteria include the agents of anthrax, botulism, plague, and tularemia.

CHAPTER SUMMARY

- Viruses are the smallest infectious agents and contain only one type of nucleic acid (DNA or RNA).
- Known viruses are highly diverse, varying in size, shape, and genetic content; some types possess a lipid envelope.
- Viruses are classified into groups, designated virus families, based on common properties, such as virion morphology, genome structure, virus protein properties, and strategies of replication.
- Viruses are obligate intracellular parasites and multiply only in living cells. The viral nucleic acid encodes virus-specific products, and the host cell provides energy, biochemical precursors, and biosynthetic machinery.
- Steps in viral replication include attachment to a cell via binding to specific receptors on the cell surface, entry into the cell, uncoating of the viral genome, regulated expression of viral transcripts, synthesis of viral proteins, replication of viral genomic nucleic acid, assembly of new progeny viruses, and release of new virions from the cell. The duration of replication cycles varies widely among different virus types. The infected cells may be killed or may survive with little damage. Not all infections lead to new progeny virus.
- New viral diseases are emerging, termed “emerging infectious diseases,” as new agents are recognized, known agents evolve and spread, and new host populations become infected.
- Some viruses are potential bioterrorism agents based on ease of host-to-host transmission and mortality rates.

REVIEW QUESTIONS

1. Some viruses are characterized by helical symmetry of the viral nucleocapsid. Which of the following statements about viruses with helical symmetry is most accurate?
 - (A) All enveloped viruses with helical symmetry are classified into the same virus family.
 - (B) Helical nucleocapsids are found primarily in DNA-containing viruses.
 - (C) All human viruses with helical nucleocapsids possess an envelope.
 - (D) Excess empty helical particles containing no nucleic acid are commonly produced in infected cells.
2. Virus-infected cells often develop morphologic changes referred to as cytopathic effects. Which of the following statements about virus-induced cytopathic changes is most accurate?
 - (A) They are pathognomonic for an infecting virus.
 - (B) They are rarely associated with cell death.
 - (C) They may include giant cell formation.
 - (D) They can only be seen with an electron microscope.
3. Viruses usually initiate infection by first interacting with receptors on the surface of cells. Which of the following statements is most accurate about cellular receptors for viruses?
 - (A) Cellular receptors for viruses have no known cellular function.
 - (B) All viruses within a given family use the same cellular receptor.
 - (C) All cells in a susceptible host express the viral receptor.
 - (D) Successful infection of a cell by a virus may involve interaction with more than one type of receptor.
4. Which of the following can be used to quantitate the titer of infectious viruses?
 - (A) Plaque assay
 - (B) Electron microscopy
 - (C) Hemagglutination
 - (D) Polymerase chain reaction
 - (E) Enzyme immunoassay
5. Which one of the following states a principle regarding viral nucleic acid?
 - (A) Viruses contain both RNA and DNA.
 - (B) Some viruses contain a segmented genome.
 - (C) Purified viral nucleic acid from any virus is usually infectious.
 - (D) Viral genome sizes are similar among known human viruses.
6. Two mutants of poliovirus have been isolated, one (MutX) with a mutation in gene X and the second (MutY) with a mutation in gene Y. If cells are infected with each mutant alone, no virus is produced. If a cell is coinfecting with both MutX and MutY, which one of the following is most likely to occur?
 - (A) Reassortment of genome segments may occur and give rise to a viable wild-type virus.
 - (B) The genomes may be reverse transcribed to DNA and both MutX and MutY viruses produced.
 - (C) Complementation between the mutant gene products may occur and both MutX and MutY viruses produced.
 - (D) The cells will transform at high frequency because they will not be killed by the poliovirus mutants.
7. Which one of the following viruses possesses an RNA genome that is infectious when purified?
 - (A) Influenza virus
 - (B) Poliovirus
 - (C) Papillomavirus
 - (D) Measles virus
 - (E) Rotavirus
8. Viruses belonging to which of the following groups are likely to establish latent infections?
 - (A) Poxviruses
 - (B) Filoviruses
 - (C) Herpesviruses
 - (D) Influenza viruses
 - (E) Caliciviruses
9. Some viruses encode for a viral RNA-dependent RNA polymerase. Which of the following states a principle about viral RNA polymerases?
 - (A) All RNA viruses carry RNA polymerase molecules inside virus particles because they are needed to initiate the next infectious cycle.
 - (B) Antibodies against the viral RNA polymerase neutralize virus infectivity.
 - (C) Negative-strand RNA viruses supply their own RNA-dependent RNA polymerase because eukaryotic cells lack such enzymes.
 - (D) The viral RNA polymerase protein also serves as a major core structural protein in the virus particle.

10. Which of the following statements regarding virus morphology is true?
 - (A) All RNA viruses are spherical in shape.
 - (B) Some viruses contain flagella.
 - (C) Some viruses with DNA genomes contain a primitive nucleus.
 - (D) Viral surface proteins protect the viral genome from nucleases.
 - (E) Helical nucleocapsids are found with single-stranded DNA viruses.
11. Many viruses can be grown in the laboratory. Which of the following statements about virus propagation is not true?
 - (A) Some viruses can be propagated in cell-free media.
 - (B) Some mammalian viruses can be cultivated in hen's eggs.
 - (C) Some viruses with broad host ranges can multiply in many types of cells.
 - (D) Some human viruses can be grown in mice.
 - (E) Most virus preparations have particle-to-infectious unit ratios greater than 1.
12. Laboratory infections can be acquired when working with viruses unless good laboratory safety practices are followed. Which of the following is not a good biosafety practice?
 - (A) Use of biosafety hoods
 - (B) Use of laboratory coats and gloves
 - (C) Avoidance of pipetting by mouth
 - (D) Flushing experimental waste down laboratory sink
 - (E) Not eating or drinking in the laboratory
13. Small viruses are in the same size range as which of the following?
 - (A) *Staphylococcus* species
 - (B) Serum globulin
 - (C) Red blood cells
 - (D) Eukaryotic ribosomes
 - (E) Mitochondria
14. Which of the following is not an important factor contributing to the phenomenon of emerging viral diseases?
 - (A) International air travel
 - (B) Antibiotic resistance
 - (C) Deforestation
 - (D) War
 - (E) Organ and tissue transplantation
15. Arboviruses are classified into several different virus families but are grouped together based on which of the following common characteristics?
 - (A) Replicate only in humans
 - (B) Contain both RNA and DNA

- (C) Are transmitted by vectors
- (D) Cause hemorrhagic fevers
- (E) Cause encephalitis

Pathogenesis and Control of Viral Diseases

PRINCIPLES OF VIRAL DISEASES

The fundamental process of viral infection is the viral replicative cycle. The cellular response to that infection may range from no apparent effect to cytopathology with accompanying cell death to hyperplasia or cancer.

Viral disease is some harmful abnormality that results from viral infection of the host organism. **Clinical disease** in a host consists of overt signs and symptoms. A **syndrome** is a specific group of signs and symptoms. Viral infections that fail to produce any symptoms in the host are said to be inapparent (subclinical). In fact, most viral infections do not result in the production of disease (Figure 30-1).

Important principles that pertain to viral disease include the following: (1) many viral infections are subclinical; (2) the same disease syndrome may be produced by a variety of viruses; (3) the same virus may produce a variety of diseases; and (4) the outcome in any particular case is determined by both viral and host factors and is influenced by the environmental context and genetics of each.

Viral pathogenesis is the process that occurs when a virus infects a cell and causes cellular changes. **Disease pathogenesis** is a subset of events during an infection that results in disease manifestation in the host. A virus is **pathogenic** for a particular host if it can infect and cause signs of disease in that host. A strain of a certain virus is more **virulent** than another strain if it commonly produces more severe disease in a susceptible host. Viral virulence in intact animals is not necessarily related to cytopathogenicity for cultured cells; viruses highly cytotoxic in vitro may be harmless in vivo, and, conversely, noncytotoxic viruses may cause severe disease.

Important features of two general categories of acute viral diseases (local, systemic) are compared in Table 30-1.

PATHOGENESIS OF VIRAL DISEASES

To produce disease, viruses must enter a host, come in contact with susceptible cells, replicate, and produce cellular injury. Understanding mechanisms of viral pathogenesis at the molecular level is necessary to design effective antiviral strategies. Much of our knowledge of viral pathogenesis is

based on cell culture and animal models because such systems can be readily manipulated and studied.

Steps in Viral Pathogenesis

Specific steps involved in viral pathogenesis are the following: viral entry into the host, primary viral replication, viral spread, cellular injury, host immune response, viral clearance or establishment of persistent infection, and viral shedding.

A. Entry and Primary Replication

Most viral infections are initiated when viruses attach and enter cells of one of the body surfaces—skin, respiratory tract, gastrointestinal tract, urogenital tract, or conjunctiva. The majority of these enter their hosts through the mucosa of the respiratory or gastrointestinal tract (Table 30-2). However, some viruses can be introduced directly into tissues or the bloodstream through skin wounds, needles (eg, hepatitis B and C and human immunodeficiency virus [HIV]), blood transfusions, or insect vectors (arboviruses).

After entry, the viral nucleic acid and virion-associated proteins interact with cellular macromolecules to ultimately produce new virions that are released from the host cell by shedding or cell lysis. The specific mechanisms of viral replication are highly variable and can be quite complex, relying on one or more intermediate stages of production. The released virions are then able to attach and infect other cells in the immediate vicinity, causing local spread of infection.

