Excessive or unreasonable anxiety about life circumstances (generalized anxiety disorder, GAD), panic disorders, and agoraphobia also are amenable to drug therapy, sometimes in conjunction with psychotherapy. The benzodiazepines continue to be widely used for the management of acute anxiety states and for rapid control of panic attacks. They are also used, though less commonly, in the long-term management of GAD and panic disorders. Anxiety symptoms may be relieved by many benzodiazepines, but it is not always easy to demonstrate the superiority of one drug over another. **Alprazolam** has been used in the treatment of panic disorders and agoraphobia and appears to be more selective in these conditions than other benzodiazepines. The choice of benzodiazepines for anxiety is based on several sound pharmacologic principles: (1) a rapid onset of action; (2) a relatively high therapeutic index (see drug B in Figure 22-1), plus availability of **flumazenil** for treatment of overdose; (3) a low risk of drug interactions based on liver enzyme induction; and (4) minimal effects on cardiovascular or autonomic functions.

Disadvantages of the benzodiazepines include the risk of dependence, depression of CNS functions, and amnestic effects. In addition, the benzodiazepines exert additive CNS depression when administered with other drugs, including ethanol. The patient should be warned of this possibility to avoid impairment of performance of any task requiring mental alertness and motor coordination. In the treatment of generalized anxiety disorders and certain phobias, newer antidepressants, including selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs), are now considered by many authorities to be drugs of first choice (see Chapter 30). However, these agents have a slow onset of action and thus minimal effectiveness in acute anxiety states.

Sedative-hypnotics should be used with appropriate caution to minimize adverse effects. A dose should be prescribed that does not impair mentation or motor functions during waking hours. Some patients may tolerate the drug better if most of the daily dose is given at bedtime, with smaller doses during the day. Prescriptions should be written for short periods, since there is little justification for long-term therapy (defined as use of therapeutic doses for 2 months or longer). The physician should make an effort to assess the efficacy of therapy from the patient's subjective responses. Combinations of antianxiety agents should be avoided, and people taking sedatives should be cautioned about the consumption of **alcohol** and the concurrent use of over-the-counter medications containing antihistaminic or anticholinergic drugs (see Chapter 64).

### Orexin Receptor Antagonists: Sleep-Enabling Drugs

Orexin A and B are peptides found in specific hypothalamic neurons that are involved in the control of wakefulness and that are silent during sleep. Orexin levels increase in the day and decrease at night. Loss of orexin neurons is associated with narcolepsy, a disorder characterized by daytime sleepiness and cataplexy. Animal studies show that orexin receptor antagonists have sleep-enabling effects. This has prompted the development of a new class of hypnotic drugs, orexin antagonists, which include the drugs **lemborexant** and **suvorexant**. There are two known orexin receptors, OX<sub>1</sub> and OX<sub>2</sub>. They are both G protein-coupled receptors that bind both orexin A and B, with OX<sub>2</sub> having 5- to 10-fold higher affinity for orexin B.

**Suvorexant** and **lemborexant** act as antagonists at both OX<sub>1</sub> and OX<sub>2</sub> receptors.

## TREATMENT OF SLEEP PROBLEMS

Sleep disorders are common and often result from inappropriate lifestyle, inadequate treatment of underlying medical conditions, or psychiatric illness. True primary insomnia is rare. Recent studies confirm that insufficient sleep, especially in adolescents and in the elderly, impacts many aspects of psychiatric and physical health, with 8–9 hours of sleep per 24 hours recommended for both groups. Nonpharmacologic therapies that are useful for sleep problems include proper diet and exercise, avoiding stimulants before going to sleep, ensuring a comfortable sleeping environment, and retiring at a regular time each night. In some cases, however, the patient will need and should be given a sedative-hypnotic for a limited period. The abrupt discontinuance of many drugs in the sedative-hypnotic class can lead to rebound insomnia.

Benzodiazepines can cause a dose-dependent decrease in both REM and slow-wave sleep, though to a lesser extent than the barbiturates. The newer hypnotics, **zolpidem**, **zaleplon**, **eszopiclone**, and **suvorexant**, are less likely than the benzodiazepines to change sleep patterns. However, little is known about the clinical impact of sleep pattern effects. The drug selected should be one that provides sleep of fairly rapid onset (decreased sleep latency) and sufficient duration, with minimal “hangover” effects such as drowsiness, dysphoria, and mental or motor depression the following day. Older drugs such as chloral hydrate, **secobarbital**, and **pentobarbital** may be used in special circumstances (eg, institutionalized patients), but benzodiazepines, **zolpidem**, **zaleplon**, **eszopiclone**, or **suvorexant** are preferred. Daytime sedation is more common with benzodiazepines that have slow elimination rates (eg, **lorazepam**) and those that are biotransformed to active metabolites (eg, **flurazepam**, **quazepam**). If benzodiazepines are used nightly, tolerance can occur, which may lead to dose increases by the patient to produce the desired effect. Anterograde amnesia occurs to some degree with all benzodiazepines used for hypnosis.

**Eszopiclone**, **zaleplon**, and **zolpidem** have efficacies similar to those of the hypnotic benzodiazepines in the management of sleep disorders. Favorable clinical features of **zolpidem** and the other newer hypnotics include rapid onset of activity and modest day-after psychomotor depression with few amnestic effects. **Zolpidem**, one of the most frequently prescribed hypnotic drugs in the United States, is available in a biphasic release formulation that provides sustained drug levels for sleep maintenance. **Zaleplon** acts rapidly, and because of its short half-life, the drug appears to have value in the management of patients who awaken early in the sleep cycle. At recommended doses, **zaleplon** and **eszopiclone** (despite a relatively long half-life) appear to cause less amnesia or day-after somnolence than **zolpidem** or benzodiazepines.

**Suvorexant** is FDA-approved for treatment of both sleep-onset and sleep-maintenance insomnia. The most common adverse effect of **suvorexant** is next-day somnolence.

The drugs in this class commonly used for sedation and hypnosis are listed in **Table 22–3** together with recommended doses. *Note:* The failure of insomnia to remit after 7–10 days of treatment may indicate the presence of a primary psychiatric or medical illness that should be evaluated. Long-term use of hypnotics is an irrational and dangerous medical practice.

## Dosages of drugs used commonly for sedation and hypnosis.

Sedation		Hypnosis	
Drug	Dosage	Drug	Dosage (at Bedtime)
Alprazolam	0.25–0.5 mg 2–3 times daily	Chloral hydrate	500–1000 mg
Buspirone	5–10 mg 2–3 times daily	Estazolam	0.5–2 mg
Chlordiazepoxide	10–20 mg 2–3 times daily	Eszopiclone	1–3 mg
Clorazepate	5–7.5 mg twice daily	Lemborexant	5 mg
Diazepam	5 mg twice daily	Lorazepam	2–4 mg
Halazepam	20–40 mg 3–4 times daily	Quazepam	7.5–15 mg
Lorazepam	1–2 mg once or twice daily	Secobarbital	100–200 mg
Oxazepam	15–30 mg 3–4 times daily	Suvorexant	10 mg
Phenobarbital	15–30 mg 2–3 times daily	Tasimelteon	10 mg
		Temazepam	7.5–30 mg
		Triazolam	0.125–0.5 mg
		Zaleplon	5–20 mg
		Zolpidem	2.5–10 mg

## OTHER THERAPEUTIC USES

Table 22–2 summarizes several other important clinical uses of drugs in the sedative-hypnotic class. Drugs used in the management of seizure disorders and as intravenous agents in anesthesia are discussed in Chapters 24 and 25.

For sedative and possible amnestic effects during medical or surgical procedures such as endoscopy and bronchoscopy—as well as for premedication prior to anesthesia—oral formulations of shorter-acting drugs are preferred.

Long-acting drugs such as [chlordiazepoxide](#) and [diazepam](#) and, to a lesser extent, [phenobarbital](#) are administered in progressively decreasing doses to patients during withdrawal from physiologic dependence on ethanol or other sedative-hypnotics. Parenteral [lorazepam](#) is used to suppress the symptoms of delirium tremens.

[Meprobamate](#) and the benzodiazepines have frequently been used as central muscle relaxants, though evidence for general efficacy without accompanying sedation is lacking. A possible exception is [diazepam](#), which has useful relaxant effects in skeletal muscle spasticity of central origin (see Chapter 27).

Psychiatric uses of benzodiazepines other than treatment of anxiety states include the initial management of mania and the control of drug-induced hyperexcitability states (eg, phencyclidine intoxication). Sedative-hypnotics are also used occasionally as diagnostic aids in neurology and psychiatry.

## CLINICAL TOXICOLOGY OF SEDATIVE-HYPNOTICS

### Direct Toxic Actions

Many of the common adverse effects of sedative-hypnotics result from dose-related depression of the CNS. Relatively low doses may lead to drowsiness, impaired judgment, and diminished motor skills, sometimes with a significant impact on driving ability, job performance, and personal relationships. Sleep driving and other somnambulist behavior with no memory of the event have occurred with the sedative-hypnotic drugs used in

sleep disorders, prompting the FDA in 2007 to issue warnings of this potential hazard. Benzodiazepines may cause a significant dose-related anterograde amnesia; they can significantly impair ability to learn new information, particularly that involving effortful cognitive processes, while leaving the retrieval of previously learned information intact. This effect is utilized for uncomfortable clinical procedures, eg, endoscopy, because the patient is able to cooperate during the procedure but amnesic regarding it afterward. The criminal use of benzodiazepines in cases of “date rape” is based on their dose-dependent amnesic effects. Hangover effects are not uncommon following use of hypnotic drugs with long elimination half-lives. Because elderly patients are more sensitive to the effects of sedative-hypnotics, doses approximately half of those used in younger adults are safer and usually as effective. *The most common reversible cause of confusional states in the elderly is overuse of sedative-hypnotics.* At higher doses, toxicity may present as lethargy or a state of exhaustion or, alternatively, as gross symptoms equivalent to those of ethanol intoxication. The physician should be aware of variability among patients in terms of doses causing adverse effects. An increased sensitivity to sedative-hypnotics is more common in patients with cardiovascular disease, respiratory disease, or hepatic impairment and in older patients. Sedative-hypnotics can exacerbate breathing problems in patients with chronic pulmonary disease and in those with symptomatic sleep apnea.

Sedative-hypnotics are the drugs most frequently involved in deliberate overdoses, in part because of their general availability as very commonly prescribed pharmacologic agents. The benzodiazepines are considered to be safer drugs in this respect, since they have flatter dose-response curves. Epidemiologic studies on the incidence of drug-related deaths support this general assumption—eg, 0.3 deaths per million tablets of **diazepam** prescribed versus 11.6 deaths per million capsules of **secobarbital** in one study. **Alprazolam** is purportedly more toxic in overdose than other benzodiazepines. Many factors other than the specific sedative-hypnotic influence such data—particularly the presence of other CNS depressants, including ethanol. Most serious cases of drug overdose, intentional or accidental, involve polypharmacy; when combinations of agents are taken, the practical safety of benzodiazepines may be significantly reduced.

The lethal dose of any sedative-hypnotic varies with the patient and the circumstances (see **Chapter 58**). If discovery of the ingestion is made early and a conservative treatment regimen is started, the outcome is rarely fatal, even following very high doses. On the other hand, for most sedative-hypnotics—with the exception of benzodiazepines and possibly the newer hypnotic drugs that have a similar mechanism of action—a dose as low as 10 times the hypnotic dose may be fatal if the patient is not discovered or does not seek help in time. With severe toxicity, the respiratory depression from central actions of the drug may be complicated by aspiration of gastric contents in the unattended patient—an even more likely occurrence if ethanol is present. Cardiovascular depression further complicates successful resuscitation. In such patients, treatment consists of ensuring a patent airway, with mechanical ventilation if needed, and maintenance of plasma volume, renal output, and cardiac function. Use of a positive inotropic drug such as **dopamine**, which preserves renal blood flow, is sometimes indicated. Hemodialysis or hemoperfusion may be used to hasten elimination of some of these drugs (see **Table 58–2**).

**Flumazenil** reverses the sedative actions of benzodiazepines, and those of **eszopiclone**, **zaleplon**, and **zolpidem**, although experience with its use in overdose of the newer hypnotics is limited. However, its duration of action is short, its antagonism of respiratory depression is unpredictable, and there is a risk of precipitation of withdrawal symptoms in long-term users of benzodiazepines. Consequently, the use of **flumazenil** in benzodiazepine overdose remains controversial and *must* be accompanied by adequate monitoring and support of respiratory function. The extensive clinical use of **triazolam** has led to reports of serious CNS effects including behavioral disinhibition, delirium, aggression, and violence. However, behavioral disinhibition may occur with any sedative-hypnotic drug, and it does not appear to be more prevalent with **triazolam** than with other benzodiazepines. Disinhibitory reactions during benzodiazepine treatment are more clearly associated with the use of very high doses and the pretreatment level of patient hostility.

Adverse effects of the sedative-hypnotics that are not referable to their CNS actions occur infrequently. Hypersensitivity reactions, including skin rashes, occur only occasionally with most drugs of this class. Reports of teratogenicity leading to fetal deformation following use of certain benzodiazepines have resulted in FDA assignment of individual benzodiazepines to either category D or X in terms of pregnancy risk. Increased incidence of miscarriage, premature birth, and low birth weight has been reported for the benzodiazepines. Most barbiturates are FDA pregnancy category D. **Eszopiclone**, **ramelteon**, **suvorexant**, **zaleplon**, and **zolpidem** are category C, while **buspirone** is a category B drug in terms of use in pregnancy. Because barbiturates enhance porphyrin synthesis, they are *absolutely contraindicated* in patients with a history of acute intermittent porphyria, variegate porphyria, hereditary coproporphyria, or symptomatic porphyria.

### Alterations in Drug Response

Depending on the dosage and the duration of use, tolerance occurs in varying degrees to many of the pharmacologic effects of sedative-hypnotics. It should not be assumed that the degree of tolerance achieved is identical for all pharmacologic effects. There is evidence that the lethal

dose range is not altered significantly by the long-term use of sedative-hypnotics. Cross-tolerance between the different sedative-hypnotics, including ethanol, can lead to an unsatisfactory therapeutic response when standard doses of a drug are used in a patient with a recent history of excessive use of these agents. However, there have been very few reports of tolerance development when **eszopiclone**, **zolpidem**, or **zaleplon** was used for less than 4 weeks.

With the long-term use of sedative-hypnotics, especially if doses are increased, a state of physiologic dependence can occur. This may develop to a degree unparalleled by any other drug group, *including the opioids*. Withdrawal from a sedative-hypnotic can have severe and life-threatening manifestations. Withdrawal symptoms range from restlessness, anxiety, weakness, and orthostatic hypotension to hyperactive reflexes and generalized seizures. Symptoms of withdrawal are usually more severe following discontinuance of sedative-hypnotics with shorter half-lives. However, **eszopiclone**, **zolpidem**, and **zaleplon** appear to be exceptions to this, because withdrawal symptoms are minimal following abrupt discontinuance of these newer short-acting agents. Symptoms are less pronounced with longer-acting drugs, which may partly accomplish their own “tapered” withdrawal by virtue of their slow elimination. Cross-dependence, defined as the ability of one drug to suppress abstinence symptoms from discontinuance of another drug, is quite marked among sedative-hypnotics. This provides the rationale for therapeutic regimens in the management of withdrawal states: Longer-acting drugs such as **chlordiazepoxide**, **diazepam**, and **phenobarbital** can be used to alleviate withdrawal symptoms of shorter-acting drugs, including ethanol.

## Drug Interactions

The most common drug interactions involving sedative-hypnotics are interactions with other CNS depressant drugs, leading to additive effects. These interactions have some therapeutic usefulness when these drugs are used as adjuvants in anesthesia practice. However, if not anticipated, such interactions can lead to serious consequences, including enhanced depression with concomitant use of many other drugs. Additive effects can be predicted with concomitant use of alcoholic beverages, opioid analgesics, anticonvulsants, antihistamines, antihypertensive agents, tricyclic antidepressants, and phenothiazines.

Interactions involving changes in the activity of hepatic drug-metabolizing enzyme systems have been discussed (see also [Chapters 4](#) and [67](#)).

### SUMMARY Sedative-Hypnotics

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>BENZODIAZEPINES</b>

<ul style="list-style-type: none"> <li>• <b>Buspirone</b></li> </ul>	Mechanism uncertain: Partial agonist at 5-HT receptors but affinity for	Slow onset (1–2 weeks) of anxiolytic effects • minimal psychomotor impairment	Generalized anxiety states	Oral activity • forms active metabolite • short half-life • <b>Toxicity:</b> Tachycardia • paresthesias • gastrointestinal distress •

D<sub>2</sub> receptors also possible

—no additive CNS depression with sedative-hypnotic drugs

*Interactions:* CYP3A4 inducers and inhibitors**PREPARATIONS AVAILABLE**

GENERIC NAME	AVAILABLE AS
<b>BENZODIAZEPINES</b>	
Alprazolam	Generic, Xanax
Chlordiazepoxide	Generic, Librium
Clonazepam	Generic, Tranxene
Clorazepate	Generic, Klonopin
Diazepam	Generic, Valium
Estazolam	Generic
Flurazepam	Generic
Lorazepam	Generic, Ativan
Midazolam	Generic, Versed
Oxazepam	Generic, Serax
Quazepam	Generic, Doral
Temazepam	Generic, Restoril
Triazolam	Generic, Halcion
<b>BENZODIAZEPINE ANTAGONIST</b>	
Flumazenil	Generic, Romazicon
<b>BARBITURATES</b>	
Amobarbital	Amytal
Mephobarbital	Mebaral (withdrawn)

Pentobarbital	Generic, Nembutal Sodium
Phenobarbital	Generic, Luminal Sodium
Secobarbital	Generic, Seconal
<b>MISCELLANEOUS DRUGS</b>	
Buspirone	Generic, BuSpar
Chloral hydrate	Generic, Aquachloral Suppettes
Eszopiclone	Generic, Lunesta
Hydroxyzine	Generic, Atarax, Vistaril
Lemborexant	Dayvigo
Meprobamate	Generic, Equanil, Miltown
Paraldehyde	Generic
Ramelteon	Rozerem
Suvorexant	Belsomra
Tasimelteon	Hetlioz
Zaleplon	Sonata
Zolpidem	Generic, Ambien, Ambien-CR, Zolpimist

### CASE STUDY ANSWER

As described in this chapter, nonpharmacologic factors are very important in the management of sleep problems: proper diet (and avoidance of snacks before bedtime), exercise, and a regular time and place for sleep. Avoidance of stimulants is very important, and the large intake of diet colas reported by the patient should be reduced, especially in the latter half of the day. If problems persist after these measures are implemented, one of the newer hypnotics ([eszopiclone](#), [zaleplon](#), or [zolpidem](#)) may be tried on a short-term basis.

## Chapter 23: The Alcohols

Todd W Vanderah; Anthony J Trevor

### CASE STUDY

#### CASE STUDY

A 19-year-old college freshman began drinking **alcohol** at 8:30 PM during a hazing event at his new fraternity. Between 8:30 and approximately midnight, he and several other pledges consumed beer and a bottle of whiskey, and then he consumed most of a bottle of rum at the urging of upperclassmen. The young man complained of feeling nauseated, lay down on a couch, and began to lose consciousness. Two upperclassmen carried him to a bedroom, placed him on his stomach, and positioned a trash can nearby. Approximately 10 minutes later, the freshman was found unconscious and covered with vomit. There was a delay in treatment because the upperclassmen called the college police instead of calling 911. After the call was transferred to 911, emergency medical technicians responded quickly and discovered that the young man was not breathing and that he had choked on his vomit. He was rushed to the hospital, where he remained in a coma for 2 days before ultimately being pronounced dead. The patient's blood **alcohol** concentration shortly after arriving at the hospital was 510 mg/dL. What was the cause of this patient's death? If he had received medical care sooner, what treatment might have prevented his death?

**Alcohol**, primarily in the form of ethyl **alcohol** (ethanol), has occupied an important place in the history of humankind for at least 8000 years. In Western society, beer and wine were a main staple of daily life until the 19th century. These relatively dilute alcoholic beverages were preferred over water, which was known—long before the discovery of microbes—to be associated with acute and chronic illness. Partially sterilized by the fermentation process and the **alcohol** content, alcoholic beverages provided calories and some nutrients and served as a main source of daily liquid intake. As systems for improved sanitation and water purification were introduced in the 1800s, beer and wine became less important components of the human diet, and the consumption of alcoholic beverages, including distilled preparations with higher concentrations of **alcohol**, shifted toward their present-day role, in many societies, as a socially acceptable form of recreation.

Today, **alcohol** is widely consumed. Like other sedative-hypnotic drugs, **alcohol** in low to moderate amounts relieves anxiety and fosters a feeling of well-being or even euphoria. However, **alcohol** is also the most commonly abused drug in the world, and the cause of vast medical and societal costs. In the United States, approximately 75% of the adult population drinks **alcohol** regularly. The majority of this drinking population is able to enjoy the pleasurable effects of **alcohol** without allowing **alcohol** consumption to become a health risk. However, 8–10% of the general population in the United States has an **alcohol-use disorder**. Individuals who use **alcohol** in dangerous situations (eg, drinking and driving or combining **alcohol** with other medications) or continue to drink **alcohol** despite adverse consequences related directly to their **alcohol** consumption suffer from **alcohol abuse** (see also [Chapter 32](#)). Individuals with **alcohol dependence** have characteristics of **alcohol** abuse and additionally exhibit physical dependence on **alcohol** (tolerance to **alcohol** and signs and symptoms upon withdrawal). They also demonstrate an inability to control their drinking and devote much time to getting and using **alcohol**, or recovering from its effects. The alcohol-use disorders are complex, with genetic as well as environmental determinants.

The societal and medical costs of **alcohol** abuse are staggering. It is estimated that more than 600,000 emergency department visits and approximately 95,000 deaths (approximately 68,000 men and 27,000 women) in the USA annually are due to **alcohol** use. This makes **alcohol** use the third-leading preventable cause of death in the United States. Once in the hospital, people with chronic alcoholism generally have poorer outcomes. In addition, each year, tens of thousands of children are born with morphologic and functional defects resulting from prenatal exposure to ethanol. Despite the investment of many resources and much basic research, alcoholism remains a common chronic disease that is difficult to treat.

## BASIC PHARMACOLOGY OF ETHANOL

### Pharmacokinetics

Ethanol is a small water-soluble molecule that is absorbed rapidly from the gastrointestinal tract. After ingestion of **alcohol** in the fasting state, peak blood **alcohol** concentrations are reached within 30 minutes. The presence of food in the stomach delays absorption by slowing gastric emptying. Distribution is rapid, with tissue levels approximating the concentration in blood. The volume of distribution for ethanol approximates total body water (0.5–0.7 L/kg). After an equivalent oral dose of **alcohol**, women have a higher peak concentration than men, in part because women have a lower total body water content and in part because of differences in first-pass metabolism. In the central nervous system (CNS), the concentration of ethanol rises quickly, since the brain receives a large proportion of total blood flow and ethanol readily crosses biologic membranes.

More than 90% of **alcohol** consumed is oxidized in the liver; much of the remainder is excreted through the lungs and in the urine. The excretion of a small but consistent proportion of **alcohol** by the lungs can be quantified with breath **alcohol** tests that serve as a basis for a legal definition of “driving under the influence” (DUI) in many countries. In most states in the USA, the **alcohol** level for driving under the influence is set at 80 mg/dL (0.08%). At levels of ethanol usually achieved in blood, the rate of oxidation follows zero-order kinetics; that is, it is independent of time and concentration of the drug. The typical adult can metabolize 7–10 g (150–220 mmol) of **alcohol** per hour, the equivalent of approximately one “drink” [10 oz (300 mL) beer, 3.5 oz (105 mL) wine, or 1 oz (30 mL) distilled 80-proof spirits]. A commercial product (“Palcohol”), approved in some states in the USA in 2015, consists of a powder to be mixed to form a drink containing 10% ethanol (approximately equivalent to wine).

Two major pathways of **alcohol** metabolism to acetaldehyde have been identified (Figure 23–1). Acetaldehyde is then oxidized to acetate by a third metabolic process.

FIGURE 23–1

Metabolism of ethanol by **alcohol** dehydrogenase and the microsomal ethanol-oxidizing system (MEOS). **Alcohol** dehydrogenase and aldehyde dehydrogenase are inhibited by **fomepizole** and **disulfiram**, respectively. NAD<sup>+</sup>, nicotinamide adenine dinucleotide; NADPH, nicotinamide adenine dinucleotide phosphate.

The primary pathway for **alcohol** metabolism involves **alcohol** dehydrogenase (ADH), a family of cytosolic enzymes that catalyze the conversion of **alcohol** to acetaldehyde (see [Figure 23–1](#), left). These enzymes are located mainly in the liver, but small amounts are found in other organs such as the brain and stomach. There is considerable genetic variation in ADH enzymes, affecting the rate of ethanol metabolism and also appearing to alter vulnerability to alcohol-abuse disorders. For example, one ADH allele (the *ADH1B\*2* allele), which is associated with rapid conversion of ethanol to acetaldehyde, has been found to be protective against **alcohol** dependence in several ethnic populations, especially East Asians.

Some metabolism of ethanol by ADH occurs in the stomach in men, but a smaller amount occurs in women, who appear to have lower levels of the gastric enzyme. This difference in gastric metabolism of **alcohol** in women probably contributes to the sex-related differences in blood **alcohol** concentrations noted above.

During conversion of ethanol by ADH to acetaldehyde, hydrogen ion is transferred from ethanol to the cofactor nicotinamide adenine dinucleotide (NAD<sup>+</sup>) to form NADH. As a net result, **alcohol** oxidation generates an excess of reducing equivalents in the liver, chiefly as NADH. The excess NADH production appears to contribute to the metabolic disorders that accompany chronic alcoholism and to both the lactic acidosis and hypoglycemia that frequently accompany acute **alcohol** poisoning.

### B. Microsomal Ethanol-Oxidizing System (MEOS)

This enzyme system, also known as the mixed function oxidase system, uses NADPH as a cofactor in the metabolism of ethanol (see [Figure 23–1](#), right) and consists primarily of cytochrome P450 2E1, 1A2, and 3A4 (see [Chapter 4](#)).

During chronic **alcohol** consumption, MEOS activity is induced. As a result, chronic **alcohol** consumption results in significant increases not only in ethanol metabolism but also in the clearance of other drugs eliminated by the cytochrome P450s that constitute the MEOS system, and in the generation of the toxic byproducts of cytochrome P450 reactions (toxins, free radicals, H<sub>2</sub>O<sub>2</sub>).

### C. Acetaldehyde Metabolism

Much of the acetaldehyde formed from **alcohol** is oxidized in the liver in a reaction catalyzed by mitochondrial NAD-dependent aldehyde dehydrogenase (ALDH). The product of this reaction is acetate (see [Figure 23–1](#)), which can be further metabolized to CO<sub>2</sub> and water, or used to form acetyl-CoA.

Oxidation of acetaldehyde is inhibited by **disulfiram**, a drug that has been used to deter drinking by patients with **alcohol** dependence. When ethanol is consumed in the presence of **disulfiram**, acetaldehyde accumulates and causes an unpleasant reaction of facial flushing, nausea, vomiting, dizziness, and headache. Several other drugs (eg, **metronidazole**, **cefotetan**, **trimethoprim**) inhibit ALDH and have been claimed to cause a disulfiram-like reaction if combined with ethanol.

Some people, primarily of East Asian descent, have genetic deficiency in the activity of the mitochondrial form of ALDH, which is encoded by the *ALDH2* gene. When these individuals drink **alcohol**, they develop high blood acetaldehyde concentrations and experience a noxious reaction similar to that seen with the combination of **disulfiram** and ethanol. This form of reduced-activity ALDH is strongly protective against alcohol-use disorders.

## Pharmacodynamics of Acute Ethanol Consumption

### A. Central Nervous System

The CNS is markedly affected by acute **alcohol** consumption. **Alcohol** causes sedation, relief of anxiety and, at higher concentrations, slurred speech, ataxia, impaired judgment, and disinhibited behavior, a condition usually called intoxication or drunkenness ([Table 23–1](#)). These CNS effects are most marked as the blood level is rising, because acute tolerance to the effects of **alcohol** occurs after a few hours of drinking. For chronic drinkers who are tolerant to the effects of **alcohol**, higher concentrations are needed to elicit these CNS effects. For example, an individual with chronic alcoholism may appear sober or only slightly intoxicated with a blood **alcohol** concentration of 300–400 mg/dL (0.30–0.40%), whereas this level is associated with marked intoxication or even coma in a nontolerant individual. The propensity of moderate doses of **alcohol** to inhibit the attention and information-

processing skills as well as the motor skills required for operation of motor vehicles has profound effects. Approximately 30–40% of all traffic accidents

www.koniginn.com fatality in the United States involve at least one person with blood alcohol near or above the legal level of intoxication, and drunken driving is a leading cause of death in young adults.

TABLE 23-1

**Blood alcohol concentration (BAC) and clinical effects in nontolerant individuals.**

BAC (mg/dL) <sup>1</sup>	Clinical Effect
50-100	Sedation, subjective "high," slower reaction times
100-200	Impaired motor function, slurred speech, ataxia
200-300	Emesis, stupor
300-400	Coma
>400	Respiratory depression, death

<sup>1</sup>In many parts of the United States, a blood level above 80-100 mg/dL for adults or 5-20 mg/dL for persons under 21 is sufficient for conviction of driving while "under the influence."

Like other sedative-hypnotic drugs, alcohol is a CNS depressant. At high blood concentrations, it induces coma, respiratory depression, and death.

Ethanol affects a large number of membrane proteins that participate in signaling pathways, including neurotransmitter receptors for amines, amino acids, opioids, and neuropeptides; enzymes such as Na<sup>+</sup>/K<sup>+</sup>-ATPase, adenylyl cyclase, phosphoinositide-specific phospholipase C; a nucleoside transporter; and ion channels. Much attention has focused on alcohol's effects on neurotransmission by glutamate and  $\gamma$ -aminobutyric acid (GABA), the main excitatory and inhibitory neurotransmitters in the CNS. Acute ethanol exposure enhances the action of GABA at GABA<sub>A</sub> receptors, which is consistent with the ability of GABA-mimetics to intensify many of the acute effects of alcohol and of GABA<sub>A</sub> antagonists to attenuate some of the actions of ethanol. Ethanol inhibits the ability of glutamate to open the cation channel associated with the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors. The NMDA receptor is implicated in many aspects of cognitive function, including learning and memory. "Blackouts"—periods of memory loss that occur with high levels of alcohol—may result from inhibition of NMDA receptor activation. Experiments that use modern genetic approaches eventually will yield a more precise definition of ethanol's direct and indirect targets. In recent years, experiments with mutant strains of mice, worms, and flies have reinforced the importance of previously identified targets and helped identify new candidates, including a calcium-regulated and voltage-gated potassium channel that may be one of ethanol's direct targets (see Box: [What Can Drunken Worms, Flies, and Mice Tell Us About Alcohol?](#)).

## What Can Drunken Worms, Flies, and Mice Tell Us About Alcohol?

For a drug like ethanol, which exhibits low potency and specificity and modifies complex behaviors, the precise roles of its many direct and indirect targets are difficult to define. Increasingly, ethanol researchers are employing genetic approaches to complement standard neurobiologic experimentation. Three experimental animal systems for which powerful genetic techniques exist—mice, flies, and worms—have yielded intriguing results.

Strains of mice with abnormal sensitivity to ethanol were identified many years ago by breeding and selection programs. Using sophisticated genetic mapping and sequencing techniques, researchers have made progress in identifying the genes that confer ethanol susceptibility or resistance traits. A more targeted approach is the use of transgenic mice to test hypotheses about specific genes. For example, after earlier experiments suggested a link between brain neuropeptide Y (NPY) and ethanol, researchers used two transgenic mouse models to further investigate the link. They found that a strain of mice that lacks the gene for NPY—NPY knockout mice—consume more ethanol than control mice and are less sensitive to ethanol's sedative effects. As would be expected if increased concentrations of NPY in the brain make mice more sensitive to ethanol, a strain of mice that overexpresses NPY drinks less [alcohol](#) than the controls even though their total consumption of food and liquid is normal. Work with other transgenic knockout mice supports the central role in ethanol responses of signaling systems that have long been believed to be involved (eg, GABA<sub>A</sub>, glutamate, [dopamine](#), opioid, and serotonin receptors) and has helped build the case for newer candidates such as NPY and corticotropin-releasing hormone, cannabinoid receptors, ion channels, and protein kinase C.

It is easy to imagine mice having measurable behavioral responses to [alcohol](#), but drunken worms and fruit flies are harder to imagine. Actually, both invertebrates respond to ethanol in ways that parallel mammalian responses. *Drosophila melanogaster* fruit flies exposed to ethanol vapor show increased locomotion at low concentrations but at higher concentrations, they become poorly coordinated, sedated, and finally immobile. These behaviors can be monitored by sophisticated laser or video tracking methods or with an ingenious “chromatography” column of air that separates relatively insensitive flies from inebriated flies, which drop to the bottom of the column. The worm *Caenorhabditis elegans* similarly exhibits increased locomotion at low ethanol concentrations and, at higher concentrations, reduced locomotion, sedation, and—something that can be turned into an effective screen for mutant worms that are resistant to ethanol—impaired egg laying. The advantage of using flies and worms as genetic models for ethanol research is their relatively simple neuroanatomy, well-established techniques for genetic manipulation, extensive libraries of well-characterized mutants, and completely or nearly completely solved genetic codes. Already, much information has accumulated about candidate proteins involved with the effects of ethanol in flies. In an elegant study on *C. elegans*, researchers found evidence that a calcium-activated, voltage-gated BK potassium channel is a direct target of ethanol. This channel, which is activated by ethanol, has close homologs in flies and vertebrates, and evidence is accumulating that ethanol has similar effects in these homologs. Genetic experiments in these model systems should provide information that will help narrow and focus research into the complex and important effects of ethanol in humans.

### B. Heart

Significant depression of myocardial contractility has been observed in individuals who acutely consume moderate amounts of [alcohol](#), ie, at a blood concentration above 100 mg/dL.

### C. Smooth Muscle

Ethanol is a vasodilator, probably as a result of both CNS effects (depression of the vasomotor center) and direct smooth muscle relaxation caused by its metabolite, acetaldehyde. In cases of severe overdose, hypothermia—caused by vasodilation—may be marked in cold environments. Preliminary evidence indicates that [flibanserin](#), a drug that interacts with 5-HT receptors, augments the hypotensive effects of ethanol and may cause severe orthostatic hypotension and syncope (see [Chapter 16](#)). Ethanol also relaxes the uterus and—before the introduction of more effective and safer uterine relaxants (eg, calcium channel antagonists)—was used intravenously for the suppression of premature labor.

## Consequences of Chronic [Alcohol](#) Consumption

Chronic [alcohol](#) consumption profoundly affects the function of several vital organs—particularly the liver—and the nervous, gastrointestinal, cardiovascular, and immune systems. Since ethanol has low potency, it requires concentrations thousands of times higher than other misused drugs

(eg, cocaine, opiates, amphetamines) to produce its intoxicating effects. As a result, ethanol is consumed in quantities that are unusually large for a pharmacologically active drug. The tissue damage caused by chronic alcohol ingestion results from a combination of the direct effects of ethanol and acetaldehyde, and the metabolic consequences of processing a heavy load of a metabolically active substance. Specific mechanisms implicated in tissue damage include increased oxidative stress coupled with depletion of glutathione, damage to mitochondria, growth factor dysregulation, and potentiation of cytokine-induced injury.

Chronic consumption of large amounts of alcohol is associated with an increased risk of death. Deaths linked to alcohol consumption are caused by liver disease, cancer, accidents, and suicide.

## A. Liver and Gastrointestinal Tract

Liver disease is the most common medical complication of alcohol abuse; an estimated 15–30% of chronic heavy drinkers eventually develop severe liver disease. Alcoholic fatty liver, a reversible condition, may progress to alcoholic hepatitis and finally to cirrhosis and liver failure. In the USA, chronic alcohol abuse is the leading cause of liver cirrhosis and of the need for liver transplantation. The risk of developing liver disease is related both to the average amount of daily consumption and to the duration of alcohol abuse. Women appear to be more susceptible to alcohol hepatotoxicity than men. Concurrent infection with hepatitis B or C virus increases the risk of severe liver disease. Cirrhosis contributes to elevated portal blood pressure and esophageal and gastric venous varices. These varices may rupture and result in massive bleeding.

The pathogenesis of alcoholic liver disease is a multifactorial process involving metabolic repercussions of ethanol oxidation in the liver, dysregulation of fatty acid oxidation and synthesis, and activation of the innate immune system by a combination of direct effects of ethanol and its metabolites and by bacterial endotoxins that access the liver as a result of ethanol-induced changes in the intestinal tract. Tumor necrosis factor- $\alpha$  appears to play a pivotal role in the progression of alcoholic liver disease and may be a fruitful therapeutic target.

Other portions of the gastrointestinal tract can also be injured. Chronic alcohol ingestion is by far the most common cause of chronic pancreatitis in the Western world. In addition to its direct toxic effect on pancreatic acinar cells, alcohol alters pancreatic epithelial permeability and promotes the formation of protein plugs and calcium carbonate-containing stones.

Individuals with chronic alcoholism are prone to gastritis and have increased susceptibility to blood and plasma protein loss during drinking, which may contribute to anemia and protein malnutrition. Alcohol also injures the small intestine, leading to diarrhea, weight loss, and multiple vitamin deficiencies.

Malnutrition from dietary deficiency and vitamin deficiencies due to malabsorption are common in alcoholism. Malabsorption of water-soluble vitamins is especially severe.

## B. Nervous System

### 1. Tolerance and dependence

The consumption of alcohol in high doses over a long period results in tolerance and in physical and psychological dependence. Tolerance to the intoxicating effects of alcohol is a complex process involving poorly understood changes in the nervous system as well as the pharmacokinetic changes described earlier. As with other sedative-hypnotic drugs, there is a limit to tolerance, so that only a relatively small increase in the lethal dose occurs with increasing alcohol use.

Chronic alcohol drinkers, when forced to reduce or discontinue alcohol, experience a withdrawal syndrome, which indicates the existence of physical dependence. Alcohol withdrawal symptoms usually consist of hyperexcitability in mild cases and seizures, toxic psychosis, and delirium tremens (eg, shaking, confusion, high blood pressure, fever, hallucinations, death) in severe ones. The dose, rate, and duration of alcohol consumption determine the intensity of the withdrawal syndrome. When consumption has been very high, merely reducing the rate of consumption may lead to signs of withdrawal.

Psychological dependence on alcohol is characterized by a compulsive desire to experience the rewarding effects of alcohol and, for current drinkers, a desire to avoid the negative consequences of withdrawal. People who have recovered from alcoholism and become abstinent still experience periods of intense craving for alcohol that can be triggered by environmental cues associated in the past with drinking, such as familiar places, groups of people, or events.

The molecular basis of **alcohol** tolerance and dependence is not known with certainty, nor is it known whether the two phenomena reflect opposing effects on a shared molecular pathway. Tolerance may result from ethanol-induced up-regulation of a pathway in response to the continuous presence of ethanol. Dependence may result from overactivity of that same pathway after the ethanol effect dissipates and before the system has time to return to a normal ethanol-free state.

Chronic exposure of animals or cultured cells to **alcohol** elicits a multitude of adaptive responses involving neurotransmitters and their receptors, ion channels, and enzymes that participate in signal transduction pathways. Up-regulation of the NMDA subtype of glutamate receptors and voltage-sensitive  $\text{Ca}^{2+}$  channels may underlie the seizures that accompany the **alcohol** withdrawal syndrome. GABA neurotransmission is believed to play a significant role in tolerance and withdrawal because (1) sedative-hypnotic drugs that enhance GABAergic neurotransmission are able to substitute for **alcohol** during **alcohol** withdrawal, and (2) there is evidence of down-regulation of GABA<sub>A</sub>-mediated responses with chronic **alcohol** exposure.

Like other drugs of abuse, ethanol modulates neural activity in the brain's mesolimbic **dopamine** reward circuit and increases **dopamine** release in the nucleus accumbens (see [Chapter 32](#)). **Alcohol** affects local concentrations of serotonin, endorphin, endocannabinoid, and dopamine—neurotransmitters involved in the brain reward system. The discovery that **naltrexone**, a nonselective opioid receptor antagonist, helps patients who are recovering from alcoholism abstain from drinking supports the idea that a common neurochemical reward system is shared by very different drugs associated with physical and psychological dependence. There is also convincing evidence from animal models that ethanol intake and seeking behavior are reduced by antagonists of another important regulator of the brain reward system, the cannabinoid CB<sub>1</sub> receptor. Two other important neuroendocrine systems that appear to play key roles in modulating ethanol-seeking activity in experimental animals are the appetite-regulating system—which uses peptides such as leptin, ghrelin, and neuropeptide Y—and the stress response system, which is controlled by corticotropin-releasing factor.

## 2. Neurotoxicity

Consumption of large amounts of **alcohol** over extended periods (usually years) can lead to neurologic deficits. The most common neurologic abnormality in chronic alcoholism is generalized symmetric peripheral nerve injury, which begins with distal paresthesias of the hands and feet. Degenerative changes can also result in gait disturbances and ataxia. Other neurologic disturbances associated with alcoholism include dementia and, rarely, demyelinating disease.

**Wernicke-Korsakoff syndrome** is a relatively uncommon but important entity characterized by paralysis of the external eye muscles, ataxia, and a confused state that can progress to hallucinations, confabulations, coma, and death. It is associated with **thiamine** deficiency but is rarely seen in the absence of alcoholism, although reports of Wernicke-Korsakoff have been seen in patients with gastric bypass. Because of the importance of **thiamine** in this pathologic condition and the absence of toxicity associated with **thiamine** administration, all patients suspected of having Wernicke-Korsakoff syndrome (including virtually all patients who present to the emergency department with altered consciousness, seizures, or both) should receive **thiamine** therapy. Often, the ocular signs, ataxia, and confusion improve promptly upon administration of **thiamine**. However, most patients are left with a chronic disabling memory disorder known as Korsakoff psychosis.

**Alcohol** may also impair visual acuity, with painless blurring that occurs over several weeks of heavy **alcohol** consumption. Changes are usually bilateral and symmetric and may be followed by optic nerve degeneration. Ingestion of ethanol substitutes such as methanol (see section [Pharmacology of Other Alcohols](#)) causes severe visual disturbances.

## C. Cardiovascular System

### 1. Cardiomyopathy and heart failure

**Alcohol** has complex effects on the cardiovascular system. Heavy **alcohol** consumption of long duration is associated with a dilated cardiomyopathy with ventricular hypertrophy and fibrosis. In animals and humans, **alcohol** causes cardiac membrane disruption, depressed function of mitochondria and sarcoplasmic reticulum, intracellular accumulation of phospholipids and fatty acids, as well as upregulation of voltage-gated calcium channels. There is evidence that patients with alcohol-induced dilated cardiomyopathy do significantly worse than patients with idiopathic dilated cardiomyopathy, even though cessation of drinking is associated with a reduction in cardiac size and improved function. The poorer prognosis for

## 2. Arrhythmias

Heavy drinking—and especially “binge” drinking—are associated with both atrial and ventricular arrhythmias. Patients undergoing **alcohol** withdrawal syndrome can develop severe arrhythmias that may reflect abnormalities of potassium or magnesium metabolism as well as enhanced release of catecholamines. Seizures, syncope, and sudden death during **alcohol** withdrawal may be due to these arrhythmias.

## 3. Hypertension

A link between heavier **alcohol** consumption (more than three drinks per day) and hypertension has been firmly established in epidemiologic studies. **Alcohol** is estimated to be responsible for approximately 5% of cases of hypertension, independent of obesity, salt intake, coffee drinking, and cigarette smoking. A reduction in **alcohol** intake appears to be effective in lowering blood pressure in hypertensive individuals who are also heavy drinkers; the hypertension seen in this population is also responsive to standard blood pressure medications.

## 4. Coronary heart disease

Although the deleterious effects of excessive **alcohol** use on the cardiovascular system are well established, there is strong epidemiologic evidence that *moderate alcohol* consumption actually *prevents* coronary heart disease (CHD), ischemic stroke, and peripheral arterial disease. This type of relationship between mortality and the dose of a drug is called a “J-shaped” relationship. Results of these clinical studies are supported by ethanol’s ability to raise serum levels of high-density lipoprotein (HDL) cholesterol (the form of cholesterol that appears to protect against atherosclerosis; see **Chapter 35**), by its ability to inhibit some of the inflammatory processes that underlie atherosclerosis while also increasing production of the endogenous anticoagulant tissue plasminogen activator (t-PA, see **Chapter 34**), and by the presence in some alcoholic beverages such as red wine of antioxidants (eg, resveratrol, ellagic acid) and other substances that may protect against atherosclerosis. These observational studies are intriguing, but randomized clinical trials examining the possible benefit of moderate **alcohol** consumption in prevention of CHD have not been carried out.

## D. Blood

**Alcohol** indirectly affects hematopoiesis through metabolic and nutritional effects and may also directly inhibit the proliferation of all cellular elements in bone marrow. The most common hematologic disorder seen in chronic drinkers is mild anemia resulting from alcohol-related folic acid deficiency. Iron-deficiency anemia may result from gastrointestinal bleeding. **Alcohol** has also been implicated as a cause of several hemolytic syndromes, some of which are associated with hyperlipidemia and severe liver disease.

## E. Endocrine System and Electrolyte Balance

Chronic **alcohol** use has important effects on the endocrine system and on fluid and electrolyte balance. Clinical reports of gynecomastia and testicular atrophy in alcoholics with or without cirrhosis suggest a derangement in steroid hormone balance.

Individuals with chronic liver disease may have disorders of fluid and electrolyte balance, including ascites, edema, and effusions. Alterations of whole body potassium induced by vomiting and diarrhea, as well as severe secondary aldosteronism, may contribute to muscle weakness and can be worsened by diuretic therapy. The metabolic derangements caused by metabolism of large amounts of ethanol can result in hypoglycemia, as a result of impaired hepatic gluconeogenesis, and in ketosis, caused by excessive lipolytic factors, especially increased cortisol and growth hormone.

## F. Fetal Alcohol Syndrome

Chronic maternal **alcohol** abuse during pregnancy is associated with teratogenic effects, and **alcohol** is a leading cause of mental retardation and congenital malformation. The abnormalities that have been characterized as fetal **alcohol** syndrome include (1) intrauterine growth retardation, (2) microcephaly, (3) poor coordination, (4) underdevelopment of midfacial region (appearing as a flattened face), and (5) minor joint anomalies. More severe cases may include congenital heart defects and mental retardation. Although the level of **alcohol** intake required to cause serious neurologic deficits appears quite high, the threshold for more subtle neurologic deficits is uncertain.

that are similar to those in maternal blood. The fetal liver has little or no alcohol dehydrogenase activity, so the fetus must rely on maternal and placental enzymes for elimination of alcohol.

The neuropathologic abnormalities seen in humans and in animal models of fetal alcohol syndrome indicate that ethanol triggers apoptotic neurodegeneration and also causes aberrant neuronal and glial migration in the developing nervous system. In tissue culture systems, ethanol causes a striking reduction in neurite outgrowth.

### G. Immune System

The effects of alcohol on the immune system are complex; immune function in some tissues is inhibited (eg, the lung), whereas pathologic, hyperactive immune function in other tissues is triggered (eg, liver, pancreas). In addition, acute and chronic exposure to alcohol have widely different effects on immune function. The types of immunologic changes reported for the lung include suppression of the function of alveolar macrophages, inhibition of chemotaxis of granulocytes, and reduced number and function of T cells. In the liver, there is enhanced function of key cells of the innate immune system (eg, Kupffer cells, hepatic stellate cells) and increased cytokine production. In addition to the inflammatory damage that chronic heavy alcohol use precipitates in the liver and pancreas, it predisposes to infections, especially of the lung, and worsens the morbidity and increases the mortality risk of patients with pneumonia.

### H. Increased Risk of Cancer

Chronic alcohol use increases the risk for cancer of the mouth, pharynx, larynx, esophagus, and liver. Evidence also points to a small increase in the risk of breast cancer in women. A threshold level for alcohol consumption as it relates to cancer has not been determined. Alcohol itself does not appear to be a carcinogen in most test systems. However, its primary metabolite, acetaldehyde, can damage DNA, as can the reactive oxygen species produced by increased cytochrome P450 activity. Other factors implicated in the link between alcohol and cancer include changes in folate metabolism and the growth-promoting effects of chronic inflammation.

## Alcohol-Drug Interactions

Interactions between ethanol and other drugs can have important clinical effects resulting from alterations in the pharmacokinetics or pharmacodynamics of the second drug.

The most common pharmacokinetic alcohol-drug interactions stem from alcohol-induced increases of drug-metabolizing enzymes, as described in Chapter 4. Thus, prolonged intake of alcohol without damage to the liver can enhance the metabolic biotransformation of other drugs. Ethanol-mediated induction of hepatic cytochrome P450 enzymes is particularly important with regard to acetaminophen. Chronic consumption of three or more drinks per day increases the risk of hepatotoxicity due to toxic or even high therapeutic levels of acetaminophen as a result of increased P450-mediated conversion of acetaminophen to reactive hepatotoxic metabolites (see Figure 4-5). Current US Food and Drug Administration (FDA) regulations require that over-the-counter products containing acetaminophen carry a warning about the relation between ethanol consumption and acetaminophen-induced hepatotoxicity.

In contrast, acute alcohol use can inhibit metabolism of other drugs because of decreased enzyme activity or decreased liver blood flow. Phenothiazines, tricyclic antidepressants, and sedative-hypnotic drugs are the most important drugs that interact with alcohol by this pharmacokinetic mechanism.

Pharmacodynamic interactions also are of great clinical significance. The additive CNS depression that occurs when alcohol is combined with other CNS depressants, particularly sedative-hypnotics, is most important. Alcohol also potentiates the pharmacologic effects of many non-sedative drugs, including vasodilators and oral hypoglycemic agents.

## CLINICAL PHARMACOLOGY OF ETHANOL

Alcohol is the cause of more preventable morbidity and mortality than all other drugs combined with the exception of tobacco. Epidemiologic studies indicate that for men under 65, risk is increased by consumption of more than four drinks on any single day or more than 14 drinks per average week; for women and for men over 65, risk is increased by consumption of more than three drinks on a single day or seven drinks per week. The search for specific etiologic factors or the identification of significant predisposing variables for alcohol abuse has led to disappointing results. Personality type,

severe life stresses, psychiatric disorders, and parental role models are not reliable predictors of alcohol abuse. Although environmental factors clearly play a role, evidence suggests that there is a large genetic contribution to the development of alcoholism. Not surprisingly, polymorphisms in alcohol dehydrogenase and aldehyde dehydrogenase that lead to increased aldehyde accumulation and its associated facial flushing, nausea, and hypotension appear to protect against alcoholism. Much attention in genetic mapping experiments has focused on membrane-signaling proteins known to be affected by ethanol and on protein constituents of reward pathways in the brain. Polymorphisms associated with a relative insensitivity to alcohol and presumably thereby a greater risk of alcohol abuse have been identified in genes encoding an  $\alpha$  subunit of the GABA<sub>A</sub> receptor, an M<sub>2</sub> muscarinic receptor, a serotonin transporter, adenylyl cyclase, and a potassium channel. The link between a polymorphism in an opioid receptor gene and a blunted response to naltrexone raises the possibility of genotype-guided pharmacotherapy for alcohol dependence.

## MANAGEMENT OF ACUTE ALCOHOL INTOXICATION

Nontolerant individuals who consume alcohol in large quantities develop typical effects of acute sedative-hypnotic drug overdose along with the cardiovascular effects previously described (vasodilation, tachycardia) and gastrointestinal irritation. Since tolerance is not absolute, even individuals with chronic alcohol dependence may become severely intoxicated if sufficient alcohol is consumed.

The most important goals in the treatment of acute alcohol intoxication are to prevent severe respiratory depression and aspiration of vomitus. Even with very high blood ethanol levels, survival is probable as long as the respiratory and cardiovascular systems can be supported. The average blood alcohol concentration in fatal cases is above 400 mg/dL; however, the lethal dose of alcohol varies because of varying degrees of tolerance.

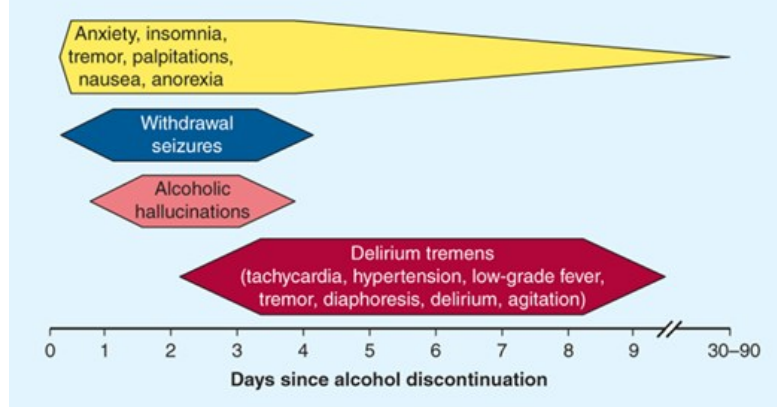

Electrolyte imbalances often need to be corrected, and metabolic alterations may require treatment of hypoglycemia and ketoacidosis by administration of glucose. Thiamine is given to protect against Wernicke-Korsakoff syndrome. Patients who are dehydrated and vomiting should also receive electrolyte solutions. If vomiting is severe, large amounts of potassium may be required as long as renal function is normal.

## MANAGEMENT OF ALCOHOL WITHDRAWAL SYNDROME

Abrupt alcohol discontinuation in an individual with alcohol dependence leads to a characteristic syndrome of motor agitation, anxiety, insomnia, and reduction of seizure threshold. The severity of the syndrome is usually proportionate to the degree and duration of alcohol abuse. However, this can be greatly modified by the use of other sedatives as well as by associated factors (eg, diabetes, injury). In its mildest form, the alcohol withdrawal syndrome of increased pulse and blood pressure, tremor, anxiety, and insomnia occurs 6–8 hours after alcohol consumption is stopped (Figure 23–2). These effects usually lessen in 1–2 days, although some, such as anxiety and sleep disturbances, can be seen at decreasing levels for several months. In some patients, more severe acute reactions occur, with withdrawal seizures or alcoholic hallucinations during the first 1–5 days of withdrawal. Alcohol withdrawal is one of the most common causes of seizures in adults. Several days later, individuals can develop the syndrome of delirium tremens, which is characterized by delirium, agitation, autonomic nervous system instability, low-grade fever, and diaphoresis.

FIGURE 23–2

Time course of events during the alcohol withdrawal syndrome. The signs and symptoms that manifest earliest are anxiety, insomnia, tremor, palpitations, nausea, and anorexia as well as (in severe syndromes) hallucinations and seizures. Delirium tremens typically develops 48–72 hours after alcohol discontinuation. The earliest symptoms (anxiety, insomnia, etc) can persist, in a milder form, for several months after alcohol discontinuation.

The major objective of drug therapy in the **alcohol** withdrawal period is prevention of seizures, delirium, and arrhythmias. Potassium, magnesium, and phosphate balance should be restored as rapidly as is consistent with renal function. **Thiamine** therapy is initiated in all cases. Individuals in mild **alcohol** withdrawal do not need any other pharmacologic assistance.

Specific drug treatment for detoxification in more severe cases involves two basic principles: substituting a long-acting sedative-hypnotic drug for **alcohol** and then gradually reducing (“tapering”) the dose of the long-acting drug. Because of their wide margin of safety, benzodiazepines are preferred. Long-acting benzodiazepines, including **chlordiazepoxide** and **diazepam**, have the advantage of requiring less frequent dosing. Since their pharmacologically active metabolites are eliminated slowly, the long-acting drugs provide a built-in tapering effect. A disadvantage of the long-acting drugs is that they and their active metabolites may accumulate, especially in patients with compromised liver function. Shorter-acting drugs such as **lorazepam** and **oxazepam** are rapidly converted to inactive water-soluble metabolites that will not accumulate, and for this reason the short-acting drugs are especially useful in alcoholic patients with liver disease. Benzodiazepines can be administered orally in mild or moderate cases, or parenterally for patients with more severe withdrawal reactions.

After the **alcohol** withdrawal syndrome has been treated acutely, sedative-hypnotic medications must be tapered slowly over several weeks. Complete detoxification is not achieved with just a few days of **alcohol** abstinence. Several months may be required for restoration of normal nervous system function, especially sleep.

## TREATMENT OF ALCOHOLISM

After detoxification, psychosocial therapy either in intensive inpatient or in outpatient rehabilitation programs serves as the primary treatment for **alcohol** dependence. Other psychiatric problems, most commonly depressive or anxiety disorders, often coexist with alcoholism and, if untreated, can contribute to the tendency of detoxified alcoholics to relapse. Treatment for these associated disorders with counseling and drugs can help decrease the rate of relapse for alcoholic patients.

Three drugs—naltrexone, **acamprosate**, and disulfiram—have FDA approval for adjunctive treatment of **alcohol** dependence.

### Naltrexone

**Naltrexone**, a relatively long-acting opioid antagonist, blocks  $\mu$ -opioid receptors (see **Chapter 31**). Alone and in combination with behavioral counseling, **naltrexone** has been shown in a number of short-term (12- to 16-week), placebo-controlled trials to reduce the rate of relapse to either drinking or **alcohol** dependence and to reduce craving for **alcohol**, especially in patients with high rates of **naltrexone** adherence. **Naltrexone** is approved by the FDA for treatment of **alcohol** dependence. Nalmefene, another opioid antagonist, appears to have similar effects in alcohol-use disorder but is not yet approved by the FDA for this indication.

**Naltrexone** is generally taken once a day in an oral dose of 50 mg for treatment of alcoholism. An extended-release formulation administered as an intramuscular injection once every 4 weeks also is effective. The drug can cause dose-dependent hepatotoxicity and should be used with caution in patients with elevated serum aminotransferase activity. The combination of **naltrexone** plus **disulfiram** should be avoided, since both drugs are

potential hepatotoxins. Administration of **naltrexone** to patients who are physically dependent on opioids precipitates an acute withdrawal syndrome, so patients must be opioid-free before initiating **naltrexone** therapy. **Naltrexone** also blocks the therapeutic analgesic effects of usual doses of opioids.

## Acamprosate

**Acamprosate** has been used in Europe for a number of years to treat **alcohol** dependence and is approved for this use by the FDA. Like ethanol, **acamprosate** has many molecular effects including actions on GABA, glutamate, serotonin, noradrenergic, and **dopamine** receptors. Probably its best-characterized actions are as a weak NMDA-receptor antagonist and a GABA<sub>A</sub>-receptor activator. In European clinical trials, **acamprosate** reduced short-term and long-term (more than 6 months) relapse rates when combined with psychotherapy. However, in a large American trial that compared **acamprosate** with **naltrexone** and with combined **acamprosate** and **naltrexone** therapy (the COMBINE study), **acamprosate** did not show a statistically significant effect alone or in combination with **naltrexone**.

**Acamprosate** is administered as one or two enteric-coated 333-mg tablets three times daily. It is poorly absorbed, and food reduces its absorption even further. **Acamprosate** is widely distributed and is eliminated renally. It does not appear to participate in drug-drug interactions. The most common adverse effects are gastrointestinal (nausea, vomiting, diarrhea) and rash. It should not be used in patients with severe renal impairment.

## Disulfiram

**Disulfiram** acts by inhibiting aldehyde dehydrogenase. **Alcohol** is metabolized as usual, but acetaldehyde accumulates. Thus, **disulfiram** causes extreme discomfort in patients who drink alcoholic beverages. **Disulfiram** alone has little effect, but flushing, throbbing headache, nausea, vomiting, sweating, hypotension, and confusion occur within a few minutes after an individual taking **disulfiram** drinks **alcohol**. The effects may last 30 minutes in mild cases or several hours in severe ones. Because adherence to **disulfiram** therapy is low and because evidence from clinical trials for its effectiveness is weak, **disulfiram** is no longer commonly used.

**Disulfiram** is rapidly and completely absorbed from the gastrointestinal tract; however, a period of 12 hours is required for its full action. Its elimination is slow, and its action may persist for several days after the last dose. The drug inhibits the metabolism of many other therapeutic agents, including **phenytoin**, oral anticoagulants, and **isoniazid**. It should not be administered with medications that contain **alcohol**, including nonprescription medications such as those listed in [Table 64–3](#). **Disulfiram** can cause small increases in hepatic transaminases. Its safety in pregnancy has not been demonstrated.

## Other Drugs

Several other drugs have shown efficacy in maintaining abstinence and reducing craving in chronic alcoholism, although none has FDA approval yet for this use. Such drugs include antiseizure agents (**topiramate**, **gabapentin**, and valproate, see [Chapter 24](#)); and **baclofen**, a GABA<sub>B</sub> receptor agonist used as a spasmolytic (see [Chapter 27](#)). Studies of **varenicline** (see [Chapter 7](#)) indicate that this nicotinic agonist drug can reduce binge drinking in mice. Clinical trials of selective serotonin reuptake inhibitors (SSRIs, see [Chapter 30](#)) and **ondansetron**, a 5-HT<sub>3</sub> antagonist (see [Chapter 62](#)) yielded negative results overall, but suggested that these agents may have benefits in certain subgroups of patients. Based on evidence from model systems, efforts are under way to explore agents that modulate cannabinoid CB<sub>1</sub> receptors, corticotropin-releasing factor receptors, and GABA receptor systems, as well as several other possible targets. Rimonabant, a CB<sub>1</sub> receptor antagonist, has been shown to suppress alcohol-related behaviors in animal models and is being tested in clinical trials of alcoholism. **Cannabidiol** (CBD) and **spironolactone** also have had recent positive studies in animal models as well as in clinical trials.

## PHARMACOLOGY OF OTHER ALCOHOLS

Other alcohols related to ethanol have wide applications as industrial solvents and occasionally cause severe poisoning. Of these, **methanol** and **ethylene glycol** are two of the most common causes of intoxication. **Isopropyl alcohol** (isopropanol, rubbing **alcohol**) is another **alcohol** that is sometimes ingested when ethanol is not available. It produces coma and gastrointestinal irritation, nausea, and vomiting, but is not usually associated with retinal or renal injury.

Methanol (methyl alcohol, wood alcohol) is widely used in the industrial production of synthetic organic compounds and as a constituent of many commercial solvents. In the home, methanol is most frequently found in the form of “canned heat” or in windshield-washing products. Poisonings occur from accidental ingestion of methanol-containing products or when it is misguidedly ingested as an ethanol substitute.

Methanol can be absorbed through the skin or from the respiratory or gastrointestinal tract and is then distributed in body water. The primary mechanism of elimination of methanol in humans is by oxidation to formaldehyde, formic acid, and  $\text{CO}_2$  (Figure 23–3).

FIGURE 23–3

Methanol is converted to the toxic metabolites formaldehyde and formate by alcohol dehydrogenase and aldehyde dehydrogenase. By inhibiting alcohol dehydrogenase, fomepizole and ethanol reduce the formation of toxic metabolites.

Source: Todd W. Vanderah:  
Basic & Clinical Pharmacology, Sixteenth Edition  
Copyright © McGraw Hill. All rights reserved.

Animal species show great variability in mean lethal doses of methanol. The special susceptibility of humans to methanol toxicity is due to metabolism to formate and formaldehyde, not due to methanol itself. Since the conversion of methanol to its toxic metabolites is relatively slow, there is often a delay of 6–30 hours before the appearance of severe toxicity.

Physical findings in early methanol poisoning are generally nonspecific, such as inebriation, gastritis, and an elevated osmolar gap (see Chapter 58). In severe cases, the odor of formaldehyde may be present on the breath or in the urine. After a delay, the most characteristic symptom in methanol poisoning—visual disturbance—occurs along with anion gap metabolic acidosis. The visual disturbance is frequently described as “like being in a snowstorm” and can progress to blindness. Changes in the retina may sometimes be detected on examination, but these are usually late. The development of bradycardia, prolonged coma, seizures, and resistant acidosis all imply a poor prognosis. The cause of death in fatal cases is sudden cessation of respiration. A serum methanol concentration higher than 20 mg/dL warrants treatment, and a concentration higher than 50 mg/dL is considered serious enough to require hemodialysis. Serum formate levels are a better indication of clinical pathology but are not widely available.

The first treatment for methanol poisoning, as in all critical poisoning situations, is support of respiration. There are three specific modalities of treatment for severe methanol poisoning: suppression of metabolism by alcohol dehydrogenase to toxic products, hemodialysis to enhance removal of methanol and its toxic products, and alkalinization to counteract metabolic acidosis.

The enzyme chiefly responsible for methanol oxidation in the liver is alcohol dehydrogenase (see Figure 23–3). Fomepizole, an alcohol dehydrogenase inhibitor, is approved for the treatment of methanol and ethylene glycol poisoning. It is administered intravenously in a loading dose of 15 mg/kg followed by 10 mg/kg every 12 hours for 48 hours and then 15 mg/kg every 12 hours thereafter until the serum methanol level falls below 20–30 mg/dL. The dosage increase after 48 hours is based on evidence that fomepizole rapidly induces its own metabolism by the cytochrome P450 system. Patients undergoing hemodialysis are given fomepizole more frequently (6 hours after the loading dose and every 4 hours thereafter).

[www.konkur.in](http://www.konkur.in) Fomepizole appears to be safe during the short time it is administered for methanol or ethylene glycol poisoning. The most common adverse effects are burning at the infusion site, headache, nausea, and dizziness. Intravenous ethanol is an alternative to [fomepizole](#). It has a higher affinity than methanol for [alcohol](#) dehydrogenase; thus, saturation of the enzyme with ethanol reduces formate production. Ethanol is used intravenously as treatment for methanol and ethylene glycol poisoning. The dose-dependent characteristics of ethanol metabolism and the variability of ethanol metabolism require frequent monitoring of blood ethanol levels to ensure appropriate [alcohol](#) concentration.

In cases of severe poisoning, hemodialysis (discussed in [Chapter 58](#)) can be used to eliminate both methanol and formate from the blood. Two other measures are commonly taken. Because of profound metabolic acidosis in methanol poisoning, treatment with bicarbonate often is necessary. Since folate-dependent systems are responsible for the oxidation of formic acid to CO<sub>2</sub> in humans (see [Figure 23-3](#)), folinic and folic acid are often administered to patients poisoned with methanol, although this has never been fully tested in clinical studies.

## ETHYLENE GLYCOL

Polyhydric alcohols such as ethylene glycol (CH<sub>2</sub>OHCH<sub>2</sub>OH) are used as heat exchangers, in antifreeze formulations, and as industrial solvents. Young children and animals are sometimes attracted by the sweet taste of ethylene glycol and, rarely, it is ingested intentionally as an ethanol substitute or in attempted suicide. Although ethylene glycol itself is relatively harmless and eliminated by the kidney, it is metabolized to toxic aldehydes and oxalate.

Three stages of ethylene glycol overdose occur. Within the first few hours after ingestion, there is transient excitation followed by CNS depression. After a delay of 4–12 hours, severe metabolic acidosis develops from accumulation of acid metabolites and lactate. Finally, deposition of oxalate crystals in renal tubules occurs, followed by delayed renal insufficiency. The key to the diagnosis of ethylene glycol poisoning is recognition of anion gap acidosis, osmolar gap, and oxalate crystals in the urine in a patient without visual symptoms.

As with methanol poisoning, early [fomepizole](#) is the standard treatment for ethylene glycol poisoning. Intravenous treatment with [fomepizole](#) is initiated immediately, as described above for methanol poisoning, and continued until the patient's serum ethylene glycol concentration drops below a toxic threshold (20–30 mg/dL). Intravenous ethanol is an alternative to [fomepizole](#) in ethylene glycol poisoning. Hemodialysis effectively removes ethylene glycol and its toxic metabolites and is recommended for patients with a serum ethylene glycol concentration above 50 mg/dL, significant metabolic acidosis, and significant renal impairment. [Fomepizole](#) has reduced the need for hemodialysis, especially in patients with less severe acidosis and intact renal function.

### SUMMARY The Alcohols and Associated Drugs

Subclass, Drug	Mechanism of Action, Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>ALCOHOLS</b>			
• Ethanol	Multiple effects on neurotransmitter receptors, ion channels, and signaling pathways	Antidote in methanol and ethylene glycol poisoning; topical antiseptic	Zero-order metabolism • duration depends on dose • <i>Toxicity:</i> Acutely, central nervous system depression and respiratory failure • chronically, damage to many systems, including liver, pancreas, gastrointestinal tract, and central and peripheral nervous systems • <i>Interactions:</i> Induces CYP2E1 • increased conversion of <a href="#">acetaminophen</a> to toxic metabolite
<ul style="list-style-type: none"> <li>• <i>Methanol: Poisonings result in toxic levels of formate, which causes characteristic visual disturbance plus coma, seizures, acidosis, and death due to respiratory failure</i></li> <li>• <i>Ethylene glycol: Poisoning creates toxic aldehydes and oxalate, which causes kidney damage and severe acidosis</i></li> </ul>			
<b>DRUGS USED IN ACUTE ETHANOL WITHDRAWAL</b>			
• Benzodiazepines	BDZ receptor	Prevention and treatment of	See <a href="#">Chapter 22</a>

agonists that facilitate GABA-mediated activation of GABA <sub>A</sub> receptors	agonists that facilitate GABA-mediated activation of GABA <sub>A</sub> receptors	acute ethanol withdrawal syndrome	
• <b>Thiamine</b> (vitamin B <sub>1</sub> )	Essential vitamin required for synthesis of the coenzyme <b>thiamine</b> pyrophosphate	Administered to patients suspected of having alcoholism (those exhibiting acute <b>alcohol</b> intoxication or <b>alcohol</b> withdrawal syndrome) to prevent Wernicke-Korsakoff syndrome	Administered parenterally • <i>Toxicity</i> : None • <i>Interactions</i> : None
<b>DRUGS USED IN CHRONIC ALCOHOLISM</b>			
• <b>Naltrexone</b>	Nonselective competitive antagonist of opioid receptors	Reduced risk of relapse in individuals with alcoholism	Available as an oral or long-acting parenteral formulation • <i>Toxicity</i> : GI effects and liver toxicity; will precipitate a withdrawal reaction in individuals physically dependent on opioids and will prevent the analgesic effect of opioids
• <b>Acamprosate</b>	Poorly understood NMDA receptor antagonist and GABA <sub>A</sub> agonist effects	Reduced risk of relapse in individuals with alcoholism	<i>Toxicity</i> : GI effects and rash
• <b>Disulfiram</b>	Inhibits aldehyde dehydrogenase, resulting in aldehyde accumulation during ethanol ingestion	Deterrent to drinking in individuals with <b>alcohol</b> dependence; rarely used	<i>Toxicity</i> : Little effect alone but severe and potentially dangerous flushing, headache, nausea, vomiting, and hypotension when combined with ethanol
<b>DRUGS USED IN ACUTE METHANOL OR ETHYLENE GLYCOL TOXICITY</b>			
• <b>Fomepizole</b>	Inhibits <b>alcohol</b> dehydrogenase, prevents conversion of methanol and ethylene glycol to toxic metabolites	Methanol and ethylene glycol poisoning	Orphan drug • <i>Toxicity</i> : Headache, nausea, dizziness, rare allergic reactions
• <i>Ethanol</i> : Higher affinity than methanol or ethylene glycol for <b>alcohol</b> dehydrogenase; used to reduce metabolism of methanol and ethylene glycol to toxic products			

## PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
<b>DRUGS FOR THE TREATMENT OF ACUTE ALCOHOL WITHDRAWAL SYNDROME (SEE ALSO CHAPTER 22 FOR OTHER BENZODIAZEPINES)</b>	
Chlordiazepoxide HCl	Generic, Librium
Diazepam	Generic, Valium
Lorazepam	Generic, Ativan
Oxazepam	Generic, Serax
Thiamine HCl	Generic
<b>DRUGS FOR THE PREVENTION OF ALCOHOL ABUSE</b>	
Acamprosate calcium	Generic, Campral
Disulfiram	Generic, Antabuse
Naltrexone HCl	Generic, Vivitrol, ReVia
<b>DRUGS FOR THE TREATMENT OF ACUTE METHANOL OR ETHYLENE GLYCOL POISONING</b>	
Ethanol	Generic
Fomepizole	Generic, Antizol

## CASE STUDY ANSWER

This young man exhibited classic signs and symptoms of acute alcohol poisoning, which is confirmed by the blood alcohol concentration. We do not know from the case whether the patient was tolerant to the effects of alcohol but note that his blood alcohol concentration was in the lethal range for a nontolerant individual. Death most likely resulted from respiratory and cardiovascular collapse prior to medical treatment, complicated by a chemical pneumonitis secondary to aspiration of vomitus. The treatment of acute alcohol poisoning includes standard supportive care of airway, breathing, and circulation (“ABCs,” see Chapter 58). Most importantly, the trachea would be intubated, vomitus removed, and mechanical ventilation begun. Intravenous access would be obtained and used to administer dextrose and thiamine, as well as electrolytes and vitamins. If a young, previously healthy individual receives medical care in time, supportive care will most likely be highly effective. As the patient recovers, it is important to be vigilant for signs and symptoms of the alcohol withdrawal syndrome. ## Chapter 24: Antiseizure Medications

Michael A. Rogawski

### CASE STUDY

#### CASE STUDY

A 23-year-old woman presents for consultation regarding her antiseizure medications. Seven years ago, this otherwise healthy young woman had a tonic-clonic seizure at home. She was rushed to the emergency department, at which time she was alert but complained of headache. A consulting neurologist prescribed **levetiracetam** 500 mg bid. Four days later, electroencephalography (EEG) showed rare right temporal sharp waves. Magnetic resonance imaging (MRI) was normal. One year after this episode, a repeat EEG was unchanged, and **levetiracetam** was increased to 1000 mg bid. The patient had no adverse effects at this dose. At age 21, she had a second tonic-clonic seizure while in college. Discussion with her roommate at that time revealed that she had had two recent episodes of 1–2 minutes of altered consciousness with lip smacking (*focal impaired awareness seizure*, formerly *complex partial seizure*). A repeat EEG showed occasional right temporal spikes. What is one possible strategy for controlling her present symptoms?

Epilepsy is a chronic disorder of brain function characterized by the recurrent and unpredictable occurrence of seizures. Approximately 1% of the world's population has epilepsy, which is the fourth most common neurologic disorder after migraine, stroke, and Alzheimer disease. Seizures that occur in people with epilepsy are transitory alterations in behavior, sensation, or consciousness caused by an abnormal, synchronized electrical discharge in the brain. Many cases of epilepsy are the result of damage to the brain, as occurs in traumatic brain injury, stroke, or infections, whereas in other cases, the epilepsy is caused by a brain tumor or developmental lesion such as a cortical or vascular malformation; these epilepsies are referred to as *symptomatic*. In other cases, genetic factors are believed to be the root cause. In most cases, the inheritance is complex (oligogenic or polygenic); rarely, a single gene defect can be identified. Genetic epilepsies in which seizures are the only clinical manifestation and there is no identifiable structural or metabolic abnormality have been called *idiopathic*. The term idiopathic generalized epilepsy (IGE) was used in conjunction with generalized epilepsies with bilateral EEG discharges including childhood absence epilepsy, juvenile myoclonic epilepsy, juvenile absence epilepsy, and generalized tonic-clonic seizures alone (formerly generalized tonic-clonic seizures on awakening). These syndromes now fall under the genetic generalized epilepsy (GGE) category, but the term idiopathic generalized epilepsy may still be applied. The most severe and intractable forms of epilepsy have associated developmental and intellectual disabilities and are referred to as developmental and epileptic encephalopathies (DEEs). In some cases, the DEE is acquired. Hypoxic-ischemic encephalopathy, perinatal stroke, infections, or trauma are causes. In other circumstances the DEE is a component of a genetic syndrome, such as tuberous sclerosis complex (TSC), that has other associated structural or metabolic brain abnormalities. Other prominent DEEs include Lennox-Gastaut syndrome (multiple etiologies), Dravet syndrome (mutations in the *SCN1A* gene in ~85% of patients), CDKL5 deficiency disorder (mutations in the *CDKL5* gene), PCDH19 clustering epilepsy (mutations in the *PCDH19* gene), GLUT1 deficiency syndrome (mutations the *SLC2A* glucose transporter gene), and infantile spasms (West syndrome; multiple etiologies).

The antiseizure medications discussed in this chapter are usually used chronically to prevent the occurrence of seizures in people with epilepsy. These medications are also, on occasion, used in people who do not have epilepsy—to prevent seizures that may occur as part of an acute illness such as meningitis or in the early period following neurosurgery or traumatic brain injury. In addition, certain antiseizure medications are used to manage bouts of increased seizure frequency (referred to as *acute repetitive seizures* or *seizure clusters*) or to terminate ongoing seizures such as in status epilepticus, prolonged febrile seizures, or neonatal seizures or following exposure to seizure-inducing nerve toxins. Seizures are occasionally caused by an acute underlying toxic or metabolic disorder, such as hypocalcemia, in which case appropriate therapy should be directed toward correcting the specific abnormality.

Epileptic seizures are classified into two main categories: (1) *focal onset seizures* (in the past called “partial” or “partial-onset” seizures), which begin in a local cortical site, and (2) *generalized onset seizures*, which involve both brain hemispheres from the onset (Table 24–1). *Focal seizures* can transition to *bilateral tonic-clonic seizures* (formerly called “secondarily generalized”). *Focal aware seizures* (previously “simple partial seizures”) have preservation of consciousness; *focal impaired awareness seizures* (formerly “complex partial seizures”) have impaired consciousness. *Tonic-clonic convulsions* (previously termed “grand mal”) are what most people typically think of as a seizure: the person loses consciousness, falls, stiffens (the tonic phase), and jerks (clonic phase). Tonic-clonic convulsions usually last for less than 3 minutes but are followed by confusion and tiredness of variable duration (“postictal period”). *Generalized tonic-clonic seizures* involve both hemispheres from the onset; they occur in patients with idiopathic (genetic) generalized epilepsies, in some classifications referred to as genetic generalized epilepsies, and have been referred to as primary generalized tonic-clonic seizures. *Generalized absence seizures* (formerly called “petit mal”) are brief episodes of unconsciousness (4–20 seconds, usually <10 seconds) with no warning and immediate resumption of consciousness (no postictal abnormality). Generalized absence seizures (typical absence seizures) most commonly occur in children with childhood absence epilepsy, which begins between 4 and 10 years (usually 5–7 years) and mostly remits by age 12. The major seizure type in infantile spasms is the epileptic spasm, which consists of a sudden flexion, extension, or mixed extension-flexion of predominantly proximal and truncal muscles. Limited forms, such as grimacing, head nodding, or subtle eye movements, can occur. Myoclonic seizures are sudden, brief (<100 milliseconds), involuntary, single or multiple contractions of muscles or muscle groups of variable topography (axial, proximal limb, distal limb). Myoclonus is less regularly repetitive and less sustained than is clonus. Atypical absences are distinct from typical absences in that they occur in DEEs such as Lennox-Gastaut syndrome; loss of awareness begins and ends less abruptly than in typical absence seizures. Atonic seizures (drop attacks), which mainly occur in the Lennox-Gastaut syndrome, are characterized by sudden loss of muscle tone, often causing a forward fall.

TABLE 24–1

**International League Against Epilepsy classification of seizure types.**

<b>Focal onset (formerly <i>partial onset</i>) seizures</b>
Focal aware seizure (formerly <i>simple partial seizure</i> )
Focal impaired awareness seizure (formerly <i>complex partial seizure</i> )
Focal-to-bilateral tonic-clonic seizure (formerly <i>partial seizure secondarily generalized</i> or <i>grand mal seizure</i> )
<b>Generalized onset seizures</b>
Generalized tonic-clonic seizure (formerly <i>primary generalized tonic-clonic seizure</i> or <i>grand mal seizure</i> )
Generalized absence seizure (formerly <i>petit mal seizure</i> ; occurs, for example, in absence epilepsy; atypical absence seizures occur in epileptic encephalopathies such as the Lennox-Gastaut syndrome)
Myoclonic seizure (occurs, for example, in juvenile myoclonic epilepsy and Dravet syndrome)
Atonic seizure ( <i>drop seizure</i> or <i>astatic seizure</i> ; occurs, for example, in the Lennox-Gastaut syndrome)
Epileptic spasms (as in infantile spasms also known as West syndrome)

Lennox-Gastaut syndrome, Dravet syndrome, and juvenile myoclonic epilepsy are epilepsy syndromes in which there are multiple different seizure types.

Antiseizure medications used in the chronic treatment of epilepsy are administered orally; the objective is to prevent the occurrence of seizures. The choice of medication depends either on the type of seizures that the patient exhibits or on the patient's syndromic classification. Appropriately chosen antiseizure medications provide adequate seizure control in about two-thirds of patients. In designing a therapeutic strategy, the use of a single medication is preferred, especially in patients who are not severely affected; such patients can benefit from the advantage of fewer adverse effects with monotherapy. For patients with hard-to-control seizures, multiple medications are usually used simultaneously. Patients who do not achieve seizure control following adequate trials with two or more appropriate medications are considered "pharmacoresistant." The basis for pharmacoresistance is not well understood. DEEs—such as Lennox-Gastaut syndrome, early infantile developmental and epileptic encephalopathy (EIDEE; Ohtahara syndrome), infantile spasms, and Dravet syndrome as well as other etiology-specific DEEs such as CDKL5 deficiency disorder—are difficult to treat with medications. Focal seizures also may be refractory to medications. In some cases, the epilepsy can be cured by surgical resection of the affected brain region. The most commonly performed epilepsy surgery is temporal lobe resection for mesial temporal lobe epilepsy; extratemporal cortical resection, when indicated, is less successful. When seizures arise from cortical injury, malformation, tumor, or a vascular lesion, lesionectomy may be curative. In addition to medications and surgery, several electrical stimulation devices are used in the treatment of epilepsy. The vagus nerve stimulator (VNS) is an implanted programmable pulse generator with a helical electrode that is wrapped around the left vagus nerve in the neck. The device, which continuously delivers open-loop stimulation according to a duty cycle, is approved for the treatment of drug-refractory focal seizures but may also be a good option for symptomatic (or cryptogenic) generalized epilepsies of the Lennox-Gastaut type, including those with intractable atonic seizures. Another device for the treatment of medically refractory focal epilepsy is the responsive neurostimulator (RNS). The RNS is an implanted closed-loop system that detects a pattern of abnormal electrical activity in the seizure focus and then delivers electrical stimulation to prevent seizure occurrence. Deep brain stimulation (DBS) via an implanted device that applies bilateral open-loop stimulation to the anterior nuclei of the thalamus is the third brain stimulation modality approved for epilepsy therapy. DBS is indicated as adjunctive therapy to medications for reducing the frequency of seizures in epilepsy characterized by focal seizures, with or without secondary generalization (focal-to-bilateral tonic-clonic). While not currently approved, stimulation in other targets such as the centromedian nucleus of the thalamus may be more effective for generalized seizures and Lennox-Gastaut syndrome. Dietary therapies, most notably ketogenic diets that are high in fat, low in carbohydrate, and that control protein intake, may be effective in refractory epilepsy. Such dietary therapies are particularly beneficial in myoclonic epilepsies, infantile spasms, Dravet syndrome, and seizures associated with tuberous sclerosis complex, and are the recommended first-line treatment GLUT1 deficiency syndrome (De Vivo disease), associated with impaired transport of glucose into the brain. Ketogenic diets are most commonly used in children but adults may also benefit.

## MECHANISMS OF ACTION

Antiseizure medications protect against seizures by interacting with one or more molecular targets in the brain. The ultimate effect of these interactions is to inhibit the local generation of seizure discharges, both by reducing the ability of neurons to fire action potentials at high rate and by reducing neuronal synchronization. In addition, antiseizure medications inhibit the spread of epileptic activity to nearby and distant sites, either by strengthening the inhibitory surround mediated by GABAergic interneurons or by reducing glutamate-mediated excitatory neurotransmission (the means through which a presynaptic neuron depolarizes and excites a postsynaptic follower neuron). The specific actions of antiseizure medications on their targets are broadly described as (1) modulation of voltage-gated sodium, calcium, or potassium channels; (2) enhancement of fast GABA-mediated synaptic inhibition; (3) modification of synaptic release processes; and (4) diminution of fast glutamate-mediated excitation. These actions can be viewed in the context of the balance between excitation mediated by glutamatergic neurons and inhibition mediated by GABAergic neurons. A propensity for seizure generation occurs when there is an imbalance favoring excitation over inhibition, which can result from either excessive excitation or diminished inhibition or both. Treatments, therefore, that either inhibit excitation or enhance inhibition have antiseizure actions to reduce seizure generation. Inhibition of excitation can be produced by effects on intrinsic excitability mechanisms in excitatory neurons (eg, sodium channel blockers) or on excitatory synaptic transmission (eg, modification of release of the excitatory neurotransmitter glutamate; AMPA receptor antagonists). Enhancement of inhibition is produced by increased activation of GABA<sub>A</sub> receptors, the mediators of inhibition in cortical areas relevant to seizures. Some drug treatments (eg, benzodiazepines, **phenobarbital**, ganaxolone) act as positive allosteric modulators of GABA<sub>A</sub> receptors, whereas others (eg, **tiagabine**, **vigabatrin**) lead to increased availability of neurotransmitter GABA. Voltage-gated potassium channels of the K<sub>v</sub>7 type also serve as an inhibitory influence on epileptiform activity. Retigabine (**ezogabine**), an opener of K<sub>v</sub>7 channels, exerts a unique antiseizure action by virtue of its ability to enhance the natural inhibitory influence of these channels. The specific sites at excitatory and inhibitory neurons and synapses where currently available antiseizure medications act to exert these diverse actions are illustrated in **Figure 24–1**. Instead of affecting mechanisms of seizure generation, a more specific approach for the treatment of epilepsy would be to target mechanisms of disease pathology, thus reducing or eliminating the underlying disease and possibly also associated comorbidities. At present, this strategy has been successful only in tuberous sclerosis complex, an

inherited neurocutaneous disorder that is characterized by hamartomatous lesions involving many organ systems, including the brain. Seizures, most commonly infantile spasms, often begin in the first year of life, but there also can be focal onset seizures and less commonly generalized onset seizures. **Everolimus**, a rapalog (analog of rapamycin) that reverses pathological mTOR signaling, reduces seizures in tuberous sclerosis. **Table 24-2** lists the various targets at which currently available antiseizure medications are thought to act and the medications that act on those targets. For some drugs, there is no consensus as to the specific molecular target (eg, valproate, **zonisamide**, **rufinamide**) or there may be multiple targets (eg, **topiramate**, **felbamate**, **cenobamate**).

**FIGURE 24-1**

Molecular targets for antiseizure medications at the excitatory glutamatergic synapse (**A**) and the inhibitory GABAergic synapse (**B**). Presynaptic targets diminishing glutamate release include  $\text{Na}_v1.6$  voltage-gated sodium channels (**phenytoin**, **carbamazepine**, **lamotrigine**, **lacosamide**, **zonisamide**, and **oxcarbazepine**); KCNQ ( $\text{K}_v7$ ) voltage-gated potassium channels (retigabine [**ezogabine**]); and  $\alpha2\delta-1$  protein (**gabapentin** and **pregabalin**), which interacts with NMDA receptors and voltage-gated calcium channels. Postsynaptic targets at excitatory synapses are AMPA receptors (**perampanel**) and KCNQ voltage-gated potassium channels (retigabine [**ezogabine**]). At inhibitory synapses and in astrocytes, **vigabatrin** inhibits GABA-transaminase (GABA-T) and **tiagabine** blocks GABA transporter 1 (GAT-1). **Phenobarbital**, **primidone** (via metabolism to **phenobarbital**), and benzodiazepines are positive allosteric modulators of synaptic  $\text{GABA}_A$  receptors; high GABA levels resulting from blockade of GABA-T may act on extrasynaptic  $\text{GABA}_A$  receptors.

TABLE 24-2

**Molecular targets of antiseizure drugs.**

Molecular Target	Antiseizure Drugs That Act on Target
<b>Voltage-gated ion channels</b>	
Voltage-gated sodium channels (Na <sub>v</sub> )	Phenytoin, fosphenytoin, <sup>1</sup> carbamazepine, oxcarbazepine, <sup>2</sup> eslicarbazepine acetate, <sup>3</sup> lamotrigine, lacosamide; possibly (or among other actions) topiramate, zonisamide, rufinamide, cenobamate
Voltage-gated calcium channels (T-type)	Ethosuximide
Voltage-gated potassium channels (K <sub>v</sub> 7)	Retigabine (ezogabine)
<b>GABA inhibition</b>	
GABA <sub>A</sub> receptors	Phenobarbital, primidone, ganaxolone; benzodiazepines including diazepam, lorazepam, clonazepam, midazolam, clobazam; stiripentol; possibly topiramate, felbamate, cenobamate, Retigabine (ezogabine)
GAT-1 GABA transporter	Tiagabine
GABA transaminase	Vigabatrin
<b>Synaptic release machinery</b>	
SV2A	Levetiracetam, brivaracetam
α2δ	Gabapentin, gabapentin enacarbil, <sup>4</sup> pregabalin
<b>Ionotropic glutamate receptors</b>	
AMPA receptor	Perampanel
<b>Disease specific</b>	
mTORC1 signaling	Everolimus
<b>Mixed/unknown<sup>5</sup></b>	Valproate, felbamate, cenobamate, topiramate, zonisamide, rufinamide, adrenocorticotropin, cannabidiol

<sup>1</sup>Fosphenytoin is a prodrug for phenytoin.

<sup>2</sup>Oxcarbazepine serves largely as a prodrug for licarbazepine, mainly S-licarbazepine.

<sup>3</sup>Eslicarbazepine acetate is a prodrug for S-licarbazepine.

<sup>4</sup>Gabapentin enacarbil is a prodrug for gabapentin.

<sup>5</sup>There is no consensus as to the mechanism of valproate; felbamate, topiramate, zonisamide, and rufinamide may have actions on as yet unidentified targets in

## PHARMACOKINETICS

Chronic antiseizure medication administration prevents the occurrence of seizures, which can, on occasion, be life threatening. Therefore, adequate drug exposure must be continuously maintained. However, many antiseizure medications also have a narrow therapeutic window; dosing must therefore avoid excessive, toxic exposure. An understanding of the pharmacokinetic properties of the drugs is essential. It is also necessary for the clinician to be cognizant of special factors that affect dosing; these factors include nonlinear relationships between dose and drug exposure and the influence of hepatic or renal impairment on clearance (see [Chapters 3](#) and [4](#)). Further, drug-drug interactions occur with many of the agents—a special issue since the drugs are often used in combination. For some antiseizure medications, drug-drug interactions are complex (see [Chapter 67](#)). For example, addition of a new drug may affect the clearance of the current drug such that the dose of the current drug must be modified. Further, the current drug may necessitate selection of a dosing regimen for the new drug that is different from dosing in a drug-naïve subject. Many antiseizure medications are metabolized by hepatic enzymes, and some, such as [carbamazepine](#), [oxcarbazepine](#), [eslicarbazepine acetate](#), [phenobarbital](#), [phenytoin](#), and [primidone](#), are strong inducers of hepatic cytochrome P450 and glucuronyl transferase enzymes. A new antiseizure drug may increase the concentration of an existing drug by inhibiting its metabolism; alternatively, the new drug may reduce the concentration of the existing drug by inducing its metabolism. Other antiseizure medications are excreted in the kidney and are less susceptible to drug-drug interactions. Some antiseizure medications, including [oxcarbazepine](#), [carbamazepine](#), [primidone](#), mephenytoin, and [clobazam](#), have active metabolites. The extent of conversion to the active forms can be affected by the presence of other drugs. Some antiseizure medications, such as [phenytoin](#), [tiagabine](#), valproate, [diazepam](#), [perampanel](#), [stiripentol](#), and ganaxolone, are highly (>90%) bound to plasma proteins. These drugs can be displaced from plasma proteins by other protein-bound drugs, resulting in a temporary rise in the free fraction. Since the free (unbound) drug is active, there can be transient toxicity. However, systemic clearance increases along with the increased free fraction, so the elevation in free concentration is eventually corrected. Some antiseizure medications, notably [levetiracetam](#), [gabapentin](#), and [pregabalin](#), are not known to have drug interactions. Antiseizure drugs can also affect other medications. Importantly, oral contraceptive levels may be reduced by strong inducers, resulting in failure of birth control.

Antiseizure medications must have reasonable oral bioavailability and must enter the central nervous system. These drugs are predominantly distributed into total body water. Plasma clearance is relatively slow; many antiseizure medications are therefore considered to be medium to long acting, such that they are administered twice or three times a day. Some have half-lives longer than 12 hours. A few, such as [zonisamide](#) and [perampanel](#), can often be administered once daily. For some drugs with short half-lives, extended-release preparations are now available, which may improve compliance. In the remainder of the chapter, the most widely used antiseizure medications, as well as some that are used only in special circumstances, are reviewed. The focal (partial onset) seizure medications are described first, followed by medications for generalized onset seizures and certain epilepsy syndromes.

## MEDICATIONS USED FOR FOCAL (PARTIAL ONSET) SEIZURES

[Carbamazepine](#) is a prototype of the antiseizure medications primarily used in the treatment of focal onset seizures. In addition to being effective in the treatment of focal seizures, [carbamazepine](#) is indicated for the treatment of tonic-clonic (grand mal) seizures. This indication derives from studies in patients whose focal onset seizures progressed to bilateral tonic-clonic seizures (previously called “secondarily generalized tonic-clonic seizures”). Medications like [carbamazepine](#) *exacerbate* certain seizure types in idiopathic (genetic) generalized epilepsies, including myoclonic and absence seizures, and are generally avoided in patients with such a diagnosis. There is evidence from anecdotal reports and small studies indicating that [carbamazepine](#), [phenytoin](#), and [lacosamide](#) may be effective and safe in the treatment of generalized tonic-clonic seizures in idiopathic generalized epilepsies. The most popular medications for the treatment of focal seizures in addition to [carbamazepine](#) are [lamotrigine](#), [lacosamide](#), and [oxcarbazepine](#); [levetiracetam](#) also is frequently used. [Phenobarbital](#) is useful if cost is an issue. [Vigabatrin](#) and [felbamate](#) are third-line drugs because of risk of toxicity.

### CARBAMAZEPINE

[Carbamazepine](#) is one of the most widely used antiseizure medications despite its limited range of activity as a treatment for focal (partial onset) and focal-to-bilateral tonic-clonic seizures. It was initially marketed for the treatment of trigeminal neuralgia, for which it is highly effective; it is usually the medication of first choice for this condition. In addition, [carbamazepine](#) is a mood stabilizer used to treat bipolar disorder.

Structurally, **carbamazepine** is an iminostilbene (dibenzazepine)—a tricyclic compound consisting of two benzene rings fused to an azepine group. The structure of **carbamazepine** is similar to that of tricyclic antidepressants such as **imipramine**, but unlike the tricyclic antidepressants, **carbamazepine** does not inhibit monoamine (serotonin and **norepinephrine**) transporters with high affinity; therefore, **carbamazepine** is not used as an antidepressant despite its ability to treat bipolar disorder.

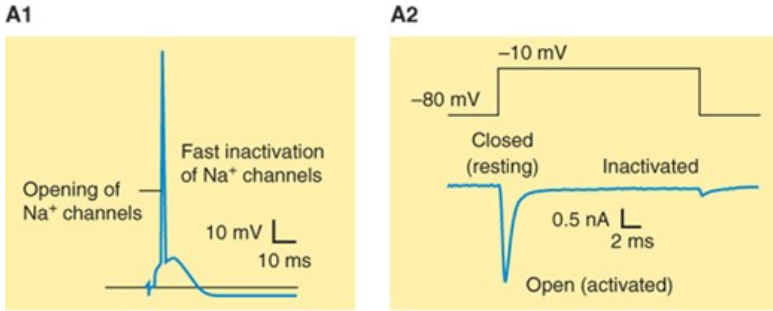

### Mechanism of Action

**Carbamazepine** is a prototypical sodium channel-blocking antiseizure medication that is thought to protect against seizures by interacting with the voltage-gated sodium channels ( $\text{Na}_v1$ ) responsible for the rising phase of neuronal action potentials (see **Chapters 14** and **21**). In the normal state, when neurons are depolarized to action potential threshold, the sodium channel protein senses the depolarization and, within a few hundred microseconds, undergoes a conformational change (gating) that converts the channel from its closed (resting) nonconducting state to the open conducting state that permits sodium flux (**Figure 24–2**). Then, within less than a millisecond, the channel enters the inactivated state, terminating the flow of sodium ions. The channel must then be repolarized before it can be activated again by a subsequent depolarization. Brain sodium channels can rapidly cycle through the resting, open, and inactivated states, allowing neurons to fire high-frequency trains of action potentials.

FIGURE 24–2

(A1) Voltage-gated sodium channels mediate the upstroke of action potentials in brain neurons. Fast inactivation of sodium channels (along with the activation of potassium channels) terminates the action potential. (A2) Voltage-clamp recording of sodium channel current following depolarization, illustrating the time course of sodium channel gating. (B) Schematic illustration of the voltage-dependent gating of sodium channels between closed, open, and inactivated states. (C1) Primary structures of the subunits of sodium channels. The main  $\alpha$  subunit, consisting of four homologous repeats (I–IV), is shown flanked by the two auxiliary  $\beta$  subunits. Cylinders represent  $\alpha$ -helical transmembrane segments. Blue  $\alpha$ -helical segments (S5, S6) form the pore region. +, S4 voltage sensors; grey circles, inactivation particle in inactivation gate loop; III-S6 and IV-S6 (red) are regions where sodium channel-blocking antiseizure medications bind. (C2) Schematic illustration of the sodium channel pore composed of the homologous repeats arrayed around the central channel pore through which sodium flows into the neuron. The S5 and S6 transmembrane  $\alpha$ -helical segments from each homologous repeat (I–IV) form the four walls of the pore. The outer pore mouth and ion selectivity filter are formed by re-entrant P-loops. The key  $\alpha$ -

Sodium channels are multimeric protein complexes, composed of (1) a large  $\alpha$  subunit that forms four subunit-like homologous domains (designated I-IV) and (2) one or more smaller  $\beta$  subunits. The ion-conducting pore is contained within the  $\alpha$  subunit, as are the elements of the channel that

undergo conformational changes in response to membrane depolarization. Carbamazepine and other sodium channel-blocking antiseizure

medications such as **phenytoin** and **lamotrigine** bind preferentially to the channel when it is in the inactivated state, causing it to be stabilized in this state. During high-frequency firing, sodium channels cycle rapidly through the inactivated state, allowing the block to accumulate. This leads to a characteristic use-dependent blocking action in which high-frequency trains of action potentials are more effectively inhibited than are either individual action potentials or the firing at low frequencies (see **Chapter 14, Figures 14-9 and 14-10**). In addition, sodium channel-blocking antiseizure medications exhibit a voltage dependence to their blocking action because a greater fraction of sodium channels exist in the inactivated state at depolarized potentials. Thus, action potentials that are superimposed on a depolarized plateau potential (as characteristically occurs with seizures) are effectively inhibited. The use dependence and voltage dependence of the blocking action of medications like **carbamazepine** provide the ability to preferentially inhibit action potentials during seizure discharges and to less effectively interfere with ordinary ongoing action potential firing (**Figure 24-3**). Such action is thought to allow such medications to prevent the occurrence of seizures without causing unacceptable neurologic impairment. It is noteworthy that sodium channel-blocking antiseizure medications act mainly on action potential firing; the medications do not directly alter excitatory or inhibitory synaptic responses. However, the effect on action potentials translates into reduced transmitter output at synapses. **Carbamazepine** and other sodium channel-blocking antiseizure medications have activity in the rodent (rat or mouse) maximal electroshock (MES) but not in the pentylenetetrazol (PTZ) test; these tests are discussed later in this chapter.

**FIGURE 24-3**

**(A)** Selective effect of a clinically relevant concentration of **lamotrigine** (50  $\mu\text{M}$ ) on action potentials and epileptic-like discharges in rat hippocampal neurons as assessed with intracellular recording. In normal recording conditions, **lamotrigine** has no effect on action potentials or on the evoked excitatory postsynaptic potentials (EPSPs) that elicit the action potential. In epileptic-like conditions (low magnesium), activation elicits initial spikes followed by repetitive epileptiform spike firing (afterdischarge). **Lamotrigine** inhibits the pathologic discharge but not the initial spikes. EPSPs were elicited by stimulation of the Schaffer collateral/commissural fibers (triangles). **(B)** Voltage and use dependence of block of human  $\text{Na}_v1.2$  voltage-activated sodium channels. Sodium currents elicited by depolarization from a holding potential of  $-90$  mV (where there is little inactivation) are minimally affected by 100  $\mu\text{M}$  of **lamotrigine**, whereas there is strong block of current elicited from  $-60$  mV (where there is more substantial inactivation). Trains of 0.7-millisecond (ms) duration pulses from  $-90$  mV (minimal inactivation) are minimally blocked in a use-dependent fashion by 100  $\mu\text{M}$  of **lamotrigine**, whereas 20-ms pulses (marked inactivation) show substantial use dependence. ## Clinical Uses

**Carbamazepine** is effective for the treatment of focal and focal-to-bilateral tonic-clonic seizures. As noted earlier, there is anecdotal evidence that **carbamazepine** may be effective in the treatment of generalized tonic-clonic seizures in idiopathic (genetic) generalized epilepsies but must be used with caution as it can exacerbate absence and myoclonic seizures. **Carbamazepine** is also effective for the treatment of trigeminal and glossopharyngeal neuralgia, and mania in bipolar disorder.

## Pharmacokinetics

**Carbamazepine** has nearly 100% oral bioavailability, but the rate of absorption varies widely among patients. Peak levels are usually achieved 6–8 hours after administration. Slowing absorption by giving the medication after meals causes a reduction in peak levels and helps the patient tolerate larger total daily doses. Extended-release formulations also may decrease the incidence of adverse effects.

Distribution is slow, and the volume of distribution is approximately 1 L/kg. Plasma protein binding is approximately 70%. **Carbamazepine** has a very low systemic clearance of approximately 1 L/kg/d at the start of therapy. The medication has a notable ability to induce its own metabolism, often causing serum concentrations to fall after a few weeks of treatment. Typically, the half-life of 36 hours observed in subjects after an initial single dose decreases to as little as 8–12 hours in subjects receiving continuous therapy. Considerable dosage adjustments are thus to be expected during the first weeks of therapy.

**Carbamazepine** is metabolized in the liver, and only about 5% of the drug is excreted unchanged. The major route of metabolism is conversion to **carbamazepine-10,11-epoxide**, which has been shown to have antiseizure activity. This reaction is primarily catalyzed by CYP3A4, although CYP2C8 also

## Dosage Recommendations & Therapeutic Levels

Carbamazepine is available in immediate-release tablets and suspensions, and extended-release forms that are usually administered twice daily. The medication is effective in children, in whom a dosage of 15–25 mg/kg/d is appropriate. In adults, the typical daily maintenance dose is 800–1200 mg/d, and the maximum recommended dose is 1600 mg/d, but rarely patients have required doses up to 2400 mg/d. Higher dosage is achieved by giving multiple divided doses daily. In patients in whom the blood is drawn just before the morning dose (trough level), therapeutic concentrations are usually 4–8 mcg/mL. Although many patients complain of diplopia at drug levels above 7 mcg/mL, others can tolerate levels above 10 mcg/mL, especially with monotherapy. Initiation of therapy should be slow, with gradual increases in dose.

## Drug Interactions

Carbamazepine stimulates the transcriptional up-regulation of CYP3A4 and CYP2B6. This autoinduction leads not only to a reduction in steady-state carbamazepine concentrations but also to an increased rate of metabolism of concomitant antiseizure medications including primidone, phenytoin, ethosuximide, valproate, clonazepam, perampanel, and ganaxolone. Some antiseizure medications such as valproate may inhibit carbamazepine clearance and increase steady-state carbamazepine blood levels. Other antiseizure medications, notably phenytoin and phenobarbital, may decrease steady-state concentrations of carbamazepine through enzyme induction. These interactions may require dosing changes. No clinically significant protein-binding interactions have been reported.