B. Viral Spread and Cell Tropism

Some viruses, such as influenza viruses (respiratory infections) and noroviruses (gastrointestinal infections), produce disease at the portal of entry and typically do not spread systemically. Others can spread to distant sites (eg, cytomegalovirus [CMV], HIV, and rabies virus) and cause additional disease manifestations (Figure 30-2). Mechanisms of viral spread vary, but the most common route is via the bloodstream or lymphatics. The presence of virus in the blood is called **viremia**. Virions may be free in the plasma (eg, enteroviruses and togaviruses) or associated with particular cell types (eg, measles virus) (Table 30-3). Viruses may multiply within those cells (eg, Epstein-Barr virus [EBV] is lymphotropic and can

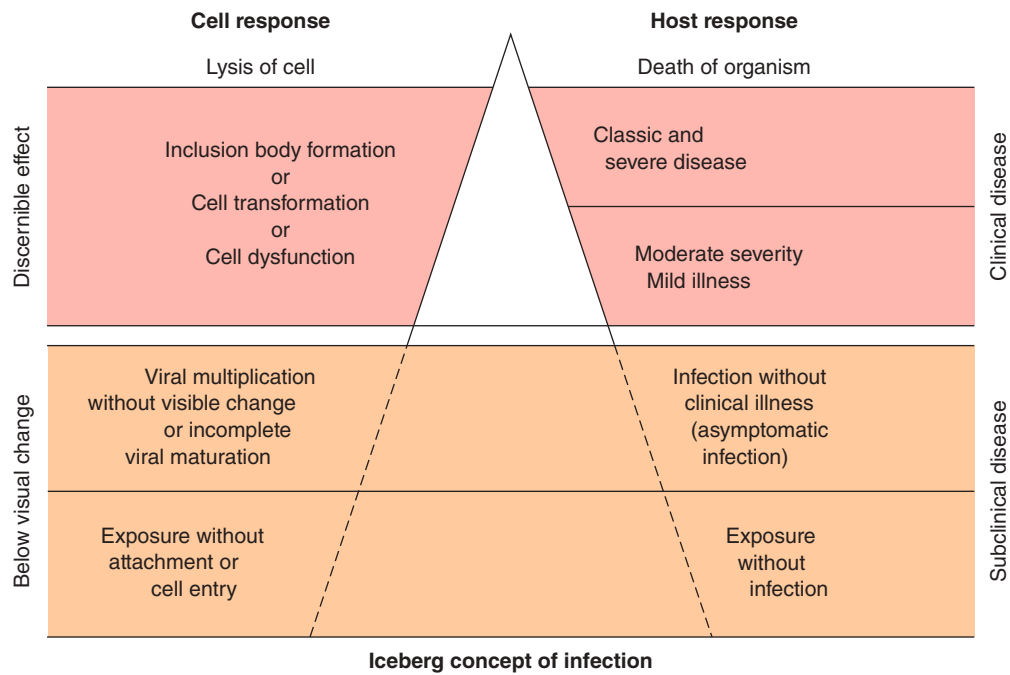

FIGURE 30-1 Types of host and cellular responses to virus infection. (Modified with permission from Evans AS: Epidemiological concepts. In Evans AS, Brachman PS [editors]: *Bacterial Infections of Humans*, 3rd ed. Plenum, 1998. With kind permission of Springer Science+Business Media.)

replicate within white blood cells as it spreads). Some viruses travel along neuronal axons to spread within the host (eg, rabies migrates to the brain, herpes simplex virus [HSV] travels to ganglia to produce latent infection).

Viruses tend to exhibit organ and cell-type specificities, or **viral tropism**. Tropism determines the pattern of systemic illness produced during a viral infection. As an example, hepatitis B virus has a tropism for liver hepatocytes, and hepatitis is the primary disease caused by the virus.

Tissue and cellular tropism by a given virus usually reflect the presence of specific **cell surface receptors** for that virus. Receptors are components of the cell surface with which a region of the viral surface (capsid or envelope) can specifically interact and initiate infection. Receptors are cell constituents that function in normal cellular metabolism but also happen to have an affinity for a particular virus. The

identity of the specific cellular receptor is known for some viruses but is unknown in many cases.

The level of cell surface receptor expression and post-translational modifications affect the ability of viruses to infect various cell types. For example, influenza virus requires cellular proteases to cleave virally encoded hemagglutinin in order to enable viruses to infect new cells, and expression of a glycolytic enzyme (neuraminidase) to release newly formed virions. Multiple rounds of viral replication will not occur in tissues that do not express the appropriate proteins.

C. Cell Injury and Clinical Illness

Destruction of virus-infected cells in the target tissues and physiologic alterations produced in the host by the tissue injury are partly responsible for the development of disease. Some tissues, such as intestinal epithelium, can rapidly regenerate and withstand extensive damage better than others, such as the brain. Some physiologic effects may result from nonlethal impairment of specialized functions of cells, such as loss of hormone production. Clinical illness from viral infection is the result of a complex series of events, and many of the factors that determine degree of illness are unknown. General symptoms associated with many viral infections, such as malaise and anorexia, may result from host response functions such as cytokine production. Clinical illness is an insensitive indicator of viral infection; inapparent infections by viruses are very common.

D. Recovery from Infection

Following a viral infection, the host will succumb, recover, or establish a chronic infection. Recovery mechanisms include both

TABLE 30-1 Important Features of Acute Viral Diseases

	Local Infections	Systemic Infections
Specific disease example	Influenza	Measles
Site of pathology	Portal of entry	Distant site
Incubation period	Relatively short	Relatively long
Viremia	Absent	Present
Duration of immunity	Variable—may be short	Usually lifelong
Role of secretory antibody (IgA) in resistance	Usually important	Usually not important

TABLE 30-2 Common Routes of Viral Infection in Humans

Route of Entry	Virus Group	Produce Local Symptoms at Portal of Entry	Produce Generalized Infection Plus Specific Organ Disease
Respiratory tract	Parvovirus		B19
	Adenovirus	Most types	
	Herpesvirus	Epstein-Barr virus, herpes simplex virus	Varicella-zoster virus
	Poxvirus		Smallpox virus
	Picornavirus	Rhinoviruses	Some enteroviruses
	Togavirus		Rubella virus
	Coronavirus	Most types	
	Orthomyxovirus	Influenza virus	
	Paramyxovirus	Parainfluenza viruses, respiratory syncytial virus	Mumps virus, measles virus
Mouth, intestinal tract	Adenovirus	Types 40 and 41	
	Calicivirus	Noroviruses	
	Herpesvirus	Epstein-Barr virus, herpes simplex virus	Cytomegalovirus
	Picornavirus		Some enteroviruses, including poliovirus, and hepatitis A virus
	Reovirus	Rotaviruses	
Skin			
Mild trauma	Papillomavirus	Most types	
	Herpesvirus	Herpes simplex virus	
	Poxvirus	Molluscum contagiosum virus, orf virus	
Injection	Hepadnavirus		Hepatitis B
	Herpesvirus		Epstein-Barr virus, cytomegalovirus
	Retrovirus		Human immunodeficiency virus
Bites	Togavirus		Many species, including eastern equine encephalitis virus
	Flavivirus		Many species, including yellow fever virus
	Rhabdovirus		Rabies virus

innate and adaptive immune responses. Interferon (IFN) and other cytokines, humoral and cell-mediated immunity, and possibly other host defense factors are involved. The relative importance of each component differs with the virus and the disease.

The importance of host factors in influencing the outcome of viral infections is illustrated by an incident in the 1940s in which 45,000 military personnel were inoculated with yellow fever virus vaccine that was contaminated with hepatitis B virus. Although the personnel were presumably subjected to comparable exposures, clinical hepatitis occurred in only 2% (914 cases), and of those only 4% developed serious disease. The genetic basis of **host susceptibility** remains to be determined for most infections.

In acute infections, recovery is associated with viral clearance and viral-specific antibody production. Establishment of a chronic infection involves complex interplay

between viral and host immune factors, and the virus may enter a life-long latent state, or subsequently reactivate and cause disease months to years later.

E. Virus Shedding

The last stage in pathogenesis is the shedding of infectious virus into the environment. This is a necessary step to maintain a viral infection in populations of hosts. Shedding usually occurs from the body surfaces involved in viral entry (see Figure 30-2). Shedding occurs at different stages of disease depending on the particular agent involved. During viral shedding, an infected individual is infectious to contacts. In some viral infections, such as rabies, humans represent dead-end infections, and shedding does not occur. Two examples of the pathogenesis caused by disseminated viral infections are shown in Figure 30-3.

FIGURE 30-2 Mechanisms of spread of virus through the body in human viral infections. + indicates possible sites of viral replication; large arrows indicate sites of shedding of virus, with illustrative examples of diseases in which that route of excretion is important. Transfer from blood is by transfusion with hepatitis B and by mosquito bite in certain arboviral infections. SSPE, subacute sclerosing panencephalitis. Host Immune Response

The outcome of viral infections reflects the interplay between viral and host factors. Nonspecific host defense mechanisms are usually elicited very soon after viral infection. The most prominent among the innate immune responses is the induction of cytokines such as IFNs (see later discussion). These responses help inhibit viral growth during the time it takes to induce specific humoral and cell-mediated immunity.

A. Innate Immune Response

The innate immune response is largely mediated by IFNs, which are host-coded proteins that are members of the large cytokine family that inhibit viral replication. They are produced very quickly (within hours) in response to viral infection or other inducers and are one of the body’s first responders in the defense against viral infection. IFNs also modulate humoral and cellular immunity and have broad cell growth regulatory activities.

There are multiple species of IFNs that fall into three general groups: designated IFN-α, IFN-β, and IFN-γ (Table 30-4). Both IFN-α and IFN-β are considered type I or viral IFNs; IFN-γ is type II or immune IFN. Infection with viruses is a potent inducer of IFN-α and IFN-β production; RNA viruses are stronger inducers of IFN than DNA viruses. IFNs also can be induced by double-stranded RNA and bacterial endotoxin. IFN-γ is not produced in response to most viruses but is induced by mitogen stimulation.

IFNs are detectable soon after viral infection in intact animals, and viral production then decreases (Figure 30-4). Antibody does not appear in the blood of the animal until several days after viral production has abated. This temporal relationship suggests that IFN plays a primary role in the nonspecific defense of the host against viral infections, as well as the fact that agammaglobulinemic individuals usually

recover from primary viral infections about as well as normal people.