## Adverse Effects

Carbamazepine may cause dose-dependent mild gastrointestinal discomfort, dizziness, blurred vision, diplopia, or ataxia; sedation occurs only at high doses, and rarely, weight gain can occur. The diplopia often occurs first and may last less than an hour during a particular time of day. Rearrangement of the divided daily dose can often remedy this complaint. A benign leukopenia occurs in many patients, but there is usually no need for intervention unless neutrophil count falls below 1000/mm<sup>3</sup>. Rash and hyponatremia are the most common reasons for discontinuation. Stevens-Johnson syndrome is rare, but the risk is significantly higher in patients with the HLA-B\*1502 allele. It is recommended that Asians, who have a 10-fold higher incidence of carbamazepine-induced Stevens-Johnson syndrome compared to other ethnic groups, be tested before starting therapy.

## OXCARBAZEPINE

Oxcarbazepine is the 10-keto analog of carbamazepine. Unlike carbamazepine, it cannot form an epoxide metabolite. Although it has been hypothesized that the epoxide is associated with carbamazepine's adverse effects, little evidence is available to document the claim that oxcarbazepine is better tolerated. Orally administered oxcarbazepine is rapidly and almost completely (>95%) absorbed. It resides in the plasma for only a short time, as it is quickly converted by non-inducible arylketone reductase to the active 10-hydroxy metabolites, *S*(+)- and *R*(-)-licarbazepine (also referred to as monohydroxy derivatives or MHDs), with a half-life of only 1–2 hours. Oxcarbazepine can be considered a prodrug, as the antiseizure resides almost exclusively in these active metabolites, which are thought to protect against seizures by blocking voltage-gated sodium channels in the same way as carbamazepine. The bulk (80%) of oxcarbazepine is converted to the *S*(+) form. MHD is cleared primarily by the kidney (95%), either unchanged (two-thirds) or as the glucuronide conjugate (one-third); fecal excretion is <4% of the dose. Less than 1% of the administered dose is excreted in the urine as unchanged oxcarbazepine. In the absence of enzyme induction, the plasma half-lives of MHD are similar to that of carbamazepine (8–15 hours) while in the presence of enzyme-inducing antiseizure medications plasma half-lives are slightly shorter (7–12 hours). Oxcarbazepine does not induce its own metabolism. Drug interactions are minimal, but oxcarbazepine has the potential to reduce the effectiveness of hormonal contraceptives.

Oxcarbazepine is less potent than carbamazepine, both in animal tests and in patients; clinical doses of oxcarbazepine may need to be 50% higher than those of carbamazepine to obtain equivalent seizure control. Oxcarbazepine is administered at a starting dose of 300–600 mg/d and may be titrated to a dose of 900–2400 mg/d. Some studies report fewer hypersensitivity reactions to oxcarbazepine, and cross-reactivity with carbamazepine does not always occur. Furthermore, the drug appears to induce hepatic enzymes to a lesser extent than carbamazepine, minimizing drug interactions. Although hyponatremia may occur more commonly with oxcarbazepine than with carbamazepine, most adverse effects of oxcarbazepine are similar to those of carbamazepine.

Eslicarbazepine acetate, a prodrug of *S*(+)-licarbazepine, provides an alternative to **oxcarbazepine**, with some minor differences. Like **oxcarbazepine**, **eslicarbazepine** acetate is converted to **eslicarbazepine** but the conversion occurs more rapidly and it is nearly completely to the *S*(+) form, with only a small amount of the *R*(-) isomer (5%) formed by chiral inversion. Whether there is a benefit to the more selective conversion to *S*(+)-licarbazepine is uncertain, especially since both enantiomers act similarly on voltage-gated sodium channels and both have similar anticonvulsant activities in animal models. **Eslicarbazepine** acetate is administered at a dosage of 400–1600 mg/d; titration is typically required for the higher doses. *S*(+)-Licarbazepine is eliminated primarily by renal excretion; dose adjustment is therefore required for patients with renal impairment. Minimal pharmacokinetic effects are observed with coadministration of **carbamazepine**, **levetiracetam**, **lamotrigine**, **topiramate**, and valproate. The dose of **phenytoin** may need to be decreased if used concomitantly with **eslicarbazepine** acetate. Oral contraceptives may be less effective with concomitant **eslicarbazepine** acetate administration.

## LACOSAMIDE

**Lacosamide** is a sodium channel-blocking antiseizure medication approved for the treatment of focal seizures. It has favorable pharmacokinetic properties and good tolerability, and it is widely prescribed.

### Mechanism of Action

Early studies suggested that **lacosamide** enhances a poorly understood type of sodium channel inactivation called slow inactivation. Recent studies, however, contradict this view and indicate that the drug binds selectively to the fast inactivated state of sodium channels—as is the case for other sodium channel-blocking antiseizure medications, except that the binding is much slower.

### Clinical Use

**Lacosamide** is approved for the treatment of focal onset seizures in patients age 17 years and older. In clinical trials with more than 1300 patients, **lacosamide** was effective at doses of 200 mg/d and had greater and roughly similar overall efficacy at 400 and 600 mg/d, respectively. Although the overall efficacy was similar at 400 and 600 mg/d, the higher dose may provide better control of focal-to-bilateral tonic-clonic (secondarily generalized) seizures; however, this dose is associated with a greater incidence of adverse effects. Adverse effects include dizziness, headache, nausea, and diplopia. Cardiac arrhythmias have been associated with **lacosamide** use. **Lacosamide** is typically administered twice daily, beginning with 50-mg doses and increasing by 100-mg increments weekly. An intravenous formulation provides short-term replacement for the oral medication. The oral solution contains aspartame, which is a source of phenylalanine and could be harmful in people with phenylketonuria.

### Pharmacokinetics

Oral **lacosamide** is rapidly and completely absorbed in adults, with no food effect. Bioavailability is nearly 100%. The plasma concentrations are proportional to oral dosage up to 800 mg. Peak concentrations occur from 1 to 4 hours after oral dosing, with an elimination half-life of 13 hours. There are no active metabolites, and protein binding is minimal. **Lacosamide** does not induce or inhibit cytochrome P450 isoenzymes, so drug interactions are minimal.

## PHENYTOIN

**Phenytoin**, first identified to have antiseizure activity in 1938, is the oldest nonsedating medication used in the treatment of epilepsy. It is prescribed for the prevention of focal seizures and generalized tonic-clonic seizures and for the acute treatment of status epilepticus. Because of its adverse effects and propensity for drug-drug interactions, **phenytoin** is no longer considered a first-line chronic therapy.

**Phenytoin**, sometimes referred to as diphenylhydantoin, is the 5,5-diphenyl-substituted analog of hydantoin. Hydantoin is a five-membered ring molecule similar structurally to barbiturates, which are based on a six-member ring. **Phenytoin** free base ( $pK_a = 8.06-8.33$ ) is poorly water soluble, but **phenytoin** sodium does dissolve in water (17 mg/mL). **Phenytoin** is most commonly prescribed in an extended-release capsule containing **phenytoin** sodium and other excipients to provide a slow and extended rate of absorption with peak blood concentrations from 4 to 12 hours. This form differs from the prompt **phenytoin** sodium capsule form that provides rapid rate of absorption with peak blood concentration from 1.5 to 3 hours. In addition, the free base is available as an immediate-release suspension and chewable tablets. **Phenytoin** is available as an intravenous solution containing propylene glycol and **alcohol** adjusted to a pH of 12. Absorption after intramuscular injection is unpredictable, and some drug precipitation in the muscle occurs; this route of administration is not recommended.

With intravenous administration, there is a risk of the potentially serious “purple glove syndrome” in which a purplish-black discoloration accompanied by edema and pain occurs distal to the site of injection. **Fosphenytoin** is a water-soluble prodrug of **phenytoin** that may have a lower incidence of purple glove syndrome. This phosphate ester compound is rapidly converted to **phenytoin** in the plasma and is used for intravenous administration and treatment of status epilepticus. **Fosphenytoin** is well absorbed after intramuscular administration, but this route is rarely appropriate for the treatment of status epilepticus.

### Mechanism of Action

**Phenytoin** is a sodium channel-blocking antiseizure medication that acts in a similar fashion to **carbamazepine** and other agents in the class.

### Clinical Uses

**Phenytoin** is effective in preventing focal onset seizures and also tonic-clonic seizures, whether they are focal-to-bilateral tonic-clonic (secondarily generalized) or occurring in the setting of an idiopathic (genetic) generalized epilepsy syndrome. **Phenytoin** may worsen other seizure types in idiopathic generalized epilepsies, including absence epilepsy and juvenile myoclonic epilepsy, and in Dravet syndrome.

### Pharmacokinetics & Drug Interactions

Absorption of **phenytoin** is highly dependent on the formulation. Particle size and pharmaceutical additives affect both the rate and the extent of absorption. Therefore, while absorption from the gastrointestinal tract is nearly complete in most patients, the time to peak may range from 3 to 12 hours. **Phenytoin** is extensively (~90%) bound to serum **albumin** and is prone to displacement in response to a variety of factors (eg, hyperbilirubinemia or drugs such as **warfarin** or valproate), which can lead to toxicity. Also, low plasma **albumin** (such as in liver disease or nephrotic syndrome) can result in abnormally high free concentrations and toxicity. Small changes in the bound fraction dramatically affect the amount of free (active) drug. Increased proportions of free drug are also present in the neonate and in the elderly. Some agents such as valproate, phenylbutazone, and sulfonamides can compete with **phenytoin** for binding to plasma proteins. Valproate also inhibits **phenytoin** metabolism. The combined effect can result in marked increases in free **phenytoin**. In all of these situations, patients may exhibit signs of toxicity when total drug levels are within the therapeutic range. Because of its high protein binding, **phenytoin** has a low volume of distribution (0.6–0.7 L/kg in adults).

**Phenytoin** is metabolized by CYP2C9 and CYP2C19 to inactive metabolites that are excreted in the urine. Only a small proportion of the dose is excreted unchanged. The elimination of **phenytoin** depends on the dose. At low blood levels, **phenytoin** metabolism follows first-order kinetics. However, as the dose increases within the therapeutic range, the maximum capacity of the liver to metabolize the drug is approached (saturation kinetics). Even small

increases in dose may be associated with large changes in **phenytoin** serum concentrations (Figure 24-4). In such cases, the half-life increases markedly, steady state is not achieved in routine fashion (since the plasma level continues to rise), and patients quickly develop symptoms of toxicity.

FIGURE 24-4

Relationship between dose and exposure for antiseizure medications (ASMs). Most antiseizure medications follow linear (first-order) kinetics, in which a constant fraction per unit time of the drug is eliminated (elimination is proportional to drug concentration). In the case of **phenytoin**, as the dose increases, there is saturation of metabolism and a shift from first-order to zero-order kinetics, in which a constant quantity per unit time is metabolized. A small increase in dose can result in a large increase in concentration. Orally administered **gabapentin** also exhibits zero-order kinetics, but in contrast to **phenytoin** where metabolism can be saturated, in the case of **gabapentin**, gut absorption, which is mediated by the large neutral amino acid system L transporter, is susceptible to saturation. The bioavailability of **gabapentin** falls at high doses as the transporter is saturated so that increases in blood levels do not keep pace with increases in dose.

The half-life of **phenytoin** in most patients varies from 12 to 36 hours, with an average of 24 hours in the low to mid therapeutic range. Much longer half-lives are observed at higher concentrations. At low blood levels, 5–7 days are needed to reach steady-state blood levels after every dosage change; at higher levels, it may be 4–6 weeks before blood levels are stable. Phenytoin—like **carbamazepine**, **phenobarbital**, and **primidone**—is a major enzyme-inducing antiseizure medication that stimulates the rate of metabolism of many coadministered antiseizure medications, including **valproate**, **tiagabine**, **ethosuximide**, **lamotrigine**, **topiramate**, **oxcarbazepine** and MHDs, **zonisamide**, **felbamate**, many benzodiazepines, and **perampanel**. Autoinduction of its own metabolism, however, is insignificant.

### Therapeutic Levels & Dosing

The therapeutic plasma level of **phenytoin** for most patients is between 10 and 20 mcg/mL. A loading dose can be given either orally or intravenously, with either **fosphenytoin** sodium injection (preferred) or **phenytoin** sodium injection. When oral therapy is started, it is common to begin adults at a dosage of 300 mg/d, regardless of body weight. This may be acceptable in some patients, but it frequently yields steady-state blood levels below 10 mcg/mL, which is the minimum therapeutic level for most patients. If seizures continue, higher doses are usually necessary to achieve plasma levels in the upper therapeutic range. Because of the kinetic factors discussed earlier, toxic levels may occur with only small increments in dosage. The **phenytoin** dosage should be increased in increments of no more than 25–30 mg/d in adults, and ample time should be allowed for the new steady state to be achieved before further increasing the dosage. A common clinical error is to increase the dosage directly from 300 mg/d to 400 mg/d; toxicity frequently occurs at a variable time thereafter. In children, a dosage of 5 mg/kg/d should be followed by readjustment after steady-state plasma levels are obtained.

Two types of oral **phenytoin** are currently available in the USA, differing in their respective rates of dissolution. The predominant form is the sodium salt in an extended-release pill intended for once- or twice-a-day use. In addition, the free acid is available as an immediate-release suspension and chewable tablets. Although a few patients being given **phenytoin** on a long-term basis have been proved to have low blood levels from poor absorption or rapid metabolism, the most common cause of low levels is poor compliance. As noted, **fosphenytoin** sodium is available for intravenous or

## Toxicity

Early signs of [phenytoin](#) administration include nystagmus and loss of smooth extraocular pursuit movements; neither is an indication for decreasing the dose. Diplopia and ataxia are the most common dose-related adverse effects requiring dosage adjustment; sedation usually occurs only at considerably higher levels. Gingival hyperplasia and hirsutism occur to some degree in most patients; the latter can be especially unpleasant in women. Long-term use is associated in some patients with coarsening of facial features and with mild peripheral neuropathy, usually manifested by diminished deep tendon reflexes in the lower extremities. Long-term use may also result in abnormalities of vitamin D metabolism, leading to osteomalacia. Low folate levels and megaloblastic anemia have been reported, but the clinical importance of these observations is unknown.

Idiosyncratic reactions to [phenytoin](#) are relatively rare. A skin rash may indicate hypersensitivity of the patient to the medication. Fever may also occur, and in rare cases, the skin lesions may be severe and exfoliative. Lymphadenopathy may rarely occur; this must be distinguished from malignant lymphoma. Hematologic complications are exceedingly rare, although agranulocytosis has been reported in combination with fever and rash.

## MEPHENYTOIN, ETHOTOIN, & PHENACEMIDE

Many analogs of [phenytoin](#) have been synthesized, but only three have been marketed in the USA, with none currently commercially available. Of the three, mephenytoin and [ethotoin](#) are hydantoin, whereas phenacemide (phenacetylurea) is a ring-opened analog of [phenytoin](#). Like [phenytoin](#), the analogs appear to be most effective against focal and generalized tonic-clonic seizures although no well-controlled clinical trials have documented their effectiveness. [Ethotoin](#) may avoid phenytoin-like side effects such as hirsutism and gingival hyperplasia but it can cause gastrointestinal disturbances, skin rash, and psychiatric side effects. It has a short half-life of 3 to 6 hours, so that dosing four times a day is required. Mephenytoin is metabolized to 5-ethyl-5-phenyl-hydantoin (nirvanol) via demethylation; nirvanol contributes most of the antiseizure activity of mephenytoin. The incidence of severe reactions such as dermatitis, agranulocytosis, or hepatitis is higher for mephenytoin than for [phenytoin](#). Phenacemide has been associated with fatal aplastic anemia and hepatic failure.

## GABAPENTIN & PREGABALIN

[Gabapentin](#) [1-(aminomethyl)cyclohexaneacetic acid] and [pregabalin](#) [(S)-3-(aminomethyl)-5-methylhexanoic acid], known as “gabapentinoids,” are amino acid-like molecules that were originally synthesized as analogs of GABA but are now known not to act through GABA mechanisms. They are used in the treatment of focal seizures and various nonepilepsy indications, such as neuropathic pain, restless legs syndrome, and anxiety disorders.

## Mechanism of Action

Despite their close structural resemblance to GABA, [gabapentin](#) and [pregabalin](#) do not act through effects on GABA receptors or any other mechanism related to GABA-mediated neurotransmission. Rather, gabapentinoids bind avidly to  $\alpha 2\delta$  proteins, specifically  $\alpha 2\delta$ -1 and  $\alpha 2\delta$ -2. These proteins serve as auxiliary subunits of voltage-gated calcium channels but also have other binding partners. Importantly,  $\alpha 2\delta$ -1 forms a heteromeric complex with presynaptic *N*-methyl-D-aspartate (NMDA) receptors. The precise way in which binding of gabapentinoids to  $\alpha 2\delta$  proteins protects against seizures is not known but may relate to a decrease in glutamate release at excitatory synapses. Despite the binding interaction with voltage-gated calcium

channels, gabapentinoids have little effect on calcium currents, suggesting that calcium channels are not the target. Rather, recent research indicates that gabapentinoids inhibit the ability of  $\alpha 2\delta$ -1 to facilitate trafficking of presynaptic NMDA receptors to the cell surface and their incorporation into synapses, but the role of these NMDA receptors in seizures is yet to be defined.

## Clinical Uses

**Gabapentin** and **pregabalin** are effective in the treatment of focal seizures; there is no evidence that they are efficacious in generalized epilepsies. Indeed, **gabapentin** may aggravate absence seizures and myoclonic seizures. **Gabapentin** is usually started at a dose of 900 mg/d (in three divided doses), but starting doses as high as 3600 mg/d can be used if a rapid response is required. Some clinicians have found that even higher dosages are needed to achieve improvement in seizure control. The recommended starting dose of **pregabalin** is 150 mg/d, but a lower starting dose (50–75 mg/d) may avoid adverse effects that can occur on therapy initiation; the effective maintenance dose range is 150–600 mg/d. Although comparative studies are lacking, gabapentinoids are generally considered less effective than other antiseizure medications for the treatment of focal seizures. Gabapentinoids are frequently used in the treatment of neuropathic pain conditions, including postherpetic neuralgia and painful diabetic neuropathy, and in the treatment of anxiety disorders. **Pregabalin** is also approved for the treatment of fibromyalgia. **Gabapentin** and **pregabalin** are generally well tolerated. The most common adverse effects are somnolence, dizziness, ataxia, headache, and tremor. These adverse effects are most troublesome at initiation of therapy and often resolve with continued dosing. Both gabapentinoids can cause weight gain and peripheral edema.

## Pharmacokinetics

**Gabapentin** and **pregabalin** are not metabolized and do not induce hepatic enzymes; they are eliminated unchanged in the urine. Both medications are absorbed by the L-amino acid transport system, which is found only in the upper small intestine. The oral bioavailability of **gabapentin** decreases with increasing dose because of saturation of this transport system. In contrast, **pregabalin** exhibits linear absorption within the therapeutic dose range. This is explained, in part, by the fact that **pregabalin** is used at much lower doses than **gabapentin** so it does not saturate the transport system. Also, **pregabalin** may be absorbed by mechanisms other than the L-amino acid transport system. Because of dependence on the transport system, absorption of **gabapentin** shows patient-to-patient variability and dosing requires individualization. **Pregabalin** bioavailability exceeds 90% and is independent of dose so that it may produce a more predictable patient response. Gabapentinoids are not bound to plasma proteins. Drug-drug interactions are negligible. The half-life of both medications is relatively short (ranging from 5 to 8 hours for **gabapentin** and 4.5 to 7.0 hours for **pregabalin**); they are typically administered two or three times per day. Sustained-release, once-a-day preparations of **gabapentin** are available. The **gabapentin** prodrug **gabapentin** enacarbil also is available in an extended-release formulation. This prodrug is actively absorbed by high-capacity nutrient transporters, which are abundant throughout the intestinal tract, and then converted to **gabapentin** presumably within the intestine, so there is dose-proportional systemic **gabapentin** exposure over a wide dose range.

## TIAGABINE

**Tiagabine**, a selective inhibitor of the GAT-1 GABA transporter, is a second-line treatment for focal seizures. It is contraindicated in generalized onset epilepsies.

## Mechanism of Action

**Tiagabine** is a lipophilic, blood-brain barrier-permeant analog of nipecotic acid, a GABA uptake inhibitor that is not active systemically. The chemical structure of **tiagabine** consists of the active moiety—nipecotic acid—and a lipophilic anchor that allows the molecule to cross the blood-brain barrier.

**Tiagabine** is highly selective for the GAT-1 GABA transporter isoform, the most abundant GABA transporter expressed in brain, and has little or no activity on the other sodium- and chloride-dependent GABA transporters, GAT-2, GAT-3, or BGT-1. The action of the GABA that is released by inhibitory

www.ukonkur.in normally terminated by reuptake into the neuron and surrounding glia by these transporters. **Tiagabine** inhibits the movement of GABA from the extracellular space—where the GABA can act on neuronal receptors—to the intracellular compartment, where it is inactive. This action of **tiagabine** causes prolongation of GABA-mediated inhibitory synaptic responses and potentiation of tonic inhibition; the latter is caused by the action of GABA on extrasynaptic GABA receptors. **Tiagabine** is considered a “rationally designed” antiseizure medication because it was developed with the understanding that potentiation of GABA action in the brain is a possible antiseizure mechanism.

### Clinical Uses

**Tiagabine** is indicated for the adjunctive treatment of focal seizures, with or without secondary generalization (focal-to-bilateral tonic-clonic). In adults, the recommended initial dose is 4 mg/d with weekly increments of 4–8 mg/d to total doses of 16–56 mg/d. Initial dosages can be given twice a day, but a change to three times a day is recommended above 30–32 mg/d. Divided doses as often as four times daily are sometimes required. Adverse effects and apparent lack of efficacy limit the use of this medication. Minor adverse events are dose related and include nervousness, dizziness, tremor, difficulty concentrating, and depression. Excessive confusion, somnolence, or ataxia may require discontinuation. Psychosis occurs rarely. Rash is an uncommon idiosyncratic adverse effect. **Tiagabine** may worsen myoclonic seizures and cause nonconvulsive status epilepticus, even in patients without a history of epilepsy.

### Pharmacokinetics

**Tiagabine** is 90–100% bioavailable, has linear kinetics, and is highly protein bound. The half-life is 5–8 hours and decreases in the presence of enzyme-inducing drugs. Food decreases the peak plasma concentration but not the area under the concentration curve (see [Chapter 3](#)). To avoid adverse effects, **tiagabine** should be taken with food. Hepatic impairment causes a slight decrease in clearance and may necessitate a lower dose. The drug is oxidized in the liver by CYP3A. Elimination is primarily in the feces (60–65%) and urine (25%).

## RETIGABINE (EZOGABINE)

Retigabine (US Adopted Name: **ezogabine**), a potassium channel opener, is indicated for the treatment of focal seizures. Because retigabine causes pigment discoloration of the skin and eye, it had limited use and its sale was discontinued. It is currently not available in the USA.

### Mechanism of Action

Retigabine is an allosteric opener of KCNQ2-5 ( $K_v7.2$ - $K_v7.5$ ) voltage-gated potassium channels, which are localized, in part, in axons and nerve terminals. Opening KCNQ potassium channels in presynaptic terminals inhibits the release of various neurotransmitters, including glutamate, which may be responsible for the seizure protection.

### Clinical Use

Doses of retigabine range from 600 to 1200 mg/d, with 900 mg/d expected to be the most common. Retigabine is administered in three divided doses, and the dose must be titrated beginning at 300 mg/d. Most adverse effects are dose-related and include dizziness, somnolence, blurred vision, confusion, and dysarthria. Urinary symptoms, including retention, hesitation, and dysuria, believed to be due to effects of the drug on KCNQ potassium channels in detrusor smooth muscle, may occur. They are generally mild and usually do not require drug discontinuation. In 2013, reports began to appear of blue pigmentation, primarily on the skin and lips, but also on the palate, and in the eyes. The discoloration appears to be due to binding of dimers of retigabine and retigabine with its N-acetyl metabolite to melanin in the skin and uveal tract of the eye. The skin and eye discoloration has not been associated with more serious adverse effects and there is no evidence of visual impairment but the dyspigmentation may be of cosmetic significance.

### Pharmacokinetics

Absorption of retigabine is not affected by food, and kinetics are linear; drug interactions are minimal. The major metabolic pathways in humans are N-glucuronidation and N-acetylation. Retigabine neither inhibits nor induces the major CYP enzymes involved in drug metabolism.

www.ck12.org  
Cenobamate is a tetrazole alkyl monocarbamate used in the treatment of focal seizures. It has broad-spectrum antiseizure activity in animal models, but a clinical assessment of its efficacy in the treatment of generalized seizures has not yet been completed.

**Cenobamate**

## Clinical Uses

The usual maintenance dose of [cenobamate](#) is 200 mg once daily. A dose of 400 mg once daily was studied in a clinical trial and had efficacy only modestly greater than the 200-mg dose. Seizure-free rates during the clinical trial were higher than observed in trials of other agents approved for the treatment of focal seizures. In long-term follow-up over more than 2 years, high seizure-free rates were maintained, raising the possibility that [cenobamate](#) may overcome pharmacoresistance in some cases. [Cenobamate](#) frequently causes central nervous system adverse effects including fatigue, dizziness, somnolence, diplopia, balance disorder, gait disturbance, dysarthria, nystagmus, and ataxia. The 400-mg dose tended to cause adverse effects more frequently than the 200-mg dose. During early clinical development, among the first 953 patients exposed to [cenobamate](#), 3 confirmed cases of drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome were reported, with 1 death. No cases of DRESS occurred in 1339 patients when therapy was initiated with a very low dose (12.5 mg/d) and the daily dose increased at 2-week intervals over 11 weeks to achieve a maintenance dose of 200 mg/d, with further slow increases to 400 mg/d, if required. [Cenobamate](#) may cause physical dependence and lead to a withdrawal syndrome characterized by insomnia, decreased appetite, depressed mood, tremor, and amnesia.

## Pharmacokinetics

[Cenobamate](#) is well absorbed following oral administration (>88%) and reaches peak levels within 1–4 hours. It has a long terminal half-life (50–60 h), which permits once-daily dosing. [Cenobamate](#) is extensively metabolized by glucuronide conjugation and oxidation, mainly by CYP2E1, CYP2A6, and CYP2B6, and to a lesser extent by CYP2C19 and CYP3A4/5. Due to pharmacokinetic drug–drug interactions, when [cenobamate](#) is added to [clobazam](#), [phenytoin](#), or [phenobarbital](#), it is advisable to proactively reduce the dose of the baseline medication.

## MEDICATIONS EFFECTIVE FOR FOCAL SEIZURES & CERTAIN GENERALIZED ONSET SEIZURE TYPES

Correct diagnosis is critical to antiseizure medication selection. The medications described in the previous section are effective for the treatment of focal onset seizures, including focal-to-bilateral tonic-clonic seizures (secondarily generalized tonic-clonic seizures), but some can worsen certain seizure types in generalized epilepsy syndromes. A variety of medications were shown initially to be effective in the treatment of focal onset seizures and are primarily used to treat these types of seizures; in addition, these medications have also found uses in the treatment of certain generalized onset seizure types. These medications are described below.

## LAMOTRIGINE

[Lamotrigine](#) is considered a sodium channel-blocking antiseizure medication; it is effective for the treatment of focal seizures, as are other medications in this category. In addition, clinical trials of [lamotrigine](#) have demonstrated effectiveness in the treatment of generalized tonic-clonic seizures in idiopathic (genetic) generalized epilepsies and in the treatment of generalized absence epilepsy. In the latter, [lamotrigine](#) is not as effective as [ethosuximide](#) or valproate. The medication is generally well tolerated; however, it can produce a potentially fatal rash (Stevens-Johnson syndrome). Although adverse effects are similar to those of other sodium channel-blocking antiseizure medications, [lamotrigine](#) paradoxically may cause insomnia instead of sedation. [Lamotrigine](#) causes fewer adverse cognitive effects than [carbamazepine](#) or [topiramate](#). It can also improve depression in patients with epilepsy and reduces the risk of relapse in bipolar disorder.

**Lamotrigine** was developed when investigators thought that the antifolate effects of certain antiseizure medications such as **phenytoin** might contribute to their effectiveness. Several phenyltriazines were developed; although their antifolate properties were weak, some were active in seizure screening tests. The antifolate activity of **lamotrigine** is not believed to contribute to its therapeutic activity in epilepsy.

**Lamotrigine**

### Mechanism of Action

The action of **lamotrigine** on voltage-gated sodium channels is similar to that of **carbamazepine**. The mechanism by which **lamotrigine** is effective against absence seizures is not known.

### Clinical Uses

Although most controlled studies have evaluated **lamotrigine** as add-on therapy, the medication is effective as monotherapy for focal seizures, and **lamotrigine** is now widely prescribed for this indication because of its excellent tolerability. Despite being less effective than **ethosuximide** and valproate for absence epilepsy, **lamotrigine** may be prescribed because of its tolerability or in females of childbearing age because it has fewer fetal risks than valproate. **Lamotrigine** is also approved for primary generalized tonic-clonic seizures and generalized seizures of the Lennox-Gastaut syndrome. Adverse effects include dizziness, headache, diplopia, nausea, insomnia, somnolence, and skin rash. The rash is a typical hypersensitivity reaction. Pediatric patients are at greater risk: serious rash occurs in approximately 0.3–0.8% of children age 2–17 years, whereas in adults, the rate is 0.08–0.3%. The risk of rash may be diminished by slow dose escalation. Thus, the titration schedule to initiate **lamotrigine** requires more than 5 weeks. **Lamotrigine**, by virtue of its effects on voltage-gated sodium channels, has effects on the heart, including the potential to cause modest QRS prolongation at therapeutic doses. There is no conclusive evidence that concern is warranted when using **lamotrigine** in patients without a history of cardiac illness. If there is a history of conduction disorder or ventricular arrhythmia, electrocardiogram monitoring may be justified. **Lamotrigine** should not be used in patients with Brugada syndrome.

### Pharmacokinetics

**Lamotrigine** is almost completely absorbed and has a volume of distribution of 1–1.4 L/kg. Protein binding is only about 55%. The drug has linear kinetics and is metabolized primarily by glucuronidation in the liver to the inactive 2-*N*-glucuronide, which is excreted in the urine. **Lamotrigine** has a half-life of approximately 24 hours in normal volunteers; this decreases to 13–15 hours in patients taking enzyme-inducing drugs. **Lamotrigine** is effective in the treatment of focal seizures in adults at dosages typically between 100 and 300 mg/d. The initial dose is 25 mg/d, increasing to 50 mg/d after 2 weeks; thereafter, titration can proceed by 50 mg/d every 1–2 weeks to a usual maintenance dose of 225–375 mg/d (in two divided doses). Therapeutic serum levels have not been established, but toxicity is infrequent with levels <10 mcg/mL. The combination of **lamotrigine** and valproate is believed to be particularly efficacious. However, valproate causes a twofold increase in the half-life of **lamotrigine** and can increase blood levels correspondingly, leading to a risk of skin rash if valproate is added to a stable regimen of **lamotrigine**. In patients receiving valproate, the initial dose of **lamotrigine** must be reduced to 12.5–25 mg every other day, with increases of 25–50 mg/d every 2 weeks as needed to a usual maintenance dose of 100–200 mg/d.

## LEVETIRACETAM

**Levetiracetam** is a broad-spectrum antiseizure agent and one of the most commonly prescribed drugs for epilepsy, primarily because of its perceived favorable adverse effect profile, broad therapeutic window, favorable pharmacokinetic properties, and lack of drug-drug interactions.

Levetiracetam

Brivaracetam

## Mechanism of Action

**Levetiracetam** is an analog of piracetam, which is purported to be a cognition enhancer. In animal testing, **levetiracetam** is not active in the MES or PTZ tests, but it does have activity against seizures in the 6-Hz and kindling models. **Levetiracetam** binds selectively to SV2A, a ubiquitous synaptic vesicle integral membrane protein, which may function as a positive effector of synaptic vesicle exocytosis. The drug accesses the luminal side of recycling synaptic vesicles by vesicular endocytosis. Binding to SV2A in the vesicle reduces the release of the excitatory neurotransmitter glutamate during trains of high-frequency activity.

## Clinical Uses

**Levetiracetam** is effective in the treatment of focal seizures in adults and children, primary generalized tonic-clonic seizures, and the myoclonic seizures of juvenile myoclonic epilepsy. Adult dosing can begin with 500 or 1000 mg/d. The dosage can be increased every 2–4 weeks by 1000 mg to a maximum dosage of 3000 mg/d. The drug is dosed twice daily. Adverse effects include somnolence, asthenia, ataxia, infection (colds), and dizziness. Less common but more serious are behavioral and mood changes, such as irritability, aggression, agitation, anger, anxiety, apathy, depression, and emotional lability. Oral formulations include extended-release tablets; an intravenous preparation also is available.

## Pharmacokinetics

Oral absorption of **levetiracetam** is rapid and nearly complete, with peak plasma concentrations in 1.3 hours. Food slows the rate of absorption but does not affect the amount absorbed. Kinetics are linear. Protein binding is less than 10%. The plasma half-life is 6–8 hours but may be longer in the elderly. Two thirds of the drug is excreted unchanged in the urine and the remainder as the inactive deaminated metabolite 2-pyrrolidone-*N*-butyric acid. The metabolism of **levetiracetam** occurs in the blood. There is no metabolism in the liver, and drug interactions are minimal.

## BRIVARACETAM

**Brivaracetam**, the 4-*n*-propyl analog of **levetiracetam**, is a high-affinity SV2A ligand recently approved for the treatment of focal (partial) onset seizures. There is no evidence that **brivaracetam** has superior efficacy to **levetiracetam** for this indication. As is the case with **levetiracetam**, **brivaracetam** use has been associated with psychiatric adverse effects including depression, insomnia, irritability, aggression, belligerence, anger, and anxiety. There is some evidence that patients experiencing such behavioral adverse effects during treatment with **levetiracetam** will benefit from a switch to **brivaracetam**. However, there is also evidence that **levetiracetam** may have reduced propensity for other adverse effects such as dizziness. Whether **brivaracetam** will prove to have the broad-spectrum activity of **levetiracetam** remains to be demonstrated although this seems likely given the similarity with **levetiracetam**. **Brivaracetam** is active in animal models of generalized epilepsies. It improved or abolished the photoparoxysmal response (abnormal occurrence of cortical spikes or spike and wave discharges on EEG in response to intermittent light stimulation) in patients with generalized epilepsies. In addition, the drug reduced the frequency of generalized seizures in a small number of patients with generalized epilepsy included in a clinical trial, and there have been case reports of favorable responses in additional patients with absence and myoclonic seizures. **Brivaracetam** exhibits linear pharmacokinetics over a wide dose range (10–600 mg, single oral dose). It is rapidly and completely absorbed after oral administration; has an elimination half-life of 7–8 hours, which allows twice-daily dosing; and has low plasma protein binding (<20%).

Coadministration of **brivaracetam** with **carbamazepine** may increase exposure to **carbamazepine** epoxide, the active metabolite of **carbamazepine**, possibly leading to adverse effects; **carbamazepine** dose reduction should be considered. Similarly, coadministration of **brivaracetam** with **phenytoin**

may increase [phenytoin](#) levels. Coadministration of other antiseizure medications is unlikely to affect [brivaracetam](#) exposure. [Brivaracetam](#) provides no added therapeutic benefit when administered in conjunction with [levetiracetam](#); both drugs act on SV2A.

## PERAMPANEL

[Perampanel](#) is an orally active AMPA receptor antagonist approved for the treatment of focal seizures and primary generalized tonic-clonic seizures in idiopathic (genetic) generalized epilepsies.

**Perampanel**

### Mechanism of Action

[Perampanel](#) is a potent noncompetitive antagonist of the AMPA receptor, a subtype of the ionotropic glutamate receptor that is the main mediator of synaptic excitation in the central nervous system (see [Figure 24–1](#)). AMPA receptors are critical to local generation of seizure activity in epileptic foci and are also responsible for the neuron-to-neuron spread of excitation. Partial blockade of AMPA receptors by therapeutic concentrations of [perampanel](#) reduces the likelihood of seizure occurrence. In generalized convulsive seizures, whether occurring as a secondarily generalized convulsion following a focal seizure or as a primary generalized seizure, excitatory cortical neurons engage subcortical centers, including the thalamus, that relay the excitation throughout both hemispheres. This spread of excitation to distant sites is mediated by AMPA receptors at the excitatory synapses that long axons make on their distant targets. [Perampanel](#) is therefore well suited to inhibit this spread of excitation, which may account for its activity in preventing secondary (focal-to-bilateral tonic-clonic) and primary generalized convulsive seizures. [Perampanel](#) binds to an allosteric site on the extracellular side of the channel, acting as a wedge to prevent channel opening.

### Clinical Use

A typical maintenance dose of [perampanel](#) for patients 12 years of age and older is 4, 6, or 8 mg/d. Higher doses may be needed in patients who are receiving CYP3A4-inducing antiseizure medications. [Perampanel](#) use is often associated with behavioral adverse reactions including aggression, hostility, irritability, and anger. The frequency of these adverse effects increases in a dose-dependent fashion, and they occur more often in younger patients and in those with learning disabilities or dementia. [Alcohol](#) use may exacerbate the level of anger. Other common adverse effects are dizziness, somnolence, and headache. Falls are more common at higher doses.

### Pharmacokinetics

[Perampanel](#) has a long half-life, typically ranging from 70 to 110 hours, which permits once-daily dosing. Because of the long half-life, steady state is not achieved for 2–3 weeks; the prescriber should make dosage changes no more frequently than at 2-week (or longer) intervals. The kinetics are linear in the dose range of 2–12 mg/d. The half-life is prolonged in moderate hepatic failure. Absorption is rapid and the drug is fully bioavailable. Although food slows the rate of absorption, the extent is not affected. [Perampanel](#) is 95% bound to plasma proteins. The drug is extensively metabolized via initial oxidation by CYP3A4 and subsequent glucuronidation.

### Drug Interactions

The most significant drug interactions with [perampanel](#) are with potent CYP3A4 inducer antiseizure medications such as [carbamazepine](#), [oxcarbazepine](#), and [phenytoin](#). Concomitant use with such agents increases the clearance of [perampanel](#) by 50–70%, which may require the use of higher [perampanel](#) doses. Of somewhat lesser concern is the potential for strong CYP3A4 inhibitors to increase the levels of [perampanel](#). [Perampanel](#) may decrease the effectiveness of levonorgestrel-containing hormonal contraceptives.

In 1903, chemists in Germany discovered that lipophilic derivatives of barbituric acid induced sleep in dogs. **Phenobarbital** was introduced into the clinical market in 1912 as a sleeping aid; it was serendipitously found to be useful in the treatment of epilepsy. In comparison with anesthetic barbiturates such as **pentobarbital**, **phenobarbital** is preferred in the chronic treatment of epilepsy because it is less sedative at antiseizure doses. Intravenous **pentobarbital**, however, is frequently used to induce general anesthesia in the treatment of drug-refractory status epilepticus. **Phenobarbital** is the oldest of the currently available antiseizure medications; however, the drug is no longer a first choice in the developed world because of its sedative properties and many drug interactions. **Phenobarbital** has long been used as a first-line treatment for seizures in neonates, and in 2022 it was approved by the US Food and Drug Administration for the treatment of neonatal seizures in term and preterm infants.

## Chemistry

Four barbituric acid derivatives were once used for epilepsy: **phenobarbital**, mephobarbital, metharbital, and **primidone**. Only **phenobarbital** and **primidone** remain in common use.

## Mechanism of Action

Barbiturates such as **phenobarbital** act as positive allosteric modulators of GABA<sub>A</sub> receptors at low concentrations (see [Figure 22-6](#)); at higher concentrations, the drugs directly activate GABA<sub>A</sub> receptors (see also [Chapter 22](#)). In contrast to benzodiazepines, which augment the frequency of GABA<sub>A</sub> receptor chloride channel opening, barbiturates increase the mean open duration of the channel without altering either channel conductance or opening frequency. **Phenobarbital** also exerts other actions on synaptic function and intrinsic neuronal excitability mechanisms; some of these could be relevant to its clinical antiseizure activity, including block of AMPA receptors or voltage-activated calcium channels.

## Clinical Uses

**Phenobarbital** is useful in the treatment of focal seizures and generalized tonic-clonic seizures. Evidence-based comparisons of **phenobarbital** with **phenytoin** and **carbamazepine** have shown no difference in seizure control, but **phenobarbital** was more likely to be discontinued due to adverse effects. **Phenobarbital** may be useful in the treatment of myoclonic seizures, such as in juvenile myoclonic epilepsy, but it is not a drug of first choice. **Phenobarbital** may worsen absence seizures and infantile spasms. Long-term administration of **phenobarbital** leads to physical dependence such that seizure threshold is reduced upon withdrawal. The drug must be discontinued gradually over several weeks to avoid the occurrence of severe seizures or status epilepticus.

## Pharmacokinetics, Therapeutic Levels, & Dosage

For pharmacokinetics, drug interactions, and toxicity of **phenobarbital**, see [Chapter 22](#). The dose of **phenobarbital** is individualized based on clinical response. Dosing information from clinical trials is limited. Doses in the range of 60–200 mg, divided two or three times daily, are typically used. The minimally effective dose may be 60 mg/d, and the median effective dose range may be 100–150 mg/d. The accepted serum concentration reference range is 15–40 mcg/mL, although many patients tolerate chronic levels above 40 mcg/mL. Mean steady-state plasma **phenobarbital** levels with 60 and 100 mg/d dosing are 14 and 21 mcg/mL, respectively.

## PRIMIDONE

**Primidone** (2-desoxyphenobarbital) is a derivative of **phenobarbital**. In the early 1950s, the drug was found to have antiseizure activity in animal models; subsequent evidence showed it to be clinically active in the treatment of epilepsy. It was widely used until the 1960s but was then largely abandoned because of its high incidence of adverse effects. It is effective for the treatment of essential tremor and is still used for this indication.

### Mechanism of Action

Primidone is metabolized to phenobarbital and phenylethylmalonamide (PEMA). All three compounds are active antiseizure agents. Although phenobarbital is roughly equally active in the MES and PTZ animal tests, primidone has greater activity in the MES test than the PTZ test, indicating that it acts more like the sodium channel-blocking antiseizure medications than phenobarbital. Also, in animal models, primidone causes relatively less acute motor impairment than phenobarbital. With chronic treatment, phenobarbital is thought to mediate most of the antiseizure activity of primidone. Attempts to determine the relative contributions of the parent drug and its two metabolites have been conducted in newborn infants, in whom drug-metabolizing enzyme systems are very immature and in whom primidone is only slowly metabolized. In these patients, primidone is effective in controlling seizures, confirming that it has intrinsic antiseizure activity. This conclusion was reinforced by studies in older patients initiating treatment with primidone, in which seizure control was obtained before phenobarbital concentrations reached the therapeutic range.

### Clinical Uses

Primidone is effective against focal seizures and generalized tonic-clonic seizures, but its overall effectiveness is less than drugs such as carbamazepine and phenytoin because of a high incidence of acute toxicity on initial administration and because of chronic sedative effects at effective doses. Use of primidone in movement disorders is discussed in Chapter 28.

### Pharmacokinetics

Primidone is completely absorbed, usually reaching peak concentrations about 3 hours after oral administration. Primidone is only 30% bound to plasma proteins. The volume of distribution is 0.6 L/kg. As shown in the text figure, primidone is metabolized by oxidation to phenobarbital, which accumulates slowly, and by scission of the heterocyclic ring to form PEMA. Both primidone and phenobarbital also undergo subsequent conjugation and excretion. Primidone has a larger clearance than most other antiseizure medications (2 L/kg/d), corresponding to a half-life of 6–8 hours. PEMA clearance is approximately half that of primidone, but phenobarbital has a very low clearance (see Table 3–1). The appearance of phenobarbital corresponds to the disappearance of primidone. During chronic therapy, the phenobarbital levels derived from primidone are usually two to three times higher than the primidone levels.

### Therapeutic Levels & Dosage

Primidone is most efficacious when plasma levels are in the range of 8–12 mcg/mL. Concomitant levels of its metabolite, phenobarbital, at steady state, usually vary from 15 to 30 mcg/mL. Dosages of 10–20 mg/kg/d are necessary to obtain these levels. Primidone should be started at a low daily dose, which is then gradually escalated over several days to a few weeks to avoid prominent sedation and gastrointestinal complaints. When adjusting doses of the drug, the parent drug reaches steady state rapidly (30–40 hours), but the active metabolites phenobarbital and PEMA reach steady state much

The dose-related adverse effects of **primidone** are similar to those of its metabolite, **phenobarbital**, except that many patients experience severe adverse effects on initial dosing including drowsiness, dizziness, ataxia, nausea, and vomiting. Tolerance to these adverse effects develops in hours to days and can be minimized by slow titration.

## FELBAMATE

**Felbamate** is a dicarbamate that is used in the treatment of focal seizures and in the Lennox-Gastaut syndrome. It is structurally related to the sedative-hypnotic **meprobamate**. **Felbamate** is generally well tolerated; some patients report *improved* alertness. However, because the drug can cause aplastic anemia and hepatic failure, **felbamate** is used only for patients with refractory seizures who respond poorly to other medications. Despite the seriousness of the adverse effects, thousands of patients worldwide use this medication.

### Mechanism of Action

**Felbamate** appears to have multiple mechanisms of action. It produces a use-dependent block of NMDA receptors, with selectivity for those containing the GluN2B (NR2B) subunit; the drug also produces a barbiturate-like potentiation of GABA<sub>A</sub> receptor responses, but is of low efficacy.

### Clinical Use

The typical starting dose of **felbamate** is 400 mg three times a day. The dose may be escalated slowly to a maximum dose of 3600 mg/d, although some patients have received doses as high as 6000 mg/d. Effective plasma levels range from 30 to 100 mcg/mL; optimal seizure control is believed to occur with concentrations below 60 mcg/mL. In addition to its usefulness in focal seizures, **felbamate** ameliorates atonic seizures as well as other seizure types in the Lennox-Gastaut syndrome.

### Pharmacokinetics & Drug Interactions

Oral **felbamate** is well absorbed (>90%). Of the absorbed dose, 30–50% is excreted unchanged in the urine. The remainder is metabolized by CYP3A4 and CYP2E1 in the liver. The mean terminal half-life of 20 hours in monotherapy decreases to 13–14 hours in the presence of **phenytoin** or **carbamazepine**. **Felbamate** decreases the clearance of **phenytoin** (by inhibition of CYP2C19) and valproate (by inhibition of  $\beta$ -oxidation) and increases their blood levels; dose reductions of these drugs may be necessary when **felbamate** is initiated. **Felbamate** reduces levels of **carbamazepine** but increases levels of the metabolite **carbamazepine** epoxide, which may be associated with adverse effects including dizziness, diplopia, or headache.

## MEDICATIONS EFFECTIVE FOR GENERALIZED ONSET SEIZURES

A limited number of antiseizure medications are first-line agents in the treatment of patients who exhibit multiple generalized onset seizure types. Valproate is especially effective and is considered the first-choice treatment for such patients. However, it has various troublesome side effects and is a known human teratogen; its use is avoided in women of childbearing potential. Other drugs that may have broad activity in generalized epilepsies are

Valproate is a first-line broad-spectrum antiseizure medication that is thought to offer protection against many seizure types. In addition, it is used as a mood stabilizer in bipolar disorder and as prophylactic treatment for migraine. Valproate was found to have antiseizure properties when used as a solvent in the search for other drugs effective against seizures.

## Chemistry

Valproic acid is a short-chain branched fatty acid that is liquid at room temperature; it is formulated as an oral syrup solution or in [gelatin](#) capsules. More commonly, however, the drug is used in a coordination complex—referred to as divalproex sodium—composed of equal parts of valproic acid and the salt sodium valproate. An extended-release divalproex formulation in a hydrophilic polymer matrix allows once-a-day oral administration. Valproic acid has a  $pK_a$  value of 4.56 and is therefore fully ionized at body pH; for that reason, the active form of the drug is the valproate ion, regardless of whether valproic acid or the salt of the acid is administered. Valproic acid is one of a series of fatty carboxylic acids that have antiseizure activity; this activity appears to be greatest for carbon chain lengths of five to eight atoms. The amides and esters of valproic acid also are active antiseizure agents.

## Mechanism of Action

The mechanism or mechanisms whereby valproate exerts its therapeutic actions are not known. Valproate has broad-spectrum efficacy in animal models, conferring seizure protection in diverse chemoconvulsant seizure models, the MES test, and the kindling models. The time course of valproate's antiseizure activity is poorly correlated with blood or tissue levels of the parent drug, an observation that has led to speculation regarding the active species.

## Clinical Uses

Valproate is one of the most versatile and effective antiseizure medications. It is widely used for myoclonic (such as in juvenile myoclonic epilepsy), atonic (as in Lennox-Gastaut syndrome), and generalized onset tonic-clonic seizures. Valproate is also effective in the treatment of generalized absence seizures and is often preferred to [ethosuximide](#) when the patient has concomitant generalized tonic-clonic seizures. Valproate is also effective in focal seizures, but it may not be as effective as [carbamazepine](#) or [phenytoin](#). Intravenous formulations can be used to treat status epilepticus.

## Pharmacokinetics

Valproate is well absorbed after an oral dose, with bioavailability greater than 80%. Peak blood levels are observed within 2 hours. Food may delay absorption, and the drug may have improved tolerability if it is administered after meals. Valproate is highly bound to plasma proteins, but protein binding becomes saturated as the concentration increases at the upper end of the therapeutic range, resulting in an increase in the plasma free

fraction of valproate from 10% at plasma concentrations up to 75 mcg/mL to 30% at levels greater than 150 mcg/mL. Such increases lead to an apparent increase in the clearance of total valproate at high doses. The half-life varies from 9 to 18 hours; extended-release formulations are therefore preferred. Because valproate is highly protein bound, it is largely confined to blood plasma; the drug has a low volume of distribution of approximately 0.15 L/kg. Valproate is extensively metabolized in the liver. A major hepatic metabolite is the glucuronide conjugate, which is excreted in the urine (approximately 30–50% of the dose). Valproate also undergoes mitochondrial  $\beta$ -oxidation (20–40%) and hepatic microsomal cytochrome P450-mediated oxidation (approximately 10%). In excess of 25 metabolites have been identified, but apart from valproic acid glucuronide, 3-oxo-valproic acid is the most abundant.

### Dosing and Therapeutic Levels

An initial daily dose of 15 mg/kg is recommended with slow titration to the therapeutic dose. Dosages of 25–30 mg/kg/d may be adequate in some patients, but others may require 60 mg/kg/d or even more. Therapeutic levels of valproate range from 50 to 100 mcg/mL, but concentrations up to 150 mcg/mL are generally tolerated and may be required.

### Drug Interactions

Valproate inhibits the metabolism of several drugs, including [phenobarbital](#) and [ethosuximide](#), leading to higher steady-state concentrations of these agents. Levels of [phenobarbital](#) may rise steeply, causing stupor or coma. Valproate displaces [phenytoin](#) from plasma proteins, causing an increase in the free fraction of [phenytoin](#), and total [phenytoin](#) concentrations in the therapeutic range may be associated with toxicity. Although valproate does not increase levels of [carbamazepine](#) itself, levels of [carbamazepine](#) epoxide may be increased. Valproate can dramatically decrease the clearance of [lamotrigine](#), resulting in a two- to threefold prolongation of [lamotrigine](#)'s half-life.

### Toxicity

The most common dose-related adverse effects of valproate are nausea, vomiting, and other gastrointestinal complaints such as abdominal pain and heartburn. The drug should be started gradually to avoid these symptoms. A fine tremor is frequently seen at higher levels. Other reversible adverse effects occurring in some patients include weight gain, increased appetite, and hair loss.

Valproate rarely causes idiosyncratic hepatic toxicity that may be severe and has been fatal. The risk is greatest for patients under 2 years of age and for those taking multiple medications. Initial aspartate aminotransferase values may not be elevated in susceptible patients, although these levels do eventually become abnormal. Most fatalities have occurred within 4 months after initiation of therapy. The other observed idiosyncratic adverse effect with valproate is thrombocytopenia, although documented cases of abnormal bleeding are lacking. Valproate can interfere with conversion of ammonia to urea. It can cause lethargy associated with increased blood ammonia concentrations. Fatal hyperammonemic encephalopathy has occurred in patients with genetic defects in urea metabolism; the drug is contraindicated in these patients.

Treatment with valproate during the first trimester of pregnancy is associated with a 1–2% risk of neural tube defects including spina bifida. In addition, an increased incidence of cardiovascular, orofacial, and digital abnormalities has been noted. Finally, cognitive impairment in offspring has been reported. These observations must be strongly considered in the choice of drugs in women of child-bearing potential.

## TOPIRAMATE

[Topiramate](#) is a broad-spectrum antiseizure medication whose chemical structure is that of a sulfamate-substituted monosaccharide derived from D-fructose. It is used in the treatment of focal seizures, primary generalized seizures, and seizures in the Lennox-Gastaut syndrome. [Topiramate](#) is also commonly used for migraine headache prophylaxis.

## Mechanism of Action

**Topiramate** likely acts through several cellular targets, which may account for its broad-spectrum activity in epilepsy and migraine. Possible sites of action relevant to its clinical activities are (1) voltage-gated sodium channels; (2) GABA<sub>A</sub> receptor subtypes; and (3) AMPA or kainate receptors. The drug is a weak inhibitor of carbonic anhydrase isoenzymes II and IV, but this is not thought to account for its antiseizure effects. In rare cases, the inhibition of carbonic anhydrase may cause metabolic acidosis of clinical importance.

## Clinical Uses

**Topiramate** is effective in the treatment of focal seizures in adults and children and in primary generalized tonic-clonic seizures. The drug is approved for the Lennox-Gastaut syndrome and may be effective in juvenile myoclonic epilepsy, infantile spasms, Dravet syndrome, and even childhood absence seizures. The initial dose in newly diagnosed patients is typically 100 mg/d, but maintenance doses usually range from 200 to 400 mg/d. Most clinicians begin at a low dose (25–50 mg/d) and increase slowly to prevent adverse effects. Cognitive side effects commonly occur with **topiramate** and are a frequent reason for discontinuation. Affected patients experience impaired expressive language function (dysnomia and diminished verbal fluency), impaired verbal memory, and a general slowing of cognitive processing. These effects are unlike those of other antiseizure medications and often occur without sedation or mood change. The incidence of cognitive side effects increases in a dose-dependent fashion, reaching 26% at a dose of 400 mg/d; however, some patients are completely unaffected even at higher dosages. Another troublesome adverse effect that commonly occurs with **topiramate** is paresthesias, typically occurring during initiation of therapy or at high doses; the symptoms may resolve with continuing treatment. Other dose-related adverse effects that occur frequently in the first 4 weeks of **topiramate** therapy are somnolence, fatigue, dizziness, nervousness, and confusion. Acute myopia and angle-closure glaucoma may require prompt drug withdrawal. Urolithiasis occurs in 0.5–1.5% of patients on long-term therapy and is more common in men. In some patients, carbonic anhydrase inhibition is associated with reduced serum bicarbonate that is usually asymptomatic but may result in nonspecific symptoms such as fatigue, anorexia, or nausea and vomiting. The potential for chronic untreated hyperchloremic non-anion gap metabolic acidosis for bone health is unknown. Decreased sweating (oligohydrosis) and an elevation in body temperature may occur during exposure to hot weather, mostly in children. Long-term **topiramate** therapy is often associated with significant weight loss, primarily due to a reduction in body fat mass. In clinical trials, 85% of adults receiving **topiramate** lost weight, which on average amounted to 5% of mean baseline body weight. Greater weight loss occurs in those with higher pretreatment weight. Weight loss is gradual and typically peaks at 12–18 months after initiation of therapy. Beneficial changes in lipid profile, glycemic control, and blood pressure may accompany the weight loss. Data in humans suggest a link between **topiramate** use in the first trimester of pregnancy and oral cleft formation in newborns (relative risk 16- to 21-fold).

## Pharmacokinetics

**Topiramate** is rapidly absorbed (about 2 hours) and is 80% bioavailable. There is minimal food effect on absorption, minimal (15%) plasma protein binding, and only moderate (20–50%) metabolism; no active metabolites are formed. The drug is primarily excreted in the urine (50–80% is unchanged). The monotherapy half-life is 20–30 hours but drops to 12–15 hours when administered with concomitant enzyme-inducing drugs. Immediate-release formulations are usually administered in two daily doses. Extended-release formulations are available that have been approved for once-daily administration. Although increased levels are seen with renal failure and hepatic impairment, there is no age or gender effect, no autoinduction, and no inhibition of metabolism, and kinetics are linear. Drug interactions do occur and can be complex, but the major effect is on **topiramate** levels rather than on the levels of other antiseizure medications. Birth control pills may be less effective in the presence of **topiramate**, and alternative modes of contraception are recommended in women taking more than 200 mg/d; however, oral contraceptives with a higher content of ethinyl estradiol (50 mcg) may be satisfactory.

**Zonisamide** is a broad-spectrum antiseizure medication that is effective for focal and generalized tonic-clonic seizures in adults and children and may also be effective in some myoclonic epilepsies and in infantile spasms. There are reports of improvement in generalized onset tonic-clonic seizures and atypical absence seizures.

There is little information on the mechanism of action of **zonisamide**. Although it does block voltage-gated sodium channels, other actions also may contribute to its antiseizure activity. **Zonisamide** has high bioavailability, modest protein binding (>50–60%), and a half-life of 1–3 days, so it can be administered once daily. The drug is extensively metabolized by acetylation to form *N*-acetyl-zonisamide, which is excreted in the urine unchanged, and by CYP3A4 to form 2-sulfamoylacetylphenol, which is excreted as the glucuronide. Maintenance doses are 200–400 mg/d in adults (maximum 600 mg/d) and 4–8 mg/kg/d in children (maximum 12 mg/kg/d). Adverse effects include drowsiness, cognitive impairment, renal stones, and potentially serious skin rashes. **Zonisamide** has no clinically significant effects on the pharmacokinetics of other antiseizure medications. However, antiseizure medications such as **carbamazepine**, **phenytoin**, and **phenobarbital** that induce CYP3A4 increase the clearance of **zonisamide**, shortening its half-life; concomitant use with CYP3A4-inducing agents may therefore require an increase in **zonisamide** dose. **Zonisamide**, like **topiramate**, contains sulfur: **zonisamide** is a sulfonamide, whereas **topiramate** contains the same sulfonamide structure but is strictly a sulfamate. They have similar pharmacologic actions, including carbonic anhydrase inhibition like **acetazolamide**, which also is a sulfonamide. Both **zonisamide** and **topiramate** are associated with weight loss. They also both (rarely) cause kidney stones and oligohydrosis. Whether these actions are related to the common sulfonamide structure is not known.

## MEDICATIONS EFFECTIVE FOR GENERALIZED ABSENCE SEIZURES

**Ethosuximide** and valproate are effective and well-tolerated treatments for generalized absence seizures in childhood absence epilepsy; **lamotrigine** is possibly effective. **Ethosuximide** is considered in this section along with trimethadione, which is of historical interest.

### ETHOSUXIMIDE

**Ethosuximide** is a first-line drug for the treatment of generalized absence seizures. It can be used as monotherapy unless generalized tonic-clonic seizures also are present, in which case valproate is preferred or **ethosuximide** can be combined with another drug effective against generalized tonic-clonic seizures.

#### Chemistry

**Ethosuximide** was introduced in 1958 as the third of three marketed succinimides; the other two, **phensuximide** and **methsuximide**, are rarely used. **Ethosuximide** and **methsuximide** have asymmetric carbons (asterisks in the following figure) and are used as racemates.

## Mechanism of Action

**Ethosuximide** is thought to act by inhibition of low-voltage-activated T-type calcium channels in thalamocortical neurons that underlie the 3-Hz spike-wave discharges of generalized absence seizures. Other ion channels affected include voltage-gated sodium channels, calcium-activated potassium channels, and inward rectifier potassium channels; these actions may contribute to the efficacy of **ethosuximide** in absence epilepsy.

## Clinical Uses

Studies in the mid-1970s provided evidence that monotherapy with **ethosuximide** is effective in the treatment of childhood generalized absence seizures. There is also evidence that it is effective in the treatment of atypical absence and epileptic negative myoclonus, a rare seizure type characterized by interruption of ongoing electromyographic activity contralateral to a lateralized spike-and-wave discharge. If **ethosuximide** in monotherapy does not lead to seizure control, the drug can be used in combination with valproate or other agents such as benzodiazepines.

## Pharmacokinetics

Absorption is complete following administration of the oral dosage forms. Peak levels are observed 3–7 hours after oral administration of the capsules. **Ethosuximide** is not protein bound. During long-term administration, approximately 20% of the dose is excreted unchanged by the kidney. The remaining drug is metabolized in the liver, principally by CYP3A hydroxylation, to inactive metabolites. **Ethosuximide** has a very low total body clearance (0.25 L/kg/d). This corresponds to a half-life of approximately 40 hours, although values from 18 to 72 hours have been reported.

## Therapeutic Levels & Dosage

In children, a common starting dose is 10–15 mg/kg/d, with titration according to clinical response to a maintenance dose of 15–40 mg/kg/d. In older children and adults, the initial dose is 250 or 500 mg/d, increasing in 250-mg increments to clinical response to a maximum of 1500 mg/d. While dosing is based on titration to maximal seizure control with acceptable tolerability, the accepted therapeutic serum concentration range is 40–100 mcg/mL (although plasma levels up to 150 mcg/mL may be necessary and tolerated in some patients). There is a linear relationship between **ethosuximide** dose and steady-state plasma levels. While the long half-life could allow once-daily dosing, **ethosuximide** is generally administered in two or even three divided doses to minimize adverse gastrointestinal effects.

## Drug Interactions & Toxicity

Administration of **ethosuximide** with valproate results in a decrease in **ethosuximide** clearance and higher steady-state concentrations owing to inhibition of **ethosuximide** metabolism. No other important drug interactions have been reported. The most common dose-related adverse effect of **ethosuximide** is gastric distress, including pain, nausea, and vomiting. When an adverse effect does occur, temporary dosage reductions may allow adaptation. Other dose-related adverse effects are transient lethargy or fatigue and, much less commonly, headache, dizziness, hiccup, and euphoria. Behavioral changes are usually in the direction of improvement. Non-dose-related or idiosyncratic adverse effects of **ethosuximide** are extremely uncommon.

Trimethadione is an oxazolinedione antiseizure medication introduced in 1945. It is no longer marketed in the USA but is available elsewhere. Trimethadione is effective in the treatment of generalized absence seizures and was the drug of choice for this seizure type until the introduction of [ethosuximide](#). Trimethadione has numerous dose-related and idiosyncratic side effects, including hemeralopia (day blindness). Because of the high propensity for side effects, trimethadione and the related oxazolinediones paramethadione and dimethadione, the major metabolite of trimethadione, are now rarely used.

## MEDICATIONS EFFECTIVE FOR MYOCLONIC SEIZURES SUCH AS IN THE SYNDROME OF JUVENILE MYOCLONIC EPILEPSY

Valproate is the drug of first choice for the treatment of myoclonic seizures. Other drugs effective in the treatment of this seizure type are [levetiracetam](#), [zonisamide](#), [topiramate](#), and [lamotrigine](#).

## MEDICATIONS EFFECTIVE FOR ATONIC SEIZURES SUCH AS IN THE LENNOX-GASTAUT SYNDROME

Valproate in combination with [lamotrigine](#) and a benzodiazepine is the most widely used treatment for atonic seizures. [Topiramate](#), [felbamate](#), and [lamotrigine](#) are used in the treatment of Lennox-Gastaut syndrome; clinical trials have shown improvement in atonic seizures. [Clobazam](#) and [rufinamide](#), discussed in this section, also are used in the treatment of seizures associated with Lennox-Gastaut syndrome and have been demonstrated in clinical trials to reduce the frequency of atonic seizures.

### CLOBAZAM

[Clobazam](#) is widely used for the treatment of focal seizures in many countries, although it is not approved for that indication in the USA, where its only approved use is for treatment of seizures associated with Lennox-Gastaut syndrome in patients 2 years of age or older. [Clobazam](#) is a 1,5-benzodiazepine and structurally different from other marketed benzodiazepines, which are 1,4-benzodiazepines. Like the 1,4-benzodiazepines, however, [clobazam](#) is a positive allosteric modulator of GABA<sub>A</sub> receptors and has similar pharmacologic activities and adverse effects. In addition, while tolerance occurs to [clobazam](#) in animal models within days to weeks of chronic administration, retrospective studies assessing the extent of tolerance in the clinical setting have suggested that tolerance is not a prominent issue in clinical treatment. Side effects that occur in a dose-dependent fashion include somnolence and sedation, dysarthria, drooling, and behavioral changes, including aggression. Withdrawal symptoms may occur with abrupt discontinuation. [Clobazam](#) has a half-life of 10–30 hours and is effective at dosages of 0.5–1 mg/kg/d. [Clobazam](#) is metabolized in the liver by CYP and non-CYP transformations, with up to 14 metabolites; however, the major metabolite is N-desmethylclobazam (norclobazam), which is produced by CYP3A4. Norclobazam is then mainly metabolized by CYP2C19 except in CYP2C19-poor metabolizers with a CYP2C19 inactive allele. With long-term administration of [clobazam](#), levels of norclobazam, which has a longer half-life than [clobazam](#), are 8–20 times higher than those of the parent. Norclobazam has antiseizure activity, although it is weaker than [clobazam](#). Nevertheless, because norclobazam levels are so much higher at steady state, seizure protection during chronic therapy is likely mainly due to norclobazam. [Cannabidiol](#), via inhibition of CYP2C19, causes a threefold increase in plasma concentrations of norclobazam. When [cannabidiol](#) is added, the [clobazam](#) dose may require reduction to avoid excessive sedation. [Clobazam](#) is a moderate inhibitor of CYP2D6 and has been shown to significantly increase the levels of drugs metabolized by this isoenzyme such as [phenytoin](#) and [carbamazepine](#). Reduced dosing may be required when these antiseizure medications are used in combination with [clobazam](#).

### RUFINAMIDE

[Rufinamide](#) is a triazole derivative identified by screening in animal seizure models. It is effective for atonic seizures in Lennox-Gastaut syndrome, but there is also some evidence of efficacy in the treatment of focal seizures. In the USA and Europe, [rufinamide](#) is only approved for treatment of seizures associated with the Lennox-Gastaut syndrome.

### Mechanism of Action

In mice and rats, [rufinamide](#) is protective in the MES test and, at higher doses, in the PTZ test. Its only known action that is relevant to seizure protection is as a blocker of voltage-gated sodium channels.

### Clinical Uses

In the Lennox-Gastaut syndrome, [rufinamide](#) is effective against all seizure types but especially against atonic seizures. Some clinical data suggest it may be effective against focal seizures. Treatment in children is typically started at 10 mg/kg/d in two equally divided doses and gradually increased to 45 mg/kg/d to a maximum of 3200 mg/d. Adults can begin with 400–800 mg/d in two equally divided doses up to a maximum of 3200 mg/d as tolerated. The drug should be given with food. The most common adverse events are somnolence and vomiting.

### Pharmacokinetics

[Rufinamide](#) is well absorbed, and plasma concentrations peak between 4 and 6 hours. The half-life is 6–10 hours, and minimal plasma protein binding is observed. Although cytochrome P450 enzymes are not involved, the drug is extensively metabolized to inactive products. Most of the drug is excreted in the urine; an acid metabolite accounts for about two thirds of the dose. Most drug-drug interactions are minor except that valproate may decrease the clearance of [rufinamide](#); dosing with valproate, particularly in children, may need to be decreased, typically by 50%.

## MEDICATIONS EFFECTIVE FOR DRAVET SYNDROME

Dravet syndrome (severe myoclonic epilepsy in infancy) is a rare genetic epileptic encephalopathy characterized by diverse generalized and focal seizure types, including myoclonic seizures, tonic-clonic seizures, absence seizures, atonic seizures, and one-sided hemiconvulsive and focal seizures. Mutations of the *SCN1A* gene encoding  $\text{Na}_v1.1$  voltage-gated sodium channels cause 79% of diagnosed cases of Dravet syndrome. Although drugs such as [clobazam](#), valproate, [topiramate](#), and [stiripentol](#) (approved only in combination with [clobazam](#) in the USA and in combination with [clobazam](#) and valproate in Europe) are used, none of these is very effective. [Cannabidiol](#) is a newly available option; it and [stiripentol](#) are the only medications specifically approved for Dravet syndrome in the USA. In patients with *SCN1A* gene mutations, sodium channel-blocking antiseizure medications are contraindicated because they worsen seizures.

### CANNABIDIOL

[Cannabidiol](#), a non-psychoactive phytocannabinoid found in *Cannabis sativa*, is approved for the treatment of seizures associated with Dravet syndrome and Lennox-Gastaut syndrome. The drug has also been found to be useful in the treatment of seizures associated with tuberous sclerosis complex. In the approved medicinal product, [cannabidiol](#) is formulated in an oil-based solution for oral administration. Other [cannabidiol](#) preparations, including oil-based solutions, are available as dietary supplements but may not be legal under federal regulations in the USA.

**Cannabidiol**

**$\Delta^9$ -Tetrahydrocannabinol**

**Cannabidiol** exhibits broad-spectrum antiseizure activity in animal seizure models, although the overall potency is weak. Unlike the structurally related psychoactive cannabinoid  $\Delta^9$ -tetrahydrocannabinol, which acts as an agonist of CB<sub>1</sub> (central nervous system) and CB<sub>2</sub> (immune system) cannabinoid receptors, **cannabidiol** is not a CB<sub>1</sub> or CB<sub>2</sub> receptor agonist and it has been shown that the antiseizure activity of **cannabidiol** is not due to an action on brain CB<sub>1</sub> receptors. The basis for the antiseizure activity of **cannabidiol** is unknown.

### Clinical Uses

In the epilepsy syndromes where it has been studied, **cannabidiol** is an effective option, and in some patients may be useful where other medications have failed. Reductions in convulsive seizures associated with Dravet syndrome and atonic seizures associated with Lennox-Gastaut syndrome have been observed. The main adverse events are somnolence (25%), decreased appetite (19%), diarrhea (19%), and fatigue (13%). Liver function test abnormalities occur in a dose-dependent fashion; concurrent valproate increases the risk. **Cannabidiol** solution is titrated to a maintenance dose of 10 mg/kg/d in two divided doses. The dose may be increased to 20 to 25 mg/kg/d if required for further seizure control.

### Pharmacokinetics

The oral bioavailability of **cannabidiol** is very low (13–19%). The approved formulation of **cannabidiol** is in sesame oil (100 mg/mL), which consists largely of long-chain triglycerides. Coadministration of the highly lipophilic **cannabidiol** with the dietary oil results in the formation of mixed micelles as the lipid is digested. Intestinal enterocytes incorporate the micelles into chylomicrons that are transferred by intestinal lymphatics directly into the systemic circulation, bypassing first-pass metabolism in the liver. Consequently, bioavailability is increased threefold in the sesame oil formulation. Bioavailability is further increased four- to fivefold by a high-fat meal. Administration with food is recommended to reduce fluctuations in systemic exposure.

**Cannabidiol** is metabolized in the liver primarily by CYP2C19 and to a lesser extent by CYP3A4 isoenzymes. **Cannabidiol** may also be glucuronidated by several UDP-glucuronosyltransferase isoforms. 7-Carboxy-cannabidiol is the major circulating metabolite and after chronic dosing has an approximately 40-fold higher AUC than **cannabidiol** itself. In animal studies, 7-carboxy-cannabidiol does not exhibit antiseizure activity. Concomitant administration of **cannabidiol** with **clobazam** resulted in increased plasma concentrations of N-desmethyloclobazam, likely by inhibition of CYP2C19 by **cannabidiol**. This can lead to excessive sedation and may require reduction in the **clobazam** dose.

## STIRIPENTOL

**Stiripentol** is an aromatic allylic **alcohol** that has activity in the treatment of Dravet syndrome. Clinical studies indicate that it reduces the frequency of prolonged seizures in children with this condition. **Stiripentol** is often used in conjunction with **clobazam** or valproate; whether it has activity by itself has not been studied in clinical trials. The drug has various effects on GABA-mediated neurotransmission including an action as a positive allosteric modulator of GABA<sub>A</sub> receptors. Two metabolites of **stiripentol** have been identified: 1-(3-methoxy-4-hydroxyphenyl)-4,4-dimethyl-1-penten-3-ol, which has antiseizure activity, and 1-(3-hydroxy-4-methoxyphenyl)-4,4-dimethyl-1-penten-3-ol, which does not. **Stiripentol** is a potent inhibitor of CYP3A4, CYP1A2, and CYP2C19 and dramatically increases the levels of **clobazam** and its active metabolite norclobazam; it also inhibits valproate metabolism. These drug-drug interactions have been proposed as the basis for the clinical effectiveness of **stiripentol**, and elevations in concomitant drugs likely contribute to some extent to efficacy. However, **stiripentol** has activity in various animal seizure models, indicating that it has antiseizure activity in its own right. Dosing is complex, typically beginning with a reduction in concomitant medications. **Stiripentol** is then started at 10–15 mg/kg/d in 2–3 divided doses and is increased gradually to a target dose of 50 mg/kg/d over 2–4 weeks as tolerated. The most frequent adverse effects are sedation/drowsiness, reduced appetite, slowing of mental function, ataxia, diplopia, nausea, and abdominal pain. **Stiripentol** exhibits nonlinear pharmacokinetics, decreasing in clearance as the dose increases.

Fenfluramine oral solution is effective for the treatment convulsive seizures in Dravet syndrome and atonic seizures in the Lennox-Gastaut syndrome. Fenfluramine, an [amphetamine](#) derivative, is an anorexigen that had been used for weight loss but was withdrawn because it induces valvular heart disease and pulmonary hypertension. Studies in patients with Dravet syndrome have shown marked reductions in convulsive seizure frequency. Common side effects are decreased appetite, diarrhea, and fatigue. Fenfluramine is a substrate of the serotonin transporter, causing inhibition of serotonin uptake and enhancing its extracellular release. Norfenfluramine, the main metabolite of fenfluramine, also causes serotonin release. The extent to which serotonin release or effects of fenfluramine on serotonin receptors or other targets contribute the antiseizure activity of the drug remains to be determined. Fenfluramine has minimal activity in rodent seizure models. Norfenfluramine activates 5-HT<sub>2B</sub> receptors on heart valve and pulmonary artery interstitial cells, leading to the formation of proliferative fibromyxoid plaques that compromise tissue integrity and function. No clinically significant cardiac effects were observed in clinical trials and in long-term monitoring for up to 3 years. [Stiripentol](#) inhibits the metabolism of fenfluramine, elevating levels of the parent and reducing levels of the norfenfluramine.

## MEDICATIONS EFFECTIVE FOR INFANTILE SPASMS (WEST SYNDROME)

Infantile spasms are treated with repository [corticotropin](#) injection gel by intramuscular or subcutaneous injection, or with oral corticosteroids such as [prednisone](#), [prednisolone](#), [methylprednisolone](#), or [dexamethasone](#). [Corticotropin](#) gel is a complex mixture of adrenocorticotropic hormone (ACTH) analogs (including N25-deamidated porcine ACTH<sub>1-39</sub>) as well as other peptides derived from porcine pituitary gland. [Vigabatrin](#) also is often used and is particularly effective in cases associated with tuberous sclerosis. Other antiseizure medications that may be helpful are valproate, [topiramate](#), [zonisamide](#), or a benzodiazepine such as [clonazepam](#) or [nitrazepam](#). [Corticotropin](#) gel and corticosteroids are associated with substantial morbidity, and [vigabatrin](#), as discussed below, has a risk of permanent loss of vision. The goal of treatment is cessation of seizures, and this generally requires [corticotropin](#), corticosteroids, or [vigabatrin](#) and is not generally achieved with the safer antiseizure agents. The mechanism of action of [corticotropin](#) and corticosteroids in the treatment of infantile spasms is unknown.

## VIGABATRIN

[Vigabatrin](#) is an analog of GABA, designed as an inhibitor of GABA transaminase (GABA-T), the enzyme responsible for the metabolism of synaptically released GABA. [Vigabatrin](#) is effective in the treatment of focal seizures (but not generalized seizures) and in the treatment of infantile spasms. Because it may cause irreversible visual loss, it is usually reserved for patients with seizures refractory to other treatments.

### Mechanism of Action

**Vigabatrin** is a specific, irreversible inhibitor of GABA-T, producing a sustained increase in the extracellular concentrations of GABA in the brain. This paradoxically leads to inhibition of synaptic GABA<sub>A</sub> receptor responses, but also prolongs the activation of extrasynaptic GABA<sub>A</sub> receptors that mediate tonic inhibition. **Vigabatrin** is effective in a wide range of animal seizure models. **Vigabatrin** is marketed as a racemate; the *S*(+) enantiomer is active and the *R*(-) enantiomer appears to be inactive.

### Clinical Uses

**Vigabatrin** is useful in the treatment of infantile spasms, especially when associated with tuberous sclerosis. The drug is also effective against focal seizures. The half-life is approximately 6–8 hours, but the pharmacodynamic activity of the drug is more prolonged and not well correlated with the plasma half-life because recovery from the drug requires synthesis of replacement GABA-T enzyme. In infants, the dosage is 50–150 mg/kg/d. In adults, **vigabatrin** is started at an oral dosage of 500 mg twice daily; a total of 2–3 g/d may be required for full effectiveness. The most important adverse effect of **vigabatrin** is irreversible retinal dysfunction. Patients may develop permanent bilateral concentric visual field constriction that is often asymptomatic but can be disabling. Minimal evidence also suggests that **vigabatrin** can also damage the central retina. The onset of vision loss can occur within weeks of starting treatment or after months or years. Other adverse effects are somnolence, headache, dizziness, and weight gain. Less common but more troublesome adverse effects are agitation, confusion, and psychosis; preexisting mental illness is a relative contraindication.

## EVEROLIMUS FOR FOCAL ONSET SEIZURES ASSOCIATED WITH TUBEROUS SCLEROSIS COMPLEX

The treatment of infantile spasms in tuberous sclerosis complex was discussed previously. Other seizure types that occur in tuberous sclerosis complex are treated with an antiseizure medication appropriate to the seizure type. Medication-refractory patients may benefit from alternative therapies such as the ketogenic diet, vagal nerve stimulation, or epilepsy surgery. The mTORC1 (mammalian target of rapamycin complex 1) inhibitor **everolimus** is now also an option to treat refractory focal onset seizures associated with the disorder.

### Mechanism of Action

Tuberous sclerosis is caused by loss-of-function mutations in the *TSC1* gene encoding the protein hamartin or in the *TSC2* gene encoding tuberin. The mutations lead to constitutive mTOR activation, resulting in abnormal cerebral cortical development with multiple focal structural malformations. The aberrant mTOR signaling leads to cortical tubers and perituberal cortical tissue with dysmorphic neurons, giant cells, reactive astrocytes, and disturbed cortical layering. The development of epilepsy is believed to be related to these structural abnormalities, but the precise basis for epileptogenesis is not understood. mTOR is one member of a family of six atypical serine/threonine protein kinases, referred to as PIKKs (PIK3-related kinases). mTOR forms the catalytic subunit of the cytosolic protein complex mTORC1, which acts as a central controller of cell growth. Drugs that inhibit mTORC1, such as rapamycin (**sirolimus**) and the rapalog **everolimus**, bind to the cyclophilin protein FKBP12, a peptidyl-prolyl isomerase. The rapamycin/rapalog-FKBP12 complex then allosterically inhibits mTORC1 by binding to mTOR (when it is associated with the adaptor protein raptor and MLST8).

### Clinical Use

Studies have indicated a consistent relationship between **everolimus** exposure and efficacy in the treatment of seizures associated with tuberous sclerosis complex. Therefore, the dosing recommendation is to target the trough (predose) **everolimus** whole blood concentration, initially within the range of 5–7 ng/mL and then to titrate to the range of 5–15 ng/mL in the event of an inadequate clinical response. The usual starting dose is 5 mg/m<sup>2</sup> orally once daily, with increments not exceeding 5 mg to achieve the desired blood concentration. The most frequent adverse reactions of **everolimus** are stomatitis, diarrhea, and pyrexia. Increasing the exposure did not result in an increase in reported adverse events.

### Pharmacokinetics

Oral **everolimus** is absorbed rapidly (30% bioavailability), and reaches peak concentration after 1.3–1.8 hours. The drug is metabolized in the liver primarily by CYP3A4 and is a substrate of the P-glycoprotein (P-gp) transporter. The dosage will likely require reduction in the presence of CYP3A4 inducers such as **phenobarbital**, **primidone**, **phenytoin**, **carbamazepine**, and **oxcarbazepine**. The elimination half-life is 30 hours. Plasma protein

Ganaxolone is a synthetic steroid structurally related to [progesterone](#) and the endogenous [progesterone](#) metabolite allopregnanolone, and also to the related steroid anesthetic alphaxalone. Ganaxolone is available as an oral suspension for the treatment of seizures associated with CDKL5 deficiency disorder, but its mechanism of action as a GABA<sub>A</sub> receptor positive allosteric modulator is compatible with broad-spectrum antiseizure activity.

Ganaxolone potentiates GABA<sub>A</sub> receptors at distinct sites on the receptor protein complex and in a functionally different way from benzodiazepines; it also acts on benzodiazepine-insensitive GABA<sub>A</sub> receptor isoforms. In support of broad clinical utility, ganaxolone confers seizure protection in a wide range of animal seizure models. In *in vitro* tests, ganaxolone does not interact appreciably with human steroid hormone receptors. In the treatment of CDKL5 deficiency disorder, ganaxolone reduced the occurrence of major motor seizures. There is evidence from long-term follow-up studies of undiminished efficacy for more than 1 year. Consistent with the GABA<sub>A</sub> receptor mechanism, there is a high incidence of somnolence and sedation in clinical use.

Ganaxolone has low oral bioavailability, and absorption is enhanced markedly by food; administration with food is recommended. Ganaxolone is dosed in three divided doses per day (single dose maximum 600 mg). The divided dosing schedule maintains trough levels greater than those believed to be required for seizure control. The approved dosage form exhibits nonlinear absorption such that the plasma exposure is unlikely to rise substantially with doses greater than 600 mg. Ganaxolone is highly protein bound (99%) and is metabolized in the liver by CYP3A4/5, CYP2B6, CYP2C19, and CYP2D6. An increased dose may be required when used adjunctively with CYP3A4 inducers. Mass balance studies in humans indicate that two metabolites are present in plasma at much higher concentrations than the parent: an oxy-dehydro unconjugated derivative, which is inactive at GABA<sub>A</sub> receptors, and a ganaxolone sulfate conjugate.

## OTHER MEDICATIONS USED IN MANAGEMENT OF SEIZURES AND EPILEPSY

### BENZODIAZEPINES

Seven benzodiazepines play roles in the treatment of seizures and epilepsy (see also [Chapter 22](#)). All produce their functional effects by positive allosteric modulation of GABA<sub>A</sub> receptors; however, subtle structural differences among the benzodiazepines result in differences in their pharmacokinetic properties. Certain benzodiazepines are the initial acute treatment for seizures, either in status epilepticus or acute repetitive seizures (seizure clusters). However, two prominent aspects of benzodiazepines limit their usefulness in the chronic therapy of epilepsy. The first is their pronounced sedative effects; however, in children, there may be a paradoxical hyperactivity, as is the case with other sedative agents such as barbiturates. The second problem is tolerance with chronic dosing, in which seizures may respond initially but recur within a few months. As a result of these limitations, benzodiazepines are infrequently used in the chronic treatment of epilepsy.

**Diazepam** given intravenously is a first-line treatment for status epilepticus. It is also used in a rectal gel formulation or nasal spray for the treatment of acute repetitive seizures (seizure clusters). The drug is occasionally given orally on a long-term basis, although it is not considered very effective in this application because tolerance limits its efficacy. As discussed in more detail in Additional Topics below, **lorazepam** is more commonly used in the treatment of status epilepticus because it has a more prolonged duration of action after bolus intravenous injection. **Lorazepam** is also available as an oral concentrate that may be administered buccally, and in some countries a sublingual tablet is available. **Lorazepam** can also be administered nasally. There is evidence that intramuscular **midazolam**, which is well absorbed from muscle and rapidly acting, is preferred in the out-of-hospital treatment of status epilepticus because the delay required to achieve intravenous access may be avoided. **Midazolam** is available as a nasal spray for the treatment of acute repetitive seizures (seizure clusters) and in buccal (oromucosal) dosage form in some countries. **Clonazepam** is a long-acting **clonazepam** on a milligram basis is one of the most potent antiseizure agents known. It has documented efficacy in the treatment of absence,

atonic and myoclonic seizures. As is the case for all benzodiazepines, sedation is prominent, especially on initiation of therapy; starting doses should be small. Maximal tolerated doses are usually in the range of 0.1–0.2 mg/kg/d, but many weeks of gradually increasing daily doses may be needed to achieve these dosages in some patients. Intravenous **clonazepam**, not available in the USA, is commonly used as a first therapy for status epilepticus in Europe and elsewhere in the world. **Nitrazepam** is not marketed in the USA but is used in many other countries, especially for infantile spasms and myoclonic seizures. **Clorazepate dipotassium** is approved in the USA for the treatment of focal seizures. Drowsiness and lethargy are common adverse effects, but as long as the drug is increased gradually, dosages as high as 90 mg/d can be given. **Clobazam** is described earlier in this chapter in the section on atonic seizures.

## CARBONIC ANHYDRASE INHIBITORS

Carbonic anhydrases are enzymes that catalyze the interconversion between CO<sub>2</sub> and bicarbonate (see [Chapter 15](#)). Inhibitors of carbonic anhydrases, particularly the cytosolic forms CA II and CA VII, exhibit antiseizure activity. Bicarbonate efflux through GABA<sub>A</sub> receptors can exert a depolarizing (excitatory) influence that is especially relevant during intense GABA<sub>A</sub> receptor activation, as occurs during seizures, when there is diminution of the hyperpolarizing chloride gradient. Carbonic anhydrase inhibition prevents the replenishment of intracellular bicarbonate and depresses the depolarizing action of bicarbonate.

The prototypical carbonic anhydrase inhibitor is the sulfonamide **acetazolamide** (see [Chapter 15](#)), which has broad-spectrum antiseizure activity in animal models. In addition, **acetazolamide** is believed to have clinical antiseizure activity, at least transiently, against most types of seizures including focal and generalized tonic-clonic seizures and especially generalized absence seizures. However, **acetazolamide** is rarely used for chronic therapy because tolerance develops rapidly, with return of seizures usually within a few weeks. The drug is often used in the intermittent treatment of menstrual seizure exacerbations in women. The usual dosage is approximately 10 mg/kg/d to a maximum of 1000 mg/d.

Another sulfonamide carbonic anhydrase inhibitor, **sulthiame**, was introduced in Europe in the early 1960s and was used for the treatment of focal and myoclonic seizures but fell out of favor. Clinical trials and case reports have indicated that the drug is effective in benign focal epilepsy with centrotemporal spikes (BECTS) and infantile spasms; in some countries it is considered the drug of choice for BECTS. Sulthiame is available in Europe, Japan, Australia, and Israel but not in the USA.

As noted previously, **topiramate** and **zonisamide** are sulfur-containing molecules with weak carbonic anhydrase activity. There is little evidence that this activity is a major factor in their therapeutic effects.

## ADDITIONAL TOPICS

### THERAPEUTIC DRUG MONITORING

The pharmacokinetic behavior of most antiseizure medications varies markedly from patient to patient so that dosing must be individualized. Therapeutic drug concentration monitoring is often used as an aid to dosing. Established reference ranges are available for most of the older antiseizure medications ([Table 24–3](#)). Such ranges are generally not available for newer drugs, although there may be information on blood levels associated with efficacy. In all cases, the ranges should be interpreted flexibly given individual variability in response. Drug levels can be helpful (1) to guide dose adjustments when there is a change in drug formulation, (2) when breakthrough seizures occur, (3) when an interacting medication is added to or removed from a patient's regimen, (4) during pregnancy, (5) to establish an individual therapeutic concentration range when a patient is in remission, (6) to determine whether adverse effects are related to drug levels, and (7) to assess adherence.

TABLE 24–3

**Blood (serum/plasma) concentration reference ranges for some antiseizure drugs.<sup>1</sup>**

Antiseizure Drug	Reference Range <sup>1</sup>	
	μmol/L	mcg/mL
	45–63	10–14

Brivaracetam	1–10	0.2–2
Cannabidiol <sup>2</sup>	1.0	0.3
Carbamazepine	15–45	4–12
Cenobamate <sup>3</sup>	58–88	15–23
Clobazam	Clobazam: 0.1–1 Norclobazam: 1–10	Clobazam: 0.03–0.30 Norclobazam: 0.3–3
Clonazepam	0.04–0.12	0.013–0.038
Eslicarbazepine acetate <sup>4</sup>	12–140	3–36
Ethosuximide	300–600	40–100
Everolimus	5.2–15.7 nmol/L	5–15 ng/mL
Felbamate	125–250	30–60
Fenfluramine <sup>5</sup>	<216 nmol/L	<50 ng/mL
Gabapentin	70–120	12–21
Ganaxolone <sup>6</sup>	241–709 nmol/L	85–250 ng/mL
Lacosamide	10–40	3–10
Lamotrigine	10–50	3–13
Levetiracetam	30–240	5–41
Oxcarbazepine <sup>4</sup>	12–140	3–36
Perampanel	0.1–1.1	0.05–0.4
Phenobarbital	65–172	15–40
Phenytoin	40–80	10–20
Pregabalin	10–35	2–6
Primidone	Primidone: 37–55 Phenobarbital: 65–129	Primidone: 8–12 Phenobarbital: 15–30
Retigabine (ezogabine)	No data	
Rufinamide	15–130	4–31

Stimulant <sup>7</sup>	34–51	8–12
Sulthiame	7–34	2–10
Tiagabine	0.05–0.53	0.02–0.2
Topiramate	6–30	2–10
Valproate	300–600	40–100
Vigabatrin	6–279	0.8–36
Zonisamide	47–188	10–40

<sup>1</sup>These data are provided only as a general guideline. Many patients will respond better at different levels, and some patients may have drug-related adverse events within the listed reference ranges.

<sup>2</sup>No reference range available. Value given is mean plasma concentration in children and adult clinical trial responders receiving a mean dose of 27.1 mg/kg/day.

<sup>3</sup>No reference range available. Range bounds are mean steady-state plasma concentrations for trial subjects receiving daily doses of 200 mg and 400 mg.

<sup>4</sup>Monohydroxy metabolites (combination of [eslicarbazepine](#) and *R*-licarbazepine).

<sup>5</sup>Concentration range in clinical studies was 5.1–712.5 ng/mL (22–3081 nmol/L); most patients never had concentrations >50 ng/mL (216 nmol/L); toxicity has been associated with concentrations ≥240 ng/mL (1038 nmol/L).

<sup>6</sup>Range is minimum and maximum concentrations in clinical trial of seizures associated with CDKL5 deficiency disorder. Patients achieving favorable seizure control had mean levels of 120 ng/mL (340 nmol/L).

<sup>7</sup>Not well established; values given were associated with positive response in Dravet syndrome.

## STATUS EPILEPTICUS

Status epilepticus, a serious neurological emergency, is an abnormally prolonged seizure, or repeated seizures with incomplete recovery of consciousness. Status epilepticus presents in two forms: (1) **generalized convulsive status epilepticus** characterized by prominent motor symptoms (bilateral rhythmic jerking of the limbs) and impaired consciousness, and (2) **nonconvulsive status epilepticus**, a persistent change in behavior (manifested as a change in cognition, memory, arousal, affect, motor learning, or motor behavior) with continuous epileptiform EEG activity but without major motor signs (tonic or clonic activity). Nonconvulsive status epilepticus encompasses several distinct conditions: (1) absence status epilepticus of the typical, atypical, or myoclonic forms, (2) focal status epilepticus with or without impairment of consciousness, which may have focal motor or sensory features; and (3) nonconvulsive status epilepticus in coma, which often occurs after treatment of convulsive status epilepticus.

Convulsive status epilepticus is a life-threatening emergency that requires immediate treatment. Traditionally, convulsive status epilepticus was defined as more than 30 minutes of either (1) continuous seizure activity or (2) two or more sequential seizures without full recovery of consciousness between seizures. Because persistent seizure activity is believed to cause permanent neuronal injury and because the majority of seizures terminate in 2 to 3 minutes, it is now generally accepted that treatment should be begun when the seizure duration reaches 5 minutes for generalized tonic-clonic seizures and 10 minutes for nonconvulsive seizures. It is noteworthy that convulsive status epilepticus may evolve to nonconvulsive status epilepticus. The initial treatment of convulsive and nonconvulsive status epilepticus is similar except that with the latter there is less urgency to achieve seizure control so therapy can be begun more cautiously with lower medication doses.

The initial treatment of choice is a benzodiazepine, either intravenous [lorazepam](#) or [diazepam](#) or intramuscular [midazolam](#). [Lorazepam](#) is less lipophilic than [diazepam](#) (logP values of 2.4 and 2.8, respectively) and does not undergo redistribution from brain to peripheral tissues as rapidly as

[diazepam](#), [lorazepam](#) has a slightly longer onset of action than [diazepam](#), approximating 2 minutes, but a longer duration of action. Clinically effective [diazepam](#) concentrations in the brain following an intravenous bolus fall rapidly as the drug exits the central compartment into peripheral fat. [Lorazepam](#) has less extensive peripheral tissue uptake, allowing clinically effective concentrations to remain in the central compartment much longer. Although [lorazepam](#) is now used more frequently than [diazepam](#) because of the perceived pharmacokinetic advantage, recent appraisals of the clinical data have not found evidence to favor [lorazepam](#). Intravenous [clonazepam](#) may be used as a first treatment for status epilepticus outside the USA. In the prehospital setting, rectal [diazepam](#), intranasal [midazolam](#), or buccal [midazolam](#) are acceptable alternative first treatments if the preferred options are not available. Because of the short effective duration of action of benzodiazepines, unless the cause of the status epilepticus has been definitively corrected, a second therapy is administered. Intravenous [levetiracetam](#), valproate, [fosphenytoin](#), or [phenytoin](#) are acceptable choices. They are equally effective in terminating benzodiazepine-refractory convulsive status epilepticus and have similar rates of adverse effects. Seizure cessation occurs in approximately one-half of patients receiving any of the three drugs after failure of a benzodiazepine. Intravenous [phenobarbital](#) is highly effective at terminating status epilepticus, but it has a long half-life causing persistent side effects including severe sedation, respiratory depression, and hypotension. Intravenous [lacosamide](#) also has been used as a second treatment for status epilepticus. Intravenous loading with [lacosamide](#) is usually well tolerated, but due to its effects on the heart including the potential to induce arrhythmias, electrocardiographic monitoring is prudent. If the second therapy fails to stop the seizures, an additional second therapy agent is often tried. Refractory status epilepticus occurs when seizures continue or recur at least 30 minutes after treatment with first and second therapy agents. Refractory convulsive status epilepticus is treated with anesthetic doses of [pentobarbital](#), [propofol](#), [midazolam](#), or thiopental. Case reports indicate that [ketamine](#) may be effective. If status epilepticus continues or recurs 24 hours or more after the onset of anesthesia, the condition is considered super-refractory. Often, super-refractory status epilepticus is recognized when anesthetics are withdrawn and seizures recur. There are no established therapies for super-refractory status epilepticus other than to reinstitute general anesthesia.

Special considerations apply to the treatment of certain forms of nonconvulsive status epilepticus. Absence status epilepticus can often be effectively treated with a benzodiazepine followed by intravenous valproate. Long-term control is usually achieved with oral [ethosuximide](#) or valproate. Absence status epilepticus can occur when an inappropriate antiseizure medication, such as [vigabatrin](#), [tiagabine](#), [carbamazepine](#), or [phenytoin](#), is used in a patient with idiopathic (genetic) generalized epilepsy. Focal nonconvulsive status epilepticus with or without impairment of consciousness generally responds to intravenous antiseizure medications, and general anesthetics are avoided. Nonconvulsive status epilepticus in coma is often refractory to antiseizure medications and may require general anesthesia.

### ACUTE REPETITIVE SEIZURES (SEIZURE CLUSTERS)

Acute repetitive seizures, also referred to as seizure clusters, are groups of seizures that occur more frequently than the patient's habitual seizure frequency. The clusters can occur rapidly over several minutes, or they may occur over a longer time period of 1 or 2 days. In acute repetitive seizures, there is complete recovery between seizures so that patients do not meet the definition of status epilepticus. However, the condition is concerning nevertheless because, in the absence of treatment, prolonged seizures or status epilepticus can occur. Acute repetitive seizures can be treated in the emergency department with intravenous benzodiazepines or other antiseizure medications. In the USA, [diazepam](#) rectal gel and [midazolam](#) and [diazepam](#) nasal sprays are approved for the out-of-hospital treatment of acute repetitive seizures. Intranasal [lorazepam](#) injection solution delivered with a nasal atomizer or instilled by drop into the nostril also has been shown to be efficacious but is not approved for this route of administration in the USA. Buccal (oromucosal) [midazolam](#), in which the treatment solution is administered to the buccal mucosa using an oral syringe, is commonly used in Europe and elsewhere in the world. [Lorazepam](#) oral solution concentrate, available in the USA, can be administered buccally. [Lorazepam](#) solutions require refrigeration; [diazepam](#) and [midazolam](#) are stable at room temperature. [Lorazepam](#) buccal/sublingual tablets are available outside the USA. Some clinicians in the USA use oral swallowed benzodiazepine tablets on an off-label basis. Outside the USA, rectal [paraldehyde](#) is sometimes used. Administering rectal medications can be difficult, time consuming, and an embarrassing experience for the patient and caregivers; such products are generally limited to use in children because of the social stigma and the mechanical difficulties of positioning adults.

### TERATOGENICITY

Most women with epilepsy who become pregnant require continued drug therapy for seizure control (see also [Chapter 59](#)). No antiseizure medication is known to be completely safe for the developing fetus. Valproate is a known human teratogen. First-trimester exposure is associated with an approximately threefold increased risk of major congenital malformations, most commonly spina bifida (absolute risk, 6–9%). [Phenobarbital](#) use during pregnancy is also associated with an elevated risk of major congenital malformation, most often cardiac defects. First-trimester in utero exposure to [topiramate](#) is associated with an approximately 10-fold increase in oral clefts risk (absolute risk, 1.4%). If possible, valproate,

phenobarbital, and topiramate should be avoided in women of childbearing potential, and if the drugs cannot be eliminated, they should be used at the lowest dose possible because the risk, at least for valproate, has been shown to be dose-dependent. Other antiseizure medications may present a lower risk of major congenital malformations (or the risk is poorly understood), but the risk for most drugs, including carbamazepine, phenytoin, and levetiracetam, is not zero. In addition to congenital malformations, there is evidence that first-trimester exposure is associated with cognitive impairment. In particular, fetal exposure to valproate is associated with a dose-dependent reduction in cognitive abilities across a range of domains including IQ. Fetal exposure to lamotrigine or levetiracetam may be safer with regard to cognition than other antiseizure medications, and these two agents also have the lowest risks of major congenital malformations. Polytherapy may increase the risk of neurodevelopmental deficits, particularly when one of the drugs is valproate. In addition, there is evidence that valproate exposure may be associated with an increased risk of autism spectrum disorder.

## BREASTFEEDING

Some antiepileptic drugs such as primidone, levetiracetam, gabapentin, lamotrigine, and topiramate penetrate into breast milk in relatively high concentrations. For example, in one study, plasma concentrations of lamotrigine in breastfeeding infants were 18.3% of maternal plasma concentrations. Other antiseizure medications that are highly protein bound, such as valproate, phenobarbital, phenytoin, and carbamazepine, do not penetrate into breast milk substantially. Case series have not reported adverse effects on the newborn of antiseizure medication exposure via breast milk, although there are some reports of sedation with the barbiturates and benzodiazepines. As a general rule, breastfeeding should not be discouraged given the lack of evidence of harm and the known positive benefits.

## SUICIDALITY

An analysis of suicidal behavior during clinical trials of antiseizure medications was carried out by the US Food and Drug Administration in 2008. The presence of either suicidal behavior or suicidal ideation was 0.37% in patients taking active drugs and 0.24% in patients taking placebo. This led to an alert of an increased risk of suicide in people taking antiseizure medications. Following the report, several studies have addressed the issue in various ways but have not provided convincing data that, as a class, antiseizure medications induce suicide-related behaviors. In addition, an analysis of data from placebo-controlled clinical trials of more recently approved antiseizure medications (eslicarbazepine, perampanel, brivaracetam, cannabidiol, and cenobamate) where suicidality was investigated prospectively found no evidence of increased risk of suicidal ideation or suicide attempt in relation to placebo. Whether or not antiseizure medications are associated with increased suicidality, psychiatric disorders are more frequent in people with epilepsy than in the general population. The cause of death in persons with epilepsy is much more frequently suicide (11.5%) than in the population at large (1%). It is therefore crucial to routinely assess patients with epilepsy for depression and suicide risk.

## WITHDRAWAL

Antiseizure medications may not need to be taken indefinitely. Children who are seizure free for periods longer than 2–4 years while on antiseizure medications will remain so when medications are withdrawn in 70% of cases. The risk of recurrence depends on the seizure syndrome. Resolution of seizures is common for generalized absence epilepsy but not for juvenile myoclonic epilepsy. Other risk factors for recurrence are an abnormal EEG, the presence of neurologic deficits, or when seizure control had been difficult to achieve. There is little information on antiseizure medication withdrawal in seizure-free adults. Withdrawal is believed to be more likely to be successful in patients with generalized epilepsies who exhibit a single seizure type, whereas longer duration of epilepsy, an abnormal neurologic examination, an abnormal EEG, and certain epilepsy syndromes, including juvenile myoclonic epilepsy, are associated with increased risk of recurrence. Medications are generally withdrawn slowly over a 1- to 3-month period or longer. Abrupt cessation may be associated with return of seizures and even a risk of status epilepticus. Some medications are more easily withdrawn than others. Physical dependence occurs with barbiturates and benzodiazepines, and there is a well-recognized risk of rebound seizures with abrupt withdrawal.

## MEDICATION DEVELOPMENT FOR EPILEPSY

Most antiseizure medications have been identified by tests in rodent (rat or mouse) models. The **maximal electroshock (MES)** test, in which animals receive an electrical stimulus, with tonic hindlimb extension as the endpoint, has been the most productive model. The MES test led to the identification of many of the sodium channel-blocking antiseizure medications. Another model, the **pentylentetrazol (PTZ)** test, in which animals receive a dose of the chemical convulsant PTZ (an antagonist of GABA<sub>A</sub> receptors) sufficient to cause clonic seizures, also has been widely used. The 6-

**Hz seizure test** is a distinct electrical stimulation model that responds differently to antiseizure agents than does the MES test. Immediately after the stimulation, animals (usually mice but rats can be used) exhibit a limbic-type seizure characterized by forelimb clonus followed by stereotyped, automatic behaviors, including twitching of the vibrissae and Straub tail. In the **kindling model**, mice or rats repeatedly receive a mild electrical stimulus in the amygdala or hippocampus over the course of a number of days, causing them to develop a permanent propensity for limbic seizures when they later are stimulated. The kindling model can be used to assess the ability of a chemical compound to protect against focal seizures. Animals with a genetic susceptibility to absence-like episodes are useful in identifying drugs for the treatment of absence seizures. In addition to empirical screening of chemical compounds in such animal models, a few antiseizure medications have been identified by in vitro screening against a molecular target. Examples of targets that have been used to identify approved antiseizure medications include  $\gamma$ -aminobutyric acid (GABA) transaminase (**vigabatrin**), GAT-1 GABA transporter (**tiagabine**), AMPA receptors (**perampanel**), or the synaptic vesicle protein SV2A (**brivaracetam**).

## ANTISEIZURE MEDICATIONS IN DEVELOPMENT

Several potential new antiseizure medications are in clinical development for the treatment of focal seizures, including XEN1101, a potent Kv7.2/Kv7.3 (KCNQ2/KCNQ3) potassium channel opener; darigabat, a subtype selective  $\alpha_2, \alpha_3, \alpha_5$  GABA<sub>A</sub> receptor positive modulator; and NBI-921352, a potent and highly selective state-dependent Nav1.6 sodium channel inhibitor. Various small molecule and gene therapies, including antisense oligonucleotide and adeno-associated virus capsid based, are in development for diverse DEEs. Some treatments in late-stage development for acute seizures emergencies include Staccato (thermal aerosol inhaled) **alprazolam** to terminate acute seizures; **diazepam** buccal film (Libervant) for acute repetitive seizures; and ganaxolone for refractory status epilepticus.

### SUMMARY Antiseizure Medications

Type, Drug	Mechanism of Action	Pharmacokinetics	Clinical Applications	Toxicities, Interactions
<b>SODIUM CHANNEL BLOCKERS</b>				
• <b>Carbamazepine</b>	Sodium channel blocker	Rapidly absorbed orally, with bioavailability 75–85% • peak levels in 4–5 h • plasma protein binding 75% • extensively metabolized in liver primarily by CYP3A4, in part to active carbamazepine-10,11-epoxide • $t_{1/2}$ of parent in adults initially 25–65 h, decreasing to 8–20 h with autoinduction	Focal and focal-to-bilateral tonic-clonic seizures; trigeminal neuralgia	<i>Toxicity:</i> Nausea, diplopia, ataxia, hyponatremia, headache • <i>Interactions:</i> <b>Phenytoin</b> , valproate, <b>fluoxetine</b> , <b>verapamil</b> , macrolide antibiotics, <b>isoniazid</b> , propoxyphene, <b>danazol</b> , <b>phenobarbital</b> , <b>primidone</b> , many others
<ul style="list-style-type: none"> <li>• <b>Oxcarbazepine:</b> Similar to <b>carbamazepine</b>; 100% bioavailability; active 10-hydroxyoxcarbazepine (<b>licarbazepine</b> or <b>MHD</b>) metabolite 40% protein binding; 1–2 h <math>t_{1/2}</math> but active metabolites with <math>t_{1/2}</math> of 8–12 h; fewer interactions reported</li> <li>• <b>Eslicarbazepine</b> acetate: Similar pharmacokinetics to <b>oxcarbazepine</b> but approved by regulatory authorities for once daily dosing</li> </ul>				
• <b>Lamotrigine</b>	Sodium channel blocker	Nearly complete (~90%) absorption • peak levels in 1–3 h • protein binding 55% • extensively metabolized; no active metabolites • $t_{1/2}$ 8–35 h	Focal seizures, generalized tonic-clonic seizures, absence seizures, other generalized seizures; bipolar depression	<i>Toxicity:</i> Dizziness, headache, diplopia, rash • <i>Interactions:</i> Valproate, <b>carbamazepine</b> , <b>oxcarbazepine</b> , <b>phenytoin</b> , <b>phenobarbital</b> , <b>primidone</b> , succinimides, <b>sertraline</b> , <b>topiramate</b>
• <b>Lacosamide</b>	Sodium	Complete absorption • peak levels in 1–	Focal seizures	<i>Toxicity:</i> Dizziness, headache, nausea • cardiac

	channel blocker, slow blocking kinetics	2 h • protein binding <30% • no active metabolites • $t_{1/2}$ 12–14 h		arrhythmia • <i>Interactions</i> : Minimal
• <a href="#">Phenytoin</a> , <a href="#">fosphenytoin</a>	Sodium channel blocker	Absorption is formulation-dependent • highly bound to plasma proteins • no active metabolites • dose-dependent elimination, $t_{1/2}$ 12–36 h • <a href="#">fosphenytoin</a> is for IV, IM routes	Focal seizures, tonic-clonic seizures	<i>Toxicity</i> : Diplopia, ataxia, gingival hyperplasia, hirsutism, neuropathy • <i>Interactions</i> : <a href="#">Phenobarbital</a> , <a href="#">carbamazepine</a> , <a href="#">isoniazid</a> , <a href="#">felbamate</a> , <a href="#">oxcarbazepine</a> , <a href="#">topiramate</a> , <a href="#">fluoxetine</a> , <a href="#">fluconazole</a> , <a href="#">digoxin</a> , <a href="#">quinidine</a> , <a href="#">cyclosporine</a> , steroids, oral contraceptives, others
<b>BROAD SPECTRUM</b>				
• Valproate	Unknown	Nearly complete (>90%) absorption • peak levels formulation-dependent • highly (90%) bound to plasma proteins • extensively metabolized in liver • $t_{1/2}$ 5–16 h	Generalized tonic-clonic seizures, focal seizures, absence seizures, myoclonic seizures, other generalized seizure types; migraine prophylaxis	<i>Toxicity</i> : Nausea, tremor, weight gain, hair loss, teratogenic, hepatotoxic • <i>Interactions</i> : <a href="#">Phenobarbital</a> , <a href="#">phenytoin</a> , <a href="#">carbamazepine</a> , <a href="#">lamotrigine</a> , <a href="#">felbamate</a> , <a href="#">rifampin</a> , <a href="#">ethosuximide</a> , <a href="#">primidone</a>
• <a href="#">Levetiracetam</a>	SV2A ligand	Nearly complete (~95%) absorption • peak levels in 1–2 h • not bound to plasma proteins • minimal metabolism in blood to inactive metabolite; ~66% excreted unchanged in urine • $t_{1/2}$ 6–11 h	Focal seizures, generalized tonic-clonic seizures, myoclonic seizures	<i>Toxicity</i> : Nervousness, dizziness, depression, seizures • <i>Interactions</i> : Rare
• <a href="#">Brivaracetam</a> : Similar to <a href="#">levetiracetam</a> but interaction with <a href="#">carbamazepine</a>				
• <a href="#">Topiramate</a>	Multiple actions	Bioavailability ~80% • peak levels in 2–4 h • minimal (15%) plasma protein binding • variable metabolism; no active metabolites; 20–70% excreted unchanged in the urine • $t_{1/2}$ 20–30 h, but decreases with concomitant drugs	Focal seizures, primary generalized seizures, Lennox-Gastaut syndrome; migraine prophylaxis	<i>Toxicity</i> : Somnolence, cognitive slowing, confusion, paresthesias • <i>Interactions</i> : <a href="#">Phenytoin</a> , <a href="#">carbamazepine</a> , oral contraceptives, <a href="#">lamotrigine</a> , <a href="#">lithium</a>
• <a href="#">Zonisamide</a>	Unknown	Nearly complete (>90%) absorption • peak concentrations in 2–6 h • modest (40–60%) plasma protein binding • moderate (>50%) metabolism in liver; 30% excreted unchanged in urine • $t_{1/2}$ 50–70 h	Focal seizures, generalized tonic-clonic seizures, myoclonic seizures	<i>Toxicity</i> : Drowsiness, cognitive impairment, confusion, skin rashes • <i>Interactions</i> : Minimal

• <b>Rufinamide</b>	Sodium channel blocker and other mechanisms	Well absorbed orally (>85%) • peak concentrations in 4–6 h • low (35%) plasma protein binding • $t_{1/2}$ 6–10 h • metabolized in liver by carboxylesterase 1; no active metabolites • metabolite mostly excreted in urine (~70%)	Lennox-Gastaut syndrome, focal seizures	<i>Toxicity:</i> Somnolence, vomiting, pyrexia, diarrhea • <i>Interactions:</i> Not metabolized via P450 enzymes, but there may be interactions with other antiseizure medications
<b>GABAPENTINOIDS</b>				
• <b>Gabapentin</b>	$\alpha 2\delta$ ligand	Bioavailability 50%, decreasing with increasing doses • peak concentrations in 2–3 h • not bound to plasma proteins • not metabolized; 100% excreted unchanged in urine • $t_{1/2}$ 5–9 h	Focal seizures; neuropathic pain; postherpetic neuralgia; anxiety	<i>Toxicity:</i> Somnolence, dizziness, ataxia • <i>Interactions:</i> Minimal
• <b>Pregabalin</b>	$\alpha 2\delta$ ligand	Nearly complete (~90%) absorption • peak concentrations in 1–2 h • not bound to plasma proteins • not metabolized; 98% excreted unchanged in urine • $t_{1/2}$ 4.5–7 h	Focal seizures; neuropathic pain; postherpetic neuralgia; fibromyalgia; anxiety	<i>Toxicity:</i> Somnolence, dizziness, ataxia • <i>Interactions:</i> Minimal
<b>BARBITURATES</b>				
• <b>Phenobarbital</b>	Positive allosteric modulator of GABA <sub>A</sub> receptors • reduces excitatory synaptic responses	Nearly complete (>90%) absorption • peak concentrations in 0.5–4 h • modest (55%) plasma protein binding • extensively metabolized in liver; no active metabolites; 20–25% excreted unchanged in urine • $t_{1/2}$ 75–140 h	Focal seizures, generalized tonic-clonic seizures, myoclonic seizures, neonatal seizures; sedation	<i>Toxicity:</i> Sedation, cognitive impairment, ataxia, hyperactivity • <i>Interactions:</i> Valproate, carbamazepine, felbamate, phenytoin, cyclosporine, felodipine, lamotrigine, nifedipine, nimodipine, steroids, theophylline, verapamil, others
• <b>Primidone</b>	Sodium channel blocker-like but converted to <b>phenobarbital</b>	Nearly complete (>90%) absorption • minimal (10%) plasma protein binding • peak concentrations in 2–6 h • extensively metabolized in liver; 2 active metabolites ( <b>phenobarbital</b> and phenylethylmalonamide); 65% excreted unchanged in urine • $t_{1/2}$ 10–25 h	Generalized tonic-clonic seizures, focal seizures	<i>Toxicity:</i> Sedation, cognitive impairment, ataxia, hyperactivity • <i>Interactions:</i> Similar to <b>phenobarbital</b>
<b>ABSENCE SEIZURE-SPECIFIC</b>				
• <b>Ethosuximide</b>	Inhibit low-threshold calcium channels (T-	Nearly complete (>90%) absorption • peak concentrations in 3–7 h • not bound to plasma proteins • extensively metabolized in liver; no active	Absence seizures	<i>Toxicity:</i> Nausea, headache, dizziness, lethargy • <i>Interactions:</i> Valproate, <b>phenobarbital</b> , <b>phenytoin</b> , carbamazepine, rifampicin

type)  
metabolites; 20% excreted unchanged  
in urine •  $t_{1/2}$  20–60 h

### BENZODIAZEPINES

• <b>Diazepam</b>	Positive allosteric modulator of GABA <sub>A</sub> receptors	Nearly complete (>90%) oral or rectal absorption • peak concentrations in 1–1.5 h • IV for status epilepticus • highly (95–98%) bound to plasma proteins • extensively metabolized by CYP3A4 and CYP2C19 to N-desmethyldiazepam and other active metabolites • $t_{1/2}$ of N-desmethyldiazepam up to 100 h	Status epilepticus, acute repetitive seizures (seizure clusters); sedation, anxiety, muscle relaxation (muscle spasms, spasticity), acute <b>alcohol withdrawal</b>	<i>Toxicity:</i> Sedation • <i>Interactions:</i> Additive with sedative-hypnotics
• <b>Clonazepam</b>	Positive allosteric modulator of GABA <sub>A</sub> receptors	Bioavailability >80% • peak concentrations in 1–4 h • highly (86%) bound to plasma proteins • extensively metabolized in liver by CYP3A4; no active metabolites • $t_{1/2}$ 12–56 h	Absence seizures, myoclonic seizures, infantile spasms	<i>Toxicity:</i> Similar to <b>diazepam</b> • <i>Interactions:</i> Additive with sedative-hypnotics
• <b>Clobazam</b>	Positive allosteric modulator of GABA <sub>A</sub> receptors	Bioavailability >95% • protein binding 80–90% • extensively metabolized to N-desmethyloclobazam, which is pharmacologically active • parent: $t_{1/2}$ 10–30 h • N-desmethyl metabolite: $t_{1/2}$ 36–46 h	Focal seizures, seizures associated with Lennox-Gastaut syndrome and Dravet syndrome	<i>Toxicity:</i> Somnolence, sedation, lethargy <i>Interactions:</i> Increases levels of <b>phenytoin</b> and <b>carbamazepine</b> ; <b>cannabidiol</b> increases levels of N-desmethyloclobazam

• **Lorazepam:** Used for status epilepticus; rapidly conjugated to **lorazepam glucuronide**, which is inactive;  $t_{1/2}$  12 h

• **Midazolam:** Used for status epilepticus and acute repetitive seizures (seizure clusters); water soluble at pH <4 but becomes highly lipid soluble at physiological pH, minimizing pain on injection and contributing to rapid onset of action; converted by CYP3A isoenzymes to active metabolite 1-hydroxymidazolam;  $t_{1/2}$  1.5–3 h

### GABA MECHANISMS OTHER THAN BARBITURATE AND BENZODIAZEPINE

• <b>Tiagabine</b>	GAT-1 GABA transporter inhibitor	Nearly complete (~90%) absorption • peak concentrations in 0.5–2 h • highly (96%) bound to plasma proteins • extensively metabolized in liver; no active metabolites; <2% excreted unchanged in urine • $t_{1/2}$ 2–9 h	Focal seizures	<i>Toxicity:</i> Nervousness, dizziness, depression, seizures • <i>Interactions:</i> <b>Phenobarbital</b> , <b>phenytoin</b> , <b>carbamazepine</b> , <b>primidone</b>
• <b>Vigabatrin</b>	Irreversible inhibitor of GABA transaminase	Complete absorption • peak concentrations in 1 h • not bound to plasma proteins • not metabolized; eliminated unchanged in urine • $t_{1/2}$ 5–8 h (not relevant because of irreversible action)	Focal seizures, infantile spasms	<i>Toxicity:</i> Drowsiness, dizziness, psychosis, visual field loss • <i>Interactions:</i> Minimal

• Ganaxolone	Positive allosteric modulator of GABA <sub>A</sub> receptors (non-benzodiazepine site)	Absorption increases with high fat meal • peak concentrations in 2–3 h • highly (99%) bound to plasma proteins • extensively metabolized in liver • $t_{1/2}$ 34 h	Seizures associated with cyclin-dependent kinase-like 5 (CDKL5) deficiency disorder; evidence of efficacy in other epilepsies	<i>Toxicity:</i> Symptoms of central nervous system depression, including lethargy, drowsiness, sedation, and hypersomnia • <i>Interactions:</i> CYP3A4 inducers decrease exposure
<b>POTASSIUM CHANNEL OPENER</b>				
• Retigabine (ezogabine)	Opens KCNQ potassium channels	Bioavailability ~60% • peak concentrations in 0.5–2 h • moderately (~80%) bound to plasma proteins • extensively metabolized in liver; 36% excreted unchanged in urine • $t_{1/2}$ 7–11 h	Focal seizures	<i>Toxicity:</i> Dizziness, somnolence, confusion, blurred vision • <i>Interactions:</i> Minimal
<b>AMPA RECEPTOR BLOCKER</b>				
• Perampanel	Noncompetitive block of AMPA receptors	Complete absorption • peak concentrations in 0.5–3 h • highly (95%) bound to plasma proteins • extensively metabolized in liver • $t_{1/2}$ 25–129 h	Focal and focal-to-bilateral tonic-clonic seizures, generalized tonic-clonic seizures	<i>Toxicity:</i> Dizziness, somnolence, headache; psychiatric syndromes • <i>Interactions:</i> Substantial, with increased clearance caused by CYP3A inducers
<b>CANNABINOID</b>				
• Cannabidiol (sesame oil formulation)	Unknown	Absorption enhanced by high-fat meal • peak concentrations in 2.5–5 h • highly (>94%) bound to plasma proteins • extensively metabolized in liver • $t_{1/2}$ 14 h (single dose study)	Seizures associated with Lennox-Gastaut syndrome, Dravet syndrome, and tuberous sclerosis complex	<i>Toxicity:</i> Diarrhea, nausea, somnolence, headache • <i>Interactions:</i> Clobazam (threefold increase in N-desmethylclobazam), valproate (increased risk of liver enzyme elevation)
<b>CARBAMATE</b>				
• Felbamate	NMDA receptor blocker; low-efficacy positive allosteric modulator of GABA <sub>A</sub> receptors	Well absorbed (>90%) • no food effect • 22–25% bound to plasma proteins, primarily albumin • 40–50% excreted unchanged in urine • $t_{1/2}$ 20–23 h	Focal seizures; seizures associated with Lennox-Gastaut syndrome	<i>Toxicity:</i> Anorexia, nausea, vomiting, insomnia, anxiety, weight loss, dizziness, headache, somnolence, aplastic anemia, hepatic failure • <i>Interactions:</i> Increases phenytoin, valproate and phenobarbital; reduces carbamazepine but increases carbamazepine epoxide; phenytoin, carbamazepine, and phenobarbital reduce felbamate concentrations
•	Sodium channel	Well absorbed (>88%) • no food effect • peak concentrations in 1–4 h • >60%	Focal seizures	<i>Toxicity:</i> Somnolence, dizziness, fatigue, balance disorder, gait disturbance, dysarthria,

blocker; low-efficacy positive allosteric modulator of GABA<sub>A</sub> receptors

bound to plasma proteins, primarily **albumin** • extensively metabolized in liver •  $t_{1/2}$  50–60 h

nystagmus, and ataxia; DRESS; short QT interval • *Interactions:* Increases **phenytoin**; may also increase **phenobarbital** and N-desmethylclobazam; decreases **carbamazepine**, **lamotrigine**

### AROMATIC ALLYLIC ALCOHOL

#### • Stiripentol

Positive allosteric modulator of GABA<sub>A</sub> receptors; increases **clobazam** and **norclobazam** levels

Used in combination with **clobazam** or **valproate** • bioavailability 30% •  $t_{1/2}$  4.5–13 h (dose-dependent) • highly (>99%) bound to plasma proteins  
• metabolized in liver

Dravet syndrome (USA: adjunctive use in conjunction with **clobazam**; European Union: adjunctive use in conjunction with **clobazam** and **valproate**)

*Toxicity:* Sedation/drowsiness, reduced appetite, slowing of mental function, ataxia, diplopia, nausea, and abdominal pain  
*Interactions:* **Clobazam**, **valproate**; also **carbamazepine**, **phenobarbital**, **phenytoin**

### SUBSTITUTED AMPHETAMINE

#### • Fenfluramine

Serotonin release

Bioavailability 68–74% • no food effect • peak concentration 3–5 h •  $t_{1/2}$  20 h • metabolized to **norfenfluramine** by CYP1A2, CYP2B6, CYP2D6

Convulsive seizures associated with Dravet syndrome; atonic seizures associated with Lennox-Gastaut syndrome

*Toxicity:* Decreased appetite, diarrhea, fatigue • *Interactions:* concomitant **stiripentol** increases fenfluramine exposure and reduces norfenfluramine exposure; fenfluramine does not affect **valproate**, **stiripentol**, **clobazam**, or **norclobazam**

### PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
Brivaracetam	Generic, Briviact
Cannabidiol	Epidiolex
Carbamazepine forms	
Carbamazepine	Generic, Tegretol, Eptol, Teril
Carbamazepine extended release	Generic, Tegretol-XR, Carbatrol, Equetro, Curatil Prolonged-Release

Carbamazepine injection	Carnexiv (discontinued in USA)
Cenobamate	Xcopri, Ontozry
Clobazam	Generic, Onfi, Sympazan
Clonazepam forms	
Clonazepam tablet	Generic, Klonopin, Rivatril, Rivotril, Anteplepsin, Clonotril, Iktorivil, others
Clonazepam orally disintegrating tablet	Generic
Clonazepam oral solution	Generic, Rivotril oral solution (not available USA)
Clonazepam injection	Generic, Rivotril injection (not available in USA)
Clorazepate dipotassium	Generic, Tranxene
Corticotropin	Acthar Gel
Diazepam forms	
Diazepam	Generic, Valium, others
Diazepam oral solution concentrate	Generic, Diazepam Intensol
Diazepam injection	Generic
Diazepam rectal gel	Diastat Acudial
Diazepam intranasal	Valtoco
Eslicarbazepine acetate	Aptiom, Stedesa
Ethosuximide	Generic, Zarontin
Ethotoin	Peganone (discontinued in USA)
Everolimus	Afinitor
Felbamate	Generic, Felbatol
Fenfluramine	Fintepla
Fosphenytoin sodium injection	Generic, Cerebyx
Gabapentin	Generic, Neurontin, Gralise
Gabapentin enacarbil	Horizant
Ganaxolone	Ztalmy

Lacosamide forms	
Lacosamide	Generic, Vimpat
Lacosamide injection	Generic, Vimpat injection
Lamotrigine forms	
Lamotrigine	Generic, Lamictal
Lamotrigine extended release	Generic, Lamictal XR
Levetiracetam forms	
Levetiracetam	Generic, Keppra, Spritam
Levetiracetam extended release	Generic, Keppra XR, Elepsia XR
Levetiracetam injection	Generic, Keppra injection
Lorazepam forms	
Lorazepam	Generic, Ativan
Lorazepam oral solution concentrate	Generic, Lorazepam Intensol
Lorazepam injection	Generic, Ativan injection
Mephenytoin	Mesantoin (discontinued in USA)
Methsuximide	Celontin
Midazolam forms	
Midazolam hydrochloride injection	Generic, Versed, Seizalam
Midazolam hydrochloride syrup	Generic
Midazolam oromucosal solution (buccal)	Epistatus, Buccolam
Midazolam nasal spray	Nayzilam, Nasolam
Oxcarbazepine	Generic, Trileptal, Oxtellar XR
Pentobarbital sodium injection	Generic, Nembutal Sodium injection
Perampanel	Fycompa
Phenobarbital forms	
Phenobarbital	Generic, Luminal Sodium, others

Phenobarbital sodium injection	Generic, Sezaby
Phenytoin sodium forms	
Phenytoin sodium extended	Generic, Dilantin, Phenytek
Phenytoin sodium injectable	Generic, phenytoin sodium injection
Pregabalin forms	
Pregabalin	Generic, Lyrica
Pregabalin extended release	Generic, Lyrica CR
Primidone	Generic, Mysoline
Retigabine (ezogabine)	Potiga, Trobalt (discontinued)
Rufinamide	Generic, Banzel
Stiripentol	Diacomit
Tiagabine	Generic, Gabitril
Topiramate forms	
Topiramate	Generic, Topamax, Eprontia
Topiramate extended release	Generic, Trokendi XR, Qudexy XR
Trimethadione	Tridione (discontinued)
Valproate/valproic acid forms	
Valproic acid	Generic, Depakene
Divalproex sodium delayed release	Generic, Depakote
Divalproex sodium extended release	Generic, Depakote ER
Valproate sodium injection	Generic, Depacon
Vigabatrin	Generic, Sabril, Vigradone
Zonisamide	Generic, Zonegran, Zonisade

**Lamotrigine** was gradually added to the regimen to a dosage of 200 mg bid. Since then, the patient has been seizure-free for almost 2 years but now comes to the office for a medication review. Gradual discontinuation of **levetiracetam** is planned if the patient continues to do well for another year, although risk of recurrent seizures is always present when medications are withdrawn.

## Chapter 25: General Anesthetics

Helge Eilers; Spencer Yost

### CASE STUDY

#### CASE STUDY

An elderly man with type 2 diabetes mellitus and ischemic pain in a lower extremity is scheduled for femoral-to-popliteal artery bypass surgery. He has a history of hypertension and coronary artery disease with symptoms of stable angina. He can walk only half a block before pain in his legs forces him to stop. He has a 50-pack-year smoking history but stopped 2 years ago. Medications include [atenolol](#), [atorvastatin](#), and [hydrochlorothiazide](#).

The nurse in the preoperative holding area obtains the following vital signs: temperature 36.8°C (98.2°F), blood pressure 168/100 mm Hg, heart rate 78 bpm, [oxygen](#) saturation by pulse oximeter 96% while breathing room air; he reports pain 5/10 in the right lower leg after walking into the hospital. What anesthetic agents will you choose for his anesthetic plan? Why? Does the choice of anesthetic make a difference?

For centuries, humans relied on natural medicines and physical methods to control surgical pain. Historical texts describe the sedative effects of cannabis, henbane, mandrake, and opium poppy. Physical methods such as cold, nerve compression, carotid artery occlusion, and cerebral concussion were also employed, with variable effectiveness. Although surgery was performed under ether anesthesia as early as 1842, the first public demonstration of surgical general anesthesia in 1846 is generally accepted as the start of the modern era of anesthesia. For the first time, physicians had a reliable means to keep their patients from experiencing pain during surgical procedures.

The neurophysiologic state produced by general anesthetics is characterized by five primary effects: **unconsciousness**, **amnesia**, **analgesia**, **inhibition of autonomic reflexes**, and **skeletal muscle relaxation**. None of the currently available anesthetic agents used alone can achieve all five of these desired effects well. An ideal anesthetic drug should also induce rapid, smooth loss of consciousness, be rapidly reversible upon discontinuation, and possess a wide margin of safety.

The modern practice of anesthesiology relies on the use of combinations of intravenous and inhaled drugs (**balanced anesthesia** techniques) to take advantage of the favorable properties of each agent while minimizing their adverse effects. The choice of anesthetic technique is determined by the type of diagnostic, therapeutic, or surgical intervention that the patient needs. For minor superficial surgery or invasive diagnostic procedures, oral or parenteral sedatives can be combined with local anesthetics in a technique termed **monitored anesthesia care** (MAC) (see Box: [Sedation & Monitored Anesthesia Care](#), and [Chapter 26](#)). This approach can provide profound analgesia, while retaining the patient's ability to maintain a patent airway and to respond to verbal commands. For more invasive surgical procedures, anesthesia may begin with a preoperative benzodiazepine, be induced with a rapidly acting intravenous drug (eg, [propofol](#) or thiopental), and be maintained with inhaled agents (eg, volatile agents, nitrous oxide), intravenous drugs (eg, [propofol](#), opioid analgesics), or both.

Many diagnostic and minor therapeutic surgical procedures can be performed without general anesthesia (GA) using sedation-based anesthetic techniques. In this setting, regional (nerve block) or local anesthesia supplemented with a benzodiazepine or **propofol** with or without opioid analgesics (or **ketamine**) will allow a patient to tolerate superficial surgical or interventional procedures. This anesthetic technique is known as **monitored anesthesia care**, abbreviated as **MAC**, and should not be confused with the minimal alveolar concentration for the comparison of potencies of inhaled anesthetics (see text and Box: **What Does Anesthesia Represent & How Does It Work?**). The technique typically begins with intravenous **midazolam** to produce anxiolysis, amnesia, and mild sedation, followed by a titrated, variable-rate **propofol** infusion (to provide moderate to deep levels of sedation). A potent opioid analgesic or **ketamine** may be added to blunt pain associated with the injection of local anesthesia and the procedure itself.

Another approach, used primarily by non-anesthesiologists, is called **conscious sedation**. This technique produces alleviation of anxiety and pain with less alteration of the level of consciousness by using smaller doses of sedative medications. In this state, the patient retains the ability to maintain a patent airway and remains responsive to verbal commands. Using intravenous anesthetic drugs such as benzodiazepines and/or opioid analgesics (eg, **fentanyl**) in conscious sedation protocols carries the added advantage of being rapidly reversible by specific receptor antagonist drugs (**flumazenil** and **naloxone**, respectively) if a particular patient displays unusual sensitivity to them.

MAC or conscious sedation can also help supplement regional anesthesia techniques such as peripheral nerve blocks or neuraxial anesthesia.

A specialized form of sedation is occasionally required for critically ill patients in the intensive care unit (ICU) that require invasive cardiopulmonary support such as mechanical ventilation or extracorporeal membrane oxygenation (ECMO). In this situation, sedative-hypnotic drugs and low doses of intravenous anesthetic infusions may be combined. **Propofol**, **fentanyl**, and **dexmedetomidine** are popular choices for this indication.

**Deep sedation** is similar to a light state of general anesthesia characterized by decreased consciousness from which the patient is not easily aroused. The transition from deep sedation to general anesthesia is fluid and can be difficult to define. Because deep sedation is accompanied by loss of verbal responsiveness, protective airway reflexes, and the ability to maintain a patent airway, this state may be indistinguishable from general anesthesia. A practitioner with expertise in airway management (anesthesiologist or nurse anesthetist) must be present.

Intravenous agents used in deep sedation protocols mainly include the sedative-hypnotics **propofol** and **midazolam**, sometimes in combination with potent opioid analgesics or **ketamine**, depending on the level of pain associated with the surgery or procedure.

## MECHANISM OF GENERAL ANESTHETIC ACTION

General anesthetics have been in successful clinical use for more than 175 years, yet their mechanism of action remains unknown. The principal effect that is common to all anesthetic agents is suppression of the normal activity of the central nervous system (CNS). Initial research focused on identifying a single biologic site of action for these drugs. This “unitary theory” of anesthetic action has been supplanted by a more complex model of molecular targets located at multiple levels of the CNS. Ongoing research has focused on cellular, molecular, and network sites to understand the mechanism of general anesthesia.

Anesthetics affect neurons at various **cellular** locations, but the primary focus has been on the **synapse**. A presynaptic action may alter the release of neurotransmitters, whereas a postsynaptic effect may change the frequency or amplitude of impulses exiting the synapse. The cumulative effect of these actions may produce strengthened inhibition or diminished excitation within key areas of the CNS. Studies on isolated spinal cord tissue have demonstrated that excitatory transmission is impaired more strongly by anesthetics than inhibitory effects are potentiated.

The principal **molecular** targets of anesthetic action that have been studied are neuronal ion channels that mediate impulse conduction in the CNS. Chloride channels ( $\gamma$ -aminobutyric acid-A [GABA<sub>A</sub>] and glycine receptors) and potassium channels (K<sub>2P</sub>, possibly K<sub>V</sub>, and K<sub>ATP</sub> channels) remain the primary *inhibitory* ion channels considered possible sites of anesthetic action. *Excitatory* ion channel targets include those activated by **acetylcholine** (nicotinic and muscarinic receptors), by glutamate (amino-3-hydroxy-5-methyl-4-isoxazol-propionic acid [AMPA], kainate, and *N*-methyl-D-aspartate [NMDA] receptors), or by serotonin (5-HT<sub>2</sub> and 5-HT<sub>3</sub> receptors). **Figure 25–1** depicts the relation of these inhibitory and excitatory targets of

**FIGURE 25-1**

Recently, researchers using new investigational tools such as extended array electroencephalography and functional magnetic resonance imaging have focused on neural **networks** within the brain that are altered by general anesthetics (see Box: [What Does Anesthesia Represent & How Does It Work?](#) for more details). Nevertheless, the principal barrier to understanding the mechanism of action of anesthetic agents is the lack of a coherent, widely accepted explanation for how CNS neuronal activity gives rise to the fundamental properties of brain function such as memory, sensation,

## INHALED ANESTHETICS

A clear distinction should be made between gaseous and volatile anesthetics, both of which are administered by inhalation. *Gaseous* anesthetics (**nitrous oxide, xenon**) have high vapor pressures and low boiling points so that they are in gas form at room temperature. *In contrast, volatile* anesthetics (**halothane, isoflurane, desflurane, sevoflurane**) have lower vapor pressures and relatively higher boiling points so that they are liquids at room temperature (20°C) and sea-level ambient pressure. The physical characteristics of volatile anesthetics determine that they need to be administered using precision vaporizers. Figure 25–2 shows the chemical structures of important, clinically used, inhaled anesthetics.

## PHARMACOKINETICS

Inhaled anesthetics, both volatile and gaseous, are taken up through gas exchange in the alveoli of the lung for distribution to the effect compartments within the body. The kinetic goal of delivering anesthetic gases this way is to rapidly achieve an effective concentration of the agent at the lung: blood interface. When this equilibrium is reached we presume that the effect site concentration within the CNS (brain and spinal cord) has also been reached. Several factors determine how quickly the alveolar and subsequent CNS concentrations change.

## Uptake & Distribution

### A. Factors Controlling Uptake

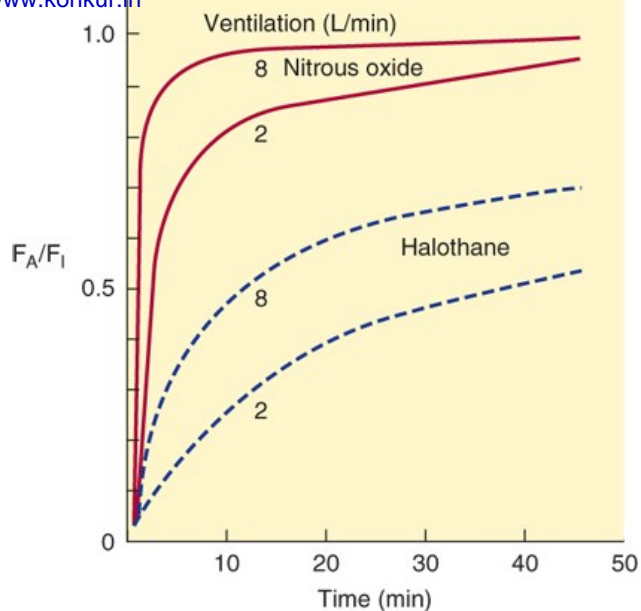

#### 1. Inspired concentration and ventilation

The driving force for uptake of an inhaled anesthetic into the body is the ratio between inspired and alveolar concentration. The most important parameter that can be controlled by the anesthesiologist to change alveolar concentration quickly is the *inspired concentration or partial pressure*. The partial pressure is the fraction of a gas mixture that a particular component comprises. For example, a mixture of gases that may be delivered by an anesthesia machine—70% nitrous oxide, 29% oxygen, and 1% isoflurane at normal barometric pressure (760 mm Hg)—contains partial pressures of 532 mm Hg nitrous oxide, 220 mm Hg oxygen, and 7.6 mm Hg isoflurane. The partial pressure of anesthetic in the inspired gas mixture determines the maximum partial pressure that can be achieved in the alveoli as well as the rate of rise of the partial pressure in the alveoli. To accelerate induction, the anesthesiologist increases the inspired anesthetic partial pressure to create a steeper gradient between inspired and alveolar partial pressure. This fractional rise of anesthetic partial pressure during induction is expressed as a ratio of alveolar concentration ( $F_A$ ) over inspired concentration ( $F_I$ ); the faster  $F_A/F_I$  approaches 1 (representing inspired-to-alveolar equilibrium), the faster anesthesia onset will be during inhaled induction of anesthesia.

The other parameter under control of the anesthesiologist that directly determines the rate of rise of  $F_A/F_I$  is alveolar ventilation. By increasing the tidal volume and respiratory rate the anesthesiologist can quickly deliver a larger mass of anesthetic agent to the alveoli of the lung. The tendency for a given inhaled anesthetic to pass from the gas phase of the alveoli into pulmonary capillary blood is determined by the blood:gas partition coefficient (see the following section [Solubility](#) and [Table 25-1](#)). As increased ventilation supplies more anesthetic molecules to the alveoli, a highly soluble anesthetic (blood:gas partition coefficient  $>1$ ) will traverse the alveolar capillary membrane and be taken up by the pulmonary flow, preventing a rise in its alveolar partial pressure. Thus, increased ventilation will replenish the alveolar anesthetic concentration for a highly soluble anesthetic but is not necessary for an anesthetic with low solubility. Therefore, an increase in ventilation accelerates the rise in alveolar partial pressure of an anesthetic with low blood solubility very little, but can significantly increase the partial pressure of agents with moderate to high blood solubility such as halothane. As seen in [Figure 25-3](#), a fourfold increase in the ventilation rate almost doubles the  $F_A/F_I$  ratio for halothane during the first few minutes of administration but increases the  $F_A/F_I$  ratio for the low solubility gas nitrous oxide by only 15%. Thus, hyperventilation increases the speed of induction of anesthesia with inhaled anesthetics that would normally have a slow onset.

FIGURE 25-3

Effect of ventilation on  $F_A/F_I$  and induction of anesthesia. Increased ventilation (8 L/min versus 2 L/min) accelerates the rate of rise toward equilibration of both halothane and nitrous oxide but results in a larger percentage increase for halothane in the first few minutes of induction.

TABLE 25-1

#### Pharmacologic properties of inhaled anesthetics.

Anesthetic	Blood:Gas Partition Coefficient <sup>1</sup>	Brain:Blood Partition Coefficient <sup>1</sup>	Minimal Alveolar Concentration (MAC) (%) <sup>2</sup>	Metabolism	Comments
Nitrous oxide	0.47	1.1	>100	None	Incomplete anesthetic; rapid onset and recovery
Desflurane	0.42	1.3	6-7	<0.05%	Low volatility; poor induction agent (pungent); rapid recovery
Sevoflurane	0.69	1.7	2.0	2-5% (fluoride)	Rapid onset and recovery; unstable in soda-lime
Isoflurane	1.40	2.6	1.40	<2%	Medium rate of onset and recovery
Enflurane	1.80	1.4	1.7	8%	Medium rate of onset and recovery
Halothane	2.30	2.9	0.75	>40%	Medium rate of onset and recovery

<sup>1</sup>Partition coefficients (at 37°C) are from multiple literature sources.

<sup>2</sup>MAC is the anesthetic concentration that produces immobility in 50% of patients exposed to a noxious stimulus.

As described above, the rate of rise of  $F_A/F_I$  is an important determinant of the speed of induction, but is opposed by the uptake of anesthetic into the blood. Uptake is determined by pharmacokinetic characteristics of each anesthetic agent as well as patient factors.

One of the most important factors influencing the transfer of an anesthetic from the lungs to the arterial blood is its solubility characteristics (see Table 25-1). As described above, the blood:gas partition coefficient is a useful index of solubility and defines the relative affinity of an anesthetic for the blood compared to the affinity for inspired gas phase. Desflurane, sevoflurane, and nitrous oxide, which are relatively insoluble in blood, display low partition coefficients. When an anesthetic with low blood solubility partitions between gas in the lung and pulmonary capillary blood, equilibrium is quickly established and the blood concentration rises rapidly (Figure 25-4, top; nitrous oxide, desflurane, sevoflurane). Conversely, for anesthetics with greater solubility (Figure 25-4, bottom; halothane, isoflurane), more molecules dissolve in the blood before partial pressure changes significantly, and arterial concentration of the gas increases less rapidly. A blood:gas partition coefficient of 0.47 for nitrous oxide means that at equilibrium, the concentration in blood is less than half the concentration in the alveolar space (gas). A larger blood:gas partition coefficient causes a greater uptake of anesthetic into the pulmonary blood flow and therefore increases the time required for  $F_A/F_I$  to approach equilibrium (Figure 25-4).

FIGURE 25-4

The alveolar anesthetic concentration ( $F_A$ ) approaches the inspired anesthetic concentration ( $F_I$ ) fastest for the least soluble agents.

### 3. Cardiac output

Changes in the flow rate of blood through the lungs also affect the uptake of anesthetic gases from the alveolar space. An increase in pulmonary blood flow (ie, increased cardiac output) will increase the uptake of anesthetic, thereby slowing the rate by which  $F_A/F_I$  rises and decreasing the rate of induction of anesthesia. Furthermore, one should consider the effect of cardiac output in combination with the tissue distribution and uptake of anesthetic into other tissue compartments. The increased uptake of anesthetic into the blood caused by increased cardiac output will be distributed to all tissues. Since cerebral blood flow is well regulated and maintained relatively constant at clinical anesthetic concentrations, the increased anesthesia uptake caused by increased cardiac output will predominantly be distributed to tissues that are not involved in the site of action of the anesthetic. Conversely, low-cardiac-output states such as in patients with heart failure predispose to overdosage with soluble agents, as the rate of rise in alveolar concentrations will be markedly increased.

The anesthetic partial pressure difference between alveolar and mixed venous blood is dependent mainly on uptake of the anesthetic by the tissues, including non-neural tissues. Depending on the rate and extent of tissue uptake, venous blood returning to the lungs may contain significantly less anesthetic than arterial blood leaving the heart. Anesthetic uptake into tissues is influenced by factors similar to those that determine transfer of the anesthetic from the lung to the intravascular space, including tissue:blood partition coefficients (see [Table 25-1](#)), rates of blood flow to the tissues, and concentration gradients. The greater this difference in anesthetic gas concentrations, the more time it will take to achieve equilibrium with brain tissue.

During the induction phase of anesthesia (and the initial phase of the maintenance period), the tissues that exert greatest influence on the arteriovenous anesthetic concentration gradient are those that are highly perfused (eg, brain, heart, liver, kidneys, and splanchnic bed). Combined, these tissues receive over 75% of the resting cardiac output. In the case of volatile anesthetics with relatively high solubility in highly perfused tissues, venous blood concentration initially is very low, and equilibrium with the alveolar space is achieved slowly.

During maintenance of anesthesia with inhaled anesthetics, the drug continues to be transferred between various tissues at rates dependent on the solubility of the agent, the concentration gradient between the blood and the respective tissue, and the tissue blood flow. Although muscle and skin constitute 50% of the total body mass, anesthetics accumulate more slowly in these tissues than in highly perfused tissues (eg, brain) because they receive only one fifth of the resting cardiac output. Although most anesthetic agents are highly soluble in adipose (fatty) tissues, the relatively low blood perfusion to these tissues delays accumulation, and equilibrium is unlikely to occur with most anesthetics during a typical 1- to 3-hour operation.

The combined effect of ventilation, solubility in the different tissues, cardiac output, and blood flow distribution determines the rate of rise of  $F_A/F_I$  characteristic of each drug. [Figure 25-5](#) schematically compares how uptake and distribution proceed with two widely different agents. The anesthetic state is achieved when the partial pressure of the anesthetic in the brain reaches a threshold concentration determined by its **potency** (MAC; see [Table 25-1](#) and [Box: What Does Anesthesia Represent & How Does It Work?](#)). For relatively insoluble agents like [desflurane](#) and [sevoflurane](#), the alveolar partial pressure can quickly equilibrate through the blood and brain compartments to reach anesthetizing concentrations.

FIGURE 25-5

Why induction of anesthesia is slower with more soluble anesthetic gases. In this schematic diagram, solubility in blood is represented by the relative size of the blood compartment (the more soluble, the larger the compartment). Relative partial pressures of the agents in the compartments are indicated by the degree of filling of each compartment. For a given concentration or partial pressure of the two anesthetic gases in the inspired air, it will take much longer for the blood partial pressure of the more soluble gas (halothane) to rise to the same partial pressure as in the alveoli. Since the concentration of the anesthetic agent in the brain can rise no faster than the concentration in the blood, the onset of anesthesia will be slower with halothane than with nitrous oxide.

Source: Todd W. Vanderah:  
Basic & Clinical Pharmacology, Sixteenth Edition  
Copyright © McGraw Hill. All rights reserved.

However, for an agent like halothane, its greater solubility in blood and other tissue compartments (higher partition coefficients) results in a steeper decline in the concentration gradient from alveolus to brain, causing a slower onset of anesthesia. Therefore, administering a larger concentration of halothane and increasing alveolar ventilation are the two strategies used by anesthesiologists to speed the rate of induction with halothane.

Recovery from inhalation anesthesia occurs by the same principles that are important during induction. Many of the factors that speed induction also speed recovery: high fresh gas flows, decreased solubility, high cerebral blood flow, and increased ventilation. The time to recovery from inhaled anesthetics depends on the rate of removal of the drug from the brain. One of the most important factors governing rate of recovery is again the blood:gas partition coefficient of the anesthetic agent. When the anesthesiologist discontinues the administration of the anesthetic agent to the lung, the inspired and alveolar concentrations fall rapidly. Insoluble anesthetics that prefer the gas phase over blood will then rapidly diffuse into the alveoli and be removed from the body by the process of lung ventilation. Other factors controlling rate of recovery include pulmonary blood flow (cardiac output) and tissue solubility of the anesthetic.

Two features differentiate the recovery phase from the induction phase. First, transfer of an anesthetic from the lungs to blood during induction can be enhanced by increasing its concentration in inspired air, but the reverse transfer process cannot be enhanced because the concentration in the lungs cannot be reduced below zero. Second, at the beginning of the recovery phase, the anesthetic gas tension in different tissues throughout the body may be quite variable, depending on the specific agent solubility and the duration of anesthesia. In contrast, at the start of induction of anesthesia, the initial anesthetic tension is zero in all tissues.

Inhaled anesthetics that are relatively insoluble in blood (ie, possess low blood:gas partition coefficients) and brain are eliminated faster than the more soluble anesthetics. The washout of nitrous oxide, [desflurane](#), and [sevoflurane](#) occurs at a rapid rate, leading to a more rapid recovery from their anesthetic effects compared with halothane and [isoflurane](#). Halothane is approximately twice as soluble in brain tissue and five times more soluble in blood than nitrous oxide and [desflurane](#); its elimination therefore takes place more slowly, and recovery from halothane- and isoflurane-based anesthesia is predictably less rapid.

The duration of exposure to the anesthetic is a significant factor in the speed of emergence from anesthesia, especially in the case of the more soluble anesthetics. Accumulation of anesthetics in muscle, skin, and fat increases with prolonged exposure (especially in obese patients), and blood concentration may decline slowly after discontinuation as the anesthetic is slowly eliminated from these tissues. Although recovery after a short exposure to anesthesia may be rapid even with the more soluble agents, recovery is slow after prolonged administration of halothane or [isoflurane](#).

### 1. *Ventilation*

Two parameters that can be manipulated by the anesthesiologist are useful in controlling the speed of induction of and recovery from inhaled anesthesia: (1) concentration of anesthetic in the inspired gas and (2) alveolar ventilation. As stated above, since the concentration of anesthetic in the inspired gas cannot be reduced below zero, hyperventilation is the only way to speed recovery.

### 2. *Metabolism*

Modern inhaled anesthetics are eliminated mainly by ventilation and are only metabolized to a very small extent; thus, metabolism of these drugs does not play a significant role in the termination of their effect. However, metabolism may have important implications for their toxicity (see section [Toxicity of Anesthetic Agents](#)). Hepatic metabolism may also contribute to the elimination of and recovery from some older volatile anesthetics. For example, halothane is eliminated more rapidly during recovery than enflurane, which would not be predicted from their respective tissue solubility. This increased elimination occurs because over 40% of inspired halothane is metabolized during an average anesthetic procedure, whereas less than 10% of enflurane is metabolized over the same period.

In terms of the extent of hepatic metabolism, the rank order for the inhaled anesthetics is halothane > enflurane > [sevoflurane](#) > [isoflurane](#) > [desflurane](#) > nitrous oxide (see [Table 25–1](#)). Nitrous oxide is not metabolized by human tissues. However, bacteria in the gastrointestinal tract may be able to break down the nitrous oxide molecule.

## PHARMACODYNAMICS

### Organ System Effects of Inhaled Anesthetics

#### A. CNS Effects

Anesthetic potency is currently described by the minimal alveolar concentration (MAC) required to prevent a response to a surgical incision (see Box: [What Does Anesthesia Represent & How Does It Work?](#)). This parameter was first described by investigators in the 1960s and remains the best clinical guide for administering inhaled anesthetics, especially since improved medical technology can now provide instantaneous, accurate determination of gas concentrations.

### What Does Anesthesia Represent & How Does It Work?

Anesthetic action has three principal components: immobility, amnesia, and unconsciousness. The exact cellular, molecular, or physiologic mechanisms for producing these effects are largely unknown.

#### Immobility

Immobility is the easiest anesthetic end point to measure. Edmond Eger and colleagues introduced the concept of **minimal alveolar concentration (MAC)** to quantify the **potency** of an inhalational anesthetic. They defined 1.0 MAC as the alveolar partial pressure of an inhalational anesthetic at which 50% of a population of unparalyzed patients remained immobile at the time of abdominal surgery skin incision. Anesthetic immobility is mediated primarily by neural inhibition within the spinal cord but may also include inhibited nociceptive transmission to the brain. This concept is the most convenient measure by which anesthesiologists compare the potency of inhaled agents and guide the conduct of patient anesthesia.

#### Amnesia

The ablation of memory occurs in several locations in the CNS, including the hippocampus, amygdala, prefrontal cortex, and regions of the sensory and motor cortices. Memory researchers differentiate two types of remembrance that should be abolished under anesthesia: (1) explicit memory, ie, specific awareness or consciousness under anesthesia; and (2) implicit memory, the unconscious acquisition of information under adequate levels of anesthesia. Their studies have found that formation of both types of memory is reliably prevented at low MAC values (0.2–0.4 MAC). Prevention of explicit memory (awareness) has spurred the development of monitors such as the bispectral index, patient state index, electroencephalogram (EEG), and entropy monitor of auditory evoked potentials to help recognize inadequate depth of anesthesia.

#### Unconsciousness

The ability of anesthetic drugs to abolish consciousness requires action at anatomic locations responsible for the formation of human consciousness. Neuroscientists studying consciousness identify three regions in the brain involved in generating personal awareness: the cerebral cortical hemispheres, the thalamus, and the reticular activating system. Neural pathways emanating from these regions seem to synchronize as an interacting system to produce the mental state in which humans are awake, aware, and perceiving.

Our current state of understanding supports the following framework: sensory stimuli conducted through the reticular formation of the brainstem into supratentorial signaling loops, connecting the thalamus with various regions of the cortex, are the foundation of consciousness. These neural pathways involved in the development of consciousness are reversibly disrupted by anesthetic agents.

Inhaled anesthetics (and intravenous anesthetics, discussed later) decrease the metabolic activity of the brain. Decreased cerebral metabolic rate (CMR) generally causes a reduction in blood flow within the brain. However, volatile anesthetics may also produce cerebral vasodilation, which can increase cerebral blood flow. The net effect on cerebral blood flow (increase, decrease, or no change) depends on the concentration of anesthetic delivered. At 0.5 MAC, the reduction in CMR is greater than the vasodilation caused by anesthetics, so cerebral blood flow is decreased. Conversely, at 1.5 MAC, vasodilation by the anesthetic is greater than the reduction in CMR, so cerebral blood flow is increased. In between, at 1.0 MAC, the effects are balanced and cerebral blood flow is unchanged. An increase in cerebral blood flow is clinically undesirable in patients who have increased intracranial pressure because of brain tumor, intracranial hemorrhage, or head injury. Therefore, administration of high concentrations of volatile anesthetics is best avoided in patients with increased intracranial pressure. Hyperventilation can be used to attenuate this response—decreasing the  $P_{aCO_2}$  (the partial pressure of carbon dioxide in arterial blood) through hyperventilation causes cerebral vasoconstriction. If the patient is hyperventilated before the volatile agent is started, the increase in intracranial pressure can be minimized.

Nitrous oxide can increase cerebral blood flow and cause increased intracranial pressure. This effect is most likely caused by activation of the sympathetic nervous system (as described below). Therefore, nitrous oxide may be combined with other agents (intravenous anesthetics) or

Potent inhaled anesthetics produce a basic pattern of change to brain electrical activity as recorded by standard electroencephalography (EEG). **Isoflurane, desflurane, sevoflurane**, halothane, and enflurane produce initial activation of the EEG at low doses and then slowing of electrical activity up to doses of 1.0–1.5 MAC. At higher concentrations, EEG suppression increases to the point of electrical silence with **isoflurane** at 2.0–2.5 MAC. Isolated epileptic-like patterns may also be seen between 1.0 and 2.0 MAC, especially with **sevoflurane** and enflurane, but frank clinical seizure activity has been observed only with enflurane. Nitrous oxide used alone causes fast electrical oscillations emanating from the frontal cortex at doses associated with analgesia and depressed consciousness.

Traditionally, anesthetic effects on the brain produce four stages or levels of increasing depth of CNS depression (**Guedel's signs**, derived from observations of the effects of inhaled diethyl ether): **Stage I—analgesia**: The patient initially experiences analgesia without amnesia. Later in stage I, both analgesia and amnesia are produced. **Stage II—excitement**: During this stage, the patient appears delirious and may vocalize but is completely amnesic. Respiration is rapid, and heart rate and blood pressure increase. Duration and severity of this light stage of anesthesia are shortened by rapidly increasing the concentration of the agent. **Stage III—surgical anesthesia**: This stage begins with slowing of respiration and heart rate and extends to complete cessation of spontaneous respiration (apnea). Four planes of stage III are described based on changes in ocular movements, eye reflexes, and pupil size, indicating increasing depth of anesthesia. **Stage IV—medullary depression**: This deep stage of anesthesia represents severe depression of the CNS, including the vasomotor center in the medulla and respiratory center in the brainstem. Without circulatory and respiratory support, death would rapidly ensue in stage IV.

## B. Cardiovascular Effects

Halothane, enflurane, **isoflurane, desflurane**, and **sevoflurane** all depress normal cardiac contractility (halothane and enflurane more so than **isoflurane, desflurane**, and **sevoflurane**). As a result, all volatile agents tend to decrease mean arterial pressure in direct proportion to their alveolar concentration. With halothane and enflurane, the reduced arterial pressure is caused primarily by myocardial depression (reduced cardiac output) and there is little change in systemic vascular resistance. In contrast, **isoflurane, desflurane**, and **sevoflurane** produce greater vasodilation with minimal effect on cardiac output. These differences may have important implications for patients with heart failure. Because **isoflurane, desflurane**, and **sevoflurane** better preserve cardiac output as well as reduce preload (ventricular filling) and afterload (systemic vascular resistance), these agents may be better choices for patients with impaired myocardial function.

Nitrous oxide also depresses myocardial function in a concentration-dependent manner. This depression may be significantly offset by a concomitant activation of the sympathetic nervous system resulting in preservation of cardiac output. Therefore, administration of nitrous oxide in combination with the more potent volatile anesthetics can minimize circulatory depressant effects by both anesthetic-sparing and sympathetic-activating actions.

Because all inhaled anesthetics produce a dose-dependent decrease in arterial blood pressure, activation of autonomic nervous system reflexes may trigger increased heart rate. However, halothane, enflurane, and **sevoflurane** have little effect on heart rate, probably because they attenuate baroreceptor input into the autonomic nervous system. **Desflurane** and **isoflurane** significantly increase heart rate because they cause less depression of the baroreceptor reflex. In addition, **desflurane** can trigger transient sympathetic activation—with elevated catecholamine levels—to cause marked increases in heart rate and blood pressure during administration of high **desflurane** concentrations or when **desflurane** concentrations are changed rapidly.

Inhaled anesthetics tend to reduce myocardial **oxygen** consumption, which reflects depression of normal cardiac contractility and decreased arterial blood pressure. In addition, inhaled anesthetics produce coronary vasodilation. The net effect of decreased **oxygen** demand and increased coronary flow (**oxygen** supply) is improved myocardial oxygenation. However, other factors, such as surgical stimulation, intravascular volume status, blood **oxygen** levels, and withdrawal of perioperative  $\beta$  blockers, may tilt the **oxygen** supply-demand balance toward myocardial ischemia in specific patients.

## C. Respiratory Effects

All volatile anesthetics possess varying degrees of bronchodilating properties, an effect of value in patients with active wheezing and in status asthmaticus. However, airway irritation, which may provoke coughing or breath-holding, is induced by the pungency of some volatile anesthetics. The pungency of **isoflurane** and **desflurane** makes these agents less suitable for induction of anesthesia in patients with active bronchospasm. These reactions rarely occur with halothane and **sevoflurane**, which are considered nonpungent. Therefore, the bronchodilating action of halothane and **sevoflurane** makes them the agents of choice in patients with underlying airway problems. Nonpungency and rapid increases in alveolar anesthetic

www.konkur.in  
www.konkur.in also make [sevoflurane](#) an excellent choice for smooth and rapid inhalation inductions in pediatric and adult patients. Nitrous oxide is also nonpungent and can facilitate inhalational induction of anesthesia in a patient with bronchospasm.

The control of breathing is significantly affected by inhaled anesthetics. With the exception of nitrous oxide, all inhaled anesthetics in current use cause a dose-dependent decrease in tidal volume and an increase in respiratory rate, resulting in a rapid, shallow breathing pattern. However, the increase in respiratory rate varies among agents and does not fully compensate for the decrease in tidal volume, resulting in decreased alveolar ventilation. In addition, all volatile anesthetics are respiratory depressants, as defined by a reduced ventilatory response to increased levels of carbon dioxide in the blood. The degree of ventilatory depression varies among the volatile agents, with [isoflurane](#) and enflurane being the most depressant. By this hypoventilation mechanism, all volatile anesthetics increase the resting level of  $Paco_2$  in spontaneously breathing patients.

Volatile anesthetics also raise the apneic threshold ( $Paco_2$  level below which apnea occurs through lack of  $CO_2$ -driven respiratory stimulation) and decrease the ventilatory response to hypoxia. Clinically, the respiratory depressant effects of anesthetics are overcome by assisting (controlling) ventilation mechanically. The ventilatory depression produced by inhaled anesthetics may be counteracted by surgical stimulation; however, low, subanesthetic concentrations of volatile anesthetic present after surgery in the early recovery period can continue to depress the compensatory increase in ventilation normally caused by hypoxia.

Inhaled anesthetics also depress mucociliary function in the airway. During prolonged exposure to inhaled anesthetics, mucus pooling may result in atelectasis and the development of postoperative respiratory complications, including hypoxemia, mucous plugging, and respiratory infections.

#### **D. Renal Effects**

Inhaled anesthetics tend to decrease glomerular filtration rate (GFR) and urine flow. Renal blood flow may also be decreased by some agents, but filtration fraction is increased, implying that autoregulatory control of efferent arteriole tone helps compensate and limits the reduction in GFR. In general these anesthetic effects are minor compared with the stress of surgery itself and usually reversible after discontinuation of the anesthetic.

#### **E. Hepatic Effects**

Volatile anesthetics cause a concentration-dependent decrease in portal vein blood flow that parallels the decline in cardiac output produced by these agents. However, total hepatic blood flow may be relatively preserved as hepatic artery blood flow to the liver may increase or stay the same. Although transient changes in liver function tests may occur following exposure to volatile anesthetics, persistent elevation in liver enzymes is rare except following repeated exposures to halothane (see section [Toxicity of Anesthetic Agents](#)).

#### **F. Effects on Uterine Smooth Muscle**

Nitrous oxide appears to have little effect on uterine musculature. However, the halogenated anesthetics are potent uterine muscle relaxants and produce this effect in a concentration-dependent fashion. This pharmacologic effect can be helpful when profound uterine relaxation is required for intrauterine fetal manipulation or manual extraction of a retained placenta during delivery. However, it can also lead to increased uterine bleeding after delivery when uterine contraction is desired.

### **Toxicity of Anesthetic Agents**

#### **A. Acute Toxicity**

Volatile anesthetics have a narrow therapeutic range and must be administered in a well-controlled, monitored setting by trained practitioners. When delivered in this way the risk of acute organ injury is low. The effects described below are rare or of historical interest only. However, concern over neurotoxicity of volatile anesthetics, especially in the developing brain is an active area of research.

##### **1. Nephrotoxicity**

Metabolism of enflurane and [sevoflurane](#) may generate compounds that are potentially nephrotoxic. Although their metabolism can liberate nephrotoxic [fluoride](#) ions, significant renal injury has been reported only for enflurane with prolonged exposure. The insolubility and rapid elimination of [isoflurane](#) may prevent toxicity. This drug may be degraded by carbon dioxide absorbents in anesthesia machines to form a

nephrotoxic vinyl ether compound termed “compound A,” which, in high concentrations, has caused proximal tubular necrosis in rats. Nevertheless, there have been no reports of renal injury in humans receiving **sevoflurane** anesthesia. Moreover, exposure to **sevoflurane** does not produce any change in standard markers of renal function.

## 2. Hematotoxicity

Prolonged exposure to nitrous oxide decreases methionine synthase activity, which theoretically could cause megaloblastic anemia. Megaloblastic bone marrow changes have been observed in patients after 12-hour exposure to 50% nitrous oxide. Chronic exposure of dental personnel to nitrous oxide in inadequately ventilated dental operating suites is a potential occupational hazard.

All inhaled anesthetics can produce some carbon monoxide (CO) from their interaction with strong bases in dry carbon dioxide absorbers. CO binds to hemoglobin with high affinity, reducing **oxygen** delivery to tissues. **Desflurane** produces the most CO, and intraoperative formation of CO has been reported. CO production can be avoided simply by using fresh carbon dioxide absorbent and by preventing its complete desiccation.

## 3. Malignant hyperthermia

Malignant hyperthermia is a heritable genetic disorder of skeletal muscle that occurs in susceptible individuals exposed to volatile anesthetics while undergoing general anesthesia (see **Chapter 16** and **Table 16–4**). The depolarizing muscle relaxant **succinylcholine** may also trigger malignant hyperthermia. The malignant hyperthermia syndrome consists of muscle rigidity, hyperthermia, rapid onset of tachycardia and hypercapnia, hyperkalemia, and metabolic acidosis following exposure to one or more triggering agents. Malignant hyperthermia is a rare but important cause of anesthetic morbidity and mortality. A specific biochemical abnormality—an increase in free cytosolic calcium concentration in skeletal muscle cells—may be the underlying cellular basis of malignant hyperthermia. Treatment includes administration of **dantrolene** (to reduce calcium release from the sarcoplasmic reticulum) and appropriate measures to reduce body temperature and restore electrolyte and acid-base balance (see **Chapters 16** and **27**). A new formulation of **dantrolene** with improved solubility has become available that can speed the treatment of this rare but potentially fatal reaction.

Malignant hyperthermia susceptibility is characterized by genetic heterogeneity, and several predisposing clinical myopathies have been identified. It has been associated with mutations in the gene coding for the skeletal muscle ryanodine receptor (RyR1, the calcium release channel on the sarcoplasmic reticulum), and mutant alleles of the gene encoding the  $\alpha_1$  subunit of the human skeletal muscle L-type voltage-dependent calcium channel. However, the genetic loci identified to date account for less than 50% of malignant hyperthermia-susceptible individuals, and genetic testing cannot definitively determine malignant hyperthermia susceptibility. Currently, the most reliable test to establish susceptibility is the in vitro caffeine-halothane contracture test using skeletal muscle biopsy samples. Genetic counseling is recommended for family members of a person who has experienced a documented malignant hyperthermia reaction in the operating room.

## 4. Hepatotoxicity (*halothane hepatitis*)

Hepatic dysfunction following surgery and general anesthesia is most likely caused by hypovolemic shock, infection conferred by blood transfusion, or other surgical stresses rather than by volatile anesthetic toxicity. However, a small subset of individuals previously exposed to halothane developed fulminant hepatic failure. The incidence of severe hepatotoxicity following exposure to halothane was estimated to be in the range of 1 in 20,000–35,000. The mechanisms underlying halothane hepatotoxicity remain unclear, but studies in animals implicate the formation of reactive metabolites that either cause direct hepatocellular damage (eg, free radicals) or initiate immune-mediated responses. Cases of hepatitis following exposure to other volatile anesthetics, including enflurane, **isoflurane**, and **desflurane**, have rarely been reported.

## 5. Neurotoxicity

Neuronal toxicity of volatile anesthesia in young infants whose brains are still undergoing neurogenesis is an emerging concern, first identified in animal studies. In vitro studies have also found increased levels of apoptosis in cultured neurons exposed to clinical levels of volatile anesthetics. Human data is difficult to obtain but a recently reported epidemiologic study that followed a cohort of children receiving either general anesthesia or nerve block anesthesia for hernia repair in the first 3 months of life found no difference in IQ testing at 5 years of age. The neurotoxicity of longer or multiple exposures to volatile anesthetics is unknown.

### 1. Mutagenicity, teratogenicity, and reproductive effects

Under normal conditions, inhaled anesthetics including nitrous oxide are neither mutagens nor carcinogens in patients. Nitrous oxide can be directly teratogenic in animals under conditions of extremely high exposure. Halothane, enflurane, [isoflurane](#), [desflurane](#), and [sevoflurane](#) may be teratogenic in rodents as a result of physiologic changes associated with the anesthesia rather than through a direct teratogenic effect.

The most consistent finding in surveys conducted to determine the reproductive success of female operating room personnel who may have low-level chronic exposure to anesthetic agents has been a questionably higher-than-expected incidence of miscarriages. However, there are several problems in interpreting these studies. The association of obstetric problems with surgery and anesthesia in pregnant patients is also an important consideration. In the United States, at least 50,000 pregnant women each year undergo anesthesia and surgery for indications unrelated to pregnancy. The risk of abortion is clearly higher following this experience. It is not obvious, however, whether the underlying disease, surgery, anesthesia, or a combination of these factors is the cause of the increased risk.

### 2. Carcinogenicity

Epidemiologic studies suggested an increase in the cancer rate in operating room personnel who were exposed to trace concentrations of anesthetic agents. However, no study has demonstrated the existence of a causal relationship between anesthetics and cancer. Many other factors might account for the questionably positive results seen after a careful review of epidemiologic data. Anesthesia machines are now equipped with gas scavenging systems to remove concentrations of anesthetics administered to patients, and operating rooms rely on high air exchange rates to remove trace concentrations of anesthetics released from anesthesia machines.

## ENVIRONMENTAL IMPACT OF INHALED ANESTHETICS

The primary inhalational anesthetics in clinical use, [sevoflurane](#), [isoflurane](#), [desflurane](#), and nitrous oxide, are known to act as greenhouse gases but their contribution to global temperature rise and climate change are considered small compared with other industrial processes. In current practice these gases are administered to patients, exhaled with little metabolism, and then collected by anesthesia machine scavenging systems for venting out of the building directly into the atmosphere. By their intrinsic chemical nature these compounds are hundreds to thousands of times more potent than carbon dioxide (CO<sub>2</sub>) in their global warming potential. Moreover, each of these gases possess widely varying atmospheric lifetimes. For example, the tropospheric lifetime of [sevoflurane](#), [isoflurane](#), [desflurane](#), and nitrous oxide are 1.4, 3.6, 10, and 114 years, respectively. The medical use of nitrous oxide for anesthesia has been estimated to represent 1–3% of the annual U.S. nitrous oxide emission. Because of this increased awareness, clinical guidelines for decreasing the amount of inhaled anesthetics used have been proposed. The current trend is to use the agents in ultra-low total gas flow techniques (0.5–1.0 liter per minute), to avoid adding nitrous oxide as a carrier admixture gas with room air, and to restrict the use of [desflurane](#).

## INTRAVENOUS ANESTHETICS

Intravenous nonopioid anesthetics play an essential role in the practice of modern anesthesia. They are used to facilitate rapid induction of anesthesia and have replaced inhalation as the preferred method of anesthesia induction in most settings except for pediatric anesthesia. Intravenous agents are also commonly used to provide sedation during monitored anesthesia care and for patients in ICU settings. With the introduction of [propofol](#), intravenous anesthesia also became a good option for the maintenance of anesthesia. However, similar to the inhaled agents, the currently available intravenous anesthetics are not ideal anesthetic drugs in the sense of producing all and only the five desired effects (unconsciousness, amnesia, analgesia, inhibition of autonomic reflexes, and skeletal muscle relaxation). Therefore, **balanced anesthesia** employing multiple drugs (inhaled anesthetics, sedative-hypnotics, opioids, neuromuscular blocking drugs) is generally used to achieve the desired combination of effects while minimizing unwanted effects.

The intravenous anesthetics used for induction of general anesthesia are lipophilic and preferentially partition into highly perfused lipophilic tissues (brain, spinal cord), which accounts for their rapid onset of action. Regardless of the extent and speed of their metabolism, termination of the effect of a single bolus is determined by redistribution of the drug into less perfused and inactive tissues such as skeletal muscle and fat. Thus, all drugs used for induction of anesthesia have similar durations of action when administered as a single bolus dose despite significant differences in their

Thiopental	3-5	5-10	2.5	2-4	83	3.4	11

Note: The duration of action reflects the duration after a typical single IV dose given for induction of anesthesia. Data are for average adult patients.

CL, clearance; NA, not applicable; V<sub>dss</sub>, volume of distribution at steady state.

## PROPOFOL

In most countries, **propofol** is the drug most frequently administered for the induction of anesthesia, and it has largely replaced barbiturates in this setting. Because its pharmacokinetic profile allows for continuous infusions, **propofol** is a good alternative to inhaled anesthetics for maintenance of anesthesia and is also a common choice for sedation in the setting of monitored anesthesia care. When used during maintenance of anesthesia, **propofol** infusion can be supplemented with intravenous opioids and neuromuscular blockers as needed to completely avoid the use of inhaled anesthetics (total intravenous anesthesia, TIVA). Alternatively, a **propofol** infusion might be used to reduce the required concentration of inhaled anesthetics so that undesired effects can be minimized. Increasingly, **propofol** is also used for sedation in the ICU as well as conscious sedation and short-duration general anesthesia in locations outside the operating room (eg, interventional radiology suites, emergency department; see Box: [Sedation & Monitored Anesthesia Care](#), earlier).

**Propofol** (2,6-diisopropylphenol) is an alkyl **phenol** with hypnotic properties that is chemically distinct from other groups of intravenous anesthetics (see [Figure 25-6](#)). Because of its poor solubility in water, it is formulated as an emulsion containing 10% soybean oil, 2.25% glycerol, and 1.2% lecithin, the major component of the egg yolk phosphatide fraction. Hence, susceptible patients may experience allergic reactions. The solution appears milky white and slightly viscous, has a pH of approximately 7, and has a **propofol** concentration of 1% (10 mg/mL). In some countries, a 2% formulation is available. Although retardants of bacterial growth are added to the formulations, solutions should be used as soon as possible (unused drug must be discarded 12 hours after opening the vial), and proper sterile technique is essential. The addition of metabisulfite in one of the formulations has raised concern regarding its use in patients with reactive airway disease (eg, asthma) or sulfite allergies.

The presumed mechanism of action of **propofol** is through potentiation of the chloride current mediated through the GABA<sub>A</sub> receptor complex.

**Propofol** is rapidly metabolized in the liver; the resulting water-soluble compounds are presumed to be inactive and are excreted through the kidneys. Plasma clearance is high and exceeds hepatic blood flow, indicating the importance of extrahepatic metabolism, which presumably occurs in the lungs and may account for the elimination of up to 30% of a bolus dose of the drug (see [Table 25-2](#)). The recovery from **propofol** is more complete, with less “hangover” than that observed with thiopental, likely due to the high plasma clearance. However, as with other intravenous drugs, transfer of **propofol** from the plasma (central) compartment and the associated termination of drug effect after a single bolus dose are mainly the result of redistribution from highly perfused (brain) to less-well-perfused (skeletal muscle) compartments ([Figure 25-7](#)). As with other intravenous agents, awakening after an induction dose of **propofol** usually occurs within 8–10 minutes. The kinetics of **propofol** (and other intravenous anesthetics) after a single bolus dose or continuous infusion are best described by means of a three-compartment model. Such models have been used as the basis for developing systems of target-controlled infusions.

**FIGURE 25-7**

Redistribution of thiopental after an intravenous bolus administration. The redistribution curves for bolus administration of other intravenous anesthetics are similar, explaining the observation that recovery times are the same despite remarkable differences in metabolism. Note that the time axis is not linear.

Copyright © McGraw Hill. All rights reserved.

The **context-sensitive half-time** of a drug describes the elimination half-time after discontinuation of a continuous infusion as a function of the duration of the infusion. It is an important parameter in assessing the suitability of a drug for use as maintenance anesthetic. The context-sensitive half-time of **propofol** is brief, even after a prolonged infusion, and therefore, recovery occurs relatively promptly ([Figure 25-8](#)).

**FIGURE 25-8**

The context-sensitive half-time of common intravenous anesthetics. Even after a prolonged infusion, the half-time of **propofol** is relatively short, which makes **propofol** the preferred choice for intravenous maintenance of anesthesia. **Ketamine** and **etomidate** have similar characteristics, but their use is limited by other effects.

## Organ System Effects

### A. CNS Effects

**Propofol** acts as hypnotic but does not have analgesic properties. Although the drug leads to a general suppression of CNS activity, excitatory effects such as twitching or spontaneous movement are occasionally observed during induction of anesthesia. These effects may resemble seizure activity; however, most studies support an anticonvulsant effect of **propofol**, and the drug may be safely administered to patients with seizure disorders.

**Propofol** decreases cerebral blood flow and the cerebral metabolic rate for **oxygen** ( $CMRO_2$ ), which decreases intracranial pressure (ICP) and intraocular pressure; the magnitude of these changes is comparable to that of thiopental. Although **propofol** can produce a desired decrease in ICP, the combination of reduced cerebral blood flow and reduced mean arterial pressure due to peripheral vasodilation can critically decrease cerebral perfusion pressure.

When administered in large doses, **propofol** produces burst suppression in the EEG, an end point that has been used when administering intravenous anesthetics for neuroprotection during neurosurgical procedures. Evidence from animal studies suggests that **propofol**'s neuroprotective effects during focal ischemia are similar to those of thiopental and **isoflurane**.

### B. Cardiovascular Effects

Compared with other induction drugs, **propofol** produces the most pronounced decrease in systemic blood pressure; this is a result of profound vasodilation in both arterial and venous circulations leading to reductions in preload and afterload. This effect on systemic blood pressure is more pronounced with increased age, in patients with reduced intravascular fluid volume, and with rapid injection. Because the hypotensive effects are further augmented by the inhibition of the normal baroreflex response, the vasodilation only leads to a small increase in heart rate. In fact, profound bradycardia and asystole after the administration of **propofol** have been described in healthy adults despite prophylactic anticholinergic drugs.

### C. Respiratory Effects

**Propofol** is a potent respiratory depressant and generally produces apnea after an induction dose. A maintenance infusion reduces minute ventilation through reductions in tidal volume and respiratory rate, with the effect on tidal volume being more pronounced. In addition, the ventilatory response to hypoxia and hypercapnia is reduced. **Propofol** causes a greater reduction in upper airway reflexes than thiopental does, which makes it well suited for instrumentation of the airway, such as placement of a laryngeal mask airway.

### D. Other Effects

Although **propofol**, unlike volatile anesthetics, does not augment neuromuscular block, studies have found good intubating conditions after **propofol** induction without the use of neuromuscular blocking agents. Unexpected tachycardia occurring during **propofol** anesthesia should prompt laboratory

www.konkon.in for possible metabolic acidosis (propofol infusion syndrome). An interesting and desirable side effect of propofol is its antiemetic activity. Pain on injection is a common complaint and can be reduced by premedication with an opioid or coadministration with lidocaine. Dilution of propofol and the use of larger veins for injection can also reduce the incidence and severity of injection pain.

## Clinical Uses & Dosage

The most common use of propofol is to facilitate induction of general anesthesia by bolus injection of 1–2.5 mg/kg IV. Increasing age, reduced cardiovascular reserve, or premedication with benzodiazepines or opioids reduces the required induction dose; children require higher doses (2.5–3.5 mg/kg IV). Generally, titration of the induction dose helps to prevent severe hemodynamic changes. Propofol is often used for maintenance of anesthesia either as part of a balanced anesthesia regimen in combination with volatile anesthetics, nitrous oxide, sedative-hypnotics, and opioids or as part of a total intravenous anesthetic technique, usually in combination with opioids. Therapeutic plasma concentrations for maintenance of anesthesia normally range between 3 and 8 mcg/mL (typically requiring a continuous infusion rate between 100 and 200 mcg/kg/min) when combined with nitrous oxide or opioids. In many countries (other than the United States), propofol is frequently administered utilizing target-controlled infusion (TCI). TCI uses pharmacokinetic models based on patient characteristics (height, weight, gender, and age) to control an infusion pump based on target plasma concentrations entered by the anesthesiologist. The models incorporate context-sensitive half-time and automatically set the infusion rate to reach or maintain the target concentration entered, thereby replacing the manual administration of the boluses and infusion estimated by the anesthesiologist. Data suggest that induction using TCI provides better hemodynamic stability. TCI is often combined with the use of the bispectral index (BIS) or other monitors of processed EEG signals. Pharmacologic models also exist for other drugs such as opioid analgesics and allow TCI application for multiple drugs.

When used for sedation of mechanically ventilated patients in the ICU or for sedation during procedures, the required plasma concentration is 1–2 mcg/mL, which can be achieved with a continuous infusion at 25–75 mcg/kg/min. Because of its pronounced respiratory depressant effect and narrow therapeutic range, propofol should be administered only by individuals trained in airway management.

Subanesthetic doses of propofol can be used to treat postoperative nausea and vomiting (10–20 mg IV as bolus or 10 mcg/kg/min as an infusion).

## FOSPROPOFOL

As previously noted, injection pain during administration of propofol is often perceived as severe, and the lipid emulsion has several disadvantages. Intense research has focused on finding alternative formulations or related drugs that would address some of these problems. Fospropofol is a water-soluble prodrug of propofol, is rapidly metabolized by alkaline phosphatase, and produces propofol, phosphate, and formaldehyde. The formaldehyde is metabolized by aldehyde dehydrogenase in the liver and in erythrocytes. The available fospropofol formulation is a sterile, aqueous, colorless, and clear solution that is supplied in a single-dose vial at a concentration of 35 mg/mL under the trade name Lusedra.

## Pharmacokinetics & Organ System Effects

Because the active compound is propofol and fospropofol is a prodrug that requires metabolism to form propofol, the pharmacokinetics are more complex than for propofol itself. Multicompartment models with two compartments for fospropofol and three for propofol have been used to describe the kinetics.

The effect profile of fospropofol is similar to that of propofol, but onset and recovery are prolonged compared with propofol because the prodrug must first be converted into an active form. Although patients receiving fospropofol do not appear to experience the injection pain typical of propofol, a common adverse effect is the experience of paresthesia, often in the perianal region, which occurs in up to 74% of patients. The mechanism for this effect is unknown.

## Clinical Uses & Dosage

Fospropofol is approved for sedation during monitored anesthesia care. Supplemental oxygen must be administered to all patients receiving the drug. As with propofol, airway compromise is a major concern. Hence, it is recommended that fospropofol be administered only by personnel trained in airway management. The recommended standard dosage is an initial bolus dose of 6.5 mg/kg IV followed by supplemental doses of 1.6 mg/kg IV as needed. For patients weighing more than 90 kg or less than 60 kg, 90 or 60 kg should be used to calculate the dose, respectively. The dose should be reduced by 25% in patients older than 65 years and in those with an American Society of Anesthesiologists status of 3 or 4.

This section focuses on the use of **thiopental** and **methohexital** for induction of general anesthesia; however, these barbiturate hypnotics have been largely replaced as induction agents by **propofol**. Other barbiturates and general barbiturate pharmacology are discussed in [Chapter 22](#).

The anesthetic effect of barbiturates presumably involves a combination of enhancement of inhibitory transmission and inhibition of excitatory neurotransmission (see [Figure 25-1](#)). Although the effects on inhibitory transmission probably result from activation of the GABA<sub>A</sub> receptor complex, the effects on excitatory transmission are less well understood.

### Pharmacokinetics

Thiopental and **methohexital** undergo hepatic metabolism, mostly by oxidation but also by *N*-dealkylation, desulfuration, and destruction of the barbituric acid ring structure. Barbiturates should not be administered to patients with acute intermittent porphyria because they increase the production of porphyrins through stimulation of aminolevulinic acid synthetase. **Methohexital** has a shorter elimination half-time than thiopental due to its larger plasma clearance (see [Table 25-2](#)), leading to a faster and more complete recovery after bolus injection. Although thiopental is metabolized more slowly and has a long elimination half-time, recovery after a single bolus injection is comparable to that of **methohexital** and **propofol** because it depends on redistribution to inactive tissue sites rather than on metabolism ([Figure 25-7](#)). However, if administered through repeated bolus injections or continuous infusion, recovery will be markedly prolonged because elimination will depend on metabolism under these circumstances (see also context-sensitive half-time, [Figure 25-8](#)).

### Organ System Effects

#### A. CNS Effects

Barbiturates produce dose-dependent CNS depression ranging from sedation to general anesthesia when administered as bolus injections. They do not produce analgesia; instead, some evidence suggests they may reduce the pain threshold, causing hyperalgesia. Barbiturates are potent cerebral vasoconstrictors and produce predictable decreases in cerebral blood flow, cerebral blood volume, and ICP. As a result, they decrease CMRO<sub>2</sub> consumption in a dose-dependent manner up to a dose at which they suppress all EEG activity. The ability of barbiturates to decrease ICP and CMRO<sub>2</sub> makes these drugs useful in the management of patients with space-occupying intracranial lesions. They may provide neuroprotection from focal cerebral ischemia (stroke, surgical retraction, temporary clips during aneurysm surgery), but likely will not reduce the injury after global cerebral ischemia (eg, from cardiac arrest). Except for **methohexital**, barbiturates decrease electrical activity on the EEG and can be used as anticonvulsants. In contrast, **methohexital** activates epileptic foci and may therefore be useful to facilitate electroconvulsive therapy or during the identification of epileptic foci during surgery.

#### B. Cardiovascular Effects

The decrease in systemic blood pressure associated with administration of barbiturates for induction of anesthesia is primarily due to peripheral vasodilation and is usually smaller than the blood pressure decrease associated with **propofol**. There are also direct negative inotropic effects on the heart. However, inhibition of the baroreceptor reflex is less pronounced than with **propofol**; thus, compensatory increases in heart rate limit the decrease in blood pressure and make it transient. The depressant effects on systemic blood pressure are increased in patients with hypovolemia, cardiac tamponade, cardiomyopathy, coronary artery disease, or cardiac valvular disease because such patients are less able to compensate for the effects of peripheral vasodilation. Hemodynamic effects are also more pronounced with larger doses and rapid injection.

#### C. Respiratory Effects

Barbiturates are respiratory depressants, and a usual induction dose of thiopental or **methohexital** typically produces transient apnea, which will be more pronounced if other respiratory depressants are also administered. Barbiturates lead to decreased minute ventilation through reduced tidal volumes and respiratory rate and also decrease the ventilatory responses to hypercapnia and hypoxia. Resumption of spontaneous breathing after an anesthetic induction dose of a barbiturate is characterized by a slow breathing rate and decreased tidal volume. Suppression of laryngeal reflexes and

instrumentation in the absence of neuromuscular blocking drugs. Furthermore, stimulation of the upper airway or trachea (eg, by secretions, laryngeal mask airway, direct laryngoscopy, tracheal intubation) during inadequate depression of airway reflexes may result in laryngospasm or bronchospasm. This phenomenon is not unique to barbiturates but is true whenever the dose of the anesthetic drug is inadequate to suppress the airway reflexes.

#### D. Other Effects

Accidental intra-arterial injection of barbiturates results in excruciating pain and intense vasoconstriction, often leading to severe tissue injury involving gangrene. Approaches to treatment include blockade of the sympathetic nervous system (eg, stellate ganglion block) in the involved extremity. If extravasation occurs, some authorities recommend local injection of the area with 0.5% **lidocaine** (5–10 mL) in an attempt to dilute the barbiturate concentration. Life-threatening allergic reactions to barbiturates are rare, with an estimated occurrence of 1 in 30,000 patients. However, barbiturate-induced histamine release occasionally is seen.

#### Clinical Uses & Dosage

The principal clinical use of thiopental (3–5 mg/kg IV) or **methohexital** (1–1.5 mg/kg IV) is for induction of anesthesia (unconsciousness), which usually occurs in less than 30 seconds. Patients may experience a garlic or onion taste after administration. Solutions of thiopental sodium for intravenous injection have a pH range of 10–11 to maintain stability. Rapid co-injection with depolarizing and nondepolarizing muscle relaxants, which have much lower pH, may cause precipitation of insoluble thiopentone acid. Barbiturates such as **methohexital** (20–30 mg/kg) may be administered per rectum to facilitate induction of anesthesia in mentally challenged patients and uncooperative pediatric patients. When a barbiturate is administered with the goal of neuroprotection, an isoelectric EEG indicating maximal reduction of  $CMRO_2$  has traditionally been used as the end point. More recent data demonstrating equal protection after smaller doses have challenged this practice. The use of smaller doses is less frequently associated with hypotension, thus making it easier to maintain adequate cerebral perfusion pressure, especially in the setting of increased ICP.

### BENZODIAZEPINES

Benzodiazepines commonly used in the perioperative period include **midazolam**, **lorazepam**, and less frequently, **diazepam**. Benzodiazepines are unique among the group of intravenous anesthetics in that their action can readily be terminated by administration of their selective antagonist, **flumazenil**. Their most desired effects are anxiolysis and anterograde amnesia, which are extremely useful for premedication.

The chemical structure and pharmacodynamics of the benzodiazepines are discussed in detail in [Chapter 22](#).

#### Pharmacokinetics in the Anesthesia Setting

The highly lipid-soluble benzodiazepines rapidly enter the CNS, which accounts for their rapid onset of action, followed by redistribution to inactive tissue sites and subsequent termination of the drug effect. Additional information regarding the pharmacokinetics of the benzodiazepines may be found in [Chapter 22](#).

Despite its prompt passage into the brain, **midazolam** is considered to have a slower effect-site equilibration time than **propofol** and thiopental. In this regard, intravenous doses of **midazolam** should be sufficiently spaced to permit the peak clinical effect to be recognized before a repeat dose is considered. **Midazolam** has the shortest context-sensitive half-time, which makes it the only one of the three benzodiazepine drugs suitable for continuous infusion (see [Figure 25-8](#)).

#### Organ System Effects

##### A. CNS Effects

Benzodiazepines decrease  $CMRO_2$  and cerebral blood flow but to a smaller extent than **propofol** or the barbiturates. There appears to be a ceiling effect for benzodiazepine-induced decreases in  $CMRO_2$  as evidenced by **midazolam**'s inability to produce an isoelectric EEG. Patients with decreased intracranial compliance demonstrate little or no change in ICP after the administration of **midazolam**. Although neuroprotective properties have not been shown for benzodiazepines, these drugs are potent anticonvulsants used in the treatment of status epilepticus, **alcohol** withdrawal, and local

anesthetic-induced seizures. The CNS effects of benzodiazepines can be promptly terminated by administration of the selective benzodiazepine antagonist **flumazenil**, which improves their safety profile.

### B. Cardiovascular Effects

If used for the induction of anesthesia, **midazolam** produces a greater decrease in systemic blood pressure than comparable doses of **diazepam**. These changes are most likely due to peripheral vasodilation inasmuch as cardiac output is not changed. Similar to other intravenous induction agents, **midazolam**'s effect on systemic blood pressure is exaggerated in hypovolemic patients.

### C. Respiratory Effects

Benzodiazepines alone produce minimal depression of ventilation, although transient apnea may follow rapid intravenous administration of **midazolam** for induction of anesthesia, especially in the presence of opioid premedication. Benzodiazepines decrease the ventilatory response to carbon dioxide, but this effect is not usually significant if they are administered alone. More severe respiratory depression can occur when benzodiazepines are administered together with opioids. Another problem affecting ventilation is airway obstruction induced by the hypnotic effects of benzodiazepines, especially in patients at risk for obstructive sleep apnea.

### D. Other Effects

Pain during intravenous and intramuscular injection and subsequent thrombophlebitis are most pronounced with **diazepam** and reflect the poor water solubility of this benzodiazepine, which requires an organic solvent in the formulation. Despite its better solubility, eliminating the need for an organic solvent, **midazolam** may also produce pain on injection. Allergic reactions to benzodiazepines are rare to nonexistent.

## Clinical Uses & Dosage

Benzodiazepines are most commonly used for preoperative medication, intravenous sedation, and suppression of seizure activity. Less frequently, **midazolam** and **diazepam** may also be used to induce general anesthesia. The slow onset and prolonged duration of action of **lorazepam** limit its usefulness as preoperative medication or for induction of anesthesia, especially when rapid and sustained awakening at the end of surgery is desirable. Although **flumazenil** (8–15 mcg/kg IV) may be useful for treating patients experiencing delayed awakening, its duration of action is brief (about 20 minutes) and resedation may occur.

The amnestic, anxiolytic, and sedative effects of benzodiazepines make this class of drugs the most popular choice for preoperative medication. **Midazolam** (1–2 mg IV) is effective for premedication, sedation during regional anesthesia, and brief therapeutic procedures. **Midazolam** has a more rapid onset, with greater amnesia and less postoperative sedation, than **diazepam**. **Midazolam** is also the most commonly used oral premedication for children; 0.5 mg/kg administered orally 30 minutes before induction of anesthesia provides reliable sedation and anxiolysis in children without producing delayed awakening.

The synergistic effects between benzodiazepines and other drugs, especially opioids and **propofol**, can be used to achieve better sedation and analgesia but may also greatly enhance their combined respiratory depression and may lead to airway obstruction or apnea. Because benzodiazepine effects are more pronounced with increasing age, dose reduction and careful titration may be necessary in elderly patients.

General anesthesia can be induced by the administration of **midazolam** (0.1–0.3 mg/kg IV), but the onset of unconsciousness is slower than after the administration of thiopental, **propofol**, or **etomidate**. Delayed awakening is a potential disadvantage, limiting the usefulness of benzodiazepines for induction of general anesthesia despite their advantage of less pronounced circulatory effects.

## ETOMIDATE

**Etomidate** (see Figure 25–6) is an intravenous anesthetic with hypnotic but not analgesic effects and is often chosen for its minimal hemodynamic effects. Although its pharmacokinetics are favorable, endocrine side effects limit its use for continuous infusions. **Etomidate** is a carboxylated imidazole derivative that is poorly soluble in water and is therefore supplied as a 2 mg/mL solution in 35% propylene glycol. The solution has a pH of 6.9 and does not cause problems with precipitation as thiopental does. **Etomidate** appears to have GABA-like effects and seems to act primarily through potentiation of GABA<sub>A</sub>-mediated chloride current, like most other intravenous anesthetics.

An induction dose of **etomidate** produces rapid onset of anesthesia, and recovery depends on redistribution to inactive tissue sites, comparable to thiopental and **propofol**. Metabolism is primarily by ester hydrolysis to inactive metabolites, which are then excreted in urine (78%) and bile (22%). Less than 3% of an administered dose of **etomidate** is excreted as unchanged drug in urine. Clearance of **etomidate** is about five times that of thiopental, as reflected by a shorter elimination half-time (see **Table 25–2**). The duration of action is linearly related to the dose, with each 0.1 mg/kg providing about 100 seconds of unconsciousness. Because of **etomidate**'s minimal effects on hemodynamics and short context-sensitive half-time, larger doses, repeated boluses, or continuous infusions can safely be administered. **Etomidate**, like most other intravenous anesthetics, is highly protein bound (77%), primarily to **albumin**.

## Organ System Effects

### A. CNS Effects

**Etomidate** is a potent cerebral vasoconstrictor, as reflected by decreases in cerebral blood flow and ICP. These effects are similar to those produced by comparable doses of thiopental. Despite its reduction of  $CMRO_2$ , **etomidate** has failed to show neuroprotective properties in animal studies, and human studies are lacking. The frequency of excitatory spikes on the EEG after the administration of **etomidate** is greater than with thiopental. Similar to **methohexital**, **etomidate** may activate seizure foci, manifested as fast activity on the EEG, making it a useful drug in the setting of electroconvulsive therapy. In addition, spontaneous movements characterized as myoclonus occur in more than 50% of patients receiving **etomidate**, and this myoclonic activity may be associated with seizure-like activity on the EEG.

### B. Cardiovascular Effects

A characteristic and desired feature of induction of anesthesia with **etomidate** is cardiovascular stability after bolus injection. In this regard, decrease in systemic blood pressure is modest or absent and principally reflects a decrease in systemic vascular resistance. Therefore, the systemic blood pressure-lowering effects of **etomidate** are probably exaggerated in the presence of hypovolemia, and the patient's intravascular fluid volume status should be optimized before induction of anesthesia. **Etomidate** produces minimal changes in heart rate and cardiac output. Its depressant effects on myocardial contractility are minimal at concentrations used for induction of anesthesia.

### C. Respiratory Effects

The depressant effects of **etomidate** on ventilation are less pronounced than those of barbiturates, although apnea may occasionally follow rapid intravenous injection of the drug. Depression of ventilation may be exaggerated when **etomidate** is combined with inhaled anesthetics or opioids.

### D. Endocrine Effects

**Etomidate** causes adrenocortical suppression by producing a dose-dependent inhibition of  $11\beta$ -hydroxylase, an enzyme necessary for the conversion of cholesterol to cortisol (see **Figure 39–1**). This suppression lasts 4–8 hours after an induction dose of the drug. Despite concerns regarding this finding, no outcome studies have demonstrated an adverse effect when **etomidate** is given in a bolus dose. However, because of its endocrine effects, **etomidate** is not used as continuous infusion.

## Clinical Uses & Dosage

**Etomidate** is an alternative to **propofol** and barbiturates for the rapid intravenous induction of anesthesia, especially in patients with compromised myocardial contractility. After a standard induction dose (0.2–0.3 mg/kg IV), the onset of unconsciousness is comparable to that achieved by thiopental and **propofol**. Similar to **propofol**, during intravenous injection of **etomidate**, there is a high incidence of pain, which may be followed by venous irritation. Involuntary myoclonic movements are also common but may be masked by the concomitant administration of neuromuscular blocking drugs. Awakening after a single intravenous dose of **etomidate** is rapid, with little evidence of any residual depressant effects. **Etomidate** does not produce analgesia, and postoperative nausea and vomiting may be more common than after the administration of thiopental or **propofol**.

[www.wikidoc.com](https://www.wikidoc.com) (see [Figure 25-6](#)) is a partially water-soluble and highly lipid-soluble phencyclidine derivative differing from most other intravenous anesthetics in that it produces significant analgesia. The characteristic state observed after an induction dose of [ketamine](#) is known as “dissociative anesthesia,” a cataleptic state wherein the patient’s eyes often remain open with a slow nystagmic gaze. Of the two stereoisomers, the *S*(+) form is more potent than the *R*(-) isomer, but only the racemic mixture of [ketamine](#) is available as an injection drug in the USA. A formulation of *S*(+) [ketamine](#) ([Esketamine](#)) for intranasal administration was recently approved by the FDA for the treatment of acute depression (see [Chapter 30](#)).

[Ketamine](#)’s mechanism of action is complex, but the major effect is probably produced through inhibition of the NMDA receptor complex.

## Pharmacokinetics

The high lipid solubility of [ketamine](#) ensures a rapid onset of its effect. As with other intravenous induction drugs, the effect of a single bolus injection is terminated by redistribution to inactive tissue sites. Metabolism occurs primarily in the liver and involves *N*-demethylation by the cytochrome P450 system. Norketamine, the primary active metabolite, is less potent (one third to one fifth the potency of [ketamine](#)) and is subsequently hydroxylated and conjugated into water-soluble inactive metabolites that are excreted in urine. [Ketamine](#) is the only intravenous anesthetic that has low protein binding (see [Table 25-2](#)).

## Organ System Effects

If [ketamine](#) is administered as the sole anesthetic, amnesia is not as complete as with the other intravenous anesthetics. Reflexes are often preserved, but it cannot be assumed that patients are able to protect the upper airway. The eyes remain open and the pupils are moderately dilated with a nystagmic gaze. Frequently, lacrimation and salivation are increased, and premedication with an anticholinergic drug may be indicated to limit this effect.

### A. CNS Effects

In contrast to other intravenous anesthetics, [ketamine](#) is considered to be a cerebral vasodilator that *increases* cerebral blood flow, as well as CMRO<sub>2</sub>. For these reasons, [ketamine](#) has traditionally not been recommended for use in patients with intracranial pathology, especially increased ICP. Nevertheless, these perceived undesirable effects on cerebral blood flow may be blunted by the maintenance of normocapnia. Despite the potential to produce myoclonic activity, [ketamine](#) is considered an anticonvulsant and may be recommended for treatment of status epilepticus when more conventional drugs are ineffective.

Unpleasant emergence reactions after administration are the main factor limiting [ketamine](#)’s use. Such reactions may include vivid colorful dreams, hallucinations, out-of-body experiences, and increased and distorted visual, tactile, and auditory sensitivity. These reactions can be associated with fear and confusion, but a euphoric state may also be induced, which explains the potential for abuse of the drug. Children usually have a lower incidence of and less severe emergence reactions. Combination with a benzodiazepine may be indicated to limit the unpleasant emergence reactions and also increase amnesia.

### B. Cardiovascular Effects

[Ketamine](#) can produce transient but significant *increases* in systemic blood pressure, heart rate, and cardiac output, presumably by centrally mediated sympathetic stimulation. These effects, which are associated with increased cardiac workload and myocardial [oxygen](#) consumption, are not always desirable and can be blunted by coadministration of benzodiazepines, opioids, or inhaled anesthetics. Although the mechanism is more controversial, [ketamine](#) is also considered to be a direct myocardial depressant. This property is usually masked by the stimulation of the sympathetic nervous system but may become apparent in critically ill patients with limited ability to increase their sympathetic nervous system activity.

### C. Respiratory Effects

[Ketamine](#) is not thought to produce significant respiratory depression. When it is used as a single drug, the respiratory response to hypercapnia is preserved and blood gases remain stable. Transient hypoventilation and, in rare cases, a short period of apnea can follow rapid administration of a large intravenous dose for induction of anesthesia. The ability to protect the upper airway in the presence of [ketamine](#) cannot be assumed despite the presence of active airway reflexes. Especially in children, the risk for laryngospasm due to increased salivation must be considered; this risk can be

reduced by premedication with an anticholinergic drug. **Ketamine** relaxes bronchial smooth muscle and may be helpful in patients with reactive airways and in the management of patients experiencing bronchoconstriction.

## Clinical Uses & Dosage

Its unique properties, including profound analgesia, stimulation of the sympathetic nervous system, bronchodilation, and minimal respiratory depression, make **ketamine** an important alternative to the other intravenous anesthetics and a desirable adjunct in many cases despite the unpleasant psychomimetic effects. Moreover, **ketamine** can be administered by multiple routes (intravenous, intramuscular, oral, rectal, epidural), thus making it a useful option for premedication in mentally challenged and uncooperative pediatric patients.

Induction of anesthesia can be achieved with **ketamine**, 1–2 mg/kg intravenously or 4–6 mg/kg intramuscularly. Although the drug is not commonly used for maintenance of anesthesia, its short context-sensitive half-time makes **ketamine** a candidate for this purpose. For example, general anesthesia can be achieved with the infusion of **ketamine**, 15–45 mcg/kg/min, plus 50–70% nitrous oxide or by **ketamine** alone, 30–90 mcg/kg/min.

Small bolus doses of **ketamine** (0.2–0.8 mg/kg IV) may be useful during regional anesthesia when additional analgesia is needed (eg, cesarean delivery under neuraxial anesthesia with an insufficient regional block). **Ketamine** provides effective analgesia without compromise of the airway. An infusion of a subanalgesic dose of **ketamine** (3–5 mcg/kg/min) during general anesthesia and in the early postoperative period may be useful to augment opioid analgesia and reduce opioid tolerance and opioid-induced hyperalgesia. The use of **ketamine** has always been limited by its unpleasant psychotomimetic side effects, but its unique features make it a very valuable alternative in certain settings, mostly because of the potent analgesia with minimal respiratory depression. Most recently, it has become popular as an adjunct administered at subanalgesic doses to limit or reverse opioid tolerance, especially in patients with chronic pain.

## DEXMETOMIDINE

**Dexmedetomidine** is a highly selective  $\alpha_2$ -adrenergic agonist. Recognition of the usefulness of  $\alpha_2$  agonists is based on observations of decreased anesthetic requirements in patients receiving chronic **clonidine** therapy. The effects of **dexmedetomidine** can be antagonized with  $\alpha_2$ -antagonist drugs. **Dexmedetomidine** is the active *S*-enantiomer of medetomidine, a highly selective  $\alpha_2$ -adrenergic agonist imidazole derivative that is used in veterinary medicine. **Dexmedetomidine** is water soluble and available as a parenteral formulation.

### Pharmacokinetics

**Dexmedetomidine** undergoes rapid hepatic metabolism involving *N*-methylation and hydroxylation, followed by conjugation. Metabolites are excreted in the urine and bile. Clearance is high, and the elimination half-time is short (see **Table 25–2**). However, there is a significant increase in the context-sensitive half-time from 4 minutes after a 10-minute infusion to 250 minutes after an 8-hour infusion.

### Organ System Effects

#### A. CNS Effects

**Dexmedetomidine** produces its selective  $\alpha_2$ -agonist effects through activation of CNS  $\alpha_2$  receptors. Hypnosis presumably results from stimulation of  $\alpha_2$  receptors in the locus coeruleus, and the analgesic effect originates at the level of the spinal cord. The sedative effect produced by **dexmedetomidine** has a different quality than that produced by other intravenous anesthetics in that it more completely resembles a physiologic sleep state through activation of endogenous sleep pathways. **Dexmedetomidine** is likely to be associated with a decrease in cerebral blood flow without significant changes in ICP and CMRO<sub>2</sub>. It has the potential to lead to the development of tolerance and dependence.

#### B. Cardiovascular Effects

**Dexmedetomidine** infusion results in moderate decreases in heart rate and systemic vascular resistance and, consequently, a decrease in systemic blood pressure. A bolus injection may produce a transient increase in systemic blood pressure and pronounced decrease in heart rate, an effect that is probably mediated through activation of peripheral  $\alpha_2$  adrenoceptors. Bradycardia associated with **dexmedetomidine** infusion may require treatment.

Heart block, severe bradycardia, and asystole have been observed and may result from unopposed vagal stimulation. The response to anticholinergic

### C. Respiratory Effects

The effects of **dexmedetomidine** on the respiratory system are a small to moderate decrease in tidal volume and very little change in the respiratory rate. The ventilatory response to carbon dioxide is unchanged. Although the respiratory effects are mild, upper airway obstruction as a result of sedation is possible. In addition, **dexmedetomidine** has a synergistic sedative effect when combined with other sedative-hypnotics.

### Clinical Uses & Dosage

**Dexmedetomidine** is principally used for the short-term sedation of intubated and ventilated patients in an ICU setting. In the operating room, **dexmedetomidine** may be used as an adjunct to general anesthesia or to provide sedation, eg, during awake fiberoptic tracheal intubation or regional anesthesia. When administered during general anesthesia, **dexmedetomidine** (0.5–1 mcg/kg loading dose over 10–15 minutes, followed by an infusion of 0.2–0.7 mcg/kg/h) decreases the dose requirements for inhaled and injected anesthetics. Awakening and the transition to the postoperative setting may benefit from dexmedetomidine-produced sedative and analgesic effects without respiratory depression.

## OPIOID ANALGESICS IN ANESTHESIA

Opioids are analgesic agents and are distinct from general anesthetics and hypnotics. Even when high doses of opioid analgesics are administered, recall cannot be prevented reliably unless hypnotic agents such as benzodiazepines are also used. Opioid analgesics are routinely used to achieve postoperative analgesia and intraoperatively as part of a balanced anesthesia regimen as described earlier (see **Intravenous Anesthetics**). Their pharmacology and clinical use are described in greater detail in **Chapter 31**.

In addition to their use as part of a balanced anesthesia regimen, opioids in large doses have been used in combination with large doses of benzodiazepines to achieve a general anesthetic state, particularly in patients with limited circulatory reserve who undergo cardiac surgery. When administered in large doses, potent opioids such as **fentanyl** can induce chest wall (and laryngeal) rigidity, thereby acutely impairing mechanical ventilation. Furthermore, large doses of potent opioids may speed up the development of tolerance and complicate postoperative pain management.

## CURRENT CLINICAL PRACTICE

The practice of clinical anesthesia requires integrating the pharmacology and the known adverse effects of these potent drugs with the pathophysiologic state of individual patients. Every case tests the ability of the anesthesiologist to produce the depth of anesthesia required to allow invasive surgery to proceed and to achieve this safely despite frequent major medical problems.

## AWARENESS DURING ANESTHESIA

As described in this chapter inhalational and intravenous agents are used alone and in combination to induce the depression of central nervous system function that allows patients to undergo painful procedures. The job of the anesthesiologist is to gauge the intensity of the noxious stimulus and deliver the appropriate amount and combination of agents to render the patient unaware of stimulus. During light and even deep sedation it is not uncommon for patients to have some memory of events.