IFN is secreted and binds to cell receptors, where it induces an antiviral state by prompting the synthesis of other proteins that inhibit viral replication. Several pathways appear to be involved, including: (1) a dsRNA-dependent protein kinase, PKR, which phosphorylates and inactivates cellular initiation factor eIF-2 and thus prevents formation of the initiation complex needed for viral protein synthesis; (2) an oligonucleotide synthetase, 2-5A synthetase, which activates a cellular endonuclease, RNase L, which in turn degrades mRNA; (3) a phosphodiesterase, which inhibits peptide chain elongation; and (4) nitric oxide synthetase, which is induced by IFN-γ in macrophages.

Viruses display different mechanisms that block the inhibitory activities of IFNs on virus replication. Examples include specific viral proteins that block induction of expression of IFN (herpesvirus, papillomavirus, Filovirus, hepatitis C virus, rotavirus), block the activation of the key PKR protein kinase (adenovirus, herpesviruses), activate a cellular inhibitor of PKR (influenza, poliovirus), block IFN-induced signal transduction (adenovirus, herpesviruses, hepatitis B virus), or neutralize IFN-γ by acting as a soluble IFN receptor (myxoma virus).

B. Adaptive Immune Response

Both humoral and cellular components of the adaptive immune response are involved in control of viral infections. Viruses elicit a tissue response different from the response to pathogenic bacteria. Whereas polymorphonuclear leukocytes form the principal cellular response to the acute inflammation caused by pyogenic bacteria, infiltration with mononuclear cells and lymphocytes characterizes the inflammatory reaction of uncomplicated viral lesions.

Virus-encoded proteins serve as targets for the immune response. Virus-infected cells may be lysed by cytotoxic T lymphocytes as a result of recognition of viral polypeptides on the cell surface. Humoral immunity protects the host against reinfection by the same virus. Neutralizing antibody directed against capsid proteins blocks the initiation of viral infection, presumably at the stage of attachment, entry, or uncoating. Secretory IgA antibody is important in protecting against infection by viruses through the respiratory or gastrointestinal tracts.

Special characteristics of certain viruses may have profound effects on the host’s immune response. Some viruses infect and damage cells of the immune system. The most dramatic example is the human retrovirus HIV that infects T lymphocytes and destroys their ability to function, leading to acquired immunodeficiency syndrome (AIDS) (see Chapter 44).

Viruses have evolved a variety of ways that serve to suppress or evade the host immune response and thus avoid being eradicated. Often, the viral proteins involved in modulating the host response are not essential for growth of the virus in

FIGURE 30-3 Schematic illustrations of the pathogenesis of disseminated viral infections (mousepox and poliomyelitis). These viruses attach and replicate locally, spreading through the lymphatics and bloodstream to distant sites where they multiply further and can produce disease, followed by shedding into the environment from the initial site of infection. CNS, central nervous system. (Courtesy of F Fenner.)

tissue culture, and their properties are realized only in pathogenesis experiments in animals. In addition to infecting cells of the immune system and abrogating their function (HIV), they may infect neurons that express little or no class I major histocompatibility complex (MHC) (herpesvirus), or they may encode immunomodulatory proteins that inhibit MHC function (adenovirus, herpesvirus) or inhibit cytokine activity (poxvirus, measles virus). Viruses may mutate and change antigenic sites on virion proteins (influenza virus, HIV) or may downregulate the level of expression of viral cell surface proteins (herpesvirus). Virus-encoded microRNAs may target specific cellular transcripts and suppress proteins integral to the host innate immune response (polyomavirus, herpesvirus).

The immune response to one virus or vaccine may exacerbate the disease caused by subsequent infection with similar strains. For example, dengue virus hemorrhagic fever can develop in persons who already have had at least one prior infection with another dengue serotype due to the intense host response to infection.

Another potential adverse effect of the immune response is the development of autoantibodies through a process known as *molecular mimicry*. If a viral antigen elicits antibodies that additionally recognize an antigenic determinant on a cellular protein in normal tissues, cellular injury or loss of function unrelated to viral infection might result. The host may then experience postinfectious autoimmune disease, such as Guillain-Barre syndrome associated with prior measles infection.

Viral Persistence: Chronic and Latent Virus Infections

Infections are **acute** when a virus first infects a susceptible host. Viral infections are usually self-limiting, but some may persist for long periods of time in the host. Long-term virus–host interaction may take several forms. **Chronic infections** (also called **persistent infections**) are those in which replicating virus can be continuously detected, often at low levels;

TABLE 30-4 Properties of Human Interferons

Property	Type		
	Alpha	Beta	Gamma
Current nomenclature	IFN- α	IFN- β	IFN- γ
Former designation	Leukocyte	Fibroblast	Immune interferon
Type designation	Type I	Type I	Type II
Number of genes that code for family	≥ 20	1	1
Principal cell source	Most cell types	Most cell types	Lymphocytes
Inducing agent	Viruses; dsRNA	Viruses; dsRNA	Mitogens
Stability at pH 2.0	Stable	Stable	Labile
Glycosylated	No	Yes	Yes
Introns in genes	No	No	Yes
Chromosomal location of genes	9	9	12
Size of secreted protein (number of amino acids)	165	166	143
IFN receptor	IFNAR	IFNAR	IFNGR
Chromosomal location of IFN receptor genes	21	21	6

dsRNA, double-stranded RNA; IFN, interferon.

mild or no clinical symptoms may be evident. **Latent infections** are those in which the virus persists in an occult (hidden or cryptic) form most of the time when no new virus is produced. There can be intermittent flare-ups of clinical disease; infectious virus can be recovered during these times. Viral sequences may be detectable by molecular techniques in tissues harboring latent infections. **Inapparent** or **subclinical infections** are those that give no overt sign of their presence.

Chronic infections occur with a number of animal viruses, and the persistence in certain instances depends on the age of the host when infected. In humans, for example, rubella virus and CMV infections acquired in utero characteristically result in viral persistence that is of limited duration, probably because of development of the immunologic capacity to react to the infection as the infant matures. Infants infected with hepatitis B virus frequently become persistently infected (chronic carriers); most carriers are asymptomatic (see Chapter 35).

FIGURE 30-4 Illustration of kinetics of interferon and antibody synthesis after respiratory viral infection. The temporal relationships suggest that interferons are involved in the host’s early defense system against viral infections.

Herpesviruses typically produce latent infections. HSVs enter the sensory ganglia and persist in a noninfectious state (Figure 30-5). There may be periodic reactivations during which lesions containing infectious virus appear at peripheral sites (eg, fever blisters). Chickenpox virus (varicella-zoster) also becomes latent in sensory ganglia. Recurrences are rare and occur years later, usually following the distribution of a peripheral nerve (shingles). Other members of the herpesvirus family also establish latent infections, including CMV and EBV. All may be reactivated by immunosuppression. Consequently, reactivated herpesvirus infections may be a serious complication for persons receiving immunosuppressant therapy.

Persistent viral infections play a far-reaching role in human disease. Persistent viral infections are associated with certain types of cancers in humans (see Chapter 43) as well as with progressive degenerative diseases of the CNS of humans (see Chapter 42). Examples of different types of persistent viral infections are presented in Figure 30-6.

Spongiform encephalopathies are a group of chronic, progressive, fatal infections of the CNS caused by unconventional, transmissible agents called **prions** (see Chapter 42). Prions are not viruses, but are proteins whose structural alterations can cause conformational changes in host proteins leading to aggregation and dysfunction, and are transmissible similar to other infectious agents. Some examples of prion infections are scrapie in sheep, bovine spongiform encephalopathy in cattle, and kuru and Creutzfeldt-Jakob disease in humans.

Overview of Acute Viral Respiratory Infections

Many types of viruses gain access to the human body via the respiratory tract, primarily in the form of aerosolized

FIGURE 30-5 Latent infections by herpesviruses. Examples are shown for both herpes simplex and varicella-zoster viruses. Primary infections occur in childhood or adolescence, followed by establishment of latent virus in the cerebral or spinal ganglia. Later activation causes recurrent herpes simplex or zoster. CMI, cell-mediated immunity. (Modified from Mims CA, White DO: *Viral Pathogenesis and Immunology*. Copyright © 1984 by Blackwell Science Ltd. With permission from Wiley.)

droplets or saliva. This is the most frequent means of viral entry into the host. Successful infection occurs despite normal host protective mechanisms, including the mucus covering most surfaces, ciliary action, collections of lymphoid cells, alveolar macrophages, and secretory IgA. Many infections remain localized in the respiratory tract, although some viruses produce their characteristic disease symptoms after systemic spread (eg, chickenpox, measles, and rubella; see Table 30-2 and Figure 30-2).

Respiratory infections impose a heavy disease burden worldwide. Respiratory infections are the most common cause of mortality for children younger than 5 years, with diarrheal disease the second leading cause. Disease symptoms exhibited by the host depend on whether the infection is concentrated in the upper or lower respiratory tract (Table 30-5). The severity of respiratory infection can range from inapparent to overwhelming. Although definitive diagnosis requires isolation of the virus, identification of viral gene sequences, or demonstration of a rise in antibody titer, the specific viral disease can frequently be deduced by considering the major symptoms, the patient’s age, the time of year, and any pattern of illness in the community.

Overview of Viral Infections of the Gastrointestinal Tract

Many viruses initiate infection via the alimentary tract. Viruses are exposed in the intestinal tract to secretory IgA and harsh elements involved in the digestion of food: acid, bile salts (detergents), and proteolytic enzymes. Consequently, viruses able to initiate infection by this route are resistant to acid and bile salts.

Acute gastroenteritis is the designation for short-term gastrointestinal disease with symptoms ranging from mild, watery diarrhea to severe febrile illness characterized by vomiting, diarrhea, and systemic manifestations. Rotaviruses, noroviruses, and caliciviruses are major causes of gastroenteritis. Infants and children are affected most often, and large outbreaks can occur, making these a significant public health concern.