---

## PREPARATIONS AVAILABLE\*

GENERIC NAME	AVAILABLE AS
Desflurane	Suprane
Dexmedetomidine	Precedex
Diazepam	Generic, Valium
Droperidol	Generic, Inapsine
Enflurane	Enflurane, Ethrane
Etomidate	Generic, Amidate
Fospropofol	Lusedra
Halothane	Generic, Fluothane
Isoflurane	Generic, Forane, Terrell
Ketamine	Generic, Ketalar
Lorazepam	Generic, Ativan
Methohexital	Generic, Brevital
Midazolam	Generic, Versed
Nitrous oxide (gas, supplied in blue cylinders)	Generic
Propofol	Generic, Diprivan
Sevoflurane	Generic, Ultane
Thiopental	Pentothal

\*See [Chapter 31](#) for names of opioid agents used in anesthesia.

This patient presents with significant underlying cardiac risk and is scheduled to undergo major stressful surgery. Balanced anesthesia would begin with intravenous agents that cause minimal changes in blood pressure and heart rate such as a lowered dose of **propofol** or **etomidate**, combined with potent analgesics such as **fentanyl** (see [Chapter 31](#)) to block undesirable stimulation of autonomic reflexes. Maintenance of anesthesia could incorporate inhaled anesthetics that ensure unconsciousness and amnesia, additional intravenous agents to provide intraoperative and postoperative analgesia, and, if needed, neuromuscular blocking drugs (see [Chapter 27](#)) to induce muscle relaxation. The choice of inhaled agent(s) would be made based on the desire to maintain sufficient myocardial contractility, systemic blood pressure, and cardiac output for adequate perfusion of critical organs throughout the operation. If the patient's ischemic pain has been chronic and severe, a low-dose **ketamine** infusion may be administered for additional pain control. Rapid emergence from the combined effects of the chosen anesthetic drugs, which would facilitate the patient's return to a baseline state of heart function, breathing, and mentation, can be attained by understanding the known pharmacokinetic properties of the anesthetic agents as presented in this chapter.

## Chapter 26: Local Anesthetics

Mohab M. Ibrahim; Tally M. Largent-Milnes

### CASE STUDY

#### CASE STUDY

A 67-year-old woman is scheduled for elective total knee arthroplasty. What local anesthetic agents would be most appropriate if surgical anesthesia were to be administered using a spinal or an epidural technique, and what potential complications might arise from their use? What anesthetics would be most appropriate for providing postoperative analgesia via an indwelling epidural or peripheral nerve catheter?

Simply stated, local anesthesia refers to loss of sensation in a limited region of the body. This is accomplished by disruption of afferent neural traffic via inhibition of impulse generation or propagation. Such blockade may bring with it other physiologic changes such as muscle paralysis and suppression of somatic or visceral reflexes, and these effects might be desirable or undesirable depending on the particular circumstances. Nonetheless, in most cases, it is the loss of sensation, or at least the achievement of localized analgesia, that is the primary goal.

Although local anesthetics are often used as analgesics, it is their ability to provide complete loss of all sensory modalities that is their distinguishing characteristic. The contrast with general anesthesia should be obvious, but it is perhaps worthwhile to emphasize that with local anesthesia the drug is delivered directly to the target organ, and the systemic circulation serves only to diminish or terminate its effect. Local anesthesia can also be produced by various chemical or physical means. However, in routine clinical practice, it is achieved with a rather narrow spectrum of compounds, and recovery is normally spontaneous, predictable, and without residual effects. The development of these compounds has a rich history (see Box: [Historical Development of Local Anesthesia](#)), punctuated by serendipitous observations, delayed starts, and an evolution driven more by concerns for safety than improvements in efficacy.

Although the numbing properties of **cocaine** were recognized for centuries, one might consider September 15, 1884, to mark the “birth of local anesthesia.” Based on work performed by Carl Koller, **cocaine**’s numbing effect on the cornea was demonstrated before the Ophthalmological Congress in Heidelberg, ushering in the era of surgical local anesthesia. Unfortunately, with widespread use came recognition of **cocaine**’s significant central nervous system (CNS) and cardiac toxicity, which along with its addiction potential, tempered enthusiasm for this application. As the early investigator Mattison commented, “the risk of untoward results have robbed this peerless drug of much favor in the minds of many surgeons, and so deprived them of a most valued ally.” As **cocaine** was known to be a benzoic acid ester, the search for alternative local anesthetics focused on this class of compounds, resulting in the identification of **benzocaine** shortly before the turn of the last century. However, **benzocaine** proved to have limited utility due to its marked hydrophobicity, and was thus relegated to topical anesthesia, a use for which it still finds limited application in current clinical practice. The first useful injectable local anesthetic, procaine, was introduced shortly thereafter by Einhorn, and its structure has served as the template for the development of the most commonly used modern local anesthetics. The three basic structural elements of these compounds can be appreciated by review of **Table 26–1**: an aromatic ring, conferring lipophilicity; an ionizable tertiary amine, conferring hydrophilicity; and an intermediate chain connecting these via an ester or amide linkage.

One of procaine’s limitations was its short duration of action, a drawback overcome with the introduction of **tetracaine** in 1928. Unfortunately, **tetracaine** demonstrated significant toxicity when employed for high-volume peripheral blocks, ultimately reducing its common usage to spinal anesthesia. Both procaine and **tetracaine** shared another drawback: their ester linkage conferred instability, and particularly in the case of procaine, the free aromatic acid released during ester hydrolysis of the parent compound was believed to be the source of relatively frequent allergic reactions.

Löfgren and Lundqvist circumvented the problem of instability with the introduction of **lidocaine** in 1948. **Lidocaine** was the first in a series of amino-amide local anesthetics that would come to dominate the second half of the 20th century. **Lidocaine** had a longer (and more favorable) duration of action than procaine, and less systemic toxicity than **tetracaine**. To this day, it remains one of the most versatile and widely used anesthetics. Nonetheless, some applications required more prolonged block than that afforded by **lidocaine**, a pharmacologic void that was filled with the introduction of **bupivacaine**, a more lipophilic and more potent anesthetic. Unfortunately, **bupivacaine** was found to have greater propensity for significant effects on cardiac conduction and function, which at times proved lethal. Recognition of this potential for cardiac toxicity led to changes in anesthetic practice, and significant toxicity became sufficiently rare for it to remain a widely used anesthetic for nearly every regional technique in modern clinical practice. Nonetheless, this inherent cardiotoxicity would drive developmental work leading to the introduction of two additions to the anesthetic armamentarium, levobupivacaine and **ropivacaine**. The former is the *S*(–) enantiomer of **bupivacaine**, which has less affinity for cardiac sodium channels than its *R*(+) counterpart. **Ropivacaine**, another *S*(–) enantiomer, shares this reduced affinity for cardiac sodium channels, while being slightly less potent than **bupivacaine** or levobupivacaine. However, despite the reduced channel affinity, a recent advisory panel of the American Society of Regional Anesthesia concluded that in most clinical settings **ropivacaine** and **bupivacaine** probably have similar toxicity when administered on an equipotent basis.

TABLE 26–1

**Structure and properties of some ester and amide local anesthetics.<sup>1</sup>**

	Structure	Potency (Procaine = 1)	Duration of Action
<b>Esters</b>			

		2	Medium
Procaine (Novocain)		1	Short
Tetracaine (Pontocaine)		16	Long
Benzocaine		Surface use only	
<b>Amides</b>			
Lidocaine (Xylocaine)		4	Medium
Mepivacaine (Carbocaine, Isocaine)		2	Medium
Bupivacaine (Marcaine), Levobupivacaine (Chirocaine)		16	Long
Ropivacaine (Naropin)		16	Long

<sup>1</sup>Other chemical types are available including ethers ([pramoxine](#)), ketones ([dyclonine](#)), and phenetidine derivatives ([phenacaine](#)).

## BASIC PHARMACOLOGY OF LOCAL ANESTHETICS

### Chemistry

Most local anesthetic agents consist of a lipophilic group (eg, an aromatic ring) connected by an intermediate chain via an ester or amide to an ionizable group (eg, a tertiary amine) ([Table 26-1](#)). In addition to the general physical properties of the molecules, specific stereochemical configurations are associated with differences in the potency of stereoisomers (eg, [levobupivacaine](#), [ropivacaine](#)). Because ester links are more prone to hydrolysis than amide links, esters usually have a shorter duration of action.

Local anesthetics are weak bases and are usually made available clinically as salts to increase solubility and stability. In the body, they exist either as the uncharged base or as a cation (see [Chapter 1](#), section Ionization of Weak Acids and Weak Bases). The relative proportions of these two forms are governed by their  $pK_a$  and the pH of the body fluids according to the Henderson-Hasselbalch equation, which can be expressed as:

$$pK_a = pH - \log \frac{[\text{base}]}{[\text{conjugate acid}]}$$

If the concentration of base and conjugate acid are equal, the second portion of the right side of the equation drops out, as  $\log 1 = 0$ , leaving:

$$pK_a = pH \text{ (when base concentration = conjugate acid concentration)}$$

Thus,  $pK_a$  can be seen as an effective way to consider the tendency for compounds to exist in a charged or uncharged form, ie, the lower the  $pK_a$ , the greater the percentage of uncharged weak bases at a given pH. Because the  $pK_a$  of most local anesthetics is in the range of 7.5–9.0, the charged, cationic form will constitute the larger percentage at physiologic pH. A glaring exception is [benzocaine](#), which has a  $pK_a$  around 3.5, and thus exists solely as the nonionized base under normal physiologic conditions.

This issue of ionization is of critical importance because the cationic form is the most active at the receptor site. However, the story is a bit more complex, because the receptor site for local anesthetics is at the inner vestibule of the sodium channel, and the charged form of the anesthetic penetrates biologic membranes poorly. Thus, the uncharged form is important for cell penetration. After penetration into the cytoplasm, equilibration leads to formation and binding of the charged cation at the sodium channel, and hence the production of a clinical effect ([Figure 26-1](#)). Drug may also reach the receptor laterally through what has been termed the hydrophobic pathway. As a clinical consequence, local anesthetics are less effective when they are injected into infected tissues because the low extracellular pH favors the charged form, with less of the neutral base available for diffusion across the membrane. Conversely, adding bicarbonate to a local anesthetic—a strategy sometimes used in clinical practice—will raise the effective concentration of the nonionized form and thus shorten the onset time of a regional block.

**FIGURE 26-1**

Schematic diagram depicting paths of local anesthetic (LA) to receptor sites. Extracellular anesthetic exists in equilibrium between charged and uncharged forms. The charged cation penetrates lipid membranes poorly; intracellular access is thus achieved by passage of the uncharged form. Intracellular re-equilibration results in formation of the more active charged species, which binds to the receptor at the inner vestibule of the sodium channel. Anesthetic may also gain access more directly by diffusing laterally within the membrane (hydrophobic pathway).

## Pharmacokinetics

When local anesthetics are used for local, peripheral, and central neuraxial anesthesia—their most common clinical applications—systemic absorption, distribution, and elimination serve only to diminish or terminate their effect. Thus, classic pharmacokinetics plays a lesser role than with systemic therapeutics, yet remains important to the anesthetic's duration and critical to the potential development of adverse reactions, specifically cardiac and CNS toxicity.

Some pharmacokinetic properties of the commonly used amide local anesthetics are summarized in [Table 26-2](#). The pharmacokinetics of the ester-based local anesthetics have not been extensively studied owing to their rapid breakdown in plasma (elimination half-life <1 minute).

TABLE 26-2

### Pharmacokinetic properties of several amide local anesthetics.

Agent	$t_{1/2}$ Distribution (min)	$t_{1/2}$ Elimination (h)	$V_{dss}$ (L)	CL (L/min)
Bupivacaine	28	3.5	72	0.47
Lidocaine	10	1.6	91	0.95
Mepivacaine	7	1.9	84	0.78
Prilocaine	5	1.5	261	2.84
Ropivacaine	23	4.2	47	0.44

CL, clearance;  $V_{dss}$ , volume of distribution at steady state per 70 kg body weight.

### A. Absorption

Systemic absorption of injected local anesthetic from the site of administration is determined by several factors, including dosage, site of injection, drug-tissue binding, local tissue blood flow, use of a vasoconstrictor (eg, [epinephrine](#)), and the physicochemical properties of the drug itself. Anesthetics that are more lipid soluble are generally more potent, have a longer duration of action, and take longer to achieve their clinical effect. Extensive protein binding also serves to increase the duration of action.

Application of a local anesthetic to a highly vascular area such as the tracheal mucosa or the tissue surrounding intercostal nerves results in more rapid absorption and thus higher blood levels than if the local anesthetic is injected into a poorly perfused tissue such as subcutaneous fat. When used for major conduction blocks, the peak serum levels will vary as a function of the specific site of injection, with intercostal blocks among the highest,

and sciatic and femoral among the lowest (Figure 26-2). When vasoconstrictors are used with local anesthetics, the resultant reduction in blood flow serves to reduce the rate of systemic absorption and thus diminishes peak levels. This effect is generally most evident with the shorter-acting, less potent, and less lipid-soluble anesthetics.

## B. Distribution

### 1. Localized

As local anesthetic is usually injected directly at the site of the target organ, distribution within this compartment plays an essential role with respect to achievement of clinical effect. For example, anesthetics delivered into the subarachnoid space will be diluted with cerebrospinal fluid (CSF) and the pattern of distribution will be dependent upon a host of factors, among the most critical being the specific gravity relative to that of CSF and the patient's position. Solutions are termed hyperbaric, isobaric, and hypobaric, and will respectively descend, remain relatively static, or ascend, within the subarachnoid space due to gravity when the patient sits upright. A review and analysis of relevant literature cited 25 factors that have been invoked as determinants of spread of local anesthetic in CSF, which can be broadly classified as characteristics of the anesthetic solution, CSF constituents, patient characteristics, and techniques of injection. Somewhat similar considerations apply to epidural and peripheral blocks.

The peak blood levels achieved during major conduction anesthesia will be minimally affected by the concentration of anesthetic or the speed of injection. The disposition of these agents can be well approximated by a two-compartment model. The initial alpha phase reflects rapid distribution in blood and highly perfused organs (eg, brain, liver, heart, kidney), characterized by a steep exponential decline in concentration. This is followed by a slower declining beta phase reflecting distribution into less well perfused tissue (eg, muscle, gut), and may assume a nearly linear rate of decline. The potential toxicity of the local anesthetics is affected by the protective effect afforded by uptake by the lungs, which serve to attenuate the arterial concentration, though the time course and magnitude of this effect have not been adequately characterized.

### C. Metabolism and Excretion

The local anesthetics are converted to more water-soluble metabolites in the liver (amide type) or in plasma (ester type), which are excreted in the urine. Since local anesthetics in the uncharged form diffuse readily through lipid membranes, little or no urinary excretion of the neutral form occurs. Acidification of urine promotes ionization of the tertiary amine base to the more water-soluble charged form, leading to more rapid elimination. Ester-type local anesthetics are hydrolyzed very rapidly in the blood by circulating butyrylcholinesterase to inactive metabolites. For example, the half-lives of procaine and **chloroprocaine** in plasma are less than a minute. However, excessive concentrations may accumulate in patients with reduced or absent plasma hydrolysis secondary to atypical plasma cholinesterase.

The amide local anesthetics undergo complex biotransformation in the liver, which includes hydroxylation and *N*-dealkylation by liver microsomal cytochrome P450 isozymes. There is considerable variation in the rate of liver metabolism of individual amide compounds, with **prilocaine** (fastest) > **lidocaine** > **mepivacaine** > **ropivacaine** ≈ **bupivacaine** and levobupivacaine (slowest). As a result, toxicity from amide-type local anesthetics is more likely to occur in patients with hepatic disease. For example, the average elimination half-life of **lidocaine** may be increased from 1.6 hours in normal patients ( $t_{1/2}$ , see **Table 26-2**) to more than 6 hours in patients with severe liver disease. Many other drugs used in anesthesia are metabolized by the same P450 isozymes, and concomitant administration of these competing drugs may slow the hepatic metabolism of the local anesthetics. Decreased hepatic elimination of local anesthetics would also be anticipated in patients with reduced hepatic blood flow. For example, the hepatic elimination of **lidocaine** in patients anesthetized with volatile anesthetics (which reduce liver blood flow) is slower than in patients anesthetized with intravenous anesthetic techniques. Delayed metabolism due to impaired hepatic blood flow may likewise occur in patients with heart failure.

## Pharmacodynamics

### A. Mechanism of Action

#### 1. Membrane potential

The primary mechanism of action of local anesthetics is blockade of voltage-gated sodium channels (see **Figure 26-1**). The excitable membrane of nerve axons, like the membrane of cardiac muscle (see **Chapter 14**) and neuronal cell bodies (see **Chapter 21**), maintains a resting transmembrane potential of  $-90$  to  $-60$  mV. During excitation, the sodium channels open, and a fast, inward sodium current quickly depolarizes the membrane toward the sodium equilibrium potential ( $+40$  mV). As a result of this depolarization process, the sodium channels close (inactivate) and potassium channels open. The outward flow of potassium repolarizes the membrane toward the potassium equilibrium potential (about  $-95$  mV); repolarization returns the sodium channels to the rested state with a characteristic recovery time that determines the refractory period. The transmembrane ionic gradients are maintained by the sodium pump. These ionic fluxes are similar to, but simpler than, those in heart muscle, and local anesthetics have similar effects in both tissues.

#### 2. Sodium channel isoforms

Each sodium channel consists of a single alpha subunit containing a central ion-conducting pore associated with accessory beta subunits. The pore-forming alpha subunit is actually sufficient for functional expression, but the kinetics and voltage dependence of channel gating are modified by the beta subunit. A variety of different sodium channels have been characterized by electrophysiologic recording, and subsequently isolated and cloned, while mutational analysis has allowed for identification of the essential components of the local anesthetic binding site. Nine members of a mammalian family of sodium channels have been so characterized and classified as  $Na_v1.1$ – $Na_v1.9$ , where the chemical symbol represents the primary

ion, the subscript denotes the physiologic regulator (in this case voltage), the initial number denotes the gene, and the number following the period indicates the particular isoform.

### 3. Channel blockade

Biologic toxins such as batrachotoxin, aconitine, veratridine, and some scorpion venoms bind to receptors within the channel and prevent inactivation. This results in prolonged influx of sodium through the channel and depolarization of the resting potential. The marine toxins tetrodotoxin (TTX) and saxitoxin have clinical effects that largely resemble those of local anesthetics (ie, block of conduction without a change in the resting potential). However, in contrast to the local anesthetics, the toxin binding site is located near the extracellular surface. The sensitivity of these channels to TTX varies, and subclassification based on this pharmacologic sensitivity has important physiologic and therapeutic implications. Six of the aforementioned channels are sensitive to nanomolar concentration of this biotoxin (TTX-S), while three are resistant (TTX-R). Such differences, along with their variable neuronal distribution, raise the possibility of targeting specific neuronal subpopulations. Such fine-tuned analgesic therapy has the theoretical potential of providing effective analgesia, while limiting the significant adverse effects produced by nonspecific sodium channel blockers.

When progressively increasing concentrations of a local anesthetic are applied to a nerve fiber, the threshold for excitation increases, impulse conduction slows, the rate of rise of the action potential declines, action potential amplitude decreases, and, finally, the ability to generate an action potential is completely abolished. These progressive effects result from binding of the local anesthetic to more and more sodium channels. If the sodium current is blocked over a critical length of the nerve, propagation across the blocked area is no longer possible. In myelinated nerves, the critical length appears to be two to three nodes of Ranvier. At the minimum dose required to block propagation, the resting potential is not significantly altered.

The blockade of sodium channels by most local anesthetics is both voltage- and time-dependent: Channels in the rested state, which predominate at more negative membrane potentials, have a much lower affinity for local anesthetics than activated (open state) and inactivated channels, which predominate at more positive membrane potentials (see Figure 14-10). Therefore, the effect of a given drug concentration is more marked in rapidly firing axons than in resting fibers (Figure 26-3). Between successive action potentials, a portion of the sodium channels will recover from the local anesthetic block (see Figure 14-10). The recovery from drug-induced block is 10–1000 times slower than the recovery of channels from normal inactivation (as shown for the cardiac membrane in Figure 14-4). As a result, the refractory period is lengthened and the nerve conducts fewer action potentials.

FIGURE 26-3

Effect of repetitive activity on the block of sodium current produced by a local anesthetic in a myelinated axon. A series of 25 pulses was applied, and the resulting sodium currents (downward deflections) are superimposed. Note that the current produced by the pulses rapidly decreased from the first to the 25th pulse. A long rest period after the train resulted in recovery from block, but the block could be reinstated by a subsequent train. nA, nanoamperes. the membrane (which favors the low-affinity rested state). Conversely, increases in extracellular potassium depolarize the membrane potential and favor the inactivated state, enhancing the effect of local anesthetics.

#### 4. Other effects

Currently used local anesthetics bind to the sodium channel with low affinity and poor specificity, and there are multiple other sites for which their affinity is nearly the same as that for sodium channel binding. Thus, at clinically relevant concentrations, local anesthetics are potentially active at countless other channels (eg, potassium and calcium), enzymes (eg, adenylyl cyclase, carnitine-acylcarnitine translocase), and receptors (eg, *N*-methyl-D-aspartate [NMDA], G protein-coupled, 5-HT<sub>3</sub>, neurokinin-1 [substance P receptor]). The role that such ancillary effects play in achievement of local anesthesia appears to be important but is poorly understood. Further, interactions with these other sites are likely the basis for numerous differences between the local anesthetics with respect to anesthetic effects (eg, differential block) and toxicities that do not parallel anesthetic potency, and thus are not adequately accounted for solely by blockade of the voltage-gated sodium channel.

The actions of circulating local anesthetics at such diverse sites exert a multitude of effects, some of which go beyond pain control, including some that are also potentially beneficial. For example, there is evidence to suggest that the blunting of the stress response and improvements in perioperative outcome that may occur with epidural anesthesia derive in part from an action of the anesthetic beyond its sodium channel block. Circulating local anesthetics also demonstrate antithrombotic effects, including having an impact on coagulation, platelet aggregation, and the microcirculation, as well as modulation of inflammation.

### B. Structure-Activity Characteristics of Local Anesthetics

The smaller and more highly lipophilic local anesthetics have a faster rate of interaction with the sodium channel receptor. As previously noted, potency is also positively correlated with lipid solubility. **Lidocaine**, procaine, and **mepivacaine** are more water soluble than **tetracaine**, **bupivacaine**, and **ropivacaine**. The latter agents are more potent and have longer durations of local anesthetic action. These long-acting local anesthetics also bind more extensively to proteins and can be displaced from these binding sites by other protein-bound drugs. In the case of optically active agents (eg, **bupivacaine**), the *R*(+) isomer can usually be shown to be slightly more potent than the *S*(-) isomer (levobupivacaine).

### C. Neuronal Factors Affecting Block

#### 1. Differential block

Since local anesthetics are capable of blocking all nerves, their actions are not limited to the desired loss of sensation from sites of noxious (painful) stimuli. With central neuraxial techniques (spinal or epidural), motor paralysis may impair respiratory activity, and autonomic nerve blockade may promote hypotension. Further, while motor paralysis may be desirable during surgery, it may be a disadvantage in other settings. For example, motor weakness occurring as a consequence of epidural anesthesia during obstetrical labor may limit the ability of the patient to bear down (ie, “push”) during delivery. Similarly, when used for postoperative analgesia, weakness may hamper ability to ambulate without assistance and pose a risk of falling, while residual autonomic blockade may interfere with bladder function, resulting in urinary retention and the need for bladder catheterization. These issues are particularly problematic in the setting of ambulatory (same-day) surgery, which represents an ever-increasing percentage of surgical caseloads.

#### 2. Intrinsic susceptibility of nerve fibers

Nerve fibers differ significantly in their susceptibility to local anesthetic blockade. It has been traditionally taught, and still often cited, that local anesthetics preferentially block smaller diameter fibers first because the distance over which such fibers can passively propagate an electrical impulse is shorter. However, a variable proportion of large fibers are blocked prior to the disappearance of the small fiber component of the compound action potential. Most notably, myelinated nerves tend to be blocked before unmyelinated nerves of the same diameter. For example, preganglionic B fibers are blocked before the smaller unmyelinated C fibers involved in pain transmission (**Table 26-3**).

Relative size and susceptibility of different types of nerve fibers to local anesthetics.

Fiber Type	Function	Diameter ( $\mu\text{m}$ )	Myelination	Conduction Velocity (m/s)	Sensitivity to Block
<b>Type A</b>					
Alpha	Proprioception, motor	12–20	Heavy	70–120	+
Beta	Touch, pressure	5–12	Heavy	30–70	++
Gamma	Muscle spindles	3–6	Heavy	15–30	++
Delta	Pain, temperature	2–5	Heavy	5–25	+++
<b>Type B</b>	Preganglionic autonomic	<3	Light	3–15	++++
<b>Type C</b>					
Dorsal root	Pain	0.4–1.2	None	0.5–2.3	++++
Sympathetic	Postganglionic	0.3–1.3	None	0.7–2.3	++++

Another important factor underlying differential block derives from the state- and use-dependent mechanism of action of local anesthetics. Blockade by these drugs is more marked at higher frequencies of depolarization. Sensory (pain) fibers have a high firing rate and relatively long action potential duration. Motor fibers fire at a slower rate and have a shorter action potential duration. As type A delta and C fibers participate in high-frequency pain transmission, this characteristic may favor blockade of these fibers earlier and with lower concentrations of local anesthetics. The potential impact of such effects mandates cautious interpretation of non-physiologic experiments evaluating intrinsic susceptibility of nerves to conduction block by local anesthetics.

### 3. Anatomic arrangement

In addition to the effect of intrinsic vulnerability to local anesthetic block, the anatomic organization of the peripheral nerve bundle may impact the onset and susceptibility of its components. As one would predict based on the necessity of having proximal sensory fibers join the nerve trunk last, the core will contain sensory fibers innervating the most distal sites. Anesthetic placed outside the nerve bundle will thus reach and anesthetize the proximal fibers located at the outer portion of the bundle first, and sensory block will occur in sequence from proximal to distal.

## CLINICAL PHARMACOLOGY OF LOCAL ANESTHETICS

Local anesthetics can provide highly effective analgesia in well-defined regions of the body. The most common routes of administration include a topical application (eg, nasal mucosa), wound or incision site infiltration, injection in the vicinity of peripheral nerve endings or major nerve trunks, and injection into the epidural or subarachnoid spaces surrounding the spinal cord (Figure 26-4). In addition, recent clinical practice has seen the development of truncal blocks that target fascial planes (eg, transversus abdominis or erector spinae), as well as expansion of the use of local infiltration anesthesia (LIA), particularly in the setting of total joint arthroplasty.

FIGURE 26-4

Schematic diagram of the typical sites of injection of local anesthetics in and around the spinal canal. When local anesthetics are injected extradurally, it is referred to as an epidural block. A caudal block is a specific type of epidural block in which a needle is inserted into the caudal canal via the sacral

hiatus. Injections around peripheral nerves are known as peripheral blocks (eg, paravertebral block). Finally, injection into cerebrospinal fluid in the subarachnoid (intrathecal) space is referred to as a spinal block.

Basic & Clinical Pharmacology, Sixteenth Edition  
Copyright © McGraw Hill. All rights reserved.

## Clinical Block Characteristics

In clinical practice, there is generally an orderly evolution of block components beginning with sympathetic transmission and progressing to temperature, pain, light touch, and finally motor block. This is most readily appreciated during the onset of spinal anesthesia, where a spatial discrepancy can be detected in modalities, the most vulnerable components achieving greater dermatomal (cephalad) spread. Thus, loss of the sensation of cold (often assessed by a wet [alcohol](#) sponge) will be roughly two segments above the analgesic level for pinprick, which in turn will be roughly two segments rostral to loss of light touch recognition. However, because of the anatomic considerations noted earlier for peripheral nerve trunks, onset with peripheral blocks is more variable, and proximal motor weakness may precede the onset of more distal sensory loss. Additionally, the anesthetic solution is not generally deposited evenly around a nerve bundle, and longitudinal spread and radial penetration into the nerve trunk are far from uniform.

With respect to differential block, it is worth noting that “successful” surgical anesthesia may require loss of tactile sensation, not just the ablation of pain, as some patients will find even the sensation of touch distressing during surgery, often fearing that the procedure may become painful. Further, while differences may exist in modalities, it is not possible with conventional techniques to produce surgical anesthesia without some loss of motor

### A. Effect of Added Vasoconstrictors

Several benefits may be derived from addition of a vasoconstrictor to a local anesthetic. First, localized neuronal uptake is enhanced because of higher sustained local tissue concentrations that can translate clinically into a longer duration block. This may enable adequate anesthesia for more prolonged procedures, extended duration of postoperative pain control, and lower total anesthetic requirement. Second, peak blood levels will be lowered as absorption is more closely matched to metabolism and elimination, and the risk of systemic toxic effects is reduced. Moreover, when incorporated into a spinal anesthetic, **epinephrine** may not only contribute to the prolongation of the local anesthetic effect via its vasoconstrictor properties, but also exert a direct analgesic effect mediated by postsynaptic  $\alpha_2$  adrenoceptors within the spinal cord. Recognition of this potential has led to the clinical use of the  $\alpha_2$  agonist **clonidine** as a local anesthetic adjuvant for spinal anesthesia.

Conversely, the inclusion of **epinephrine** may also have untoward effects. The addition of **epinephrine** to anesthetic solutions can potentiate the neurotoxicity of local anesthetics used for peripheral nerve blocks or spinal anesthesia. Further, the use of a vasoconstrictor agent in an area that lacks adequate collateral flow (eg, digital block) is generally avoided, although some have questioned the validity of this proscription.

### B. Intentional Use of Systemic Local Anesthetics

Although the principal use of local anesthetics is to achieve anesthesia in a restricted area, these agents are sometimes deliberately administered systemically to take advantage of suppressive effects on pain processing. In addition to documented reductions in anesthetic requirement and postoperative pain, systemic administration of local anesthetics has been used with some success in the treatment of chronic pain, and this effect may outlast the duration of anesthetic exposure. The achievement of pain control by systemic administration of local anesthetics is thought to derive, at least in part, from the suppression of abnormal ectopic discharge, an effect observed at concentrations of local anesthetic an order of magnitude lower than those required for blockade of propagation of action potentials in normal nerves. Consequently, these effects can be achieved without the adverse effects that would derive from the failure of normal nerve conduction. Escalating doses of anesthetic appear to exert the following systemic actions: (1) low concentrations may preferentially suppress ectopic impulse generation in chronically injured peripheral nerves; (2) moderate concentrations may suppress central sensitization, which would explain therapeutic benefit that may extend beyond the anesthetic exposure; and (3) higher concentrations will produce general analgesic effects and may culminate in serious toxicity.

## Toxicity

Local anesthetic toxicity derives from two distinct processes: (1) systemic effects following inadvertent intravascular injection or absorption of the local anesthetic from the site of administration; and (2) neurotoxicity resulting from local effects produced by direct contact with neural elements.

### A. Risk Factors for Local Anesthetic Toxicity

Some patients may be more predisposed to local anesthetic toxicity. Appreciating the risk factors for local anesthetic toxicity will facilitate better monitoring to decrease the incidence of adverse effects. Additionally, understanding who may be at greater risk for local anesthetics toxicity may encourage taking additional precautions to prepare resuscitation plans. The following are considered at high risk for local anesthetic toxicity.

#### 1. Extremes of age

Individuals under 4 months of age or the elderly. Individuals under the age of 4 months have low hepatic clearance and low levels of alpha-1-acid glycoprotein (AAG). AAG is an acute phase protein produced by the liver and peripheral tissues with a high affinity for local anesthetics. Low levels of AAG will render more local anesthetics in the free form in the plasma. For the elderly, in addition to low hepatic clearance, nerves are more sensitive to local anesthetics, which necessitate lower doses.

#### 2. Pregnancy

Pregnancy induces several physiological changes that may interfere with the pharmacokinetics of local anesthetics. Decreased levels of AAG and increased sensitivity to local anesthetics secondary to hormonal changes increase the risks of local anesthetics during pregnancy. The absorption of

Local anesthetics may increase secondary to increased cardiac output in pregnancy, thus leading to the increased serum concentration of local anesthetics.

### 3. Organ dysfunction

Patients with renal or hepatic disease may be predisposed to local anesthetic toxicity. Renal disease may result in metabolic acidosis, which may cause a rapid increase in the local anesthetic levels in the plasma. Patients with end-stage hepatic disease may have reduced levels of AAG and **albumin**, thus allowing more local anesthetics to be in the unbound form in the plasma.

## B. Systemic Toxicity

The dose of local anesthetic used for epidural anesthesia or high-volume peripheral blocks is sufficient to produce major clinical toxicity, even death. To minimize risk, maximum recommended doses for each drug for each general application have been promulgated. The concept underlying this approach is that absorption from the site of injection should appropriately match metabolism, thereby preventing toxic serum levels. However, these recommendations do not consider patient characteristics or concomitant risk factors, nor do they take into account the specific peripheral nerve block performed, which has a significant impact on the rate of systemic uptake (see [Figure 26–2](#)). Most importantly, they fail to afford protection from toxicity induced by inadvertent intravascular injection (occasionally into an artery, but more commonly a vein).

### 1. CNS toxicity

All local anesthetics have the ability to produce sedation, light-headedness, visual and auditory disturbances, and restlessness when high plasma concentrations result from rapid absorption or inadvertent intravascular administration. An early symptom of local anesthetic toxicity is circumoral and tongue numbness and a metallic taste. At higher concentrations, nystagmus and muscular twitching occur, followed by tonic-clonic convulsions. Local anesthetics apparently cause depression of cortical inhibitory pathways, thereby allowing unopposed activity of excitatory neuronal pathways. This transitional stage of unbalanced excitation (ie, seizure activity) is then followed by generalized CNS depression. However, this classic pattern of evolving toxicity has been largely characterized in human volunteer studies (which are ethically constrained to low doses) and by graded administration in animal models. Deviations from such classic progression are common in clinical toxicity and will be influenced by a host of factors, including patient vulnerability, the particular local anesthetic administered, concurrent drugs, and the rate of rising of serum drug levels. For example, in a literature review of reported clinical cases of local anesthetic cardiac toxicity, prodromal signs of CNS toxicity occurred in only 18% of cases.

When large doses of a local anesthetic are required (eg, for major peripheral nerve block or local infiltration for major plastic surgery), premedication with a parenteral benzodiazepine (eg, **diazepam** or **midazolam**) may provide some prophylaxis against local anesthetic-induced CNS toxicity. However, such premedication will have little, if any, effect on cardiovascular toxicity, potentially delaying the recognition of a life-threatening overdose. If seizures do occur, it is critical to prevent hypoxemia and acidosis, which potentiate anesthetic toxicity. Rapid tracheal intubation can facilitate adequate ventilation and oxygenation, and is essential to prevent pulmonary aspiration of gastric contents in patients at risk. The effect of hyperventilation is complex, and its role in resuscitation following anesthetic overdose is somewhat controversial. While generally not recommended, it is possible that hyperventilation might offer some benefit if used to counteract significant metabolic acidosis. Seizures induced by local anesthetics should be rapidly controlled to prevent patient harm and exacerbation of acidosis. A recent practice advisory from the American Society of Regional Anesthesia considered benzodiazepines as first-line drugs. However, small doses of **propofol** (eg, 0.25–0.5 mg/kg) were considered acceptable alternatives, as they are often more immediately available in the setting of local anesthetic administration, while higher doses were to be avoided, particularly in the setting of hemodynamic instability. The motor activity of the seizure can be effectively terminated by the administration of a neuromuscular blocker, though this will not diminish the CNS manifestations, and efforts must include therapy directed at the underlying seizure activity.

### 2. Cardiotoxicity

The most feared complications associated with local anesthetic administration result from the profound effects these agents can have on cardiac conduction and function. In 1979, an editorial by Albright reviewed the circumstances of six deaths associated with the use of **bupivacaine** and etidocaine. This seminal publication suggested that these relatively new lipophilic and potent anesthetics had greater potential for cardiotoxicity and that cardiac arrest could occur concurrently or immediately following seizures and, most importantly, in the absence of hypoxia or acidosis. Although [Telegram @pharm\\_s](#) sharply criticized, subsequent clinical experience, unfortunately, reinforced Albright's concern—within 4 years, the US Food and

Drug Administration (FDA) had received reports of 12 cases of cardiac arrest associated with the use of 0.75% **bupivacaine** for epidural anesthesia in obstetrics. Further support for enhanced cardiotoxicity of these anesthetics came from animal studies demonstrating that doses of **bupivacaine** and etidocaine as low as two-thirds of those producing convulsions could induce arrhythmias, while the margin between CNS and cardiac toxicity was less than half that for **lidocaine**. In response, the FDA banned the use of 0.75% **bupivacaine** in obstetrics. In addition, the incorporation of a test dose became ingrained as a standard of anesthetic practice, along with the practice of fractionated administration of local anesthetic.

Although the reduction in **bupivacaine**'s anesthetic concentration and changes in anesthetic practice did much to reduce the risk of cardiotoxicity, the recognized differences in the toxicity of the stereoisomers comprising **bupivacaine** created an opportunity for the development of potentially safer anesthetics (see [Chapter 1](#)). Investigations demonstrated that the enantiomers of the racemic mixture **bupivacaine** were not equivalent with respect to cardiotoxicity, the *S*(-) enantiomer having a better therapeutic advantage, leading to the subsequent marketing of levobupivacaine. This was followed shortly thereafter by **ropivacaine**, a slightly less potent anesthetic than **bupivacaine**. It should be noted, however, that the reduction in toxicity afforded by these compounds is only modest. In fact, a recent advisory panel of the American Society of Regional Anesthesia (ASRA) concluded that in most clinical settings **ropivacaine** and **bupivacaine** likely have similar toxicity when administered on an equipotent basis. Thus, the risk of significant cardiotoxicity remains a very real concern when any of these anesthetics are administered for high-volume blocks.

### 3. Reversal of **bupivacaine** toxicity

Recently, a series of clinical events, serendipitous observations, systematic experimentation, and astute clinical decisions have identified a relatively simple, practical, and apparently effective therapy for resistant **bupivacaine** cardiotoxicity using intravenous infusion of lipid. Furthermore, this therapy appears to have applications that extend beyond **bupivacaine** cardiotoxicity to the cardiac or CNS toxicity induced by an overdose of any lipid-soluble drug (see Box: [Lipid Resuscitation](#)).

#### Lipid Resuscitation

Based on a case of apparent cardiotoxicity from a very low dose of **bupivacaine** in a patient with carnitine deficiency, G. L. Weinberg postulated that this metabolic derangement led to enhanced toxicity due to the accumulation of fatty acids within the cardiac myocyte. He hypothesized that administration of lipid would similarly potentiate **bupivacaine** cardiotoxicity, but experiments performed to test this hypothesis demonstrated exactly the opposite effect. Accordingly, he began systematic laboratory investigations, which clearly demonstrated the potential efficacy of an **intravenous lipid emulsion (ILE)** for resuscitation from **bupivacaine** cardiotoxicity. Clinical confirmation came 8 years later with the report of the successful resuscitation of a patient who sustained an anesthetic-induced (**bupivacaine** plus **mepivacaine**) cardiac arrest refractory to standard advanced cardiac life support procedures (ACLS). Numerous similar reports of successful resuscitations soon followed, extending this clinical experience to other anesthetics including levobupivacaine and **ropivacaine** local anesthetic-induced CNS toxicity, as well as toxicity induced by other classes of compounds, eg, bupropion-induced cardiovascular collapse and multiform ventricular tachycardia provoked by **haloperidol**. Laboratory investigations have likewise provided evidence of efficacy for treatment of diverse toxic challenges (eg, **verapamil**, **clomipramine**, and **propranolol**).

Our understanding of the mechanisms by which lipid is effective is incomplete, but has advanced significantly over the last two decades. Almost certainly an important effect is related to its ability to extract a lipophilic drug from aqueous plasma, thus reducing its effective concentration at tissue targets, a mechanism initially termed "lipid sink." More recently, the more dynamic term "lipid shuttle" has been favored to reflect the redistribution of drug from organs susceptible to toxicity to organs where drug might be stored, detoxified, or excreted. However, this alone does not appear adequate to account for the magnitude of clinical effect, suggesting that other mechanisms contribute to the efficacy of lipid rescue. Consistent with this, there is experimental evidence demonstrating beneficial cardiotoxic and vasoconstrictive effects as well as postconditioning (through activation of prosurvival kinases).

Although numerous questions remain, the evolving evidence is sufficient to warrant administration of lipid in cases of systemic anesthetic toxicity. Its use has been promulgated by a task force of the American Society of Regional Anesthesia (<https://www.asra.com/advisory-guidelines/article/3/checklist-for-treatment-of-local-anesthetic-systemic-toxicity>), and administration of lipid has been incorporated into the most recent revision of ACLS guidelines for Cardiac Arrest in Special Situations. Importantly, **propofol** cannot be administered for this purpose, as the relatively enormous volume of this solution required for lipid therapy would deliver lethal quantities of **propofol**.

### 1. Neural injury

From the early introduction of spinal anesthesia into clinical practice, sporadic reports of neurologic injury associated with this technique raised concern that local anesthetic agents were potentially neurotoxic. Following injuries associated with Durocaine—a spinal anesthetic formulation containing procaine—initial attention focused on the vehicle components. However, experimental studies found 10% procaine alone induced similar injuries in cats, whereas the vehicle did not. Concern for anesthetic neurotoxicity reemerged in the early 1980s with a series of reports of major neurologic injury occurring with the use of **chlorprocaine** for epidural anesthesia. In these cases, there was evidence that anesthetic intended for the epidural space was inadvertently administered intrathecally. As the dose required for spinal anesthesia is roughly an order of magnitude less than for epidural anesthesia, injury was apparently the result of excessive exposure of the more vulnerable subarachnoid neural elements.

With changes in vehicle formulation and in clinical practice, concern for toxicity again subsided, only to reemerge a decade later with reports of cauda equina syndrome associated with continuous spinal anesthesia (CSA). In contrast to the more common single-injection technique, CSA involves placing a catheter in the subarachnoid space to permit repetitive dosing to facilitate adequate anesthesia and maintenance of block for extended periods. In these cases, the local anesthetic was evidently administered to a relatively restricted area of the subarachnoid space; in order to extend the block to achieve adequate surgical anesthesia, multiple repetitive doses of anesthetic were then administered. By the time the block was adequate, neurotoxic concentrations had accumulated in a restricted area of the caudal region of the subarachnoid space. Most notably, the anesthetic involved in the majority of these cases was **lidocaine**, a drug most clinicians considered to be the least toxic of agents. This was followed by reports of neurotoxic injury occurring with **lidocaine** intended for epidural administration that had inadvertently been administered intrathecally, similar to the cases involving **chlorprocaine** a decade earlier. The occurrence of neurotoxic injury with CSA and subarachnoid administration of epidural doses of **lidocaine** served to establish vulnerability whenever excessive anesthetic was administered intrathecally, regardless of the specific anesthetic used. Of even more concern, subsequent reports provided evidence for injury with spinal **lidocaine** administered at the high end of the recommended clinical dosage, prompting recommendations for a reduction in maximum dose. These clinical reports (as well as concurrent experimental studies) served to dispel the concept that modern local anesthetics administered at clinically relevant doses and concentrations were incapable of inducing neurotoxic injury.

The mechanism of local anesthetic neurotoxicity has been extensively investigated in cell cultures, isolated axons, and in vivo models. These studies have demonstrated myriad deleterious effects including conduction failure, membrane damage, enzyme leakage, cytoskeletal disruption, accumulation of intracellular calcium, disruption of axonal transport, growth cone collapse, and apoptosis. It is not clear what role these factors or others play in clinical injury. It is clear, however, that injury does not result from the blockade of the voltage-gated sodium channel per se, and thus clinical effect and toxicity are not tightly linked.

### 2. Transient neurologic symptoms (TNS)

In addition to the very rare but devastating neural complications that can occur with neuraxial (spinal and epidural) administration of local anesthetics, a syndrome of transient pain or dysesthesia, or both, has been recently linked to use of **lidocaine** for spinal anesthesia. Although these symptoms are not associated with sensory loss, motor weakness, or bowel and bladder dysfunction, the pain can be quite severe, often exceeding that induced by the surgical procedure. TNS occurs even at modest doses of anesthetic and has been documented in as many as one-third of patients receiving **lidocaine**, with increased risk associated with certain patient positions during surgery (eg, lithotomy) and with ambulatory anesthesia. The risk with other anesthetics varies considerably. For example, the incidence is only slightly reduced with procaine or **mepivacaine** but appears to be negligible with **bupivacaine**, **prilocaine**, and **chlorprocaine**. The etiology and significance of TNS remain to be established, but differences between factors affecting TNS and experimental animal toxicity argue strongly against a common mechanism mediating these symptoms and persistent or permanent neurologic deficits. Nonetheless, the high incidence of TNS with spinal **lidocaine** has led to decreased use for this procedure, though **lidocaine**'s popularity for all other applications, including epidural anesthesia, remains intact. Rather ironically, **chlorprocaine**, once considered a more toxic anesthetic, is now gaining popularity for short-duration spinal anesthesia as an alternative to **lidocaine**, a compound that had been considered the gold standard for safety for over half a century, and had been used for well over 50 million spinal anesthetic procedures.

## COMMONLY USED LOCAL ANESTHETICS & THEIR APPLICATIONS

Approved for use in the USA as a dental anesthetic in April 2000, articaine is unique among the amino-amide anesthetics in having a thiophene, rather than a benzene ring, as well as an additional ester group that is subject to metabolism by plasma esterases (see [Table 26-1](#)). The modification of the ring serves to enhance lipophilicity, and thus improve tissue penetration, while inclusion of the ester leads to a shorter plasma half-life (approximately 20 minutes), potentially imparting a better therapeutic index with respect to systemic toxicity. These characteristics have led to widespread popularity in dental anesthesia, where it is generally considered to be more effective, and possibly safer, than [lidocaine](#), the prior standard. Balanced against these positive attributes are concerns that the development of persistent paresthesias, while rare, may be three times more common with articaine. However, [prilocaine](#) has been associated with an even higher relative incidence (twice that of articaine). Importantly, these are the only two dental anesthetics that are formulated as 4% solutions; the others are all marketed at lower concentrations (eg, the maximum concentration of [lidocaine](#) used for dental anesthesia is 2%), and it is well established that anesthetic neurotoxicity is, to some extent, concentration-dependent. Thus, it is quite possible that enhanced risk derives from the formulation rather than from an intrinsic property of the anesthetic. In a recent survey of US and Canadian dental schools, over half of respondents indicated that 4% articaine is no longer used for mandibular nerve block.

## BENZOCAINE

As previously noted, [benzocaine](#)'s pronounced lipophilicity has relegated its application to topical anesthesia. However, despite over a century of use for this purpose, its popularity has recently diminished owing to increasing concerns regarding its potential to induce methemoglobinemia. Elevated levels can be due to inborn errors or can occur with exposure to an oxidizing agent, and such is the case with significant exposure to [benzocaine](#) (or nitrites, see [Chapter 12](#)). Because methemoglobin does not transport [oxygen](#), elevated levels pose a serious risk, with severity obviously paralleling blood levels.

## BUPIVACAINE

Based on concerns for cardiotoxicity, [bupivacaine](#) is often avoided for techniques that demand high volumes of concentrated anesthetics, such as epidural or peripheral nerve blocks performed for surgical anesthesia. In contrast, relatively low concentrations ( $\leq 0.25\%$ ) are frequently used to achieve prolonged peripheral anesthesia and analgesia for postoperative pain control, and the drug enjoys similar popularity where anesthetic infiltration is used to control pain from a surgical incision. It is often the agent of choice for epidural infusions used for postoperative pain control and for labor analgesia. Finally, it has a comparatively unblemished record as a spinal anesthetic, with a relatively favorable therapeutic index with respect to neurotoxicity, and little, if any, risk of TNS. However, spinal [bupivacaine](#) is not well suited for outpatient or ambulatory surgery, because its relatively long duration of action can delay recovery, resulting in a longer stay prior to discharge to home.

## CHLOROPROCAINE

The introduction of [chloroprocaine](#) into clinical practice in 1951 represented a reversion to the earlier amino-ester template. [Chloroprocaine](#) gained widespread use as an epidural agent in obstetrical anesthesia where its rapid hydrolysis served to minimize risk of systemic toxicity or fetal exposure. The unfortunate reports of neurologic injury associated with apparent intrathecal misplacement of large doses intended for the epidural space led to its near abandonment. However, although [chloroprocaine](#) was never exonerated with respect to these early neurologic injuries associated with epidural anesthesia, it is now appreciated that high doses of any local anesthetic are capable of inducing neurotoxic injury.

The frequent occurrence of TNS with [lidocaine](#) administered as a spinal anesthetic created an anesthetic void that [chloroprocaine](#) appeared well suited to fill. The onset and duration of action of spinal [chloroprocaine](#) are even shorter than those of [lidocaine](#), while presenting little, if any, risk of TNS. These favorable characteristics provoked considerable off-label use of a preservative-free (epidural) solution, and ultimately led to the approval and marketing of Clorotekal, a [chloroprocaine](#) formulation specifically indicated for spinal anesthesia. Nonetheless, documented use of [chloroprocaine](#) as a spinal anesthetic is relatively limited when compared with compounds such as [lidocaine](#) and [bupivacaine](#), and additional experience will be required to firmly establish its safety profile. In addition to [chloroprocaine](#)'s emerging use for spinal anesthesia, it still finds some current use as an epidural anesthetic, particularly in circumstances where there is an indwelling catheter and the need for quick attainment of surgical anesthesia, such as caesarian section for a laboring parturient with a compromised fetus.

## COCAINE

Current clinical use of [cocaine](#) is largely restricted to topical anesthesia for ear, nose, and throat procedures, where its intense vasoconstriction can

serve to reduce bleeding. Even here, use has diminished in favor of other anesthetics combined with vasoconstrictors because of concerns about systemic toxicity, as well as the inconvenience of dispensing and handling this controlled substance.

## ETIDOCAINE

Introduced along with [bupivacaine](#), etidocaine has had limited application due to its poor block characteristics. It has a tendency to produce an inverse differential block (ie, compared with other anesthetics such as [bupivacaine](#), it produces excessive motor relative to sensory block), which is rarely a favorable attribute.

## LEVOBUPIVACAINE

As previously discussed, this *S*(-) enantiomer of [bupivacaine](#) is somewhat less cardiotoxic than the racemic mixture. It is also less potent and tends to have a longer duration of action, although the magnitude of these effects is too small to have any substantial clinical significance.

## LIDOCAINE

Aside from the issue of a high incidence of TNS with spinal administration, [lidocaine](#) has had an excellent record as an intermediate duration anesthetic and remains the reference standard against which most anesthetics are compared.

## MEPIVACAINE

Although structurally similar to [bupivacaine](#) and [ropivacaine](#) (see [Table 26-1](#)), [mepivacaine](#) displays clinical properties that are comparable to [lidocaine](#). However, it differs from [lidocaine](#) with respect to vasoactivity, as it has a tendency toward vasoconstriction rather than vasodilation. This characteristic likely accounts for its slightly longer duration of action, which has made it a popular choice for major peripheral blocks. [Lidocaine](#) has retained its dominance over [mepivacaine](#) for epidural anesthesia, where the routine placement of a catheter negates the importance of a longer duration. More importantly, [mepivacaine](#) is slowly metabolized by the fetus, making it a poor choice for epidural anesthesia in the parturient. When used for spinal anesthesia, [mepivacaine](#) has a slightly lower incidence of TNS than [lidocaine](#).

## PRILOCAINE

[Prilocaine](#) has the highest clearance of the amino-amide anesthetics, imparting reduced risk of systemic toxicity. Unfortunately, this is somewhat offset by its propensity to induce methemoglobinemia, which results from accumulation of one of its metabolites, ortho-toluidine, an oxidizing agent. As a spinal anesthetic, [prilocaine](#)'s duration of action is slightly longer than that of [lidocaine](#), and the limited data suggest it carries a low risk of TNS. It is gaining increasing use for spinal anesthesia in Europe, where it has been marketed specifically for this purpose. No approved formulation exists in the USA, and there is no formulation that would be appropriate to use for spinal anesthesia as an off-label indication.

## ROPIVACAINE

[Ropivacaine](#) is an *S*(-) enantiomer in a homologous series that includes [bupivacaine](#) and [mepivacaine](#), distinguished by its chirality and the propyl group off the piperidine ring (see [Table 26-1](#)). Its perceived reduced cardiotoxicity has led to widespread use for high-volume peripheral blocks. However, as previously mentioned, such reduction in toxicity is modest, and its actual advantage over [bupivacaine](#) in most clinical settings has been questioned. Nonetheless, it remains a popular choice for high-volume blocks as well as epidural infusions for control of labor or postoperative pain. Although there is some evidence to suggest that [ropivacaine](#) might produce a more favorable differential block than [bupivacaine](#), the lack of equivalent clinical potency adds complexity to such comparisons.

## EMLA

The term *eutectic* is applied to mixtures in which the combination of elements has a lower melting temperature than its component elements. [Lidocaine](#) and [prilocaine](#) can combine to form such a mixture, which is marketed as EMLA (Eutectic Mixture of Local Anesthetics). This formulation, containing 2.5% [lidocaine](#) and 2.5% [prilocaine](#), permits anesthetic penetration of the keratinized layer of skin, producing localized numbness. It is commonly used in pediatrics to anesthetize the skin prior to venipuncture for intravenous catheter placement.

### Sustained-Release Formulations

The provision of prolonged analgesia or anesthesia, as in the case of postoperative pain management, has traditionally been accomplished by the placement of a catheter to permit continuous administration of anesthetic. More recently, efforts have focused on drug delivery systems that can slowly release anesthetic, thereby providing extended duration without the drawbacks of a catheter. Current developmental efforts have focused on diverse methods of achieving this goal, and one formulation, Exparel, which uses liposomal encapsulation for sustained release of [bupivacaine](#), received FDA approval in 2011. Although this initial approval was limited to infiltration analgesia, it has since been expanded to include interscalene block, while other indications are likely to follow.

### Less Toxic Agents; More Selective Agents

It has been clearly demonstrated that anesthetic neurotoxicity does not result from the blockade of the voltage-gated sodium channel. Thus, effect and tissue toxicity are not mediated by a common mechanism, establishing the possibility of developing compounds with considerably better therapeutic indexes. In addition, the intense binding of site 1 sodium channel biotoxins presents an alternative strategy for providing prolonged block, obviating the need for catheter placement and continuous anesthetic infusion. One such compound, **neosaxitoxin**, is currently undergoing clinical investigation.

As previously discussed, the identification and subclassification of families of neuronal sodium channels have spurred research aimed at the development of more selective sodium channel blockers. The variable neuronal distribution of these isoforms and the unique role that some play in pain signaling suggest that selective blockade of these channels may greatly improve the therapeutic index of sodium channel modulators. For example, compounds specifically targeting  $Na_v1.7$  hold therapeutic promise for effective non-opiate pain control. These channels have abundant representation in dorsal root ganglia: humans with loss-of-function mutations of  $Na_v1.7$  show congenital insensitivity to pain (CIP); while gain-of-function mutations are associated with severe chronic pain syndromes. A number of compounds with specificity for  $Na_v1.7$  have been identified and are currently under clinical development.

## SUMMARY Drugs Used for Local Anesthesia

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities
<b>AMIDES</b>				
<ul style="list-style-type: none"> <li>• <b>Lidocaine</b></li> </ul>	Blockade of sodium channels	Slows, then blocks, action potential propagation	Short-duration procedures • topical (mucosal), intravenous, infiltration, spinal, epidural, minor and major peripheral blocks	Parenteral (eg, peripheral block, but varies significantly based on specific site) • duration 1–2 h • 2–4 h with <b>epinephrine</b> • <i>Toxicity</i> : Central nervous system (CNS) excitation (high-volume blocks) and local neurotoxicity
<ul style="list-style-type: none"> <li>• <b>Bupivacaine</b></li> </ul>	Same as <b>lidocaine</b>	Same as <b>lidocaine</b>	Longer-duration procedures (but not used topically or intravenously)	Parenteral • duration 3–6 h • <i>Toxicity</i> : CNS excitation • cardiovascular collapse (high-volume blocks)
<ul style="list-style-type: none"> <li>• <b>Prilocaine, mepivacaine</b>: Like <b>lidocaine</b> (but also risk of methemoglobinemia with <b>prilocaine</b>)</li> <li>• <b>Articaine</b>: Popular dental anesthetic</li> <li>• <b>Ropivacaine, levobupivacaine</b>: Like <b>bupivacaine</b></li> </ul>				
<b>ESTERS</b>				
<ul style="list-style-type: none"> <li>• <b>Chlorprocaine</b></li> </ul>	Like <b>lidocaine</b>	Like <b>lidocaine</b>	Very short procedures (not generally used topically or intravenously)	Parenteral • duration 30–60 min • 60–90 min with <b>epinephrine</b> • <i>Toxicity</i> : Like <b>lidocaine</b>
<ul style="list-style-type: none"> <li>• <b>Cocaine</b></li> </ul>	Same as above • also has sympathomimetic effects	Same as above	Procedures requiring high surface activity and vasoconstriction	Topical or parenteral • duration 1–2 h • <i>Toxicity</i> : CNS excitation, convulsions, cardiac arrhythmias, hypertension, stroke
<ul style="list-style-type: none"> <li>• <b>Procaine</b>: Like <b>chlorprocaine</b> (but not used epidurally)</li> <li>• <b>Tetracaine</b>: Used primarily for spinal anesthesia; duration 2–3 h</li> <li>• <b>Benzocaine</b>: Used exclusively for topical anesthesia</li> </ul>				

## PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
Articaine	Septocaine
Benzocaine (topical)	Generic
Bupivacaine	Generic, Marcaine, Sensorcaine
Chloroprocaine	Generic, Nesacaine
Cocaine (topical)	Generic
Dibucaine (topical)	Generic, Nupercainal
Dyclonine (topical lozenge)	Cepacol, Sucrets, Dyclone
Intravenous lipid emulsion for overdose	Intralipid
Levobupivacaine	Chirocaine, others
Lidocaine	Generic, Xylocaine
Lidocaine and hydrocortisone (patch)	Generic
Lidocaine and bupivacaine mixture	Duocaine
Lidocaine and prilocaine eutectic mixture (topical)	EMLA cream
Mepivacaine	Generic, Carbocaine
Pramoxine (topical)	Generic, Tronothane
Prilocaine	Citanest
Procaine	Generic, Novocain
Proparacaine (ophthalmic)	Generic, Alcaine, others
Ropivacaine	Generic, Naropin
Tetracaine	Generic, Pontocaine

If a spinal anesthetic technique were selected, **bupivacaine** would be an excellent choice. It has an adequately long duration of action and a relatively unblemished record with respect to neurotoxic injury and transient neurologic symptoms, which are the complications of most concern with spinal anesthetic technique. Although **bupivacaine** has greater potential for cardiotoxicity, this is not a concern when the drug is used for spinal anesthesia because of the extremely low doses required for intrathecal administration. If an epidural technique were chosen for the surgical procedure, the potential for systemic toxicity would need to be considered, making **lidocaine** or **mepivacaine** (generally with **epinephrine**) preferable to **bupivacaine** (or even **ropivacaine** or **levobupivacaine**) because of their better therapeutic indexes with respect to cardiotoxicity. However, systemic toxicity is a lesser (but not nonexistent) concern with epidural or peripheral nerve administration for postoperative pain control, as it involves administration of more dilute anesthetic at a slower rate. The most common agents used for this indication are **bupivacaine**, **ropivacaine**, and **levobupivacaine**.

## Chapter 27: Skeletal Muscle Relaxants

Marieke Kruidering-Hall; Lundy J. Campbell

### CASE STUDY

#### CASE STUDY

An 80-kg 35-year-old woman with a BMI of 32 is undergoing right knee surgery for a meniscus tear. The surgeon and the patient both request general anesthesia for the procedure. In addition to obesity, the patient has hypertension (treated with [hydrochlorothiazide](#)) and insulin-dependent diabetes, and she takes an oral contraceptive pill. She has no known drug allergies. Her physical examination is remarkable only for obesity and a Mallampati class 3 airway (indicating extremely limited space from tongue base to roof of mouth and probable difficulty in intubating). Because of her diabetes and risk for delayed gastric emptying, you elect to use endotracheal intubation to protect her airway during the procedure.

After induction of anesthesia with [propofol](#), you administer a dose of [rocuronium](#) to achieve skeletal muscle relaxation and to facilitate endotracheal intubation. Once fully relaxed, you attempt direct laryngoscopy but are unable to visualize her airway. You make changes to the patient's position, and use a different technique, but you are still unable to perform intubation.

You switch back to bag/mask ventilation, but it has now become more difficult to achieve adequate tidal volumes. You decide to reverse the neuromuscular blockade and wake the patient. (1) What agents could be used to reverse the neuromuscular blockade? (2) What would be the most appropriate agent to use in this scenario? (3) What problems may occur with your chosen agent?

Drugs that affect skeletal muscle function include two different therapeutic groups: those used during surgical procedures and in the intensive care unit (ICU) to produce muscle paralysis (ie, **neuromuscular blockers**), and those used to reduce spasticity in a variety of painful conditions (ie, **spasmolytics** and **antispasmodics**). Neuromuscular blocking drugs interfere with transmission at the neuromuscular end plate and lack central nervous system (CNS) activity. These compounds are used primarily as adjuncts during general anesthesia to optimize surgical conditions and to facilitate endotracheal intubation in order to ensure adequate ventilation. Drugs in the spasmolytic group have traditionally been called “centrally acting” muscle relaxants and are used primarily to treat chronic back pain and painful fibromyalgic conditions. [Dantrolene](#), an agent that has no significant central effects and is used primarily to treat a rare anesthetic-related complication, malignant hyperthermia, is also discussed in this chapter.

## NEUROMUSCULAR BLOCKING DRUGS

### History

During the 16th century, European explorers found that natives in the Amazon Basin of South America were using curare, an arrow poison that produced skeletal muscle paralysis, to kill animals. The active compound, *d*-tubocurarine, and its modern synthetic analogs have had a major influence on the practice of anesthesia and surgery and have proved useful in understanding the basic mechanisms involved in neuromuscular transmission.

### Normal Neuromuscular Function

The mechanism of neuromuscular transmission at the motor end plate is similar to that described for preganglionic cholinergic nerves in [Chapter 6](#).

The arrival of an action potential at the motor nerve terminal causes an influx of calcium and release of the neurotransmitter [acetylcholine](#).

www.studycart24.com  
www.studycart24.com then diffuses across the synaptic cleft to activate nicotinic receptors located on the motor end plate, present at a density of  $10,000/\mu\text{m}^2$  in some species. As noted in Chapter 7, the adult  $N_M$  receptor is composed of five peptides: two alpha peptides, one beta, one gamma, and one delta peptide (Figure 27-1). The binding of two acetylcholine molecules to receptors on the  $\alpha$ - $\beta$  and  $\delta$ - $\alpha$  subunits causes opening of the channel. The subsequent movement of sodium and potassium through the channel is associated with a graded depolarization of the end plate membrane (see Figure 7-4, panel B). This change in voltage is termed the motor end plate potential. The magnitude of the end plate potential is directly related to the amount of acetylcholine released. If the potential is small, the permeability and the end plate potential return to normal without an impulse being propagated from the end plate region to the rest of the muscle membrane. However, if the end plate potential is large, the adjacent muscle membrane is depolarized, and an action potential will be propagated along the entire muscle fiber. Muscle contraction is then initiated by excitation-contraction coupling. The released acetylcholine is quickly removed from the end plate region by both diffusion and enzymatic destruction by the local acetylcholinesterase enzyme.

FIGURE 27-1

The adult nicotinic acetylcholine receptor (nAChR) is an intrinsic membrane protein with five distinct subunits ( $\alpha_2 \beta \delta \gamma$ ). **(A)** Cartoon of one of five subunits of the AChR in the end plate surface of adult mammalian muscle. Each subunit contains four helical domains labeled M1–M4. The M2 domains line the channel pore. **(B)** Cartoon of the full nAChR. The N termini of two subunits cooperate to form two distinct binding pockets for acetylcholine (ACh). These pockets occur at the  $\alpha$ - $\beta$  and the  $\delta$ - $\alpha$  subunit interfaces. Binding of one molecule of ACh enhances the receptor's affinity for the second molecule, followed by multiple intermediate steps leading to channel opening. These steps are the subject of intense investigation.

At least two additional types of **acetylcholine** receptors are found within the neuromuscular apparatus. One type is located on the presynaptic motor axon terminal, and activation of these receptors mobilizes additional transmitter for subsequent release by moving more **acetylcholine** vesicles toward the synaptic membrane. The second type of receptor is found on extrajunctional cells and is not normally involved in neuromuscular transmission. However, under certain conditions (eg, prolonged immobilization, thermal burns), these receptors may proliferate sufficiently to affect subsequent neuromuscular transmission. This proliferation of extrajunctional **acetylcholine** receptors may be clinically relevant when using depolarizing or nondepolarizing skeletal muscle relaxant drugs and is described later.

Skeletal muscle relaxation and paralysis can occur from interruption of function at several sites along the pathway from the CNS to myelinated somatic nerves, unmyelinated motor nerve terminals, nicotinic **acetylcholine** receptors, the motor end plate, the muscle membrane, and the intracellular muscular contractile apparatus itself.

Blockade of end plate function can be accomplished by two basic mechanisms. First, pharmacologic blockade of the physiologic agonist **acetylcholine** is characteristic of the antagonist neuromuscular blocking drugs (ie, nondepolarizing neuromuscular blocking drugs). These drugs prevent access of the transmitter to its receptor and thereby prevent depolarization. The prototype of this nondepolarizing subgroup is **d-tubocurarine**. The second mechanism of blockade can be produced by an excess of a depolarizing agonist, such as **acetylcholine**. This seemingly paradoxical effect of **acetylcholine** also occurs at the ganglionic nicotinic **acetylcholine** receptor. The prototypical depolarizing blocking drug is **succinylcholine**. A similar depolarizing block can be produced by **acetylcholine** itself when high local concentrations are achieved in the synaptic cleft (eg, by cholinesterase inhibitor intoxication) and by **nicotine** and other nicotinic agonists. However, the neuromuscular block produced by depolarizing drugs other than **succinylcholine** cannot be precisely controlled and is of no clinical value.

## BASIC PHARMACOLOGY OF NEUROMUSCULAR BLOCKING DRUGS

### Chemistry

All of the available neuromuscular blocking drugs bear a structural resemblance to **acetylcholine**. For example, **succinylcholine** is two **acetylcholine** molecules linked end-to-end (Figure 27-2). In contrast to the linear structure of **succinylcholine** and other depolarizing drugs, the nondepolarizing agents (eg, **pancuronium**) conceal the “double-acetylcholine” structure in one of two types of bulky, semi-rigid ring systems (see Figure 27-2). Examples of the two major families of nondepolarizing blocking drugs—the isoquinoline and steroid derivatives—are shown in Figures 27-3 and 27-4. Another feature common to all currently used neuromuscular blockers is the presence of one or two quaternary nitrogens, which makes them poorly lipid soluble and limits entry into the CNS.

#### FIGURE 27-2

Structural relationship of **succinylcholine**, a depolarizing agent, and **pancuronium**, a nondepolarizing agent, to **acetylcholine**, the neuromuscular transmitter. **Succinylcholine**, originally called diacetylcholine, is simply two molecules of **acetylcholine** linked through the acetate methyl groups. **Pancuronium** may be viewed as two acetylcholine-like fragments (outlined in color) oriented on a steroid nucleus.

### Pharmacokinetics of Neuromuscular Blocking Drugs

All of the neuromuscular blocking drugs are highly polar compounds and inactive orally; they must be administered parenterally.

The rate of disappearance of a nondepolarizing neuromuscular blocking drug from the blood is characterized by a rapid initial distribution phase followed by a slower elimination phase. Neuromuscular blocking drugs are highly ionized, do not readily cross cell membranes, and are not strongly bound in peripheral tissues. Therefore, their volume of distribution (80–140 mL/kg) is only slightly larger than the blood volume.

The duration of neuromuscular blockade produced by nondepolarizing relaxants is strongly correlated with the elimination half-life. Drugs that are excreted by the kidney typically have longer half-lives, leading to longer durations of action (>35 minutes). Drugs eliminated by the liver tend to have shorter half-lives and durations of action (Table 27–1). All steroidal muscle relaxants are metabolized to their 3-hydroxy, 17-hydroxy, or 3,17-dihydroxy products in the liver. The 3-hydroxy metabolites are usually 40–80% as potent as the parent drug. Under normal circumstances, metabolites are not formed in sufficient quantities to produce a significant degree of neuromuscular blockade during or after anesthesia. However, if the parent compound is administered for several days in the ICU setting, the 3-hydroxy metabolite may accumulate and cause prolonged paralysis because it has a longer half-life than the parent compound. The remaining metabolites possess minimal neuromuscular blocking properties.

TABLE 27–1

**Pharmacokinetic and dynamic properties of neuromuscular blocking drugs.**

Drug	Elimination	Clearance (mL/kg/min)	Approximate Duration of Action (minutes)	Approximate Potency Relative to Tubocurarine
<b>Isoquinoline derivatives</b>				
Atracurium	Spontaneous <sup>1</sup>	6.6	20–35	1.5
Cisatracurium	Mostly spontaneous	5–6	25–44	1.5
Tubocurarine	Kidney (40%)	2.3–2.4	>50	1
<b>Steroid derivatives</b>				
Pancuronium	Kidney (80%)	1.7–1.8	>35	6

Succinylcholine	Plasma ChE <sup>2</sup> (100%)	>100	>8	0.4

<sup>1</sup>Nonenzymatic and enzymatic hydrolysis of ester bonds.

<sup>2</sup>Butyrylcholinesterase (pseudocholinesterase).

The intermediate-acting steroid muscle relaxants (eg, **vecuronium** and **rocuronium**) tend to be more dependent on biliary excretion or hepatic metabolism for their elimination. These muscle relaxants are more commonly used clinically than the long-acting steroid-based drugs (eg, **pancuronium**). The duration of action of these relaxants may be prolonged significantly in patients with impaired liver function.

**Atracurium** (see Figure 27–3) is an intermediate-acting isoquinoline nondepolarizing muscle relaxant that is no longer in widespread clinical use. In

www.kdajournal.in  
In addition to hepatic metabolism, **atracurium** is inactivated by a form of spontaneous breakdown known as Hofmann elimination. The main breakdown products are laudanosine and a related quaternary acid, neither of which possesses neuromuscular blocking properties. Laudanosine is slowly metabolized by the liver and has a longer elimination half-life (ie, 150 minutes). It readily crosses the blood-brain barrier, and high blood concentrations may cause seizures and an increase in the volatile anesthetic requirement. During surgical anesthesia, blood levels of laudanosine typically range from 0.2 to 1 mcg/mL; however, with prolonged infusions of **atracurium** in the ICU, laudanosine blood levels may exceed 5 mcg/mL.

**Atracurium** has several stereoisomers, and the potent isomer **cisatracurium** has become one of the most common muscle relaxants in use today. Although **cisatracurium** resembles **atracurium**, it has less dependence on hepatic inactivation, produces less laudanosine, and is much less likely to release histamine. From a clinical perspective, **cisatracurium** has all the advantages of **atracurium** with fewer adverse effects. Therefore, **cisatracurium** has virtually replaced **atracurium** in clinical practice.

**Gantacurium** represents a new class of nondepolarizing neuromuscular blockers, called asymmetric mixed onium chlorofumarates. It is degraded nonenzymatically by adduction of the amino acid **cysteine** and ester bond hydrolysis. Gantacurium is currently in phase 3 clinical trials and not yet available for widespread clinical use. Preclinical and clinical data indicate gantacurium has a rapid onset of effect and predictable duration of action (very short, similar to **succinylcholine**) that can be reversed with **neostigmine** or more quickly (within 1–2 minutes), with administration of L-cysteine. At doses above three times the ED<sub>95</sub>, cardiovascular adverse effects (eg, hypotension) have occurred, probably due to histamine release. No bronchospasm or pulmonary vasoconstriction has been reported at these higher doses.

## B. Depolarizing Relaxant Drugs

The extremely short duration of action of **succinylcholine** (5–10 minutes) is due to its rapid hydrolysis by butyrylcholinesterase and pseudocholinesterase in the liver and plasma, respectively. Plasma cholinesterase metabolism is the predominant pathway for **succinylcholine** elimination. The primary metabolite of **succinylcholine**, succinylmonocholine, is rapidly broken down to succinic acid and choline. Because plasma cholinesterase has an enormous capacity to hydrolyze **succinylcholine**, only a small percentage of the original intravenous dose ever reaches the neuromuscular junction. In addition, because there is little if any plasma cholinesterase at the motor end plate, a succinylcholine-induced blockade is terminated by its diffusion away from the end plate into extracellular fluid. Therefore, the circulating levels of plasma cholinesterase influence the duration of action of **succinylcholine** by determining the amount of the drug that reaches the motor end plate.

Neuromuscular blockade produced by **succinylcholine** can be prolonged in patients with an abnormal genetic variant of plasma cholinesterase. The **dibucaine number** is a measure of the ability of a patient to metabolize **succinylcholine** and can be used to identify at-risk patients. Under standardized test conditions, **dibucaine** inhibits the normal enzyme by 80% and the abnormal enzyme by only 20%. Many genetic variants of plasma cholinesterase have been identified, although the dibucaine-related variants are the most important. Given the rarity of these genetic variants, plasma cholinesterase testing is not a routine clinical procedure but may be indicated for patients with a family history of plasma cholinesterase deficiency. Another reasonable strategy is to avoid the use of **succinylcholine** where practical in patients with a possible family history of plasma cholinesterase deficiency.

## Mechanism of Action

The interactions of drugs with the **acetylcholine** receptor-end plate channel have been described at the molecular level. Several modes of action of drugs on the receptor are illustrated in **Figure 27–5**.

**FIGURE 27–5**

Schematic diagram of the interactions of drugs with the **acetylcholine** receptor on the end plate channel (structures are purely symbolic). **Top:** The action of the normal agonist, **acetylcholine** (red) in opening the channel. **Bottom, left:** A nondepolarizing blocker, eg, **rocuronium** (yellow), is shown as preventing the opening of the channel when it binds to the receptor. **Bottom, right:** A depolarizing blocker, eg, **succinylcholine** (blue), both occupying the receptor and blocking the channel. Normal closure of the channel gate is prevented, and the blocker may move rapidly in and out of the pore. Depolarizing blockers may desensitize the end plate by occupying the receptor and causing persistent depolarization. An additional effect of drugs on the end plate channel may occur through changes in the lipid environment surrounding the channel (not shown). General anesthetics and alcohols may impair neuromuscular transmission by this mechanism.

### A. Nondepolarizing Relaxant Drugs

All the neuromuscular blocking drugs in current use in the USA except [succinylcholine](#) are classified as nondepolarizing agents. Although it is no longer in widespread clinical use, [d-tubocurarine](#) is considered the prototype neuromuscular blocker. When small doses of nondepolarizing muscle relaxants are administered, they act predominantly at the nicotinic receptor site by competing with [acetylcholine](#). The least potent nondepolarizing relaxants (eg, [rocuronium](#)) have the fastest onset and the shortest duration of action. In larger doses, nondepolarizing drugs can enter the pore of the ion channel (see [Figure 27-5](#)) to produce a more intense motor blockade. This action further weakens neuromuscular transmission and diminishes the ability of the acetylcholinesterase inhibitors (eg, [neostigmine](#), [edrophonium](#), [pyridostigmine](#)) to antagonize the effect of nondepolarizing muscle relaxants.

Nondepolarizing relaxants can also block prejunctional sodium channels. As a result of this action, muscle relaxants interfere with the mobilization of [acetylcholine](#) at the nerve ending and cause fade of evoked nerve twitch contractions ([Figure 27-6](#) and described below). One consequence of the surmountable nature of the postsynaptic blockade produced by nondepolarizing muscle relaxants is the fact that tetanic stimulation (rapid delivery of electrical stimuli to a peripheral nerve) releases a large quantity of [acetylcholine](#) and is followed by transient posttetanic facilitation of the twitch strength (ie, relief of blockade). An important clinical consequence of this principle is the reversal of residual blockade by cholinesterase inhibitors. The characteristics of a nondepolarizing neuromuscular blockade are summarized in [Table 27-2](#) and [Figure 27-6](#).

FIGURE 27-6

Muscle contraction responses to different patterns of nerve stimulation used in monitoring skeletal muscle relaxation. The alterations produced by a nondepolarizing blocker and depolarizing and desensitizing blockade by [succinylcholine](#) are shown. In the train-of-four (TOF) pattern, four stimuli are

applied at 2 Hz. The TOF ratio (TOF-R) is calculated from the strength of the fourth contraction divided by that of the first. In the double-burst pattern, three stimuli are applied at 50 Hz, followed by a 700 ms rest period and then repeated. In the posttetanic potentiation pattern, several seconds of 50 Hz stimulation are applied, followed by several seconds of rest and then by single stimuli at a slow rate (eg, 0.5 Hz). The number of detectable posttetanic twitches is the posttetanic count (PTC), \* first posttetanic contraction.

No Drug	Nondepolarizing Block	Depolarizing Block	
		Phase I	Phase II
<b>Train-of-four</b>  TOF-R = 1.0	<b>Fade</b>  TOF-R = 0.4	<b>Constant but diminished</b>  TOF-R = 1.0	<b>Fade</b>  TOF-R = 0.4

Comparison of a typical nondepolarizing muscle relaxant (**rocuronium**) and a depolarizing muscle relaxant (**succinylcholine**).

		Succinylcholine	
	Rocuronium	Phase I	Phase II
Administration of tubocurarine	Additive	Antagonistic	Augmented <sup>1</sup>
Administration of succinylcholine	Antagonistic	Additive	Augmented <sup>1</sup>
Effect of neostigmine	Antagonistic	Augmented <sup>1</sup>	Antagonistic
Initial excitatory effect on skeletal muscle	None	Fasciculations	None
Response to a tetanic stimulus	Unsustained (fade)	Sustained <sup>2</sup> (no fade)	Unsustained (fade)
Posttetanic facilitation	Yes	No	Yes
Rate of recovery	30–60 min <sup>3</sup>	4–8 min	>20 min <sup>3</sup>

<sup>1</sup>It is not known whether this interaction is additive or synergistic (super additive).

<sup>2</sup>The amplitude is decreased, but the response is sustained.

<sup>3</sup>The rate depends on the dose and on the completeness of neuromuscular blockade.

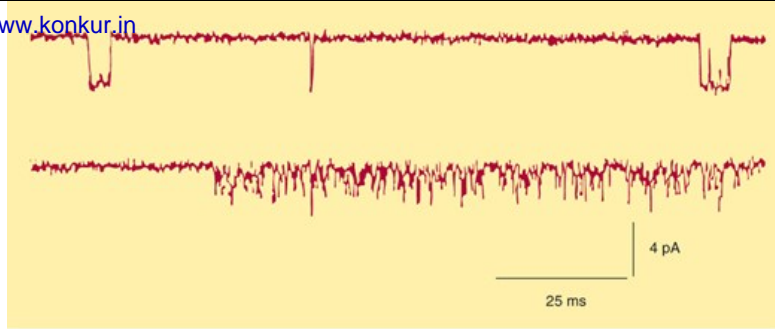

**B. Depolarizing Relaxant Drugs**

**1. Phase I block (depolarizing)**

Succinylcholine is the only clinically useful depolarizing blocking drug. Its neuromuscular effects are like those of acetylcholine except that succinylcholine produces a longer effect at the myoneural junction. Succinylcholine reacts with the nicotinic receptor to open the channel and cause depolarization of the motor end plate, and this in turn spreads to the adjacent membranes, causing transient contractions of muscle motor units. Data from single-channel recordings indicate that depolarizing blockers can enter the channel to produce a prolonged “flickering” of the ion conductance (Figure 27-7). Because succinylcholine is not metabolized effectively at the synapse, the depolarized membranes remain depolarized and unresponsive to subsequent impulses (ie, a state of depolarizing blockade). Furthermore, because excitation-contraction coupling requires end plate repolarization (“repriming”) and repetitive firing to maintain muscle tension, a flaccid paralysis results. In contrast to the nondepolarizing drugs, this so-called phase I (depolarizing) block is augmented, not reversed, by cholinesterase inhibitors.

FIGURE 27-7

Action of succinylcholine on single-channel end plate receptor currents in frog muscle. Currents through a single AChR channel were recorded using the patch clamp technique. The upper trace was recorded in the presence of a low concentration of succinylcholine; the downward deflections represent openings of the channel and passage of inward (depolarizing) current. The lower trace was recorded in the presence of a much higher concentration of succinylcholine and shows prolonged “flickering” of the channel as it repetitively opens and closes or is “plugged” by the drug. (Reproduced with permission from Marshall CG, Ogden DC, Colquhoun D. The actions of suxamethonium (succinylcholine) as an agonist and channel blocker at the nicotinic receptor of frog muscle. J Physiol. 1990;428:155–174.)

Source: Todd W. Vanderah:  
Basic & Clinical Pharmacology, Sixteenth Edition  
Copyright © McGraw Hill. All rights reserved.

The characteristics of a depolarizing neuromuscular blockade are summarized in Table 27-2 and Figure 27-6.

## 2. Phase II block (desensitizing)

With prolonged exposure to **succinylcholine**, the initial end plate depolarization decreases, and the membrane becomes repolarized. Despite this repolarization, the membrane cannot easily be depolarized again because it is *desensitized*. The mechanism for this desensitizing phase is unclear, but some evidence indicates that channel block may become more important than agonist action at the receptor in phase II of **succinylcholine's** neuromuscular blocking action. Regardless of the mechanism, the channels behave as if they are in a prolonged closed state (see Figure 27-6). Later in phase II, the characteristics of the blockade are nearly identical to those of a nondepolarizing block (ie, a nonsustained twitch response to a tetanic stimulus) (see Figure 27-6), with possible reversal by acetylcholinesterase inhibitors.

# CLINICAL PHARMACOLOGY OF NEUROMUSCULAR BLOCKING DRUGS

## Skeletal Muscle Paralysis

Before the introduction of neuromuscular blocking drugs, profound skeletal muscle relaxation for intracavitary operations could be achieved only by producing levels of volatile (inhaled) anesthesia deep enough to produce profound depressant effects on the cardiovascular and respiratory systems. The adjunctive use of neuromuscular blocking drugs makes it possible to achieve adequate muscle relaxation for all types of surgical procedures without the cardiorespiratory depressant effects produced by deep anesthesia.

## Assessment of Neuromuscular Transmission

Monitoring the effect of muscle relaxants during surgery (and recovery following the administration of cholinesterase inhibitors) typically involves the use of a device that produces transdermal electrical stimulation of one of the peripheral nerves to the hand or facial muscles and recording of the evoked contractions (ie, twitch responses). The motor responses to different patterns of peripheral nerve stimulation can be recorded in the operating room during the procedure (see Figure 27-6). The standard approach for monitoring the clinical effects of muscle relaxants during surgery uses peripheral nerve stimulation to elicit motor responses, which are visually observed by the anesthesiologist. The three most commonly used patterns include (1) single-twitch stimulation, (2) train-of-four (TOF) stimulation, and (3) tetanic stimulation. Two other modalities are also available to monitor neuromuscular transmission: double-burst stimulation and posttetanic count.

With single-twitch stimulation, a single supramaximal electrical stimulus is applied to a peripheral nerve at frequencies from 0.1 Hz to 1.0 Hz. The higher frequency is often used during induction and reversal to more accurately determine the peak (maximal) drug effect. TOF stimulation involves four successive supramaximal stimuli given at intervals of 0.5 second (2 Hz). Each stimulus in the TOF causes the muscle to contract, and the relative magnitude of the response of the fourth twitch compared with the first twitch is the TOF ratio. With a depolarizing block, all four twitches are reduced in a dose-related fashion. With a nondepolarizing block, the TOF ratio decreases (“fades”) and is inversely proportional to the degree of blockade. During recovery from nondepolarizing block, the amount of fade decreases and the TOF ratio approaches 1.0. Recovery to a TOF ratio greater than 0.7 is typically necessary for resumption of spontaneous ventilation. However, complete clinical recovery from a nondepolarizing block is considered to require a TOF greater than 0.9. Fade in the TOF response after administration of **succinylcholine** signifies the development of a phase II block.

Tetanic stimulation, consists of a very rapid (30–100 Hz) delivery of electrical stimuli for several seconds. During a nondepolarizing neuromuscular

block (and a phase II block after **succinylcholine**), the response is not sustained, and fade of the twitch response is observed. Fade in response to tetanic stimulation is normally considered a presynaptic event. However, the degree of fade depends primarily on the degree of neuromuscular blockade. During a partial nondepolarizing blockade, tetanic nerve stimulation is followed by an increase in the posttetanic twitch response, so-called *posttetanic facilitation* of neuromuscular transmission. During intense neuromuscular blockade, there is no response to either tetanic or posttetanic stimulation. As the intensity of the block diminishes, the response to posttetanic twitch stimulation reappears. The reappearance of the first response to twitch stimulation after tetanic stimulation reflects the duration of profound (clinical) neuromuscular blockade. To determine the posttetanic count, 5 seconds of 50 Hz tetany is applied, followed by 3 seconds of rest, followed by 1 Hz pulses for about 10 seconds (10 pulses). The counted number of muscle twitches provides an estimation of the depth of blockade. For instance, a posttetanic count of 2 suggests no twitch response (by TOF) for about 20–30 minutes, and a posttetanic count of 5 correlates to a no-twitch response (by TOF) of about 10–15 minutes (see [Figure 27-6](#), bottom panel).

The double-burst stimulation pattern is another mode of electrical nerve stimulation developed with the goal of allowing for manual detection of residual neuromuscular blockade when it is not possible to record the responses to single-twitch, TOF, or tetanic stimulation. In this pattern, three nerve stimuli are delivered at 50 Hz followed by a 700 ms rest period and then by two or three additional stimuli at 50 Hz. It is easier to detect fade in the responses to double-burst stimulation than to TOF stimulation. The absence of fade in response to double-burst stimulation implies that clinically significant residual neuromuscular blockade does not exist.

A more quantitative approach to neuromuscular monitoring involves monitoring using a force transducer for measuring the evoked response (ie, movement) of the thumb to TOF stimulation over the ulnar nerve at the wrist. This device has the advantage of being integrated in the anesthesia machine and also provides a more accurate graphic display of the percentage of fade to TOF stimulation.

#### A. Nondepolarizing Relaxant Drugs

During anesthesia, administration of tubocurarine, 0.1–0.4 mg/kg IV, initially causes motor weakness, followed by the skeletal muscles becoming flaccid and inexcitable to electrical stimulation ([Figure 27-8](#)). In general, larger muscles (eg, abdominal, trunk, paraspinal, diaphragm) are more resistant to neuromuscular blockade and recover more rapidly than smaller muscles (eg, facial, foot, hand). The diaphragm is usually the last muscle to be paralyzed. Assuming that ventilation is adequately maintained, no adverse effects occur with skeletal muscle paralysis. When administration of muscle relaxants is discontinued, recovery of muscles usually occurs in reverse order, with the diaphragm regaining function first. The pharmacologic effect of tubocurarine, 0.3 mg/kg IV, usually lasts 45–60 minutes. However, subtle evidence of residual muscle paralysis detected using a neuromuscular monitor may last for another hour, increasing the likelihood of adverse outcomes, eg, aspiration and decreased hypoxic drive. Potency and duration of action of the other nondepolarizing drugs are shown in [Table 27-1](#). In addition to the duration of action, the most important property distinguishing the nondepolarizing relaxants is the time to onset of the blocking effect, which determines how rapidly the patient's trachea can be intubated. Of the currently available nondepolarizing drugs, **rocuronium** has the most rapid onset time (60–120 seconds).

FIGURE 27-8

Neuromuscular blockade from tubocurarine during equivalent levels of **isoflurane** and halothane anesthesia in patients. Note that **isoflurane** augments the block far more than does halothane. MAC, minimal alveolar concentration.

Following the administration of **succinylcholine**, 0.75–1.5 mg/kg IV, transient muscle fasciculations occur over the chest and abdomen within 30 seconds, although general anesthesia and the prior administration of a small dose of a nondepolarizing muscle relaxant tend to attenuate them. As paralysis develops rapidly (<90 seconds), the arm, neck, and leg muscles are initially relaxed followed by the respiratory muscles. As a result of **succinylcholine**'s rapid hydrolysis by cholinesterase in the plasma (and liver), the neuromuscular block typically lasts less than 10 minutes (see **Table 27-1**).

### Cardiovascular Effects

**Vecuronium**, **cisatracurium**, and **rocuronium** have minimal, if any, cardiovascular effects. The other nondepolarizing muscle relaxants (ie, **pancuronium** and **atracurium**) produce cardiovascular effects that are mediated by autonomic or histamine receptors (**Table 27-3**). Tubocurarine and, to a lesser extent, **atracurium** can produce hypotension as a result of systemic histamine release, and with larger doses, ganglionic blockade may occur with tubocurarine. Premedication with an antihistaminic compound attenuates tubocurarine-induced hypotension. **Pancuronium** causes a moderate increase in heart rate and a smaller increase in cardiac output, with little or no change in systemic vascular resistance. Although pancuronium-induced tachycardia is primarily due to a vagolytic action, release of **norepinephrine** from adrenergic nerve endings and blockade of neuronal uptake of **norepinephrine** may be secondary mechanisms. Bronchospasm may be produced by neuromuscular blockers that release histamine (eg, **atracurium**), but after induction of general anesthesia, insertion of an endotracheal tube is the most common cause of bronchospasm.

TABLE 27-3

**Effects of neuromuscular blocking drugs on other tissues.**

Drug	Effect on Autonomic Ganglia	Effect on Cardiac Muscarinic Receptors	Tendency to Cause Histamine Release
<b>Isoquinoline derivatives</b>			
<b>Atracurium</b>	None	None	Slight
<b>Cisatracurium</b>	None	None	None
Tubocurarine	Weak block	None	Moderate
<b>Steroid derivatives</b>			
<b>Pancuronium</b>	None	Moderate block	None
<b>Rocuronium</b> <sup>1</sup>	None	Slight	None
<b>Vecuronium</b>	None	None	None
<b>Other agents</b>			
Gallamine	None	Strong block	None
<b>Succinylcholine</b>	Stimulation	Stimulation	Slight

<sup>1</sup>Allergic reactions have been reported.

www.donkey.in  
The negative inotropic and chronotropic responses to **succinylcholine** can be attenuated by administration of an anticholinergic drug (eg, **glycopyrrolate**, **atropine**). With large doses of **succinylcholine**, positive inotropic and chronotropic effects may be observed. On the other hand, bradycardia has been repeatedly observed when a second dose of **succinylcholine** is given less than 5 minutes after the initial dose. This transient bradycardia can be prevented by thiopental, **atropine**, and ganglionic-blocking drugs, and by pretreating with a small dose of a nondepolarizing muscle relaxant (eg, **rocuronium**). Direct myocardial effects, increased muscarinic stimulation, and ganglionic stimulation contribute to this bradycardic response.

## Other Adverse Effects of Depolarizing Blockade

### A. Hyperkalemia

Patients with burns, nerve damage or neuromuscular disease, closed head injury, and other trauma may develop proliferation of extrajunctional **acetylcholine** receptors. During administration of **succinylcholine**, potassium is released from muscles, likely due to fasciculations. If the proliferation of extrajunctional receptors is great enough, sufficient potassium may be released to result in cardiac arrest. The exact time course of receptor proliferation is unknown; therefore, it is best to avoid the use of **succinylcholine** in these cases.

### B. Increased Intraocular Pressure

Administration of **succinylcholine** may be associated with the rapid onset of an increase in intraocular pressure (<60 seconds), peaking at 2–4 minutes, and declining after 5 minutes. The mechanism may involve tonic contraction of myofibrils or transient dilation of ocular choroidal blood vessels. Despite the increase in intraocular pressure, the use of **succinylcholine** for ophthalmologic operations is not contraindicated unless the anterior chamber is open (“open globe”) due to trauma.

### C. Increased Intra gastric Pressure

In heavily muscled patients, the fasciculations associated with **succinylcholine** may cause an increase in intra gastric pressure ranging from 5 to 40 cm H<sub>2</sub>O, increasing the risk for regurgitation and aspiration of gastric contents. This complication is more likely to occur in patients with delayed gastric emptying (eg, those with diabetes), traumatic injury (eg, an emergency case), esophageal dysfunction, and morbid obesity.

### D. Muscle Pain

Myalgias are a common postoperative complaint of heavily muscled patients and those who receive large doses (>1.5 mg/kg) of **succinylcholine**. The true incidence of myalgias related to muscle fasciculations is difficult to establish because of confounding factors, including the anesthetic technique, type of surgery, and positioning during the operation. However, the incidence of myalgias has been reported to vary from less than 1% to 20%. It occurs more frequently in ambulatory than in bedridden patients. The pain is thought to be secondary to the unsynchronized contractions of adjacent muscle fibers just before the onset of paralysis. However, there is controversy over whether the incidence of muscle pain following **succinylcholine** is actually higher than with nondepolarizing muscle relaxants when other potentially confounding factors are taken into consideration.

## Interactions with Other Drugs

### A. Anesthetics

Inhaled (volatile) anesthetics potentiate the neuromuscular blockade produced by nondepolarizing muscle relaxants in a dose-dependent fashion. Of the general anesthetics that have been studied, inhaled anesthetics augment the effects of muscle relaxants in the following order: **isoflurane** (most), **sevoflurane**, **desflurane**, halothane, and nitrous oxide (least) (see **Figure 27–8**). The most important factors involved in this interaction are the following: (1) nervous system depression at sites proximal to the neuromuscular junction (ie, CNS); (2) increased muscle blood flow (ie, due to peripheral vasodilation produced by volatile anesthetics), which allows a larger fraction of the injected muscle relaxant to reach the neuromuscular junction; and (3) decreased sensitivity of the postjunctional membrane to depolarization.

A rare interaction of **succinylcholine** with volatile anesthetics results in **malignant hyperthermia**, a condition caused by abnormal release of calcium from stores in skeletal muscle. This condition is treated with **dantrolene** and is discussed below under Spasmolytic & Antispasmodic Drugs and in

Numerous reports have described enhancement of neuromuscular blockade by antibiotics (eg, aminoglycosides). Many of the antibiotics have been shown to cause a depression of evoked release of **acetylcholine** similar to that caused by administering magnesium. The mechanism of this prejunctional effect appears to be blockade of specific P-type calcium channels in the motor nerve terminal.

### C. Local Anesthetics and Antiarrhythmic Drugs

In small doses, local anesthetics can depress posttetanic potentiation via a prejunctional neural effect. In large doses, local anesthetics can block neuromuscular transmission. With these higher doses, local anesthetics block acetylcholine-induced muscle contractions as a result of blockade of the nicotinic receptor ion channels. Experimentally, similar effects can be demonstrated with sodium channel-blocking antiarrhythmic drugs such as **quinidine**. However, at the doses used for cardiac arrhythmias, this interaction is of little or no clinical significance. Higher doses of **bupivacaine** have been associated with cardiac arrhythmias independent of the muscle relaxant used.

### D. Other Neuromuscular Blocking Drugs

The end plate-depolarizing effect of **succinylcholine** can be antagonized by administering a small dose of a nondepolarizing blocker. To prevent the fasciculations associated with **succinylcholine** administration, a small nonparalyzing dose of a nondepolarizing drug can be given before **succinylcholine** (eg, *d*-tubocurarine, 2 mg IV, or **pancuronium**, 0.5 mg IV). Although this dose usually reduces fasciculations and postoperative myalgias, it can increase the amount of **succinylcholine** required for relaxation by 50–90% and can produce a feeling of weakness in awake patients. Therefore, “pre-curarization” before **succinylcholine** is no longer widely practiced.

## Effects of Diseases & Aging on the Neuromuscular Response

Several diseases can diminish or augment the neuromuscular blockade produced by nondepolarizing muscle relaxants. Myasthenia gravis enhances the neuromuscular blockade produced by these drugs. Advanced age is associated with a prolonged duration of action from nondepolarizing relaxants as a result of decreased clearance of the drugs by the liver and kidneys. As a result, the dosage of neuromuscular blocking drugs should be reduced in older patients (>70 years).

Conversely, patients with severe burns and those with upper motor neuron disease are resistant to nondepolarizing muscle relaxants. This desensitization is probably caused by proliferation of extrajunctional receptors, which results in an increased dose requirement for the nondepolarizing relaxant to block a sufficient number of receptors.

## Reversal of Nondepolarizing Neuromuscular Blockade

The cholinesterase inhibitors effectively antagonize the neuromuscular blockade caused by nondepolarizing drugs. Their general pharmacology is discussed in **Chapter 7**. **Neostigmine** and **pyridostigmine** antagonize nondepolarizing neuromuscular blockade by increasing the availability of **acetylcholine** at the motor end plate, mainly by inhibition of acetylcholinesterase. To a lesser extent, these cholinesterase inhibitors also increase the release of this transmitter from the motor nerve terminal. In contrast, **edrophonium** antagonizes neuromuscular blockade purely by inhibiting acetylcholinesterase activity. **Edrophonium** has a more rapid onset of action but may be less effective than **neostigmine** in reversing the effects of nondepolarizing blockers in the presence of profound neuromuscular blockade. These differences are important in determining recovery from *residual block*, the neuromuscular blockade remaining after completion of surgery and movement of the patient to the recovery room. Unsuspected residual block may result in hypoventilation, leading to hypoxia and even apnea, especially if patients have received central depressant medications in the early recovery period.

**Sugammadex** is a reversal agent approved for rapid reversal of the steroid neuromuscular blocking agents **rocuronium** and **vecuronium**. Although it has been in clinical use in Europe since 2008, its approval in the USA was delayed because of concerns that it causes a low incidence of anaphylaxis and hypersensitivity reactions. **Sugammadex** is a modified  $\gamma$ -cyclodextrin (a large ring structure with 16 polar hydroxyl groups facing inward and 8 polar carboxyl groups facing outward) that binds tightly to **rocuronium** in a 1:1 ratio. By binding to plasma **rocuronium**, **sugammadex** decreases the free plasma concentration and establishes a concentration gradient for **rocuronium** to diffuse away from the neuromuscular junction back into the

Currently, three dose ranges are recommended for **sugammadex**: 2 mg/kg to reverse shallow neuromuscular blockade (spontaneous recovery has reached the second twitch in TOF stimulation), 4 mg/kg to reverse deeper blockade (1–2 posttetanic count and no response to TOF stimulation), and 16 mg/kg for immediate reversal following administration of a single dose of 1.2 mg/kg of **rocuronium**. In patients with normal renal function (defined as a creatinine clearance [CrCl] > 80 mL/min), the sugammadex-rocuronium complex is typically excreted unchanged in the urine within 24 hours. In patients with renal insufficiency, complete urinary elimination may take much longer. The plasma half-life of **sugammadex** in patients with renal impairment increases significantly as CrCl is reduced. In mild to moderate renal insufficiency (CrCl between 30 and 80 mL/min), the half-life varies between 4 and 6 hours. This increases dramatically in patients with severe renal impairment (CrCl > 30 mL/min), in whom the half-life is extended to 19 hours. The ability to dialyze **sugammadex** is variable, although some studies have demonstrated the ability to dialyze it using a high-flux method. Therefore, **sugammadex** is not recommended for use in patients with severe renal impairment unless absolutely necessary.

**Sugammadex** is associated with a few significant adverse reactions. Most importantly, **sugammadex** may cause anaphylaxis, which occurred in 0.3% of patients who received the 16 mg/kg dose in the US Food and Drug Administration (FDA) studies. Hypersensitivity reactions, such as nausea, pruritus, and urticaria, are more common than anaphylaxis, and also occur more frequently with higher doses of **sugammadex**. Other significant adverse reactions include marked bradycardia that may progress to cardiac arrest within minutes of administration and coagulopathy, with an approximately 25% elevation of activated partial thromboplastin time and prothrombin time/international normalized ratio values that may last up to 1 hour.

Because **sugammadex** binds the steroidal neuromuscular blocking agents **rocuronium** and **vecuronium**, it is not surprising that it can also block other steroidal drugs. The two most important of these drugs are progesterone-based contraceptives and the selective estrogen receptor modulator **toremifene**. When **sugammadex** is administered to a woman who is taking hormonal contraceptives that contain **progesterone**, the **progesterone** may be bound by **sugammadex**, and the efficacy of the contraceptive is decreased as if the woman missed one or two doses. The manufacturer recommends that an alternative nonhormonal contraceptive be used for 7 days following **sugammadex** administration. **Sugammadex** also very tightly binds **toremifene**, which may be used to treat metastatic breast cancer (see **Chapter 40**). Not only will the efficacy of **toremifene** be reduced, but displacement of **rocuronium** from **sugammadex** may result, and prolonged neuromuscular blockade could occur.

## Uses of Neuromuscular Blocking Drugs

### A. Surgical Relaxation

One of the most important applications of the neuromuscular blockers is in facilitating intracavitary surgery, especially in intra-abdominal and intrathoracic procedures.

### B. Endotracheal Intubation

By relaxing the pharyngeal and laryngeal muscles, neuromuscular blocking drugs facilitate laryngoscopy and placement of an endotracheal tube. Endotracheal tube placement ensures an adequate airway and minimizes the risk of pulmonary aspiration during general anesthesia.

### C. Control of Ventilation

In critically ill patients who have ventilatory failure from various causes (eg, severe bronchospasm, pneumonia, chronic obstructive airway disease), it may be necessary to control ventilation to provide adequate gas exchange and to prevent atelectasis. In the ICU, neuromuscular blocking drugs are frequently administered to reduce chest wall resistance (ie, improve thoracic compliance), decrease **oxygen** utilization, and improve ventilator synchrony.

### D. Treatment of Convulsions

Neuromuscular blocking drugs (ie, **succinylcholine**) are occasionally used to attenuate the peripheral (motor) manifestations of convulsions associated with status epilepticus, local anesthetic toxicity, or electroconvulsive therapy. Although this approach is effective in eliminating the muscular manifestations of the seizures, it has no effect on the central processes because neuromuscular blocking drugs do not cross the blood-brain barrier.

www.dorland.com Muscle relaxants include neuromuscular blockers, spasmolytics, and antispasmodics. Spasmolytics and antispasmodics are used to treat two conditions: spasms from peripheral musculoskeletal conditions (antispasmodics) and spasticity from upper motor neuron lesions (spasmolytics).

Spasticity presents as intermittent or sustained involuntary contraction of skeletal muscle, causing stiffness that interferes with mobility and speech. It is characterized by an increase in tonic stretch reflexes and flexor muscle spasms (ie, increased basal muscle tone) together with muscle weakness. It is often associated with spinal injury, cerebral palsy, multiple sclerosis, and stroke. The mechanisms underlying clinical spasticity appear to involve not only the stretch reflex arc itself but also higher centers in the CNS, with damage to descending pathways in the spinal cord resulting in hyperexcitability of the alpha motor neurons in the cord. The important components involved in these processes are shown in [Figure 27-9](#). Pharmacologic therapy may ameliorate some of the symptoms of spasticity by modifying the stretch reflex arc or by interfering directly with skeletal muscle (ie, excitation-contraction coupling).

FIGURE 27-9

Schematic illustration of the structures involved in the stretch reflex (right half) showing innervation of extrafusal (striated muscle) fibers by alpha motor neurons and of intrafusal fibers (within muscle spindle) by gamma motor neurons. The left half of the diagram shows an inhibitory reflex arc, which includes an intercalated inhibitory interneuron. (Reproduced with permission from Waxman SG: *Clinical Neuroanatomy*, 26th ed. New York, NY: McGraw Hill; 2009.)

Drugs that modify the reflex arc may modulate excitatory or inhibitory synapses (see [Chapter 21](#)). Thus, to reduce the hyperactive stretch reflex, it is desirable to reduce the activity of the Ia fibers that excite the primary motor neuron or to enhance the activity of the inhibitory internuncial neurons. These structures are shown in greater detail in [Figure 27-10](#).

FIGURE 27-10

Postulated sites of spasmolytic action of [tizanidine](#) ( $\alpha_2$ ), benzodiazepines ( $GABA_A$ ), and [baclofen](#) ( $GABA_B$ ) in the spinal cord. [Tizanidine](#) may also have a postsynaptic inhibitory effect. [Dantrolene](#) acts on the sarcoplasmic reticulum in skeletal muscle. Glu, glutamatergic neuron.

A variety of pharmacologic agents described as depressants of the spinal “polysynaptic” reflex arc (eg, barbiturates [[phenobarbital](#)] and glycerol ethers [[mephenesin](#)]) have been used to treat these conditions of excess skeletal muscle tone. However, as illustrated in [Figure 27–10](#), nonspecific depression of synapses involved in the stretch reflex could reduce the desired GABAergic inhibitory activity, as well as the excitatory glutamatergic transmission. Currently available drugs can provide significant relief from painful muscle spasms, but they are less effective in improving meaningful function (eg, mobility and return to work).

## Diazepam

As described in [Chapter 22](#), benzodiazepines facilitate the action of GABA in the CNS. [Diazepam](#) acts at GABA<sub>A</sub> synapses, and its action in reducing spasticity is at least partly mediated in the spinal cord because it is somewhat effective in patients with cord transection. Although [diazepam](#) can be used in patients with muscle spasm of almost any origin (including local muscle trauma), it also produces sedation at the doses required to reduce muscle tone. The initial dosage is 4 mg/d, and it is gradually increased to a maximum of 60 mg/d. Other benzodiazepines have been used as spasmolytics (eg, [midazolam](#)), but clinical experience with them is limited.

[Meprobamate](#) and [carisoprodol](#) are sedatives that have been used as central muscle relaxants, although evidence for their efficacy without sedation is lacking. [Carisoprodol](#) is a schedule IV drug; it is metabolized to [meprobamate](#), which is also a schedule IV drug. Withdrawal of [carisoprodol](#) and [meprobamate](#) after extensive use elicits physical withdrawal, with anxiety, tremors, muscle twitching, insomnia, and auditory and visual hallucinations.

## Baclofen

[Baclofen](#) (*p*-chlorophenyl-GABA) was designed to be an orally active GABA-mimetic agent and is an agonist at GABA<sub>B</sub> receptors. Activation of these receptors by [baclofen](#) results in hyperpolarization by three distinct actions: (1) closure of presynaptic calcium channels, (2) increased postsynaptic K<sup>+</sup> conductance, and (3) inhibition of dendritic calcium influx channels. Through reduced release of excitatory transmitters in both the brain and the spinal cord, [baclofen](#) suppresses activity of Ia sensory afferents, spinal interneurons, and motor neurons (see [Figure 27–10](#)). [Baclofen](#) may also reduce pain in patients with spasticity, perhaps by inhibiting the release of substance P (neurokinin 1) in the spinal cord.

**Baclofen**

[Baclofen](#) is as effective as [diazepam](#) and [tizanidine](#) (discussed below) in reducing spasticity and is less sedating than [diazepam](#). [Baclofen](#) does

not reduce overall muscle strength as much as [dantrolene](#). It is rapidly and completely absorbed after oral administration and has a plasma half-life of 3–4 hours. Dosage is started at 15 mg twice daily, increasing as tolerated to 100 mg daily. Studies have confirmed that intrathecal catheter administration of [baclofen](#) can control severe spasticity and muscle pain that is not responsive to medication by other routes of administration. Owing to the poor egress of [baclofen](#) from the spinal cord, peripheral symptoms are rare. Therefore, higher central concentrations of the drug may be tolerated. Partial tolerance to the effect of the drug may occur after several months of therapy but can be overcome by upward dosage adjustments to maintain the beneficial effect. This tolerance was not confirmed in a recent study and decreased response may represent unrecognized catheter malfunctions. Although a major disadvantage of this therapeutic approach is the difficulty of maintaining the drug delivery catheter in the subarachnoid space, risking an acute withdrawal syndrome upon treatment interruption, long-term intrathecal [baclofen](#) therapy can improve the quality of life for patients with severe spastic disorders. Adverse effects of high-dose [baclofen](#) include excessive somnolence, respiratory depression, and coma. Patients can become tolerant to the sedative effect with chronic administration. Increased seizure activity has been reported in epileptic patients. Withdrawal from [baclofen](#) must be done very slowly. [Baclofen](#) should be used with caution during pregnancy; although there are no reports of [baclofen](#) directly causing human fetal malformations, animal studies using high doses show that it causes impaired sternal ossification and omphalocele.

Oral [baclofen](#) has been studied in many other medical conditions, including patients with intractable low back pain, stiff person syndrome, trigeminal neuralgia, cluster headache, intractable hiccups, tic disorder, gastroesophageal reflux disease, and cravings for [alcohol](#), [nicotine](#), and [cocaine](#) (see [Chapter 32](#)). Efficacy of oral [baclofen](#) has not been established in patients with stroke, Parkinson disease, or cerebral palsy.

## TIZANIDINE

As noted in [Chapter 11](#),  $\alpha_2$ -adrenoceptor agonists such as [clonidine](#) and other imidazoline compounds have a variety of effects on the CNS that are not fully understood. Among these effects is the ability to reduce muscle spasm. [Tizanidine](#) is a congener of [clonidine](#) that has been studied for its spasmolytic actions. [Tizanidine](#) has significant  $\alpha_2$ -agonist effects, but it reduces spasticity in experimental models at doses that cause fewer cardiovascular effects than [clonidine](#) or [dexmedetomidine](#). [Tizanidine](#) has approximately one tenth to one fifteenth of the blood pressure-lowering effects of [clonidine](#). Neurophysiologic studies in animals and humans suggest that [tizanidine](#) reinforces both presynaptic and postsynaptic inhibition in the cord. It also inhibits nociceptive transmission in the spinal dorsal horn. [Tizanidine](#)'s actions are believed to be mediated via restoration of inhibitory suppression of the group II spinal interneurons without inducing any changes in intrinsic muscle properties.

Clinical trials with oral [tizanidine](#) report efficacy in relieving muscle spasm comparable to [diazepam](#), [baclofen](#), and [dantrolene](#). [Tizanidine](#) causes markedly less muscle weakness but produces a different spectrum of adverse effects, including drowsiness, hypotension in 16–33%, dizziness, dry mouth, asthenia, and hepatotoxicity, requiring monitoring of liver function, blood pressure, and renal function. The drowsiness can be managed by taking the drug at night. [Tizanidine](#) displays linear pharmacokinetics, and dosage requirements vary considerably among patients. Treatment is initiated at 2 mg every 6–8 hours and can be titrated up to a maximum of 36 mg/d. Dosage must be adjusted in patients with hepatic or renal impairment. [Tizanidine](#) is involved in drug-drug interactions; plasma levels increase in response to CYP1A2 inhibition. Conversely, [tizanidine](#) induces CYP11A1 activity, which is responsible for converting cholesterol to pregnenolone. In addition to its effectiveness in spastic conditions, [tizanidine](#) also appears to be effective for management of chronic migraine. Abrupt withdrawal should be avoided because it results in rebound hypertension, tachycardia, and increased spasms.

## OTHER CENTRALLY ACTING SPASMOLYTIC DRUGS

[Gabapentin](#) is an antiepileptic drug (see [Chapter 24](#)) that has shown considerable promise as a spasmolytic agent in several studies involving patients with multiple sclerosis. [Pregabalin](#) is a newer analog of [gabapentin](#) that may also prove useful in relieving painful disorders that involve a muscle spasm component. Progabide and glycine have also been found in preliminary studies to reduce spasticity. Progabide is a GABA<sub>A</sub> and GABA<sub>B</sub> agonist and has active metabolites, including GABA itself. Glycine is another inhibitory amino acid neurotransmitter (see [Chapter 21](#)) that appears to possess pharmacologic activity when given orally and readily passes the blood-brain barrier. Idrocilamide and [riluzole](#) are newer drugs for the treatment of amyotrophic lateral sclerosis (ALS) that appear to have spasm-reducing effects, possibly through inhibition of glutamatergic transmission in the CNS, although several other mechanisms have been proposed—such as stabilizing the inactivated state of voltage-dependent sodium channels.

## BOTULINUM TOXIN

The therapeutic use of botulinum toxin (BoNT) for ophthalmic purposes and for local muscle spasm was mentioned in [Chapter 6](#). This neurotoxin produces chemodeneration and local paralysis when injected into a muscle. Seven immunologically distinct toxins share homologous subunits. The single-chain polypeptide BoNT has little activity until it is cleaved into a heavy chain (100 kDa) and a light chain (50 kDa). The light chain, a zinc-dependent protease, prevents release of [acetylcholine](#) by interfering with vesicle fusion, through proteolytically cleaving SNAP<sup>\*</sup>-25 (BoNT-A, BoNT-E) or synaptobrevin-2 (BoNT-B, BoNT-D, BoNT-F). Local facial injections of botulinum toxin are widely used for the short-term treatment (1–3 months per treatment) of wrinkles associated with aging around the eyes and mouth. Local injection of botulinum toxin has also become a useful treatment for generalized spastic disorders (eg, cerebral palsy). Most clinical studies to date have involved administration in one or two limbs, and the benefits appear to persist for weeks to several months after a single treatment. BoNT has virtually replaced anticholinergic medications used in the treatment of dystonia. More recently, FDA approval was granted for treatment of incontinence due to overactive bladder and for chronic migraine. Most studies have used several formulations of type A BoNT, but type B is also available.

Adverse effects include respiratory tract infections, muscle weakness, urinary incontinence, falls, fever, and pain. While immunogenicity is currently of much less concern than in the past, experts still recommend that injections not be administered more frequently than every 3 months. Studies to determine safety of more frequent administration are underway. Besides occasional complications, a major limitation of BoNT treatment is its high cost. In addition, post-marketing reports of systemic and potentially fatal effects from spread of the toxin, generated a black box warning. The risk is greatest for children treated for spasticity, but toxicity can occur in adults as well.

## DANTROLENE

[Dantrolene](#) is a hydantoin derivative related to [phenytoin](#) that has a unique mechanism of spasmolytic activity. In contrast to the centrally acting drugs, [dantrolene](#) reduces skeletal muscle strength by interfering with excitation-contraction coupling in the muscle fibers. The normal contractile response involves release of calcium from its stores in the sarcoplasmic reticulum (see [Figures 13–1](#) and [27–10](#)). This activator calcium brings about the tension-generating interaction of actin with myosin. Calcium is released from the sarcoplasmic reticulum via a calcium channel, called the **ryanodine receptor (RyR) channel** because the plant alkaloid ryanodine combines with a receptor on the channel protein. In the case of the skeletal muscle RyR1 channel, ryanodine facilitates the open configuration.

[Dantrolene](#) interferes with the release of activator calcium through this sarcoplasmic reticulum calcium channel by binding to the RyR1 and blocking the opening of the channel. Motor units that contract rapidly are more sensitive to the drug's effects than are slower-responding units. Cardiac muscle and smooth muscle are minimally depressed because the release of calcium from their sarcoplasmic reticulum involves a different RyR channel (RyR2).

Treatment with [dantrolene](#) is usually initiated with 25 mg daily as a single dose, increasing to a maximum of 100 mg four times daily as tolerated. Only about one-third of an oral dose of [dantrolene](#) is absorbed, and the elimination half-life of the drug is approximately 8 hours. Major adverse effects are generalized muscle weakness, sedation, and occasionally hepatitis.

A special application of [dantrolene](#) is in the treatment of **malignant hyperthermia**, a rare heritable disorder that can be triggered by a variety of stimuli, including general anesthetics (eg, volatile anesthetics) and neuromuscular blocking drugs (eg, [succinylcholine](#); see also [Chapter 16](#)). Patients at risk for this condition have a hereditary alteration in Ca<sup>2+</sup>-induced Ca<sup>2+</sup> release via the RyR1 channel or impairment in the ability of the sarcoplasmic reticulum to sequester calcium via the Ca<sup>2+</sup> transporter (see [Figure 27–10](#)). Several mutations associated with this risk have been identified. After administration of one of the triggering agents, there is a sudden and prolonged release of calcium, with massive muscle contraction, lactic acid production, and increased body temperature. Prompt treatment is essential to control acidosis and body temperature and to reduce calcium release. The latter is accomplished by administering intravenous [dantrolene](#), starting with a dose of 1 mg/kg IV, and repeating as necessary to a maximum dose of 10 mg/kg.

## ANTISPASMODICS: DRUGS USED TO TREAT ACUTE LOCAL MUSCLE SPASM

A large number of less well-studied, centrally active drugs (eg, **carisoprodol**, **chlorzoxazone**, **cyclobenzaprine**, **metaxalone**, **methocarbamol**, and **orphenadrine**) are promoted for the relief of acute muscle spasm caused by local tissue trauma or muscle strains. It has been suggested that these drugs act primarily at the level of the brainstem. **Cyclobenzaprine** may be regarded as the prototype of the group. **Cyclobenzaprine** is structurally related to the tricyclic antidepressants and produces antimuscarinic side effects. It is ineffective in treating muscle spasm due to cerebral palsy or spinal cord injury. As a result of its strong antimuscarinic actions, **cyclobenzaprine** may cause significant sedation, as well as confusion and transient visual hallucinations. The dosage of **cyclobenzaprine** for acute injury-related muscle spasm is 20–40 mg/d orally in divided doses. This drug class carries risks of significant adverse events and abuse potential.

### SUMMARY Skeletal Muscle Relaxants

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>DEPOLARIZING NEUROMUSCULAR BLOCKING AGENT</b>				
<ul style="list-style-type: none"> <li><b>Succinylcholine</b></li> </ul>	Agonist at nicotinic <b>acetylcholine</b> (ACh) receptors, especially at neuromuscular junctions • depolarizes • may stimulate ganglionic nicotinic ACh and cardiac muscarinic ACh receptors	Initial depolarization causes transient contractions, followed by prolonged flaccid paralysis • depolarization is then followed by repolarization that is also accompanied by paralysis	Placement of endotracheal tube at start of anesthetic procedure • rarely, control of muscle contractions in status epilepticus	Rapid metabolism by plasma cholinesterase • normal duration ~5 min • <b>Toxicities:</b> Arrhythmias • hyperkalemia • transient increased intra-abdominal, intraocular pressure • postoperative muscle pain
<b>NONDEPOLARIZING NEUROMUSCULAR BLOCKING AGENTS</b>				
<ul style="list-style-type: none"> <li><b>d-Tubocurarine</b></li> </ul>	Competitive antagonist at nACh receptors, especially at neuromuscular junctions	Prevents depolarization by ACh, causes flaccid paralysis • can cause histamine release with hypotension • weak block of cardiac muscarinic ACh receptors	Prolonged relaxation for surgical procedures • superseded by newer nondepolarizing agents	Renal excretion • duration, ~40–60 min • <b>Toxicities:</b> Histamine release • hypotension • prolonged apnea
<ul style="list-style-type: none"> <li><b>Cisatracurium</b></li> </ul>	Similar to tubocurarine	Like tubocurarine but lacks histamine release and antimuscarinic effects	Prolonged relaxation for surgical procedures • relaxation of respiratory muscles to facilitate mechanical ventilation in intensive care unit	Not dependent on renal or hepatic function • duration ~25–45 min • <b>Toxicities:</b> Prolonged apnea but less toxic than <b>atracurium</b>
<ul style="list-style-type: none"> <li><b>Rocuronium</b></li> </ul>	Similar to <b>cisatracurium</b>	Like <b>cisatracurium</b> but slight antimuscarinic effect	Like <b>cisatracurium</b> • useful in patients with renal impairment	Hepatic metabolism • duration ~20–35 min • <b>Toxicities:</b> Like <b>cisatracurium</b>

## CENTRALLY ACTING SPASMOLYTIC DRUGS

• <b>Baclofen</b>	GABA <sub>B</sub> agonist, facilitates spinal inhibition of motor neurons	Pre- and postsynaptic inhibition of motor output	Severe spasticity due to cerebral palsy, multiple sclerosis, stroke	Oral, intrathecal • <i>Toxicities:</i> Sedation, weakness; rebound spasticity upon abrupt withdrawal
• <b>Diazepam</b>	Facilitates GABAergic transmission in central nervous system (see <a href="#">Chapter 22</a> )	Increases interneuron inhibition of primary motor afferents in spinal cord • central sedation	Chronic spasm due to cerebral palsy, stroke, spinal cord injury • acute spasm due to muscle injury	Hepatic metabolism • duration ~12–24 h • <i>Toxicities:</i> See <a href="#">Chapter 22</a>
• <b>Tizanidine</b>	α <sub>2</sub> -Adrenoceptor agonist in the spinal cord	Pre- and postsynaptic inhibition of reflex motor output	Spasm due to multiple sclerosis, stroke, amyotrophic lateral sclerosis	Oral • renal and hepatic elimination • duration 3–6 h • <i>Toxicities:</i> Weakness, sedation, hypotension, hepatotoxicity (rare), rebound hypertension upon abrupt withdrawal

## CENTRALLY ACTING ANTISPASMODIC DRUGS

• <b>Cyclobenzaprine</b>	Poorly understood inhibition of muscle stretch reflex in spinal cord	Reduction in hyperactive muscle reflexes • antimuscarinic effects	Acute spasm due to muscle injury • inflammation	Hepatic metabolism • duration, ~4–6 h • <i>Toxicities:</i> Strong antimuscarinic effects
--------------------------	--	---	---	--

- *Methocarbamol, orphenadrine, others: Like cyclobenzaprine with varying degrees of antimuscarinic effect. Class side effect: strong central nervous system depression; note carisoprodol is a schedule IV drug.*

## DIRECT-ACTING MUSCLE RELAXANTS

• <b>Dantrolene</b>	Blocks RyR1 Ca <sup>2+</sup> -release channels in the sarcoplasmic reticulum of skeletal muscle	Reduces actin-myosin interaction • weakens skeletal muscle contraction	IV: Malignant hyperthermia • Oral: Spasm due to cerebral palsy, spinal cord injury, multiple sclerosis	IV, oral • duration 4–6 h • <i>Toxicities:</i> Muscle weakness • Black box warning: hepatotoxicity
• <b>Botulinum toxin</b>	Inhibits synaptic exocytosis through clipping of vesicle fusion proteins in presynaptic nerve terminal	Flaccid paralysis	Upper and lower limb spasm due to cerebral palsy, multiple sclerosis; cervical dystonia, overactive bladder, migraine, hyperhidrosis	Direct injection into muscle • duration 2–3 months • <i>Toxicities:</i> Muscle weakness, falls • Black box warning: potential spread of toxin leading to excessive weakness reported after use for cerebral palsy with spasticity

## PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
<b>NEUROMUSCULAR BLOCKING DRUGS</b>	
Atracurium	Generic
Cisatracurium	Generic, Nimbex
Pancuronium	Generic
Rocuronium	Generic, Zemuron
Succinylcholine	Generic, Anectine, Quelicin
Tubocurarine	Generic
Vecuronium	Generic, Norcuron
<b>REVERSAL AGENTS</b>	
Neostigmine	Generic
Edrophonium	Generic
Sugammadex	Bridion
<b>SPASMOLYTICS, ANTISPASMODICS</b>	
Baclofen	Generic, Gablofen, Lioresal
Botulinum toxin type A	Botox, Dysport, Xeomin
Botulinum toxin type B	Myobloc
Carisoprodol	Generic, Soma
Chlorzoxazone	Generic
Cyclobenzaprine	Generic, Amrix, Fexmid, Flexeril
Dantrolene	Generic, Dantrium, Revonto
Diazepam	Generic, Valium, Diastat

<i>Note:</i> This drug is labeled for use only in epilepsy and postherpetic neuralgia.	
Metaxalone	Generic, Skelaxin
Methocarbamol	Generic, Robaxin
Orphenadrine	Generic, Antiflex, Banflex, Norflex, Flexoject, Flexon, Mio-Rel, Myolin, Norflex Injectable, Orfro, Orphenate
Riluzole	Generic, Rilutek, Tiglutik
<i>Note:</i> This drug is labeled only for use in amyotrophic lateral sclerosis.	
Tizanidine	Generic, Zanaflex

### CASE STUDY ANSWER

This patient presents problems that make her management more difficult than the average. She is at higher risk of difficulty with airway management because of obesity, and both obesity and diabetes raise the risk of aspiration. Therefore, the decision to use an endotracheal tube for her airway management is reasonable.

As the case progresses, you are experiencing difficulty with mask ventilation, and the decision to abort the procedure and awaken the patient is probably the best response. In order to do so, the neuromuscular blockade must be fully reversed so she will be able to breathe on her own once awakened.

There are two options for reversal of neuromuscular blockade with **rocuronium** (and with **vecuronium**): **sugammadex**, or **neostigmine** combined with **glycopyrrolate**. **Sugammadex** would be the most appropriate agent. As described in **Chapter 7**, **neostigmine** works to increase the level of **acetylcholine** at the neuromuscular junction by inhibiting the enzymatic breakdown of **acetylcholine**. **Glycopyrrolate** (**Chapter 8**) is given to block the bradycardia associated with increased cholinergic activity. However, if the patient is still fully relaxed with **rocuronium**, **neostigmine** will not sufficiently increase **acetylcholine** to allow full reversal. In contrast, **sugammadex** actively binds **rocuronium** and removes it from the neuromuscular junction. In order to fully reverse an intubating dose of **rocuronium**, a **sugammadex** dose of 16 mg/kg should be administered. This will reverse the effect of **rocuronium** within 1.5–3.0 minutes. **Sugammadex** is renally cleared, so it should not be used in patients in renal failure (creatinine clearance less than 30 mL/min) unless absolutely necessary. This patient has insulin-dependent diabetes, so her creatinine clearance may be abnormally low. If this were the case, the benefit of **sugammadex** would still outweigh its potential risk. In addition, some studies have found that **sugammadex** may be dialyzable, and could therefore be removed by that method if needed. This patient is also taking an oral contraceptive agent, and it would be necessary to counsel her that **sugammadex** may interfere with the efficacy of that agent and the FDA recommends use of another method of contraception for the following 7 days. Other issues that may occur with **sugammadex** use include anaphylaxis, especially when using the maximum dose of 16 mg/kg, marked bradycardia, hypotension, nausea and vomiting, and headache.

## Chapter 28: Pharmacologic Management of Parkinsonism & Other Movement

### Disorders

Michael J. Aminoff

## CASE STUDY

### CASE STUDY

A 76-year-old retired banker complains of a shuffling gait with occasional falls over the last year. He has developed a stooped posture, drags his left leg when walking, and is unsteady on turning. He remains independent in all activities of daily living, but he has become more forgetful and occasionally sees his long-deceased father in his bedroom. Examination reveals hypomimia, hypophonia, a slight rest tremor of the right hand and chin, mild rigidity, and impaired rapid alternating movements in all limbs. Neurologic and general examinations are otherwise normal. What is the likely diagnosis and prognosis?

The patient is started on a **dopamine** agonist, and the dose is gradually built up to the therapeutic range. Was this a good choice of medications?

Six months later, the patient and his wife return for follow-up. It now becomes apparent that he is falling asleep at inappropriate times, such as at the dinner table, and when awake, he spends much of the time in arranging and rearranging the table cutlery or in picking at his clothes. To what is his condition due, and how should it be managed? Would you recommend surgical treatment?

Several types of abnormal movement are recognized. **Tremor** consists of a rhythmic oscillatory movement around a joint and is best characterized by its relation to activity. Tremor at rest is characteristic of parkinsonism, when it is often associated with rigidity and an impairment of voluntary activity. Tremor may occur during maintenance of sustained posture (postural tremor) or during movement (intention tremor). A conspicuous postural tremor is the cardinal feature of benign essential or familial tremor. Intention tremor occurs in patients with a lesion of the brainstem or cerebellum, especially when the superior cerebellar peduncle is involved; it may also occur as a manifestation of toxicity from **alcohol** or certain other drugs.

**Chorea** consists of irregular, unpredictable, involuntary muscle jerks that occur in different parts of the body and impair voluntary activity. In some instances, the proximal muscles of the limbs are most severely affected, and because the abnormal movements are then particularly violent, the term *ballismus* has been used to describe them. Chorea may be hereditary or acquired and may occur as a complication of a number of general medical disorders and of therapy with certain drugs.

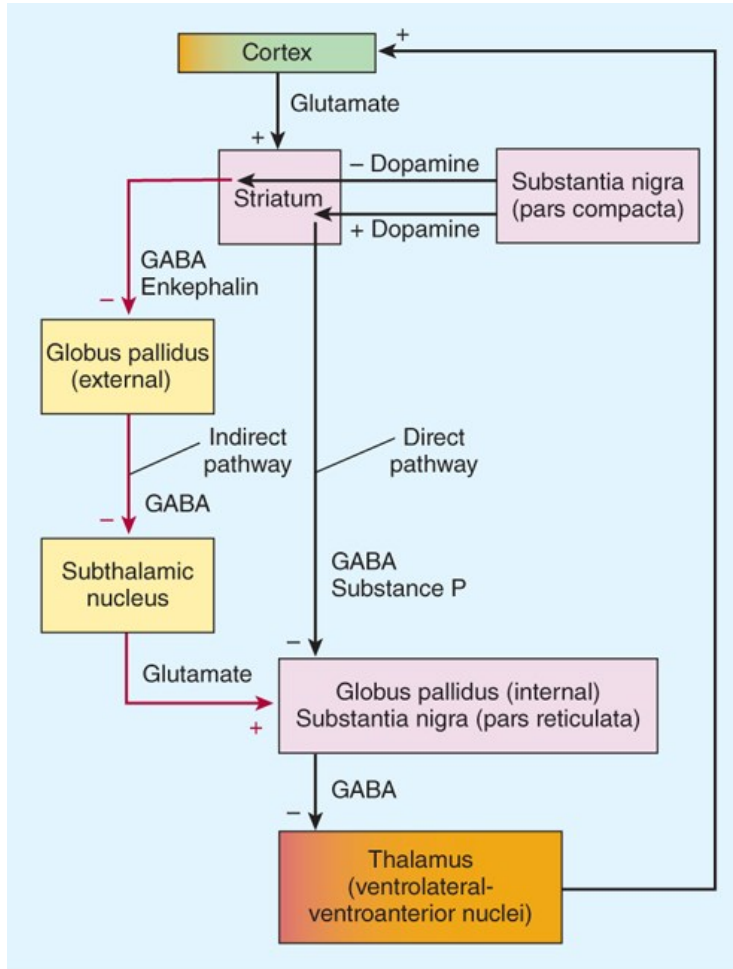

Abnormal movements may be slow and writhing in character (**athetosis**) and, in some instances, are so sustained that they are more properly regarded as abnormal postures (**dystonia**). Athetosis or dystonia may occur with perinatal brain damage, with focal or generalized cerebral lesions, as an acute complication of certain drugs, as an accompaniment of diverse neurologic disorders, or as an isolated inherited phenomenon of uncertain cause known as isolated generalized torsion dystonia or dystonia musculorum deformans. Various genetic loci have been reported depending on the age of onset, mode of inheritance, and response to dopaminergic therapy. The physiologic basis is uncertain, and treatment is unsatisfactory. Patients with dystonia commonly have psychiatric complications, such as depression, that affect the quality of life. These may be secondary to the dystonia or a nonmotor manifestation of the underlying disorder.

**Tics** are sudden coordinated abnormal movements that tend to occur repetitively, particularly about the face and head, especially in children, and can be suppressed voluntarily for short periods of time. Common tics include repetitive sniffing or shoulder shrugging. Tics may be single or multiple and transient or chronic. Gilles de la Tourette syndrome is characterized by chronic multiple tics; its pharmacologic management is discussed at the end of this chapter.

Many of the movement disorders have been attributed to disturbances of the basal ganglia. The basic circuitry of the basal ganglia involves three interacting neuronal loops that include the cortex and thalamus as well as the basal ganglia themselves (Figure 28-1). However, the precise function of these anatomic structures is not yet fully understood, and it is not possible to relate individual symptoms to involvement at specific sites.

FIGURE 28-1

Functional circuitry between the cortex, basal ganglia, and thalamus. The major neurotransmitters are indicated. In Parkinson disease, there is degeneration of the pars compacta of the substantia nigra, leading to overactivity in the indirect pathway (red) and increased glutamatergic activity by the subthalamic nucleus.

## PARKINSONISM & PARKINSON DISEASE

Parkinsonism is characterized by a combination of rigidity, bradykinesia, tremor, and postural instability that can occur for a variety of reasons but is usually idiopathic (Parkinson disease or paralysis agitans). Bradykinesia should be present before a diagnosis of Parkinson disease is made. Focal dystonic features may be present. Cognitive decline occurs in many patients as the disease advances. Other nonmotor symptoms include affective disorders (anxiety or depression); confusion, cognitive impairment, or personality changes; apathy; fatigue; abnormalities of autonomic function (eg, sphincter or sexual dysfunction, dysphagia and choking, sweating abnormalities, sialorrhea, or disturbances of blood pressure regulation); sleep disorders; and sensory complaints or pain. The disease is incurable, is generally progressive, and leads to increasing disability with time, but pharmacologic treatment may relieve motor symptoms and improve the quality of life for many years. Patients with Parkinson disease may develop hyposmia, constipation, depression, anxiety, or rapid-eye-movement (REM) sleep behavior disorder in a preclinical phase before onset of the motor

Parkinsonism may also have a hereditary basis, may follow exposure to various toxins (eg, manganese dusts, carbon disulfide, carbon monoxide), may develop after multiple subcortical white-matter infarcts or recurrent head injury (as in boxers), and may occur in association with other neurologic disorders.

## Pathogenesis

The pathogenesis of Parkinson disease seems to relate to a combination of impaired degradation of proteins, intracellular protein accumulation and aggregation, oxidative stress, mitochondrial damage, inflammatory cascades, and apoptosis. Studies in twins suggest that genetic factors are important, especially when the disease occurs in patients under age 50. Recognized genetic abnormalities account for 10–15% of cases. Mutations of the  $\alpha$ -synuclein gene at 4q21 or duplication and triplication of the normal synuclein gene are associated with Parkinson disease, which is now widely recognized as a *synucleinopathy*. Mutations of the leucine-rich repeat kinase 2 (*LRRK2*) gene at 12cen, and the *UCHL1* gene may also cause autosomal dominant parkinsonism. Mutations in the *parkin* gene (6q25.2–q27) cause early-onset, autosomal recessive, familial parkinsonism, or sporadic juvenile-onset parkinsonism. Several other genes or chromosomal regions have been associated with familial forms of the disease. Environmental or endogenous toxins may also be important in the etiology of the disease. Epidemiologic studies reveal that cigarette smoking, coffee, anti-inflammatory drug use, and high serum uric acid levels are protective, whereas the incidence of the disease is increased in those working in teaching, health care, or farming, and in those with lead or manganese exposure or with vitamin D deficiency.

The finding of Lewy bodies (intracellular inclusion bodies containing  $\alpha$ -synuclein) in fetal dopaminergic cells transplanted into the brain of parkinsonian patients some years previously has provided some support for suggestions that Parkinson disease may represent a prion disease.

Staining for  $\alpha$ -synuclein has revealed that pathology is more widespread than previously recognized, developing initially in the olfactory nucleus and the medulla or lower brainstem (stage 1 of Braak scale), then higher in the medulla and the pons of the brainstem (stage 2), extending to the midbrain and in particular the substantia nigra (stage 3), the mesocortex and thalamus (stage 4), the neocortex (stage 5), and then spreading more extensively in the neocortex (stage 6). The motor features of Parkinson disease develop at stage 3 on the Braak scale.

The normally high concentration of dopamine in the basal ganglia of the brain is reduced in parkinsonism, and pharmacologic attempts to restore dopaminergic activity with levodopa and dopamine agonists alleviate many of the motor features of the disorder. An alternative but complementary approach has been to restore the normal balance of cholinergic and dopaminergic influences on the basal ganglia with antimuscarinic drugs. The pathophysiologic basis for these therapies is that in idiopathic parkinsonism, there is a loss of dopaminergic neurons in the substantia nigra that normally inhibit the output of GABAergic cells in the corpus striatum (Figure 28-2). Drugs that induce parkinsonian syndromes either are dopamine receptor antagonists (eg, antipsychotic agents; see Chapter 29) or lead to the destruction of the dopaminergic nigrostriatal neurons (eg, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine [MPTP]; see below). Various other neurotransmitters, such as norepinephrine, are also depleted in the brain in parkinsonism, but these deficiencies are of uncertain clinical relevance.

FIGURE 28-2

Schematic representation of the sequence of neurons involved in parkinsonism. A simplified version of the involved circuitry is shown. **Top:** Dopaminergic neurons (red) originating in the substantia nigra normally inhibit the GABAergic output from the striatum, whereas cholinergic neurons (green) exert an excitatory effect. **Bottom:** In parkinsonism, there is a selective loss of dopaminergic neurons (dashed, red).

## LEVODOPA

Dopamine does not cross the blood-brain barrier and if given into the peripheral circulation has no therapeutic effect in parkinsonism. However, (-)-3-(3,4-dihydroxyphenyl)-L-alanine (levodopa), the immediate metabolic precursor of dopamine, does enter the brain (via an L-amino acid transporter, LAT), where it is decarboxylated to dopamine (see Figure 6-5). Several noncatecholamine dopamine receptor agonists have also been developed and may lead to clinical benefit, as discussed in the text that follows.

Dopamine receptors are discussed in detail in Chapters 21 and 29. They exist in five subtypes. D<sub>1</sub> and D<sub>5</sub> receptors are classified as the D<sub>1</sub> receptor family based on genetic and biochemical factors; D<sub>2</sub>, D<sub>3</sub>, and D<sub>4</sub> are grouped as belonging to the D<sub>2</sub> receptor family. Dopamine receptors of the D<sub>1</sub> type are located in the pars compacta of the substantia nigra and presynaptically on striatal axons coming from cortical neurons and from dopaminergic cells in the substantia nigra. The D<sub>2</sub> receptors are located postsynaptically on striatal neurons and presynaptically on axons in the substantia nigra belonging to neurons in the basal ganglia. The benefits of dopaminergic antiparkinsonism drugs appear to depend mostly on stimulation of the D<sub>2</sub> receptors. However, D<sub>1</sub>-receptor stimulation may also be required for maximal benefit, and one of the newer drugs is D<sub>3</sub> selective. Dopamine agonist or partial agonist ergot derivatives such as lergotriple and bromocriptine that are powerful stimulators of the D<sub>2</sub> receptors have antiparkinsonism properties, whereas certain dopamine blockers that are selective D<sub>2</sub> antagonists can induce parkinsonism.

## Chemistry

Dopa is the amino acid precursor of dopamine and norepinephrine (discussed in Chapter 6). Its structure is shown in Figure 28-3. Levodopa is the levorotatory stereoisomer of dopa.

## Pharmacokinetics

Levodopa is rapidly absorbed from the small intestine, but its absorption depends on the rate of gastric emptying and the pH of the gastric contents. Ingestion of food delays the appearance of levodopa in the plasma. Moreover, certain amino acids from ingested food can compete with the drug for absorption from the gut and for transport from the blood to the brain. Plasma concentrations usually peak between 1 and 2 hours after an oral dose, and the plasma half-life is usually between 1 and 3 hours, although it varies considerably among individuals. About two-thirds of the dose appears in the urine as metabolites within 8 hours of an oral dose, the main metabolic products being 3-methoxy-4-hydroxyphenyl acetic acid (homovanillic acid, HVA) and dihydroxyphenylacetic acid (DOPAC). Unfortunately, only about 1–3% of administered levodopa actually enters the brain unaltered; the remainder is metabolized extracerebrally, predominantly by decarboxylation to dopamine, which does not penetrate the blood-brain barrier. Accordingly, levodopa must be given in large amounts when used alone. However, when given in combination with a dopa decarboxylase inhibitor that does not penetrate the blood-brain barrier, the peripheral metabolism of levodopa is reduced, plasma levels of levodopa are higher, plasma half-life is longer, and more dopa is available for entry into the brain (Figure 28–4). Indeed, concomitant administration of a peripheral dopa decarboxylase inhibitor such as carbidopa may reduce the daily requirements of levodopa by approximately 75%.

Fate of orally administered levodopa and the effect of carbidopa, estimated from animal data. The width of each pathway indicates the absolute amount of the drug at each site, whereas the percentages shown denote the relative proportion of the administered dose. The benefits of co-administration of carbidopa include reduction of the amount of levodopa required for benefit and of the absolute amount diverted to peripheral tissues and an increase in the fraction of the dose that reaches the brain. GI, gastrointestinal. (Data from Nutt JG, Fellman JH: Pharmacokinetics of levodopa. Clin Neuropharmacol 1984;7(1):35-49.)

## Clinical Use

The best results of levodopa treatment are obtained in the first few years of treatment. This is sometimes because the daily dose of levodopa must be reduced over time to avoid adverse effects at doses that were well tolerated initially. Some patients become less responsive to levodopa, perhaps because of loss of dopaminergic nigrostriatal nerve terminals or some pathologic process directly involving striatal dopamine receptors. For such reasons, the benefits of levodopa treatment often begin to diminish after about 3 or 4 years of therapy, regardless of the initial therapeutic response. Although levodopa therapy does not stop the progression of parkinsonism, its early initiation lowers the mortality rate. However, long-term therapy may lead to a number of problems in management such as the on-off phenomenon discussed below. The most appropriate time to introduce levodopa therapy must therefore be determined individually.

When levodopa is used, it is generally given in combination with **carbidopa** (see Figure 28-3), a peripheral dopa decarboxylase inhibitor, which reduces peripheral conversion to dopamine. Combination treatment is started with a small dose, eg, carbidopa 25 mg, levodopa 100 mg three times daily, and gradually increased. It should be taken 30-60 minutes before meals. Most patients ultimately require carbidopa 25 mg, levodopa 250 mg

three or four times daily. Some physicians prefer to keep treatment with this agent at a low level (eg, carbidopa-levodopa 25/100 three times daily) when possible, and if necessary, to add a dopamine agonist, in the belief that this reduces the risk of development of response fluctuations. However, the occurrence of response fluctuations probably depends on disease progression rather than pharmacologic management, and any benefit of dopamine agonists in this regards is probably because they are less effective than levodopa. A controlled-release formulation of carbidopa-levodopa is available and may be helpful in patients with established response fluctuations or as a means of reducing dosing frequency. Even more helpful for response fluctuations is an extended-release formulation (**Rytary**) that consists of capsules containing beads that release carbidopa and levodopa (present in a 1:4 ratio) at different rates over a prolonged time as they dissolve in the stomach. It is substituted for the regular (immediate-release) formulation using dosing guidelines provided by its manufacturer (Table 28-1).

TABLE 28-1

**Substitution of Rytary for immediate-release carbidopa/levodopa.**

Current Levodopa Total Daily Dose (mg)	Rytary Dose (Carbidopa/Levodopa) (mg) <sup>1</sup>
Zero	23.75/95, 1 cap TID
400-549	23.75/95, 3 caps TID
550-749	23.75/95, 4 caps QID
750-949	36.25/145, 3 caps TID
950-1249	48.75/195, 3 caps TID
1250 or more	48.75/195, 4 caps TID or
	61.25/245, 3 caps TID

<sup>1</sup>Dose levels recommended by the manufacturers.

A formulation of carbidopa-levodopa (10/100, 25/100, 25/250) that disintegrates in the mouth and is swallowed with the saliva (**Parcopa**) is available commercially and is best taken about 1 hour before meals. The combination (**Stalevo**) of levodopa, carbidopa, and a catechol-*O*-methyltransferase (COMT) inhibitor (entacapone) is discussed in a later section. Finally, therapy by *infusion* of carbidopa-levodopa into the duodenum or upper jejunum appears to be safe and is superior to a number of oral combination therapies in patients with advanced levodopa-responsive parkinsonism with response fluctuations. A permanent access tube is inserted via a percutaneous endoscopic gastrostomy in patients who have responded well to carbidopa-levodopa gel administered through a nasoduodenal tube. A morning bolus (100-300 mg of levodopa) is delivered via a portable infusion pump, followed by a continuous maintenance dose (40-120 mg/h), with supplemental bolus doses as required.

Levodopa can ameliorate many of the clinical motor features of parkinsonism, but it is particularly effective in relieving bradykinesia and any disabilities resulting from it. When it is first introduced, about one third of patients respond very well and one third less well. Most of the remainder either are unable to tolerate the medication or simply do not respond at all, especially if they do not have classic Parkinson disease.

## Adverse Effects

### A. Gastrointestinal Effects

When levodopa is given without a peripheral decarboxylase inhibitor, anorexia and nausea and vomiting occur in about 80% of patients. These adverse effects can be minimized by taking the drug in divided doses, with or immediately after meals, and by increasing the total daily dose very slowly. Antacids taken 30-60 minutes before levodopa may also be beneficial. The vomiting has been attributed to stimulation of the chemoreceptor trigger zone located in the brainstem but outside the blood-brain barrier. Fortunately, tolerance to this emetic effect develops in many patients. If not,

an additional dose of carbidopa (Lodosyn; 25 mg) taken with the regular levodopa dose is often helpful, even though the usual maximum requirement of carbidopa is 75 mg daily. Domperidone (not available in the USA) may also relieve persistent nausea, as may ondansetron. Antiemetics such as phenothiazines should be avoided because they reduce the antiparkinsonism effects of levodopa and may exacerbate the disease.

When levodopa is given in combination with carbidopa, adverse gastrointestinal effects are much less frequent and troublesome, occurring in less than 20% of cases, so that patients can tolerate proportionately higher doses.

### B. Cardiovascular Effects

A variety of cardiac arrhythmias have been described in patients receiving levodopa, including tachycardia, ventricular extrasystoles, and rarely, atrial fibrillation. This effect has been attributed to increased catecholamine formation peripherally. The incidence of such arrhythmias is low, even in the presence of established cardiac disease, and may be reduced still further if the levodopa is taken in combination with a peripheral decarboxylase inhibitor.

Postural hypotension is common, but often asymptomatic, and tends to diminish with continuing treatment. However, it sometimes develops later in the disease course. Hypertension may also occur, especially in the presence of nonselective monoamine oxidase inhibitors or sympathomimetics or when massive doses of levodopa are being taken.

### C. Behavioral Effects

A wide variety of adverse mental effects have been reported, including depression, anxiety, agitation, insomnia, somnolence, sleep attacks, confusion, delusions, hallucinations, nightmares, euphoria, and other changes in mood or personality. Such adverse effects are more common in patients taking levodopa in combination with a decarboxylase inhibitor rather than levodopa alone, presumably because higher levels are reached in the brain. They may be precipitated by intercurrent illness or surgery. It may be necessary to reduce or withdraw the medication. Several atypical antipsychotic agents that have low affinity for dopamine D<sub>2</sub> receptors (clozapine, olanzapine, quetiapine, and risperidone; see [Chapter 29](#)) are now available and may be particularly helpful in counteracting such behavioral complications. **Pimavanserin** (34 mg daily), a selective serotonin 5-HT<sub>2A</sub> inverse agonist, is also helpful for treating the hallucinations and delusions of Parkinson disease psychosis. It should not be used for dementia-related psychosis and should be avoided in patients with QT prolongation.

Confusion and hallucinations developing in parkinsonian patients is more likely due to treatment with anticholinergic agents, amantadine, or dopamine agonists rather than to levodopa.

The **dopamine dysregulation syndrome** is characterized by compulsive overuse of dopaminergic medication as well as by other impulsive behaviors; such impulse control disorders are more common with dopamine agonists than levodopa and are discussed later. Management involves the close regulation of dopaminergic intake.

**Punding** designates the performance of stereotyped, complex, but purposeless motor activity, such as sorting or lining up various objects or repetitive grooming behavior. It responds to reduction in dose of dopaminergic agents or to atypical antipsychotic agents.

### D. Dyskinesias and Response Fluctuations

Dyskinesias occur in up to 80% of patients receiving levodopa therapy for more than 10 years. The character of dopa dyskinesias varies between patients but tends to remain constant in individual patients. Chorea-athetosis of the face and distal extremities is the most common presentation. The development of dyskinesias is dose related, but there is considerable individual variation in the dose required to produce them. Their pathogenesis is unclear, but they may relate to an unequal distribution of striatal dopamine. Dopaminergic denervation plus chronic pulsatile stimulation of dopamine receptors with levodopa has been associated with development of dyskinesias. A lower incidence of dyskinesias occurs when levodopa is administered continuously (eg, intraduodenally or intrajejunally) and with drug delivery systems that enable a more continuous delivery of dopaminergic medication. Reduction of levodopa dose or the dose of adjunctive medications (discussed later) will alleviate dyskinesias in many instances, but motor symptoms of parkinsonism then worsen. Much less commonly, dyskinesias occur as patients respond to levodopa and again as the benefit wears off, and these “diphasic dyskinesias” may be best managed by dividing the daily dose into more frequent smaller doses or by replacing some of the levodopa with a dopamine receptor agonist. Mild dyskinesias require no treatment. Amantadine may help to reduce more troublesome dyskinesias, as may clozapine, a number of other compounds are being studied as possible antidyskinetic agents.

Certain fluctuations in clinical response to levodopa occur with increasing frequency as treatment continues. In some patients, these fluctuations relate to the timing of levodopa intake (**wearing-off** reactions or **end-of-dose akinesia**). In other instances, fluctuations in clinical state are unrelated to the timing of doses (**on-off phenomenon**). In the on-off phenomenon, off-periods of marked akinesia alternate over the course of a few hours with on-periods of improved mobility but often marked dyskinesia. These fluctuations may be helped by taking the main protein meal in the evening rather than during the day, by adjustments to levodopa dose and dosing interval, and by the use of longer-acting formulations of levodopa and adjunctive medications. An inhaled formulation of levodopa also is available commercially for the intermittent treatment of off-periods. Surgical treatment should be considered (discussed later). For patients with severe off-periods who are unresponsive to other measures, subcutaneously injected apomorphine may provide temporary benefit but may increase dyskinesias. The on-off phenomenon is most likely to occur in patients who responded well to treatment initially. The exact mechanism is unknown.

#### E. Miscellaneous Adverse Effects

Mydriasis may occur and may precipitate an attack of acute glaucoma in some patients. Other reported but rare adverse effects include various blood dyscrasias; a positive Coombs' test with evidence of hemolysis; hot flushes; aggravation or precipitation of gout; abnormalities of smell or taste; brownish discoloration of saliva, urine, or vaginal secretions; priapism; and mild—usually transient—elevations of blood urea nitrogen and of serum transaminases, alkaline phosphatase, and bilirubin.

#### Drug Holidays

A drug holiday (discontinuance of the drug for 3–21 days) may temporarily improve responsiveness to levodopa and alleviate some of its adverse effects but is usually of little help in the management of the on-off phenomenon. Furthermore, a drug holiday carries the risks of aspiration pneumonia, venous thrombosis, pulmonary embolism, and depression resulting from the immobility accompanying severe parkinsonism. For these reasons and because of the temporary nature of any benefit, drug holidays are not recommended.

#### Drug Interactions

Pharmacologic doses of pyridoxine (vitamin B<sub>6</sub>) enhance the extracerebral metabolism of levodopa and may therefore prevent its therapeutic effect unless a peripheral decarboxylase inhibitor is also taken. Levodopa should not be given to patients taking monoamine oxidase A inhibitors or within 2 weeks of their discontinuance because such a combination can lead to hypertensive crises.

#### Contraindications

Levodopa should not be given to psychotic patients because it may exacerbate the mental disturbance. It is also contraindicated in patients with angle-closure glaucoma, but those with chronic open-angle glaucoma may be given levodopa if intraocular pressure is well controlled and can be monitored. When combined with carbidopa, the risk of cardiac dysrhythmia is slight, even in patients with cardiac disease. Patients with active peptic ulcer must be managed carefully, since gastrointestinal bleeding has occasionally occurred with levodopa. Because levodopa is a precursor of skin melanin and conceivably may activate malignant melanoma, it should be used with particular care in patients with a history of melanoma or with suspicious undiagnosed skin lesions; such patients should be monitored regularly by a dermatologist.

### DOPAMINE RECEPTOR AGONISTS

Drugs acting directly on postsynaptic dopamine receptors may have a beneficial effect in addition to that of levodopa (Figure 28–5). Unlike levodopa, they do not require enzymatic conversion to an active metabolite, act directly on the postsynaptic dopamine receptors, have no potentially toxic metabolites, and do not compete with other substances for active transport into the blood and across the blood-brain barrier. Moreover, drugs selectively affecting certain (but not all) dopamine receptors may have more limited adverse effects than levodopa. Several dopamine agonists have antiparkinsonism activity. The older dopamine agonists (bromocriptine and pergolide) are ergot (ergoline) derivatives (see Chapter 16) and are rarely—if ever—used to treat parkinsonism. Their side effects are of more concern than those of the newer agents (pramipexole and ropinirole).

Pharmacologic strategies for dopaminergic therapy of Parkinson disease. Drugs and their effects are indicated (see text). COMT, catechol-O-methyltransferase; DOPAC, dihydroxyphenylacetic acid; L-DOPA, levodopa; MAO, monoamine oxidase; 3-MT, 3-methoxytyramine; 3-OMD, 3-O-methyldopa.

There is no evidence that one agonist is superior to another; individual patients, however, may respond to one but not another of these agents. Moreover, their duration of action varies and is lengthened by extended-release preparations. Apomorphine is a potent dopamine agonist but is discussed separately in a later section in this chapter because it is used primarily as a rescue drug for patients with disabling response fluctuations to levodopa.

Dopamine agonists have been used as first-line therapy for Parkinson disease, and their use is associated with a lower incidence of the response fluctuations and dyskinesias that occur with long-term levodopa therapy. Dopaminergic therapy is therefore often initiated with a dopamine agonist, although, compared with levodopa, the agonists generally provide less symptomatic benefit and are more likely to cause mental side effects, somnolence, and edema. In other instances, a low dose of carbidopa plus levodopa (eg, Sinemet, 25/100 three times daily) is introduced, and a dopamine agonist is then added. In either case, the dose of the dopamine agonist is built up gradually depending on response and tolerance. Dopamine agonists may also be given to patients with parkinsonism who are taking levodopa and who have end-of-dose akinesia or on-off phenomenon or are becoming resistant to treatment with levodopa. In such circumstances, it is generally necessary to lower the dose of levodopa to prevent intolerable adverse effects. The response to a dopamine agonist is generally disappointing in patients who have never responded to levodopa.

### Bromocriptine

Bromocriptine is a  $D_2$  agonist; its structure is shown in Table 16-7. This drug has been widely used to treat Parkinson disease in the past but is now rarely used for this purpose. The usual daily dose of bromocriptine for parkinsonism varies between 7.5 and 30 mg. To minimize adverse effects, the

## Pergolide

Pergolide, another ergot derivative, directly stimulates both D<sub>1</sub> and D<sub>2</sub> receptors. It too has been widely used for parkinsonism but is no longer available in the United States because its use has been associated with the development of valvular heart disease. It is nevertheless still used in some countries.

## Pramipexole

Pramipexole is not an ergot derivative, but it has preferential affinity for the D<sub>3</sub> receptor. It is effective as monotherapy for mild parkinsonism and is also helpful in patients with advanced disease, permitting the dose of levodopa to be reduced and smoothing out response fluctuations. Pramipexole may ameliorate affective symptoms. A possible neuroprotective effect has been suggested by its ability to scavenge hydrogen peroxide and enhance neurotrophic activity in mesencephalic dopaminergic cell cultures.

### Pramipexole

Pramipexole is rapidly absorbed after oral administration, reaching peak plasma concentrations in approximately 2 hours, and is excreted largely unchanged in the urine. It is started at a dosage of 0.125 mg three times daily, doubled after 1 week, and again after another week. Further increments in the daily dose are by 0.75 mg at weekly intervals, depending on response and tolerance. Most patients require between 0.5 and 1.5 mg three times daily. Renal insufficiency may necessitate dosage adjustment. An extended-release preparation is now available and is taken once daily at a dose equivalent to the total daily dose of standard pramipexole. The extended-release preparation is generally more convenient for patients and avoids swings in blood levels of the drug over the day.

## Ropinirole

Another nonergoline derivative, ropinirole (now available in a generic preparation) is a relatively pure D<sub>2</sub> receptor agonist that is effective as monotherapy in patients with mild disease and as a means of smoothing the response to levodopa in patients with more advanced disease and response fluctuations. It is introduced at 0.25 mg three times daily, and the total daily dose is then increased by 0.75 mg at weekly intervals until the fourth week and by 1.5 mg thereafter. In most instances, a dosage between 2 and 8 mg three times daily is necessary. Ropinirole is metabolized by CYP1A2; other drugs metabolized by this isoform may significantly reduce its clearance. A prolonged-release preparation taken once daily is available.

### Ropinirole

## Rotigotine

The dopamine agonist rotigotine, delivered daily through a skin patch, is approved for treatment of early Parkinson disease. It supposedly provides more continuous dopaminergic stimulation than oral medication in early parkinsonism; its efficacy in more advanced disease is less clear. Benefits and side effects are similar to those of other dopamine agonists but reactions may also occur at the application site and are sometimes serious. Treatment is usually started with the 2 mg/24 hours patch and titrated weekly as necessary by increasing the patch size to 4 mg/24 hours and then to 6 mg/24

## Adverse Effects of Dopamine Agonists

### A. Gastrointestinal Effects

Anorexia and nausea and vomiting may occur when a dopamine agonist is introduced and can be minimized by taking the medication with meals. Constipation, dyspepsia, and symptoms of reflux esophagitis may also occur. Bleeding from peptic ulceration has been reported.

### B. Cardiovascular Effects

Postural hypotension may occur, particularly at the initiation of therapy. Painless digital vasospasm is a dose-related complication of long-term treatment with the ergot derivatives (bromocriptine or pergolide). When cardiac arrhythmias occur, they are an indication for discontinuing treatment. Peripheral edema is sometimes problematic. Cardiac valvulopathy may occur with pergolide.

### C. Dyskinesias

Abnormal movements similar to those introduced by levodopa may occur and are reversed by reducing the total dose of dopaminergic drugs being taken.

### D. Mental Disturbances

Confusion, hallucinations, delusions, and other psychiatric reactions may develop as a feature of Parkinson disease or as complications of dopaminergic treatment and are more common and severe with dopamine receptor agonists than with levodopa. They tend to occur earlier in older patients and become more common as the disease advances. There appears to be no difference between the various dopamine agonists in their ability to induce these disorders. They may respond to atypical antipsychotic agents such as clozapine, olanzapine, quetiapine, and risperidone or to pimavanserin.

Disorders of impulse control may occur either as an exaggeration of a previous tendency or as a new phenomenon and may lead to compulsive gambling, shopping, betting, sexual activity, and other behaviors (see [Chapter 32](#)). Their prevalence varies in different reports but may be as high as 45% in parkinsonian patients treated with dopamine agonists. They relate to activation of D<sub>2</sub> or D<sub>3</sub> dopamine receptors in the mesocorticolimbic system, may occur with one dopamine agonist and not another, and may occur at any time after the initiation of treatment. They have been associated with increasing dose and duration of treatment; in some patients, a dose reduction may ameliorate them. They resolve on withdrawal of the offending medication. Impulse control disorders are generally under-reported by patients and their families and often unrecognized by health care professionals. Risk factors include an impulsive personality, a history of drug use or other addictive behaviors, and a family history of gambling disorders.

A withdrawal syndrome develops in occasional patients tapered off a dopamine agonist. It consists of a combination of distressing physical and psychological symptoms that are refractory to levodopa and other dopaminergic medications, that may persist for months or longer, and for which no other cause can be found. Anxiety, agitation, panic attacks, depression, suicidal ideation, irritability, fatigue, postural hypotension, nausea, vomiting, diaphoresis, and drug cravings may occur. Risk factors include impulse control behavior disorders and higher dopamine agonist dosage. There is no effective treatment. The dopamine agonist should be reintroduced and tapered more gradually if possible.

Treatment with dopamine agonists should not be stopped abruptly, because doing so may rarely lead to an akinetic (parkinsonian) crisis or to a syndrome resembling neuroleptic malignant syndrome (discussed later).

### E. Miscellaneous

Headache, nasal congestion, increased arousal, pulmonary infiltrates, pleural and retroperitoneal fibrosis, and erythromelalgia are other reported adverse effects of the ergot-derived dopamine agonists. Erythromelalgia consists of red, tender, painful, swollen feet and, occasionally, hands, at times associated with arthralgia; symptoms and signs clear within a few days of withdrawal of the causal drug. In rare instances, an uncontrollable tendency to fall asleep at inappropriate times has occurred, particularly in patients receiving pramipexole or ropinirole; this requires discontinuation of the

## Contraindications

Dopamine agonists are contraindicated in patients with a history of psychotic illness or recent myocardial infarction, or with active peptic ulceration. The ergot-derived agonists are best avoided in patients with peripheral vascular disease.

## MONOAMINE OXIDASE INHIBITORS

Two types of monoamine oxidase have been distinguished in the nervous system. Monoamine oxidase A metabolizes norepinephrine, serotonin, and dopamine; monoamine oxidase B metabolizes dopamine selectively. **Selegiline** (deprenyl) (see [Figure 28-3](#)), a selective irreversible inhibitor of monoamine oxidase B at normal doses (at higher doses it inhibits monoamine oxidase A as well), retards the breakdown of dopamine (see [Figure 28-5](#)); in consequence, it enhances and prolongs the antiparkinsonism effect of levodopa (thereby allowing the dose of levodopa to be reduced) and may reduce mild on-off or wearing-off phenomena. It is therefore used as adjunctive therapy for patients with a declining or fluctuating response to levodopa. The standard dose of selegiline is 5 mg with breakfast and 5 mg with lunch. Selegiline may cause insomnia when taken later during the day.

Selegiline has only a minor therapeutic effect on parkinsonism when given alone. Studies in animals suggest that it may reduce disease progression, but trials to test the effect of selegiline on the progression of parkinsonism in humans have yielded ambiguous results. The findings in a large multicenter study were taken to suggest a beneficial effect in slowing disease progression but may simply have reflected a symptomatic response.

**Rasagiline**, another monoamine oxidase B inhibitor, is more potent than selegiline in preventing MPTP-induced parkinsonism and is being used as monotherapy for early treatment in patients with mild symptoms. The standard dosage is 1 mg/d. Rasagiline is also used as adjunctive therapy at a dosage of 0.5 or 1 mg/d to prolong the effects of carbidopa-levodopa in patients with advanced disease and response fluctuations. A large double-blind, placebo-controlled, delayed-start study (the ADAGIO trial) to evaluate whether it had neuroprotective benefit (ie, slowed the disease course) yielded unclear results: a daily dose of 1 mg met all the end points of the study and did seem to slow disease progression, but a 2-mg dose failed to do so. These findings are difficult to explain, and the decision to use rasagiline for neuroprotective purposes therefore remains an individual one.

A third monoamine oxidase B inhibitor, **safinamide**, has been used to reduce response fluctuations in patients taking carbidopa-levodopa, diminishing off-periods in patients with wearing-off effect or on-off phenomena. It is not effective as monotherapy for Parkinson disease. The starting dose is 50 mg orally once daily, increased after 2 weeks to 100 mg once daily.

Monoamine oxidase B inhibitors should not be taken by patients receiving meperidine, tramadol, methadone, propoxyphene, cyclobenzaprine, or St. John's wort. The antitussive dextromethorphan should also be avoided by patients taking one of the monoamine oxidase B inhibitors; indeed, it is wise to advise patients to avoid all over-the-counter cold preparations. Rasagiline, selegiline, or safinamide should not be taken with other monoamine oxidase inhibitors and should be used with care in patients receiving tricyclic antidepressants or serotonin reuptake inhibitors because of the theoretical risk of acute toxic interactions of the serotonin syndrome type (see [Chapter 16](#)), but this is rarely encountered in practice. The adverse effects of levodopa, especially dyskinesias, mental changes, nausea, and sleep disorders, may be increased by these drugs. Hypertension may be precipitated or aggravated.

The combined administration of levodopa and an inhibitor of both forms of monoamine oxidase (ie, a nonselective inhibitor) must be avoided, because it may lead to hypertensive crises, probably due to the peripheral accumulation of norepinephrine.

## CATECHOL-O-METHYLTRANSFERASE INHIBITORS

Inhibition of dopa decarboxylase is associated with compensatory activation of other pathways of levodopa metabolism, especially catechol-O-methyltransferase (COMT), and this increases plasma levels of 3-O-methyl-dopa (3-OMD). Elevated levels of 3-OMD have been associated with a poor therapeutic response to levodopa, perhaps in part because 3-OMD competes with levodopa for an active carrier mechanism that governs its transport across the intestinal mucosa and the blood-brain barrier. Selective COMT inhibitors such as **tolcapone** and **entacapone** also prolong the action of levodopa by diminishing its peripheral metabolism (see [Figure 28-5](#)). Levodopa clearance is decreased, and relative bioavailability of levodopa is thus increased. Neither the time to reach peak concentration nor the maximal concentration of levodopa is increased. These agents may be helpful in patients receiving levodopa who have developed response fluctuations, leading to a smoother response, more prolonged on-time, and the option of reducing total daily levodopa dose. There is no benefit in taking a COMT inhibitor either alone or with levodopa as initial therapy for parkinsonism.

[www.kopksu.in](http://www.kopksu.in) and entacapone are both widely available, but entacapone is generally preferred because it has not been associated with hepatotoxicity.

The pharmacologic effects of tolcapone and entacapone are similar, and both are rapidly absorbed, bound to plasma proteins, and metabolized before excretion. However, tolcapone has both central and peripheral effects, whereas the effect of entacapone is peripheral. The half-life of both drugs is approximately 2 hours, but tolcapone is slightly more potent and has a longer duration of action. Tolcapone is taken in a standard dosage of 100 mg three times daily; some patients require a daily dose of twice that amount. By contrast, entacapone (200 mg) needs to be taken with each dose of levodopa, up to six times daily.

**Opicapone** (Ongentys) is a newer long-acting, peripherally selective, catechol-*O*-methyl transferase inhibitor that is taken once daily at bedtime, in a 50-mg dose. As with the other COMT inhibitors, it decreases the duration of daily off-periods and increases on-time in patients with a fluctuating response to levodopa.

Adverse effects of the COMT inhibitors relate in part to increased levodopa exposure and include dyskinesias, nausea, and confusion. It is often necessary to lower the daily dose of levodopa by about 30% in the first 48 hours to avoid or reverse such complications. Other adverse effects include diarrhea, abdominal pain, orthostatic hypotension, sleep disturbances, and an orange discoloration of the urine. Tolcapone may cause an increase in liver enzyme levels and has been associated rarely with death from acute hepatic failure; accordingly, it should not be used in patients with abnormal liver function test results. Its use in the USA requires signed patient consent (as provided in the product labeling) plus monitoring of liver function tests every 2–4 weeks during the first 6 months and periodically but less frequently thereafter. The medication should be withdrawn and not reintroduced if hepatic damage becomes evident. No such toxicity has been reported with entacapone.

The commercial preparation named **Stalevo** consists of a combination of levodopa with both carbidopa and entacapone. It is available in three strengths: Stalevo 50 (50 mg levodopa plus 12.5 mg carbidopa and 200 mg entacapone), Stalevo 100 (100 mg, 25 mg, and 200 mg, respectively), and Stalevo 150 (150 mg, 37.5 mg, and 200 mg, respectively). Use of this preparation simplifies the drug regimen and requires the consumption of fewer tablets than otherwise. The combination agent may provide greater symptomatic benefit than carbidopa-levodopa alone. However, despite the convenience of a single combination preparation, use of Stalevo rather than carbidopa-levodopa has been associated with earlier occurrence and increased frequency of dyskinesia. There is no evidence that the use of Stalevo is associated with an increased risk for cardiovascular events (myocardial infarction, stroke, cardiovascular death).

## APOMORPHINE

Subcutaneous injection of apomorphine hydrochloride (**Apokyn**), a potent nonergoline dopamine agonist that interacts with postsynaptic D<sub>2</sub> receptors in the caudate nucleus and putamen, is effective for the temporary relief (“rescue”) of off-periods of akinesia in patients on optimized dopaminergic therapy. It is rapidly taken up in the blood and then the brain, leading to clinical benefit that begins within about 10 minutes of injection and persists for up to 2 hours. The optimal dose is identified by administering increasing test doses until adequate benefit is achieved or a maximum of 0.6 mL (6 mg) is reached, with the supine and standing blood pressures monitored before injection and then every 20 minutes for an hour after it. Most patients require a dose of 0.3–0.6 mL (3–6 mg), and this should be given usually no more than about three times daily, but occasionally up to five times daily. Apomorphine can also be given as continuous therapy by infusion to reduce off-time and response fluctuations.

Nausea is often troublesome, especially at the initiation of apomorphine treatment; accordingly, oral pretreatment with the antiemetic trimethobenzamide (300 mg three times daily) for 3 days is recommended before apomorphine is introduced and is then continued for at least 1 month, if not indefinitely. Other adverse effects include dyskinesias, drowsiness, insomnia, chest pain, sweating, hypotension, syncope, constipation, diarrhea, mental or behavioral disturbances, panniculitis, and bruising at the injection site. Apomorphine should be prescribed only by physicians familiar with its potential complications and interactions. It should not be used in patients taking serotonin 5-HT<sub>3</sub> antagonists because severe hypotension may result.

## AMANTADINE

Amantadine, an antiviral agent, was by chance found to have relatively weak antiparkinsonism properties. Its mode of action in parkinsonism is unclear, but it may potentiate dopaminergic function by influencing the synthesis, release, or reuptake of dopamine. It has been reported to antagonize the effects of adenosine at adenosine A<sub>2A</sub> receptors, which may inhibit D<sub>2</sub> receptor function. Release of catecholamines from peripheral stores has also been documented. Amantadine is an antagonist of the NMDA-type glutamate receptor, suggesting an antidyskinetic effect. It is available

in an immediate-release formulation (**Symmetrel**; standard dose, 100 mg orally two or three times daily) and extended-release formulations (**Gocovri**, once daily at bedtime; **Osmolex**, 129–322 mg once daily in the morning).

### Pharmacokinetics

Peak plasma concentrations of amantadine are reached 1–4 hours after an oral dose of the immediate-release preparation. The plasma half-life is between 2 and 4 hours, with most of the drug being excreted unchanged in the urine.

### Clinical Use

Amantadine is less efficacious than levodopa, and its benefits may be short-lived, often disappearing after only a few weeks of treatment. Nevertheless, during that time it may favorably influence the bradykinesia, rigidity, and tremor of parkinsonism. Amantadine may also help in reducing iatrogenic dyskinesias in patients with advanced disease.

### Adverse Effects

Amantadine has several undesirable central nervous system effects, all of which can be reversed by stopping the drug. These include restlessness, depression, suicidal ideation, irritability, impulse-control disorders, somnolence, insomnia, agitation, excitement, hallucinations, confusion, and psychosis. Overdosage may produce an acute toxic psychosis. With doses several times higher than recommended, convulsions have occurred.

Livedo reticularis sometimes occurs in patients taking amantadine and usually clears within 1 month after the drug is withdrawn. Other dermatologic reactions have also been described. Peripheral edema, another well-recognized complication, is not accompanied by signs of cardiac, hepatic, or renal disease and responds to diuretics. Other adverse reactions to amantadine include headache, heart failure, postural hypotension, urinary retention, and gastrointestinal disturbances (eg, anorexia, nausea, constipation, and dry mouth).

Amantadine should be used with caution in patients with a history of seizures, heart failure, or moderate or severe renal disease. Discontinuation of the medication should be gradual, as abrupt withdrawal may lead to an acute confusional state, hyperpyrexia, and abrupt worsening of parkinsonism.

## ISTRADefYLLINE

Istradefylline is an analog of caffeine and a selective antagonist of the adenosine  $A_{2A}$  receptor. It can be taken orally (20 or 40 mg daily) to reduce off-periods and improve motor function in patients taking carbidopa-levodopa. Side effects include dyskinesias, dizziness, constipation, nausea, hallucinations, and sleeplessness. Hallucinations, psychoses, or impulsive or compulsive behaviors may necessitate dose reductions or discontinuation of the drug.

## ACETYLCHOLINE-BLOCKING DRUGS

Several centrally acting antimuscarinic preparations are available that differ in their potency and in their efficacy in different patients. Some of these drugs were discussed in [Chapter 8](#). These agents may improve the tremor and rigidity of parkinsonism but have little effect on bradykinesia. They are more effective than placebo. Some of the more commonly used drugs are listed in [Table 28–2](#).

**Some drugs with antimuscarinic properties used in parkinsonism.**

Drug	Usual Daily Dose (mg)
Benztropine mesylate	1–6
Biperiden	2–12
Orphenadrine	150–400
Procyclidine	7.5–30
Trihexyphenidyl	6–20

**Clinical Use**

Treatment is started with a low dose of one of the drugs in this category, the dosage gradually being increased until benefit occurs or until adverse effects limit further increments. If patients do not respond to one drug, a trial with another member of the drug class is warranted and may be successful.

**Adverse Effects**

Antimuscarinic drugs have several undesirable central nervous system and peripheral effects (see [Chapter 8](#)) and are poorly tolerated by the elderly or cognitively impaired. Dyskinesias occur in rare cases. Acute suppurative parotitis sometimes occurs as a complication of dryness of the mouth.

If medication is to be withdrawn, this should be accomplished gradually rather than abruptly to prevent acute exacerbation of parkinsonism. For contraindications to the use of antimuscarinic drugs, see [Chapter 8](#).

**SURGICAL PROCEDURES**

Ablative surgical procedures for parkinsonism have generally been replaced by functional, reversible lesions induced by high-frequency deep brain stimulation, which has a lower morbidity.

Stimulation of the subthalamic nucleus or globus pallidus by an implanted electrode and stimulator has yielded good results for the management of the clinical fluctuations or the dyskinesias occurring in moderate parkinsonism. The anatomic substrate for such therapy is indicated in [Figure 28-1](#). Such procedures are contraindicated in patients with secondary or atypical parkinsonism, dementia, or failure to respond to dopaminergic medication. The level of antiparkinsonian medication can often be reduced in patients undergoing deep brain stimulation, and this may help to ameliorate dose-related adverse effects of medication. Patients with medically refractory tremor-predominant parkinsonism who are reluctant to undergo surgery may respond to focused ultrasound thalamotomy.

In a controlled trial of the transplantation of dopaminergic tissue (fetal substantia nigra tissue), symptomatic benefit occurred in younger (less than 60 years old) but not older parkinsonian patients. In another trial, benefits were inconsequential. Furthermore, uncontrollable dyskinesias occurred in some patients in both studies, perhaps from a relative excess of dopamine from continued fiber outgrowth from the transplant. Additional basic studies are required before further trials of cellular therapies—in particular, stem cell therapies—are undertaken, and such approaches therefore remain investigational.

**NEUROPROTECTIVE THERAPY**

Agents that have been investigated as potential neuroprotective agents to slow disease progression are antioxidants, antiapoptotic

agents, glutamate antagonists, intraparenchymally administered neurotrophic factor, and anti-inflammatory drugs. None of these agents has been shown to be effective in this context, however, and their use for therapeutic purposes is not indicated at this time. Specifically, coenzyme Q10, creatine, pramipexole, and pioglitazone have not been found to be effective despite early hopes to the contrary. The urate precursor inosine, and isradipine, a dihydropyridine calcium-channel blocker with relatively high affinity for  $C_{av}1.3$  channels, also failed to show benefit in randomized controlled trials. The possibility that rasagiline has a protective effect was discussed earlier.

Other agents currently being studied as disease-modifying agents include deferiprone (a potent iron chelator) and exenatide, a glucagon-like peptide-1 (GLP-1) receptor agonist (see [Chapter 41](#)) that affects various cellular processes likely to be involved in the etiology of Parkinson disease.

Active and passive immunization against  $\alpha$ -synuclein or an  $\alpha$ -synuclein-mimicking peptide is also being explored. The procedures are generally well-tolerated, without treatment-associated adverse events other than mild injection-site reactions, and lead to generation of antibodies against  $\alpha$ -synuclein.

Recent work suggests that an assay for misfolded  $\alpha$ -synuclein in the spinal fluid has high sensitivity and specificity in distinguishing Parkinson disease from healthy controls and may serve as a useful biomarker of the disease, even before it becomes manifest clinically. If confirmed, this would permit those at risk of the disease to start protective treatment before they become symptomatic.

## GENE THERAPY

Several phase 1 (safety) or phase 2 trials of gene therapy for Parkinson disease have been completed in the USA. All trials involved infusion into the striatum of adeno-associated virus type 2 as the vector for the gene. The genes were for glutamic acid decarboxylase (GAD, to facilitate synthesis of GABA, an inhibitory neurotransmitter), infused into the subthalamic nucleus to cause inhibition; for aromatic acid decarboxylase (AADC), infused into the putamen to increase metabolism of levodopa to dopamine; and for neurturin (a growth factor that may enhance the survival of dopaminergic neurons), infused into the putamen. All agents were deemed safe. A phase 2 study of the GAD gene has been completed and the results are encouraging, but one for neurturin infused into the substantia nigra as well as the putamen was disappointing. In a phase 1b trial of AADC in moderately advanced disease, motor function and quality of life stabilized or improved, and medication requirements were reduced in some patients. The results of a European study involving bilateral intrastriatal delivery of ProSavin, a lentiviral vector-based gene therapy with three genes (decarboxylase, tyrosine hydroxylase, and GTP-cyclohydrolase 1) aimed at restoring local and continuous dopamine production in patients with advanced Parkinson disease, have also been encouraging.

## THERAPY FOR NONMOTOR MANIFESTATIONS

Persons with cognitive decline may respond to rivastigmine (1.5–6 mg twice daily), memantine (5–10 mg daily), or donepezil (5–10 mg daily) (see [Chapter 60](#)); with affective disorders to antidepressants or anxiolytic agents (see [Chapter 30](#)); with psychosis to atypical antipsychotic agents or pimavanserin; with excessive daytime sleepiness to modafinil (100–400 mg in the morning) (see [Chapter 9](#)); and with bladder and bowel disorders to appropriate symptomatic therapy (see [Chapter 8](#)).

## GENERAL COMMENTS ON DRUG MANAGEMENT OF PATIENTS WITH PARKINSONISM

Parkinson disease generally follows a progressive course. Moreover, the benefits of levodopa therapy often diminish as the disease advances, and serious adverse effects may complicate long-term levodopa treatment. Nevertheless, dopaminergic therapy at a relatively early stage may be most effective in alleviating motor symptoms of parkinsonism and may also favorably affect the mortality rate due to the disease. Therefore, several strategies have evolved for optimizing dopaminergic therapy, as summarized in [Figure 28-5](#). Symptomatic treatment of mild parkinsonism is probably best avoided until there is some degree of disability or functional limitation or until symptoms begin to impact the patient's lifestyle or cause significant social impairment.

When symptomatic treatment becomes necessary, a trial of rasagiline, selegiline, amantadine, or an antimuscarinic drug (in young patients) may be worthwhile. With disease progression, dopaminergic therapy becomes necessary. This can conveniently be initiated with either carbidopa-levodopa therapy or a dopamine agonist, either alone or in combination, although an agonist is best avoided in patients older than 70 or when risk factors for impulse control disorders are present. Carbidopa-levodopa is the most effective symptomatic treatment of the motor disturbances of parkinsonism. Physical therapy is helpful in improving mobility. In patients with severe parkinsonism and long-term complications of levodopa therapy such as the

on-off phenomenon, a trial of treatment with the newer extended-release formulation of carbidopa-levodopa (Rytary), a COMT inhibitor, or rasagiline may be helpful. Regulation of dietary protein intake may also improve response fluctuations. Deep brain stimulation is often helpful in patients with response fluctuations or dyskinesias who fail to respond adequately to these measures. Treating patients who are young or have mild parkinsonism with rasagiline may delay disease progression and merits consideration, although evidence of benefit is incomplete.

## DRUG-INDUCED PARKINSONISM

Reserpine and the related drugs tetrabenazine, deutetabenazine, and valbenazine deplete biogenic monoamines from their storage sites, whereas haloperidol, metoclopramide, and the phenothiazines block dopamine receptors. These drugs may therefore produce a parkinsonian syndrome, usually within 3 or 4 months after introduction. The disorder tends to be symmetric, with inconspicuous tremor, but this is not always the case. The syndrome is related to high dosage and clears over several weeks or months after withdrawal. If treatment is necessary, antimuscarinic agents are preferred. Levodopa is of no help if neuroleptic drugs are continued and may in fact aggravate the mental disorder for which antipsychotic drugs were prescribed originally.

In 1983, a drug-induced form of parkinsonism was discovered in individuals who attempted to synthesize and use a narcotic drug related to meperidine but actually synthesized and self-administered MPTP, as discussed in the Box: [MPTP & Parkinsonism](#).

### MPTP & Parkinsonism

Reports in the early 1980s of a rapidly progressive form of parkinsonism in young persons opened a new area of research in the etiology and treatment of parkinsonism. The initial report described apparently healthy young people who attempted to support their opioid habit with a meperidine analog synthesized by an amateur chemist. They unwittingly self-administered 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and subsequently developed a very severe form of parkinsonism.

MPTP is a protoxin that is converted by monoamine oxidase B to *N*-methyl-4-phenylpyridinium (MPP<sup>+</sup>). MPP<sup>+</sup> is selectively taken up by cells in the substantia nigra through an active mechanism normally responsible for dopamine reuptake. MPP<sup>+</sup> inhibits mitochondrial complex I, thereby inhibiting oxidative phosphorylation. The interaction of MPP<sup>+</sup> with complex I probably leads to cell death and thus to striatal dopamine depletion and parkinsonism.

Recognition of the effects of MPTP suggested that spontaneously occurring Parkinson disease may result from exposure to an environmental toxin that is similarly selective in its target. However, no such toxin has yet been identified. It also suggested a successful means of producing an experimental model of Parkinson disease in animals, especially nonhuman primates. This model is useful in the development of new antiparkinsonism drugs. Pretreatment of exposed animals with a monoamine oxidase B inhibitor such as selegiline prevents the conversion of MPTP to MPP<sup>+</sup> and thus protects against the occurrence of parkinsonism. This observation has provided one reason to believe that selegiline or rasagiline may retard the progression of Parkinson disease in humans.

## ATYPICAL PARKINSONISM SYNDROMES

Several disorders characterized by parkinsonism differ from classic Parkinson disease because of inconspicuous tremor, symmetry of the neurologic findings, and the presence of additional findings (eg, dysautonomia, cerebellar deficits, eye movement abnormalities, or early cognitive and behavioral changes). These disorders include **multisystem atrophy**, **progressive supranuclear palsy**, **corticobasal degeneration** (in which parkinsonism may be markedly asymmetric), and **diffuse Lewy body disease**. The prognosis is worse than for Parkinson disease, and the response to antiparkinsonian treatment may be limited. Treatment is symptomatic.

## OTHER MOVEMENT DISORDERS

### Tremor

Tremor consists of rhythmic oscillatory movements. Physiologic postural tremor, which is a normal phenomenon, is enhanced in amplitude by anxiety, fatigue, thyrotoxicosis, and intravenous epinephrine or isoproterenol. **Propranolol** reduces its amplitude and, if administered intra-arterially,

agents, the response to isoproterenol in the perfused limb, presumably through some peripheral action. Certain drugs—especially the bronchodilators, valproate, tricyclic antidepressants, and lithium—may produce a dose-dependent exaggeration of the normal physiologic tremor that is reversed by discontinuing the drug. Although the tremor produced by sympathomimetics such as terbutaline (a bronchodilator) is blocked by propranolol, which antagonizes both  $\beta_1$  and  $\beta_2$  receptors, it is not blocked by metoprolol, a  $\beta_1$ -selective antagonist; this suggests that such tremor is mediated mainly by the  $\beta_2$  receptors.

**Essential tremor** is a postural tremor, sometimes familial with autosomal dominant inheritance, which is clinically similar to physiologic tremor. Dysfunction of  $\beta_1$  receptors has been implicated in some instances, since the tremor may respond dramatically to standard doses of metoprolol as well as to propranolol. The tremor may involve the hands, head, voice, and—much less commonly—the legs. Patients may become functionally limited or socially withdrawn, quality of life is affected, and some patients report being seriously disabled by the tremor.

The most useful therapeutic approach is with propranolol, but whether the response depends on a central or peripheral action is unclear. The pharmacokinetics, pharmacologic effects, and adverse reactions of propranolol are discussed in [Chapter 10](#). Total daily doses of propranolol on the order of 120 mg or more (range, 60–320 mg) are usually required, divided into two doses; reported adverse effects have been few. Propranolol should be used with caution in patients with heart failure, heart block, asthma, depression, or hypoglycemia. Other adverse effects include fatigue, malaise, lightheadedness, and impotence. Patients can be instructed to take their own pulse and call the physician if significant bradycardia develops. Long-acting propranolol is also effective and is preferred by many patients because of its convenience. Some patients prefer to take a single dose of propranolol when they anticipate their tremor is likely to be exacerbated, for example, by social situations. Metoprolol is sometimes useful in treating tremor when patients have concomitant pulmonary disease that contraindicates use of propranolol.

Drugs potentiating GABA<sub>A</sub> receptors in the central nervous system (such as phenobarbital, primidone, topiramate, and benzodiazepines) also improve tremor, but phenobarbital is not used clinically because of its sedating effect. **Primidone** (an antiepileptic drug; see [Chapter 24](#)), in gradually increasing doses up to 250 mg three times daily, is also effective in providing symptomatic control in some cases. Patients with tremor are very sensitive to primidone and often cannot tolerate the doses used to treat seizures; they should be started on 50 mg once daily and the daily dose increased by 50 mg every 2 weeks depending on response. In many instances, a dose of 125 mg two or three times daily is sufficient.

**Topiramate**, another antiepileptic drug, may also be helpful in a dose of 400 mg daily, built up gradually. **Alprazolam** (in doses up to 3 mg daily) or **gabapentin** (100–2400 mg/d; typically 1200 mg/d) is helpful in some patients. Gabapentin binds to the  $\alpha_2\delta$  subunit of calcium channels. It produces less consistent relief of tremor but is associated with fewer side effects than primidone. Other patients are helped by intramuscular injections of botulinum toxin, but dose-dependent weakness may complicate symptomatic benefit. Thalamic stimulation by an implanted electrode and stimulator is worthwhile in advanced cases refractory to pharmacotherapy. Thalamotomy by magnetic resonance imaging-guided focused ultrasound or stereotactic radiosurgery is also effective in reducing upper-extremity tremor. Diazepam, chlordiazepoxide, mephenesin, and antiparkinsonism agents have been advocated in the past but are generally of little benefit. Small quantities of alcohol may suppress essential tremor for a short time but should not be recommended as a treatment strategy because of possible behavioral and other complications of alcohol.

**Intention tremor** is present during movement but not at rest; sometimes it occurs as a toxic manifestation of alcohol or drugs such as phenytoin. Withdrawal or reduction in dosage provides dramatic relief. There is no satisfactory pharmacologic treatment for intention tremor due to other neurologic disorders.

**Rest tremor** is usually due to parkinsonism.

## Huntington Disease

Huntington disease is an autosomal dominant inherited disorder caused by an abnormality (expansion of a CAG trinucleotide repeat that codes for a polyglutamine tract) of the *huntingtin* gene on chromosome 4. An autosomal recessive form may also occur. Huntington disease-like (HDL) disorders are not associated with an abnormal CAG trinucleotide repeat number of the *huntingtin* gene. Autosomal dominant (*HDL1*, 20pter-p12; *HDL2*, 16q24.3) and recessive forms (*HDL3*, 4p15.3) occur.

Huntington disease is characterized by progressive chorea and dementia that usually begin in adulthood. The development of chorea seems to be related to an imbalance of dopamine, acetylcholine, GABA, and perhaps other neurotransmitters in the basal ganglia ([Figure 28–6](#)). Pharmacologic treatment of chorea results from functional overactivity in dopaminergic nigrostriatal pathways, perhaps because of increased responsiveness

of postsynaptic dopamine receptor that normally antagonizes dopamine. Drugs that impair dopaminergic neurotransmission, either by depleting central monoamines (eg, reserpine, tetrabenazine, deutetabenazine, valbenazine) or by blocking dopamine receptors (eg, phenothiazines, butyrophenones), often alleviate chorea, whereas dopamine-like drugs such as levodopa tend to exacerbate it.

FIGURE 28-6

Schematic representation of the sequence of neurons involved in Huntington chorea. The complex anatomic circuitry has been simplified. **Top:** Dopaminergic neurons (red) originating in the substantia nigra normally inhibit the output of the spiny GABAergic neurons from the striatum, whereas cholinergic neurons (green) exert an excitatory effect. **Bottom:** In Huntington chorea, some cholinergic neurons may be lost, but even more GABAergic neurons (black) degenerate.

Both GABA and the enzyme (glutamic acid decarboxylase) concerned with its synthesis are markedly reduced in the basal ganglia of patients with Huntington disease, and GABA receptors are usually implicated in inhibitory pathways. There is also a significant decline in concentration of choline acetyltransferase, the enzyme responsible for synthesizing acetylcholine, in the basal ganglia of these patients. These findings may be of pathophysiologic significance and have led to attempts to alleviate chorea by enhancing central GABA or acetylcholine activity, but with disappointing results. Consequently, the most commonly used drugs for controlling dyskinesia in patients with Huntington disease are still those that interfere with dopamine activity. With all the latter drugs, however, reduction of abnormal movements may be associated with iatrogenic parkinsonism.

**Tetrabenazine** (12.5–50 mg orally three times daily) depletes cerebral dopamine and reduces the severity of chorea. It has less troublesome adverse effects than reserpine, which has also been used for this purpose. Tetrabenazine is metabolized by cytochrome P450 (CYP2D6), and genotyping has therefore been recommended to determine metabolizer status (CYP2D6 expression) in patients needing doses exceeding 50 mg/d. For poor metabolizers, the maximum recommended dose is 50 mg daily (25 mg/dose); otherwise, a maximum dose of 100 mg daily can be used. Treatment with postsynaptic dopamine receptor blockers such as phenothiazines and butyrophenones may also be helpful. **Haloperidol** is started in a small dose, eg, 1 mg twice daily, and increased every 4 days depending on the response. If haloperidol is not helpful, treatment with increasing doses of **fluphenazine** in a similar dose, eg, 1 mg twice daily, sometimes helps. Several recent reports suggest that **olanzapine** may also be useful; the dose varies with the patient, but 10 mg daily is often sufficient, although doses as high as 30 mg daily are sometimes required. The pharmacokinetics and clinical properties of these drugs are considered in greater detail elsewhere in this book. Selective serotonin reuptake inhibitors may reduce depression, aggression, and agitation. However, strong CYP2D6 inhibitors should be used with caution, as it may be necessary to decrease the dose of tetrabenazine taken concurrently.

**Deutetabenazine** is a selective inhibitor of the vesicular monoamine 2 transporter (VMAT2) that modulates dopamine stores. It seems as effective as tetrabenazine for treating the chorea of Huntington disease and improving overall motor function, and may have fewer side effects. The dose is built up weekly from 6 mg daily to a maximum of 24 mg twice daily with food (18 mg twice daily in poor CYP2D6 metabolizers). It may cause agitation,

restlessness, and parkinsonism. Other adverse effects are sedation, dry mouth, diarrhea, insomnia, and fatigue. QT prolongation may occur. Deutetrabenazine is contraindicated in patients on monoamine oxidase inhibitors, reserpine, or tetrabenazine, and in those who are severely depressed or suicidal. **Valbenazine**, discussed later, is also now approved for treating chorea in patients with Huntington disease.

Other important aspects of management include genetic counseling, speech therapy, physical and occupational therapy, dysphagia precautions, and provision of social services.

## Other Forms of Chorea

**Benign hereditary chorea** is inherited (usually autosomal dominant; possibly also autosomal recessive) or arises spontaneously. Chorea develops in early childhood and does not progress during adult life; dementia does not occur. In patients with *TITF-1* gene mutations, thyroid and pulmonary abnormalities may also be present (brain-thyroid-lung syndrome). Familial chorea may also occur as part of the chorea-acanthocytosis syndrome, together with orolingual tics, vocalizations, cognitive changes, seizures, peripheral neuropathy, and muscle atrophy; serum  $\beta$ -lipoproteins are normal. Mutations of the gene encoding chorein at 9q21 may be causal. Treatment of these hereditary disorders is symptomatic. Tetrabenazine (0.5 mg/kg/d for children and 37.5 mg/d for adults) may improve chorea in some instances. The efficacy in this context of the newer selective VMAT2 blockers deutetrabenazine and valbenazine is unclear.

Treatment is directed at the underlying cause when chorea occurs as a complication of general medical disorders such as thyrotoxicosis, polycythemia vera rubra, systemic lupus erythematosus, hypocalcemia, and hepatic cirrhosis. Drug-induced chorea is managed by withdrawal of the offending substance, which may be levodopa, an antimuscarinic drug, amphetamine, lithium, phenytoin, or an oral contraceptive. Neuroleptic drugs may also produce an acute or tardive dyskinesia (discussed below). Sydenham's chorea is temporary and usually so mild that pharmacologic management of the dyskinesia is unnecessary, but dopamine-blocking drugs are effective in suppressing it.

## Ballismus

The biochemical basis of ballismus is unknown, but the pharmacologic approach to management is the same as for chorea. Treatment with tetrabenazine, haloperidol, perphenazine, or other dopamine-blocking drugs may be helpful.

## Athetosis & Dystonia

The physiologic basis of these disorders is unknown, and there is no satisfactory medical treatment for them. A subset of patients respond well to levodopa medication (dopa-responsive dystonia), which is therefore worthy of trial. Occasional patients with dystonia may respond to diazepam, amantadine, antimuscarinic drugs (in high dosage), carbamazepine, baclofen, haloperidol, or phenothiazines. A trial of these pharmacologic approaches is worthwhile, though often not successful. Patients with focal dystonias such as blepharospasm or torticollis often benefit from injection of botulinum toxin into the overactive muscles. Deep brain stimulation may be helpful in medically intractable cases. The role of repetitive transcranial magnetic stimulation and transcranial direct current stimulation to induce plastic changes in the brain is being explored.

## Tics

The pathophysiologic basis of tics is unknown. Chronic multiple tics (**Gilles de la Tourette syndrome**) may require symptomatic treatment if the disorder is severe or is having a significant impact on the patient's life. Education of patients, family, and teachers is important. Comprehensive behavioral intervention may help adults with Tourette syndrome. Pharmacologic therapy may be necessary when tics interfere with social life or otherwise impair activities of daily living.

Treatment is with drugs that block dopamine receptors or deplete dopamine stores, such as fluphenazine, pimozide, and tetrabenazine. These drugs reduce the frequency and intensity of tics by about 60%. **Pimozide**, a dopamine receptor antagonist, may be helpful in patients as a first-line treatment or in those who are either unresponsive to or intolerant of the other agents mentioned. Treatment is started at 1 mg/d, and the dosage is increased by 1 mg every 5 days; most patients require 7–16 mg/d. It has similar side effects to haloperidol but may cause irregularities of cardiac rhythm. **Haloperidol** has been used for many years to treat tic disorders. Patients are better able to tolerate this drug if treatment is started with a small dosage (eg, 0.25 or 0.5 mg daily) and then increased gradually (eg, by 0.25 mg every 4 or 5 days) over the following weeks depending on response and tolerance. Most patients ultimately require a total daily dose of 3–8 mg. Adverse effects include extrapyramidal movement disorders, sedation, dryness of the mouth, blurred vision, and gastrointestinal disturbances. **Deutetrabenazine** and **aripiprazole** (see [Chapter 29](#)) have also been found

blocker, produced significant reduction in tic severity in children with Tourette syndrome in a phase 2b randomized controlled clinical trial. The drug was well tolerated and further studies are planned.

Although not approved by the US Food and Drug Administration (FDA) for the treatment of tics or Tourette syndrome, certain  $\alpha_2$ -adrenergic agonists may be preferred as an initial treatment because they are less likely to cause extrapyramidal side effects than neuroleptic agents. **Clonidine** reduces motor or vocal tics in about 50% of children so treated. It may act by reducing activity in noradrenergic neurons in the locus coeruleus. It is introduced at a dose of 2–3 mcg/kg/d, increasing after 2 weeks to 4 mcg/kg/d and then, if required, to 5 mcg/kg/d. It may cause an initial transient fall in blood pressure. The most common adverse effect is sedation; other adverse effects include reduced or excessive salivation and diarrhea. **Guanfacine**, another  $\alpha_2$ -adrenergic agonist, has also been used. Both of these drugs may be particularly helpful for behavioral symptoms, such as impulse control disorders.

Atypical antipsychotics, such as risperidone and aripiprazole, may be especially worthwhile in patients with significant behavioral problems. Clonazepam, baclofen, topiramate, and carbamazepine have also been used to treat tics in preference to dopamine receptor blockers with their potential side effects. The pharmacologic properties of these drugs are discussed elsewhere in this book.

Injection of botulinum toxin A at the site of problematic tics is sometimes helpful when these are focal simple tics. Treatment of any associated attention deficit disorder (eg, with clonidine patch, guanfacine, pemoline, methylphenidate, or dextroamphetamine) or obsessive-compulsive disorder (with selective serotonin reuptake inhibitors or clomipramine) may be required.

Deep brain stimulation is sometimes worthwhile in otherwise intractable cases.

### Drug-Induced Dyskinesias

Levodopa or dopamine agonists produce diverse dyskinesias as a dose-related phenomenon in patients with Parkinson disease; dose reduction reverses them. Chorea may also develop in patients receiving phenytoin, carbamazepine, amphetamines, lithium, and oral contraceptives, and it resolves with discontinuance of the offending medication. Dystonia has resulted from administration of dopaminergic agents, lithium, serotonin reuptake inhibitors, carbamazepine, and metoclopramide; and postural tremor from theophylline, caffeine, lithium, valproic acid, thyroid hormone, tricyclic antidepressants, and isoproterenol.

The pharmacologic basis of the acute dyskinesia or dystonia sometimes precipitated by the first few doses of a phenothiazine is not clear. In most instances, parenteral administration of an antimuscarinic drug such as benztropine (2 mg intravenously), diphenhydramine (50 mg intravenously), or biperiden (2–5 mg intravenously or intramuscularly) is helpful, whereas in other instances diazepam (10 mg intravenously) alleviates the abnormal movements.

**Tardive dyskinesia**, a disorder characterized by a variety of abnormal movements, is a common complication of long-term neuroleptic or metoclopramide drug treatment (see [Chapter 29](#)). Its precise pharmacologic basis is unclear. A reduction in dose of the offending medication, a dopamine receptor blocker, commonly worsens the dyskinesia, whereas an increase in dose may suppress it. The drugs most likely to provide immediate symptomatic benefit are those interfering with dopaminergic function, either by depletion (eg, reserpine, tetrabenazine) or receptor blockade (eg, phenothiazines, butyrophenones). Paradoxically, the receptor-blocking drugs are the ones that also cause the dyskinesia.

**Deutetrabenazine** and **valbenazine** are selective inhibitors of VMAT2, which modulates dopamine release, and both ameliorate tardive dyskinesia. Deutetrabenazine was discussed earlier. Valbenazine is started in a dose of 40 mg once daily for 1 week and then increased to 80 mg once daily. Somnolence and QT prolongation may occur. Adverse effects include anticholinergic effects, impaired balance and falls, headache, akathisia, arthralgia, and nausea and vomiting. Valbenazine should not be used with monoamine oxidase inhibitors; its dose should be reduced in patients receiving a strong inhibitor of CYP2D6 (eg, paroxetine, fluoxetine) or CYP3A4 (eg, carbamazepine, phenytoin).

**Tardive dystonia** is usually segmental or focal; generalized dystonia is less common and occurs in younger patients. Treatment is the same as for tardive dyskinesia, but anticholinergic drugs may also be helpful; focal dystonias may also respond to local injection of botulinum A toxin. **Tardive akathisia** is treated similarly to drug-induced parkinsonism. **Rabbit syndrome**, another neuroleptic-induced disorder, is manifested by rhythmic vertical movements about the mouth; it may respond to anticholinergic drugs.

Because the tardive syndromes that develop in adults are often irreversible and have no satisfactory treatment, care must be taken to reduce the likelihood of their occurrence. Antipsychotic medication should be prescribed only when necessary and should be withheld periodically to assess the need for continued treatment and to unmask incipient dyskinesia. Thioridazine, a phenothiazine with a piperidine side chain, is an effective antipsychotic agent that seems less likely than most to cause extrapyramidal reactions, perhaps because it has little effect on dopamine receptors in the striatal system. Finally, antimuscarinic drugs should not be prescribed routinely in patients receiving neuroleptics, because the combination may increase the likelihood of dyskinesia.

**Neuroleptic malignant syndrome** is a rare complication of treatment with neuroleptics and certain antiemetic agents (such as metoclopramide and promethazine). A somewhat similar syndrome may occur with withdrawal of dopaminergic therapy in parkinsonian patients. It is characterized by rigidity, fever, changes in mental status, and autonomic dysfunction (see [Table 16-4](#)). Symptoms typically develop over 1–3 days (rather than minutes to hours as in malignant hyperthermia) and may occur at any time during treatment. The serum creatine kinase level is increased to very high levels. Treatment includes withdrawal of antipsychotic drugs, lithium, and anticholinergics; reduction of body temperature; and rehydration. A markedly elevated blood pressure should be lowered. Benzodiazepines (diazepam or lorazepam) help in reducing agitation. Dantrolene, dopamine agonists, levodopa, or amantadine may also be helpful, but there is a high mortality rate (up to 20%) with neuroleptic malignant syndrome.

### Restless Legs Syndrome

Restless legs syndrome is characterized by an unpleasant creeping discomfort that seems to arise deep within the legs and occasionally the arms. Symptoms occur particularly when patients are relaxed, especially when they are lying down or sitting, and they lead to an urge to move about. Such symptoms may delay the onset of sleep. A sleep disorder associated with periodic movements during sleep may also occur. The cause is unknown, but the disorder is especially common among pregnant women and also among uremic or diabetic patients with neuropathy. In most patients, no obvious predisposing cause is found, but several genetic loci have been associated with it.

Symptoms may resolve with correction of coexisting iron-deficiency anemia or a low-normal serum ferritin level, or with avoidance of caffeine, sleep deprivation, and various medications that can provoke or exacerbate them, such as serotonergic antidepressants, neuroleptics, metoclopramide, and antihistamines. They often respond to pharmacologic agents. Dopaminergic therapy can be initiated with long-acting dopamine agonists (eg, oral **pramipexole** 0.125–0.75 mg or **ropinirole** 0.25–4.0 mg once daily) or with the rotigotine skin patch to avoid the augmentation that may be associated especially with carbidopa-levodopa (25/100 or 50/200 taken about 1 hour before bedtime). Augmentation refers to the earlier onset or enhancement of symptoms; earlier onset of symptoms at rest; and a briefer response to medication. When augmentation occurs with levodopa, a dopamine agonist should be substituted. If it occurs in patients receiving an agonist, the daily dose should be divided, another agonist tried, or other medications substituted. Dopamine agonist therapy may be associated with development of impulse control disorders.

**Gabapentin** is effective in reducing the severity of restless legs syndrome and is taken once or twice daily (in the evening and before sleep). The starting dose is 300 mg daily, building up depending on response and tolerance (to approximately 1800 mg daily). Oral gabapentin enacarbil (600 or 1200 mg once daily) or **pregabalin** (150–300 mg daily, in divided doses) may also help. **Clonazepam**, 1 mg daily, is also sometimes worthwhile, especially for those with intermittent symptoms. When **opiates** are required, those with long half-lives or low addictive potential should be used. Oxycodone is often effective; the dose is individualized.

### Wilson Disease

A recessively inherited disorder of copper metabolism due to mutations in the copper-transporting gene, *ATP7B*, Wilson disease is characterized biochemically by reduced serum copper and ceruloplasmin concentrations, with increased urinary copper excretion; pathologically by markedly increased concentration of copper in the brain and viscera; and clinically by hepatic, neurologic, and psychiatric dysfunction. Neurologic signs include tremor, choreiform movements, rigidity and hypokinesia (parkinsonism), ataxia, cognitive changes, and dysarthria and dysphagia. Siblings of affected patients should be screened for asymptomatic Wilson disease. Kayser-Fleischer rings, brownish deposits of copper in Descemet membrane in the cornea, are seen in virtually all patients with neurologic abnormalities and in approximately half of those with only hepatic manifestations.

Treatment should start promptly, even in presymptomatic cases, continue indefinitely, and be monitored by laboratory tests and neurologic examination. It involves the removal of excess copper, followed by maintenance of copper balance. Dietary copper should also be kept below 2 mg daily. **Penicillamine** (dimethylcysteine) has been used for many years as the primary agent to remove copper. It is a chelating agent that forms a ring complex with copper (see [Chapter 57](#)). It is readily absorbed from the gastrointestinal tract and rapidly excreted in the urine. A common starting dose

in adults is 500 mg three or four times daily. After remission occurs, it may be possible to lower the maintenance dose, generally to not less than 1 g daily, which must thereafter be continued indefinitely. Adverse effects include nausea and vomiting, nephrotic syndrome, a lupus-like syndrome, pemphigus, myasthenia, arthropathy, optic neuropathy, and various blood dyscrasias. In about 10% of instances, neurologic worsening occurs with penicillamine. Treatment should be monitored by frequent urinalysis and complete blood counts and serum creatinine determination. Patients receiving penicillamine should also take pyridoxine, 25 mg daily, unless it is part of the penicillamine formulation, to prevent pyridoxine deficiency.

**Trientine hydrochloride**, another chelating agent, is preferred by many over penicillamine because of the lesser likelihood of drug reactions or neurologic worsening. It may be used in a daily dose of 1–1.5 g. Trientine appears to have few adverse effects other than mild anemia due to iron deficiency in a few patients. **Tetrathiomolybdate** may be better than trientine for preserving neurologic function in patients with neurologic involvement and is taken both with and between meals. It is currently undergoing clinical trials (phase 3) and is not yet commercially available or approved by the FDA.

Zinc acetate administered orally increases the fecal excretion of copper and can be used in combination with these other agents. The dose is 50 mg three times a day. Zinc sulfate (200 mg/d orally) has also been used to decrease copper absorption. Zinc blocks copper absorption from the gastrointestinal tract by induction of intestinal cell metallothionein. Its main advantage is its low toxicity compared with that of other anticopper agents, although it may cause gastric irritation when introduced.

Liver transplantation is sometimes necessary to restore hepatic function and ameliorate portal hypertension when medical treatment is inadequate. Its role in the management of patients with primarily neurologic manifestations is unclear. In such patients survival is poorer but transplantation has been proposed as rescue therapy in patients with neurologic involvement resistant to anticopper therapies.