Enteroviruses, coronaviruses, and adenoviruses also infect the gastrointestinal tract, but those infections are typically asymptomatic. Some enteroviruses, notably polioviruses, and hepatitis A virus are important causes of systemic disease but do not produce intestinal symptoms.

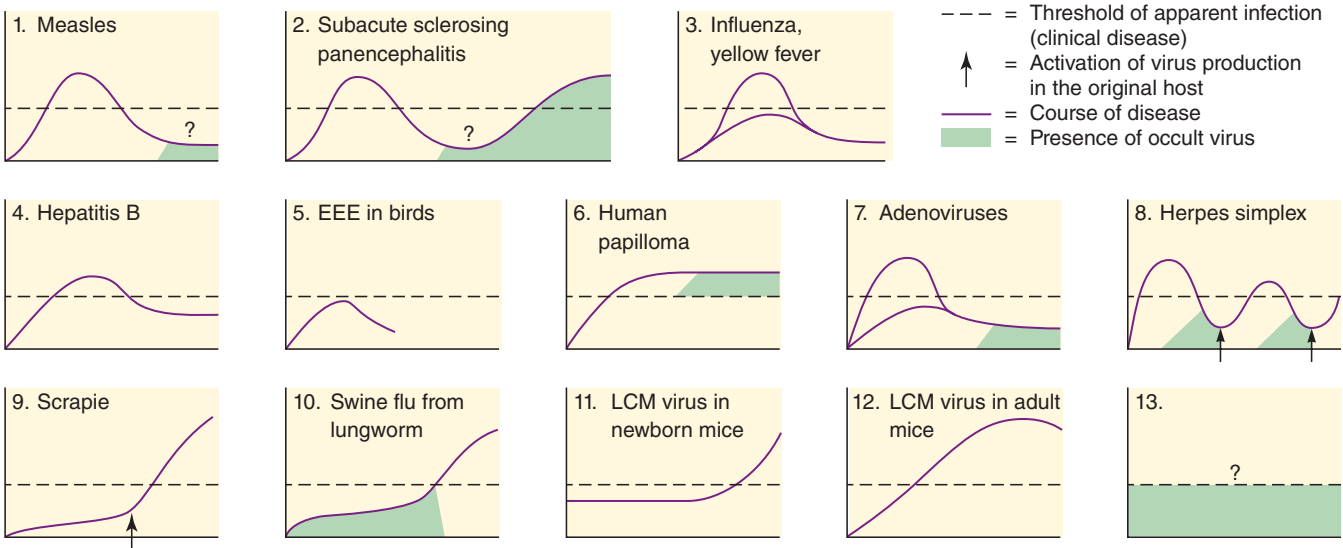

FIGURE 30-6 Different types of virus–host interactions: apparent (clinical disease), inapparent (subclinical), chronic, latent, occult, and slow infections. **(1)** Measles runs an acute, almost always clinically apparent course resulting in long-lasting immunity. **(2)** Measles may also be associated with persistence of latent infection in subacute sclerosing panencephalitis (see Chapter 40). **(3)** Yellow fever and influenza follow a pattern similar to that of measles except that infection may be more often subclinical than clinical. **(4)** In hepatitis B, recovery from clinical disease may be associated with chronic infection in which fully active virus persists in the blood. **(5)** Some infections are, in a particular species, always subclinical, such as eastern equine encephalomyelitis (EEE) in some species of birds that then act as reservoirs of the virus. **(6)** For human papillomavirus, the course of infection is chronic; when cervical cancer develops, the virus present is occult (not replicating). **(7)** Infection of humans with certain adenoviruses may be clinical or subclinical. There may be a long latent infection during which virus is present in small quantity; virus may also persist after the illness. **(8)** The periodic reactivation of latent HSV, which may recur throughout life in humans, often follows an initial acute episode of stomatitis in childhood. **(9)** Infection may be unrecognized for long periods of time before it becomes apparent. Examples of such “slow” infections characterized by long incubation periods are scrapie in sheep and kuru in humans (caused by prions, not viruses). **(10)** In pigs that have eaten virus-bearing lungworms, swine “flu” is occult until the appropriate stimulus induces viral production and, in turn, clinical disease. **(11)** Lymphocytic choriomeningitis (LCM) virus may be established in mice by in utero infection. A form of immunologic tolerance develops in which virus-specific T cells are not activated. Antibody is produced against viral proteins; this antibody and circulating LCM virus form antigen–antibody complexes that produce immune complex disease in the host. The presence of LCM virus in this chronic infection (circulating virus with little or no apparent disease) may be revealed by transmission to an indicator host (eg, adult mice from a virus-free stock). **(12)** All adult mice develop classic acute symptoms of LCM and frequently die. **(13)** The possibility is shown of infection with an occult virus that is not detectably replicating. Proof of the presence of such a virus remains a difficult task that, however, is attracting the attention of cancer investigators (see Chapter 43).

TABLE 30-5 Viral Infections of the Respiratory Tract

Syndromes	Main Symptoms	Most Common Viral Causes ^a		
		Infants	Children	Adults
Common cold	Nasal obstruction, nasal discharge	Rhino Adeno	Rhino Adeno	Rhino Corona
Pharyngitis	Sore throat	Adeno	Adeno Coxsackie	Adeno Coxsackie
Laryngitis or croup	Hoarseness, “barking” cough	Parainfluenza Influenza	Parainfluenza Influenza	Parainfluenza Influenza
Tracheobronchitis	Cough	Parainfluenza Respiratory syncytial	Parainfluenza Influenza	Influenza Adeno
Bronchiolitis	Cough, dyspnea	Respiratory syncytial Parainfluenza	Rare	Rare
Pneumonia	Cough, chest pain	Respiratory syncytial Influenza	Influenza Parainfluenza	Influenza Adeno

^aMost commonly reported respiratory viruses vary, depending on the study design, subject population, detection methods, and other factors (eg, time of year).

Overview of Viral Skin Infections

The keratinized epithelium of the skin is a tough barrier to the entry of viruses. However, a few viruses are able to breach this barrier and initiate infection of the host (see Table 30-2). Some obtain entry through small abrasions of the skin (poxviruses, papillomaviruses, HSVs), others are introduced by the bite of arthropod vectors (arboviruses) or infected vertebrate hosts (rabies virus, herpes B virus), and still others are injected during blood transfusions or other manipulations involving contaminated needles, such as acupuncture and tattooing (hepatitis B virus, HIV).

A few agents remain localized and produce lesions at the site of entry (eg, papillomaviruses, molluscum contagiosum), but most spread to other sites. The epidermal layer is devoid of blood vessels and nerve fibers, so viruses that infect epidermal cells tend to stay localized. Viruses that are introduced deeper into the dermis have access to blood vessels, lymphatics, dendritic cells, and macrophages and usually spread and cause systemic infections.

Many of the generalized skin rashes associated with viral infections develop because virus spreads to the skin via the bloodstream after replication at some other site. Such infections originate by another route (eg, measles virus infections occur via the respiratory tract), with hematogenous spreading to the skin and rash formation.

Lesions in viral skin rashes are designated as macules, papules, vesicles, or pustules. Macules, which are caused by local dilation of dermal blood vessels, progress to papules if edema and cellular infiltration are present in the area. Vesicles occur if the epidermis becomes focally detached, and they become pustules if an inflammatory reaction delivers polymorphonuclear leukocytes to the lesion. Ulceration and scabbing follow. Hemorrhagic and petechial rashes occur when there is disruption of the dermal vessels.

Skin lesions frequently play no role in viral transmission. Infectious virus is not shed from the maculopapular rash of measles or from rashes associated with arbovirus infections. In contrast, skin lesions are important in the spread of poxviruses and HSVs. Infectious virus particles are present in high titers in the fluid of these vesiculopustular rashes, and they are able to initiate infection by direct contact with other hosts. However, even in these instances, it is believed that virions in oropharyngeal secretions may be more important to disease transmission than the skin lesions.

Overview of Viral Infections of the Central Nervous System

Viruses can gain access to the brain by two routes: by the bloodstream (hematogenous spread) and by peripheral nerve fibers (neuronal spread). Access from the blood may occur by growth through the endothelium of small cerebral vessels; by passive transport across the vascular endothelium; by passage through the choroid plexus to the cerebrospinal fluid; or by transport within infected monocytes, leukocytes,

or lymphocytes. After the blood–brain barrier is breached, more extensive spread throughout the brain and spinal cord is possible. There tends to be a correlation between the level of viremia achieved by a bloodborne neurotropic virus and its neuroinvasiveness.

The other pathway to the CNS is via peripheral nerves. Virions can be taken up at sensory nerve or motor endings and be moved within axons, through endoneural spaces, or by Schwann cell infections. Herpesviruses travel in axons to be delivered to dorsal root ganglia neurons.

The routes of spread are not mutually exclusive, and a virus may use more than one method. Many viruses, including herpes-, toga-, flavi-, entero-, rhabdo-, paramyxo-, and bunyaviruses, can infect the CNS and cause meningitis, encephalitis, or both. Encephalitis caused by HSV is the most common viral cause of sporadic encephalitis in humans.

Pathologic reactions to cytotoxic viral infections of the CNS include necrosis, inflammation, and phagocytosis by glial cells. The cause of symptoms in some other CNS infections, such as rabies, is unclear. The postinfectious encephalitis that occurs after measles infections (about one per 1000 cases) and more rarely after rubella infections is characterized by autoimmune demyelination without neuronal degeneration.