#### SUMMARY Drugs Used for Selected Movement Disorders

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>LEVODOPA AND COMBINATIONS</b>				
<ul style="list-style-type: none"> <li>Levodopa</li> </ul>	Transported into the central nervous system (CNS) and converted to dopamine (which does not enter the CNS); also converted to dopamine in the periphery	Ameliorates all motor symptoms of Parkinson disease and causes significant peripheral dopaminergic effects (see text)	Parkinson disease: Most efficacious therapy but not always used as the first drug due to development of disabling response fluctuations over time	Oral • ~6–8 h effect • <i>Toxicity</i> : Gastrointestinal upset, arrhythmias, dyskinesias, on-off and wearing-off phenomena, behavioral disturbances • <i>Interactions</i> : Use with carbidopa greatly diminishes required dosage and is now standard • use with COMT or MAO-B inhibitors prolongs duration of effect
<ul style="list-style-type: none"> <li><i>Levodopa + carbidopa (Sinemet, others): Carbidopa inhibits peripheral metabolism of levodopa to dopamine and reduces required dosage and toxicity; carbidopa does not enter CNS</i></li> <li><i>Levodopa + carbidopa + entacapone (Stalevo): Entacapone is a catechol-O-methyltransferase (COMT) inhibitor (see below)</i></li> </ul>				
<b>DOPAMINE AGONISTS</b>				
<ul style="list-style-type: none"> <li>Pramipexole</li> </ul>	Direct agonist at D <sub>3</sub> receptors, nonergot	Reduces symptoms of parkinsonism • smooths out fluctuations in levodopa	Parkinson disease: Can be used as initial therapy • also effective in on-off phenomenon	Oral • ~8 h effect • <i>Toxicity</i> : Nausea and vomiting, postural hypotension, dyskinesias, confusion, impulse control disorders, sleepiness

- *Ropinirole: Similar to pramipexole; nonergot; relatively pure D<sub>2</sub> agonist*
- *Bromocriptine: Ergot derivative; potent agonist at D<sub>2</sub> receptors; more toxic than pramipexole or ropinirole; now rarely used for antiparkinsonian effect*
- *Apomorphine: Nonergot; subcutaneous route useful for rescue treatment in levodopa-induced dyskinesia; high incidence of nausea and vomiting*

### MONOAMINE OXIDASE (MAO) INHIBITORS

- |              |   |  |   |   |
|--------------|---|--|---|---|
| • Rasagiline | Inhibits MAO-B selectively; higher doses also inhibit MAO-A | Increases dopamine stores in neurons; may have neuroprotective effects | Parkinson disease: Adjunctive to levodopa • smooths levodopa response | Oral • <i>Toxicity &amp; interactions:</i> May cause serotonin syndrome with meperidine, and theoretically also with selective serotonin reuptake inhibitors, tricyclic antidepressants |
|--------------|---|--|---|---|

- *Selegiline: Like rasagiline, adjunctive use with levodopa; may be less potent than rasagiline*
- *Safinamide: Also used as adjunct to levodopa in patients with response fluctuations*

### COMT INHIBITORS

- |              |   |  |                   |  |
|--------------|---|--|-------------------|--|
| • Entacapone | Inhibits COMT in periphery • does not enter CNS | Reduces metabolism of levodopa and prolongs its action | Parkinson disease | Oral • <i>Toxicity:</i> Increased levodopa toxicity • nausea, dyskinesias, confusion |
|--------------|---|--|-------------------|--|

- *Tolcapone: Like entacapone but enters CNS; some evidence of hepatotoxicity, elevation of liver enzymes*
- *Opicapone: Taken once daily*

### ANTIMUSCARINIC AGENTS

- |               |  |   |                   |   |
|---------------|--|---|-------------------|---|
| • Benztropine | Antagonist at M receptors in basal ganglia | Reduces tremor and rigidity • little effect on bradykinesia | Parkinson disease | Oral • <i>Toxicity:</i> Typical antimuscarinic effects—sedation, mydriasis, urinary retention, constipation, confusion, dry mouth |
|---------------|--|---|-------------------|---|

- *Biperiden, orphenadrine, procyclidine, trihexyphenidyl: Similar antimuscarinic agents with CNS effects*

### DRUGS USED IN HUNTINGTON DISEASE

- |   |   |                        |   |  |
|---|---|------------------------|---|--|
| • Tetrabenazine, deutetabenazine, reserpine | Deplete amine transmitters, especially dopamine, from nerve endings | Reduce chorea severity | Huntington disease • other applications, see <a href="#">Chapter 11</a> | Oral • <i>Toxicity:</i> Hypotension, sedation, depression, diarrhea • deutetabenazine is the least toxic |
|---|---|------------------------|---|--|

- *Haloperidol, fluphenazine, other neuroleptics, olanzapine: Dopamine receptor blockers, sometimes helpful*

## DRUGS USED IN TOURETTE SYNDROME

<ul style="list-style-type: none"> <li>Pimozide, haloperidol</li> </ul>	Block central D <sub>2</sub> receptors	Reduce vocal and motor tic frequency, severity	Tourette syndrome • other applications, see <a href="#">Chapter 11</a>	Oral • <i>Toxicity</i> : Parkinsonism, other dyskinesias • sedation • blurred vision • dry mouth • gastrointestinal disturbances • pimozide may cause cardiac rhythm disturbances
<ul style="list-style-type: none"> <li><i>Clonidine, guanfacine</i>: Effective in ~50% of patients; see <a href="#">Chapter 11</a> for basic pharmacology</li> <li><i>Phenothiazines, atypical antipsychotics, tetrabenazine, deutetrabenazine, clonazepam, carbamazepine, topiramate</i>: Often of value</li> </ul>				

## PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
Amantadine	Generic, Gocovri, Osmolex ER, Symmetrel
Apomorphine	Apokyn
Benztropine	Generic, Cogentin
Biperiden	Akineton
Bromocriptine	Generic, Parlodel
Carbidopa	Lodosyn
Carbidopa/levodopa	Generic, Parcopa, Rytary, Sinemet
Carbidopa/levodopa/entacapone	Generic, Stalevo
Deutetrabenazine	Austedo
Entacapone	Generic, Comtan
Levodopa	Dopar, Inbrija, others
Opicapone	Ongentys
Orphenadrine	Generic, various
Penicillamine	Cuprimine, Depen
Pergolide*	Permax, other

Pramipexole	Generic, Mirapex
Procyclidine	Kemadrin
Rasagiline	Azilect
Ropinirole	Generic, Requip, Requip XL
Safinamide	Xadago
Selegiline (deprenyl)	Emsam
Tetrabenazine	Xenazine
Tolcapone	Tasmar
Trientine	Syprine
Trihexyphenidyl	Generic, Artane, others
Valbenazine	Ingrezza

\* Not available in the United States.

### CASE STUDY ANSWER

The history is suggestive of parkinsonism, but the inconspicuous tremor and early cognitive changes raise the possibility of atypical parkinsonism rather than classic Parkinson disease. The prognosis of these disorders is worse than that of classic Parkinson disease. Given the cognitive changes and his age, the use of a dopamine agonist was unwise, as these agents are more likely than levodopa to exacerbate or precipitate behavioral and cognitive disturbances. Sleep attacks may occur spontaneously but are especially noted in patients receiving dopamine agonists. The patient has also developed punding, which is a recognized adverse effect of dopaminergic medication. Surgical treatment (deep brain stimulation) is contraindicated in patients with cognitive changes or atypical parkinsonism.

## Chapter 29: Antipsychotic Agents & Lithium

Charles DeBattista

### CASE STUDY

#### CASE STUDY

A 19-year-old male student is brought into the clinic by his mother, who has been concerned about her son's erratic behavior and strange beliefs.\* He destroyed a TV because he felt the TV was sending harassing messages to him. In addition, he reports hearing voices telling him that family members are trying to poison his food. As a result, he is not eating. After a diagnosis is made, **haloperidol** is prescribed at a gradually increasing dose on an outpatient basis. The drug improves the patient's positive symptoms but ultimately causes intolerable adverse effects including severe akathisia. Although more costly, **lurasidone** is then prescribed, which, over the course of several weeks of treatment, improves his symptoms and is tolerated by the patient. What signs and symptoms would support an initial diagnosis of schizophrenia? In the treatment of schizophrenia, what benefits do the second-generation antipsychotic drugs offer over the traditional agents such as **haloperidol**? In addition to the management of schizophrenia, what other clinical indications warrant consideration of the use of drugs nominally classified as antipsychotics?

\*The author thanks Herbert Meltzer, MD, PhD, for his contributions to prior editions of this chapter.

### ANTIPSYCHOTIC AGENTS

Antipsychotic drugs are able to reduce psychotic symptoms in a wide variety of conditions, including schizophrenia, bipolar disorder, psychotic depression, psychoses associated with dementia, and drug-induced psychoses. They are also able to improve mood and reduce anxiety and sleep disturbances, but they are not the treatment of choice when these symptoms are the primary disturbance in nonpsychotic patients. A **neuroleptic** is a subtype of antipsychotic drug that produces a high incidence of **extrapyramidal side effects (EPS)** at clinically effective doses, or catalepsy in laboratory animals. The **second-generation** or "**atypical**" **antipsychotic drugs** are now the most widely used type of antipsychotic drug.

#### History

Reserpine and **chlorpromazine** were the first drugs found to be useful to reduce psychotic symptoms in schizophrenia. Reserpine was used only briefly for this purpose and is no longer of interest as an antipsychotic agent. **Chlorpromazine** is a neuroleptic agent; that is, it produces catalepsy in rodents and EPS in humans. The discovery that its antipsychotic action was related to **dopamine** (D or DA)-receptor blockade led to the identification of other compounds as antipsychotics between the 1950s and 1970s. The discovery of **clozapine** in 1959 led to the realization that antipsychotic drugs need not cause EPS in humans at clinically effective doses. **Clozapine** was called an "atypical" antipsychotic drug because of this dissociation; it produces fewer EPS at equivalent antipsychotic doses in humans and laboratory animals. As a result, there has been a major shift in clinical practice away from typical or first-generation antipsychotic drugs toward the use of an ever-increasing number of atypical or second-generation drugs, which have other advantages as well. The introduction of antipsychotic drugs led to massive changes in disease management, including brief instead of life-long hospitalizations. These drugs have also proved to be of great value in studying the pathophysiology of schizophrenia and other psychoses. It should be noted that schizophrenia and bipolar disorder are no longer believed by many to be separate disorders but rather to be part of a continuum of brain disorders with psychotic features.

#### Nature of Psychosis & Schizophrenia

www.pharm.k  
delusions (false beliefs); various types of hallucinations, usually auditory or visual, but sometimes tactile or olfactory; and grossly disorganized thinking in a clear sensorium. Schizophrenia is a particular kind of psychosis characterized mainly by a clear sensorium but a marked thinking and perceptual disturbance. Schizophrenia is the most common psychotic disorder, present in about 1% of the population and responsible for approximately half of long-term psychiatric hospitalizations. Psychosis is not unique to schizophrenia and is not present in all patients with schizophrenia at all times.

Schizophrenia is considered to be a neurodevelopmental disorder. This implies that structural and functional changes in the brain are present even in utero in some patients, or that they develop during childhood and adolescence, or both. Twin, adoption, and family studies have established that schizophrenia is a genetic disorder with high heritability. No single gene is involved. Current theories involve multiple genes with common and rare mutations, including large deletions and insertions (copy number variations), combining to produce a very variegated clinical presentation and course.

## THE SEROTONIN HYPOTHESIS OF SCHIZOPHRENIA

The discovery that indole hallucinogens such as LSD (lysergic acid diethylamide) and mescaline are serotonin (5-HT) agonists led to the search for endogenous hallucinogens in the urine, blood, and brains of patients with schizophrenia. This proved fruitless, but the identification of many 5-HT-receptor subtypes led to the pivotal discovery that 5-HT<sub>2A</sub>-receptor and possibly 5-HT<sub>2C</sub> stimulation was the basis for the hallucinatory effects of these agents.

It has been found that 5-HT<sub>2A</sub>-receptor blockade is a key factor in the mechanism of action of the main class of second-generation antipsychotic drugs, of which **clozapine** is the prototype and which includes, in order of their introduction around the world, melperone, **risperidone**, zotepine, blonanserin, **olanzapine**, **quetiapine**, **ziprasidone**, **aripiprazole**, sertindole, **paliperidone**, **iloperidone**, **asenapine**, **lurasidone**, **cariprazine**, and **brexpiprazole**. These drugs are *inverse agonists* of the 5-HT<sub>2A</sub> receptor; that is, they block the constitutive activity of these receptors. These receptors modulate the release of **dopamine**, **norepinephrine**, glutamate, GABA, and **acetylcholine**, among other neurotransmitters in the cortex, limbic region, and striatum. Stimulation of 5-HT<sub>2A</sub> receptors leads to depolarization of glutamate neurons, but also stabilization of *N*-methyl-D-aspartate (NMDA) receptors on postsynaptic neurons. It has been found that hallucinogens can modulate the stability of a complex consisting of 5-HT<sub>2A</sub> and NMDA receptors.

5-HT<sub>2C</sub>-receptor stimulation provides a further means of modulating cortical and limbic dopaminergic activity. Stimulation of 5-HT<sub>2C</sub> receptors leads to inhibition of cortical and limbic **dopamine** release. Many atypical antipsychotic drugs, eg, **clozapine**, **asenapine**, and **olanzapine**, are 5-HT<sub>2C</sub> inverse agonists. 5-HT<sub>2C</sub> agonists are currently being studied as antipsychotic agents.

## THE DOPAMINE HYPOTHESIS OF SCHIZOPHRENIA

The **dopamine** hypothesis for schizophrenia was the second neurotransmitter-based concept to be developed but is no longer considered adequate to explain all aspects of schizophrenia, especially the cognitive impairment. Nevertheless, it is still highly relevant to understanding the major dimensions of schizophrenia, such as positive (hallucinations, delusions) and negative symptoms (emotional blunting, social withdrawal, lack of motivation), cognitive impairment, and possibly depression. It is also essential to understanding the mechanisms of action of most and probably all antipsychotic drugs.

Several lines of evidence suggest that excessive limbic dopaminergic activity plays a role in psychosis. (1) Many antipsychotic drugs strongly block postsynaptic D<sub>2</sub> receptors in the central nervous system, especially in the mesolimbic and striatal-frontal system; this includes partial **dopamine** agonists, such as **aripiprazole**, **brexpiprazole**, and bifeprunox. (2) Drugs that increase dopaminergic activity, such as **levodopa**, amphetamines, and **bromocriptine** and **apomorphine**, either aggravate schizophrenia psychosis or produce psychosis de novo in some patients. (3) Dopamine-receptor density has been found postmortem to be increased in the brains of schizophrenics who have not been treated with antipsychotic drugs. (4) Some but not all postmortem studies of schizophrenic subjects have reported increased **dopamine** levels and D<sub>2</sub>-receptor density in the nucleus accumbens, caudate, and putamen. (5) Imaging studies have shown increased amphetamine-induced striatal **dopamine** release, increased baseline occupancy of striatal D<sub>2</sub> receptors by extracellular **dopamine**, and other measures consistent with increased striatal **dopamine** synthesis and release.

Telegram: @pharm\_k  
However, the **dopamine** hypothesis is far from a complete explanation of all aspects of schizophrenia. *Diminished* cortical or hippocampal

dopaminergic activity has been suggested to underlie the cognitive impairment and negative symptoms of schizophrenia. Postmortem and in vivo imaging studies of cortical, limbic, nigral, and striatal dopaminergic neurotransmission in schizophrenic subjects have reported findings consistent with diminished dopaminergic activity in these regions. Decreased dopaminergic innervation in medial temporal cortex, dorsolateral prefrontal cortex, and hippocampus and decreased levels of DOPAC, a metabolite of [dopamine](#), in the anterior cingulate have been reported in postmortem studies. Imaging studies have found increased prefrontal D<sub>1</sub>-receptor levels that correlated with working memory impairments.

The fact that several of the atypical antipsychotic drugs have much less effect on D<sub>2</sub> receptors and yet are effective in schizophrenia has redirected attention to the role of other [dopamine](#) receptors and to nondopamine receptors. Serotonin receptors—particularly the 5-HT<sub>2A</sub>-receptor subtype—may mediate synergistic effects or protect against the extrapyramidal consequences of D<sub>2</sub> antagonism. As a result of these considerations, the direction of research has changed to a greater focus on compounds that may act on several transmitter-receptor systems, eg, serotonin and glutamate. The atypical antipsychotic drugs share the property of weak D<sub>2</sub>-receptor antagonism and more potent 5-HT<sub>2A</sub>-receptor blockade.

## THE GLUTAMATE HYPOTHESIS OF SCHIZOPHRENIA

Glutamate is the major excitatory neurotransmitter in the brain (see [Chapter 21](#)). Phencyclidine (PCP) and [ketamine](#) are noncompetitive inhibitors of the NMDA receptor that exacerbate both cognitive impairment and psychosis in patients with schizophrenia. PCP and a related drug, MK-801, increase locomotor activity and, acutely or chronically, a variety of cognitive impairments in rodents and primates. These effects are widely employed as a means to develop novel antipsychotic and cognitive-enhancing drugs. Selective 5-HT<sub>2A</sub> antagonists, as well as atypical antipsychotic drugs, are much more potent than D<sub>2</sub> antagonists in blocking these effects of PCP and MK-801. This was the starting point for the hypothesis that hypofunction of NMDA receptors, located on GABAergic interneurons, leading to diminished inhibitory influences on neuronal function, contributed to schizophrenia. The diminished GABAergic activity can induce disinhibition of downstream glutamatergic activity, which can lead to hyperstimulation of cortical neurons through non-NMDA receptors. Preliminary evidence suggests that LY2140023, a drug that acts as an agonist of the metabotropic 2/3 glutamate receptor (mGluR2/3), may be effective in schizophrenia.

The NMDA receptor, an ion channel, requires glycine for full activation. It has been suggested that in patients with schizophrenia, the glycine site of the NMDA receptor is not fully saturated. There have been several trials of high doses of glycine to promote glutamatergic activity, but the results are far from convincing. Currently, glycine transport inhibitors are in development as possible psychotropic agents.

Ampakines are drugs that potentiate currents mediated by AMPA-type glutamate receptors. In behavioral tests, ampakines are effective in correcting behaviors in various animal models of schizophrenia and depression. They protect neurons against neurotoxic insults, in part by mobilizing growth factors such as brain-derived neurotrophic factor (BDNF, see also [Chapter 30](#)).

## BASIC PHARMACOLOGY OF ANTIPSYCHOTIC AGENTS

### Chemical Types

A number of chemical structures have been associated with antipsychotic properties. The drugs can be classified into several groups as shown in [Figures 29-1](#) and [29-2](#).

FIGURE 29-1

Structural formulas of some older antipsychotic drugs: phenothiazines, thioxanthenes, and butyrophenones. Only representative members of each type are shown.

Three subfamilies of phenothiazines, based primarily on the side chain of the molecule, were once the most widely used of the antipsychotic agents. Aliphatic derivatives (eg, **chlorpromazine**) and piperidine derivatives (eg, **thioridazine**) are the least potent. These drugs produce more sedation and weight gain. Piperazine derivatives are more potent (effective in lower doses) but not necessarily more efficacious. The piperazine derivatives are also more selective in their pharmacologic effects (Table 29–1).

TABLE 29–1

**Antipsychotic drugs: Relation of chemical structure to potency and toxicities.**

Chemical Class	Drug	D <sub>2</sub> /5-HT <sub>2A</sub> Ratio <sup>1</sup>	Clinical Potency	Extrapyramidal Toxicity	Sedative Action	Hypotensive Actions
Phenothiazines						
Aliphatic	<b>Chlorpromazine</b>	High	Low	Medium	High	High
Piperazine	<b>Fluphenazine</b>	High	High	High	Low	Very low
Thioxanthene	<b>Thiothixene</b>	Very high	High	Medium	Medium	Medium
Butyrophenone	<b>Haloperidol</b>	Medium	High	Very high	Low	Very low
Dibenzodiazepine	<b>Clozapine</b>	Very low	Medium	Very low	Low	Medium
Benzisoxazole	<b>Risperidone</b>	Very low	High	Low <sup>2</sup>	Low	Low
Thienobenzodiazepine	<b>Olanzapine</b>	Low	High	Very low	Medium	Low
Dibenzothiazepine	<b>Quetiapine</b>	Low	Low	Very low	Medium	Low to medium
Dihydroindolone	<b>Ziprasidone</b>	Low	Medium	Very low	Low	Very low
Dihydrocarbostyryl	<b>Aripiprazole</b>	Medium	High	Very low	Very low	Low

<sup>1</sup>Ratio of affinity for D<sub>2</sub> receptors to affinity for 5-HT<sub>2A</sub> receptors.

<sup>2</sup>At dosages below 8 mg/d.

The National Institute of Mental Health (NIMH)-funded Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) reported that **perphenazine**, a piperazine derivative, was as effective as atypical antipsychotic drugs, with the modest exception of **olanzapine**, and concluded that first-generation antipsychotic drugs are the treatment of choice for schizophrenia based on their lower cost. However, there were numerous flaws in the design, execution, and analysis of this study, leading to it having only modest impact on clinical practice. In particular, it failed to consider issues such as dosage of **olanzapine**, inclusion of treatment resistant patients, encouragement of patients to switch medications inherent in the design, risk for tardive dyskinesia following long-term use of even low-dose typical antipsychotics, and the necessity of large sample sizes in equivalency studies.

**B. Thioxanthene Derivatives**

This group of drugs is exemplified primarily by **thiothixene**.

**C. Butyrophenone Derivatives**

This group, of which **haloperidol** is the most widely used, has a very different structure from those of the two preceding groups. **Haloperidol**, a butyrophenone, is the most widely used first-generation antipsychotic drug, despite its high level of EPS relative to other typical antipsychotic drugs. Diphenylbutylpiperidines are closely related compounds. The butyrophenones and congeners tend to be more potent and to have fewer autonomic effects but greater extrapyramidal effects than phenothiazines (see [Table 29–1](#)).

#### D. Miscellaneous Structures

**Pimozide** and **molindone** are first-generation antipsychotic drugs. There is no significant difference in efficacy between these newer typical and the older typical antipsychotic drugs.

#### E. Second-Generation Antipsychotic Drugs

**Clozapine**, **asenapine**, **olanzapine**, **quetiapine**, **paliperidone**, **risperidone**, **sertindole**, **ziprasidone**, **zotepine**, **brexpiprazole**, **cariprazine**, **lurasidone**, and **aripiprazole** are second-generation antipsychotic drugs (some of which are shown in [Figure 29–2](#)). **Clozapine** is the prototype. **Paliperidone** is 9-hydroxyrisperidone, the active metabolite of **risperidone**. **Risperidone** is rapidly converted to 9-hydroxyrisperidone in vivo in most patients, except for about 10% of patients who are poor metabolizers. Sertindole is approved in some European countries but not in the USA.

These drugs have complex pharmacology, but they share a greater ability to alter 5-HT<sub>2A</sub>-receptor activity than to interfere with D<sub>2</sub>-receptor action. In most cases, they act as partial agonists at the 5-HT<sub>1A</sub> receptor, which produces synergistic effects with 5-HT<sub>2A</sub> receptor antagonism. Most are also either 5-HT<sub>6</sub> or 5-HT<sub>7</sub> receptor antagonists.

Sulpride and sulpiride constitute another class of atypical agents. They have equivalent potency for D<sub>2</sub> and D<sub>3</sub> receptors, but they are also 5-HT<sub>7</sub> antagonists. They dissociate EPS and antipsychotic efficacy. However, they also produce marked increases in serum prolactin levels and are not as free of the risk of tardive dyskinesia as are drugs such as **clozapine** and **quetiapine**. They are not approved in the USA.

**Cariprazine** represents another type of second-generation agent. In addition to D<sub>2</sub>/5-HT<sub>2</sub> antagonism, **cariprazine** is also a D<sub>3</sub> partial agonist with selectivity for the D<sub>3</sub> receptor. **Cariprazine**'s selectivity for the D<sub>3</sub> receptor may be associated with greater effects on the negative symptoms of schizophrenia. This drug was approved in 2015 in the USA.

#### F. Glutamatergic Antipsychotics

No glutamate-specific agents are currently approved for the treatment of schizophrenia. However, several agents are in late clinical testing. Among these is **bitopertin**, a glycine transporter 1 (GlyT1) inhibitor. As noted earlier, glycine is a required co-agonist with glutamate at NMDA receptors. Initial phase 2 studies indicated that bitopertin used adjunctively with standard antipsychotics significantly improved negative symptoms of schizophrenia, but subsequent trials have been disappointing. **Sarcosine** (*N*-methylglycine), another GlyT1 inhibitor, in combination with a standard antipsychotic has also shown benefit in improving both negative and positive symptoms of schizophrenia in acutely ill as well as in patients with more chronic schizophrenia.

Another class of investigational antipsychotic agents includes the metabotropic glutamate receptor agonists. Eight metabotropic glutamate receptors are divided into three groups: group I (mGluR1,5), group II (mGluR2,3), and group III (mGluR4,6,7,8). mGluR2,3 inhibits glutamate release presynaptically. Several mGluR2,3 agents are being investigated in the treatment of schizophrenia. One agent, pomaglumetad methionil, showed antipsychotic efficacy in early phase 2 trials, but subsequent trials failed to show benefit in either positive or negative symptoms of schizophrenia. Other metabotropic glutamate receptor agonists are being explored for the treatment of negative and cognitive symptoms of schizophrenia.

#### Pharmacokinetics

##### A. Absorption and Distribution

Most antipsychotic drugs are readily but incompletely absorbed. Furthermore, many undergo significant first-pass metabolism. Thus, oral doses of **chlorpromazine** and **thioridazine** have systemic availability of 25–35%, whereas **haloperidol**, which has less first-pass metabolism, has an average

Most antipsychotic drugs are highly lipid soluble and protein bound (92–99%). They tend to have large volumes of distribution (usually more than 7 L/kg). They generally have a much longer clinical duration of action than would be estimated from their plasma half-lives. This is paralleled by prolonged occupancy of D<sub>2</sub> dopamine receptors in the brain by the typical antipsychotic drugs.

Metabolites of chlorpromazine may be excreted in the urine weeks after the last dose of chronically administered drug. Long-acting injectable formulations may cause some blockade of D<sub>2</sub> receptors 3–6 months after the last injection. Time to recurrence of psychotic symptoms is highly variable after discontinuation of antipsychotic drugs. The average time for relapse in stable patients with schizophrenia who discontinue their medication is 6 months. Clozapine is an exception in that relapse after discontinuation is usually rapid and severe. Thus, clozapine should never be discontinued abruptly unless clinically needed because of adverse effects such as myocarditis or agranulocytosis, which are true medical emergencies.

## B. Metabolism

Most antipsychotic drugs are almost completely metabolized by oxidation or demethylation, catalyzed by liver microsomal cytochrome P450 enzymes. CYP2D6, CYP1A2, and CYP3A4 are the major isoforms involved (see Chapter 4). Drug-drug interactions should be considered when combining antipsychotic drugs with various other psychotropic drugs or drugs—such as ketoconazole—that inhibit various cytochrome P450 enzymes. At the typical clinical doses, antipsychotic drugs do not usually interfere with the metabolism of other drugs.

## Pharmacodynamics

The first phenothiazine antipsychotic drugs, with chlorpromazine as the prototype, proved to have a wide variety of central nervous system, autonomic, and endocrine effects. Although efficacy of these drugs is primarily driven by D<sub>2</sub>-receptor blockade, their adverse actions were traced to blocking effects at a wide range of receptors including  $\alpha$  adrenoceptors and muscarinic, H<sub>1</sub> histaminic, and 5-HT<sub>2</sub> receptors.

## A. Dopaminergic Systems

Five dopaminergic systems or pathways are important for understanding schizophrenia and the mechanism of action of antipsychotic drugs. The first pathway—the one most closely related to behavior and psychosis—is the **mesolimbic-mesocortical** pathway, which projects from cell bodies in the ventral tegmentum in separate bundles of axons to the limbic system and neocortex. The second system—the **nigrostriatal** pathway—consists of neurons that project from the substantia nigra to the dorsal striatum, which includes the caudate and putamen; it is involved in the coordination of voluntary movement. Blockade of the D<sub>2</sub> receptors in the nigrostriatal pathway is responsible for EPS. The third pathway—the **tuberoinfundibular** system—arises in the arcuate nuclei and periventricular neurons and releases dopamine into the pituitary portal circulation. Dopamine released by these neurons physiologically inhibits prolactin secretion from the anterior pituitary. The fourth dopaminergic system—the **medullary-periventricular** pathway—consists of neurons in the motor nucleus of the vagus whose projections are not well defined. This system may be involved in eating behavior. The fifth pathway—the **incertohypothalamic** pathway—forms connections from the medial zona incerta to the hypothalamus and the amygdala. It appears to regulate the anticipatory motivational phase of copulatory behavior in rats.

After dopamine was identified as a neurotransmitter in 1959, it was shown that its effects on electrical activity in central synapses and on production of the second messenger cAMP synthesized by adenylyl cyclase could be blocked by antipsychotic drugs such as chlorpromazine, haloperidol, and thiothixene. This evidence led to the conclusion in the early 1960s that these drugs should be considered **dopamine-receptor antagonists** and was a key factor in the development of the dopamine hypothesis of schizophrenia described earlier in this chapter. The antipsychotic action is now thought to be produced (at least in part) by their ability to block the effect of dopamine (D<sub>2</sub> receptors inhibit the activity of adenylyl cyclase in the mesolimbic system).

## B. Dopamine Receptors and Their Effects

At present, five dopamine receptors have been described, consisting of two separate families, the D<sub>1</sub>-like (D<sub>1</sub>, D<sub>5</sub>) and D<sub>2</sub>-like (D<sub>2</sub>, D<sub>3</sub>, D<sub>4</sub>) receptor groups. The D<sub>1</sub> receptor is coded by a gene on chromosome 5, increases cAMP by G<sub>s</sub>-coupled activation of adenylyl cyclase, and is located mainly in the

putamen, nucleus accumbens, and olfactory tubercle and cortex. The other member of this family, D<sub>5</sub>, is coded by a gene on chromosome 4, also increases cAMP, and is found in the hippocampus and hypothalamus. The therapeutic potency of antipsychotic drugs does not correlate with their affinity for binding to the D<sub>1</sub> receptor (Figure 29-3, top) nor did a selective D<sub>1</sub> antagonist prove to be an effective antipsychotic in patients with schizophrenia. The D<sub>2</sub> receptor is coded on chromosome 11, decreases cAMP (by G<sub>i</sub>-coupled inhibition of adenylyl cyclase), and inhibits calcium channels but opens potassium channels. It is found both pre- and postsynaptically on neurons in the caudate-putamen, nucleus accumbens, and olfactory tubercle. A second member of this family, the D<sub>3</sub> receptor, also coded by a gene on chromosome 11, is thought to also decrease cAMP and is located in the frontal cortex, medulla, and midbrain. D<sub>4</sub> receptors also decrease cAMP and are concentrated in the cortex.

FIGURE 29-3

Correlations between the therapeutic potency of antipsychotic drugs and their affinity for binding to dopamine D<sub>1</sub> (top) or D<sub>2</sub> receptors (bottom). Potency is indicated on the horizontal axes; it decreases to the right. Binding affinity for D<sub>1</sub> receptors was measured by displacing the selective D<sub>1</sub> ligand SCH 23390; affinity for D<sub>2</sub> receptors was similarly measured by displacing the selective D<sub>2</sub> ligand haloperidol. Binding affinity decreases upward. (Reproduced with permission from Seeman P: Dopamine receptors and the dopamine hypothesis of schizophrenia. Synapse 1987;1(2):133-152.)

The first-generation antipsychotic agents block D<sub>2</sub> receptors stereoselectively for the most part, and their binding affinity is very strongly correlated with clinical antipsychotic and extrapyramidal potency (Figure 29–3, bottom). In vivo imaging studies of D<sub>2</sub>-receptor occupancy indicate that for antipsychotic efficacy, the typical antipsychotic drugs must be given in sufficient doses to achieve at least 60% occupancy of striatal D<sub>2</sub> receptors. This is not required for some second-generation antipsychotic drugs such as [clozapine](#) and [olanzapine](#), which are effective at lower occupancy levels of 30–50%, most likely because of their concurrent high occupancy of 5-HT<sub>2A</sub> receptors. The first-generation antipsychotic drugs produce EPS when the occupancy of striatal D<sub>2</sub> receptors reaches 80% or higher.

Positron emission tomography (PET) studies with [aripiprazole](#) show very high occupancy of D<sub>2</sub> receptors, but this drug does not cause EPS because it is a partial D<sub>2</sub>-receptor agonist. [Aripiprazole](#) also gains therapeutic efficacy through its 5-HT<sub>2A</sub> antagonism and possibly 5-HT<sub>1A</sub> partial agonism.

These findings have been incorporated into the [dopamine](#) hypothesis of schizophrenia. However, additional factors complicate interpretation of [dopamine](#) receptor data. For example, [dopamine](#) receptors exist in both high- and low-affinity forms, and it is not known whether schizophrenia or the antipsychotic drugs alter the proportions of receptors in these two forms.

has been convincingly demonstrated that antagonism of any **dopamine** receptor other than the D<sub>2</sub> receptor plays a role in the action of antipsychotic drugs. Selective and relatively specific D<sub>1</sub>-, D<sub>3</sub>-, and D<sub>4</sub>-receptor antagonists have been tested repeatedly with no evidence of antipsychotic action. Most of the newer atypical antipsychotic agents and some of the traditional ones have a higher affinity for the 5-HT<sub>2A</sub> receptor than for the D<sub>2</sub> receptor (see [Table 29-1](#)), suggesting an important role for the serotonin 5-HT system in the etiology of schizophrenia and the action of these drugs.

### C. Novel Pharmacodynamic Targets

While currently available antipsychotics predominately act on the D<sub>2</sub> receptor, there are at least 2 current agents that appear to have little affinity for the D<sub>2</sub> receptor; **clozapine** and **pimavanserin**. **Pimavanserin** is primarily a 5HT<sub>2</sub> antagonist approved for the treatment of psychosis in Parkinson's disease while **clozapine** also is a 5HT<sub>2</sub> antagonist with differential effects on D<sub>1</sub>-D<sub>4</sub> receptors. While that available antipsychotics have proven extremely helpful in mitigating positive psychotic symptoms including hallucinations and delusions that often have intolerable side effects and have not been particularly effective in treating negative and cognitive symptoms. Two drugs in late-stage development with a novel pharmacodynamic profile offer some hope of treating patients for whom the currently available agents have proven ineffective or too difficult to tolerate. Xenomeline is a muscarine M<sub>1</sub>/M<sub>4</sub> agonist while Ulotaront is a Trace Amine Associated Receptor -1 agonist (TAAR-1). Both of these drugs have shown efficacy in the treatment of schizophrenia and lack the EPS and metabolic side effects of first- and second-generation antipsychotics. In addition, Xenomaline has shown benefit for treating cognitive symptoms of schizophrenia and both drugs may have benefits for treating negative symptoms. Xenomaline is expected to undergo FDA review in 2023 for possible approval while ulotarant has been given a breakthrough designation by the FDA for the treatment of schizophrenia and is expected to seek approval by 2024.

### D. Differences among Antipsychotic Drugs

Although almost all effective antipsychotic drugs block D<sub>2</sub> receptors, the degree of this blockade in relation to other actions on receptors varies considerably among drugs. Vast numbers of ligand-receptor binding experiments have been performed in an effort to discover a single receptor action that would best predict antipsychotic efficacy. A summary of the relative receptor-binding affinities of several key agents in such comparisons illustrates the difficulty in drawing simple conclusions from such experiments:

**Chlorpromazine:**  $\alpha_1 = 5\text{-HT}_{2A} > D_2 > D_1$

**Haloperidol:**  $D_2 > \alpha_1 > D_4 > 5\text{-HT}_{2A} > D_1 > H_1$

**Clozapine:**  $D_4 = \alpha_1 > 5\text{-HT}_{2A} > D_2 = D_1$

**Olanzapine:**  $5\text{-HT}_{2A} > H_1 > D_4 > D_2 > \alpha_1 > D_1$

**Aripiprazole:**  $D_2 = 5\text{-HT}_{2A} > D_4 > \alpha_1 = H_1 \gg D_1$

**Quetiapine:**  $H_1 > \alpha_1 > M_{1,3} > D_2 > 5\text{-HT}_{2A}$

Thus, most of the second-generation and some first-generation antipsychotic agents are at least as potent in inhibiting 5-HT<sub>2</sub> receptors as they are in inhibiting D<sub>2</sub> receptors. **Aripiprazole** and **brexpiprazole** appear to be partial agonists of D<sub>2</sub> receptors. Varying degrees of antagonism of  $\alpha_2$  adrenoceptors are also seen with **risperidone**, **clozapine**, **olanzapine**, **quetiapine**, and **aripiprazole**.

Current research is directed toward discovering novel antipsychotic compounds that either are more selective for the mesolimbic system (to reduce their effects on the extrapyramidal system) or have effects on central neurotransmitter receptors—such as those for **acetylcholine** and excitatory amino acids—that have been proposed as new targets for antipsychotic action.

In contrast to the difficult search for receptors responsible for antipsychotic *efficacy*, the differences in receptor effects of various antipsychotics do explain many of their *toxicities* ([Tables 29-1](#) and [29-2](#)). In particular, extrapyramidal toxicity appears to be consistently associated with high D<sub>2</sub>

#### E. Psychological Effects

Most antipsychotic drugs cause unpleasant subjective effects in nonpsychotic individuals. The mild to severe EPS, including akathisia, sleepiness, restlessness, and autonomic effects, are unlike any associated with more familiar sedatives or hypnotics. Nevertheless, low doses of some of these drugs, particularly [quetiapine](#), are used to promote sleep onset and maintenance, although there is no approved indication for such usage.

People without psychiatric illness given antipsychotic drugs, even at low doses, experience impaired performance as judged by a number of psychomotor and psychometric tests. Psychotic individuals, however, may actually show improvement in their performance as the psychosis is alleviated. The ability of the second-generation antipsychotic drugs to improve some domains of cognition in patients with schizophrenia and bipolar disorder is controversial. Some individuals experience marked improvement, and for that reason, cognition should be assessed in all patients with schizophrenia and a trial of an atypical agent considered, even if positive symptoms are well controlled by first-generation agents.

#### F. Electroencephalographic Effects

Antipsychotic drugs produce shifts in the pattern of electroencephalographic (EEG) frequencies, usually slowing them and increasing their synchronization. The slowing (hypersynchrony) is sometimes focal or unilateral, which may lead to erroneous diagnostic interpretations. Both the frequency and the amplitude changes induced by psychotropic drugs are readily apparent and can be quantitated by sophisticated electrophysiologic techniques. Some antipsychotic agents lower the seizure threshold and induce EEG patterns typical of seizure disorders; however, with careful dosage titration, most can be used safely in epileptic patients.

#### G. Endocrine Effects

Older typical antipsychotic drugs, as well as [risperidone](#) and [paliperidone](#), produce elevations of prolactin (see Adverse Effects, below). Newer antipsychotics such as [olanzapine](#), [quetiapine](#), [aripiprazole](#), and [brexpiprazole](#) cause no or minimal increases of prolactin and reduce the risks of extrapyramidal system dysfunction and tardive dyskinesia, reflecting their diminished D<sub>2</sub> antagonism.

#### H. Cardiovascular Effects

The low-potency phenothiazines frequently cause orthostatic hypotension and tachycardia. Mean arterial pressure, peripheral resistance, and stroke volume are decreased. These effects are predictable from the autonomic actions of these agents (see [Table 29-2](#)). Abnormal electrocardiograms have been recorded, especially with [thioridazine](#). Changes include prolongation of QT interval and abnormal configurations of the ST segment and T waves. These changes are readily reversed by withdrawing the drug. Since [thioridazine](#) is associated with torsades de pointes and an increased risk of sudden death, the branded drug was removed from the market in 2005, and its use currently is as a second-line agent if other drugs have proved intolerable or ineffective.

**Adverse pharmacologic effects of antipsychotic drugs.**

Type	Manifestations	Mechanism
Autonomic nervous system	Loss of accommodation, dry mouth, difficulty urinating, constipation	Muscarinic cholinergic blockade
	Orthostatic hypotension, impotence, failure to ejaculate	$\alpha$ -Adrenoceptor blockade
Central nervous system	Parkinson syndrome, akathisia, dystonias	Dopamine-receptor blockade
	Tardive dyskinesia	Supersensitivity of dopamine receptors
	Toxic-confusional state	Muscarinic blockade
Endocrine system	Amenorrhea-galactorrhea, infertility, impotence	Dopamine-receptor blockade resulting in hyperprolactinemia
Other	Weight gain	Possibly combined H <sub>1</sub> and 5-HT <sub>2</sub> blockade

Among the newest antipsychotics, prolongation of the QT or QT<sub>c</sub> interval has received much attention. Because this was believed to indicate an increased risk of dangerous arrhythmias, **ziprasidone** and **quetiapine** are accompanied by warnings. There is, however, no evidence that this has actually translated into increased incidence of arrhythmias.

The atypical antipsychotics are also associated with a metabolic syndrome that may increase the risk of coronary artery disease, stroke, and hypertension.

## CLINICAL PHARMACOLOGY OF ANTIPSYCHOTIC AGENTS

### INDICATIONS

#### A. Psychiatric Indications

**Schizophrenia** is the primary indication for antipsychotic agents. However, in the last decade, the use of antipsychotics in the treatment of mood disorders such as type 1 bipolar disorder (BD-1), psychotic depression, and treatment-resistant depression has eclipsed their use in the treatment of schizophrenia.

**Catatonic** forms of schizophrenia are best managed by intravenous benzodiazepines. Antipsychotic drugs may be needed to treat psychotic components of that form of the illness after catatonia has ended, and they remain the mainstay of treatment for this condition. Unfortunately, many patients show little response, and virtually none shows a complete response.

Antipsychotic drugs are also indicated for **schizoaffective disorders**, which share characteristics of both schizophrenia and affective disorders. No fundamental difference between these two diagnoses has been reliably demonstrated. It is most likely that they are part of a continuum with bipolar psychotic disorder. The psychotic aspects of the illness require treatment with antipsychotic drugs, which may be used with other drugs such as antidepressants, **lithium**, or valproic acid.

The manic phase in **bipolar affective disorder** often requires treatment with antipsychotic agents, although **lithium** or valproic acid supplemented with high-potency benzodiazepines (eg, **lorazepam** or **clonazepam**) may suffice in milder cases. Controlled trials support the efficacy of monotherapy with second-generation antipsychotics in the acute phase (up to 4 weeks) of mania. In addition, several second-generation antipsychotics are

approved in the maintenance treatment of bipolar disorder. They appear more effective in preventing mania than in preventing depression. As mania subsides, the antipsychotic drug may be withdrawn, although maintenance treatment with atypical antipsychotic agents has become more common. Nonmanic excited states may also be managed by antipsychotics, often in combination with benzodiazepines.

An increasingly common use of antipsychotics is in the monotherapy of **acute bipolar depression** and the adjunctive use of antipsychotics with antidepressants in the treatment of **unipolar depression**. Several antipsychotics are now approved by the US Food and Drug Administration (FDA) in the management of bipolar depression including **quetiapine**, **lurasidone**, and **cariprazine**, **lumateperone** and **olanzapine** (in a combination formulation with **fluoxetine**). The antipsychotics appear more consistently effective than antidepressants in the treatment of bipolar depression and also do not increase the risk of inducing mania or increasing the frequency of bipolar cycling. Likewise, several antipsychotics, including **aripiprazole**, **quetiapine**, **brexipiprazole**, and **olanzapine** (with **fluoxetine**), are now approved in the adjunctive treatment of unipolar depression. Although many drugs are combined with antidepressants in the adjunctive treatment of major depression, antipsychotic agents are the only class of agents that have been formally evaluated for FDA approval for this purpose. Residual symptoms and partial remission are common, with antipsychotics showing consistent benefit in improving overall antidepressant response.

Some of the intramuscular antipsychotics have been approved for the control of **agitation** associated with bipolar disorder and schizophrenia. Antipsychotics such as **haloperidol** have long been used in the ICU setting to manage agitation in delirious and postsurgical patients. The intramuscular forms of **ziprasidone**, **olanzapine**, and **aripiprazole** have been shown to improve agitation within 1–2 hours, with fewer extrapyramidal symptoms than typical agents such as **haloperidol**. An alternative to antipsychotics, also now approved for the management of agitation in bipolar disorder and schizophrenia, is a sublingual analog of **etomidate**, dexmedetomidate. **Etomidate** has long been used as an anesthetic, and dexmedetomidate is a sublingual film that can be given as an alternative or an oral or IM antipsychotic. Dexmedetomidate does not carry the EPS risks of acute antipsychotics. Sedation and dry mouth have been the most common side effects in clinical trials.

Other indications for the use of antipsychotics include **Tourette syndrome** and possibly disturbed behavior in patients with **Alzheimer disease**. However, controlled trials of antipsychotics in the management of behavioral symptoms in dementia patients have generally not demonstrated efficacy. Furthermore, second-generation as well as some first-generation antipsychotics have been associated with increased mortality in these patients. Antipsychotics are not indicated for the treatment of various withdrawal syndromes, eg, opioid withdrawal. In small doses, antipsychotic drugs have been promoted (wrongly) for the relief of anxiety associated with minor emotional disorders. The antianxiety sedatives (see **Chapter 22**) are preferred in terms of both safety and acceptability to patients.

Psychotic symptoms associated with Parkinson disease represent a clinical challenge. Medications such as **levodopa** that treat the symptoms of Parkinson disease can also exacerbate psychotic symptoms. Likewise, antipsychotics that can treat the psychotic symptoms can significantly worsen the other symptoms of Parkinson disease. In 2016, a new type of antipsychotic was approved for the treatment of psychosis in Parkinson disease. **Pimavanserin** is a selective serotonin inverse agonist. As such, it has no **dopamine** antagonist properties and is not associated with EPS. **Pimavanserin** is currently being investigated as an adjunctive treatment in schizophrenia.

Irritability and behavioral dyscontrol in patients with **autism spectrum disorders (ASD)** can be challenging for care providers and patients alike. Two antipsychotics, **risperidone** and **aripiprazole**, are approved to treat irritability in ASD patients. No medications, however, are known to treat and correct the core symptoms of ASD.

## B. Nonpsychiatric Indications

Most older first-generation antipsychotic drugs, with the exception of **thioridazine**, have a strong **antiemetic** effect. This action is due to dopamine-receptor blockade, both centrally (in the chemoreceptor trigger zone of the medulla) and peripherally (on receptors in the stomach). Some drugs, such as **prochlorperazine** and **benzquinamide**, are promoted solely as antiemetics.

Phenothiazines with shorter side chains have considerable **H<sub>1</sub>-receptor-blocking** action and have been used for relief of pruritus or, in the case of **promethazine**, as preoperative sedatives. The butyrophenone **droperidol** is used in combination with the opioid **fentanyl** in **neuroleptanesthesia**. **Droperidol** has dose-associated risk of QT prolongation and has been removed from some markets. The use of these drugs in anesthesia practice is described in **Chapter 25**.

Choice among antipsychotic drugs is based mainly on differences in adverse effects and possible differences in efficacy. In addition, cost and the availability of a given agent on drug formularies also influence the choice of a specific antipsychotic. Because use of the older drugs is still common, especially for patients treated in the public sector, knowledge of such agents as [chlorpromazine](#) and [haloperidol](#) remains relevant. Thus, one should be familiar with one member of each of the three subfamilies of phenothiazines, a member of the thioxanthene and butyrophenone group, and all of the newer compounds—clozapine, [risperidone](#), [olanzapine](#), [quetiapine](#), [ziprasidone](#), [lurasidone](#), [iloperidone](#), [asenapine](#), [cariprazine](#), [lumateperone](#), and [aripiprazole](#). Each may have special advantages for selected patients. A representative group of antipsychotic drugs is presented in [Table 29-3](#).

## Some representative antipsychotic drugs.

Drug Class	Drug	Advantages	Disadvantages
Phenothiazines			
Aliphatic	<a href="#">Chlorpromazine</a> <sup>1</sup>	Generic, inexpensive	Many adverse effects, especially autonomic
Piperidine	<a href="#">Thioridazine</a> <sup>2</sup>	Slight extrapyramidal syndrome; generic	800 mg/d limit; no parenteral form; cardiotoxicity
Piperazine	<a href="#">Fluphenazine</a> <sup>3</sup>	Depot form also available (enanthate, decanoate)	Possible increased tardive dyskinesia
Thioxanthene	<a href="#">Thiothixene</a>	Parenteral form also available; possible decreased tardive dyskinesia	Uncertain
Butyrophenone	<a href="#">Haloperidol</a>	Parenteral form also available; generic	Severe extrapyramidal syndrome
Dibenzoxazepine	<a href="#">Loxapine</a>	Possible no weight gain	Uncertain
Dibenzodiazepine	<a href="#">Clozapine</a>	May benefit treatment-resistant patients; little extrapyramidal toxicity	May cause agranulocytosis in up to 2% of patients; dose-related lowering of seizure threshold
Benzisoxazole	<a href="#">Risperidone</a>	Broad efficacy; little or no extrapyramidal system dysfunction at low doses	Extrapyramidal system dysfunction and hypotension with higher doses
Thienobenzodiazepine	<a href="#">Olanzapine</a>	Effective against negative as well as positive symptoms; little or no extrapyramidal system dysfunction	Weight gain; dose-related lowering of seizure threshold
Dibenzothiazepine	<a href="#">Quetiapine</a>	Similar to <a href="#">olanzapine</a> ; perhaps less weight gain	May require high doses if there is associated hypotension; short $t_{1/2}$ and twice-daily dosing
Dihydroindolone	<a href="#">Ziprasidone</a>	Perhaps less weight gain than <a href="#">clozapine</a> , parenteral form available	QT <sub>c</sub> prolongation
Dihydrocarbostyryl	<a href="#">Aripiprazole</a>	Lower weight gain liability, long half-life, novel mechanism potential	Uncertain, novel toxicities possible

<sup>1</sup>Other aliphatic phenothiazines: promazine, triflupromazine.<sup>2</sup>Other piperidine phenothiazines: piperacetazine, mesoridazine.<sup>3</sup>Other piperazine phenothiazines: acetophenazine, [perphenazine](#), carphenazine, [prochlorperazine](#), [trifluoperazine](#).

For approximately 70% of patients with schizophrenia, and probably for a similar proportion of patients with bipolar disorder with psychotic features, first- and second-generation antipsychotic drugs are of equal efficacy for treating positive symptoms. However, the evidence favors second-generation drugs for benefit for negative symptoms and cognition, for diminished risk of tardive dyskinesia and other forms of EPS, and for lesser increases in

Some of the second-generation antipsychotic drugs produce more weight gain and increases in lipids than some first-generation drugs. A small percentage of patients develop diabetes mellitus, most often seen with [clozapine](#) and [olanzapine](#). [Ziprasidone](#) is the second-generation drug causing the least weight gain. [Risperidone](#), [lurasidone](#), [brexpiprazole](#), [paliperidone](#), and [aripiprazole](#) usually produce small increases in weight and lipids. [Asenapine](#) and [quetiapine](#) have an intermediate effect. [Clozapine](#) and [olanzapine](#) frequently result in large increases in weight and lipids. Thus, these drugs should be considered as second-line drugs unless there is a specific indication. That is the case with [clozapine](#), which at high doses (300–900 mg/d) is effective in the majority of patients with schizophrenia refractory to other drugs, provided that treatment is continued for up to 6 months. Case reports and several clinical trials suggest that high-dose [olanzapine](#), ie, doses of 30–45 mg/d, may also be efficacious in refractory schizophrenia when given over a 6-month period. [Clozapine](#) is the only second-generation antipsychotic drug approved to reduce the risk of suicide in patients with history of schizophrenia. Patients with schizophrenia who have made life-threatening suicide attempts should be seriously evaluated for switching to [clozapine](#).

New antipsychotic drugs have been shown in some trials to be more effective than older ones for treating negative symptoms. The floridly psychotic form of the illness accompanied by uncontrollable behavior probably responds equally well to all potent antipsychotics but is still frequently treated with older drugs that offer intramuscular formulations for acute and chronic treatment. Moreover, the low cost of the older drugs contributes to their widespread use despite their risk of adverse EPS effects. Several of the newer antipsychotics, including [clozapine](#), [risperidone](#), and [olanzapine](#), show superiority over [haloperidol](#) in terms of overall response in some controlled trials. More comparative studies with [aripiprazole](#) are needed to evaluate its relative efficacy. Moreover, the superior adverse-effect profile of the newer agents and low to absent risk of tardive dyskinesia suggest that these should provide the first line of treatment. Generic forms of many second-generation drugs including [clozapine](#), [olanzapine](#), [aripiprazole](#), [risperidone](#), and [quetiapine](#) have become available, and cost of these drugs is much less of a consideration than it once was.

The best guide for selecting a drug for an individual patient is the patient history of past responses to drugs. At present, [clozapine](#) is limited to those patients who have failed to respond to substantial doses of conventional antipsychotic drugs. The agranulocytosis and seizures associated with this drug prevent more widespread use. [Risperidone](#)'s improved adverse-effect profile (compared with that of [haloperidol](#)) at dosages of 6 mg/d or less and the apparently lower risk of tardive dyskinesia have contributed to its widespread use. [Olanzapine](#) and [quetiapine](#) may have even lower risks and have also achieved widespread use. At this writing, [aripiprazole](#) is the most commonly prescribed second-generation antipsychotic in the USA due to a relatively favorable side effect profile and aggressive marketing.

### Dosage

The range of effective dosages among various antipsychotic agents is broad. Therapeutic margins are substantial. At appropriate dosages, antipsychotics—with the exception of [clozapine](#) and perhaps [olanzapine](#)—are of equal efficacy in broadly selected groups of patients. However, some patients who fail to respond to one drug may respond to another; for this reason, several drugs may have to be tried to find the one most effective for an individual patient. Patients who have become refractory to two or three antipsychotic agents given in substantial doses become candidates for treatment with [clozapine](#) or high-dose [olanzapine](#). Thirty to fifty percent of patients previously refractory to standard doses of other antipsychotic drugs respond to these drugs. In such cases, the increased risk of [clozapine](#) can well be justified.

Some dosage relationships between various antipsychotic drugs, as well as possible therapeutic ranges, are shown in [Table 29–4](#).

## Dose relationships of antipsychotics.

	Minimum Effective Therapeutic Dose (mg)	Usual Range of Daily Doses (mg)
Chlorpromazine	100	100–1000
Thioridazine	100	100–800
Trifluoperazine	5	5–60
Perphenazine	10	8–64
Fluphenazine	2	2–60
Thiothixene	2	2–120
Haloperidol	2	2–60
Loxapine	10	20–160
Molindone	10	20–200
Clozapine	50	300–600
Cariprazine	1.5	1.5–4.5
Olanzapine	5	10–30
Quetiapine	150	150–800
Risperidone	4	4–16
Ziprasidone	40	80–160
Aripiprazole	10	10–30
Lumateperone	42	42

**Parenteral Preparations**

Well-tolerated parenteral forms of the high-potency older drugs [haloperidol](#) and [fluphenazine](#) are available for rapid initiation of treatment as well as for maintenance treatment in noncompliant patients. Since the parenterally administered drugs may have much greater bioavailability than the oral forms, doses should be only a fraction of what might be given orally, and the manufacturer's literature should be consulted. [Fluphenazine](#) decanoate and [haloperidol](#) decanoate are suitable for long-term parenteral maintenance therapy in patients who cannot or will not take oral medication. In addition, newer long-acting injectable (LAI) second-generation antipsychotics are now available, including formulations of [risperidone](#), [olanzapine](#), [aripiprazole](#), and [paliperidone](#). For some patients, the newer LAI drugs may be better tolerated than the older depot injectables.

www.kaplan.com Antipsychotic drugs are often given in divided daily doses, titrating to an effective dosage. Some others, such as **lumateperone** are given once a day while many clinicians dose more sedating medications such as **quetiapine** or **olanzapine** primarily at night. The low end of the dosage range in **Table 29-4** should be tried for at least several weeks. After an effective daily dosage has been defined for an individual patient, doses can be given less frequently. Once-daily doses, usually given at night, are feasible for many patients during chronic maintenance treatment. Simplification of dosage schedules leads to better compliance.

### Maintenance Treatment

A very small minority of schizophrenic patients may recover from an acute episode and require no further drug therapy for prolonged periods. In most cases, the choice is between “as needed” increased doses or the addition of other drugs for exacerbations versus continual maintenance treatment with full therapeutic dosage. The choice depends on social factors such as the availability of family or friends familiar with the early symptoms of relapse and ready access to care.

### Drug Combinations

Combining antipsychotic drugs confounds evaluation of the efficacy of the drugs being used. Use of combinations, however, is widespread, with more emerging experimental data supporting such practices. Tricyclic antidepressants or, more often, selective serotonin reuptake inhibitors (SSRIs) are often used with antipsychotic agents for symptoms of depression complicating schizophrenia. The evidence for the usefulness of this polypharmacy is minimal. **Electroconvulsive therapy (ECT)** is a useful adjunct for antipsychotic drugs, not only for treating mood symptoms, but for positive symptom control as well. Electroconvulsive therapy can augment **clozapine** when maximum doses of **clozapine** are ineffective. In contrast, adding **risperidone** to **clozapine** is not beneficial. **Lithium** or valproic acid is sometimes added to antipsychotic agents with benefit to patients who do not respond to the latter drugs alone. There is some evidence that **lamotrigine** is more effective than any of the other mood stabilizers for this indication (see below). It is uncertain whether instances of successful combination therapy represent misdiagnosed cases of mania or schizoaffective disorder. Benzodiazepines may be useful for patients with anxiety symptoms or insomnia not controlled by antipsychotics.

### Adverse Reactions

Most of the unwanted effects of antipsychotic drugs are extensions of their known pharmacologic actions (see **Tables 29-1** and **29-2**), but a few effects are allergic in nature, and some are idiosyncratic.

#### A. Behavioral Effects

The older typical antipsychotic drugs are unpleasant to take. Many patients stop taking these drugs because of the adverse effects, which may be mitigated by giving small doses during the day and the major portion at bedtime. A “pseudodepression” that may be due to drug-induced akinesia usually responds to cautious treatment with antiparkinsonism drugs. Other pseudodepressions may be due to higher doses than needed in a partially remitted patient, in which case decreasing the dose may relieve the symptoms. Toxic-confusional states may occur with very high doses of drugs that have prominent antimuscarinic actions.

#### B. Neurologic Effects

Extrapyramidal reactions occurring early during treatment with older agents include typical **Parkinson syndrome**, **akathisia** (uncontrollable restlessness), and **acute dystonic reactions** (spastic retrocollis or torticollis). Parkinsonism can be treated, when necessary, with conventional antiparkinsonism drugs of the antimuscarinic type or, in rare cases, with **amantadine**. (**Levodopa** should never be used in these patients.) Parkinsonism may be self-limiting, so an attempt to withdraw antiparkinsonism drugs should be made every 3–4 months. Akathisia and dystonic reactions also respond to such treatment, but many clinicians prefer to use a sedative antihistamine with anticholinergic properties, eg, **diphenhydramine**, which can be given either parenterally or orally.

**Tardive dyskinesia**, as the name implies, is a late-occurring syndrome of abnormal choreoathetoid movements. It is the most important unwanted effect of antipsychotic drugs. It has been proposed that it is caused by a relative cholinergic deficiency secondary to supersensitivity of **dopamine** receptors in the caudate-putamen. The prevalence varies enormously, but tardive dyskinesia is estimated to have occurred in 20–40% of chronically treated patients before the introduction of the newer atypical antipsychotics. Early recognition is important, since advanced cases may be difficult to

reverse. Any patient with tardive dyskinesia treated with a first-generation antipsychotic drug or possibly **risperidone** or **paliperidone** could be switched to **quetiapine** or **clozapine**, the second-generation agents with the least likelihood of causing tardive dyskinesia. Most authorities agree that the first step should be to discontinue or slowly reduce the dose of the current antipsychotic agent or switch to one of the newer atypical agents. A logical second step would be to eliminate all drugs with central anticholinergic action, particularly antiparkinsonism drugs and tricyclic antidepressants. These two steps are often enough to bring about improvement.

In 2017, the first vesicular monoamine transporter type-2 (VMAT-2) inhibitor, **valbenazine**, was approved for the treatment of tardive dyskinesia. It was joined by **deutetrabenazine**, a second VMAT-2 agent in 2018. The VMAT-2 inhibitors selectively bind to the transporter to decrease **dopamine** release in a reversible manner. Tardive dyskinesia is thought to be the result of postsynaptic **dopamine** hypersensitivity, and VMAT-2 inhibitors are more selective for **dopamine** than other monoamines. In the clinical trials leading to FDA approval, between 40% and 60% of patients were rated to be much or very much improved in their tardive dyskinesia. The most common side effects of **valbenazine** and **deutetrabenazine** are fatigue, somnolence, and headaches. Gastrointestinal side effects and akathisia also have been reported with the VMAT-2 inhibitors. Less commonly, QT prolongation also has been reported with both **valbenazine** and **deutetrabenazine**.

**Seizures**, though recognized as a complication of **chlorpromazine** treatment, were so rare with the high-potency older drugs as to merit little consideration. However, de novo seizures may occur in 2–5% of patients treated with **clozapine**. Use of an anticonvulsant is able to control seizures in most cases.

#### C. Autonomic Nervous System Effects

Most patients are able to tolerate the antimuscarinic adverse effects of antipsychotic drugs. Those who are made too uncomfortable or who develop urinary retention or other severe symptoms can be switched to an agent without significant antimuscarinic action. Orthostatic hypotension or impaired ejaculation—common complications of therapy with **chlorpromazine** or mesoridazine—should be managed by switching to drugs with less marked adrenoceptor-blocking actions.

#### D. Metabolic and Endocrine Effects

Weight gain is very common, especially with **clozapine** and **olanzapine**, and requires monitoring of food intake, especially carbohydrates. Hyperglycemia may develop, but whether secondary to weight gain-associated **insulin** resistance or to other mechanisms remains to be clarified. Hyperlipidemia may occur. The management of weight gain, **insulin** resistance, and increased lipids should include monitoring of weight at each visit and measurement of fasting blood sugar and lipids at 3- to 6-month intervals. Measurement of hemoglobin A<sub>1c</sub> may be useful when it is impossible to be sure of obtaining a fasting blood sugar. Diabetic ketoacidosis has been reported in a few cases. The triglyceride:HDL ratio should be less than 3.5 in fasting samples. Levels higher than that indicate increased risk of atherosclerotic cardiovascular disease.

Hyperprolactinemia in women results in the amenorrhea-galactorrhea syndrome and infertility; in men, loss of libido, impotence, and infertility may result. Hyperprolactinemia may cause osteoporosis, particularly in women. If dose reduction is not indicated, or is ineffective in controlling this pattern, switching to an atypical agent that does not raise prolactin levels, eg, **aripiprazole**, may be indicated.

#### E. Toxic or Allergic Reactions

Agranulocytosis, cholestatic jaundice, and skin eruptions occur rarely with the high-potency antipsychotic drugs currently used.

In contrast to other antipsychotic agents, **clozapine** causes agranulocytosis in a small but significant number of patients—approximately 1–2% of those treated. This serious, potentially fatal effect can develop rapidly, usually between the 6th and 18th weeks of therapy. It is not known whether it represents an immune reaction, but it appears to be reversible upon discontinuance of the drug. *Because of the risk of agranulocytosis, patients receiving clozapine must have weekly blood counts for the first 6 months of treatment and every 3 weeks thereafter.*

#### F. Ocular Complications

Deposits in the anterior portions of the eye (cornea and lens) are a common complication of **chlorpromazine** therapy. They may accentuate the normal processes of aging of the lens. **Thioridazine** is the only antipsychotic drug that causes retinal deposits, which in advanced cases may resemble retinitis pigmentosa. The deposits are usually associated with “browning” of vision. The maximum daily dose of **thioridazine** has been limited to 800 mg/d to

#### G. Cardiac Toxicity

**Thioridazine** in doses exceeding 300 mg daily is almost always associated with minor abnormalities of T waves that are easily reversible. Overdoses of **thioridazine** are associated with major ventricular arrhythmias, eg, torsades de pointes, cardiac conduction block, and sudden death; it is not certain whether **thioridazine** can cause these same disorders when used in therapeutic doses. In view of possible additive antimuscarinic and quinidine-like actions with various tricyclic antidepressants, **thioridazine** should be combined with the latter drugs only with great care. Among the atypical agents, **ziprasidone** carries the greatest risk of QT prolongation and therefore should not be combined with other drugs that prolong the QT interval, including **thioridazine**, **pimozide**, and group 1A or 3 antiarrhythmic drugs. **Clozapine** is sometimes associated with myocarditis and must be discontinued if myocarditis manifests. Sudden death due to arrhythmias is common in schizophrenia. It is not always drug-related, and there are no studies that definitively show increased risk with particular drugs. Monitoring of QT<sub>c</sub> prolongation has proved to be of little use unless the values increase to more than 500 ms and this is manifested in multiple rhythm strips or a Holter monitor study. A 20,000-patient study of **ziprasidone** versus **olanzapine** showed minimal or no increased risk of torsades de pointes or sudden death in patients who were randomized to **ziprasidone**.

#### H. Use in Pregnancy; Dysmorphogenesis

Although antipsychotic drugs appear to be relatively safe in pregnancy, a small increase in teratogenic risk could be missed. Questions about whether to use these drugs during pregnancy and whether to abort a pregnancy in which the fetus has already been exposed must be decided individually. If a pregnant woman could manage to be free of antipsychotic drugs during pregnancy, this would be desirable because of their effects on the neurotransmitters involved in neurodevelopment.

#### I. Neuroleptic Malignant Syndrome

This life-threatening disorder occurs in patients who are extremely sensitive to the extrapyramidal effects of antipsychotic agents (see also [Chapter 16](#)). The initial symptom is marked muscle rigidity. If sweating is impaired, as it often is during treatment with anticholinergic drugs, fever may ensue, often reaching dangerous levels. The stress leukocytosis and high fever associated with this syndrome may erroneously suggest an infectious process. Autonomic instability, with altered blood pressure and pulse rate, is often present.

Muscle-type creatine kinase levels are usually elevated, reflecting muscle damage. This syndrome is believed to result from an excessively rapid blockade of postsynaptic **dopamine** receptors. A severe form of extrapyramidal syndrome follows. Early in the course, vigorous treatment of the extrapyramidal syndrome with antiparkinsonism drugs is worthwhile. Muscle relaxants, particularly **diazepam**, are often useful. Other muscle relaxants, such as **dantrolene**, or **dopamine** agonists, such as **bromocriptine**, have been reported to be helpful. If fever is present, cooling by physical measures should be tried. Various minor forms of this syndrome are now recognized. Switching to an atypical drug after recovery is indicated.

#### Drug Interactions

Antipsychotics produce more important pharmacodynamic than pharmacokinetic interactions because of their multiple effects. Additive effects may occur when these drugs are combined with others that have sedative effects,  $\alpha$ -adrenoceptor-blocking action, anticholinergic effects, and—for **thioridazine** and ziprasidone—quinidine-like action.

A variety of pharmacokinetic interactions have been reported, but none are of major clinical significance.

#### Overdoses

Poisonings with antipsychotic agents (unlike tricyclic antidepressants) are rarely fatal, with the exception of those due to mesoridazine and **thioridazine** (which are no longer available in the USA). In general, drowsiness proceeds to coma, with an intervening period of agitation. Neuromuscular excitability may be increased and proceed to convulsions. Pupils are miotic, and deep tendon reflexes are decreased. Hypotension and hypothermia are the rule, although fever may be present later in the course. The lethal effects of mesoridazine and **thioridazine** are related to induction of ventricular tachyarrhythmias. Patients should be given the usual “ABCD” treatment for poisonings (see [Chapter 58](#)) and treated supportively. Management of overdoses of **thioridazine** and mesoridazine, which are complicated by cardiac arrhythmias, is similar to that for tricyclic

### Psychosocial Treatment & Cognitive Remediation

Patients with schizophrenia need psychosocial support based around activities of daily living, including housing, social activities, returning to school, obtaining the optimal level of work they may be capable of, and restoring social interactions. Unfortunately, funding for this crucial component of treatment has been minimized in recent years. Case management and therapy services are a vital part of the treatment program that should be provided to patients with schizophrenia. First-episode patients are particularly needful of this support because they often deny their illness and are noncompliant with medication.

### Benefits & Limitations of Drug Treatment

As noted at the beginning of this chapter, antipsychotic drugs have had a major impact on psychiatric treatment. First, they have shifted the vast majority of patients from long-term hospitalization to the community. For many patients, this shift has provided a better life under more humane circumstances and in many cases has made life possible without frequent use of physical restraints. For others, the tragedy of an aimless existence is now being played out in the streets of our communities rather than in mental institutions.

Second, these antipsychotic drugs have markedly shifted psychiatric thinking to a more biologic orientation. Partly because of research stimulated by the effects of these drugs on schizophrenia, we now know much more about central nervous system physiology and pharmacology than was known before the introduction of these agents. However, despite much research, schizophrenia remains a scientific mystery and a personal disaster for the patient. Although most schizophrenic patients obtain some degree of benefit from these drugs—in some cases substantial benefit—none is made well by them.

## LITHIUM, MOOD-STABILIZING DRUGS, & OTHER TREATMENT FOR BIPOLAR DISORDER

Bipolar disorder, once known as **manic-depressive** illness, was conceived of as a psychotic disorder distinct from schizophrenia at the end of the 19th century. Before that, both of these disorders were considered part of a continuum. The weight of the evidence today indicates that there *is* profound overlap in these disorders. However, there are pathophysiologically important differences, and some drug treatments are differentially effective in these disorders. According to *DSM-IV*, they are separate disease entities while research continues to define the dimensions of these illnesses and their genetic and other biologic markers.

**Lithium** was the first agent shown to be useful in the treatment of the manic phase of bipolar disorder that was not also an antipsychotic drug. **Lithium** is sometimes used adjunctively in schizophrenia. **Lithium** continues to be used for acute-phase illness as well as for prevention of recurrent manic and depressive episodes.

A group of mood-stabilizing drugs that are also anticonvulsant agents has become more widely used than **lithium**. It includes **carbamazepine** and **valproic acid** for the treatment of acute mania and for prevention of its recurrence. **Lamotrigine** is approved for prevention of recurrence. **Gabapentin**, **oxcarbazepine**, and **topiramate** are sometimes used to treat bipolar disorder but are not approved by the FDA for this indication. **Aripiprazole**, **chlorpromazine**, **olanzapine**, **quetiapine**, **risperidone**, and **ziprasidone** are approved by the FDA for treatment of the manic phase of bipolar disorder. **Olanzapine** plus **fluoxetine** in combination and **quetiapine** are approved for treatment of bipolar depression.

### Nature of Bipolar Affective Disorder

Bipolar affective disorder occurs in 1–3% of the adult population. It may begin in childhood, but most cases are first diagnosed in the third and fourth decades of life. The key symptoms of bipolar disorder in the manic phase are expansive or irritable mood, hyperactivity, impulsivity, disinhibition, diminished need for sleep, racing thoughts, psychotic symptoms in some (but not all) patients, and cognitive impairment. Depression in bipolar patients is phenomenologically similar to that of major depression, with the key features being depressed mood, diurnal variation, sleep disturbance, anxiety, and sometimes, psychotic symptoms. Mixed manic and depressive symptoms are also seen. Patients with bipolar disorder are at high risk for suicide.

The sequence, number, and intensity of manic and depressive episodes are highly variable. The cause of the mood swings characteristic of bipolar disorder is unknown, although a preponderance of catecholamine-related activity may be present. Drugs that increase this activity tend to

www.konkur.in exacerbate mania, whereas those that reduce activity of **dopamine** or **norepinephrine** relieve mania. **Acetylcholine** or glutamate also may be involved.

The nature of the abrupt switch from mania to depression experienced by some patients is uncertain. Bipolar disorder has a strong familial component, and there is abundant evidence that bipolar disorder is genetically determined.

Many of the genes that increase vulnerability to bipolar disorder are common to schizophrenia, but some genes appear to be unique to each disorder. Genome-wide association studies of psychotic bipolar disorder have shown replicated linkage to chromosomes 8p and 13q. Several candidate genes have shown association with bipolar disorder with psychotic features and with schizophrenia. These include genes for dysbindin, *DAOA/G30*, disrupted-in-schizophrenia-1 (*DISC-1*), and neuregulin 1.

## BASIC PHARMACOLOGY OF LITHIUM

**Lithium** was first used therapeutically in the mid-19th century in patients with gout. It was briefly used as a substitute for sodium chloride in hypertensive patients in the 1940s but was banned after it proved too toxic for use without monitoring. In 1949, Cade discovered that **lithium** was an effective treatment for bipolar disorder, engendering a series of controlled trials that confirmed its efficacy as monotherapy for the manic phase of bipolar disorder.

### Pharmacokinetics

**Lithium** is a small monovalent cation. Its pharmacokinetics are summarized in [Table 29-5](#).

TABLE 29-5

#### Pharmacokinetics of **lithium**.

Absorption	Virtually complete within 6–8 hours; peak plasma levels in 30 minutes to 2 hours
Distribution	In total body water; slow entry into intracellular compartment. Initial volume of distribution is 0.5 L/kg, rising to 0.7–0.9 L/kg; some sequestration in bone. No protein binding.
Metabolism	None
Excretion	Virtually entirely in urine. <b>Lithium</b> clearance about 20% of creatinine. Plasma half-life about 20 hours.
Target plasma concentration	0.6–1.4 mEq/L
Dosage	0.5 mEq/kg/d in divided doses

### Pharmacodynamics

Despite considerable investigation, the biochemical basis for mood stabilizer therapies including **lithium** and anticonvulsant mood stabilizers is not clearly understood. **Lithium** directly inhibits two signal transduction pathways. It both suppresses inositol signaling through depletion of intracellular inositol and inhibits glycogen synthase kinase-3 (GSK-3), a multifunctional protein kinase. GSK-3 is a component of diverse intracellular signaling pathways. These include signaling via **insulin**/insulin-like growth factor, brain-derived neurotrophic factor (BDNF), and the Wnt pathway. Lithium-induced inhibition of GSK-3 results in reduction of phosphorylation of  $\beta$ -catenin, which allows  $\beta$ -catenin to accumulate and translocate to the nucleus. There,  $\beta$ -catenin facilitates transcription of a variety of proteins. The pathways that are facilitated by the accumulation of  $\beta$ -catenin via GSK-3 inhibition modulate energy metabolism, provide neuroprotection, and increase neuroplasticity.

Studies on the enzyme prolyl oligopeptidase and the sodium myoinositol transporter support an inositol depletion mechanism for the mood-stabilizer action. Valproic acid may indirectly reduce GSK-3 activity and can up-regulate gene expression through inhibition of histone deacetylase. Valproic acid also inhibits inositol signaling through an inositol depletion mechanism. There is no evidence of GSK-3 inhibition by **carbamazepine**, a second

antidepressant mood stabilizer. In contrast, this drug alters neuronal morphology through an inositol depletion mechanism, as seen with **lithium** and valproic acid. The mood stabilizers may also have indirect effects on neurotransmitters and their release.

#### A. Effects on Electrolytes and Ion Transport

**Lithium** is closely related to sodium in its properties. It can substitute for sodium in generating action potentials and in  $\text{Na}^+$ - $\text{Na}^+$  exchange across the membrane. At therapeutic concentrations (~1 mEq/L), it does not significantly affect the  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchanger or the  $\text{Na}^+$ / $\text{K}^+$ -ATPase pump.

#### B. Effects on Second Messengers

Some of the enzymes affected by **lithium** are listed in **Table 29–6**. One of the best-defined effects of **lithium** is its action on inositol phosphates. Early studies of **lithium** demonstrated changes in brain inositol phosphate levels, but the significance of these changes was not appreciated until the second-messenger roles of inositol-1,4,5-trisphosphate ( $\text{IP}_3$ ) and diacylglycerol (DAG) were discovered. As described in **Chapter 2**, inositol trisphosphate and diacylglycerol are important second messengers for both  $\alpha$ -adrenergic and muscarinic transmission. **Lithium** inhibits inositol monophosphatase (IMPase) and other important enzymes in the normal recycling of membrane phosphoinositides, including conversion of  $\text{IP}_2$  (inositol diphosphate) to  $\text{IP}_1$  (inositol monophosphate) and the conversion of  $\text{IP}_1$  to inositol (**Figure 29–4**). This block leads to a depletion of free inositol and ultimately of phosphatidylinositol-4,5-bisphosphate ( $\text{PIP}_2$ ), the membrane precursor of  $\text{IP}_3$  and DAG. Over time, the effects of transmitters on the cell diminish in proportion to the amount of activity in the  $\text{PIP}_2$ -dependent pathways. The activity of these pathways is postulated to be markedly increased during a manic episode. Treatment with **lithium** would be expected to diminish activity in these circuits.

TABLE 29–6

#### Enzymes affected by **lithium** at therapeutic concentrations.

Enzyme	Enzyme Function; Action of <b>Lithium</b>
Inositol monophosphatase	The rate-limiting enzyme in inositol recycling; inhibited by <b>lithium</b> , resulting in depletion of substrate for $\text{IP}_3$ production ( <b>Figure 29–4</b> )
Inositol polyphosphate 1-phosphatase	Another enzyme in inositol recycling; inhibited by <b>lithium</b> , resulting in depletion of substrate for $\text{IP}_3$ production ( <b>Figure 29–4</b> )
Bisphosphate nucleotidase	Involved in AMP production; inhibited by <b>lithium</b> ; may be target that results in lithium-induced nephrogenic diabetes insipidus
Fructose 1,6-bisphosphatase	Involved in gluconeogenesis; inhibition by <b>lithium</b> of unknown relevance
Phosphoglucomutase	Involved in glycogenolysis; inhibition by <b>lithium</b> of unknown relevance
Glycogen synthase kinase-3	Constitutively active enzyme that appears to limit neurotrophic and neuroprotective processes; <b>lithium</b> inhibits

AMP, **adenosine** monophosphate;  $\text{IP}_3$ , inositol 1,4,5-trisphosphate.

FIGURE 29–4

**Effect of **lithium** on the  $\text{IP}_3$  (inositol trisphosphate) and DAG (diacylglycerol) second-messenger system.** The schematic diagram shows the synaptic membrane of a neuron. (PI, inorganic phosphate;  $\text{PIP}_2$ , phosphatidylinositol-4,5-bisphosphate; PLC, phospholipase C; G, coupling protein; Effects,

www.konkur.in  
activation of protein kinase C, mobilization of intracellular  $Ca^{2+}$ , etc.) Lithium, by inhibiting the recycling of inositol substrates, may cause the depletion of the second-messenger source PIP<sub>2</sub> and therefore reduce the release of IP<sub>3</sub> and DAG. Lithium may also act by other mechanisms (see text).

Studies of noradrenergic effects in isolated brain tissue indicate that lithium can inhibit norepinephrine-sensitive adenylyl cyclase. Such an effect could relate to both its antidepressant and its antimanic effects. The relationship of these effects to lithium's actions on IP<sub>3</sub> mechanisms is currently unknown.

Because lithium affects second-messenger systems involving both activation of adenylyl cyclase and phosphoinositid turnover, it is not surprising that G proteins also are found to be affected. Several studies suggest that lithium may uncouple receptors from their G proteins; indeed, two of lithium's most common side effects, polyuria and subclinical hypothyroidism, may be due to uncoupling of the vasopressin and thyroid-stimulating hormone (TSH) receptors from their G proteins.

The major current working hypothesis for lithium's therapeutic mechanism of action supposes that its effects on phosphoinositid turnover, leading to an early relative reduction of myoinositol in human brain, are part of an initiating cascade of intracellular changes. Effects on specific isoforms of protein kinase C may be most relevant. Alterations of protein kinase C-mediated signaling alter gene expression and the production of proteins implicated in long-term neuroplastic events that could underlie long-term mood stabilization.

## CLINICAL PHARMACOLOGY OF LITHIUM

### Bipolar Affective Disorder

Until the late 1990s, lithium carbonate was the universally preferred treatment for bipolar disorder, especially in the manic phase. With the approval of valproate, aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone for this indication, a smaller percentage of bipolar patients now receive lithium. This trend is reinforced by the slow onset of action of lithium, which has often been supplemented with concurrent use of antipsychotic drugs or potent benzodiazepines in severely manic patients. The overall success rate for achieving remission from the manic phase of bipolar disorder can be as high as 80% but lower among patients who require hospitalization. A similar situation applies to maintenance treatment, which is about 60% effective overall but less in severely ill patients. These considerations have led to increased use of combined treatment in severe cases. After mania is controlled, the antipsychotic drug may be stopped and benzodiazepines and lithium continued as maintenance therapy.

The depressive phase of manic-depressive disorder often requires concurrent use of other agents including antipsychotics such as quetiapine or lurasidone. Antidepressants have not shown consistent utility and may be destabilizing. Tricyclic antidepressant agents have been linked to precipitation of mania, with more rapid cycling of mood swings, although most patients do not show this effect. Similarly, selective norepinephrine-serotonin reuptake inhibitor (SNRI) agents (see Chapter 30) have been associated with higher rates of switching to mania than some other antidepressants. Selective serotonin reuptake inhibitors are less likely to induce mania but may have limited efficacy. Bupropion has shown some promise but—like tricyclic antidepressants—may induce mania at higher doses. As shown in recent controlled trials, the anticonvulsant lamotrigine is effective for some patients with bipolar depression, but results have been inconsistent. For some patients, however, one of the older monoamine oxidase inhibitors may be the antidepressant of choice. Quetiapine and the combination of olanzapine plus fluoxetine have been approved for use in

Unlike antipsychotic or antidepressant drugs, which exert several actions on the central or autonomic nervous system, **lithium** ion at therapeutic concentrations is devoid of autonomic blocking effects and of activating or sedating effects, although it can produce nausea and tremor. Most important is that the prophylactic use of **lithium** can prevent both mania and depression. Many experts believe that the aggressive marketing of newer drugs has inappropriately produced a shift to drugs that are less effective than **lithium** for substantial numbers of patients.

#### Other Applications

**Recurrent depression** with a cyclic pattern is controlled by either **lithium** or **imipramine**, both of which are superior to placebo. **Lithium** is also among the better-studied agents used to augment standard antidepressant response in **acute major depression** in those patients who have had inadequate response to monotherapy. For this application, concentrations of **lithium** at the lower end of the recommended range for bipolar disorder appear to be adequate.

**Schizoaffective disorder**, another condition with an affective component characterized by a mixture of schizophrenic symptoms and depression or excitement, is treated with antipsychotic drugs alone or combined with **lithium**. Various antidepressants are added if depression is present.

**Lithium** alone is rarely successful in treating **schizophrenia**, but adding **lithium** to an antipsychotic may salvage an otherwise treatment-resistant patient. **Carbamazepine** may work equally well when added to an antipsychotic drug.

#### Monitoring Treatment

Clinicians rely on measurements of serum **lithium** concentrations for assessing both the dosage required for treatment of acute mania and for prophylactic maintenance. These measurements are customarily taken 10–12 hours after the last dose, so all data in the literature pertaining to these concentrations reflect this interval.

An initial determination of serum **lithium** concentration should be obtained about 5 days after the start of treatment, at which time steady-state conditions should have been attained. If the clinical response suggests a change in dosage, simple arithmetic (new dose equals present dose times desired blood level divided by present blood level) should produce the desired level. The serum concentration attained with the adjusted dosage can be checked after another 5 days. Once the desired concentration has been achieved, levels can be measured at increasing intervals unless the schedule is influenced by intercurrent illness or the introduction of a new drug into the treatment program.

#### Maintenance Treatment

The decision to use **lithium** as *prophylactic* treatment depends on many factors: the frequency and severity of previous episodes, a crescendo pattern of appearance, and the degree to which the patient is willing to follow a program of indefinite maintenance therapy. Patients with a history of two or more mood cycles or any clearly defined bipolar I diagnosis are probable candidates for maintenance treatment. It has become increasingly evident that each recurrent cycle of bipolar illness may leave residual damage and worsen the long-term prognosis of the patient. Thus, there is greater consensus among experts that maintenance treatment be started as early as possible to reduce the frequency of recurrence. Although some patients can be maintained with serum levels as low as 0.6 mEq/L, the best results have been obtained with higher levels, such as 0.9 mEq/L.

#### Drug Interactions

Renal clearance of **lithium** is reduced about 25% by diuretics (eg, thiazides), and doses may need to be reduced by a similar amount. A similar reduction in **lithium** clearance has been noted with several of the newer nonsteroidal anti-inflammatory drugs that block synthesis of prostaglandins. This interaction has not been reported for either **aspirin** or **acetaminophen**. All neuroleptics tested to date, with the possible exception of **clozapine** and the newer atypical antipsychotics, may produce more severe extrapyramidal syndromes when combined with **lithium**.

#### Adverse Effects & Complications

Many adverse effects associated with **lithium** treatment occur at varying times after treatment is started. Some are harmless, but it is important to be alert to adverse effects that may signify impending serious toxic reactions.

**Tremor** is one of the most common adverse effects of **lithium** treatment, and it occurs with therapeutic doses. **Propranolol** and **atenolol**, which have been reported to be effective in essential tremor, also alleviate lithium-induced tremor. Other reported neurologic abnormalities include choreoathetosis, motor hyperactivity, ataxia, dysarthria, and aphasia. Psychiatric disturbances at toxic concentrations are generally marked by mental confusion and withdrawal. Appearance of any new neurologic or psychiatric symptoms or signs is a clear indication for temporarily stopping treatment with **lithium** and for close monitoring of serum levels.

#### **B. Decreased Thyroid Function**

**Lithium** probably decreases thyroid function in most patients exposed to the drug, but the effect is reversible or nonprogressive. Few patients develop frank thyroid enlargement, and fewer still show symptoms of hypothyroidism. Although initial thyroid testing followed by regular monitoring of thyroid function has been proposed, such procedures are not cost-effective. Obtaining a serum TSH concentration every 6–12 months, however, is prudent.

#### **C. Nephrogenic Diabetes Insipidus and Other Renal Adverse Effects**

Polydipsia and polyuria are common but reversible concomitants of **lithium** treatment, occurring at therapeutic serum concentrations. The principal physiologic lesion involved is loss of responsiveness to antidiuretic hormone (nephrogenic diabetes insipidus). Lithium-induced diabetes insipidus is resistant to **vasopressin** but responds to **amiloride** (see **Chapter 15**).

Extensive literature has accumulated concerning other forms of renal dysfunction during long-term **lithium** therapy, including chronic interstitial nephritis and minimal-change glomerulopathy with nephrotic syndrome. Some instances of decreased glomerular filtration rate have been encountered but no instances of marked azotemia or renal failure.

Patients receiving **lithium** should avoid dehydration and the associated increased concentration of **lithium** in urine. Periodic tests of renal concentrating ability should be performed to detect changes.

#### **D. Edema**

Edema is a common adverse effect of **lithium** treatment and may be related to some effect of **lithium** on sodium retention. Although weight gain may be expected in patients who become edematous, water retention does not account for the weight gain observed in up to 30% of patients taking **lithium**.

#### **E. Cardiac Adverse Effects**

The bradycardia-tachycardia (“sick sinus”) syndrome is a definite contraindication to the use of **lithium** because the ion further depresses the sinus node. T-wave flattening is often observed on the electrocardiogram but is of questionable significance.

#### **F. Use during Pregnancy**

Renal clearance of **lithium** increases during pregnancy and reverts to lower levels immediately after delivery. A patient whose serum **lithium** concentration is in a good therapeutic range during pregnancy may develop toxic levels after delivery. Special care in monitoring **lithium** levels is needed at these times. **Lithium** is transferred to nursing infants through breast milk, in which it has a concentration about one third to one half that of serum. **Lithium** toxicity in newborns is manifested by lethargy, cyanosis, poor suck and Moro reflexes, and perhaps hepatomegaly.

The issue of lithium-induced dysmorphogenesis is not settled. An earlier report suggested an increase in cardiac anomalies—especially Ebstein anomaly—in **lithium** babies, and it is listed as such in **Table 59–1** in this book. However, more recent data suggest that **lithium** carries a relatively low risk of teratogenic effects. Further research is needed in this important area.

#### **G. Miscellaneous Adverse Effects**

Transient acneiform eruptions have been noted early in **lithium** treatment. Some of them subside with temporary discontinuance of treatment and do not recur with its resumption. Folliculitis is less dramatic and probably occurs more frequently. Leukocytosis is always present during **lithium**

www.konkur.in  
treatment, probably reflecting a direct effect on leukopoiesis rather than mobilization from the marginal pool. This adverse effect has now become a therapeutic effect in patients with low leukocyte counts.

### Overdoses

Therapeutic overdoses of **lithium** are more common than those due to deliberate or accidental ingestion of the drug. Therapeutic overdoses are usually due to accumulation of **lithium** resulting from some change in the patient's status, such as diminished serum sodium, use of diuretics, or fluctuating renal function. Since the tissues will have already equilibrated with the blood, the plasma concentrations of **lithium** may not be excessively high in proportion to the degree of toxicity; any value over 2 mEq/L must be considered as indicating likely toxicity. Because **lithium** is a small ion, it is dialyzed readily. Both peritoneal dialysis and hemodialysis are effective, although the latter is preferred.

### VALPROIC ACID

Valproic acid (valproate), discussed in detail in [Chapter 24](#) as an antiepileptic, has been demonstrated to have antimanic effects and is now being widely used for this indication in the USA. (**Gabapentin** is not effective, leaving the mechanism of antimanic action of valproate unclear.) Overall, valproic acid shows efficacy equivalent to that of **lithium** during the early weeks of treatment. It is significant that valproic acid has been effective in some patients who have failed to respond to **lithium**. For example, mixed states and rapid cycling forms of bipolar disorder may be more responsive to valproate than to **lithium**. Moreover, its side-effect profile is such that one can rapidly increase the dosage over a few days to produce blood levels in the apparent therapeutic range, with nausea being the only limiting factor in some patients. The starting dosage is 750 mg/d, increasing rapidly to the 1500–2000 mg range with a recommended maximum dosage of 60 mg/kg/d.

Combinations of valproic acid with other psychotropic medications likely to be used in the management of either phase of bipolar illness are generally well tolerated. Valproic acid is an appropriate first-line treatment for mania, although it is not clear that it will be as effective as **lithium** as a maintenance treatment in all subsets of patients. Many clinicians advocate combining valproic acid and **lithium** in patients who do not fully respond to either agent alone.

### CARBAMAZEPINE

**Carbamazepine** has been considered to be a reasonable alternative to **lithium** when the latter is less than optimally efficacious. However, the pharmacokinetic interactions of **carbamazepine** and its tendency to induce the metabolism of CYP3A4 substrates make it a more difficult drug to use with other standard treatments for bipolar disorder. The mode of action of **carbamazepine** is unclear, and **oxcarbazepine** is not effective.

**Carbamazepine** may be used to treat acute mania and also for prophylactic therapy. Adverse effects (discussed in [Chapter 24](#)) are generally no greater and sometimes less than those associated with **lithium**. **Carbamazepine** may be used alone or, in refractory patients, in combination with **lithium** or, rarely, valproate.

The use of **carbamazepine** as a mood stabilizer is similar to its use as an anticonvulsant (see [Chapter 24](#)). Dosage usually begins with 200 mg twice daily, with increases as needed. Maintenance dosage is similar to that used for treating epilepsy, ie, 800–1200 mg/d. Plasma concentrations between 3 and 14 mg/L are considered desirable, although the optimal therapeutic range has not been established. Blood dyscrasias have figured prominently in the adverse effects of **carbamazepine** when it is used as an anticonvulsant, but they have not been a major problem with its use as a mood stabilizer. Overdoses of **carbamazepine** are a major emergency and should generally be managed like overdoses of tricyclic antidepressants (see [Chapter 58](#)).

### OTHER DRUGS

**Lamotrigine** is approved as a maintenance treatment for bipolar disorder. Although not effective in treating acute mania, it appears effective in reducing the frequency of recurrent depressive cycles and may have some utility in the treatment of bipolar depression. A number of novel agents are under investigation for bipolar depression, including **riluzole**, a neuroprotective agent that is approved for use in amyotrophic lateral sclerosis; **ketamine**, a noncompetitive NMDA antagonist previously discussed as a drug believed to model schizophrenia but thought to act by producing relative enhancement of AMPA receptor activity; and AMPA receptor potentiators.

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>PHENOTHIAZINES</b>

---	---	-----------------------	--	--

### PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
<b>ANTIPSYCHOTIC AGENTS</b>	
Aripiprazole	Abilify
Asenapine	Saphris, Secuado
Brexipiprazole	Rexulti
Cariprazine	Vraylar
Chlorpromazine	Generic, Thorazine
Clozapine	Generic, Clozaril, others
Fluphenazine	Generic
Fluphenazine decanoate	Generic, Prolixin Decanoate
Haloperidol	Generic, Haldol
Haloperidol ester	Haldol Decanoate
	Fanapt

Loxapine	Adasuve
Lumateperone	Caplyta
Lurasidone	Latuda
Molindone	Moban
Olanzapine	Generic, Zyprexa
Paliperidone	Invega
Perphenazine	Generic, Trilafon
Pimavanserin	Nuplazid
Pimozide	Orap
Prochlorperazine	Generic, Compazine
Quetiapine	Generic, Seroquel
Risperidone	Generic, Risperdal
Thioridazine	Generic, Mellaril
Thiothixene	Generic, Navane
Trifluoperazine	Generic, Stelazine
Ziprasidone	Generic, Geodon
<b>MOOD STABILIZERS</b>	
Carbamazepine	Generic, Tegretol
Divalproex	Generic, Depakote
Lamotrigine	Generic, Lamictal
Lithium carbonate	Generic, Eskalith
Topiramate	Generic, Topamax
Valproic acid	Generic, Depakene

Schizophrenia is characterized by a disintegration of thought processes and emotional responsiveness. Symptoms commonly include auditory hallucinations, paranoid or bizarre delusions, disorganized thinking and speech, and social and occupational dysfunction. For many patients, first-generation (eg, [haloperidol](#)) and second-generation agents (eg, [risperidone](#)) are of equal efficacy for treating positive symptoms. Second-generation agents are often more effective for treating negative symptoms and cognitive dysfunction and have lower risk of tardive dyskinesia and hyperprolactinemia. Other indications for the use of selected antipsychotics include bipolar disorder, psychotic depression, Tourette syndrome, disturbed behavior in patients with Alzheimer disease, and, in the case of older drugs (eg, [chlorpromazine](#)), treatment of emesis and pruritus.

## Chapter 30: Antidepressant Agents

Charles DeBattista

### CASE STUDY

#### CASE STUDY

A 47-year-old woman presents to her primary care physician with a chief complaint of fatigue. She indicates that she was promoted to senior manager in her company approximately 11 months earlier. Although her promotion was welcome and came with a sizable raise in pay, it resulted in her having to move away from an office and group of colleagues she very much enjoyed. In addition, her level of responsibility increased dramatically. The patient reports that for the last 7 weeks, she has been waking up at 3 AM every night and been unable to go back to sleep. She dreads the day and the stresses of the workplace. As a consequence, she is not eating as well as she might and has dropped 7% of her body weight in the last 3 months. She also reports being so stressed that she breaks down crying in the office occasionally and has been calling in sick frequently. When she comes home, she finds she is less motivated to attend to chores around the house and has no motivation, interest, or energy to pursue recreational activities that she once enjoyed such as hiking. She describes herself as “chronically miserable and worried all the time.” Her medical history is notable for chronic neck pain from a motor vehicle accident for which she is being treated with **tramadol** and **meperidine**. In addition, she is on **hydrochlorothiazide** and **propranolol** for hypertension. The patient has a history of one depressive episode after a divorce that was treated successfully with **fluoxetine**. Medical workup including complete blood cell count, thyroid function tests, and a chemistry panel reveals no abnormalities. She is started on **fluoxetine** for a presumed major depressive episode and referred for cognitive behavioral psychotherapy. What CYP450 and pharmacodynamic interactions might be associated with **fluoxetine** use in this patient? Which class of antidepressants would be contraindicated in this patient?

The diagnosis of depression still rests primarily on the clinical interview. Major depressive disorder (MDD) is characterized by depressed mood most of the time for at least 2 weeks or loss of interest or pleasure in most activities, or both. In addition, depression is characterized by disturbances in sleep and appetite as well as deficits in cognition and energy. Thoughts of guilt, worthlessness, and suicide are common. Coronary artery disease, diabetes, and stroke appear to be more common in depressed patients, and depression may considerably worsen the prognosis for patients with a variety of comorbid medical conditions.

According to the Centers for Disease Control and Prevention, antidepressants are consistently among the three most commonly prescribed classes of medications in the USA. The wisdom of such widespread use of antidepressants is debated. However, it is clear that American physicians have been increasingly inclined to use antidepressants to treat a host of conditions and that patients have been increasingly receptive to their use.

The primary indication for antidepressant agents is the treatment of MDD. Major depression, with a lifetime prevalence of around 17% in the USA and a point prevalence of 5%, is associated with substantial morbidity and mortality. MDD represents one of the most common causes of disability in the developed world. In addition, major depression is commonly associated with a variety of medical conditions—from chronic pain to coronary artery disease. When depression coexists with other medical conditions, the patient's disease burden increases, and the quality of life—and often the prognosis for effective treatment—decreases significantly.

Some of the growth in antidepressant use may be related to the broad application of these agents for conditions other than major depression. For example, antidepressants have received US Food and Drug Administration (FDA) approvals for the treatment of panic disorder, generalized anxiety disorder (GAD), post-traumatic stress disorder (PTSD), and obsessive-compulsive disorder (OCD). In addition, antidepressants are commonly used to treat pain disorders such as neuropathic pain and the pain associated with fibromyalgia. Some antidepressants are used for treating premenstrual dysphoric disorder (PMDD), mitigating the vasomotor symptoms of menopause, and treating stress urinary incontinence. Thus, antidepressants have

## PATHOPHYSIOLOGY OF MAJOR DEPRESSION

There has been a marked shift in the last decade in our understanding of the pathophysiology of major depression. In addition to the older idea that a deficit in function or amount of monoamines (the **monoamine hypothesis**) is central to the biology of depression, there is evidence that neurotrophic and endocrine factors play a major role (the **neurotrophic hypothesis**). Histologic studies, structural and functional brain imaging research, genetic findings, and steroid research all suggest a complex pathophysiology for MDD with important implications for drug treatment.

### Neurotrophic Hypothesis

There is substantial evidence that nerve growth factors such as **brain-derived neurotrophic factor (BDNF)** are critical in the regulation of neural plasticity, resilience, and neurogenesis. The evidence suggests that depression is associated with the loss of neurotrophic support and that effective antidepressant therapies increase neurogenesis and synaptic connectivity in cortical areas such as the hippocampus. BDNF is thought to exert its influence on neuronal survival and growth effects by activating the tyrosine kinase receptor B in both neurons and glia (**Figure 30-1**).

FIGURE 30-1

The neurotrophic hypothesis of major depression. Changes in trophic factors (especially brain-derived neurotrophic factor, BDNF) and hormones appear to play a major role in the development of major depression (**A**). Successful treatment results in changes in these factors (**B**). CREB, cAMP response element-binding (protein); BDNF, brain-derived neurotrophic factor. (Reproduced with permission from Nestler EJ, Barrot M, DiLeone RJ, Eisch AJ, Gold SJ, Monteggia LM. Neurobiology of depression. *Neuron* 2002 Mar 28;34(1):13-25.)

Copyright © McGraw Hill. All rights reserved.

Several lines of evidence support the neurotrophic hypothesis. Animal and human studies indicate that stress and pain are associated with a drop in BDNF levels and that this loss of neurotrophic support contributes to atrophic structural changes in the hippocampus and perhaps other areas such as the medial frontal cortex and anterior cingulate. The hippocampus is known to be important in both contextual memory and regulation of the

www.kozhikode.com  
hypothalamic-pituitary-adrenal (HPA) axis. Likewise, the anterior cingulate plays a role in the integration of emotional stimuli and attention functions, whereas the medial orbital frontal cortex is also thought to play a role in memory, learning, and emotion.

Over 30 structural imaging studies suggest that major depression is associated with a 5–10% loss of volume in the hippocampus, although some studies have not replicated this finding. Depression and chronic stress states have also been associated with a substantial loss of volume in the anterior cingulate and medial orbital frontal cortex. Loss of volume in structures such as the hippocampus also appears to increase as a function of the duration of illness and the amount of time that the depression remains untreated.

Another source of evidence supporting the neurotrophic hypothesis of depression comes from studies of the direct effects of BDNF on emotional regulation. Direct infusion of BDNF into the midbrain, hippocampus, and lateral ventricles of rodents has an antidepressant-like effect in animal models. Moreover, all known classes of antidepressants are associated with an increase in BDNF levels in animal models with chronic (but not acute) administration. This increase in BDNF levels is consistently associated with increased neurogenesis in the hippocampus in these animal models. Other interventions thought to be effective in the treatment of major depression, including electroconvulsive therapy, also appear to robustly stimulate BDNF levels and hippocampus neurogenesis in animal models.

Human studies seem to support the animal data on the role of neurotrophic factors in stress states. Depression appears to be associated with a drop in BDNF levels in the cerebrospinal fluid and serum as well as with a decrease in tyrosine kinase receptor B activity. Conversely, administration of antidepressants increases BDNF levels in clinical trials and may be associated with an increase in hippocampus volume in some patients.

Much evidence supports the neurotrophic hypothesis of depression, but not all evidence is consistent with this concept. Animal studies in BDNF knockout mice have not always suggested an increase in depressive or anxious behaviors that would be expected with a deficiency of BDNF. In addition, some animal studies have found an increase in BDNF levels after some types of social stress and an increase rather than a decrease in depressive behaviors with lateral ventricle injections of BDNF.

A proposed explanation for the discrepant findings on the role of neurotrophic factors in depression is that there are polymorphisms for BDNF that may yield very different effects. Mutations in the *BDNF* gene have been found to be associated with altered anxiety and depressive behavior in both animal and human studies.

Thus, the neurotrophic hypothesis continues to be intensely investigated and has yielded new insights and potential targets in the treatment of MDD.

## Monoamines & Other Neurotransmitters

The monoamine hypothesis of depression (Figure 30–2) suggests that depression is related to a deficiency in the amount or function of cortical and limbic serotonin (5-HT), norepinephrine (NE), and dopamine (DA).

FIGURE 30–2

The amine hypothesis of major depression. Depression appears to be associated with changes in serotonin or norepinephrine signaling in the brain (or both) with significant downstream effects. Most antidepressants cause changes in amine signaling. AC, adenylyl cyclase; CREB, cAMP response element-binding (protein); DAG, diacyl glycerol; 5-HT, serotonin; IP<sub>3</sub>, inositol trisphosphate; MAO, monoamine oxidase; NET, norepinephrine transporter; PKC, protein kinase C; PLC, phospholipase C; SERT, serotonin transporter.

Source: Todd W. Vanderah:  
Basic & Clinical Pharmacology, Sixteenth Edition  
Copyright © McGraw Hill. All rights reserved.

Evidence to support the monoamine hypothesis comes from several sources. It has been known for many years that reserpine treatment, which is known to deplete monoamines, is associated with depression in a subset of patients. Similarly, depressed patients who respond to serotonergic antidepressants such as **fluoxetine** often rapidly suffer relapse when given diets free of **tryptophan**, a precursor of serotonin synthesis. Patients who respond to noradrenergic antidepressants such as **desipramine** are less likely to relapse on a tryptophan-free diet. Moreover, depleting catecholamines in depressed patients who have previously responded to noradrenergic agents likewise tends to be associated with relapse. Administration of an inhibitor of **norepinephrine** synthesis is also associated with a rapid return of depressive symptoms in patients who respond to noradrenergic but not necessarily in patients who had responded to serotonergic antidepressants.

Another line of evidence supporting the monoamine hypothesis comes from genetic studies. A functional polymorphism exists for the promoter region of the serotonin transporter gene, which regulates how much of the transporter protein is available. Subjects who are homozygous for the s (short) allele may be more vulnerable to developing major depression and suicidal behavior in response to stress. In addition, homozygotes for the s allele may also be less likely to respond to and tolerate serotonergic antidepressants. Conversely, subjects with the l (long) allele tend to be more resistant to stress and may be more likely to respond to serotonergic antidepressants.

Studies of depressed patients have sometimes shown an alteration in monoamine function. For example, some studies have found evidence of alteration in serotonin receptor numbers (5-HT<sub>1A</sub> and 5-HT<sub>2C</sub>) or **norepinephrine** ( $\alpha_2$ ) receptors in depressed and suicidal patients, but these findings have not been consistent. A reduction in the primary serotonin metabolite 5-hydroxyindoleacetic acid in the cerebrospinal fluid is associated with violent and impulsive behavior, including violent suicide attempts. However, this finding is not specific to major depression and is associated more generally with violent and impulsive behavior.

Finally, perhaps the most convincing line of evidence supporting the monoamine hypothesis is the fact that (at the time of this writing) all available antidepressants appear to have significant effects on the monoamine system. All classes of antidepressants appear to enhance the synaptic availability of 5-HT, [norepinephrine](#), or [dopamine](#). Attempts to develop antidepressants that work on other neurotransmitter systems have not been effective to date.

The monoamine hypothesis, like the neurotrophic hypothesis, is at best incomplete. Many studies have not found an alteration in function or levels of monoamines in depressed patients. In addition, some candidate antidepressant agents under study do not act directly on the monoamine system.

In addition to the monoamines, the excitatory neurotransmitter glutamate appears to be important in the pathophysiology of depression. A number of studies of depressed patients have found elevated glutamate content in the cerebrospinal fluid of depressed patients and decreased [glutamine](#)/glutamate ratios in their plasma. In addition, postmortem studies have revealed significant increases in the frontal and dorsolateral prefrontal cortex of depressed patients. Likewise, structural neuroimaging studies have consistently found volumetric changes in the brain areas of depressed patients in which glutamate neurons and their connections are most abundant, including the amygdala and hippocampus.

Antidepressants are known to impact glutamate neurotransmission in a variety of ways. For example, chronic antidepressant use is associated with reducing glutamatergic transmission, including the presynaptic release of glutamate in the hippocampus and cortical areas. Similarly, the chronic administration of antidepressants significantly reduces depolarization-evoked release of glutamate in animal models. Stress is known to enhance the release of glutamate in rodents, and antidepressants inhibit stress-induced presynaptic release of glutamate in these models.

Given the effect of antidepressants on the glutamate system, there has been a growing interest in the development of pharmaceutical agents that might modulate the glutamate system. [Ketamine](#) and [esketamine](#) (the (S) + enantiomer of [ketamine](#)) are both potent, high-affinity, noncompetitive *N*-methyl-D-aspartate (NMDA) receptor antagonists but have many other pharmacodynamic properties (see below). [Esketamine](#) was approved as an adjunctive treatment for resistant major depression in 2019. In 2022, the combination of [bupropion](#) and [dextromethorphan](#) also was approved for the treatment of major depression. Among the putative mechanisms of action proposed for [dextromethorphan](#) is as an NMDA antagonist as well as actions on the sigma-1 receptor. In addition, a number of other NMDA receptor antagonists, partial antagonists, and metabotropic glutamate receptor modulators (see [Chapter 29](#)) are under investigation as potential antidepressants.

## Neuroendocrine Factors in the Pathophysiology of Depression

Depression is associated with a number of hormonal abnormalities. Among the most replicated of these findings are abnormalities in the HPA axis in patients with MDD. For example, MDD is associated with elevated cortisol levels (see [Figure 30-1](#)), nonsuppression of adrenocorticotropic hormone (ACTH) release in the [dexamethasone](#) suppression test, and chronically elevated levels of corticotropin-releasing hormone. The significance of these HPA abnormalities is unclear, but they are thought to indicate a dysregulation of the stress hormone axis. More severe types of depression, such as psychotic depression, tend to be associated with HPA abnormalities more commonly than milder forms of major depression. It is well known that both exogenous glucocorticoids and endogenous elevation of cortisol are associated with mood symptoms and cognitive deficits similar to those seen in MDD.

Thyroid dysregulation also has been reported in depressed patients. Up to 25% of depressed patients are reported to have abnormal thyroid function. These abnormalities include a blunting of response of thyrotropin to thyrotropin-releasing hormone and elevations in circulating thyroxine during depressed states. Clinical hypothyroidism often presents with depressive symptoms, which resolve with thyroid hormone supplementation. Thyroid hormones are also commonly used in conjunction with standard antidepressants to augment therapeutic effects of the latter.

Finally, sex steroids also are implicated in the pathophysiology of depression. Estrogen deficiency states, which occur in the postpartum and postmenopausal periods, are thought to play a role in the etiology of depression in some women. Likewise, severe [testosterone](#) deficiency in men is sometimes associated with depressive symptoms. Hormone replacement therapy in hypogonadal men and women may be associated with an improvement in mood and depressive symptoms.

## Integration of Hypotheses Regarding the Pathophysiology of Depression

The several pathophysiologic hypotheses just described are not mutually exclusive. It is evident that the monoamine, neuroendocrine, and neurotrophic systems are interrelated in important ways. For example, HPA and steroid abnormalities may contribute to suppression of transcription

of the BDNF gene. Glucocorticoid receptors are found in high density in the hippocampus. Binding of these hippocampal glucocorticoid receptors by cortisol during chronic stress states such as major depression may decrease BDNF synthesis and may result in volume loss in stress-sensitive regions such as the hippocampus. The chronic activation of monoamine receptors by antidepressants appears to have the opposite effect of stress and results in an increase in BDNF transcription. In addition, activation of monoamine receptors appears to down-regulate the HPA axis and may normalize HPA function.

One of the weaknesses of the monoamine hypothesis is the fact that amine levels increase immediately with antidepressant use, but maximum beneficial effects of most antidepressants are not seen for many weeks. The time required to synthesize neurotrophic factors has been proposed as an explanation for this delay of antidepressant effects. Appreciable protein synthesis of products such as BDNF typically takes 2 weeks or longer and coincides with the clinical course of antidepressant treatment.

## BASIC PHARMACOLOGY OF ANTIDEPRESSANTS

### CHEMISTRY & SUBGROUPS

The currently available antidepressants make up a remarkable variety of chemical types. These differences and the differences in their molecular targets provide the basis for distinguishing several subgroups.

#### A. Selective Serotonin Reuptake Inhibitors

The selective serotonin reuptake inhibitors (SSRIs) represent a chemically diverse class of agents that have as their primary action the inhibition of the serotonin transporter (SERT; [Figure 30-3](#)). [Fluoxetine](#) was introduced in the United States in 1988 and quickly became one of the most commonly prescribed medications in medical practice. The development of [fluoxetine](#) emerged out of the search for chemicals that had high affinity for monoamine receptors but lacked the affinity for histamine, [acetylcholine](#), and  $\alpha$  adrenoceptors that is seen with the tricyclic antidepressants (TCAs). There are currently six available SSRIs, and they are the most common antidepressants in clinical use. In addition to their use in major depression, SSRIs have indications in GAD, PTSD, OCD, panic disorder, PMDD, and bulimia. [Fluoxetine](#), [sertraline](#), and [citalopram](#) exist as isomers and are formulated in the racemic forms, whereas [paroxetine](#) and [fluvoxamine](#) are not optically active. [Escitalopram](#) is the (*S*) enantiomer of [citalopram](#). As with all antidepressants, SSRIs are highly lipophilic. The popularity of SSRIs stems largely from their ease of use, safety in overdose, relative tolerability, cost (all are available as generic products), and broad spectrum of uses.

#### FIGURE 30-3

## B. Serotonin-Norepinephrine Reuptake Inhibitors

Two classes of antidepressants act as combined serotonin and norepinephrine reuptake inhibitors: selective **serotonin-norepinephrine reuptake inhibitors (SNRIs)** and **TCAs**.

### 1. Selective serotonin-norepinephrine reuptake inhibitors

The SNRIs include **venlafaxine**, its metabolite **desvenlafaxine**, **duloxetine**, and **levomilnacipran**. **Levomilnacipran** is the active enantiomer of a racemic SNRI, **milnacipran**. **Milnacipran** has been approved for the treatment of fibromyalgia in the USA and has been used in the treatment of depression in Europe for many years. In addition to their use in major depression, SNRIs have applications in the treatment of pain disorders including neuropathies and fibromyalgia. SNRIs are also used in the treatment of generalized anxiety, stress urinary incontinence, and vasomotor symptoms of menopause.

R =  $CH_3$  : **Venlafaxine**  
R = H : **Desvenlafaxine**

SNRIs are chemically unrelated to each other. **Venlafaxine** was discovered in the process of evaluating chemicals that inhibit binding of **imipramine**. **Venlafaxine**'s in vivo effects are similar to those of **imipramine** but with a more favorable adverse-effect profile. All SNRIs bind the serotonin (SERT) and **norepinephrine** (NET) transporters, as do the TCAs. However, unlike the TCAs, the SNRIs do not have much affinity for other receptors. **Venlafaxine** and **desvenlafaxine** are bicyclic compounds, whereas **duloxetine** is a three-ring structure unrelated to the TCAs. **Milnacipran** contains a cyclopropane ring and is provided as a racemic mixture.

**Duloxetine****2. Tricyclic antidepressants**

The TCAs were the dominant class of antidepressants until the introduction of SSRIs in the 1980s and 1990s. Nine TCAs are available in the USA, and they all have an iminodibenzyl (tricyclic) core (Figure 30-4). The chemical differences between the TCAs are relatively subtle. For example, the prototype TCA **imipramine** and its metabolite, **desipramine**, differ by only a methyl group in the propylamine side chain. However, this minor difference results in a substantial change in their pharmacologic profiles. **Imipramine** is highly anticholinergic and is a relatively strong serotonin as well as **norepinephrine** reuptake inhibitor. In contrast, **desipramine** is much less anticholinergic and is a more potent and somewhat more selective **norepinephrine** reuptake inhibitor than is **imipramine**.

**FIGURE 30-4**

Structures of some tricyclic antidepressants (TCAs).

Source: Todd W. Vanderah:  
 Basic & Clinical Pharmacology, Sixteenth Edition  
 Copyright © McGraw Hill. All rights reserved.

At present, the TCAs are used primarily in depression that is unresponsive to more commonly used antidepressants such as the SSRIs or SNRIs. Their loss of popularity stems in large part from relatively poorer tolerability compared with newer agents, difficulty of use, and lethality in overdose. Other uses for TCAs include the treatment of pain conditions, enuresis, and insomnia.

**C. 5-HT<sub>2</sub> Receptor Modulators**

Two antidepressants are thought to act primarily as antagonists at the 5-HT<sub>2</sub> receptor: **trazodone** and **nefazodone**. **Trazodone**'s structure includes a triazolo moiety that is thought to impart antidepressant effects. Its primary metabolite, m-chlorophenylpiperazine (m-cpp), is a potent 5-HT<sub>2</sub>

antagonist. **Trazodone** was among the most commonly prescribed antidepressants until it was supplanted by the SSRIs in the late 1980s. The most

**Nefazodone** is chemically related to **trazodone**. Its primary metabolites, hydroxynefazodone and m-cpp, are both inhibitors of the 5-HT<sub>2</sub> receptor.

**Nefazodone** received an FDA black box warning in 2001 implicating it in hepatotoxicity, including lethal cases of hepatic failure. Although still available generically, **nefazodone** is no longer commonly prescribed. The primary indications for both **nefazodone** and **trazodone** are major depression, although both have also been used in the treatment of anxiety disorders.

**Trazodone**

**Nefazodone**

**Vortioxetine** is a newer agent that acts as an antagonist of the 5-HT<sub>3</sub>, 5-HT<sub>7</sub>, and 5-HT<sub>1D</sub> receptors, a partial agonist of the 5-HT<sub>1B</sub> receptor, and an agonist of the 5-HT<sub>1A</sub> receptor. It also inhibits the serotonin transporter, but its actions are not primarily related to SERT inhibition and it is therefore not classified as an SSRI. **Vortioxetine** has demonstrated efficacy in major depression in a number of controlled clinical studies. In addition, **vortioxetine** is approved in Europe and the USA to treat cognitive dysfunction associated with depression.

#### D. Tetracyclic and Unicyclic Antidepressants

A number of antidepressants do not fit neatly into the other classes. Among these are **bupropion**, **mirtazapine**, **amoxapine**, **vilazodone**, and **maprotiline** (Figure 30-5). **Bupropion** has a unicyclic aminoketone structure. Its unique structure results in a different side-effect profile than most antidepressants (described below). **Bupropion** somewhat resembles **amphetamine** in chemical structure and, like the stimulant, has central nervous system (CNS) activating properties.

**FIGURE 30-5**

Structures of the tetracyclics, **amoxapine**, **maprotiline**, and **mirtazapine** and the unicyclic, **bupropion**.

Source: Todd W. Vanderah:  
Basic & Clinical Pharmacology, Sixteenth Edition  
Copyright © McGraw Hill. All rights reserved.

**Mirtazapine** was introduced in 1994 and, like **bupropion**, is one of the few antidepressants not commonly associated with sexual effects. It has a tetracyclic chemical structure and belongs to the piperazino-azepine group of compounds.

**Mirtazapine**, **amoxapine**, and **maprotiline** have tetracyclic structures. **Amoxapine** is the *N*-demethylated metabolite of **loxapine**, an older antipsychotic drug. **Amoxapine** and **maprotiline** share structural similarities and side effects comparable to the TCAs. As a result, these tetracyclics are not commonly prescribed in current practice. Their primary use is in MDD that is unresponsive to other agents. **Vilazodone** has a multi-ring structure that allows it to bind potently to the serotonin transporter but minimally to the **dopamine** and **norepinephrine** transporter.

#### E. Monoamine Oxidase Inhibitors

Arguably the first modern class of antidepressants, monoamine oxidase inhibitors (MAOIs) were introduced in the 1950s but are now rarely used in clinical practice because of toxicity and potentially lethal food and drug interactions. Their primary use now is in the treatment of depression unresponsive to other antidepressants. However, MAOIs have also been used historically to treat anxiety states, including social anxiety and panic disorder. In addition, **selegiline** is used in the treatment of Parkinson disease (see [Chapter 28](#)).

Current MAOIs include the hydrazine derivatives **phenelzine** and **isocarboxazid** and the nonhydrazines **tranylcypromine**, **selegiline**, and **moclobemide** (the latter is not available in the USA). The hydrazines and **tranylcypromine** bind irreversibly and nonselectively with MAO-A and B, whereas other MAOIs may have more selective or reversible properties. Some of the MAOIs such as **tranylcypromine** resemble **amphetamine** in chemical structure, whereas other MAOIs such as **selegiline** have amphetamine-like metabolites. As a result, these MAOIs tend to have substantial CNS-stimulating effects.

www.konkur.in became the first non-monoamine-specific agent approved in the adjunctive treatment of major depression in 2019. Esketamine is the (S)-enantiomer of racemic ketamine that has been in use since early 1960s. Ketamine was developed in 1962 as a short-acting analog of phencyclidine. Phencyclidine proved to be unsuitable for use as an anesthetic because of its tendency to produce a prolonged delirium. Thus, phencyclidine never was approved for use in humans although it did become a drug of abuse (PCP, “angel dust”).

In contrast to phencyclidine, ketamine has been approved since 1970 in the USA and used in anesthesia and critical care medicine to provide sedation without the degree of cardiorespiratory suppression found in some anesthetics. Observations beginning around 2006 led to an interest in the off-label use of ketamine in treatment-resistant depression. The advantages over existing antidepressants include rapid onset (often within 24 hours) and ketamine’s efficacy in patients who had not responded to standard antidepressants. Disadvantages include a short duration of activity (5–7 days), IV route of administration, a tendency to produce dissociative symptoms, and risk of abuse. Esketamine was developed as an intranasal preparation for use in treatment-resistant depression. It may have somewhat fewer dissociative effects than ketamine but has a similar side-effect profile. Esketamine has also been studied as a rapid treatment for acute suicidal ideation and is currently under review for this second indication.

Dextromethorphan, which is a moderate NMDA antagonist, has been available as an antitussive agent since the 1950s. In 2022 it was approved in combination with bupropion as a rapidly acting treatment for depression. In addition to its NMDA antagonism, dextromethorphan has other pharmacodynamic properties that could contribute to antidepressant effects including some serotonin reuptake–blocking activity, as well as alpha-2 noradrenergic, sigma-1, and even modest mu-opioid agonism. Dextromethorphan, like PCP and ketamine, has been abused although not at the levels of the dissociative anesthetics. A number of small studies since 2011 have suggested a possible role for dextromethorphan in the treatment of depression. However, dextromethorphan is rapidly metabolized via the CYP2D6 pathway, rendering it difficult to achieve adequate serum levels. Quinidine is a CYP2D6 inhibitor that has been combined with dextromethorphan and was approved in 2010 for the treatment of pseudobulbar affect. Studies of the combination of quinidine combined with dextromethorphan, including a phase 2 program, did not demonstrate consistent efficacy. The combination of dextromethorphan with an approved antidepressant, bupropion, which also is a CYP2D6 inhibitor, made pharmacodynamic and pharmacodynamic sense. The combination was proven effective in the treatment of depression in both a phase 2 and phase 3 program, leading to FDA approval in 2022.

#### G. Allosteric Modulators of GABA<sub>A</sub>

Brexanolone (allopregnanolone) is a member of a new class of neurosteroid antidepressants that are thought to act primarily on the GABA system. Allopregnanolone is a derivative of progesterone and like other GABA<sub>A</sub> agents is thought to have anxiolytic and anticonvulsant properties. Brexanolone has been studied as a rapidly acting IV antidepressant in women with postpartum depression and is administered as a 60-hour IV infusion. Like ketamine and esketamine, brexanolone acts rapidly with evidence of response by 60 hours. Unlike ketamine and esketamine, the effect appears durable at least 30 days after infusion and is not associated with dissociative symptoms or risk of abuse. In late 2018, an FDA advisory panel voted to 17 to 1 to support approval of brexanolone as the first drug indicated for the treatment of postpartum depression. Other modulators of GABA<sub>A</sub> include zuranolone (Sage 217), which is being evaluated as an oral drug for general major depression and ganaxolone, which is being evaluated in the treatment of PTSD.

## PHARMACOKINETICS

The antidepressants share several pharmacokinetic features (Table 30–1). Most have fairly rapid oral absorption, achieve peak plasma levels within 2–3 hours, are tightly bound to plasma proteins, undergo hepatic metabolism, and are renally cleared. However, even within classes, the pharmacokinetics of individual antidepressants varies considerably.

TABLE 30–1

Pharmacokinetic profiles of selected antidepressants.

<sup>1</sup>Desvenlafaxine has similar properties but is less completely metabolized.

MAOIs, monoamine oxidase inhibitors; ND, no data found; SNRIs, serotonin-norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors.

### A. Selective Serotonin Reuptake Inhibitors

The prototype SSRI, **fluoxetine**, differs from other SSRIs in some important respects (see [Table 30–1](#)). **Fluoxetine** is metabolized to an active product, norfluoxetine, which may have plasma concentrations greater than those of **fluoxetine**. The elimination half-life of norfluoxetine is about three times longer than **fluoxetine** and contributes to the longest half-life of all the SSRIs. As a result, **fluoxetine** has to be discontinued 4 weeks or longer before an MAOI can be administered to mitigate the risk of serotonin syndrome.

**Fluoxetine** and **paroxetine** are potent inhibitors of the CYP2D6 isoenzyme, and this contributes to potential drug interactions (see [Drug Interactions](#)). In contrast, **fluvoxamine** is an inhibitor of CYP3A4, whereas **citalopram**, **escitalopram**, and **sertraline** have more modest CYP interactions.

### B. Serotonin-Norepinephrine Reuptake Inhibitors

#### 1. Selective serotonin-norepinephrine reuptake inhibitors

**Venlafaxine** is extensively metabolized in the liver via the CYP2D6 isoenzyme to *O*-desmethylvenlafaxine (**desvenlafaxine**). Both have similar half-lives of about 8–11 hours. Despite the relatively short half-lives, both drugs are available in formulations that allow once-daily dosing. **Venlafaxine** and **desvenlafaxine** have the lowest protein binding of all antidepressants (27–30%). Unlike most antidepressants, **desvenlafaxine** is conjugated and does not undergo extensive oxidative metabolism. At least 45% of **desvenlafaxine** is excreted unchanged in the urine compared with 4–8% of **venlafaxine**.

**Duloxetine** is well absorbed and has a half-life of 12–15 hours but is dosed once daily. It is tightly bound to protein (97%) and undergoes extensive oxidative metabolism via CYP2D6 and CYP1A2. Hepatic impairment significantly alters **duloxetine** levels unlike **desvenlafaxine**.

Both **milnacipran** and **levomilnacipran** are well absorbed after oral dosing. Both have shorter half-lives and lower protein binding than **venlafaxine** (see [Table 30–1](#)). **Milnacipran** and **levomilnacipran** are largely excreted unchanged in the urine. **Levomilnacipran** also undergoes desethylation via 3A3/4.

#### 2. Tricyclic antidepressants

The TCAs tend to be well absorbed and have long half-lives (see [Table 30–1](#)). As a result, most are dosed once daily at night because of their sedating effects. TCAs undergo extensive metabolism via demethylation, aromatic hydroxylation, and glucuronide conjugation. Only about 5% of TCAs are excreted unchanged in the urine. The TCAs are substrates of the CYP2D6 system, and the serum levels of these agents tend to be substantially influenced by concurrent administration of drugs such as **fluoxetine**. In addition, genetic polymorphism for CYP2D6 may result in low or extensive metabolism of the TCAs.

### C. 5-HT Receptor Modulators

**Trazodone** and **nefazodone** are rapidly absorbed and undergo hepatic metabolism. Both drugs are bound to protein and have limited bioavailability because of extensive metabolism. Because of their short half-lives split dosing is generally required when these drugs are used as antidepressants. However, **trazodone** is often prescribed as a single dose at night as a hypnotic in lower doses than are used in the treatment of depression. Both **trazodone** and **nefazodone** have active metabolites that also exhibit 5-HT<sub>2</sub> antagonism. **Nefazodone** is a potent inhibitor of the CYP3A4 system and may interact with drugs metabolized by this enzyme (see **Drug Interactions**). **Vortioxetine** is not a potent inhibitor of CYP isoenzymes. However, it is extensively metabolized through oxidation by CYP2D6 and other isoenzymes and then undergoes subsequent glucuronic acid conjugation. It is tightly bound to protein and has linear and dose-proportional pharmacokinetics.

### D. Tetracyclic and Unicyclic Agents

**Bupropion** is rapidly absorbed and has a mean protein binding of 85%. It undergoes extensive hepatic metabolism and has a substantial first-pass effect. It has three active metabolites including hydroxybupropion; the latter is being developed as an antidepressant. **Bupropion** has a biphasic elimination with the first phase lasting about 1 hour and the second phase lasting 14 hours.

**Amoxapine** is also rapidly absorbed with protein binding of about 85%. The half-life is variable, and the drug is often given in divided doses. **Amoxapine** undergoes extensive hepatic metabolism. One of the active metabolites, 7-hydroxyamoxapine, is a potent D<sub>2</sub> blocker and is associated with antipsychotic effects. **Maprotiline** is similarly well absorbed orally and 88% bound to protein. It undergoes extensive hepatic metabolism.

**Mirtazapine** is demethylated followed by hydroxylation and glucuronide conjugation. Several CYP isozymes are involved in the metabolism of **mirtazapine**, including 2D6, 3A4, and 1A2. The half-life of **mirtazapine** is 20–40 hours, and it is usually dosed once in the evening because of its sedating effects.

**Vilazodone** is well absorbed (see **Table 30–1**), and absorption is increased when it is given with a fatty meal. It is extensively metabolized by CYP3A4 with minor contributions by CYP2C19 and CYP2D6. Only 1% of **vilazodone** is excreted unchanged in the urine.

### E. Monoamine Oxidase Inhibitors

The different MAOIs are metabolized via different pathways but tend to have extensive first-pass effects that may substantially decrease bioavailability. **Tranlycypromine** is ring hydroxylated and *N*-acetylated, whereas acetylation appears to be a minor pathway for **phenelzine**. **Selegiline** is *N*-demethylated and then hydroxylated. The MAOIs are well absorbed from the gastrointestinal tract.

Because of the prominent first-pass effects and their tendency to inhibit MAO in the gut (resulting in tyramine pressor effects), alternative routes of administration are being developed. For example, **selegiline** is available in both transdermal and sublingual forms that bypass both gut and liver. These routes decrease the risk of food interactions and provide substantially increased bioavailability.

### F. NMDA Receptor Antagonists

The pharmacokinetics of racemic **ketamine** (usually given IV) and **esketamine** (intranasal) are similar but differ in part as a function of different routes of administration. Intranasal **esketamine** is 48% bioavailable, while bioavailability of IV **ketamine** is complete. **Esketamine** has a terminal half-life of 7–12 hours while its major metabolite, noresketamine, has a half-life of about 8 hours. IV **ketamine** has a half-life of approximately 3 hours. The time to reach maximum plasma concentration for intranasal **esketamine** is 20–40 minutes from the last nasal spray. Less than 1% of **esketamine** is excreted unchanged, with 78% of all metabolites found in the urine and 2% in feces. Racemic IV **ketamine** is cleared rapidly (95 L/h/70 kg), with 91% of the dose recovered in urine and 3% in feces.

**Bupropion** and a putative NMDA antagonist, **dextromethorphan**, have been combined in an extended-release formulation for the treatment of depression. **Bupropion** inhibits the metabolism of **dextromethorphan** via CYP2D6. Peak serum levels are achieved for the combination tablet in 3 hours, and the tablet has a *t*<sub>1/2</sub> of 22 hours after 8 days of administration. In CYP2D6 extensive metabolizers, approximately 37–52% of the orally

administered dose of **dextromethorphan** is recovered in the urine. Less than 2% of the administered dose is excreted as unchanged parent drug in the

### G. GABA<sub>A</sub> Modulators

IV **brexanolone** is extensively metabolized by non-CYP450 routes including glucuronidation, sulfation, and ketoreduction. Only 1% of the dose is excreted unchanged, with 47% of the metabolites found in the urine and 42% in the feces. The drug is heavily bound to protein (99%) and is extensively distributed to tissues, with a volume of distribution of 3 L/kg. The terminal half-life of **brexanolone** is about 9 hours with continuous administration over 60 hours. However, the initial half-life of **brexanolone** is only about 40 minutes, consistent with its rapid sedating effects.

## PHARMACODYNAMICS

As previously noted, all currently available antidepressants enhance monoamine neurotransmission by one of several mechanisms. The most common mechanism is inhibition of the activity of SERT, NET, or both monoamine transporters (**Table 30-2**). Antidepressants that inhibit SERT, NET, or both include the SSRIs and SNRIs (by definition) and the TCAs. Another mechanism for increasing the availability of monoamines is inhibition of their enzymatic degradation (by the MAOIs). Additional strategies for enhancing monoamine effects include binding presynaptic autoreceptors (**mirtazapine**) or specific postsynaptic receptors (5-HT<sub>2</sub> antagonists and **mirtazapine**). Ultimately, the increased availability of monoamines for binding in the synaptic cleft results in a cascade of events that enhance the transcription of some proteins and the inhibition of others. It is the net production of these proteins, including BDNF, glucocorticoid receptors,  $\beta$  adrenoceptors, and other proteins, that appears to determine the benefits as well as the toxicity of a given agent.

TABLE 30-2

Vortioxetine <sup>1</sup>	ND	ND	ND	ND	+	+++

<sup>1</sup>Vortioxetine is an agonist or partial agonist at 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptors, an antagonist at 5-HT<sub>3</sub> and 5-HT<sub>7</sub> receptors, and an inhibitor of SERT.

ACh M, acetylcholine muscarinic receptor;  $\alpha_1$ , alpha<sub>1</sub>-adrenoceptor; H<sub>1</sub>, histamine<sub>1</sub> receptor; 5-HT<sub>2</sub>, serotonin 5-HT<sub>2</sub> receptor; ND, no data found; NET, norepinephrine transporter; SERT, serotonin transporter.

### A. Selective Serotonin Reuptake Inhibitors

The serotonin transporter (SERT) is a glycoprotein with 12 transmembrane regions embedded in the axon terminal and cell body membranes of serotonergic neurons. When extracellular serotonin binds to receptors on the transporter, conformational changes occur in the transporter and serotonin,  $\text{Na}^+$ , and  $\text{Cl}^-$  are moved into the cell. Binding of intracellular  $\text{K}^+$  then results in the release of serotonin inside the cell and return of the transporter to its original conformation. SSRIs allosterically inhibit the transporter by binding the SERT receptor at a site other than the serotonin binding site. At therapeutic doses, about 80% of the activity of the transporter is inhibited. Functional polymorphisms exist for SERT that determine the activity of the transporter (see [Table 30-2](#)).

SSRIs have modest effects on other neurotransmitters. Unlike TCAs and SNRIs, there is little evidence that SSRIs have prominent effects on  $\beta$  adrenoceptors or the [norepinephrine](#) transporter, NET. Binding to the serotonin transporter is associated with tonic inhibition of the [dopamine](#) system, although there is substantial interindividual variability in this effect. The SSRIs do not bind aggressively to histamine, muscarinic, or other receptors.

### B. Drugs That Block Both Serotonin and Norepinephrine Transporters

A large number of antidepressants have mixed inhibitory effects on both serotonin and [norepinephrine](#) transporters. The newer agents in this class ([venlafaxine](#) and [duloxetine](#)) are termed SNRIs; those in the older group are termed TCAs on the basis of their structures. The NET is structurally very similar to the 5-HT transporter. Like the serotonin transporter, it is a 12-transmembrane domain complex that allosterically binds SNRIs and TCAs. The NET also has a moderate affinity for [dopamine](#).

#### 1. Serotonin-norepinephrine reuptake inhibitors

SNRIs bind both the serotonin and the [norepinephrine](#) transporters. [Venlafaxine](#) is a weak inhibitor of NET, whereas [desvenlafaxine](#), [duloxetine](#), [milnacipran](#), and [levomilnacipran](#) are more balanced inhibitors of both SERT and NET. Nonetheless, the affinity of most SNRIs tends to be much greater for SERT than for NET. The SNRIs differ from the TCAs in that they lack the potent antihistamine,  $\alpha$ -adrenergic blocking, and anticholinergic effects of the TCAs. As a result, the SNRIs tend to be favored over the TCAs in the treatment of MDD and pain syndromes because of their better tolerability.

#### 2. Tricyclic antidepressants

The TCAs resemble the SNRIs in function, and their antidepressant activity is thought to relate primarily to their inhibition of 5-HT and [norepinephrine](#) reuptake. Within the TCAs, there is considerable variability in affinity for SERT versus NET. For example, [clomipramine](#) has relatively very little affinity for NET but potently binds SERT. This selectivity for the serotonin transporter contributes to [clomipramine](#)'s known benefits in the treatment of OCD. On the other hand, the secondary amine TCAs, [desipramine](#) and [nortriptyline](#), are relatively more selective for NET. Although the tertiary amine TCA [imipramine](#) has more serotonin effect initially, its metabolite, [desipramine](#), then balances this effect with more NET inhibition.

Common adverse effects of the TCAs, including dry mouth and constipation, are attributable to the potent antimuscarinic effects of many of these drugs. The TCAs also tend to be potent antagonists of the histamine  $\text{H}_1$  receptor. TCAs such as [doxepin](#) are sometimes prescribed as hypnotics and used in treatments for pruritus because of their antihistamine properties. The blockade of  $\alpha$  adrenoceptors can result in substantial orthostatic hypotension, particularly in older patients.

### C. 5-HT Receptor Modulators

The principal action of both [nefazodone](#) and [trazodone](#) appears to be blockade of the 5-HT<sub>2A</sub> receptor. Inhibition of this receptor in both animal and human studies is associated with substantial antianxiety, antipsychotic, and antidepressant effects. Conversely, agonists of the 5-HT<sub>2A</sub> receptor, eg, lysergic acid (LSD) and mescaline, are often hallucinogenic and anxiogenic. The 5-HT<sub>2A</sub> receptor is a G protein-coupled receptor and is distributed throughout the neocortex.

[www.konkur.in](http://www.konkur.in) Nefazodone is a weak inhibitor of both SERT and NET but is a potent antagonist of the postsynaptic 5-HT<sub>2A</sub> receptor, as are its metabolites. Trazodone

is also a weak but selective inhibitor of SERT with little effect on NET. Its primary metabolite, m-cpp, is a potent 5-HT<sub>2</sub> antagonist, and much of trazodone's benefits as an antidepressant might be attributed to this effect. Trazodone also has weak to moderate presynaptic  $\alpha$ -adrenergic-blocking properties and is a modest antagonist of the H<sub>1</sub> receptor.

As described above, vortioxetine has multimodal effects on a variety of 5-HT receptors and is an allosteric inhibitor of SERT. It has no known direct activity on norepinephrine or dopamine receptors.

#### D. Tetracyclic and Unicyclic Antidepressants

The actions of bupropion remain poorly understood. Bupropion and its major metabolite hydroxybupropion are modest to moderate inhibitors of norepinephrine and dopamine reuptake in animal studies. However, these effects seem less than are typically associated with antidepressant benefit. A more significant effect of bupropion is presynaptic release of catecholamines. In animal studies, bupropion appears to substantially increase the presynaptic availability of norepinephrine, and dopamine to a lesser extent. Bupropion has virtually no direct effects on the serotonin system.

Mirtazapine has a complex pharmacology. It is an antagonist of the presynaptic  $\alpha_2$  autoreceptor and enhances the release of both norepinephrine and 5-HT. In addition, mirtazapine is an antagonist of 5-HT<sub>2</sub> and 5-HT<sub>3</sub> receptors. Finally, mirtazapine is a potent H<sub>1</sub> antagonist, which is associated with the drug's sedative effects.

The actions of amoxapine and maprotiline resemble those of TCAs such as desipramine. Both are potent NET inhibitors and less potent SERT inhibitors. In addition, both possess anticholinergic properties. Unlike the TCAs or other antidepressants, amoxapine is a moderate inhibitor of the postsynaptic D<sub>2</sub> receptor. As such, amoxapine possesses some antipsychotic properties.

Vilazodone is a potent serotonin reuptake inhibitor and a partial agonist of the 5-HT<sub>1A</sub> receptor. Partial agonists of the 5-HT<sub>1A</sub> receptor such as buspirone are thought to have mild to moderate antidepressant and anxiolytic properties.

#### E. Monoamine Oxidase Inhibitors

MAOIs act by mitigating the actions of monoamine oxidase in the neuron and increasing monoamine content. There are two forms of monoamine oxidase. MAO-A is present in both dopamine and norepinephrine neurons and is found primarily in the brain, gut, placenta, and liver; its primary substrates are norepinephrine, epinephrine, and serotonin. MAO-B is found primarily in serotonergic and histaminergic neurons and is distributed in the brain, liver, and platelets. MAO-B acts primarily on dopamine, tyramine, phenylethylamine, and benzylamine. Both MAO-A and -B metabolize tryptamine.

MAOIs are classified by their specificity for MAO-A or -B and whether their effects are reversible or irreversible. Phenelzine and tranylcypromine are examples of irreversible, nonselective MAOIs. Moclobemide is a reversible and selective inhibitor of MAO-A but is not available in the USA. Moclobemide can be displaced from MAO-A by tyramine, and this mitigates the risk of food interactions. In contrast, selegiline is an irreversible MAO-B-specific agent at low doses. Selegiline is useful in the treatment of Parkinson disease at these low doses, but at higher doses it becomes a nonselective MAOI similar to other agents.

#### F. NMDA Receptor Antagonists

While ketamine and esketamine are thought to act primarily as noncompetitive antagonists of the NMDA receptor, these drugs have multiple other pharmacodynamic actions that could contribute to efficacy in depression and other disorders. These include interactions with opioid receptors, monoaminergic receptors, cholinergic receptors, and voltage-sensitive Ca<sup>2+</sup> channels. Despite its use as an anesthetic, ketamine does not appear to act on GABA receptors.

The effects of ketamine and esketamine on monoamines are not as well established as NMDA effects. Most but not all studies suggest that ketamine can significantly increase dopaminergic activity through dopamine reuptake inhibition. This dopaminergic effect would be consistent with the euphoric and psychotomimetic effects of the drug. In addition, ketamine is thought to enhance the activity of descending serotonergic pathways that may be important in both the antidepressant and analgesic properties of the drug.

**Brexanolone** has been proposed to reset dysregulated brain function in depressive episodes through modulation of the GABA<sub>A</sub> receptor. GABA<sub>A</sub> receptors are ligand-gated, chloride-conducting ion channels ([Chapter 22](#)) that have been shown to mediate inhibition of neural networks including those associated with limbic overactivity in major depression. **Brexanolone** is a positive allosteric modulator of GABA<sub>A</sub> receptors both pre- and postsynaptically. As such it induces rapid phasic and tonic inhibition of multiple GABA networks responsible for regulating and maintaining those networks. **Brexanolone** is also thought to increase tonic inhibition through effects on GABA trafficking to and from neuronal surfaces and laterally between synaptic and extrasynaptic locations. **Zuranolone** (Sage 217) is similar and is in phase 2 trials.

## CLINICAL PHARMACOLOGY OF ANTIDEPRESSANTS

### Clinical Indications

#### A. Depression

The FDA indication for the use of the antidepressants in the treatment of major depression is fairly broad. Most antidepressants are approved for both acute and long-term treatment of major depression. Acute episodes of MDD tend to last about 6–14 months untreated, but at least 20% of episodes last 2 years or longer.

The goal of acute treatment of MDD is remission of all symptoms. Since antidepressants may not achieve their maximum benefit for 1–2 months or longer, it is not unusual for a trial of therapy to last 8–12 weeks at therapeutic doses. The antidepressants are successful in achieving remission in about 30–40% of patients within a single trial of 8–12 weeks. If an inadequate response is obtained, therapy is often switched to another agent or augmented by addition of another drug. For example, **bupropion**, an atypical antipsychotic, or **mirtazapine** might be added to an SSRI or SNRI to augment antidepressant benefit if monotherapy is unsuccessful. Seventy to eighty percent of patients are able to achieve remission with sequenced augmentation or switching strategies. Once an adequate response is achieved, continuation therapy is recommended for a minimum of 6–12 months to reduce the substantial risk of relapse.

Approximately 85% of patients who have a single episode of MDD will have at least one recurrence in a lifetime. Many patients have multiple recurrences, and these recurrences may progress to more serious, chronic, and treatment-resistant episodes. Thus, it is not unusual for patients to require maintenance treatment to prevent recurrences. Although maintenance treatment studies of more than 5 years are uncommon, long-term studies with TCAs, SNRIs, and SSRIs suggest a significant protective benefit when given chronically. Thus, it is commonly recommended that patients be considered for long-term maintenance treatment if they have had two or more serious MDD episodes in the previous 5 years or three or more serious episodes in a lifetime.

It is not clear whether antidepressants are useful for all subtypes of depression. For example, patients with bipolar depression may not benefit much from antidepressants even when added to mood stabilizers. In fact, the antidepressants are sometimes associated with switches into mania or more rapid cycling. There has also been some debate about the overall efficacy of antidepressants in unipolar depression, with some meta-analyses showing large effects and others showing more modest effects. Although this debate is not likely to be settled immediately, there is little debate that antidepressants have important benefits for most patients.

Psychotherapeutic interventions such as cognitive behavioral therapy appear to be as effective as antidepressant treatment for mild to moderate forms of depression. However, cognitive behavioral therapy tends to take longer to be effective and is generally more expensive than antidepressant treatment. Psychotherapy is often combined with antidepressant treatment, and the combination appears more effective than either strategy alone.

#### B. Anxiety Disorders

After major depression, anxiety disorders represent the most common application of antidepressants. A number of SSRIs and SNRIs have been approved for all the major anxiety disorders, including PTSD, OCD, social anxiety disorder, GAD, and panic disorder. Panic disorder is characterized by recurrent episodes of brief overwhelming anxiety, which often occur without a precipitant. Patients may begin to fear having an attack, or they avoid situations in which they might have an attack. In contrast, GAD is characterized by a chronic, free-floating anxiety and undue worry that tends to be

chronic in nature. Although older antidepressants and drugs of the sedative-hypnotic class are still occasionally used for the treatment of anxiety disorders, SSRIs and SNRIs have largely replaced them.

The benzodiazepines (see [Chapter 22](#)) provide much more rapid relief of both generalized anxiety and panic than do any of the antidepressants. However, the antidepressants appear to be at least as effective as, and perhaps more effective than, benzodiazepines in the long-term treatment of these anxiety disorders. Furthermore, antidepressants do not carry the risks of dependence and tolerance that may occur with the benzodiazepines.

OCD is known to respond to serotonergic antidepressants. It is characterized by repetitive anxiety-provoking thoughts (obsessions) or repetitive behaviors (compulsions) aimed at reducing anxiety. [Clomipramine](#) and several of the SSRIs are approved for the treatment of OCD, and they are moderately effective. Behavior therapy is usually combined with the antidepressant for additional benefits.

Social anxiety disorder is an uncommonly diagnosed but a fairly common condition in which patients experience severe anxiety in social interactions. This anxiety may limit their ability to function adequately in their jobs or interpersonal relationships. Several SSRIs and [venlafaxine](#) are approved for the treatment of social anxiety. The efficacy of the SSRIs in the treatment of social anxiety is greater in some studies than their efficacy in the treatment of MDD.

PTSD is manifested when a traumatic or life-threatening event results in intrusive anxiety-provoking thoughts or imagery, hypervigilance, nightmares, and avoidance of situations that remind the patient of the trauma. SSRIs are considered first-line treatment for PTSD and can benefit a number of symptoms including anxious thoughts and hypervigilance. Other treatments, including psychotherapeutic interventions, are usually required in addition to antidepressants.

### C. Pain Disorders

Antidepressants possess analgesic properties independent of their mood effects. TCAs have been used in the treatment of neuropathic and other pain conditions since the 1960s. Medications that possess both [norepinephrine](#) and 5-HT reuptake blocking properties are often useful in treating pain disorders. Ascending corticospinal monoamine pathways appear to be important in the endogenous analgesic system. In addition, chronic pain conditions are commonly associated with major depression. TCAs continue to be commonly used for some of these conditions, and SNRIs are increasingly used. In 2010, [duloxetine](#) was approved for the treatment of chronic joint and muscle pain. As mentioned earlier, [milnacipran](#) is approved for the treatment of fibromyalgia in the USA and for MDD in other countries. Other SNRIs, eg, [desvenlafaxine](#), are being investigated for a variety of pain conditions from postherpetic neuralgia to chronic back pain.

### D. Premenstrual Dysphoric Disorder

Approximately 5% of women in the child-bearing years will have prominent mood and physical symptoms during the late luteal phase of almost every cycle; these may include anxiety, depressed mood, irritability, insomnia, fatigue, and a variety of other physical symptoms. These symptoms are more severe than those typically seen in premenstrual syndrome (PMS) and can be quite disruptive to vocational and interpersonal activities. The SSRIs are known to be beneficial to many women with PMDD, and [fluoxetine](#) and [sertraline](#) are approved for this indication. Treating for 2 weeks out of the month in the luteal phase may be as effective as continuous treatment. The rapid effects of SSRIs in PMDD may be associated with rapid increases in pregnenolone levels.

### E. Smoking Cessation

[Bupropion](#) was approved in 1997 as a treatment for smoking cessation. Approximately twice as many people treated with [bupropion](#) as with placebo have a reduced urge to smoke. In addition, patients taking [bupropion](#) appear to experience fewer mood symptoms and possibly less weight gain while withdrawing from [nicotine](#) dependence. [Bupropion](#) appears to be about as effective as [nicotine](#) patches in smoking cessation. The mechanism by which [bupropion](#) is helpful in this application is unknown, but the drug may mimic [nicotine](#)'s effects on [dopamine](#) and [norepinephrine](#) and may inhibit nicotinic receptors. [Nicotine](#) is also known to have antidepressant effects in some people, and [bupropion](#) may substitute for this effect.

Other antidepressants also may have a role in the treatment of smoking cessation. [Nortriptyline](#) has been shown to be helpful in smoking cessation, but the effects have not been as consistent as those seen with [bupropion](#).

www.konkur.in  
Bulimia and anorexia nervosa are potentially devastating disorders. Bulimia is characterized by episodic intake of large amounts of food (binges) followed by ritualistic purging through emesis, the use of laxatives, or other methods. Medical complications of the purging, such as hypokalemia, are common and dangerous. Anorexia is a disorder in which reduced food intake results in a loss of weight of 15% or more of ideal body weight, and the person has a morbid fear of gaining weight and a highly distorted body image. Anorexia is often chronic and may be fatal in 10% or more of cases.

Antidepressants appear to be helpful in the treatment of bulimia but not anorexia. **Fluoxetine** was approved for the treatment of bulimia in 1996, and other antidepressants have shown benefit in reducing the binge-purge cycle. The primary treatment for anorexia at this time is refeeding, family therapy, and cognitive behavioral therapy.

**Bupropion** may have some benefits in treating obesity. Nondepressed, obese patients treated with **bupropion** were able to lose somewhat more weight and maintain the loss relative to a similar population treated with placebo. However, the weight loss was not robust, and there appear to be more effective options for weight loss (see [Chapter 16](#)).

### G. Other Uses for Antidepressants

Antidepressants are used for many other on- and off-label applications. Enuresis in children is an older labeled use for some TCAs, but they are less commonly used now because of their side effects. The SNRI **duloxetine** is approved in Europe for the treatment of urinary stress incontinence. Many of the serotonergic antidepressants appear to be helpful for treating vasomotor symptoms in perimenopause. **Desvenlafaxine** is under consideration for FDA approval for the treatment of these vasomotor symptoms, and studies have suggested that SSRIs, **venlafaxine**, and **nefazodone** also may provide benefit. Although serotonergic antidepressants are commonly associated with inducing sexual adverse effects, some of these effects might prove useful for some sexual disorders. For example, SSRIs are known to delay orgasm in some patients. For this reason, SSRIs are sometimes used to treat premature ejaculation. In addition, **bupropion** has been used to treat sexual adverse effects associated with SSRI use, although its efficacy for this use has not been consistently demonstrated in controlled trials.

## CHOOSING AN ANTIDEPRESSANT

The choice of an antidepressant depends first on the indication. Not all conditions are equally responsive to all antidepressants. However, in the treatment of MDD, it is difficult to demonstrate that one antidepressant is consistently more effective than another. Thus, the choice of an antidepressant for the treatment of depression rests primarily on practical considerations such as cost, availability, adverse effects, potential drug interactions, the patient's history of response or lack thereof, and patient preference. Other factors such as the patient's age, gender, and medical status also may guide antidepressant selection. For example, older patients are particularly sensitive to the anticholinergic effects of the TCAs. On the other hand, the CYP3A4-inhibiting effects of the SSRI **fluvoxamine** may make this a problematic choice in some older patients because **fluvoxamine** may interact with many other medications that an older patient may require. There is some suggestion that female patients may respond to and tolerate serotonergic better than noradrenergic or TCA antidepressants, but the data supporting this gender difference have not been consistent. Patients with narrow-angle glaucoma may have an exacerbation with noradrenergic antidepressants, whereas **bupropion** and other antidepressants are known to lower the seizure threshold in epilepsy patients.

At present, SSRIs are the most commonly prescribed first-line agents in the treatment of both MDD and anxiety disorders. Their popularity comes from their ease of use, tolerability, and safety in overdose. The starting dose of the SSRIs is usually the same as the therapeutic dose for most patients, and so titration may not be required. In addition, most SSRIs are now generically available and inexpensive. Other agents, including the SNRIs, **bupropion**, and **mirtazapine**, also are reasonable first-line agents for the treatment of MDD. **Bupropion**, **mirtazapine**, and **nefazodone** are the antidepressants with the least association with sexual adverse effects and are often prescribed for this reason. However, **bupropion** is not thought to be effective in the treatment of the anxiety disorders and may be poorly tolerated in anxious patients. The primary indication for **bupropion** is in the treatment of major depression, including seasonal (winter) depression. Off-label uses of **bupropion** include the treatment of attention deficit hyperactivity disorder (ADHD), and **bupropion** is commonly combined with other antidepressants to augment therapeutic response. The primary indication for **mirtazapine** is in the treatment of major depression. However, its strong antihistamine properties have contributed to its occasional use as a hypnotic and as an adjunctive treatment to more activating antidepressants.

The TCAs and MAOIs are now relegated to second- or third-line treatments for MDD. Both the TCAs and the MAOIs are potentially lethal in overdose, require titration to achieve a therapeutic dose, have serious drug interactions, and have many troublesome adverse effects. As a consequence, their

use in the treatment of MDD or anxiety is now reserved for patients who have been unresponsive to other agents. Clearly, there are patients whose depression responds only to MAOIs or TCAs. Thus, TCAs and MAOIs are probably underused in treatment-resistant depressed patients.

The use of antidepressants outside the treatment of MDD tends to require specific agents. For example, the TCAs and SNRIs appear to be useful in the treatment of pain conditions, but other antidepressant classes appear to be far less effective. SSRIs and the highly serotonergic TCA [clomipramine](#) are effective in the treatment of OCD, but noradrenergic antidepressants have not proved to be as helpful for this condition. [Bupropion](#) and [nortriptyline](#) have usefulness in the treatment of smoking cessation, but SSRIs have not been proven useful. Thus, outside the treatment of depression, the choice of antidepressant is primarily dependent on the known benefit of a particular antidepressant or class for a particular indication.

## DOSING

The optimal dose of an antidepressant depends on the indication and on the patient. For SSRIs, SNRIs, and a number of newer agents, the starting dose for the treatment of depression is usually a therapeutic dose ([Table 30-3](#)). Patients who show little or no benefit after at least 4 weeks of treatment may benefit from a higher dose even though it has been difficult to show a clear advantage for higher doses with SSRIs, SNRIs, and other newer antidepressants. The dose is generally titrated to the maximum dosage recommended or to the highest dosage tolerated if the patient is not responsive to lower doses. Some patients may benefit from doses lower than the usual minimum recommended therapeutic dose. TCAs and MAOIs typically require titration to a therapeutic dosage over several weeks. Dosing of the TCAs may be guided by monitoring TCA serum levels.

TABLE 30-3

### Antidepressant dose ranges.

Drug	Usual Therapeutic Dosage (mg/d)
<b>SSRIs</b>	
<a href="#">Citalopram</a>	20–60
<a href="#">Escitalopram</a>	10–30
<a href="#">Fluoxetine</a>	20–60
<a href="#">Fluvoxamine</a>	100–300
<a href="#">Paroxetine</a>	20–60
<a href="#">Sertraline</a>	50–200
<b>SNRIs</b>	
<a href="#">Venlafaxine</a>	75–375
<a href="#">Desvenlafaxine</a>	50–200
<a href="#">Duloxetine</a>	40–120
<a href="#">Milnacipran</a>	100–200
<b>Tricyclics</b>	
<a href="#">Amitriptyline</a>	150–300

Clomipramine	100–250
Desipramine	150–300
Doxepin	150–300
Imipramine	150–300
Nortriptyline	50–150
Protriptyline	15–60
Trimipramine maleate	150–300
<b>5-HT<sub>2</sub> antagonists</b>	
Nefazodone	300–500
Trazodone	150–300
<b>Tetracyclics and unicyclics</b>	
Amoxapine	150–400
Bupropion	200–450
Maprotiline	150–225
Mirtazapine	15–45
<b>MAOIs</b>	
Isocarboxazid	30–60
Phenelzine	45–90
Selegiline	20–50
Tranylcypromine	30–60
<b>NMDA antagonists</b>	
Esketamine (intranasal)	56–84
Ketamine (IV)	0.5 mg/kg/h
Dextromethorphan + bupropion	Bup 105 mg/Dex 45 mg BID
<b>GABA<sub>A</sub> modulators</b>	
Brexanolone (IV)	30–90 mcg/kg/h

Some anxiety disorders may require higher doses of antidepressants than are used in the treatment of major depression. For example, patients treated for OCD often require maximum or somewhat higher than maximum recommended MDD doses to achieve optimal benefits. Likewise, the minimum dose of [paroxetine](#) for the effective treatment of panic disorder is higher than the minimum dose required for the effective treatment of depression.

In the treatment of pain disorders, modest doses of TCAs are often sufficient. For example, 25–50 mg/d of [imipramine](#) might be beneficial in the treatment of pain associated with a neuropathy, but this would be a subtherapeutic dose in the treatment of MDD. In contrast, SNRIs are usually prescribed in pain disorders at the same doses used in the treatment of depression.

## ADVERSE EFFECTS

Although some potential adverse effects are common to all antidepressants, most of their adverse effects are specific to a subclass of agents and to their pharmacodynamic effects. An FDA warning applied to all antidepressants is the risk of increased suicidality in patients younger than 25. The warning suggests that use of antidepressants is associated with suicidal ideation and gestures, but not completed suicides, in up to 4% of patients under 25 who were prescribed antidepressants in clinical trials. This rate is about twice the rate seen with placebo treatment. For those over 25, there is either no increased risk or a reduced risk of suicidal thoughts and gestures on antidepressants, particularly after age 65. Although a small minority of patients may experience a treatment-emergent increase in suicidal ideation with antidepressants, the *absence* of treatment of a major depressive episode in all age groups is a particularly important risk factor in completed suicides.

### A. Selective Serotonin Reuptake Inhibitors

The adverse effects of the most commonly prescribed antidepressants—the SSRIs—can be predicted from their potent inhibition of SERT. SSRIs enhance serotonergic tone, not just in the brain but throughout the body. Increased serotonergic activity in the gut is commonly associated with nausea, gastrointestinal upset, diarrhea, and other gastrointestinal symptoms. Gastrointestinal adverse effects usually emerge early in the course of treatment and tend to improve after the first week. Increasing serotonergic tone at the level of the spinal cord and above is associated with diminished sexual function and interest. As a result, at least 30–40% of patients treated with SSRIs report loss of libido, delayed orgasm, or diminished arousal. The sexual effects often persist as long as the patient remains on the antidepressant but may diminish with time.

Other adverse effects related to the serotonergic effects of SSRIs and [vortioxetine](#) include an increase in headaches and insomnia or hypersomnia. Some patients gain weight while taking SSRIs, particularly [paroxetine](#). Sudden discontinuation of short half-life SSRIs such as [paroxetine](#) and [sertraline](#) is associated with a *discontinuation syndrome* in some patients characterized by dizziness, paresthesias, and other symptoms beginning 1 or 2 days after stopping the drug and persisting for 1 week or longer.

Most antidepressants are category C agents by the FDA teratogen classification system. There is an association of [paroxetine](#) with cardiac septal defects in first trimester exposures. Thus, [paroxetine](#) is a category D agent. Other possible associations of SSRIs with post-birth complications, including pulmonary hypertension, have not been clearly established.

### B. Serotonin-Norepinephrine Reuptake Inhibitors and Tricyclic Antidepressants

SNRIs have many of the serotonergic adverse effects associated with SSRIs. In addition, SNRIs may also have noradrenergic effects, including increased blood pressure and heart rate, and CNS activation, such as insomnia, anxiety, and agitation. The hemodynamic effects of SNRIs tend not to be problematic in most patients. A dose-related increase in blood pressure has been seen more commonly with the immediate-release form of [venlafaxine](#) than with other SNRIs. Likewise, there are more reports of cardiac toxicity with [venlafaxine](#) overdose than with either the other SNRIs or SSRIs. [Duloxetine](#) is rarely associated with hepatic toxicity in patients with a history of liver damage. All the SNRIs have been associated with a discontinuation syndrome resembling that seen with SSRI discontinuation.

The primary adverse effects of TCAs have been described in the previous text. Anticholinergic effects are perhaps the most common. These effects include dry mouth, constipation, urinary retention, blurred vision, and confusion. They are more common with tertiary amine TCAs such as [amitriptyline](#) and [imipramine](#) than with the secondary amine TCAs [desipramine](#) and [nortriptyline](#). The potent  $\alpha$ -blocking property of TCAs often results

in orthostatic hypotension. H<sub>1</sub> antagonism by the TCAs is associated with weight gain and sedation. The TCAs are class 1A antiarrhythmic agents (see [www.konkur.in](http://www.konkur.in) [Chapter 14](#)) and are arrhythmogenic at higher doses. Sexual effects are common, particularly with highly serotonergic TCAs such as [clomipramine](#). The TCAs have a prominent discontinuation syndrome characterized by cholinergic rebound and flulike symptoms.

### C. 5-HT Receptor Modulators

The most common adverse effects associated with the 5-HT<sub>2</sub> antagonists are sedation and gastrointestinal disturbances. Sedative effects, particularly with [trazodone](#), can be quite pronounced. Thus, it is not surprising that the treatment of insomnia is currently the primary application of [trazodone](#). The gastrointestinal effects appear to be dose-related and are less pronounced than those seen with SNRIs or SSRIs. Sexual effects are uncommon with [nefazodone](#) or [trazodone](#) treatment as a result of the relatively selective serotonergic effects of these drugs on the 5-HT<sub>2</sub> receptor rather than on SERT. However, [trazodone](#) has rarely been associated with inducing priapism. Both [nefazodone](#) and [trazodone](#) are  $\alpha$ -blocking agents and may result in a dose-related orthostatic hypotension in some patients. [Nefazodone](#) has been associated with hepatotoxicity, including rare fatalities and cases of fulminant hepatic failure requiring transplantation. The rate of serious hepatotoxicity with [nefazodone](#) has been estimated at 1 in 250,000 to 1 in 300,000 patient-years of [nefazodone](#) treatment.

As with the SSRIs, the most common adverse effects of [vortioxetine](#) are serotonergic and include dose-dependent gastrointestinal effects, particularly nausea, as well as sexual dysfunction. Higher doses of [vortioxetine](#) tend to increase the rate of GI and sexual side effects. The teratogenic risks of [vortioxetine](#) are not known but like most other antidepressants, it is considered a category C agent.

### D. Tetracyclics and Unicyclics

[Amoxapine](#) is sometimes associated with a parkinsonian syndrome due to its D<sub>2</sub>-blocking action. [Mirtazapine](#) has significant sedative effect.

[Maprotiline](#) has a moderately high affinity for NET and may cause TCA-like adverse effects and, rarely, seizures. [Bupropion](#) is occasionally associated with agitation, insomnia, and anorexia. [Vilazodone](#) may have somewhat higher rates of gastrointestinal upset, including diarrhea and nausea, than the SSRIs.

### E. Monoamine Oxidase Inhibitors

The most common adverse effects of the MAOIs leading to discontinuation of these drugs are orthostatic hypotension and weight gain. In addition, the irreversible nonselective MAOIs are associated with the highest rates of sexual effects of all the antidepressants. Anorgasmia is fairly common with therapeutic doses of some MAOIs. The amphetamine-like properties of some MAOIs contribute to activation, insomnia, and restlessness in some patients. [Phenelzine](#) tends to be more sedating than either [selegiline](#) or [tranylcypromine](#). Confusion is also sometimes associated with higher doses of MAOIs. Because they block metabolism of tyramine and similar ingested amines, MAOIs may cause dangerous interactions with certain foods and with serotonergic drugs (see Interactions). Finally, MAOIs have been associated with a sudden discontinuation syndrome manifested in a delirium-like presentation with psychosis, excitement, and confusion.

### F. NMDA Receptor Antagonists

The adverse effects of [ketamine](#) and [esketamine](#) are consistent with their pharmacologic profile. The short-term adverse effects of these drugs include sedation, dissociation, hypertension, nausea, tachycardia, and cognitive impairment. Most of these effects occur in close proximity to the administration of the drug and usually dissipate in minutes to hours. In the registration trials for [esketamine](#), 8–17% of patients had a systolic blood pressure increase of >40 mm Hg and >25 mm Hg diastolic in the first 1.5 hours after administration. Up to 75% of patients had dissociative symptoms (eg, depersonalization, derealization, out-of-body experiences, distortions of time), although these tended to be most common in the first 2 hours of administration. Therefore, the [esketamine](#) prescribing protocol will require that patients be observed in the clinic for at least 2 hours after administration.

[Ketamine](#) has been a significant drug of abuse in some parts of the world, notably in parts of China and southeast Asia. Long-term abuse of [ketamine](#) has been associated with dependence, psychotomimetic effects (including auditory and visual hallucinations and paranoid delusions), and bladder inflammation and ulcerations. In the long-term depression trials with intranasal [esketamine](#) given intermittently (twice weekly for 4 weeks, once weekly for 4 weeks, and once every other week thereafter), there have not been cases of addiction, bladder ulcerations, or other long-term side effects seen in

**Dextromethorphan** has more rarely been abused at higher doses. In clinical trials of the combination pill with **bupropion** approved for depression, an increase in anxiety was the only side effect that led to discontinuation at rates higher than 1% (2% of trial participants). The most common side effects of the combination pill were dizziness, headaches, dry mouth, and diarrhea.

### G. GABA<sub>A</sub> Receptor Modulators

The most common adverse effects of IV **brexanolone** in clinical trials were headaches, dizziness, and somnolence. About 27% of patients in the postpartum depression trials experienced sedation compared with 14% of the placebo-treated patients. **Brexanolone** has a terminal half-life of about 12 hours, and the sedation did not appear to persist after the infusion stopped. There was a rare adverse effect of syncope and loss of consciousness in 4 patients (1.4%) during the infusion, which resolved with discontinuation of the infusion. Another 4% of patients had excessive sedation or near loss of consciousness relieved by the discontinuation of the infusion. Overall, the rate of adverse events in the **brexanolone** group was about the same as the rate in the placebo group, and <2% of brexanolone-treated patients discontinued because of side effects. It is anticipated that IV **brexanolone** will be administered by home health nurses, physicians in the clinic, or infusion centers that will be available for the entire 60-hour infusion to assess for excessive sedation or other side effects.

A number of oral GABA<sub>A</sub> receptor modulators are currently in development for the treatment of major depression and anxiety disorders, which would potentially circumvent the need for lengthy IV infusion.

## OVERDOSE

Suicide attempts are a common and unfortunate consequence of major depression. The lifetime risk of completing suicide in patients previously hospitalized with MDD may be as high as 15%. Overdose is among the most common methods used in suicide attempts, and antidepressants, especially the TCAs, are frequently involved. Overdose can induce lethal arrhythmias, including ventricular tachycardia and fibrillation. In addition, blood pressure changes and anticholinergic effects including altered mental status and seizures are sometimes seen in TCA overdoses. A 1500-mg dose of **imipramine** or **amitriptyline** (less than 7 days' supply at antidepressant doses) is enough to be lethal in many patients. Toddlers taking 100 mg will likely show evidence of toxicity. Treatment typically involves cardiac monitoring, airway support, and gastric lavage. Sodium bicarbonate is often administered to displace the TCA from cardiac sodium channels.

An overdose with an MAOI can produce a variety of effects including autonomic instability, hyperadrenergic symptoms, psychotic symptoms, confusion, delirium, fever, and seizures. Management of MAOI overdoses usually involves cardiac monitoring, vital signs support, and lavage.

Compared with TCAs and MAOIs, the other antidepressants are generally much safer in overdose. Fatalities with SSRI overdose alone are extremely uncommon. Similarly, SNRIs tend to be much safer in overdose than the TCAs. However, **venlafaxine** has been associated with some cardiac toxicity in overdose and appears to be less safe than SSRIs. **Bupropion** is associated with seizures in overdose, and **mirtazapine** may be associated with sedation, disorientation, and tachycardia. With the newer agents, fatal overdoses often involve the combination of the antidepressant with other drugs, including **alcohol**. Management of overdose with the newer antidepressants usually involves emptying of gastric contents and vital sign support as the initial intervention.

## DRUG INTERACTIONS

Antidepressants are commonly prescribed with other psychotropic and nonpsychotropic agents. There is potential for drug interactions with all antidepressants, but the most serious of these involve the MAOIs and, to a lesser extent, the TCAs.

### A. Selective Serotonin Reuptake Inhibitors

The most common interactions with SSRIs are pharmacokinetic interactions. For example, **paroxetine** and **fluoxetine** are potent CYP2D6 inhibitors (Table 30-4). Thus, administration with 2D6 substrates such as TCAs can lead to dramatic and sometimes unpredictable elevations in the tricyclic drug concentration. The result may be toxicity from the TCA. Similarly, **fluvoxamine**, a CYP3A4 inhibitor, may elevate the levels of concurrently administered substrates for this enzyme such as **diltiazem** and induce bradycardia or hypotension. Other SSRIs, such as **citalopram** and **escitalopram**, are relatively free of pharmacokinetic interactions. The most serious interactions with the SSRIs are pharmacodynamic interactions with MAOIs that produce a

## Some antidepressant–CYP450 drug interactions.

Enzyme	Substrates	Inhibitors	Inducers
1A2	Tertiary amine tricyclic antidepressants (TCAs), <a href="#">duloxetine</a> , <a href="#">theophylline</a> , <a href="#">phenacetin</a> , TCAs (demethylation), <a href="#">clozapine</a> , <a href="#">diazepam</a> , <a href="#">caffeine</a>	<a href="#">Fluvoxamine</a> , <a href="#">fluoxetine</a> , <a href="#">moclobemide</a> , <a href="#">ramelteon</a>	Tobacco, <a href="#">omeprazole</a>

## B. Selective Serotonin–Norepinephrine Reuptake Inhibitors and Tricyclic Antidepressants

The SNRIs have relatively fewer CYP450 interactions than the SSRIs. [Venlafaxine](#) is a substrate but not an inhibitor of CYP2D6 or other isoenzymes, whereas [desvenlafaxine](#) is a minor substrate for CYP3A4. [Duloxetine](#) is a moderate inhibitor of CYP2D6 and so may elevate TCA and levels of other CYP2D6 substrates. Since [milnacipran](#) is neither a substrate nor potent inducer of CYP450 isoenzymes, is not tightly protein bound, and is largely excreted unchanged in the urine, it is unlikely to have clinically significant pharmacokinetic drug interactions. On the other hand, [levomilnacipran](#) is reported to be a substrate of CYP3A4, and the dosage of the drug should be lowered when combined with potent inhibitors of CYP3A4 such as [ketoconazole](#). Like all serotonergic antidepressants, SNRIs are contraindicated in combination with MAOIs.

Elevated TCA levels may occur when these drugs are combined with CYP2D6 inhibitors or from constitutional factors. About 7% of the Caucasian population in the USA has a CYP2D6 polymorphism that is associated with slow metabolism of TCAs and other 2D6 substrates. Combination of a known CYP2D6 inhibitor and a TCA in a patient who is a slow metabolizer may result in markedly increased effects. Such an interaction has been implicated, though rarely, in cases of TCA toxicity. There may also be additive anticholinergic or antihistamine effects when TCAs are combined with other agents that share these properties such as [benztropine](#) or [diphenhydramine](#). Similarly, antihypertensive drugs may exacerbate the orthostatic hypotension induced by TCAs.

## C. 5-HT Receptor Modulators

[Nefazodone](#) is an inhibitor of the CYP3A4 isoenzyme, so it can raise the level and thus exacerbate adverse effects of many 3A4-dependent drugs. For example, [triazolam](#) levels are increased by concurrent administration of [nefazodone](#) such that a reduction in [triazolam](#) dosage by 75% is recommended. Likewise, administration of [nefazodone](#) with [simvastatin](#) has been associated with 20-fold increase in plasma levels of [simvastatin](#).

[Trazodone](#) is a substrate but not a potent inhibitor of CYP3A4. As a result, combining [trazodone](#) with potent inhibitors of CYP3A4, such as [ritonavir](#) or [ketoconazole](#), may lead to substantial increases in [trazodone](#) levels.

[Vortioxetine](#) is a substrate of CYP2D6 and 2B6, and it is recommended that the dose be cut in half when it is coadministered with [fluoxetine](#) or

[www.konkur.in](http://www.konkur.in) [bupropion](#). Inducers of CYP isoenzymes such as [rifampin](#), [clbamazepine](#), and [phenytoin](#) will lower serum levels of [vortioxetine](#) and may require increasing the dose of [vortioxetine](#).

#### D. Tetracyclic and Unicyclic Antidepressants

[Bupropion](#) is metabolized primarily by CYP2B6, and its metabolism may be altered by drugs such as [cyclophosphamide](#), which is a substrate of 2B6. The major metabolite of [bupropion](#), hydroxybupropion, is a moderate inhibitor of CYP2D6 and so can raise [desipramine](#) levels. [Bupropion](#) should be avoided in patients taking MAOIs.

[Mirtazapine](#) is a substrate for several CYP450 enzymes including 2D6, 3A4, and 1A2. Consequently, drugs that inhibit these isozymes may raise [mirtazapine](#) levels. However, [mirtazapine](#) is not an inhibitor of these enzymes. The sedating effects of [mirtazapine](#) may be additive with those of CNS depressants such as [alcohol](#) and benzodiazepines.

[Amoxapine](#) and [maprotiline](#) share most drug interactions common to the TCA group. Both are CYP2D6 substrates and should be used with caution in combination with inhibitors such as [fluoxetine](#). [Amoxapine](#) and [maprotiline](#) also both have anticholinergic and antihistaminic properties that may be additive with drugs that share a similar profile.

Since [vilazodone](#) is primarily a substrate of CYP3A4, strong CYP3A4 inhibitors such as [ketoconazole](#) can increase the serum concentration of [vilazodone](#) by 50% or more. On the other hand, [vilazodone](#) is neither a potent inhibitor nor a strong inducer of any CYP isoenzymes. It may be a mild inducer of CYP2C19.

#### E. Monoamine Oxidase Inhibitors

MAOIs are associated with two classes of serious drug interactions. The first of these is the pharmacodynamic interaction of MAOIs with serotonergic agents including SSRIs, SNRIs, and most TCAs along with some analgesic agents such as [meperidine](#). These combinations of an MAOI with a serotonergic agent may result in a life-threatening **serotonin syndrome** (see [Chapter 16](#)). The serotonin syndrome is thought to be caused by overstimulation of 5-HT receptors in the central gray nuclei and the medulla. Symptoms range from mild to lethal and include a triad of cognitive (delirium, coma), autonomic (hypertension, tachycardia, diaphoresis), and somatic (myoclonus, hyperreflexia, tremor) effects. Most serotonergic antidepressants should be discontinued at least 2 weeks before starting an MAOI. [Fluoxetine](#), because of its long half-life, should be discontinued for 4–5 weeks before an MAOI is initiated. Conversely, an MAOI must be discontinued for at least 2 weeks before starting a serotonergic agent.

The second serious interaction with MAOIs occurs when an MAOI is combined with tyramine in the diet or with sympathomimetic substrates of MAO. An MAOI prevents the breakdown of tyramine in the gut, and this results in high serum levels that enhance peripheral noradrenergic effects, including raising blood pressure dramatically. Patients on an MAOI who ingest large amounts of dietary tyramine may experience malignant hypertension and subsequently a stroke or myocardial infarction. Thus, patients taking MAOIs require a low-tyramine diet and should avoid foods such as aged cheeses, tap beer, soy products, and dried sausages, which contain high amounts of tyramine (see [Chapter 9](#)). Similar sympathomimetics also may cause significant hypertension when combined with MAOIs. Thus, over-the-counter cold preparations that contain [pseudoephedrine](#) and phenylpropanolamine are contraindicated in patients taking MAOIs.

#### F. NMDA Receptor Antagonists

[Ketamine](#) and [esketamine](#) have relatively modest CYP450 interactions but a number of potential pharmacodynamic interactions. [Esketamine](#) is a weak inducer of CYP2B6 and CYP3A4. It is not a substrate of p-glycoprotein.

Among the adverse effects of [ketamine](#) and [esketamine](#) are sedation, hypertension, and tachycardia. CNS depressants such as [alcohol](#), benzodiazepines, and barbiturates can increase the sedation associated with [esketamine](#) and [ketamine](#). Stimulants ([methylphenidate](#), [dextroamphetamine](#), [modafinil](#), [armodafinil](#)), MAOIs, and sympathomimetics can all increase blood pressure and heart rate when combined with [ketamine](#) and [esketamine](#).

[Dextromethorphan](#) is metabolized via CYP2D6, as is the major active metabolite of [bupropion](#), hydroxybupropion. Thus, CYP2D6 inhibitors will increase the serum level of both drugs and might increase the adverse effects including seizures, while CYP2D6 inducers will decrease the serum level of combination pill and decrease efficacy. The combination pill is contraindicated with MAOIs because of the risk of a serotonin syndrome or

## G. GABA<sub>A</sub> Receptor Modulators

**Brexanolone** is metabolized via multiple alternate pathways and thus is not likely to have significant pharmacokinetic interactions. CYP450 inducers or inhibitors are not expected to have a significant effect on **brexanolone** levels. **Brexanolone** appears to be a weak inhibitor of CYP2C9 in vitro, but clinical studies have not demonstrated an effect on the pharmacokinetics of co-administered **phenytoin** (a CYP2C9 substrate). **Brexanolone** is expected to be frequently prescribed with other antidepressants; no clinically significant interactions have been noted.

### SUMMARY Antidepressants

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>SELECTIVE SEROTONIN REUPTAKE INHIBITORS (SSRIs)</b>				
<ul style="list-style-type: none"> <li>Fluoxetine</li> <li>Citalopram</li> <li>Escitalopram</li> <li>Paroxetine</li> <li>Sertraline</li> </ul>	Highly selective blockade of serotonin transporter (SERT) • little effect on norepinephrine transporter (NET)	Acute increase of serotonergic synaptic activity • slower changes in several signaling pathways and neurotrophic activity	Major depression, anxiety disorders • panic disorder • obsessive-compulsive disorder • post-traumatic stress disorder • perimenopausal vasomotor symptoms • eating disorder (bulimia)	Half-lives from 15 to 75 h • oral activity • <i>Toxicity</i> : Well tolerated but cause sexual dysfunction • risk of serotonin syndrome with MAOIs • <i>Interactions</i> : Some CYP inhibition ( <b>fluoxetine</b> 2D6, 3A4; <b>fluvoxamine</b> 1A2; <b>paroxetine</b> 2D6)
<ul style="list-style-type: none"> <li><b>Fluvoxamine</b>: Similar to above but approved only for obsessive-compulsive behavior</li> </ul>				
<b>SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS (SNRIs)</b>				
<ul style="list-style-type: none"> <li>Duloxetine</li> <li>Venlafaxine</li> <li>Levomilnacipran</li> </ul>	Moderately selective blockade of NET and SERT	Acute increase in serotonergic and adrenergic synaptic activity • otherwise like SSRIs	Major depression, chronic pain disorders • fibromyalgia, perimenopausal symptoms	<i>Toxicity</i> : Anticholinergic, sedation, hypertension ( <b>venlafaxine</b> ) • <i>Interactions</i> : Some CYP2D6 inhibition ( <b>duloxetine</b> , <b>desvenlafaxine</b> ) • CYP3A4 interactions with <b>levomilnacipran</b>
<ul style="list-style-type: none"> <li><b>Desvenlafaxine</b>: Desmethyl metabolite of <b>venlafaxine</b>, metabolism is by phase II rather than CYP phase I</li> <li><b>Milnacipran</b>: Approved only for fibromyalgia in the USA; significantly more selective for NET than SERT; little effect on DAT</li> </ul>				
<b>TRICYCLIC ANTIDEPRESSANTS (TCAs)</b>				
<ul style="list-style-type: none"> <li>Imipramine</li> <li>Many others</li> </ul>	Mixed and variable blockade of NET and SERT	Like SNRIs plus significant blockade of autonomic nervous system and histamine receptors	Major depression not responsive to other drugs • chronic pain disorders • incontinence • obsessive-compulsive disorder ( <b>clomipramine</b> )	Long half-lives • CYP substrates • active metabolites • <i>Toxicity</i> : Anticholinergic, $\alpha$ -blocking effects, sedation, weight gain, arrhythmias, and seizures in overdose • <i>Interactions</i> : CYP inducers and inhibitors

## 5-HT RECEPTOR MODULATORS

<ul style="list-style-type: none"> <li>Nefazodone</li> <li>Trazodone</li> </ul>	Inhibition of 5-HT <sub>2A</sub> receptor • nefazodone also blocks SERT weakly	Trazodone forms a metabolite (m-cpp) that blocks 5-HT <sub>2A,2C</sub> receptors	Major depression • sedation and hypnosis (trazodone)	Relatively short half-lives • active metabolites • Toxicity: Modest $\alpha$ - and H <sub>1</sub> -receptor blockade (trazodone) • Interactions: Nefazodone inhibits CYP3A4
<ul style="list-style-type: none"> <li>Vortioxetine</li> </ul>	Antagonist at 5-HT <sub>3</sub> , 5-HT <sub>7</sub> , 5-HT <sub>1D</sub> receptors; partial agonist at 5-HT <sub>1B</sub> receptor, agonist at 5-HT <sub>1A</sub> receptor; inhibits SERT	Complex modulation of serotonergic systems	Major depression	Extensively metabolized via CYP2D6 and glucuronic acid conjugation • Toxicity: GI disturbances, sexual dysfunction • Interactions: Additive with serotonergic agents

## TETRACYCLICS, UNICYCLIC

<ul style="list-style-type: none"> <li>Bupropion</li> <li>Amoxapine</li> <li>Maprotiline</li> <li>Mirtazapine</li> </ul>	Increased norepinephrine and dopamine activity (bupropion) • NET > SERT inhibition (amoxapine, maprotiline) • increased release of norepinephrine, 5-HT (mirtazapine)	Presynaptic release of catecholamines but no effect on 5-HT (bupropion) • amoxapine and maprotiline resemble TCAs	Major depression • smoking cessation (bupropion) • sedation (mirtazapine) • amoxapine and maprotiline rarely used	Extensive metabolism in liver • Toxicity: Lowers seizure threshold (amoxapine, bupropion); sedation and weight gain (mirtazapine) • Interactions: CYP2D6 inhibitor (bupropion)
--	---	---	---	--

## MONOAMINE OXIDASE INHIBITORS (MAOIs)

<ul style="list-style-type: none"> <li>Phenelzine</li> <li>Tranlycypromine</li> <li>Selegiline</li> </ul>	Blockade of MAO-A and MAO-B (phenelzine, nonselective) • MAO-B irreversible selective MAO-B inhibition (low-dose selegiline)	Transdermal formulation of selegiline achieves levels that inhibit MAO-A	Major depression unresponsive to other drugs • Parkinson disease (selegiline)	Very slow elimination • Toxicity: Hypotension, insomnia • Interactions: Hypertensive crisis with tyramine, other indirect sympathomimetics • serotonin syndrome with serotonergic agents, meperidine
---	--	--	---	--

## NMDA RECEPTOR ANTAGONISTS

<ul style="list-style-type: none"> <li>Ketamine (off-label)</li> <li>Esketamine</li> </ul> <p>Bupropion + dextromethorphan</p>	Noncompetitive antagonism at the NMDA receptor NE agonist, DA reuptake inhibitor, NMDA antagonist, sigma-1 agonist	Anesthesia; possible increase in serotonergic activity, dopaminergic activity Combination tablet for major depression	Ketamine: anesthesia Esketamine: refractory depression (outside USA: anesthesia)	Ketamine: IV Esketamine: nasal inhalation, rapid onset of action • Toxicity: Dissociative symptoms, possible abuse, BP increase
--	---	--	---	--

GABA<sub>A</sub> RECEPTOR MODULATORS

	Positive allosteric	Unclear: possibly	Postpartum depression only	IV infusion over 60 hours • Toxicity:
--	---------------------	-------------------	----------------------------	---------------------------------------

modulator of the GABA<sub>A</sub> chloride channel, binding site distinct from benzodiazepine site

replaces endogenous allopregnanolone, which decreases markedly after delivery

Excessive sedation, possible loss of consciousness

## PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
<b>SELECTIVE SEROTONIN REUPTAKE INHIBITORS</b>	
Citalopram	Generic, Celexa
Escitalopram	Generic, Lexapro
Fluoxetine	Generic, Prozac, Prozac Weekly
Fluvoxamine*	Generic
Paroxetine	Generic, Paxil
Sertraline	Generic, Zoloft
<b>SEROTONIN NOREPINEPHRINE REUPTAKE INHIBITORS</b>	
Desvenlafaxine	Pristiq
Duloxetine	Generic, Cymbalta
Levomilnacipran	Fetzima
Milnacipran†	Savella
Venlafaxine	Generic, Effexor
<b>5-HT RECEPTOR MODULATORS</b>	
Nefazodone	Generic
Trazodone	Generic, Desyrel
Vortioxetine	Trintellix

**TRICYCLICS**

Amitriptyline	Generic, Elavil
Amoxapine	Generic
Clomipramine *	Generic, Anafranil
Desipramine	Generic, Norpramin
Doxepin	Generic, Sinequan
Imipramine	Generic, Tofranil
Nortriptyline	Generic, Pamelor
Protriptyline	Generic, Vivactil
Trimipramine	Surmontil

**TETRACYCLIC AND UNICYCLIC AGENTS**

Amoxapine	Generic
Bupropion	Generic, Wellbutrin
Maprotiline	Generic
Mirtazapine	Generic, Remeron
Vilazodone	Viibryd

**MONOAMINE OXIDASE INHIBITORS**

Isocarboxazid	Marplan
Phenelzine	Generic, Nardil
Selegiline	Generic, Eldepryl
Tranylcypromine	Generic, Parnate

**NMDA RECEPTOR MODULATORS**

Esketamine	Spravato, Ketanest
Bupropion + dextromethorphan	Auvelity

**GABA<sub>A</sub> RECEPTOR MODULATORS**

Brexanolone†	Zulresso
--------------	----------

\*Labeled only for obsessive-compulsive disorder.

†Labeled only for fibromyalgia.

‡Labeled only for postpartum depression.

### CASE STUDY ANSWER

The patient has previously responded to **fluoxetine**, so this drug is an obvious choice. However, she is taking other drugs and **fluoxetine**, the prototype SSRI, has a number of pharmacokinetic and pharmacodynamic interactions. **Fluoxetine** is a CYP450 2D6 inhibitor and thus can inhibit the metabolism of 2D6 substrates such as **propranolol** and other  $\beta$  blockers; tricyclic antidepressants; **tramadol**; opioids such as **methadone**, **codeine**, and **oxycodone**; antipsychotics such as **haloperidol** and **thioridazine**; and many other drugs. This inhibition of metabolism can result in significantly higher plasma levels of the concurrent drug, and this may lead to an increase in adverse reactions associated with that drug.

As a potent inhibitor of the serotonin transporter, **fluoxetine** is associated with a number of pharmacodynamic interactions involving serotonergic neurotransmission. The combination of **tramadol** with **fluoxetine** has occasionally been associated with a serotonin syndrome, characterized by diaphoresis, autonomic instability, myoclonus, seizures, and coma. The combination of **fluoxetine** with an MAOI is contraindicated because of the risk of a fatal serotonin syndrome. In addition, **mepiridine** is specifically contraindicated in combination with an MAOI. An interaction with **hydrochlorothiazide** is not likely.

## Chapter 31: Opioid Agonists & Antagonists

Mark A. Schumacher; Allan I. Basbaum; Ramana K. Naidu

### CASE STUDY

#### CASE STUDY

A 48-year-old man with a body mass index (BMI) of 33 (obesity) and history of obstructive sleep apnea presents to the emergency department with severe back pain following a fall from a ladder. He complains of severe pain without loss of consciousness or focal neurologic deficits. What is the most appropriate immediate treatment for his pain? Are any special precautions needed?

**Morphine**, the prototypic opioid agonist, has been used throughout history to relieve acute severe pain with remarkable efficacy.\* The opium poppy is the source of crude opium from which Sertürner in 1803 isolated **morphine**, the pure alkaloid, naming it after Morpheus, the Greek god of dreams. It remains the standard against which all drugs that have strong analgesic action are compared. These drugs are collectively known as opioids and include not only the natural and semisynthetic alkaloid derivatives from opium but also synthetic surrogates, other opioid-like drugs whose actions are blocked by the nonselective antagonist **naloxone**, plus several endogenous peptides that interact with the different subtypes of opioid receptors.

\*In memory of Walter (Skip) Way, MD.

### BASIC PHARMACOLOGY OF THE OPIOIDS

#### Source

Opium, the source of morphine, is obtained from the poppy, *Papaver somniferum* and *P album*. After incision, the poppy seed pod exudes a white substance that turns into a brown gum that is crude opium. Opium contains many alkaloids, the principal one being morphine, which is present in a concentration of about 10%. Codeine can also be found in opium and is synthesized commercially from morphine.

#### Classification & Chemistry

The term **opioid** describes all compounds that work at opioid receptors. The term **opiate** specifically describes the naturally occurring alkaloids: morphine, codeine, thebaine, and papaverine. In contrast, **narcotic** was originally used to describe sleep-inducing medications, but in the United States, its usage has shifted into a legal term.

Opioid drugs include full agonists, partial agonists, and antagonists—measures of intrinsic activity or efficacy. Morphine is a full agonist at the **μ (mu)-opioid receptor**, the major analgesic opioid receptor (Table 31–1). Opioids may also differ in receptor-binding affinity. For example, morphine exhibits a greater binding affinity at the μ-opioid receptor than does codeine. Other opioid receptor subtypes include **δ (delta)** and **κ (kappa)** nociception/**opioid-receptor-like subtype 1 (ORL-1)** receptors. Simple substitution of an allyl group on the nitrogen of the full *agonist* morphine plus addition of a single hydroxyl group results in naloxone, a strong μ-receptor *antagonist*. The structures of some of these compounds are shown later in this chapter. Some opioids, eg, nalbuphine, a **mixed agonist-antagonist**, are capable of producing an agonist (or partial agonist) effect at one opioid receptor subtype and an antagonist effect at another. The receptor-activating properties and affinities of opioid analgesics can be manipulated by pharmaceutical chemistry; in addition, certain opioid analgesics are modified in the liver, resulting in compounds with greater analgesic action. Chemically, the opioids derived from opium are phenanthrene derivatives and include four or more fused rings, while most of the synthetic opioids are simpler molecules.

**Opioid receptor subtypes, their functions, and their endogenous peptide affinities.**

Receptor Subtype	Functions	Endogenous Opioid Peptide Affinity
μ(mu)	Supraspinal and spinal analgesia; sedation; inhibition of respiration; slowed gastrointestinal transit; modulation of hormone and neurotransmitter release	Endorphins > enkephalins > dynorphins
δ(delta)	Supraspinal and spinal analgesia; modulation of hormone and neurotransmitter release	Enkephalins > endorphins and dynorphins
κ(kappa)	Supraspinal and spinal analgesia; psychotomimetic effects; slowed gastrointestinal transit	Dynorphins >> endorphins and enkephalins

**Endogenous Opioid Peptides**

Opioid alkaloids (eg, morphine) produce analgesia through actions at central nervous system (CNS) receptors that also respond to certain endogenous peptides with opioid-like pharmacologic properties. The general term currently used for these endogenous substances is **endogenous opioid peptides**.

Three families of endogenous opioid peptides have been described: the **endorphins**, the pentapeptide **enkephalins** (methionine-enkephalin [**met-enkephalin**] and leucine-enkephalin [**leu-enkephalin**]), and the **dynorphins**. These three families of endogenous opioid peptides have overlapping affinities for opioid receptors (see [Table 31-1](#)).

The endogenous opioid peptides are derived from three precursor proteins: prepro-opiomelanocortin (POMC), preproenkephalin (proenkephalin A), and preprodynorphin (proenkephalin B). POMC contains the met-enkephalin sequence, β-endorphin, and several nonopioid peptides, including adrenocorticotrophic hormone (ACTH), β-lipotropin, and melanocyte-stimulating hormone. Preproenkephalin contains six copies of met-enkephalin and one copy of leu-enkephalin. Leu- and met-enkephalin have slightly higher affinity for the δ (delta) than for the μ-opioid receptor (see [Table 31-1](#)). Preprodynorphin yields several active opioid peptides that contain the leu-enkephalin sequence. These are **dynorphin A**, **dynorphin B**, and α and β **neendorphins**. Painful stimuli can evoke release of endogenous opioid peptides under the stress associated with pain or the anticipation of pain, and they diminish the perception of pain.

In contrast to the analgesic role of leu- and met-enkephalin, an analgesic action of dynorphin A—through its binding to κ-opioid receptors—remains controversial. Dynorphin A is also found in the dorsal horn of the spinal cord. Increased levels of dynorphin occur in the dorsal horn after tissue injury and inflammation. This elevated dynorphin level is proposed to *increase* pain and induce a state of long-lasting *sensitization* and hyperalgesia. The pronociceptive action of dynorphin in the spinal cord appears to be independent of the opioid receptor system. Beyond their role in pain, κ-opioid receptor agonists can also function as antipruritic agents.

The principal receptor for this novel system is the G protein–coupled **orphanin opioid-receptor–like subtype 1 (ORL1)**. Its endogenous ligand has been termed **nociceptin** by one group of investigators and **orphanin FQ** by another group. This ligand-receptor system is currently known as the *N/OFQ* system. Nociceptin is structurally similar to dynorphin except for the absence of an N-terminal tyrosine; it acts only at the ORL1 receptor, now known as **NOP**. The *N/OFQ* system is widely expressed in the CNS and periphery, reflecting its equally diverse biology and pharmacology. As a result of experiments using highly selective NOP receptor ligands, the *N/OFQ* system has been implicated in both pro- and antinociceptive activity as well as in the modulation of drug reward, learning, mood, anxiety, and cough processes, and of Parkinsonism.

**Pharmacokinetics of Exogenous Opioids**

## Common opioid analgesics.

Generic Name	Receptor Effects <sup>1</sup>			Approximately Equivalent Dose (mg)	Oral: Parenteral Potency Ratio	Duration of Analgesia (hours)	Maximum Efficacy
	μ	δ	κ				
Morphine <sup>2</sup>	+++		+	10	Low	4-5	High
Hydromorphone	+++			1.5	Low	4-5	High
Oxymorphone	+++			1.5	Low	3-4	High
Methadone	+++			10 <sup>3</sup>	High	4-6	High
Meperidine	+++			60-100	Medium	2-4	High
Fentanyl	+++			0.1	Low	1-1.5	High
Sufentanil	+++	+	+	0.02	Parenteral only	1-1.5	High
Alfentanil	+++			Titrated	Parenteral only	0.25-0.75	High
Remifentanil	+++			Titrated <sup>4</sup>	Parenteral only	0.05 <sup>5</sup>	High
Levorphanol	+++			2-3	High	4-5	High
Codeine	±			30-60	High	3-4	Low
Hydrocodone <sup>6</sup>	±			5-10	Medium	4-6	Moderate
Oxycodone <sup>2,7</sup>	++			4.5	Medium	3-4	Mod-High
Pentazocine	±		+	30-50	Medium	3-4	Moderate
Nalbuphine	-		++	10	Parenteral only	3-6	High
Buprenorphine	±	-	-	0.3	Low	4-8	High
Butorphanol	±		+++	2	Parenteral only	3-4	High

<sup>1</sup> +++, +, strong agonist; ±, partial or weak agonist; -, antagonist.

<sup>2</sup> Available in sustained-release forms, morphine (MS Contin); oxycodone (OxyContin).

<sup>3</sup> No consensus—may have higher potency.

<sup>4</sup> Administered as an infusion at 0.025-0.2 mcg/kg/min.

<sup>6</sup>Available in tablets containing acetaminophen (Norco, Vicodin, Lortab, others).

<sup>7</sup>Available in tablets containing acetaminophen (Percocet); aspirin (Percodan).

## A. Absorption

Most opioid analgesics are well absorbed when given by subcutaneous, intramuscular, and oral routes. However, because of the first-pass effect, the oral dose of the opioid (eg, morphine) to elicit a therapeutic effect may need to be much higher than the parenteral dose. As there is considerable interpatient variability in first-pass opioid metabolism, prediction of an effective oral dose is difficult. Certain analgesics such as codeine and oxycodone are effective orally because they have reduced first-pass metabolism. By avoiding first-pass metabolism, nasal insufflation of certain opioids can rapidly result in therapeutic blood levels. Other routes of opioid administration include oral mucosa via lozenges, and the transdermal route via patches. The latter can provide delivery of potent analgesics over days.

## B. Distribution

The uptake of opioids by various organs and tissues is a function of both physiologic and chemical factors. Although all opioids bind to plasma proteins with varying affinity, the drugs rapidly leave the blood compartment and localize in highest concentrations in highly perfused tissues such as the brain, lungs, liver, kidneys, and spleen. Drug concentrations in skeletal muscle may be much lower, but this tissue serves as the main reservoir because of its greater bulk. Even though blood flow to fatty tissue is much lower than to the highly perfused tissues, accumulation can be very important, particularly after frequent high-dose administration or continuous infusion of highly lipophilic opioids that are slowly metabolized, eg, fentanyl.

## C. Metabolism

The opioids are converted in large part to polar metabolites (mostly glucuronides), which are then readily excreted by the kidneys. For example, morphine, which contains free hydroxyl groups, is primarily conjugated to morphine-3-glucuronide (M3G), a compound with neuroexcitatory properties. The neuroexcitatory effects of M3G do not appear to be mediated by  $\mu$  receptors and are under further study. In contrast, approximately 10% of morphine is metabolized to morphine-6-glucuronide (M6G), an active metabolite with analgesic potency four to six times that of its parent compound. However, these relatively polar metabolites have limited ability to cross the blood-brain barrier and probably do not contribute significantly to the usual CNS effects of a single dose of morphine. Importantly, accumulation of these metabolites may produce unexpected adverse effects in patients with renal failure or when exceptionally large doses of morphine are administered or high doses are administered over long periods. This can result in M3G-induced CNS excitation (seizures) or enhanced and prolonged opioid action produced by M6G. CNS uptake of M3G and, to a lesser extent, M6G can be enhanced by co-administration of probenecid or of drugs that inhibit the P-glycoprotein drug transporter.

### 1. Hepatic P450 metabolism

Hepatic oxidative metabolism is the primary route of degradation of the phenylpiperidine opioids (fentanyl, meperidine, alfentanil, sufentanil) and eventually leaves only small quantities of the parent compound unchanged for excretion. However, accumulation of a demethylated metabolite of meperidine, normeperidine, may occur in patients with decreased renal function and in those receiving multiple high doses of the drug. In high concentrations, normeperidine may cause seizures. In contrast, no active metabolites of fentanyl have been reported. The P450 isozyme CYP3A4 metabolizes fentanyl by *N*-dealkylation in the liver. CYP3A4 is also present in the mucosa of the small intestine and contributes to the first-pass metabolism of fentanyl when it is taken orally.

Codeine, oxycodone, and hydrocodone undergo metabolism in the liver by P450 isozyme CYP2D6, resulting in the production of metabolites of greater potency. For example, codeine is demethylated to morphine, which is then conjugated. Hydrocodone is metabolized to hydromorphone and, like morphine, hydromorphone is conjugated, yielding hydromorphone-3-glucuronide (H3G), which has CNS excitatory properties. Hydromorphone cannot form a 6-glucuronide metabolite. Similarly, oxycodone is metabolized to oxymorphone, which is then conjugated to oxymorphone-3-glucuronide (O3G).

Genetic polymorphism of CYP2D6 has been documented and linked to the variation in analgesic and adverse responses seen among patients. In contrast, the metabolites of oxycodone and hydrocodone may be of minor consequence; the parent compounds are currently believed to be directly responsible for the majority of their analgesic actions. However, oxycodone and its metabolites can accumulate under conditions of renal failure and have been associated with prolonged action and sedation. In the case of codeine, conversion to morphine may be of greater importance because codeine itself has relatively low affinity for opioid receptors. As a result, some patients (so-called poor metabolizers) may experience no significant analgesic effect. In contrast, there have been case reports of an exaggerated response to codeine due to enhanced metabolic conversion to morphine (ie, ultra-rapid metabolizers; see [Chapters 4 and 5](#)) resulting in respiratory depression and death. For this reason, routine use of codeine, especially in pediatric age groups, is now being eliminated in the United States.

The synthetic opioid methadone is metabolized through several CYP450 pathways, in part accounting for its highly variable bioavailability. The most important hepatic pathway for metabolism is CYP2B6.

Although genetic testing of CYP450 pathways is not common, these tests are available and becoming cheaper. Over the next several decades, personalized medicine will help patients who need opioids (and their prescribers) understand which opioids may not be good options for them.

## 2. Plasma esterase metabolism

Esters (eg, heroin, remifentanyl) are rapidly hydrolyzed by common plasma and tissue esterases. Heroin (diacetylmorphine) is hydrolyzed to monoacetylmorphine and finally to morphine, which is then conjugated with glucuronic acid.

## D. Excretion

Polar metabolites, including glucuronide conjugates of opioid analgesics, are excreted mainly in the urine. Small amounts of unchanged drug may also be found in the urine. In addition, glucuronide conjugates are found in the bile, but enterohepatic circulation represents only a small portion of the excretory process of these polar metabolites. In patients with renal impairment the effects of active polar metabolites should be considered before the administration of potent opioids such as morphine or hydromorphone—especially when given at high doses—due to the risk of sedation and respiratory depression.

## Pharmacodynamics

### A. Mechanism of Action

Opioid agonists produce analgesia by binding to specific G protein–coupled receptors (GPCRs) that are located in brain and spinal cord regions involved in the transmission and modulation of pain ([Figure 31–1](#)). Some effects may be mediated by opioid receptors on peripheral sensory nerve endings.

FIGURE 31–1

Potential receptor mechanisms of analgesic drugs. The primary afferent neuron (cell body not shown) originates in the periphery and carries pain signals to the dorsal horn of the spinal cord, where it synapses via glutamate and neuropeptide transmitters with the secondary neuron. Pain stimuli can be attenuated in the periphery (under inflammatory conditions) by opioids acting at  $\mu$ -opioid receptors (MOR) or blocked in the afferent axon by local anesthetics (not shown). Action potentials reaching the dorsal horn can be attenuated at the presynaptic ending by opioids and calcium blockers (ziconotide), by  $\alpha_2$  agonists, and possibly, by drugs that increase synaptic concentrations of norepinephrine by blocking reuptake (tapentadol).

Opioids also inhibit the postsynaptic neuron, as do certain neuropeptide antagonists acting at tachykinin (NK1) and other neuropeptide receptors. Inset: Morphine (M) binds and activates the  $\mu$ -opioid receptor (MOR) coupling to  $G_{i/o}$ -mediated calcium channel inhibition and potassium channel activation. Analgesia (left) and  $\beta$ -arrestin–mediated side effects: respiratory depression, constipation, and tolerance (right). Biased ligand (closed triangle) targets a structural aspect of the MOR that facilitates  $G_{i/o}$  coupling (analgesia) over  $\beta$ -arrestin (side effects).

### 1. Receptor types

As noted previously, three major classes of opioid receptors ( $\mu$ ,  $\delta$ , and  $\kappa$ ) have been identified in various nervous system sites and in other tissues (see [Table 31-1](#)). Each of the three major receptors has now been cloned. All are members of the G protein-coupled family of receptors and show significant amino acid sequence homologies. Multiple receptor subtypes have been proposed based on pharmacologic criteria, including  $\mu_1$ ,  $\mu_2$ ;  $\delta_1$ ,  $\delta_2$ ; and  $\kappa_1$ ,  $\kappa_2$ , and  $\kappa_3$ . However, genes encoding only one subtype from each of the  $\mu$ ,  $\delta$ , and  $\kappa$  receptor families have thus far been isolated and characterized. One plausible explanation is that  $\mu$ -receptor subtypes arise from alternate splice variants of a common gene. This idea has been supported by the identification of receptor splice variants in mice and humans, and a recent report pointed to the selective association of a  $\mu$ -opioid receptor splice variant (MOR1D) with the induction of itch rather than the suppression of pain.

Since an opioid may function with different potencies as an agonist, partial agonist, or antagonist at more than one receptor class or subtype, it is not surprising that these agents are capable of diverse pharmacologic effects.

### 2. Cellular actions

At the molecular level, opioid receptors form a family of proteins that physically couple to G proteins and through this interaction affect ion channel gating, modulate intracellular Ca<sup>2+</sup> disposition, and alter protein phosphorylation (see [Chapter 2](#)). The opioids have two well-established direct G<sub>i/o</sub> protein-coupled actions on neurons: (1) they close voltage-gated Ca<sup>2+</sup> channels on presynaptic nerve terminals and thereby reduce transmitter release, and (2) they open K<sup>+</sup> channels and hyperpolarize and thus inhibit postsynaptic neurons. [Figure 31-1](#) schematically illustrates these effects.

The presynaptic action—depressed transmission—has been demonstrated for a large number of neurotransmitters, including glutamate, the principal excitatory amino acid released from nociceptive nerve terminals, as well as acetylcholine, norepinephrine, serotonin, and substance P.

### 3. Relation of physiologic effects to receptor type

The majority of currently available opioid analgesics act primarily at the  $\mu$ -opioid receptor (see Table 31–2). Analgesia and the euphoriant, respiratory depressant, and physical dependence properties of morphine result principally from actions at  $\mu$  receptors. In fact, the  $\mu$  receptor was originally defined using the relative potencies for clinical analgesia of a series of opioid alkaloids. However, opioid analgesic effects are complex and include interaction with  $\delta$  and  $\kappa$  receptors. This is supported in part by the study of genetic knockouts of the  $\mu$ ,  $\delta$ , and  $\kappa$  genes in mice. The development of  $\mu$ -receptor-selective agonists could be clinically useful if their side-effect profiles (respiratory depression, risk of dependence) were more favorable than those found with current  $\mu$ -receptor agonists, such as morphine. Although morphine does act at  $\kappa$  and  $\delta$  receptor sites, it is unclear to what extent this contributes to its analgesic action. The endogenous opioid peptides differ from most of the alkaloids in their affinity for the  $\delta$  and  $\kappa$  receptors (see Table 31–1).

In an effort to develop opioid analgesics with a reduced incidence of respiratory depression or propensity for addiction and dependence, compounds that show preference for  $\kappa$ -opioid receptors have been developed. Butorphanol and nalbuphine have shown some clinical success as analgesics, but they can cause dysphoric reactions and have limited potency. It is of interest that butorphanol has also been shown to cause significantly greater analgesia in women than in men. In fact, gender-based differences in analgesia mediated by  $\mu$ - and  $\delta$ -receptor activation have been widely reported.

Another approach to improve the therapeutic window of drugs that target opioid receptors is to develop opioid-like molecules that are analgesic but have significantly reduced adverse side effects (respiratory depression, constipation, and dependence). This effort is driven by structural studies of the mu opioid receptor that revealed different amino acid sequences, through which ligand binding to GPCRs influences multiple downstream signaling pathways. For example, morphine exerts its analgesic action via  $G_{i/o}$  signaling, but adverse side effects are proposed to occur by engaging the  $\beta$ -arrestin pathway. To avoid the latter pathway, “biased agonists” have been developed that are biased toward  $G_i$  signaling (see Figure 31–1, inset).

Comparable studies have targeted biased agonist development of kappa opioid receptor agonists that lack the dysphoric effects typical of KOR agonists but retain analgesic efficacy as well as profound anti-pruritic effects. Complementary to this approach are the synergistic combinations of opioids that also target peripheral opioid receptors. In light of reports that these biased agonists may, in fact, represent partial agonists, like buprenorphine, caution in interpreting the mechanism of action of these novel opioids is advised.

Another means to reduce opioid side-effects is based on reports of heterodimerization of different opioid receptors, eg, of the mu (MOR) and delta (DOR) opioid receptor. In this case, a hybrid MOR agonist and DOR antagonist retained analgesic action in the tail flick test, but tolerance and dependence were reduced compared to morphine. Other studies have reported heterodimerization between MOR and nonopioid receptors, eg, the nociceptin/orphanin F/Q receptor (NOP). Interestingly, a bifunctional peptide-based hybrid that exerts an agonist action at the MOR and the NOP produced significant analgesic effects with reduced adverse effects. More recently, heterodimers were identified between the MOR and the Gal1 subtype of galanin receptors, contributing a major source of dopamine to nucleus accumbens-mediated reward. Such MOR-GAL1 heterodimers have been implicated in the relatively low-rewarding properties of methadone compared with morphine. The implication is that development of opioid analgesics that preferentially target the MOR-GAL1 heterodimer may provide analgesia with significantly reduced misuse potential.

Of course, an alternative is to identify peripheral or CNS sites where selective targeting can increase the therapeutic window. To this end, recent studies reported that targeting the mu opioid receptor in the lateral habenula can exert significant analgesic actions without reward. Moreover, a rewarding effect only occurred in a pain model, presumably as a consequence of pain relief that may involve regulation of mesolimbic dopaminergic circuitry.