There are several rare neurodegenerative disorders, sometimes referred to as slow virus infections, that are uniformly fatal. Features of these infections include a long incubation period (months to years) followed by the onset of clinical illness and progressive deterioration, resulting in death in weeks to months; usually only the CNS is involved. Some of these infections, such as progressive multifocal leukoencephalopathy (JC polyomavirus) in immunocompromised hosts and subacute sclerosing panencephalitis (measles virus), are caused by typical viruses. In contrast, the subacute spongiform encephalopathies, typified by scrapie, are prion diseases. In those infections, characteristic neuropathologic changes occur, but no inflammatory or immune response is elicited.

Overview of Congenital Viral Infections

Few viruses produce disease in the human fetus. Most maternal viral infections do not result in viremia and fetal involvement. However, if the virus crosses the placenta and infection occurs in utero, serious damage may be done to the fetus.

Three principles are involved in the production of congenital defects: (1) the ability of the virus to infect the pregnant woman and be transmitted to the fetus; (2) the stage of gestation at which infection occurs; and (3) the ability of the virus to cause damage to the fetus directly (by infection of the fetus) or indirectly (by infection of the mother), resulting in an altered fetal environment (eg, fever). The sequence of events that may occur before and after viral invasion of the fetus is shown in Figure 30-7.

Rubella virus and CMV are presently the primary viruses responsible for congenital defects in humans (see Chapters 33

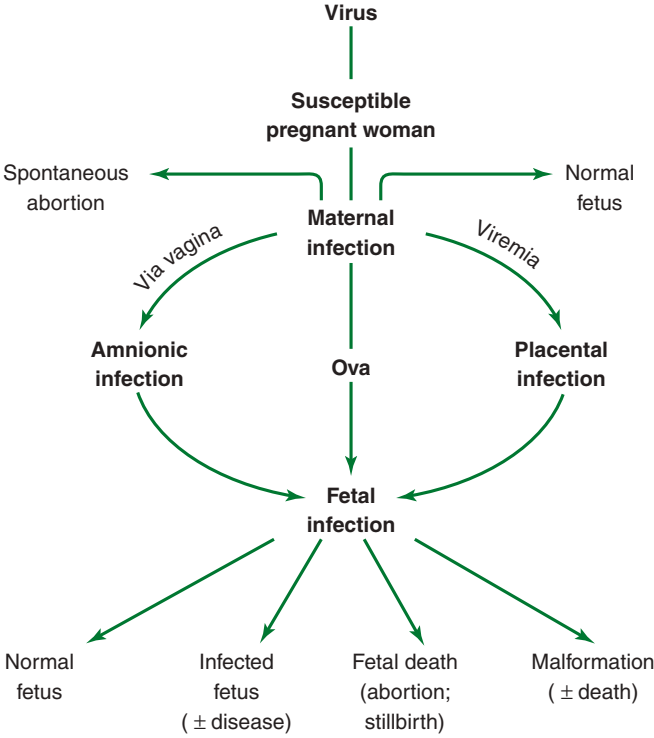

FIGURE 30-7 Viral infection of the fetus. (Courtesy of L Catalano and J Sever.)

and 40). Congenital infections can also occur with herpes simplex, varicella-zoster, hepatitis B, measles, and mumps virus, as well as with HIV, parvovirus, and some enteroviruses (Table 30-6).

In utero infections may result in fetal death, premature birth, intrauterine growth retardation, or persistent postnatal infection. Developmental malformations, including congenital heart defects, cataracts, deafness, microcephaly, and limb hypoplasia, may result. Viral infection and multiplication

may destroy rapidly replicating fetal cells or alter cell function. Lytic viruses, such as herpes simplex, may result in fetal death. Less cytolytic viruses, such as rubella, may slow the rate of cell division. If this occurs during a critical phase in organ development, structural defects and congenital anomalies may result.

Many of the same viruses can produce serious disease in newborns (see Table 30-6). Such infections may be contracted from the mother during delivery (perinatal) from contaminated genital secretions, stool, or blood. Less commonly, infections may be acquired during the first few weeks after birth (postnatal) from maternal sources, family members, hospital personnel, or blood transfusions. For example, HIV can be transmitted by the breast milk of an infected mother.

Effect of Host Age

Host age is a factor in viral pathogenicity. More severe disease is often produced in newborns. In addition to maturation of the immune response with age, there seem to be age-related changes in the susceptibility of certain cell types to viral infection. Viral infections usually can occur in all age groups but may have their major impact at different times of life. Examples include rubella, which is most serious during gestation; rotavirus, which is most serious for infants; and St. Louis encephalitis, which is most serious in elderly adults.

Diagnosis of Viral Infections

There are several different ways in which viral infections are diagnosed (Figure 30-8) (see Chapter 47). Rapid antigen detection methods use virus-specific monoclonal antibodies for detection. Nucleic acid or polymerase chain reaction (PCR) tests use specific primers and probes to detect viral nucleic acid. The PCR tests can be multiplexed, allowing detection of multiple viruses concurrently. Virus culture and serological testing for specific antibody responses are

TABLE 30-6 Acquisition of Significant Perinatal Viral Infections

Virus	Severity by Time of Infection			Neonatal Incidence (per 1000 Live Births)
	Prenatal (In Utero)	Natal (During Delivery)	Postnatal (After Delivery)	
Rubella	+	–	Rare	0.1–0.7
Cytomegalovirus	+	++	+	5–25
Herpes simplex	+	++	+	0.03–0.5
Varicella-zoster	+	Rare	Rare	Rare
Hepatitis B	+	++	+	0–7
Enterovirus	+	++	+	Uncommon
Human immunodeficiency virus	+	++	+	Variable
Parvovirus B19	+	–	Rare	Rare

Signs and symptoms: Patient is observed for manifestations of typical virus infections. This is herpes simplex, type 1.

Cells taken from patient are examined for evidence of viral infection, such as cytopathic effects (1) or virus antigen detected by fluorescent staining (2).

Culture techniques: Viruses require a living host to multiply.

Electron microscope is used to view virus directly. Viruses are sufficiently unique in structure that they can be differentiated to family or genus.

Genetic analysis (PCR): Detection of viral nucleic acid using specific probes.

Serological testing for antibodies

FIGURE 30-8 Summary of methods used to diagnose viral infections. Antigen detection tests and nucleic acid assays are most commonly used diagnostically because results can be obtained quickly. (Reproduced with permission from Talaro KP: *Foundations in Microbiology: Basic Principles*, 6th ed. McGraw-Hill, 2008. © McGraw-Hill Education.)

slow to provide results but are useful for epidemiologic and research studies. More recently developed nucleic acid-based technology such as automated multiplexed PCR, high-density microarrays, and deep sequencing allow for detection of multiple viruses in a single assay. Because there are relatively few targeted antiviral therapies, knowledge of the specific infecting viral agent may not alter patient treatment, but it can be useful to determine the prognosis and for patient management.

PREVENTION AND TREATMENT OF VIRAL INFECTIONS

Antiviral Chemotherapy

Unlike viruses, bacteria and protozoans do not rely on host cellular machinery for replication, so processes specific to these organisms provide ideal targets for the development of antibacterial and antiprotozoal drugs. Because viruses are obligate intracellular parasites, antiviral agents must be capable of selectively inhibiting viral functions without damaging the host, making the development of such drugs very difficult. Another limitation is that many rounds of virus replication occur during the incubation period and the virus has spread before symptoms appear, making drug treatment after the development of clinical symptoms relatively ineffective.

There is a need for antiviral drugs active against viruses for which vaccines are not available or not highly effective because of a multiplicity of serotypes (eg, rhinoviruses) or because of constantly changing viral antigens (eg, influenza, HIV). Antivirals can be used to treat established infections when vaccines would not be effective. Antivirals are needed to reduce morbidity and economic loss caused by viral infections and to treat increasing numbers of immunosuppressed patients who are at increased risk of severe disease.

Molecular virology studies are succeeding in identifying virus-specific functions that can serve as targets for antiviral therapy. Stages during viral infections that could be targeted include attachment of virus to host cells, uncoating of the viral genome, viral nucleic acid synthesis, translation of viral proteins, and assembly and release of progeny virus particles. It has been very difficult to develop antivirals that can distinguish viral from host replicative processes, but there have been successful drugs developed, particularly for chronic infections (eg, HIV, hepatitis C). A number of compounds have been developed that are of value in treatment of viral diseases (Table 30-7). The mechanisms of action vary among antivirals, and can target a viral protein enzymatic activity or block host-virus protein interaction. Some drugs must be activated by enzymes in the cell before it can act as an inhibitor of viral replication; the most selective drugs are activated by a virus-encoded enzyme in the infected cell.

Future work is necessary to minimize the emergence of drug-resistant variant viruses, to reduce drug toxicities, to design more specific antivirals based on molecular insights

into the structure of other viral targets, and to develop antivirals for viruses for which no drugs currently exist.

A. Nucleoside and Nucleotide Analogs

The majority of available antiviral agents are nucleoside analogs. They inhibit nucleic acid replication by inhibition of viral polymerases essential for nucleic acid replication. In addition, some analogs are incorporated into the nucleic acid as chain terminators and block further synthesis.

Analogues can inhibit cellular enzymes as well as virus-encoded enzymes. The most effective analogs are those that are able to specifically inhibit virus-encoded enzymes, with minimal inhibition of analogous host cell enzymes. Because of high mutation rates, virus variants resistant to the drug usually arise over time, sometimes quite rapidly. The use of combinations of antiviral drugs can delay the emergence of resistant variants (eg, “triple-drug” therapy used to treat HIV infections).

B. Reverse Transcriptase Inhibitors

Nonnucleoside reverse transcriptase inhibitors act by binding directly to virally encoded reverse transcriptase and inhibiting its activity. However, resistant mutants emerge rapidly, making these useful only in the context of multi-drug therapy.

C. Protease Inhibitors

Protease inhibitors were first designed by computer modeling as peptidomimetic agents that fit into the active site of the HIV protease enzyme. Such drugs inhibit the viral protease that is required at the late stage of the replicative cycle to cleave the viral *gag* and *gag-pol* polypeptide precursors to form the mature virion core and activate the reverse transcriptase that will be used in the next round of infection. Protease inhibitors have been used successfully for treatment of HIV and HCV infections.

D. Integrase Inhibitors

HIV integrase inhibitors block the activity of viral integrase, a key enzyme in HIV replication. Without integration of virally encoded DNA into the host chromosome, the life cycle cannot continue. Raltegravir was the first integrase inhibitor to be approved in 2007.

E. Fusion Inhibitors

HIV fusion inhibitors act by disrupting the fusion of viral envelope with the cell membrane, preventing cellular infection. The prototype agent, enfuvirtide, is a peptide that binds to gp41 and blocks the required conformational change that initiates membrane fusion.

F. Other Types of Antiviral Agents

A number of other types of compounds have been shown to possess some antiviral activity under certain conditions.

TABLE 30-7 Examples of Antiviral Compounds Used for Treatment of Viral Infections

Drug	Nucleoside Analog	Mechanism of Action	Viral Spectrum
Acyclovir	Yes	Viral polymerase inhibitor	Herpes simplex, varicella-zoster
Adefovir	Yes	Viral polymerase inhibitor	HBV
Amantadine	No	Blocks viral uncoating	Influenza A
Boceprevir	No	HCV protease inhibitor	HCV
Cidofovir	No	Viral polymerase inhibitor	Cytomegalovirus, herpes simplex, polyomavirus
Didanosine (ddI)	Yes	Reverse transcriptase inhibitor	HIV-1, HIV-2
Entecavir	Yes	Reverse transcriptase inhibitor	HBV
Foscarnet	No	Viral polymerase inhibitor	Herpesviruses, HIV-1, HBV
Enfuvirtide	No	HIV fusion inhibitor (blocks viral entry)	HIV-1
Ganciclovir	Yes	Viral polymerase inhibitor	Cytomegalovirus
Indinavir	No	HIV protease inhibitor	HIV-1, HIV-2
Interferon (pegylated interferon)	No	Immune response activator	HCV, HBV, others
Lamivudine (3TC)	Yes	Reverse transcriptase inhibitor	HIV-1, HIV-2, HBV
Lopinavir	No	HIV protease inhibitor	HIV-1
Maraviroc	No	Entry inhibitor (blocks binding to CCR5)	HIV-1
Nevirapine	No	Reverse transcriptase inhibitor	HIV-1
Oseltamivir	No	Viral neuraminidase inhibitor	Influenza A and B
Raltegravir	No	Integrase inhibitor	HIV-1
Ribavirin	Yes	Perhaps blocks capping of viral mRNA	Respiratory syncytial virus, influenza A and B, Lassa fever, HCV, others
Ritonavir	No	HIV protease inhibitor	HIV-1, HIV-2
Saquinavir	No	HIV protease inhibitor	HIV-1, HIV-2
Simeprevir	No	HCV protease inhibitor	HCV
Sofosbuvir	Yes	Viral polymerase inhibitor	HCV
Stavudine (d4T)	Yes	Reverse transcriptase inhibitor	HIV-1, HIV-2
Telaprevir	No	HCV protease inhibitor	HCV
Telbivudine	Yes	Viral polymerase inhibitor	HBV
Tenofovir	Yes	Viral polymerase inhibitor	HBV
Trifluridine	Yes	Viral polymerase inhibitor	Herpes simplex, cytomegalovirus, vaccinia
Valacyclovir	Yes	Viral polymerase inhibitor	Herpesviruses
Vidarabine	Yes	Viral polymerase inhibitor	Herpesviruses, vaccinia, HBV
Zalcitabine (ddC)	Yes	Reverse transcriptase inhibitor	HIV-1, HIV-2, HBV
Zidovudine (AZT)	Yes	Reverse transcriptase inhibitor	HIV-1, HIV-2, HTLV-1

HBV, hepatitis B virus; HCV, hepatitis C virus; HIV-1, HIV-2, human immunodeficiency virus types 1 and 2; HTLV-1, human T-cell leukemia virus type 1; mRNA, messenger RNA.

Amantadine and **rimantadine** specifically inhibit influenza A viruses by blocking viral uncoating. They must be administered very early in infection to have a significant effect.

Oseltamivir is a neuraminidase inhibitor that prevents the release of influenza virus particles from infected cells.

Foscarnet (phosphonoformic acid) is an organic analog of inorganic pyrophosphate. It selectively inhibits viral DNA polymerases and reverse transcriptases at the pyrophosphate-binding site.

Acyclovir is a guanosine analog DNA polymerase inhibitor used for the treatment of HSV and varicella-zoster virus infections. The prodrug valacyclovir is an esterified version that can be taken orally and is metabolized to acyclovir.

Ganciclovir is a nucleoside DNA polymerase inhibitor active against CMV whose specificity comes from phosphorylation by virus-specific kinases only in virally infected cells. Valganciclovir is the orally available prodrug for ganciclovir.

Viral Vaccines

The purpose of viral vaccines is to use the adaptive immune response of the host to prevent viral disease. Several vaccines have proved to be remarkably effective at reducing the incidence of viral disease (Figure 30-9). Vaccination is the most cost-effective method of prevention of serious viral infections.

A. General Principles

Immunity to viral infection is based on the development of an immune response to specific antigens located on the surface of virus particles or virus-infected cells. For enveloped viruses, the important antigens are the surface glycoproteins. Although infected animals may develop antibodies against virion core proteins or nonstructural proteins involved in viral replication, that immune response is believed to play little or no role in the development of resistance to infection.

Vaccines are available for the prevention of several significant human diseases. Currently available vaccines (Table 30-8) are described in detail in the chapters dealing with specific virus families and diseases.

The pathogenesis of a particular viral infection influences the objectives of immunoprophylaxis. Mucosal immunity (local IgA) is important in resistance to infection by viruses that replicate in mucosal membranes (rhinoviruses, influenza viruses, rotaviruses) or invade through the mucosa (papillomavirus). Viruses that have a viremic mode of spread (polio, hepatitis A and B, yellow fever, varicella, mumps, measles) are controlled by serum IgG antibodies. Cell-mediated immunity also is involved in protection against systemic infections (measles, herpes).

Certain characteristics of a virus or of a viral disease may complicate the generation of an effective vaccine. The existence of many serotypes, as with rhinoviruses, and of large numbers of antigenic variants in animal reservoirs, as with influenza virus, makes vaccine production difficult. Other hurdles include the integration of viral DNA into host

FIGURE 30-9 Historical incidence of various viral diseases in the United States. Date of introduction of vaccine indicated by arrows. (Data from the Centers for Disease Control and Prevention.)

TABLE 30-8 Virus Vaccines Approved in the United States

Use	Vaccine	Type	Cell Substrate
Common	Hepatitis A	Killed	Human diploid fibroblasts (MRC-5)
	Hepatitis B	Subunit (HBsAg)	Yeast (recombinant DNA)
	Influenza A and B	Killed	Embryonated chicken eggs
	Influenza A and B	Live (intranasal)	Embryonated chicken eggs
	Measles	Live	Chicken embryo fibroblasts
	Mumps	Live	Embryonated chicken eggs and chicken embryo fibroblasts
	Papilloma	Subunit (L1)	Yeast (recombinant DNA)
	Poliovirus (IPV)	Killed	Monkey kidney cells (Vero)
	Poliovirus (OPV)	Live	Monkey kidney cells
	Rabies	Killed	Human diploid fibroblasts (MRC-5) or rhesus fetal lung diploid cells or chicken fibroblasts
	Rotavirus ^a	Live	Monkey kidney cells (Vero)
	Rubella	Live	Human diploid fibroblasts (WI-38)
	Varicella	Live	Human diploid fibroblasts (MRC-5)
	Zoster	Live	Human diploid fibroblasts (MRC-5)
Special situations	Adenovirus ^b	Live	Human diploid fibroblasts (WI-38)
	Japanese encephalitis ^c	Killed	Mouse brain
	Smallpox	Live	Calf lymph
	Yellow fever ^c	Live	Embryonated chicken eggs

HBsAg, hepatitis B surface antigen; IPV, inactivated polio vaccine; OPV, oral polio vaccine.

^aA live rotavirus vaccine was withdrawn from the market in 1999 because of an association with intussusception of infants. The vaccines approved in 2006 and 2008 are different and have not been associated with intussusception.

^bUsed by U.S. military.

^cUsed when traveling in endemic areas.

chromosomal DNA (retroviruses) and infection of cells of the host’s immune system (HIV).

B. Killed-Virus Vaccines

Inactivated (killed-virus) vaccines are made by purifying viral preparations to a certain extent and then inactivating viral infectivity in a way that does minimal damage to the viral structural proteins; mild formalin treatment is frequently used (Table 30-9). For some diseases, killed-virus vaccines are currently the only ones available.

Killed-virus vaccines prepared from whole virions generally stimulate the development of circulating antibody against the coat proteins of the virus, conferring some degree of resistance to that virus strain.

Advantages of inactivated vaccines are that there is no reversion to virulence by the vaccine virus and that vaccines can be made when no acceptable attenuated virus is available. Disadvantages of killed-virus vaccines include relatively brief immunity requiring boosting shots to maintain effectiveness, poor cell-mediated response, and occasional hypersensitivity to subsequent infection.

C. Attenuated Live-Virus Vaccines

Live-virus vaccines use virus mutants that antigenically overlap with wild-type virus but are restricted in some step in the pathogenesis of disease (see Table 30-9).

The genetic basis for the attenuation of most viral vaccines is not known because they were selected empirically by serial passages in animals or cell cultures (usually from a species different from the natural host). As more is learned about viral genes involved in disease pathogenesis, attenuated candidate vaccine viruses can be engineered in the laboratory.

Attenuated live-virus vaccines have the advantage of acting more like the natural infection with regard to their effect on immunity. They multiply in the host and tend to stimulate longer-lasting antibody production, induce a good cell-mediated response, and induce antibody production and resistance at the portal of entry (Figure 30-10). Disadvantages of attenuated live-virus vaccines include a risk of reversion to greater virulence, severe infection in immunocompromised hosts, and limited storage and shelf life in some cases. Additionally, unrecognized adventitious agents have been found in vaccine stocks (eg, simian polyomavirus SV40 and porcine circovirus).

TABLE 30-9 Comparison of Characteristics of Killed- and Live-Virus Vaccines

Characteristic	Killed Vaccine	Live Vaccine
Number of doses	Multiple	Single
Need for adjuvant	Yes	No
Duration of immunity	Shorter	Longer
Effectiveness of protection (more closely mimics natural infection)	Lower	Greater
Immunoglobulins produced	IgG	IgA and IgG
Mucosal immunity produced	Poor	Yes
Cell-mediated immunity produced	Poor	Yes
Reversion to virulence	No	Possible
Excretion of vaccine virus and transmission to nonimmune contacts	No	Possible
Interference by other viruses in host	No	Possible
Stability at room temperature	High	Low

D. Proper Use of Vaccines

An effective vaccine does not protect against disease until it is administered in the proper dosage to susceptible individuals. Failure to reach all sectors of the population with complete

courses of immunization is reflected in the continued occurrence of measles outbreaks in populations who refuse immunization. Herd immunity refers to the fact that the risk of infection among susceptible individuals in a population is reduced by the presence of adequate numbers of immune individuals. This effect is reflected in dramatic decreases in the incidence of disease, even when all susceptible individuals have not been vaccinated. However, the threshold of immunity needed for this indirect protective effect depends on many factors, including the transmissibility of the infectious agent, the nature of the vaccine-induced immunity, and the distribution of the immune individuals. Individuals protected by herd immunity remain susceptible to infection upon exposure. This can lead to outbreaks of disease when a group of susceptible individuals accumulate, such as mumps outbreaks among university students in the United States.

Certain viral vaccines are recommended for use by the general public. Other vaccines are recommended only for use by persons at special risk because of occupation, travel, or lifestyle. In general, live-virus vaccines are contraindicated for pregnant women and immunocompromised individuals.

E. Future Vaccine Prospects

Molecular biology and modern technologies are combining to allow novel approaches to vaccine development. Many of these approaches avoid the incorporation of viral nucleic acid in the final product, improving vaccine safety. Examples of what is ongoing in this field can be listed as follows. The ultimate success of these new approaches remains to be determined.

FIGURE 30-10 Serum and secretory antibody response to orally administered, live attenuated polio vaccine and to intramuscular inoculation of killed polio vaccine. (Reproduced with permission from Ogra PL, Fishaut M, Gallagher MR: Viral vaccination via the mucosal routes. *Rev Infect Dis* 1980;2:352. By permission of Oxford University Press.)

1. Use of recombinant DNA techniques to insert the gene coding for the protein of interest into the genome of an avirulent virus that can be administered as the vaccine (eg, vaccinia virus).
2. Including in the vaccine only those subviral components needed to stimulate protective antibody, thus minimizing the occurrence of adverse reactions to the vaccine.
3. Use of purified proteins isolated from purified virus or synthesized from cloned genes (a recombinant hepatitis B virus vaccine contains viral proteins synthesized in yeast cells). Expression of cloned gene(s) sometimes results in formation of empty virus-like particles.
4. Use of synthetic peptides that correspond to antigenic determinants on a viral protein, thus avoiding any possibility of reversion to virulence since no viral nucleic acid would be present, although the immune response induced by synthetic peptides is considerably weaker than that induced by intact protein.
5. Development of edible vaccines whereby transgenic plants synthesizing antigens from pathogenic viruses may provide new cost-effective ways of delivering vaccines.
6. Use of naked DNA vaccines—potentially simple, cheap, and safe—in which recombinant plasmids carrying the gene for the protein of interest are injected into host cells which produce the immunizing protein.

7. Administration of vaccine locally to stimulate antibody at the portal of entry (eg, aerosol vaccines for respiratory disease viruses).

CHAPTER SUMMARY

- Viral pathogenesis is the process when a virus infects a host.
- Most viruses enter their hosts through the respiratory or gastrointestinal tract.
- Most viral infections are inapparent and do not result in clinical disease.
- Most viral infections are self-limiting and are cleared by the host, but some lead to chronic (persistent) long-term infections.
- Both innate and adaptive immune responses (both humoral and cellular components) are important in recovery from viral infections.
- Interferons are cytokines that are central to the antiviral innate immune response of the host.
- Both viral and host factors determine the outcome of viral infections.
- Some viruses cause localized infections at the primary site of entry; other viruses spread and produce disease at distant sites in the body.
- A few viruses can infect the fetus in utero and may cause serious damage, leading to fetal death or congenital defects.
- Effective antiviral drugs must selectively inhibit viral functions and not cell processes.
- Viral vaccines are the most effective method for preventing viral infections; vaccines are available against several serious viral diseases.
- Both killed-virus and live-virus vaccines are available; each type has certain advantages and disadvantages.
- New technologies and research are enabling antiviral drug development and novel vaccine approaches.

REVIEW QUESTIONS

1. Interferons are an important part of the host defense against viral infections. What is interferon's principal mode of action?
 - (A) It is present in the serum of healthy individuals, providing a viral surveillance role.
 - (B) It coats viral particles and blocks their attachment to cells.
 - (C) It induces synthesis of one or more cellular proteins that inhibit translation or transcription.
 - (D) It protects the virus-infected cell that produced it from cell death.
2. A 9-month-old girl is taken to the emergency room because of fever and persistent cough. Rales are heard in her left chest on physical examination. An infiltrate in her left lung is seen on the chest radiograph. Pneumonia is diagnosed. Which of the following is the most likely cause?
 - (A) Rotavirus
 - (B) Rhinovirus
 - (C) Adenovirus
 - (D) Respiratory syncytial virus
 - (E) Coxsackievirus
3. Which one of the following is a fundamental principle of viral disease causation?
 - (A) One virus type induces a single disease syndrome.
 - (B) Many viral infections are subclinical and do not produce clinical disease.
 - (C) The type of disease produced by a virus can be predicted by the morphology of that virus.
 - (D) A particular disease syndrome has a single viral cause.
4. The skin is a formidable barrier to virus entry, but a few viruses are able to breach this barrier and initiate infection of the host. Which of the following is an example of a virus that enters through skin abrasions?
 - (A) Adenovirus
 - (B) Rotavirus
 - (C) Rhinovirus
 - (D) Papilloma virus
 - (E) Influenza virus
5. A 40-year-old man has HIV/AIDS characterized by a low CD4 count and a high viral load. Highly active antiretroviral therapy (HAART) will be initiated. One of the drugs under consideration is a nucleoside analog that inhibits viral reverse transcriptase and is active against both HIV and hepatitis B virus. That drug is
 - (A) Acyclovir
 - (B) Amantadine
 - (C) Ribavirin
 - (D) Saquinavir
 - (E) Lamivudine
 - (F) Fuzeon
6. Regarding the HIV/AIDS patient in Question 5, a peptidomimetic agent that blocks virus-mediated cleavage of viral structural protein precursors is chosen as a second drug. That drug is
 - (A) Acyclovir
 - (B) Amantadine
 - (C) Ribavirin
 - (D) Saquinavir
 - (E) Lamivudine
 - (F) Fuzeon
7. A 63-year-old woman is hospitalized for treatment of leukemia. One day after admission she develops chills, fever, cough, headache, and myalgia. She states that her husband had a similar illness a few days earlier. There is major concern about a respiratory virus outbreak in the staff of the chemotherapy ward and in the patients on that ward. A synthetic amine that inhibits influenza A virus by blocking viral uncoating is chosen for prophylactic treatment of the staff and patients. That drug is
 - (A) Acyclovir
 - (B) Amantadine
 - (C) Ribavirin
 - (D) Saquinavir
 - (E) Lamivudine
 - (F) Fuzeon
8. Which one of the following statements describes an advantage of killed-virus vaccines over attenuated live-virus vaccines?
 - (A) Killed-virus vaccines induce a broader range of immune responses than do attenuated live-virus vaccines.
 - (B) Killed-virus vaccines more closely mimic natural infections than do attenuated live-virus vaccines.

- (C) Killed-virus vaccines pose no risk that vaccine virus might be transmitted to susceptible contacts.
- (D) Killed-virus vaccines are efficacious against respiratory virus infections because they induce good mucosal immunity.
9. What type of hepatitis B vaccine is currently in use in the United States?
- (A) Synthetic peptide vaccine
- (B) Killed-virus vaccine
- (C) Attenuated live-virus vaccine
- (D) Subunit vaccine produced using recombinant DNA
10. Which one of the following phrases accurately describes viral neutralizing antibodies?
- (A) Directed against viral protein determinants on the outside of the virus particle
- (B) Appear in the host sooner after viral infection than interferon
- (C) Directed against viral nucleic acid sequences
- (D) Induced only by disease-causing viruses
- (E) Of little importance to immunity to viral infection
11. Many viruses use the respiratory tract as the route of entry to initiate infections. Which of the following virus groups does not?
- (A) Adenovirus
- (B) Coronavirus
- (C) Hepadnavirus
- (D) Paramyxovirus
- (E) Poxvirus
12. Which of the following licensed virus vaccines is a subunit vaccine prepared using recombinant DNA technology?
- (A) Measles–mumps–rubella
- (B) Varicella
- (C) Hepatitis A
- (D) Papilloma
- (E) Rotavirus
- (F) Rabies
13. Which of the following viruses is the most common cause of neonatal infections in the United States?
- (A) Rubella
- (B) Parvovirus B19
- (C) Hepatitis B
- (D) Cytomegalovirus
- (E) Varicella
- (F) Human immunodeficiency virus
14. Which one of the following statements concerning interferons is *least* accurate?
- (A) Interferons are proteins that influence host defenses in many ways, one of which is the induction of an antiviral state.
- (B) Interferons are synthesized only by virus-infected cells.
- (C) Interferons inhibit a broad range of viruses, not just the virus that induced the interferon.
- (D) Interferons induce the synthesis of a ribonuclease that degrades viral mRNA.
15. Each of the following statements concerning viral vaccines is correct *except*
- (A) In live attenuated vaccines, the virus has lost its ability to cause disease but has retained its ability to induce neutralizing antibody.
- (B) In live attenuated vaccines, the possibility of reversion to virulence is of concern.
- (C) With inactivated vaccines, IgA mucosal immunity is usually induced.
- (D) With inactivated vaccines, protective immunity is mainly caused by the production of IgG.

Parvoviruses

Parvoviruses are the smallest DNA animal viruses. Because of the limited coding capacity of their genome, viral replication is dependent on functions supplied by replicating host cells or by coinfecting helper viruses. Parvovirus B19 is pathogenic for humans and has a tropism for erythroid progenitor cells. It is the cause of erythema infectiosum (“Fifth disease”), a common childhood exanthem; a polyarthralgia–arthritis syndrome in normal adults; aplastic crisis in patients with hemolytic disorders; chronic anemia in immunocompromised individuals; and fetal death. The human bocaviruses have been detected in respiratory specimens from children with acute respiratory disease and in stool samples, but a role in disease is unproven.

PROPERTIES OF PARVOVIRUSES

Important properties of parvoviruses are listed in Table 31-1. It is noteworthy that there are both autonomously replicating and defective parvoviruses that require a helper virus for replication.

Structure and Composition

The icosahedral, nonenveloped particles are 18–26 nm in diameter (Figure 31-1). The particles have a molecular weight of $5.5\text{--}6.2 \times 10^6$ and a heavy buoyant density of $1.39\text{--}1.42 \text{ g/cm}^3$. Virions are extremely resistant to inactivation. They are stable between a pH of 3 and 9 and withstand heating at 56°C for 60 minutes, but they can be inactivated by formalin, β -propiolactone, and oxidizing agents.

Virions contain two coat proteins that are encoded by an overlapping, in-frame DNA sequence, so that VP2 is identical in sequence to the carboxy portion of VP1. The major capsid protein, VP2, represents about 90% of virion protein. The genome is about 5 kb, linear, single-stranded DNA. Autonomous parvoviruses usually encapsidate primarily DNA strands complementary to viral mRNA; defective viruses tend to encapsidate DNA strands of both polarities with equal frequency into separate virions.

Classification

There are two subfamilies of Parvoviridae: the **Parvovirinae**, which infect vertebrates, and the **Densovirinae**, which infect

insects. The Parvovirinae comprise five genera. Human parvovirus B19 is the most common member of the *Erythroparvovirus* genus. The three human bocaviruses are in the *Bocaparvovirus* genus. Feline panleukopenia virus and canine parvovirus, both serious causes of veterinary diseases, are classified as members of the *Protoparvovirus* genus, as are isolates from many other animals. The genus *Dependovirus* contains members that are defective and depend on a helper virus (an adenovirus or herpesvirus) for replication. Human adeno-associated viruses (AAVs) have not been linked with any disease but are candidate vectors for gene therapy treatments.

Parvovirus Replication

It is difficult to culture human B19 parvovirus. Only primary erythroid progenitors are known to be permissive for B19 infection. The cellular receptor for B19 is blood group P antigen (globoside). P antigen is expressed on mature erythrocytes, erythroid progenitors, megakaryocytes, endothelial cells, placenta, and fetal liver and heart, which helps explain the narrow tissue tropism of B19 virus. The $\alpha 5\beta 1$ integrin is believed to be a coreceptor for B19 entry.

The parvoviruses are highly dependent on cellular functions for replication. Viral DNA replication occurs in the nucleus. The parvoviruses do not have the ability to stimulate resting cells to initiate DNA synthesis, so they must infect dividing cells. One or more cellular DNA polymerases are involved. The nonstructural protein, NS1, is required for virus replication. There are two capsid proteins. Viral replication results in cell death.

PARVOVIRUS INFECTIONS IN HUMANS

Pathogenesis and Pathology

A typical course of human parvovirus B19 infection in adults is illustrated in Figure 31-2. B19 has been implicated as the causative agent of several diseases (Table 31-2). Immature cells in the erythroid lineage are principal targets for human B19 parvovirus. Hence, the major sites of virus replication in patients are assumed to be the adult marrow, some blood cells, and the fetal liver. Viral replication causes cell death, interrupting red blood cell production. Bone marrow biopsies

TABLE 31-1 Important Properties of Parvoviruses

Virion: Icosahedral, 18–26 nm in diameter, 32 capsomeres
Composition: DNA (20%), protein (80%)
Genome: Single-stranded DNA, linear, 5.6 kb, MW 1.5–2.0 million
Proteins: One major (VP2) and one minor (VP1)
Envelope: None
Replication: Nucleus, dependent on functions of dividing host cells
Outstanding characteristics:
Environmentally stable
Human pathogen, B19, has tropism for red blood cell progenitors.

MW, molecular weight.

from infected patients show erythrocyte maturation arrest, with erythroblast intranuclear inclusions. In immunocompromised patients, persistent B19 infections occur, resulting in chronic anemia. In cases of fetal death, chronic infections may have caused severe anemia in the fetus.

Because nondefective parvoviruses require dividing host cells to replicate, known parvovirus diseases reflect that target specificity (Figure 31-3).

Both virus-specific immunoglobulin M (IgM) and IgG antibodies are made after B19 infections. Persistent parvovirus

FIGURE 31-1 Electron micrograph of parvovirus particles. (Courtesy of FA Murphy and EL Palmer.)

infections occur in patients with immune deficiencies who fail to make virus-neutralizing antibodies, resulting in anemia. Persistence of low levels of B19 DNA has also been detected in blood, skin, tonsil, liver, and synovial tissues of immunocompetent persons. The rash associated with erythema infectiosum is at least partly immune complex mediated.

FIGURE 31-2 Clinical and laboratory findings during the course of human parvovirus B19 infection in adult volunteers. The first phase of illness with flu-like symptoms coincides with viremia (days 6–12); the second phase of illness with rash appears on about day 18. (Reproduced with permission from Anderson LJ, Erdman DD: Human parvovirus B19. In Richman DD, Whitley RJ, Hayden FG [editors]. *Clinical Virology*, 3rd ed. TABLE 31-2 Human Diseases Associated with B19 Parvovirus

Syndrome	Host or Condition	Clinical Features
Erythema infectiosum	Children (Fifth disease) Adults	Cutaneous rash Arthralgia–arthritis
Transient aplastic crisis	Underlying hemolysis	Severe acute anemia
Pure red cell aplasia	Immunodeficiencies	Chronic anemia
Hydrops fetalis	Fetus	Fatal anemia

Modified with permission from Young NS: Parvoviruses. In Fields BN, Knipe DM, Howley PM (editors-in-chief). *Fields Virology*, 3rd ed. Lippincott-Raven, 1996.

B19 can be found in blood and respiratory secretions of infected patients. Transmission is presumably by the respiratory route. There is no evidence of virus excretion in feces or urine.

The virus can be transmitted parenterally by blood transfusions or by infected blood products (coagulation factors and immunoglobulin concentrates) and vertically from mother to fetus. Because B19 can be present at extremely high titers and is resistant to harsh treatments that inactivate enveloped viruses, plasma-derived clotting factor concentrates can end up contaminated and are screened for the presence of B19 DNA. The prevalence of antibodies to B19 is higher among people with hemophilia than the general population; however, the minimal level of virus in blood products able to cause infections is not known.

The pathogenesis of human bocavirus infection is not yet known, though some studies have associated its presence with respiratory disease. Because it has been found in respiratory specimens, it is presumed to infect the respiratory tract and be transmitted by the respiratory route. It has also been detected in stool and serum samples.

Several pathogenic parvoviruses of animals replicate in intestinal mucosal cells and cause enteritis. Consistent with

FIGURE 31-3 Pathogenesis of diseases caused by B19 parvovirus. **A:** In children and adults. (PRCA, pure red cell aplasia; TAC, transient aplastic crisis.) **B:** In fetal infections. (Modified with permission from Brown KE, Young NS: Parvovirus B19 infection and hematopoiesis. *Blood* Rev 1995;9:176. Copyright Elsevier.)

their highly stable nature, parvoviruses have also been found contaminating laboratory reagents.

Clinical Findings

A. Erythema Infectiosum (Fifth Disease)

The most common manifestation of human parvovirus B19 infection is erythema infectiosum, or Fifth disease. This erythematous illness is most common in children of early school age and occasionally affects adults. Fever and mild constitutional symptoms may accompany the rash, which has a typical “slapped cheek” appearance (Figure 31-4). Both sporadic cases and epidemics have been described. Joint involvement due to immune complex deposition is a prominent feature in adult cases; joints in the hands and the knees are most frequently affected. The symptoms mimic rheumatoid arthritis, and the arthropathy may persist for weeks, months, or years.

The incubation period is usually 1–2 weeks but may extend to 3 weeks. Viremia occurs 1 week after infection and persists for about 5 days. During the period of viremia, virus is present in nasal washes and gargle specimens, identifying the upper respiratory tract—most probably the pharynx—as the site of viral shedding. The first phase of illness occurs at the end of the first week; symptoms are flu-like, including fever, malaise, myalgia, chills, and itching. The first episode of illness coincides in time with viremia and reticulocytopenia and with detection of circulating IgM–parvovirus immune complexes. After an incubation period of about 2 weeks, a second phase of illness begins. The appearance of an erythematous facial rash and a lace-like rash on the limbs or trunk may be accompanied by joint symptoms, especially in adults. The illness is short-lived, with the rash fading after 2–4 days, although the joint symptoms may persist longer. Specific IgG antibodies appear about 15 days postinfection.