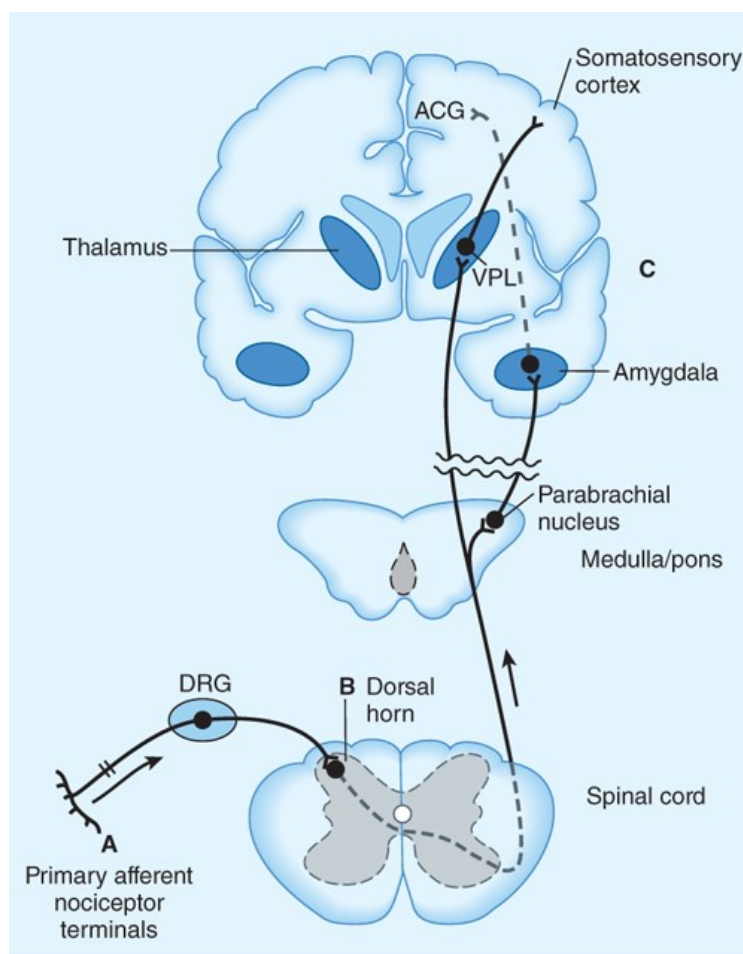

### 4. Receptor distribution and neural mechanisms of analgesia

Opioid receptor-binding sites have been localized autoradiographically with high-affinity radioligands and with antibodies to unique peptide sequences in each receptor subtype. All three major receptors are present in subregions of the central nervous system including the dorsal horn of the spinal cord. Receptors are present both on spinal cord pain transmission neurons and on the primary afferents that relay the pain message to them (Figure 31–2, sites A and B). Although opioid agonists directly inhibit dorsal horn pain transmission neurons, they also inhibit the release of excitatory transmitters from the primary afferents. Although there are reports that heterodimerization of the  $\mu$ -opioid and  $\delta$ -opioid receptors contributes to  $\mu$ -agonist efficacy (eg, inhibition of presynaptic voltage-gated calcium channel activity), a recent study using a transgenic mouse that expresses a  $\delta$ -

enhanced green fluorescent protein (eGFP) fusion protein showed little overlap of  $\mu$  receptor and  $\delta$  receptor in dorsal root ganglion neurons. Importantly, the  $\mu$  receptor is associated with TRPV1 and peptide (substance P)-expressing nociceptors, whereas  $\delta$ -receptor expression predominates in the nonpeptidergic population of nociceptors, including many primary afferents with myelinated axons. This finding is consistent with the action of intrathecal  $\mu$ -receptor- and  $\delta$ -receptor-selective ligands that are found to block heat versus mechanical pain processing, respectively. An association of the  $\delta$  but not the  $\mu$  receptor with large diameter mechanoreceptive afferents has been described. To what extent the differential expression of the  $\mu$  receptor and  $\delta$  receptor in the dorsal root ganglia is characteristic of neurons throughout the CNS remains to be determined.

FIGURE 31-2

Putative sites of action of opioid analgesics. Sites of action on the afferent pain transmission pathway from the periphery to the higher centers are shown. (A) Direct action of opioids on inflamed or damaged peripheral tissues (see Figure 31-1 for detail). (B) Inhibition also occurs in the spinal cord (see Figure 31-1). (C) Possible site of action in the amygdala. ACG, anterior cingulate gyrus; DRG, dorsal root ganglion, VPL, ventral posterolateral nucleus of the thalamus.

The fact that opioids exert a powerful analgesic effect directly on the spinal cord has been exploited clinically by direct application of opioid agonists to the spinal cord. This *spinal* action provides a regional analgesic effect while reducing the unwanted respiratory depression, nausea and vomiting, and sedation that may occur from the *supraspinal* actions of systemically administered opioids.

Under most circumstances, opioids are given systemically and thus act simultaneously at multiple sites. These include not only the ascending pathways of pain transmission beginning with specialized peripheral sensory terminals that transduce painful stimuli (see Figure 31-2) but also descending

(modulatory) pathways (Figure 31-3). At these sites, as at others, opioids directly inhibit pain neurons; yet this action results in the *activation* of descending inhibitory neurons that send processes to the spinal cord and inhibit pain transmission neurons. This activation has been shown to result from the inhibition of inhibitory neurons in several locations (Figure 31-4). Taken together, interactions at these sites increase the overall analgesic effect of opioid agonists.

FIGURE 31-3

Brainstem local circuitry underlying the modulating effect of  $\mu$ -opioid receptor (MOR)-mediated analgesia on descending pathways. The pain-inhibitory neuron is indirectly activated by opioids (exogenous or endogenous), which inhibit an inhibitory (GABAergic) interneuron. This results in *enhanced* inhibition of nociceptive processing in the dorsal horn of the spinal cord (see Figure 31-4).

Moreover, when pain-relieving opioid drugs are given systemically, they presumably act on neuronal circuits normally regulated by endogenous opioids. However, as morphine exerts its action mainly at the mu receptor, while enkephalins engage both mu and delta receptors, it is likely that different analgesia-mediating circuits may be activated by exogenous and endogenous opioids.

Animal and human clinical studies demonstrate that both endogenous and exogenous opioids can also produce analgesia at sites *outside* the CNS. Pain associated with inflammation seems especially sensitive to these peripheral opioid actions. The presence of functional  $\mu$  receptors on the peripheral terminals of sensory neurons supports this hypothesis. Furthermore, activation of peripheral  $\mu$  receptors results in a decrease in sensory neuron activity and transmitter release. The endogenous release of  $\beta$ -endorphin produced by immune cells within injured or inflamed tissue represents one source of physiologic peripheral  $\mu$ -receptor activation. Intra-articular administration of opioids, eg, following arthroscopic knee surgery, has shown some clinical benefit for up to 24 hours. For this reason, opioids selective for a peripheral site of action may be useful adjuncts in the treatment of inflammatory pain (see Box: [Ion Channels & Novel Analgesic Targets](#)). Such compounds could have the additional benefit of reducing unwanted effects such as nausea. Also of interest is a recent report that a fentanyl analog that preferentially acts within an acidic environment (namely, diseased colon) can produce analgesia without the typical adverse side effects (constipation and respiratory depression). Interestingly, this compound produces reward that appears to be secondary to its peripheral pain-relieving properties.

Even the most severe acute pain (lasting hours to days) can usually be controlled—with significant but tolerable adverse effects—using currently available analgesics, especially the opioids. However, chronic pain (lasting months to years) and especially pain arising from neuropathic causes are not very satisfactorily managed with opioids. It is now known that in chronic pain, receptors on sensory nerve terminals in the periphery contribute to increased excitability of these sensory endings (peripheral sensitization). The hyperexcitable sensory neuron bombards the spinal cord, leading to increased excitability and synaptic alterations in the dorsal horn (central sensitization). Such changes are likely important contributors to chronic inflammatory and neuropathic pain states.

In the effort to discover better analgesic drugs for chronic pain, renewed attention is being paid to the molecular basis of peripheral sensory transduction. Potentially important ion channels associated with the primary afferent nociceptor include members of the transient receptor potential family, notably the **capsaicin receptor TRPV1** (which is activated by multiple noxious stimuli such as heat, protons, and products of inflammation) and **TRPA1**, activated by inflammatory mediators, TRPM8, the receptor for menthol-mediated topical analgesia, and **P2X** receptors (which are responsive to purines released from tissue damage). Special subtypes of voltage-gated sodium channels (**Nav 1.7, 1.8, 1.9**) are uniquely associated with nociceptive neurons in dorsal root ganglia. **Lidocaine** and **mexiletine**, which are useful in some chronic pain states, may act by blocking this class of channels. Certain centipede toxins appear to selectively inhibit Nav 1.7 channels and may also be useful in the treatment of chronic pain. Genetic polymorphisms of Nav 1.7 are associated with either absence (congenital insensitivity to pain) or predisposition to pain (erythromelalgia or paroxysmal extreme pain disorder), and there may be a direct link between expressed levels of Nav 1.7 and enkephalin in sensory ganglia. Nav 1.9 is also currently under study as a therapeutic target. Because of the importance of their peripheral sites of action, therapeutic strategies that deliver agents that block peripheral pain transduction or transmission have been introduced in the form of transdermal patches and balms. In addition, products that systemically target peripheral TRPV1, TRPA1, TRPM8, and sodium channel function are in development.

Intrathecal administration of **ziconotide**, a blocker of voltage-gated N-type calcium channels, is approved for producing analgesia in patients with refractory chronic pain. Ziconotide is a synthetic peptide related to the marine snail toxin  $\Omega$ -conotoxin, which selectively blocks N-type calcium channels. **Gabapentin/pregabalin**, anticonvulsants that act at the  $\alpha 2\delta 1$  subunit of voltage-gated calcium channels, are effective treatments for neuropathic (nerve injury) pain and reduce opioid requirements postoperatively (see [Chapter 24](#)). *N*-methyl-D-aspartate (NMDA) receptors appear to play a very important role in central sensitization at both spinal and supraspinal levels. Although certain NMDA antagonists have demonstrated anti-hyperalgesic and analgesic activity (eg, **ketamine**), it has been difficult to find agents with an acceptably low profile of adverse effects or neurotoxicity. However, ketamine infused at very small doses reduces hyperalgesia and can reduce opioid requirements under conditions of opioid tolerance, eg, after major abdominal and spinal surgery. GABA and acetylcholine (through nicotinic receptors) appear to control the central synaptic release of several transmitters involved in nociception. Use of antibodies that bind nerve growth factor (NGF) has been shown to block inflammatory and back pain, but approval of their clinical use may be limited due to safety concerns. Finally, work on cannabinoids and vanilloids and their receptors suggests that  **$\Delta 9$ -tetrahydrocannabinol (THC)** as well as cannabidiol (CBD) and other minor cannabinoids, which act on CB<sub>1</sub> cannabinoid receptors and interact with the TRPV1 capsaicin receptor under certain circumstances, can synergize with  $\mu$ -receptor agonists to produce analgesia.

As our understanding of peripheral and central pain transduction improves, additional therapeutic targets and strategies will become available. Combined with our present knowledge of opioid analgesics, a “multimodal” approach to pain therapy is paramount. Multimodal analgesia involves the administration of multiple agents (eg, COX-inhibitors or nonsteroidal anti-inflammatory drugs [NSAIDs], gabapentinoids (in select patients), and selective norepinephrine receptor inhibitors with complementary mechanisms of action to provide analgesia that is superior to that provided by an individual compound. Another benefit of multimodal analgesia is reduced opioid requirements with fewer serious adverse effects.

### 5. Tolerance and dependence

With frequently repeated therapeutic doses of morphine or its surrogates, there is a gradual loss in effectiveness; this loss of effectiveness is termed tolerance. Attempts to reproduce the original analgesic response require a larger dose to be administered (with variable success). Along with tolerance, physical dependence develops. Physical dependence is defined as a characteristic **withdrawal** or **abstinence syndrome** when a drug is stopped or an antagonist is administered (see also [Chapter 32](#)).

The mechanism of development of opioid tolerance and physical dependence is poorly understood, but persistent activation of  $\mu$  receptors such as occurs with the treatment of severe chronic pain appears to play a primary role in its induction and maintenance. Current concepts have shifted away from tolerance being driven by a simple up-regulation of the cyclic adenosine monophosphate (cAMP) system. Although this process is associated with tolerance, it is not sufficient to explain it. A second hypothesis for the development of opioid tolerance and dependence is based on the concept of **receptor recycling**. Normally, activation of  $\mu$  receptors by endogenous ligands results in receptor endocytosis followed by resensitization and recycling of the receptor to the plasma membrane (see [Chapter 2](#)). However, using genetically modified mice, research now shows that the *failure* of morphine to induce endocytosis of the  $\mu$ -opioid receptor is an important component of tolerance and dependence. In further support of this idea, methadone, a  $\mu$ -receptor agonist used for the *treatment* of opioid tolerance and dependence, induces receptor endocytosis. This suggests that maintenance of normal sensitivity of  $\mu$  receptors requires reactivation by endocytosis and recycling.

The concept of **receptor uncoupling** has also gained prominence. Under this hypothesis, tolerance results from a dysfunction of structural interactions between the  $\mu$  receptor and G proteins, second-messenger systems, and their target ion channels. Uncoupling and recoupling of  $\mu$  receptor function are likely linked to receptor recycling. Recent studies demonstrate that receptor internalization of GPCRs is not merely a step in recycling to the membrane or of receptor degradation. Rather, several G protein receptors, after their internalization, can reside and remain functional in cytoplasmic endosomes. This has been demonstrated for pronociceptive ligands (eg, CGRP, substance P, PAR2) and most recently for the delta opioid receptor, which could be engaged by ligands from patient-derived inflamed colon. The NMDA-receptor ion channel complex is also a significant contributor to tolerance development and maintenance. Consistent with this mechanism, NMDA-receptor antagonists such as ketamine can block tolerance development, in part by reducing descending medullary pain facilitatory mechanisms. These studies emphasize that the development of novel NMDA-receptor antagonists or other strategies to recouple  $\mu$  receptors to their target ion channels provides hope for achieving a clinically effective means to prevent or reverse opioid analgesic tolerance.

#### 6. Opioid-induced hyperalgesia (OIH)

In addition to the development of tolerance, persistent administration of opioid analgesics can *increase* the sensation of pain, resulting in a state of hyperalgesia. This phenomenon can be produced with several opioid analgesics, including morphine, fentanyl, and remifentanyl. Some studies have implicated a microglial-expressed opioid receptor or a metabolite of morphine that binds a microglial-expressed TL4 receptor in OIH. In contrast, an earlier report demonstrated that both opioid tolerance and OIH can be prevented by selective deletion of the MOR from primary sensory neurons, not from microglia. Spinal dynorphin and activation of the bradykinin and NMDA receptors have also emerged as important candidates for the mediation of opioid-induced hyperalgesia. This is one more reason why continuously administered opioids for *chronic* noncancer pain has been questioned.

### B. Organ System Effects of Morphine and Its Surrogates

The actions described below for morphine, the prototypic opioid agonist, can also be observed with other opioid agonists, partial agonists, and those with mixed receptor effects. Characteristics of specific members of these groups are discussed below.

#### 1. Central nervous system effects

The principal effects of opioid analgesics with affinity for  $\mu$  receptors are on the CNS; the more important ones include analgesia, euphoria, sedation, and respiratory depression. With repeated use, a high degree of tolerance occurs to all of these effects ([Table 31-3](#)).

Degrees of tolerance that may develop to some of the effects of the opioids.

High	Moderate	Minimal or None
Analgesia	Bradycardia	Miosis
Euphoria, dysphoria		Constipation
Mental clouding		Convulsions
Sedation		
Respiratory depression		
Antidiuresis		
Nausea and vomiting		
Cough suppression		

a. ANALGESIA

Pain consists of both sensory and affective (emotional) components. Opioid analgesics are unique in that they can reduce both aspects of the pain experience. In contrast, nonsteroidal anti-inflammatory analgesic drugs, eg, ibuprofen, have no significant effect on the emotional aspects of pain.

b. EUPHORIA

Typically, patients or intravenous drug users who receive intravenous morphine experience a pleasant floating sensation with lessened anxiety and distress. However, dysphoria, an unpleasant state characterized by restlessness and malaise, also may occur.

c. SEDATION

Drowsiness and clouding of mentation are common effects of opioids. There is little or no amnesia. Sleep is induced by opioids more frequently in the elderly than in young, healthy individuals. Ordinarily, the patient can be easily aroused from this sleep. However, the combination of morphine with other central depressant drugs such as the sedative-hypnotics may result in very deep sleep. In standard analgesic doses, morphine (a phenanthrene) disrupts normal rapid eye movement (REM) and non-REM sleep patterns. This disrupting effect is probably characteristic of all opioids. In contrast to humans, a number of other species (cats, horses, cows, pigs) may manifest excitation rather than sedation when given opioids. These paradoxical effects are at least partially dose-dependent.

d. RESPIRATORY DEPRESSION

All of the opioid analgesics can produce significant respiratory depression by inhibiting brainstem respiratory mechanisms. Alveolar  $P_{aCO_2}$  may increase, but the most reliable indicator of this depression is a depressed response to a carbon dioxide challenge. The respiratory depression is dose-related and is influenced significantly by the degree of sensory input occurring at the time. For example, it is possible to partially overcome opioid-induced respiratory depression by a variety of stimuli. When strongly painful stimuli that have prevented the depressant action of a large dose of an opioid are relieved, respiratory depression may suddenly become marked. A small to moderate decrease in respiratory function, as measured by  $P_{aCO_2}$  elevation, may be well tolerated in the patient without prior respiratory impairment. However, in individuals with increased intracranial pressure, asthma, chronic obstructive pulmonary disease, or cor pulmonale, this decrease in respiratory function may not be tolerated. Opioid-induced respiratory depression remains one of the most difficult clinical challenges in the treatment of severe pain. Ongoing research to overcome this problem is focused on  $\mu$ -receptor pharmacology, serotonin signaling pathways in the brainstem respiratory control centers, and agonist ligands biased toward  $G_i/o$  coupling.

e. COUGH SUPPRESSION

www.konkur.in  
Suppression of the cough reflex is a well-recognized action of opioids. Codeine in particular is used to advantage in persons suffering from pathologic cough. However, cough suppression by opioids may allow accumulation of secretions and thus lead to airway obstruction and atelectasis.

#### f. MIOSIS

Constriction of the pupils is seen with virtually all opioid agonists. Miosis is a pharmacologic action to which little or no tolerance develops, even in highly tolerant addicts (see [Table 31-3](#)); thus, it is valuable in the diagnosis of opioid overdose. This action, which can be blocked by opioid antagonists, is mediated by parasympathetic pathways, which, in turn, can be blocked by atropine.

#### g. TRUNCAL RIGIDITY

Several opioids can intensify tone in the large trunk muscles. It was originally believed that truncal rigidity involved a spinal cord action of these drugs, but a supraspinal action is likely. Truncal rigidity reduces thoracic compliance and thus interferes with ventilation. The effect is most apparent when high doses of the highly lipid-soluble opioids (eg, fentanyl, sufentanil, alfentanil, remifentanil) are rapidly administered intravenously. Truncal rigidity may be overcome by administration of an opioid antagonist, which of course will also antagonize the analgesic action of the opioid. Preventing truncal rigidity while preserving analgesia requires the concomitant use of neuromuscular blocking agents.

#### h. NAUSEA AND VOMITING

The opioid analgesics can activate the brainstem chemoreceptor trigger zone to produce nausea and vomiting. As ambulation seems to increase the incidence of nausea and vomiting there may also be a vestibular component in this effect.

#### i. TEMPERATURE

Homeostatic regulation of body temperature is mediated in part by the action of endogenous opioid peptides in the brain. For example, administration of  $\mu$ -opioid receptor agonists, such as morphine to the anterior hypothalamus produces hyperthermia, whereas administration of  $\kappa$  agonists induces hypothermia.

#### j. SLEEP ARCHITECTURE

Although the mechanism by which opioids interact with circadian rhythm is unclear, they can decrease the percentage of stage 3 and 4 sleep, which may result in fatigue and other sleep disorders, including sleep-disordered breathing and central sleep apnea.

### 2. *Peripheral effects*

#### a. CARDIOVASCULAR SYSTEM

Most opioids have no significant direct effects on the heart and, other than bradycardia, no major effects on cardiac rhythm. Meperidine is an exception to this generalization because its antimuscarinic action can result in tachycardia. Blood pressure is usually well maintained in subjects receiving opioids unless the cardiovascular system is stressed, in which case hypotension may occur. This hypotensive effect is probably due to peripheral arterial and venous dilation, which has been attributed to a number of mechanisms including central depression of vasomotor-stabilizing mechanisms and release of histamine. No consistent effect on cardiac output is seen, and the electrocardiogram is not significantly affected. However, caution should be exercised in patients with decreased blood volume, because the above mechanisms make these patients susceptible to hypotension. Opioid analgesics affect cerebral circulation minimally except when  $PCO_2$  rises as a consequence of respiratory depression. Increased  $PCO_2$  leads to cerebral vasodilation associated with a decrease in cerebral vascular resistance, an increase in cerebral blood flow, and an increase in intracranial pressure.

#### b. GASTROINTESTINAL TRACT

Constipation has long been recognized as an effect of opioids, an effect that does not diminish with continued use. That is, tolerance does not develop to opioid-induced constipation (see [Table 31-3](#)). Opioid receptors exist in high density in the gastrointestinal tract, and the constipating effects of the opioids are mediated through an action on the enteric nervous system (see [Chapter 6](#)) as well as the CNS. In the stomach, motility (rhythmic contraction and relaxation) may decrease but tone (persistent contraction) may increase—particularly in the central portion; gastric secretion of hydrochloric acid is decreased. Small intestine resting tone is increased, with periodic spasms, but the amplitude of nonpropulsive contractions is markedly decreased. In the large intestine, propulsive peristaltic waves are diminished and tone is increased; this delays passage of the fecal mass and allows increased absorption of water, which leads to constipation. The large bowel actions are the basis for the use of opioids in the management of diarrhea, and constipation is a major problem in the use of opioids for control of severe cancer pain. As described later, a new generation of agents designed to block or reverse opioid-induced constipation has been introduced.

www.konkur.in  
The opioids contract biliary smooth muscle, which can result in biliary colic. The sphincter of Oddi may constrict, resulting in reflux of biliary and pancreatic secretions and elevated plasma amylase and lipase levels.

#### d. RENAL

Renal function is depressed by opioids. It is believed that in humans this is chiefly due to decreased renal plasma flow. In addition,  $\mu$  receptor opioids have an antidiuretic effect in humans. Mechanisms may involve both the CNS and peripheral sites. Opioids also enhance renal tubular sodium reabsorption. The role of opioid-induced changes in antidiuretic hormone (ADH) release is controversial. Ureteral and bladder tone are increased by therapeutic doses of the opioid analgesics. Increased sphincter tone may precipitate urinary retention, especially in postoperative patients. Occasionally, ureteral colic caused by a renal calculus is made worse by opioid-induced increase in ureteral tone.

#### e. UTERUS

The opioid analgesics may prolong labor. Although the mechanism for this action is unclear, both  $\mu$ - and  $\kappa$ -opioid receptors are expressed in human uterine muscle. Fentanyl and meperidine (pethidine) inhibit uterine contractility but only at supraclinical concentrations; morphine had no reported effects. In contrast, the  $\kappa$  agonist [3H]-D-al<sub>2</sub>,L-met<sup>5</sup>-enkephalinamide (DAMEA) inhibits contractility in human uterine muscle strips.

#### f. ENDOCRINE

Opioids stimulate the release of ADH, prolactin, and somatotropin but inhibit the release of luteinizing hormone (see [Table 31-1](#)). These effects suggest that endogenous opioid peptides, through effects in the hypothalamus, modulate these systems. Patients receiving chronic opioid therapy can have low testosterone resulting in decreased libido, energy, and mood. Women can experience dysmenorrhea or amenorrhea.

#### g. PRURITUS

The opiates, such as morphine and codeine, produce flushing and warming of the skin accompanied sometimes by sweating, urticaria, and itching. Although peripheral histamine release is an important contributor, all opioids can cause pruritus via a central (spinal cord and medullary) action on pruritoceptive neural circuits. When opioids are administered to the neuraxis by the spinal or epidural route, their usefulness may be limited by intense pruritus over the lips and torso. The incidence of opioid-induced pruritus via the neuraxial route is high, estimated at 70–100%. Of interest, the  $\kappa$  agonist/partial  $\mu$  antagonist nalbuphine and the selective  $\kappa$  agonist nalfurafine have proved effective and in some countries have been approved for the management of itch. Nalfurafine importantly is a highly biased  $\kappa$  agonist that does not produce the dysphoria typical of  $\kappa$  receptor agonists. As to mechanism, a recent preclinical study implicated a  $\kappa$  opioid receptor-expressing medullospinal inhibitory circuit in these controls. On the other hand, with respect to pain regulation, other studies underscore the complex contribution of the  $\kappa$  receptor. Indeed,  $\kappa$  antagonists reportedly can attenuate pain in a preclinical migraine model.

#### h. IMMUNE

The opioids modulate the immune system by effects on lymphocyte proliferation, antibody production, angiogenesis, and chemotaxis. In addition, leukocytes migrate to the site of tissue injury and release opioid peptides, which in turn help counter inflammatory pain. However, natural killer cell cytolytic activity and lymphocyte proliferative responses to mitogens are usually inhibited by opioids, which may play a role in tumor progression. Although the mechanisms involved are complex, activation of central opioid receptors could mediate a significant component of the changes observed in peripheral immune function. These effects are mediated by the sympathetic nervous system in the case of acute administration and by the hypothalamic-pituitary-adrenal system in the case of prolonged administration of opioids.

## CLINICAL PHARMACOLOGY OF THE OPIOID ANALGESICS

Successful management of pain is a challenging task that begins with assessment of and an attempt to understand the source and magnitude of the pain. Pain is an unpleasant sensory and emotional experience with many layers of complexity.

The amount of pain experienced by the patient is often measured by means of a pain numeric rating scale (NRS) or less frequently by marking a line on a 100-mm visual analog scale (VAS, which is more commonly used in research), as well as the verbal rating scale (VRS) with word descriptors ranging from no pain to excruciating pain. In each case, values indicate the magnitude of pain as mild (1–3), moderate (4–6), or severe (7–10). A similar scale can be used with children (Face, Legs, Activity, Cry, Consolability [FLACC] or Wong-Baker scales) and with patients who cannot speak; the Wong-Baker scale depicts five faces ranging from smiling (no pain) to crying (maximum pain). The Brief Pain Inventory is a series of questions regarding the severity of pain. Functional scales include the Oswestry Disability Index or the World Health Organization Disability Assessment Scale 2.0. There are specialized scales for patients with specific conditions including rheumatoid arthritis and dementia. More comprehensive questionnaires such as the McGill Pain

Telegram: @pharm\_dr\_k

Assesses the multiple facets of pain including both the affective and sensory experience.

For a patient in severe acute pain, administration of an opioid analgesic is usually considered a primary part of the overall management plan.

Determining the route of administration (oral, parenteral, neuraxial), duration of drug action, ceiling effect (maximal intrinsic activity), duration of therapy, potential for adverse effects, and the patient's past experience with opioids, including their genetics, social history, and family history, all should be addressed. One of the main principles in this process is to establish analgesic treatment goals before initiation of therapy. Just as important is the principle that following delivery of the therapeutic plan, its effectiveness must be monitored and reevaluated frequently, and the plan modified as necessary.

Use of opioid drugs in acute situations should be contrasted with their use in chronic pain management, in which a multitude of other factors must be considered, including the development of tolerance, dependence, and the rarer cases of diversion or misuse.

## Clinical Use of Opioid Analgesics

### A. Analgesia

Severe, *acute* pain is usually relieved with opioid analgesics having high intrinsic activity (see [Table 31-2](#)), whereas sharp, intermittent pain does not appear to be as effectively controlled.

The pain associated with cancer and other terminal illnesses typically involves a combination of mechanisms, must be treated aggressively, and often requires a multidisciplinary approach for effective management. Such conditions may require continuous use of potent opioid analgesics when cancer is active and/or invasive and when the conditions are associated with risk of tolerance and dependence. Importantly, use of multimodal analgesic strategies can reduce these risks. *However, this should not be used as a barrier to providing patients with the best possible care and quality of life.* The World Health Organization Ladder (see <http://www.who.int/cancer/palliative/painladder/en/>) was created in 1986 to promote awareness of the optimal treatment of pain for individuals with cancer and has helped improve pain care for cancer patients worldwide. Research in the hospice setting has also demonstrated that fixed-interval administration of opioid medication (ie, a regular dose at a scheduled time) is more effective in achieving pain relief than dosing on demand. Dosage forms of opioids that allow slower (sustained) release of the drug are now available, eg, sustained-release forms of [morphine](#) (MS Contin) and [oxycodone](#) (OxyContin). Their purported advantage is a longer and more stable level of analgesia. However, there is little to no evidence of the superiority of long-term (>3–6 months) use of sustained-release opioids to manage chronic noncancer or chronic low back, hip, or knee pain for 12 months when compared with nonopioid analgesic strategies. Alternately, attempts to control chronic pain with opioids alone may lead to excessive use, dependence and risk of **opioid use disorder (OUD)**, overdose, and death (see Box: [Educating Opioid Prescribers](#)).

---

The treatment of chronic pain is a difficult biopsychosocial problem, and prescribers of opioids have been caught between a number of competing forces in their attempts to relieve pain and suffering. The USA is the largest user of prescription opioids of any country and continues to experience an epidemic of opioid-related harm and death that has worsened under the SARS- COVID pandemic. Drug overdose is now the leading cause of injury-related deaths in the USA. Following a tidal wave of opioid prescriptions driven by subsequent opioid use disorder (OUD), more than 68,000 died from an opioid overdose in 2020, a leap from nearly 50,000 opioid-related deaths in 2019 and more than 16,000 deaths related to prescription opioids (wonder.cdc.gov). Overall, more than 100,000 deaths from 2020–2021 are attributed to drug overdose with opioids as the primary cause. The line between deaths from illicit versus prescription opioids is blurred since some patients may choose to cross from one opioid to another. In contrast, in several countries the medical use of opioids is prohibited or severely limited, resulting in unmanaged pain after surgery or trauma and near the end of life. Forces that have influenced excessive prescribing of opioids for chronic noncancer pain in the USA include aggressive marketing of opioids, misleading industry-led education on the abuse and addiction potential of opioids, an unjustified assumption of the superiority of opioids over nonopioid therapies for the treatment of chronic noncancer pain, and a paucity of safe, effective, and affordable (covered or reimbursed by insurance) analgesic strategies that have low abuse potential. These findings prompted the Centers for Disease Control (CDC) to create the first Opioid Prescribing Guidelines for Primary Care Prescribers caring for patients with chronic noncancer pain in 2016 that was revised in 2022 ([https://www.cdc.gov/mmwr/volumes/71/rr/rr7103a1.htm?s\\_cid=rr7103a1.htm\\_w](https://www.cdc.gov/mmwr/volumes/71/rr/rr7103a1.htm?s_cid=rr7103a1.htm_w)). The US Health and Human Services Interagency Task Force also completed a “Pain Management Best Practices” guide ([https://www.hhs.gov/sites/default/files/overview-pmtf-final-report-fact-sheet\\_508.pdf](https://www.hhs.gov/sites/default/files/overview-pmtf-final-report-fact-sheet_508.pdf)) that integrates input from a comprehensive consortium of governmental and nongovernmental health professional societies. The FDA has also instituted training programs such as a risk evaluation and mitigation strategy (REMS) program for all potent opioid prescribing to help providers better understand potential benefits versus risks of prescription opioids. State medical boards in the USA are establishing their own regulations in addition to creating prescription drug monitoring programs (PDMPs). The US Drug Enforcement Agency has focused efforts on illicit practices and distribution patterns with concerns about diversion. Major efforts to expand research in this domain are now supported through the National Institutes of Health program Helping End Addiction Long Term (HEAL). Litigation of the opioid and drug distribution industry is underway to obtain resources to support prevention and treatment and of OUD in the USA.

Prescribers are advised to learn about the local, state, and national guidelines and laws for the prescribing and monitoring of patients on opioids. A major concern from 2015 to 2019 data has been the number of fentanyl- and heroin-related deaths in persons suffering from OUD. This has resulted from opioids (counterfeit prescription pills, heroin) dealt “on the street” that have been adulterated with the much more potent **fentanyl** to increase effect. While law-enforcement efforts have been made to reduce supply, it may be more effective to reduce demand. Paramount in such reduction will be the use of multimodal nonopioid strategies in the management of chronic noncancer pain, appropriate opioid tapering, access to opioid maintenance programs, investment in addiction medicine, and development of analgesics without abuse liability.

If disturbances of gastrointestinal function prevent the use of oral sustained-release **morphine**, then a **fentanyl** transdermal system (**fentanyl** patch) can be used over long periods. Furthermore, buccal transmucosal **fentanyl** can be used for short episodes of breakthrough cancer pain (see [Alternative Routes of Administration](#)). Administration of strong opioids by nasal insufflation also is efficacious, and nasal preparations are now available in some countries. Opioid analgesics are often used during obstetric labor. Because opioids cross the placental barrier and reach the fetus, care must be taken to minimize neonatal depression. If it occurs, immediate injection of the antagonist **naloxone** will reverse the depression. The phenylpiperidine drugs (eg, **meperidine**) appear to produce less depression, particularly respiratory depression, in newborn infants than does **morphine**; this may justify their use in obstetric practice.

The acute, severe pain of renal and biliary colic often requires a strong agonist opioid for adequate relief. However, the drug-induced increase in smooth muscle tone may cause a paradoxical *increase* in pain secondary to increased spasm.

### B. Acute Pulmonary Edema

The relief produced by intravenous **morphine** in patients with dyspnea from pulmonary edema associated with left ventricular heart failure is remarkable. Proposed mechanisms include reduced anxiety (*perception* of shortness of breath) and reduced cardiac preload (reduced venous tone) and afterload (decreased peripheral resistance). However, if respiratory depression is a problem, a diuretic (**furosemide**) may be preferred for the treatment of pulmonary edema. On the other hand, **morphine** can be particularly useful when treating painful myocardial ischemia with pulmonary

### C. Cough

Suppression of cough can be obtained at doses lower than those needed for analgesia. However, in recent years, the use of opioid analgesics to allay cough has diminished largely because of the availability of a number of effective synthetic compounds that are neither analgesic nor addictive. These agents are discussed below.

### D. Diarrhea

Diarrhea from almost any cause can be controlled with the opioid analgesics, but if diarrhea is associated with infection, such use must not substitute for appropriate treatment. Crude opium preparations (eg, **paregoric**) were used in the past to control diarrhea, but now synthetic surrogates with more selective gastrointestinal effects and few or no CNS effects, eg, diphenoxylate or **loperamide**, are used. Several preparations are available specifically for this purpose (see [Chapter 62](#)).

### E. Shivering

Although all opioid agonists have some propensity to reduce shivering, **meperidine** is reported to have the most pronounced anti-shivering properties. **Meperidine** apparently blocks shivering mainly through an action on subtypes of the  $\alpha_2$  adrenoceptor.

### F. Applications in Anesthesia

The opioids are frequently used as premedicant drugs before anesthesia and surgery because of their sedative, anxiolytic, and analgesic properties. They are also used intraoperatively as a part of induction, maintenance, and preparation for postoperative analgesia. Opioids are most commonly used in cardiovascular surgery and other types of high-risk surgery in which a primary goal is to minimize cardiovascular depression. In such situations, mechanical respiratory assistance must be provided.

Because of their direct action on the neurons of the superficial dorsal horn of the spinal cord, opioids can also be used as regional analgesics, by administration into the epidural or subarachnoid spaces of the spinal column. A number of studies have demonstrated that long-lasting analgesia with minimal adverse effects can be achieved by epidural administration of 3–5 mg of **morphine**, followed by slow infusion through a catheter placed in the epidural space. It was initially assumed that the epidural application of opioids might selectively produce analgesia without impairment of motor, autonomic, or sensory functions other than pain. However, respiratory depression can occur after the drug is injected into the epidural space and may require reversal with **naloxone**. Effects such as pruritus and nausea and vomiting are common after epidural and subarachnoid administration of opioids and may also be reversed with **naloxone**. The use of epidural opioids in combination with dilute solutions of local anesthetics is common practice for postoperative analgesia following thoracic and abdominal operations and can reduce the amount of systemic opioids, thereby reducing other opioid-related side effects such as sedation or constipation. In rare cases, chronic pain management specialists may elect to implant surgically a programmable infusion pump connected to a spinal catheter for continuous infusion of opioids and/or other analgesic compounds in chronic or cancer pain management.

### G. Alternative Routes of Administration

**Patient-controlled analgesia (PCA)** is widely used for the management of breakthrough pain. With PCA, the patient controls a parenteral (usually intravenous) infusion device by pressing a button to deliver a preprogrammed dose of the desired opioid analgesic, called the **demand dose**. A programmable **lockout interval** prevents administration of another dose for a set period of time. In addition, the pumps can be programmed with a **continuous or basal infusion** (which should generally be avoided due to safety concerns unless directed by an experienced provider) and the **1-hour lockout dose** (the maximum amount of drug that can be delivered in 1 hour). Claims of better patient satisfaction are supported by well-designed clinical trials, making this approach very useful in postoperative pain control. However, healthcare personnel must be very familiar with the use of PCAs to avoid overdosage secondary to misuse or improper programming. There is a proven risk of PCA-associated respiratory depression and hypoxia that requires careful monitoring of vital signs and sedation level, and provision of supplemental **oxygen**. Continuous pulse oximetry is recommended for patients receiving PCA-administered opioids; this is not a fail-safe method for early detection of hypoventilation or apnea but rather serves as a safety net for an unrecognized adverse event. Monitoring of ventilation is ideal but is often inadequate. The risk of sedation is increased if

**Rectal suppositories** of **morphine** and **hydromorphone** have been used when oral and parenteral routes are undesirable. The **transdermal fentanyl patch** is the most common full opioid agonist in transdermal application and is indicated primarily for the management of persistent unremitting cancer pain. It can provide more consistent blood levels of drug and potentially better pain control while avoiding the need for repeated or continuous parenteral (intravenous) injections. This may be especially important in patients unable to receive opioids via the enteral route due to limited GI function. Because of the complication of fentanyl-induced respiratory depression, the FDA recommends that introduction of a transdermal **fentanyl patch** (25 mcg/h) be reserved for patients with an established oral **morphine** requirement of at least 60 mg/d for 1 week or more. Extreme caution must be exercised in any patient initiating therapy or undergoing a dose increase because the peak effects may not be realized until 24–48 hours after patch application. Another alternative to parenteral administration is the **buccal transmucosal** route, which uses a **fentanyl citrate** lozenge or “lollipop” mounted on a stick for breakthrough cancer pain. The inclusion of the transdermal **fentanyl patch** for the treatment of chronic noncancer pain is associated with an increased risk of respiratory depression, tolerance, dependence, and opioid use disorder. Evidence is lacking for its superiority over nonopioid analgesic strategies in the treatment of chronic non-cancer pain and is often reserved for patients unable to be administered or absorb enteral opioid analgesics.

The **buprenorphine patch** (Butrans) is an example of the transdermal delivery of a mixed agonist-antagonist for the treatment of chronic pain in addition to opioid maintenance or detoxification. The **intranasal** route avoids repeated parenteral drug injections and the first-pass metabolism of orally administered drugs. **Butorphanol** is the only opioid currently available in the USA in a nasal formulation, but more are expected.

### Toxicity & Undesired Effects

Direct toxic effects of the opioid analgesics that are extensions of their acute pharmacologic actions include respiratory depression, nausea, vomiting, and constipation (Table 31–4). Tolerance, dependence, diagnosis and treatment of overdose, and contraindications must be considered.

TABLE 31–4

#### Adverse effects of the opioid analgesics.

Adverse Effects with Acute Use	Adverse Effects with Chronic Use
Respiratory depression	Hypogonadism
Nausea/vomiting	Immunosuppression
Pruritus	Increased feeding
Urticaria	Increased growth hormone secretion
Constipation	Withdrawal effects
Urinary retention	Tolerance, dependence
Delirium	Abuse, addiction
Sedation	Hyperalgesia
Myoclonus	Impairment while driving
Seizures	

Drug dependence of the opioid type is marked by a relatively specific withdrawal or abstinence syndrome. Just as there are pharmacologic differences between the various opioids, there are reported differences in psychological dependence and the severity of withdrawal effects. Administration of an opioid *antagonist* to an opioid-dependent person is followed by brief but severe withdrawal symptoms (see antagonist-precipitated withdrawal, below). The potential for physical and psychological dependence of the partial agonist-antagonist opioids appears to be less than that of the strong agonist drugs.

### 1. Opioid tolerance

Opioid tolerance is the phenomenon whereby repeated doses of opioids have a diminishing analgesic effect. Clinically, it has been described as an increasing opioid dose requirement to achieve the analgesia observed at the initiation of opioid administration. Although development of tolerance begins with the first dose of an opioid, tolerance may not become clinically manifest until after 2–3 weeks of frequent exposure to ordinary therapeutic doses. Nevertheless, perioperative and critical care use of ultrapotent opioid analgesics such as **remifentanyl** have been shown to induce opioid tolerance within hours. Tolerance develops most readily when potent opioids are given at short intervals and is minimized by giving small amounts of drug with longer intervals between doses.

Although a high degree of tolerance may develop to the analgesic, sedating, and respiratory depressant effects of opioid agonists (see [Table 31–3](#)), it is still possible to produce respiratory arrest in a tolerant (or nontolerant) person with clinically used doses of opioid analgesics—especially if concurrently administered with sedating drugs such as benzodiazepines. Tolerance also develops to the antidiuretic, emetic, and hypotensive effects but not to the miotic, convulsant, and constipating actions. Following discontinuation of opioids, loss of tolerance to the sedating and respiratory effects of opioids is variable and difficult to predict. However, tolerance to the emetic effects may persist for several months after withdrawal of the drug. Therefore, opioid tolerance differs by effect, drug, time, and the individual (genetic-epigenetic factors).

Tolerance also develops to analgesics with mixed receptor effects but to a lesser extent than to the agonists. Adverse effects such as hallucinations, sedation, hypothermia, and respiratory depression are reduced after repeated administration of the mixed receptor drugs. However, tolerance to the latter agents does not generally include cross-tolerance to the agonist opioids. It is also important to note that tolerance does not develop to the antagonist actions of the mixed agents or to those of the pure antagonists.

Cross-tolerance is an extremely important characteristic of the opioids, ie, patients tolerant to **morphine** often show a reduction in analgesic response to other agonist opioids. This is particularly true of those agents with primarily  $\mu$ -receptor agonist activity. **Morphine** and its congeners exhibit cross-tolerance not only with respect to their analgesic actions but also to their euphoriant, sedative, and respiratory effects. However, the cross-tolerance existing among the  $\mu$ -receptor agonists can often be partial or incomplete. This clinical observation has led to the concept of “opioid rotation,” which has been used for many years in the treatment of cancer pain. A patient who is experiencing decreasing effectiveness of one opioid analgesic regimen is “rotated” to a different opioid analgesic (eg, **morphine** to **hydromorphone**; **hydromorphone** to **methadone**) and typically experiences significantly improved analgesia at a reduced overall equivalent dosage. Another approach is to recouple opioid receptor function as described previously through the use of adjunctive nonopioid agents. NMDA-receptor antagonists (eg, **ketamine**) have shown promise in preventing or reversing opioid-induced hyperalgesia and tolerance in animals and humans. Use of **ketamine** is increasing because well-controlled studies have shown clinical efficacy in reducing postoperative pain and opioid requirements in opioid-tolerant patients. Agents that independently enhance  $\mu$ -receptor recycling may also hold promise for improving analgesia in the opioid-tolerant patient.

### 2. Dependence

The development of physical dependence is an invariable accompaniment of tolerance to repeated administration of an opioid of the  $\mu$  type. Failure to continue administering the drug results in a characteristic withdrawal or abstinence syndrome that reflects an exaggerated rebound from the acute pharmacologic effects of the opioid.

The signs and symptoms of withdrawal include rhinorrhea, lacrimation, yawning, chills, gooseflesh (piloerection), hyperventilation, hyperthermia, mydriasis, muscular aches, vomiting, diarrhea, anxiety, and hostility. The number and intensity of the signs and symptoms are largely dependent on the degree of physical dependence that has developed. Administration of an opioid at this time suppresses abstinence signs and symptoms almost immediately.

The time of onset, intensity, and duration of abstinence depend on the drug previously used and may be related to its biologic half-life. With [fentanyl](#), heroin, or [morphine](#) withdrawal signs may start within 6–10 hours after the last dose. Peak effects are seen at 36–48 hours, after which most of the signs and symptoms gradually subside. By 5 days, most of the effects have disappeared, but some may persist for months. In the case of [meperidine](#), the withdrawal syndrome largely subsides within 24 hours, whereas with [methadone](#) several days are required to reach the peak of the abstinence syndrome, and it may last as long as 2 weeks. The slower subsidence of [methadone](#) effects is associated with a less intense immediate syndrome, and this is the basis for its use in the detoxification of heroin addicts. However, despite the loss of physical dependence on the opioid, craving for it may persist. In addition to [methadone](#), [buprenorphine](#) and the  $\alpha_2$  agonist [clonidine](#) are FDA-approved treatments for opioid analgesic detoxification (see [Chapter 32](#)).

A transient, explosive abstinence syndrome—**antagonist-precipitated withdrawal**—can be induced in a subject physically dependent on opioids by administering [naloxone](#), another antagonist, or even a partial  $\mu$  agonist such as [buprenorphine](#). Within seconds to minutes after injection of the antagonist [naloxone](#), signs and symptoms similar to those seen after abrupt discontinuance appear, peaking in 10–20 minutes and largely subsiding after 1 hour. Even in the case of [methadone](#), the antagonist-precipitated abstinence syndrome may be very severe.

In the case of agents with mixed effects, withdrawal signs and symptoms can be induced after repeated administration followed by abrupt discontinuance of [pentazocine](#), cyclazocine, or nalorphine, but the syndrome appears to be somewhat different from that produced by [morphine](#) and other agonists. Anxiety, loss of appetite and body weight, tachycardia, chills, increase in body temperature, and abdominal cramps have been noted.

### 3. Addiction

As defined by the American Society of Addiction Medicine, addiction is a primary, chronic disease of brain reward, motivation, memory, and related circuitry. Dysfunction in these circuits leads to characteristic biologic, psychological, and social manifestations. This is reflected in an individual's pathologic pursuit of reward and relief through substance use and other behaviors. Addiction is characterized by inability to abstain, impairment in behavioral control exhibited by a compulsion to use, craving, diminished recognition of significant problems with one's behaviors and interpersonal relationships, use despite consequences, and a dysfunctional emotional response (see [Chapter 32](#)).

The risk of inducing dependence and, potentially, addiction is clearly an important consideration in the therapeutic use of opioid drugs. Although opioids administered to treat acute painful conditions such as trauma or surgical intervention are widely accepted as effective, recent reports suggest that even brief perioperative exposures can increase the risk of long-term use. Therefore, certain principles should be observed by the clinician to minimize the potential harm presented by opioid-induced respiratory depression, dependence, misuse, or abuse:

- Consider using nonopioid analgesics whenever possible. Especially in chronic management, consider using other types of analgesics or compounds exhibiting less pronounced withdrawal symptoms on discontinuance.
- Frequently evaluate continuing analgesic therapy and the patient's need for opioids.
- Establish therapeutic goals before starting opioid therapy. This tends to limit the potential for physical dependence. The patient and his or her family should be included in this process.
- Once an effective dose is established, attempt to limit dosage to this level. This goal is facilitated by use of a written treatment contract that specifically prohibits early refills and having multiple prescribing physicians.
- Discuss the rights, responsibilities, and roles of patients and providers regarding controlled substances. Educate about safe opioid storage and disposal. Difficult decisions may need to be made about availability and use of opioid reversal medication ([naloxone](#)) for overdose, the proposed duration of opioid therapy, and the need for tapering or discontinuing opioid therapy.

### B. Diagnosis and Treatment of Opioid Overdosage

Intravenous injection of [naloxone](#) dramatically reverses coma due to opioid overdose but not that due to other CNS depressants. Use of the antagonist should not, of course, delay the institution of other therapeutic measures, especially respiratory support. (See also [The Opioid Antagonists](#), below, and [Chapter 58](#).) The initial epidemic of prescription opioid overuse has been accompanied by an increase in heroin-related deaths and now an even greater wave of overdose deaths in the United States driven by synthetics such as [fentanyl](#). For this reason, attention is being directed to make

**naloxone** via intranasal and intramuscular routes widely available, including as over-the-counter formulations. With ever-increasing rates of ultrapotent synthetic opioids such as fentanyl-laced products illicitly being distributed in the USA, repeated doses of **naloxone** may be needed, with 10-fold higher doses, to reverse respiratory depression.

### C. Contraindications and Cautions in Therapy

#### 1. Use of pure agonists with weak partial agonists

When a weak partial agonist such as **pentazocine** is given to a patient also receiving a full agonist (eg, **morphine**), there is a risk of diminishing analgesia or even inducing a state of withdrawal; thus combining a full agonist with partial agonist opioids should be avoided.

#### 2. Use in patients with head injuries

Carbon dioxide retention caused by respiratory depression results in cerebral vasodilation. In patients with elevated intracranial pressure, this may lead to lethal alterations in brain function.

#### 3. Use during pregnancy

In pregnant women who are chronically using opioids, the fetus may become physically dependent in utero and manifest withdrawal symptoms in the early postpartum period. Daily doses of heroin, **fentanyl**, and/or polysubstance exposure taken by the mother can result in a withdrawal syndrome in the infant, including irritability, shrill crying, diarrhea, or even seizures. As a result of the opioid epidemic in the USA and other countries, the incidence of these events has dramatically increased. Recognition of the condition known as neonatal abstinence syndrome (NAS) is aided by a careful history, physical examination, and use of validated tools and severity scales. Treatment protocols have evolved and include symptom-based treatment guidelines ranging from increased nonpharmacologic approaches to opioid replacement therapy with **morphine** or possibly **methadone** or **buprenorphine**. Nonopioid adjuncts such as **clonidine** also have been utilized with positive effect. NAS care plans may also need modification given the possibility of neonatal exposure to multiple nonopioid drugs from the mother.

#### 4. Use in patients with impaired pulmonary function

In patients with borderline respiratory reserve, the depressant properties of the opioid analgesics may lead to acute respiratory failure.

#### 5. Use in patients with impaired hepatic or renal function

Because **morphine** and its congeners are metabolized primarily in the liver, their use in patients in prehepatic coma may be questioned. Half-life is prolonged in patients with impaired renal function, and **morphine** and its active glucuronide metabolite may accumulate; dosage can often be reduced in such patients.

#### 6. Use in patients with endocrine disease

Patients with adrenal insufficiency (Addison disease) and those with hypothyroidism (myxedema) may have prolonged and exaggerated responses to opioids.

### Drug Interactions

Because seriously ill or hospitalized patients may require a large number of drugs, there is always a possibility of drug interactions when the opioid analgesics are administered. [Table 31-5](#) lists some of these drug interactions and the reasons for not combining the named drugs with opioids.

**Opioid drug interactions.**

Drug Group	Interaction with Opioids
Sedative-hypnotics	Increased central nervous system depression, particularly respiratory depression.
Antipsychotic agents	Increased sedation. Variable effects on respiratory depression. Accentuation of cardiovascular effects (antimuscarinic and $\alpha$ -blocking actions).
Monoamine oxidase inhibitors	Relative contraindication to all opioid analgesics and antitussives because of the high incidence of hyperpyrexia; hypertension also has been reported.

## SPECIFIC AGENTS

The following section describes the most important and widely used opioid analgesics, along with features peculiar to specific agents. Data about doses approximately equivalent to 10 mg of intramuscular **morphine**, oral versus parenteral efficacy, duration of analgesia, and intrinsic activity (maximum efficacy) are presented in [Table 31-2](#).

### STRONG AGONISTS

#### Phenanthrenes

**Morphine**, **hydromorphone**, and **oxycodone** are strong agonists useful in treating severe pain. These prototypic agents have been described in detail above.

**Morphine**

**Heroin** (**diamorphine**, diacetylmorphine) is potent and fast-acting, but its use is prohibited in the USA and Canada. Double-blind studies have not supported the claim that heroin is more effective than **morphine** in relieving severe pain, at least when given by the intramuscular route.

#### Phenylheptylamines

**Methadone** has undergone a dramatic revival as a potent and clinically useful analgesic. It can be administered by the oral, intravenous, subcutaneous and rectal routes. It is well absorbed from the gastrointestinal tract, and its bioavailability, although variable, far exceeds that of oral **morphine**.

**Methadone**

**Methadone** is not only a potent  $\mu$ -receptor agonist but its racemic mixture of D- and L-methadone isomers can also block both NMDA receptors and monoaminergic reuptake transporters. These nonopioid receptor properties may help explain its ability to relieve difficult-to-treat pain (neuropathic, cancer pain), especially when a previous trial of **morphine** has failed. In this regard, when analgesic tolerance or intolerable side effects have developed with the use of increasing doses of **morphine** or **hydromorphone** in progressive cancer pain, “opioid rotation” to **methadone** has provided superior analgesia at 10–20% of the morphine-equivalent daily dose. In contrast to its use in suppressing symptoms of opioid withdrawal, use of **methadone** as an analgesic typically requires administration at more frequent intervals (eg, 8 hours). However, given **methadone**’s highly variable pharmacokinetics and long half-life (~25–52 hours), the initial administration period (loading phase) should be closely monitored to avoid potentially harmful adverse effects, especially respiratory depression. Because **methadone** is metabolized by CYP2B6 and CYP3A4 isoforms in the liver, inhibition of its metabolic pathway or hepatic dysfunction has also been associated with overdose effects, including respiratory depression or prolonged QT-based cardiac arrhythmias.

**Methadone** has been widely used in the treatment of opioid use disorders. Tolerance and physical dependence develop more slowly with **methadone** than with **morphine**. The withdrawal signs and symptoms occurring after abrupt discontinuance of **methadone** are often milder, although more prolonged, than those of **morphine**. In many cases, these properties make **methadone** a useful drug for detoxification and for maintenance of chronic relapsing opioid use disorder.

For detoxification of a heroin-dependent person, low doses of **methadone** (5–10 mg orally) have been given two or three times daily for 2 or 3 days to lessen the subsequent withdrawal syndrome.

For maintenance therapy of the opioid recidivist, tolerance to 50–100 mg/d of oral **methadone** may be deliberately produced; in this state, opioid craving is diminished and there is a cross-tolerance to heroin to limit the addiction-reinforcing effects of heroin. One rationale of maintenance programs is that blocking the reinforcement obtained from illicit opioids removes the drive to obtain them, thereby reducing criminal activity and making the user more amenable to psychiatric and rehabilitative therapy. The pharmacologic basis for the use of **methadone** in maintenance programs is sound, and the sociologic basis is rational.

The concurrent administration of **methadone** to heroin addicts known to be recidivists has been questioned because of the increased risk of overdose death secondary to respiratory arrest. As the number of patients prescribed **methadone** for persistent pain has increased, so, too, has the incidence of accidental overdose and complications related to respiratory depression. Variability in **methadone** metabolism, protein binding, distribution, and nonlinear opioid dose conversion all play a role in adverse events. **Buprenorphine**, a partial  $\mu$ -receptor agonist with long-acting properties, has been found to be effective in opioid detoxification and maintenance programs and is associated with a lower risk of such overdose fatalities. To increase the access of persons with OUD, in the USA, a provider with a controlled substance DEA license may prescribe **buprenorphine** for OUD.

With the increase in access and legalization of cannabis products in many states in the USA, some authorities have suggested the use of cannabis as a treatment for OUD or to facilitate tapering of opioids. However, there is no strong evidence to support these proposals.

## Phenylpiperidines

**Fentanyl** is one of the most widely used agents in the family of synthetic opioids. The **fentanyl** subgroup now includes **sufentanil**, **alfentanil**, and **remifentanyl** in addition to the parent compound, **fentanyl**. An extremely potent analog, **carfentanyl**, is used in veterinary medicine for sedating large mammals, eg, elephants. Adulteration of street heroin and counterfeit prescription analgesic pills with **fentanyl**, carfentanyl, or related synthetics

**Fentanyl**

Among the phenylpiperidines, these opioids differ mainly in their potency and biodisposition. **Sufentanil** is five to seven times more potent than **fentanyl**. **Carfentanil** is approximately 100 times more potent than **fentanyl**. **Alfentanil** is considerably less potent than **fentanyl** but acts more rapidly and has a markedly shorter duration of action. **Remifentanil** is metabolized very rapidly by blood and nonspecific tissue esterases, making its pharmacokinetic and pharmacodynamic half-lives extremely short. Such properties are useful when these compounds are used in anesthesia practice. Although **fentanyl** is now the predominant analgesic in the phenylpiperidine class, **meperidine** continues to be used. This older opioid has significant antimuscarinic effects, which may be a contraindication if tachycardia would be a problem. **Meperidine** is also reported to have a negative inotropic action on the heart. In addition, it has the potential for producing seizures secondary to accumulation of its metabolite, normeperidine, in patients receiving high doses or with concurrent renal failure. Given this undesirable profile, use of **meperidine** as a first-line analgesic is becoming increasingly rare.

## Morphinans

**Levorphanol** is a synthetic opioid analgesic closely resembling **morphine** and has  $\mu$ -,  $\delta$ -, and  $\kappa$ -opioid agonist actions, serotonin-norepinephrine reuptake inhibition, and NMDA receptor antagonist properties.

## MILD TO MODERATE AGONISTS

### Phenanthrenes

**Codeine**, **dihydrocodeine**, and **hydrocodone** have lower binding affinity to  $\mu$ -opioid receptors than **morphine** and often have adverse effects that limit the maximum tolerated dose when one attempts to achieve analgesia comparable to that of **morphine**.

**Oxycodone** is more potent and is prescribed alone in higher doses as immediate-release or controlled-release forms for the treatment of moderate to severe pain. Combinations of **hydrocodone** or **oxycodone** with **acetaminophen** are the predominant formulations of orally administered analgesics in the United States for the treatment of mild to moderate pain. Since each controlled-release tablet of **oxycodone** contains a large quantity of **oxycodone** to allow for prolonged action, those intent on abusing the old formulation have extracted crushed tablets and injected high doses, resulting in misuse and possible fatal overdose. In 2010, the FDA approved a new formulation of the controlled-release form of **oxycodone** that reportedly prevents the tablets from being cut, broken, chewed, crushed, or dissolved to release more **oxycodone**. It is hoped that this new formulation will lead to less misuse by snorting or injection. The FDA is now requiring a Risk Evaluation and Mitigation Strategy (REMS) that will include the issuance of a medication guide to patients and a requirement for prescriber education regarding the appropriate use of opioid analgesics in the treatment of pain. (See Box: [Educating Opioid Prescribers.](#))

Codeine

### Phenylheptylamines

**Propoxyphene** is chemically related to **methadone** but has extremely low analgesic activity. Its low efficacy makes it unsuitable, even in combination with **aspirin**, for severe pain. The increasing incidence of deaths associated with its use and misuse caused it to be withdrawn in the United States.

### Phenylpiperidines

**Diphenoxylate** and its metabolite, **difenoxin**, are not used for analgesia but for the treatment of diarrhea. They are scheduled for minimal control (difenoxin is Schedule IV or V, depending on formulation; diphenoxylate Schedule V; see inside front cover) because the likelihood of their misuse is remote. The poor solubility of the compounds limits their use for parenteral injection. As antidiarrheal drugs, they are used in combination with **atropine**. The **atropine** is added in a concentration too low to have a significant antidiarrheal effect but is presumed to further reduce the likelihood of misuse.

**Loperamide** is a phenylpiperidine derivative used to control diarrhea. Due to action on peripheral  $\mu$ -opioid receptors and lack of effect on CNS receptors, investigations are ongoing as to whether it could be an effective analgesic. Its potential for misuse is considered very low because of its limited access to the brain. It is therefore available without a prescription.

The usual dose with all of these antidiarrheal agents is two tablets to start and then one tablet after each diarrheal stool.

## OPIOIDS WITH MIXED RECEPTOR ACTIONS

Partial agonists may be used in situations where patients may benefit from the profile of the drug compared with full agonists. An example would be for patients who find full  $\mu$  agonists to be too “strong” and therefore prefer a partial agonist. Care should be taken to administer any partial agonist or drug with mixed opioid receptor actions to patients receiving pure opioid agonists because of the unpredictability of both drugs’ effects; reduction of analgesia or precipitation of an explosive abstinence syndrome may result.

### Phenanthrenes

As noted above, **buprenorphine** is a potent and long-acting phenanthrene derivative that is a partial  $\mu$ -receptor agonist (low intrinsic activity) and an *antagonist* at the  $\delta$  and  $\kappa$  receptors and is therefore referred to as a mixed agonist-antagonist. Although **buprenorphine** is used as an analgesic, it can antagonize the action of more potent  $\mu$  agonists such as **morphine**. **Buprenorphine** also binds to ORL1, the orphanin receptor. Whether this property also participates in opposing  $\mu$  receptor function is under study. Administration by the sublingual route is preferred to avoid significant first-pass effect. **Buprenorphine**’s long duration of action is due to its slow dissociation from  $\mu$  receptors. This property renders its effects resistant to **naloxone** reversal. **Buprenorphine** was approved by the FDA in 2002 for the management of opioid dependence, and studies suggest it is as effective as **methadone** for the management of opioid withdrawal and detoxification in programs that include counseling, psychosocial support, and direction by physicians qualified under the Drug Addiction Treatment Act. In the USA, a special Drug Enforcement Administration (DEA) waiver and training were needed to legally prescribe **buprenorphine** for addiction. In contrast to **methadone**, high-dose administration of **buprenorphine** results in a  $\mu$ -opioid *antagonist* action, limiting its properties of analgesia and respiratory depression. However, **buprenorphine** formulations can still cause serious respiratory depression and death, particularly when extracted and injected intravenously in combination with benzodiazepines or used with other CNS depressants (ie, sedatives, antipsychotics, or **alcohol**). **Buprenorphine** is also available combined with **naloxone**, a pure  $\mu$ -opioid antagonist (as Suboxone), to help prevent its diversion for illicit intravenous misuse. A slow-release transdermal patch preparation that releases drug over a 1-week period also is available (Butrans). The FDA has also approved an implanted **buprenorphine** rod (Probuphine) that lasts for 6 months and is meant to

The management of acute postsurgical pain may be challenging in the patient who is on chronic **buprenorphine**, as its high affinity for the  $\mu$ -opioid receptor may render commonly used opioid agonists ineffective for pain management. The current recommendation is for these patients to continue their **buprenorphine** and employ nonopioid modalities to the greatest degree while educating patients on expectations. In certain cases where the surgical intervention is expected to result in severe postoperative pain not manageable with ongoing **buprenorphine**, a supervised reduction by tapering the dose may be indicated prior to surgery but rarely if ever should be stopped. Taken together, higher doses of opioids may be needed in situations where pain is severe and concurrent regional anesthetic techniques (nerve blocks) are not available. Patients need to be monitored for risk of relapse and ideally be followed closely by an addiction medicine specialist or counselor.

**Kratom**, an extract from the leaves of *Mitragyna speciosa*, has come into public view with various claims of its efficacy in opioid tapering or opioid replacement therapy. Although very limited preclinical research on its component alkaloids, mitragynine and 7-hydroxymitragynine, suggests that they can act as partial  $\mu$ -receptor agonists, a multitude of other effects and harms have been associated with kratom (*Salmonella* bacterial poisoning, hallucinations, seizures, coma, and death). Given the lack of proven benefit and increasing reports of harm, kratom is not considered either safe or effective. Nevertheless, additional studies on kratom may reveal important mechanistic insights useful for future therapeutic development.

**Pentazocine** (a benzomorphan) and **nalbuphine** are other examples of opioid analgesics with mixed agonist-antagonist properties. **Nalbuphine** is a strong  $\kappa$ -receptor *agonist* and a partial  $\mu$ -receptor *antagonist*; it is given parenterally. At higher doses there seems to be a definite ceiling—not noted with morphine—to the respiratory depressant effect. Unfortunately, when respiratory depression does occur, it may be relatively resistant to **naloxone** reversal due to its greater affinity for the receptor than **naloxone**. **Nalbuphine** is equipotent to **morphine** for analgesia and, at lower doses, can sometimes be effective for pruritus caused by opioids and nonopioids.

## Morphinans

**Butorphanol** produces analgesia equivalent to **nalbuphine** but appears to produce more sedation at equianalgesic doses. **Butorphanol** is considered to be predominantly a  $\kappa$  agonist. However, it may also act as a partial agonist or antagonist at the  $\mu$  receptor.

## Benzomorphans

**Pentazocine** is a  $\kappa$  agonist with weak  $\mu$ -antagonist or partial agonist properties. It is the oldest mixed agent available. It may be used orally or parenterally. However, because of its irritant properties, the injection of **pentazocine** subcutaneously is not recommended.

## MISCELLANEOUS

**Tramadol** is a centrally acting analgesic whose mechanism of action is also dependent on the ability of the parent drug and its metabolites to block serotonin and **norepinephrine** reuptake. Because its analgesic effect is only weakly antagonized by **naloxone**, it is thought to depend less on its low-affinity binding to the  $\mu$  receptor for therapeutic activity. The recommended dosage is 50–100 mg orally four times daily; however, its systemic concentration and analgesic effect are dependent on its variable metabolism by CYP2D6 polymorphisms. Toxicity includes association with seizures; the drug is relatively contraindicated in patients with a history of epilepsy and for use with other drugs that lower the seizure threshold. Another serious risk is the development of serotonin syndrome, especially if selective serotonin reuptake inhibitor antidepressants are being administered (see [Chapter 16](#)). Other adverse effects include nausea and dizziness, but these symptoms typically abate after several days of therapy. No clinically significant effects on respiration or the cardiovascular system have thus far been reported when used as monotherapy. Given the fact that the analgesic action of **tramadol** is largely independent of  $\mu$ -receptor action, **tramadol** has been considered as an adjunct in the treatment of neuropathic pain; however, this is based on low-quality studies of short duration.

**Tapentadol** is an analgesic with modest  $\mu$ -opioid receptor affinity and significant **norepinephrine** reuptake-inhibiting action. In animal models, its analgesic effects were only moderately reduced by **naloxone** but strongly reduced by an  $\alpha_2$ -adrenoceptor antagonist. Furthermore, its binding to the **norepinephrine** transporter (NET, see [Chapter 6](#)) was stronger than that of **tramadol**, whereas its binding to the serotonin transporter (SERT) was less than that of **tramadol**. **Tapentadol** was approved in 2008 and has been shown to be as effective as **oxycodone** in the treatment of moderate to severe pain but with a reduced profile of gastrointestinal complaints such as nausea. Clinical studies are ongoing to determine if the lack of active metabolites and lower risk of serotonin syndrome with **tapentadol** will translate to an improvement in analgesia with reduced adverse effects.

The opioid analgesics are among the most effective drugs available for the suppression of cough. This effect is often achieved at doses below those necessary to produce analgesia. The receptors involved in the antitussive effect appear to differ from those associated with the other actions of opioids. For example, the antitussive effect is also produced by stereoisomers of opioid molecules that are devoid of analgesic effects and addiction liability (see below).

The physiologic mechanism of cough is complex, and little is known about the specific mechanism of action of the opioid antitussive drugs. It appears likely that both central and peripheral effects play a role.

The opioid derivatives most commonly used as antitussives are **dextromethorphan**, **codeine**, **levopropoxyphene**, and **noscapine** (levopropoxyphene and noscapine are not available in the USA). They should be used with caution in patients taking monoamine oxidase inhibitors (see [Table 31-5](#)). Antitussive preparations usually also contain expectorants to thin and liquefy respiratory secretions. Importantly, due to increasing reports of death in young children taking **dextromethorphan** in formulations of over-the-counter “cold/cough” medications, its use in children younger than 6 years of age has been banned by the FDA. Moreover, because of variations in the metabolism of **codeine**, its use for any purpose in young children is being reconsidered.

**Dextromethorphan** is the dextrorotatory stereoisomer of a methylated derivative of **levorphanol**. It is purported to be free of addictive properties and produces less constipation than **codeine**. The usual antitussive dose is 15–30 mg three or four times daily. It is available in many over-the-counter products. **Dextromethorphan** has also been found to enhance the analgesic action of **morphine** and presumably other  $\mu$ -receptor agonists. However, misuse of its purified (powdered) form has been reported to lead to serious adverse events including death.

**Codeine**, as noted, has a useful antitussive action at doses lower than those required for analgesia. Thus, 15 mg is usually sufficient to relieve cough.

Levopropoxyphene is the stereoisomer of the weak opioid agonist dextropropoxyphene. It is devoid of opioid effects, although sedation has been described as a side effect. The usual antitussive dose is 50–100 mg every 4 hours.

## THE OPIOID ANTAGONISTS

The pure opioid antagonist drugs **naloxone**, **naltrexone**, and **nalmefene** are **morphine** derivatives with bulkier substituents at the N<sub>17</sub> position.

These agents have a relatively high affinity for  $\mu$ -opioid binding sites. They have lower affinity for the other receptors but can also reverse agonists at  $\delta$  and  $\kappa$  sites.

**Naloxone**

### Pharmacokinetics

**Naloxone** is usually given by injection and has a short duration of action (1–2 hours) when given by this route. Metabolic disposition is chiefly by glucuronide conjugation like that of the agonist opioids with free hydroxyl groups. **Naltrexone** is well absorbed after oral administration but may undergo rapid first-pass metabolism. It has a half-life of 10 hours, and a single oral dose of 100 mg blocks the effects of injected heroin for up to 48 hours. Nalmefene, the newest of these agents, is a derivative of **naltrexone** but is available only for intravenous administration. Like **naloxone**, nalmefene is used for opioid overdose but has a longer half-life (8–10 hours).

### Pharmacodynamics

When given intravenously to a morphine-treated subject, the antagonist completely and dramatically reverses the opioid effects within 1–3 minutes. In individuals who are acutely depressed by an overdose of an opioid, the antagonist effectively normalizes respiration, level of consciousness, pupil size, bowel activity, and awareness of pain. In dependent subjects who appear normal while taking opioids, **naloxone** or **naltrexone** almost instantaneously precipitates an abstinence syndrome.

There is no tolerance to the antagonistic action of these agents, nor does withdrawal after chronic administration precipitate an abstinence syndrome.

### Clinical Use

**Naloxone** is a pure antagonist and is preferred over older weak agonist-antagonist agents that had been used primarily as antagonists, eg, nalorphine and levallorphan.

The major application of **naloxone** is in the treatment of acute opioid overdose (see also [Chapter 58](#)). *It is very important that the relatively short duration of action of naloxone be borne in mind, because a severely depressed patient may recover after a single dose of naloxone and appear normal, only to relapse into coma after 1–2 hours.*

The usual initial dose of **naloxone** is 0.1–0.4 mg intravenously for life-threatening respiratory and CNS depression. Maintenance is with the same drug, 0.4–0.8 mg given intravenously, and repeated as needed—or provided as a continuous infusion under monitored conditions. Multiple doses of **naloxone** in excess of 0.8 mg per dose have been required to reverse respiratory depression induced by overdose of illicit **fentanyl** and its analogs. In using **naloxone** in the severely opioid-depressed newborn, it is important to start with doses of 5–10 mcg/kg and to consider a second dose of up to a total of 25 mcg/kg if no response is noted.

Low-dose **naloxone** (0.04 mg) has an increasing role in the treatment of adverse effects that are commonly associated with intravenous or epidural opioids. Careful titration of the **naloxone** dosage can often eliminate the itching, nausea, and vomiting while sparing the analgesia. For this purpose, oral **naloxone**, and modified analogs of **naloxone** and **naltrexone**, have been approved by the FDA. Analogs include **methylnaltrexone bromide** and **naldemedine** for the treatment of constipation in patients with opioid-induced constipation (OIC) with chronic noncancer pain and late-stage advanced illness—and **naloxegol**, **naldemedine**, and **alvimopan** for the treatment of postoperative ileus following bowel resection surgery. **Methylnaltrexone** has a quaternary amine preventing it from crossing the blood-brain barrier. **Naloxegol** is pegylated **naloxone**, which limits penetration into the CNS and through peripheral  $\mu$ -antagonism mitigates constipation. **Naldemedine** and **alvimopan** are considered peripheral  $\mu$ -receptor antagonists. The principal mechanism for the selective therapeutic effect of these agents is peripheral enteric  $\mu$ -receptor antagonism with minimal CNS penetration.

Because of its long duration of action, **naltrexone** has been proposed as a maintenance drug for addicts in treatment programs. A single dose given on alternate days blocks virtually all of the effects of a dose of heroin. More recently, a depot formulation of **naltrexone** has been developed offering extended release over weeks to months. There is evidence that **naltrexone** decreases the craving for **alcohol** in chronic alcoholics by increasing baseline  $\beta$ -endorphin release, and it has been approved by the FDA for this purpose (see [Chapter 23](#)). **Naltrexone** also facilitates abstinence from **nicotine** (cigarette smoking) with reduced weight gain. In fact, a combination of **naltrexone** plus **bupropion** ([Chapter 16](#)) may also offer an effective and synergistic strategy for weight loss.

### SUMMARY Opioids, Opioid Substitutes, and Opioid Antagonists

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities
OPIOID AGONISTS				
<ul style="list-style-type: none"> <li>Morphine</li> <li>Methadone</li> <li>Fentanyl</li> </ul>	Strong $\mu$ -receptor agonists • variable affinity for $\delta$ and $\kappa$	Analgesia • relief of anxiety • sedation • slowed	Severe pain • adjunct in anesthesia ( <b>fentanyl</b> , <b>morphine</b> ) • pulmonary edema ( <b>morphine</b> only) • maintenance	First-pass effect • duration 1–4 h except <b>methadone</b> , 4–6 h • Toxicity: Respiratory depression • severe

- *Hydromorphone, oxycodone*: Like *morphine* in efficacy, but higher potency

- *Meperidine*: Strong agonist with anticholinergic effects

- *Oxycodone*: Dose-dependent analgesia

- *Sufentanil, alfentanil, remifentanil*: Like *fentanyl* but shorter durations of action

- *Carfentanil*: Like *fentanyl* but much more potent

- **Codeine**
- **Hydrocodone**

Less efficacious than *morphine* • can antagonize strong agonists

Like strong agonists • weaker effects

Mild-moderate pain • cough (**codeine**)

Like strong agonists, toxicity dependent on genetic variation of metabolism

### MIXED OPIOID AGONIST-ANTAGONISTS

- **Buprenorphine**

Partial  $\mu$  agonist •  $\kappa$  antagonist

Like strong agonists but can antagonize their effects • also reduces craving for **alcohol**

Moderate pain • some maintenance rehabilitation programs

Long duration of action 4–8 h • may precipitate abstinence syndrome

- **Nalbuphine**

$\kappa$  Agonist •  $\mu$  antagonist

Similar to **buprenorphine**

Moderate pain

Like **buprenorphine**

### ANTITUSSIVES

- **Dextromethorphan**

Poorly understood but strong and partial  $\mu$  agonists are also effective antitussives

Reduces cough reflex • **dextromethorphan**, levopropoxyphene not analgesic

Acute debilitating cough

Duration 30–60 min • *Toxicity*: Minimal when taken as directed

- *Codeine, levopropoxyphene*: Similar to **dextromethorphan** in antitussive effect

### OPIOID ANTAGONISTS

- **Naloxone**

Antagonist at  $\mu$ ,  $\delta$ , and  $\kappa$  receptors

Rapidly antagonizes all opioid effects

Opioid overdose

Duration 1–2 h (may have to be repeated when treating overdose) • *Toxicity*: Precipitates abstinence syndrome in dependent users

- *Naltrexone, nalmefene*: Like **naloxone** but longer durations of action (10 h); **naltrexone** is used in maintenance programs and can block heroin effects for up to 48 h; **naltrexone** is also used for **alcohol** and **nicotine** dependence; when combined with **bupropion**, may be effective in weight-loss programs

### OTHER ANALGESICS USED IN MODERATE PAIN

• <a href="#">Tapentadol</a>	Moderate $\mu$ agonist, strong NET inhibitor	Analgesia	Moderate pain	Duration 4–6 h • <i>Toxicity</i> : Headache; nausea and vomiting; possible dependence
• <a href="#">Tramadol</a>	Mixed effects: weak $\mu$ agonist, moderate SERT inhibitor, weak NET inhibitor	Analgesia	Moderate pain • adjunct to opioids in chronic pain syndromes	Duration 4–6 h • <i>Toxicity</i> : Seizures • risk of serotonin syndrome

NET, [norepinephrine](#) reuptake transporter; SERT, serotonin reuptake transporter.

### PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
<b>ANALGESIC OPIOIDS</b>	
<a href="#">Alfentanil</a>	Generic, Alfenta
<a href="#">Buprenorphine</a>	Buprenex, others, Butrans (transdermal)
<a href="#">Butorphanol</a>	Generic, Stadol, Stadol NS (nasal)
<a href="#">Codeine</a> (sulfate or phosphate)	Generic
<a href="#">Fentanyl</a>	Generic, Duragesic (transdermal); <a href="#">Fentanyl</a> Buccal, <a href="#">Fentanyl</a> Actiq (lozenge)
<a href="#">Hydromorphone</a>	Generic, Dilaudid, others
<a href="#">Levomethadyl acetate</a>	Orlaam
<a href="#">Morphine sulfate</a>	
Oral, rectal, parenteral	Generic
Oral sustained-release capsules	Avinza, Kadian
Oral extended-release capsules ( <a href="#">morphine sulfate</a> / <a href="#">naltrexone</a> HCl)	Embeda

Codeine	Generic, Nubain
Oxycodone	Generic, OxyContin (sustained release)
Oxymorphone	Generic, Numorphan, others
Pentazocine	Talwin
Remifentanil	Generic, Ultiva
Sufentanil	Generic, Sufenta
<b>OTHER ANALGESICS</b>	
Tapentadol	Nucynta
Tramadol	Generic, Ultram, others
Ziconotide	Prialt
<b>ANALGESIC COMBINATIONS‡</b>	
Codeine/acetaminophen	Generic, Tylenol with Codeine, others
Codeine/aspirin	Generic, Empirin Compound, others
Hydrocodone/acetaminophen	Generic, Norco, Vicodin, Lortab, others
Hydrocodone/ibuprofen	Vicoprofen
Oxycodone/acetaminophen	Generic, Percocet, Tylox, others
Oxycodone/aspirin	Generic, Percodan
<b>OPIOID ANTAGONISTS</b>	
Alvimopan	Entereg
Methylnaltrexone	Relistor
Naldemedine	Symproic
Nalmefene	Revex
Naloxone	Generic, Narcan
Naltrexone	Generic, ReVia, Depade, Vivitrol
<b>ANTITUSSIVES</b>	
Codeine	Generic

\*Antidiarrheal opioid preparations are listed in [Chapter 62](#).

†Orphan drug approved only for the treatment of narcotic addiction.

‡Dozens of combination products are available; only a few of the most commonly prescribed are listed here. [Codeine](#) combination products available in several strengths are usually denoted No. 2 (15 mg [codeine](#)), No. 3 (30 mg [codeine](#)), and No. 4 (60 mg [codeine](#)). Prescribers should be aware of the possible danger of renal and hepatic injury with [acetaminophen](#), [aspirin](#), and nonsteroidal anti-inflammatory drugs contained in these analgesic combinations.

### CASE STUDY ANSWER

In this case of severe pain following a traumatic fall, treatment may require the administration of a potent intravenous opioid analgesic such as [morphine](#), [hydromorphone](#), or [fentanyl](#); however, concurrent use of nonopioid analgesics (such as [ketamine](#)) and other nonopioid multimodal analgesic strategies (NSAIDs) often reduce or eliminate opioid requirements and risk of respiratory failure. Given the history of obstructive sleep apnea, before an additional dose of an opioid analgesic is administered, it is expected that the patient will require frequent reevaluation of both the severity of his pain and the presence of potential adverse effects. Reevaluation of his level of consciousness, respiratory rate, fractional [oxygen](#) saturation, and other vital parameters can help achieve the goal of pain relief and minimize respiratory depression. Concurrent use of sedative agents such as benzodiazepines should be avoided if possible as they greatly increase the risk of respiratory depression, obstruction, and failure.

## Chapter 32: Drugs of Abuse

Christian Lüscher

### CASE STUDY

#### CASE STUDY

A 15-year-old high school student was brought to the emergency department after his parents found him in his room staring at the ceiling and visibly frightened. Earlier that evening, he attended a party but was depressed because his girlfriend just broke up with him. His parents are also worried about a change in his behavior over the last few months. He is failing this year at school and has stopped playing soccer. He has lost interest in school, at times seems depressed, and tells his parents that his pocket money is not sufficient.

When questioned by the intern, he reports that space-cookies were served at the party. He also says that smoking marijuana has become a habit (three to four joints a week) but denies consumption of [alcohol](#) and other drugs.

How do you explain the state he was found in? What is the difference between hashish and marijuana? What may be the link to his poor performance at school? Do all drug users necessarily use several drugs?

Drugs are abused (used in ways that are not medically approved) because they cause strong feelings of euphoria. However, repetitive exposure induces widespread adaptive changes in the brain. As a consequence, drug use may become compulsive—the hallmark of addiction.

## BASIC NEUROBIOLOGY OF DRUG ABUSE

### DEPENDENCE VERSUS ADDICTION

There is a conceptual and mechanistic separation of “dependence” and “addiction.” The older term “physical dependence” is now denoted as **dependence**, whereas “psychological dependence” is more simply called **addiction**.

Every addictive drug causes its own characteristic spectrum of acute effects, but they all induce strong feelings of euphoria and reward. With repetitive exposure, addictive drugs induce adaptive changes such as tolerance (ie, escalation of dose to maintain effect). Once the abused drug is no longer available, signs of withdrawal become apparent. A combination of such signs, referred to as the **withdrawal syndrome**, defines *dependence*. Dependence is not always a correlate of drug abuse—it can also occur with many classes of nonpsychoactive drugs, eg, sympathomimetic vasoconstrictors and bronchodilators, and organic nitrate vasodilators. *Addiction*, on the other hand, consists of compulsive, relapsing drug use despite negative consequences, at times triggered by cravings that occur in response to contextual cues (see Box: [Animal Models in Addiction Research](#)). Although dependence invariably occurs with chronic exposure, only a small percentage of subjects develop a compulsion, lose control, and become addicted. For example, very few patients who receive opioids as analgesics desire the drug after withdrawal. And only one person out of six becomes addicted within 10 years of first use of [cocaine](#). Conversely, relapse is very common in addicts after a successful withdrawal when, by definition, they are no longer dependent.

Many of the recent advances in addiction research have been made possible by the use of animal models. Since drugs of abuse are not only rewarding but also reinforcing, an animal will learn a behavior (eg, press a lever) when paired with drug administration. In such a self-administration paradigm, the number of times an animal is willing to press the lever in order to obtain a single dose reflects the strength of reinforcement and is therefore a measure of the motivation of the animal. Observing withdrawal signs specific for rodents (eg, escape jumps or “wet-dog” shakes after abrupt termination of chronic **morphine** administration) allows the quantification of dependence. When this aversive state is avoided, negative reinforcement may result (ie, the individual takes the drug to avoid withdrawal). Behavioral tests for addiction in rodents certainly do not capture the complexity of the disease. However, it is possible to model *core components* of addiction, for example, by monitoring behavioral sensitization and conditioned place preference. In the first test, an increase in locomotor activity is observed with intermittent drug exposure and may reflect enhanced incentive saliency. The latter tests for the preference of a particular environment associated with drug exposure by measuring the time an animal spends in the compartment where a drug was received compared with the compartment where only saline was injected (conditioned place preference). Both tests have in common that they are sensitive to cue-conditioned effects of addictive drugs. Subsequent exposures to the environment without the drug lead to extinction of the place preference, which can be reinstated with a low dose of the drug or the presentation of a conditioned stimulus. These persistent changes serve as a model of relapse and have been linked to synaptic plasticity of excitatory transmission in the ventral tegmental area, nucleus accumbens, and prefrontal cortex (see also Box: **The Dopamine Hypothesis of Addiction**). More sophisticated tests rely on self-administration of the drug, in which a rat or a mouse has to press a lever in order to obtain an injection of, for example, **cocaine**. Once the animal has learned the association with a conditioned stimulus (eg, light or brief sound), the simple presentation of the cue elicits drug seeking. Using an apparatus with two levers, one can demonstrate strong motivation for drug seeking. In this test the animal has to press the lever for a random duration, only after which the second lever is presented that then allows to self-administer the drug. Prolonged self-administration of addictive drugs over weeks, particularly when using intermittent access schedules, elicits behaviors in some rodents that more closely resemble human addiction. Such “addicted” rodents are very strongly motivated to seek **cocaine**, continue looking for the drug even when no longer available, and self-administer **cocaine** despite negative consequences, such as punishment in the form of an electric foot shock. The latter is a reflection of compulsion, which occurs only in a fraction of animals, reminiscent of the observation that only some drug users will become addicted, while many can maintain a recreational consumption. While there is little evidence for addicted animals in the wild, these findings suggest that addiction is a disease that does not respect species boundaries once drugs become available.

## ADDICTIVE DRUGS INCREASE THE LEVEL OF **DOPAMINE (DA)**: REINFORCEMENT

To understand the long-term changes induced by drugs of abuse, their initial molecular and cellular targets must be identified. A combination of approaches in animals and humans, including functional imaging, has revealed the mesolimbic **dopamine** system as the prime target of addictive drugs. This system originates in the **ventral tegmental area (VTA)**, a tiny structure at the tip of the brainstem, which projects to the **nucleus accumbens (NAc)**, the amygdala, the hippocampus, and the prefrontal cortex (**Figure 32-1**). Most projection neurons of the VTA are dopamine-producing neurons. When the **dopamine** neurons of the VTA begin to fire in bursts, large quantities of **dopamine** are released in the nucleus accumbens and the prefrontal cortex. Early animal studies pairing electrical stimulation of the VTA with operant responses (eg, lever pressing) that result in strong reinforcement established the central role of the mesolimbic **dopamine** system in reward processing. Direct application of drugs into the VTA also acts as a strong reinforcer, and systemic administration of drugs of abuse causes the release of **dopamine**. Even direct activation of **dopamine** neurons is sufficient to drive reinforcement and elicit adaptive behavioral changes typically observed with addictive drugs. These very selective interventions use optogenetic methods. Blue light is delivered in a freely moving mouse through light guides to activate channelrhodopsin, a light-gated cation channel that is artificially expressed in **dopamine** neurons. As a result, mice will “self-administer” light to activate VTA **dopamine** neurons. After several pairings with a specific environment, a long-lasting place preference is established. Once the light is no longer available, a seeking behavior is observed (but no actual withdrawal syndrome). Finally, some mice will self-stimulate even if they have to endure a punishment (eg, light electric shock). Conversely, inhibition of VTA **dopamine** neurons or activation of upstream inhibitory cells causes aversion. Classifying the VTA **dopamine** neurons based on their activity in response to a rewarding or aversive stimulus suggests distinct groups. The **dopamine** neurons located in the lateral part of the VTA projecting to the lateral shell of the NAc respond strongly to an unexpected reward and are the prime target of addictive drugs, which also target the medial VTA.

Major connections of the mesolimbic **dopamine** system in the brain. Schematic diagram of the brain illustrating that the **dopamine** projections (red) originate in the ventral tegmental area (VTA) and target the nucleus accumbens (NAc), prefrontal cortex (mPFC), basolateral amygdala (BLA), and ventral pallidum (VP). Neurons in the NAc fall into two classes, one expressing type 1 **dopamine** receptors (D1s) and the other expressing type 2 receptors (D2s). Both classes contain GABAergic projection neurons (green); the D1R neurons send their axons to both the VP and the VTA (where they target primarily the GABA interneurons), whereas the D2R neurons send their axons selectively to the VP. The NAc is also a site of convergence of excitatory projections from the mPFC, the ventral hippocampus (vHippo), and the BLA. The midbrain **dopamine** neurons receive a direct excitatory input (blue) from the lateral dorsal tegmentum (LDT), while the GABA neurons of the rostromedial tegmentum (RMTg) at the tail of the VTA are excited by neurons from the lateral habenula (LHb), typically when an aversive stimulus occurs. The projection from the orbitofrontal cortex (OFC) to the dorsal striatum (DS) has been implicated in compulsive drug seeking and taking. The ventral and dorsal parts of the striatum are connected by reciprocal, spiraling connections.

As a general rule, all addictive drugs elicit **dopamine** transients in the mesolimbic system. **Dopamine** also peaks in response to unexpected natural rewards and may thus code for the difference between expected and actual rewards. A very appealing hypothesis posits that **dopamine** constitutes a learning signal and addictive drugs, by their sheer pharmacological power, an excessive learning signal (see Box: **The Dopamine Hypothesis of Addiction**), which eventually biases decisions in favor of drug consumption, even when associated with major negative consequences.

## The Dopamine Hypothesis of Addiction

In the earliest version of the hypothesis described in this chapter, mesolimbic **dopamine** was believed to be the neurochemical correlate of pleasure and reward. However, during the past decades, experimental evidence has led to several revisions. Phasic **dopamine** release may actually code for the *prediction error* of reward rather than the reward itself. This distinction is based on pioneering observations in monkeys that **dopamine** neurons in the ventral tegmental area (VTA) are most efficiently activated by a reward (eg, a few drops of fruit juice) that is not anticipated. When the animal learns to predict the occurrence of a reward (eg, by pairing it with a stimulus such as a sound), **dopamine** neurons stop responding to the reward itself (juice), but increase their firing rate when the conditioned stimulus (sound) occurs. Finally, if reward is predicted but not delivered (sound but no juice), **dopamine** neurons become silent. In other words, the mesolimbic system continuously scans the reward situation. It increases its activity when reward is larger than expected and shuts down when a promised reward is omitted, thus coding for the prediction error of reward. Tonic release of **dopamine** in turn may reflect motivation.

Under physiologic conditions the phasic mesolimbic **dopamine** signal could represent a learning signal responsible for reinforcing constructive behavioral adaptation (eg, learning to press a lever for food). Indeed, animals that cannot synthesize **dopamine** because key enzymes have been ablated genetically show unconditioned reflexes and can execute previously learned behavior, but hardly acquire new responses. Addictive drugs, by directly increasing **dopamine**, would generate a strong but inappropriate learning signal, thus hijacking the reward system and leading to pathologic reinforcement. As a consequence, over time, through several intermediate steps, behavior may become compulsive in some individuals; that is, decisions are strongly biased in favor of actions to seek and take drugs. This is the hallmark of addiction.

This appealing hypothesis has been challenged by the intriguing observation that mice genetically modified to lack the primary molecular target of **cocaine**, the **dopamine** transporter DAT, still self-administer the drug. Only when transporters of other biogenic amines are also knocked out does **cocaine** completely lose its rewarding properties. However, in DAT<sup>-/-</sup> mice, in which basal synaptic **dopamine** levels are high, **cocaine** still leads to increased **dopamine** release, presumably because other cocaine-sensitive monoamine transporters (NET, SERT) are able to clear some **dopamine**. When **cocaine** is given, these transporters are also inhibited and **dopamine** is again increased. As a consequence of this substitution among monoamine transporters, **fluoxetine** (a selective serotonin reuptake inhibitor, see [Chapter 30](#)) becomes addictive in DAT<sup>-/-</sup> mice. This concept is supported by evidence showing that deletion of the cocaine-binding site on DAT leaves basal **dopamine** levels unchanged but abolishes the rewarding effect of **cocaine**.

The **dopamine** hypothesis of addiction has also been challenged by the observation that salient stimuli that are not rewarding (they may actually even be aversive and therefore negative reinforcers) also activate a subpopulation of **dopamine** neurons in the VTA. The neurons that are activated by aversive stimuli preferentially project to the prefrontal cortex and the tail of the striatum, while the **dopamine** neurons inhibited by aversive stimuli are those that mostly target the nucleus accumbens. These recent findings suggest that in parallel to the reward system, a system for aversion-learning originates in the VTA.

Regardless of the many roles of **dopamine** under physiologic conditions, all addictive drugs significantly increase its concentration in target structures of the mesolimbic projection, in particular in the dorsomedial shell of the NAc. This suggests that high levels of **dopamine** may actually be at the origin of the adaptive changes that underlie dependence and addiction, a concept that is now supported by novel techniques that allow controlling the activity of **dopamine** neurons in vivo. In fact manipulations that drive sustained activity of VTA **dopamine** neurons cause the same cellular adaptations and behavioral changes typically observed with addictive drug exposure, including late-stage symptoms such as persistence of self-stimulation during punishment.

Each addictive drug activates the mesolimbic system via its specific molecular target, engaging **distinct cellular mechanisms** to increase **dopamine** levels. The first class of drugs directly stimulates the **dopamine** neurons. This is the case for **nicotine**, which binds to excitatory nicotinic receptors expressed on the cell body of **dopamine** neurons. The second class interferes with the reuptake of **dopamine** (eg, **cocaine**) or promotes nonvesicular release (eg, amphetamines). This happens in NAc and the VTA itself because **dopamine** neurons also express somatodendritic transporters, which normally clear **dopamine** released by the dendrites. Although drugs of this class also affect transporters of other monoamines (**norepinephrine**, serotonin), action on the **dopamine** transporter remains central for addiction. This is consistent with the observations that antidepressants that block serotonin and **norepinephrine** uptake, but not **dopamine** uptake, do not cause addiction even after prolonged use. The third mechanism is indirect, **serotonin** and **acetylcholine** inhibit  $\gamma$ -aminobutyric acid (GABA) neurons that act as local inhibitory interneurons (eg, opioids, cannabis). The three groups also

differ by the molecular targets they bind to. For example, members of the last group bind to  $G_{i/o}$  protein-coupled receptors, typically of the  $G_{i/o}$  family, that inhibit neurons through postsynaptic hyperpolarization and lower presynaptic transmitter release probability. By contrast, direct activation uses ionotropic receptors or ion channels, and all reuptake blockers interfere with the **dopamine** transporter (Table 32-1 and Figure 32-2).

TABLE 32-1

The mechanistic classification of drugs of abuse.<sup>1</sup>

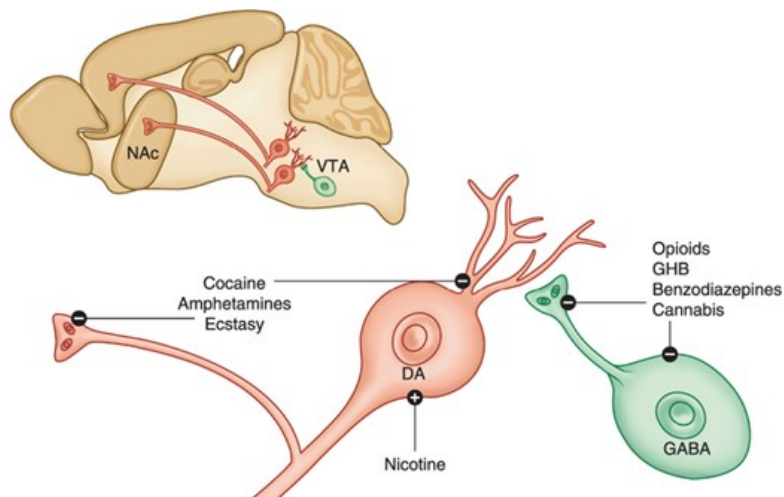

Name	Main Molecular Target	Pharmacology	Effect on Dopamine (DA) Neurons	RR <sup>2</sup>
<b>Drugs That Activate G Protein-Coupled Receptors</b>				
Opioids	$\mu$ -OR ( $G_{i/o}$ )	Agonist	Disinhibition	4
Cannabinoids	CB <sub>1</sub> R ( $G_{i/o}$ )	Agonist	Disinhibition	2
$\gamma$ -Hydroxybutyric acid (GHB)	GABA <sub>B</sub> R ( $G_{i/o}$ )	Weak agonist	Disinhibition	?
LSD, mescaline, psilocybin	5-HT <sub>2A</sub> R ( $G_q$ )	Partial agonist	—	1
<b>Drugs That Bind to Ionotropic Receptors and Ion Channels</b>				
Nicotine	nAChR ( $\alpha 4\beta 2$ )	Agonist	Excitation	4
Alcohol	GABA <sub>A</sub> R, 5-HT <sub>3</sub> R, nAChR, NMDAR, Kir3 channels		Excitation, disinhibition (?)	3
Benzodiazepines	GABA <sub>A</sub> R	Positive modulator	Disinhibition	3
Phencyclidine, ketamine	NMDAR	Antagonist	—	1
<b>Drugs That Bind to Transporters of Biogenic Amines</b>				
Cocaine	DAT, SERT, NET	Inhibitor	Blocks DA uptake	5
Amphetamine	DAT, NET, SERT, VMAT	Reverses transport	Blocks DA uptake, synaptic depletion	5
Ecstasy	SERT > DAT, NET	Reverses transport	Blocks DA uptake, synaptic depletion	?

5-HT<sub>x</sub>R, serotonin receptor; CB<sub>1</sub>R, cannabinoid-1 receptor; DAT, dopamine transporter; GABA,  $\gamma$ -aminobutyric acid; Kir3 channels, G protein-coupled inwardly rectifying potassium channels; LSD, lysergic acid diethylamide;  $\mu$ -OR,  $\mu$ -opioid receptor; nAChR, nicotinic acetylcholine receptor; NET, norepinephrine transporter; NMDAR, *N*-methyl-D-aspartate receptor; R, receptor; SERT, serotonin transporter; VMAT, vesicular monoamine transporter; ? indicates data not available.

<sup>1</sup>Drugs fall into one of three categories, targeting either G protein-coupled receptors, ionotropic receptors or ion channels, or biogenic amine transporters.

<sup>2</sup>RR, relative risk of addiction; 1 = nonaddictive; 5 = highly addictive.

## DEPENDENCE: TOLERANCE & WITHDRAWAL

With chronic exposure to addictive drugs, the brain shows signs of adaptation. For example, if **morphine** is used at short intervals, the dose has to be progressively increased over the course of several days to maintain rewarding or analgesic effects. This phenomenon is called tolerance. It may become a serious problem because of increasing side effects—eg, respiratory depression—that do not show as much tolerance and may lead to overdose-related fatalities.

Tolerance to opioids may be due to a reduction of the concentration of a drug or a shorter duration of action in a target system (pharmacokinetic tolerance). Alternatively, it may involve changes in  $\mu$ -opioid receptor function (pharmacodynamic tolerance). Many  $\mu$ -opioid receptor agonists promote robust receptor phosphorylation that triggers the recruitment of the adaptor protein  $\beta$ -arrestin, causing G proteins to uncouple from the receptor and internalize within minutes (see [Chapter 2](#)). Since this decreases signaling, it is tempting to explain tolerance by such a mechanism. However, **morphine**, which strongly induces tolerance, does not recruit  $\beta$ -arrestins and fails to promote receptor internalization (see [Chapter 31](#)).

Conversely, other agonists that drive receptor internalization very efficiently induce only modest tolerance. Based on these observations, it has been hypothesized that desensitization and receptor internalization protect the cell from overstimulation. In this model, **morphine**, by failing to trigger receptor endocytosis, disproportionately stimulates adaptive processes, which eventually cause tolerance. Although the molecular identity of these processes is still under investigation, they may be similar to the ones involved in withdrawal (see below).

Adaptive changes become fully apparent once drug exposure is terminated. This state is called **withdrawal** and is observed to varying degrees after chronic exposure to most drugs of abuse. Withdrawal from opioids in humans is particularly strong (described below). Studies in rodents have added significantly to our understanding of the neural and molecular mechanisms that underlie dependence. For example, signs of dependence, as well as analgesia and reward (positive reinforcement), are abolished in genome-wide knockout mice lacking the  $\mu$ -opioid receptor ([Chapter 31](#)), but not in mice lacking other opioid receptors ( $\delta$ ,  $\kappa$ ). If  $\mu$ -opioid receptors are selectively deleted on VTA GABA neurons of the VTA, positive reinforcement is lost, but not dependence. Such mice will still show withdrawal upon abrupt termination of opioid exposure, indicating that circuits of dependence are distinct. An input from the periventricular thalamus to the nucleus accumbens, conveying an aversive state during withdrawal, has been implicated. On the molecular level, dependence may involve adaptation of receptor signaling.  $\mu$ -opioid receptors initially inhibit adenylyl cyclase; this inhibition becomes weaker after several days of repeated exposure. The reduction of the inhibition of adenylyl cyclase is due to a counteradaptation of the enzyme system during exposure to the drug, which results in the overproduction of cAMP during subsequent withdrawal. Several mechanisms exist for this adenylyl cyclase compensatory response, including upregulation of transcription of the enzyme. Increased cAMP concentrations strongly activate the transcription factor cyclic AMP response element binding protein (CREB), leading to the regulation of downstream genes.

## ADDICTION: A DISEASE OF MALADAPTIVE LEARNING

www.kohkur.in  
Addiction is characterized by a high motivation to obtain and use a drug despite negative consequences. With time, drug use becomes compulsive (“wanting without liking”). Addiction is a recalcitrant, chronic, and stubbornly relapsing disease that is very difficult to treat.

The central problem is that even after successful withdrawal and prolonged drug-free periods, addicted individuals have a high risk of relapsing. Relapse is typically triggered by three conditions: re-exposure to the addictive drug, stress, or a context that recalls prior drug use. It appears that when paired with drug use, a neutral stimulus may undergo a switch and motivate (“trigger”) addiction-related behavior. This phenomenon may involve synaptic plasticity in the target nuclei of the mesolimbic projection (eg, projections from the medial prefrontal cortex and the ventral hippocampus to the neurons of the nucleus accumbens that express the  $D_1$  receptors). Several recent studies suggest that the recruitment of circuits in the dorsal striatum is responsible for compulsion. This switch may depend on synaptic plasticity in the nucleus accumbens of the ventral striatum (Figure 32–3), where mesolimbic dopamine afferents converge with glutamatergic afferents to modulate their function. If dopamine release codes for the prediction error of reward (see Box: The Dopamine Hypothesis of Addiction), pharmacologic stimulation of the mesolimbic dopamine system will generate an unusually strong learning signal. Unlike natural rewards, addictive drugs continue to increase dopamine even when reward is expected. Such overriding of the prediction error signal may eventually be responsible for the usurping of memory processes by addictive drugs.

FIGURE 32–3

Rules of synaptic plasticity in the striatum. The tripartite synapse between glutamatergic afferents, the GABAergic medium spiny neurons, and the ascending axons of VTA dopamine neurons can undergo several forms of synaptic plasticity. In cells that express the  $G_s$ -coupled  $D_1$  receptor, dopamine favors the appearance of long-term potentiation (LTP), while long-term depression (LTD) is inhibited. Conversely in  $D_2$  receptor-expressing cells, dopamine when released at the same time as glutamate causes LTD and opposes LTP. These rules apply when dopamine is released at the same time as afferent glutamate and may explain the predominant effect of addictive drugs. (Data from Shen W, Flajolet M, Greengard P, Surmeier DJ: Dichotomous dopaminergic control of striatal synaptic plasticity, Science 2008 Aug 8;321(5890):848-851.)

The involvement of learning and memory systems in addiction is also suggested by clinical studies. For example, the role of context in relapse is supported by the fact that soldiers who became addicted to heroin during the Vietnam War had significantly better outcomes when treated after their return home, compared with addicts who remained in the environment where they had taken the drug. In other words, cravings may recur at the presentation of contextual cues (eg, people, places, or drug paraphernalia). Current research therefore focuses on the effects of drugs on associative forms of synaptic plasticity, such as long-term potentiation (LTP), which underlie learning and memory (see Box: Synaptic Plasticity, Altered Circuit Function, & Addiction).

Long-term potentiation (LTP) and long-term depression (LTD) are forms of experience-dependent synaptic plasticity that is induced by activating glutamate receptors of the *N*-methyl-D-aspartate (NMDA) type. Since NMDA receptors are blocked by magnesium at negative potentials, their activation requires the concomitant release of glutamate (presynaptic activity) onto a receiving neuron that is depolarized (postsynaptic activity). Correlated pre- and postsynaptic activity durably enhances synaptic efficacy and triggers the formation of new connections. In contrast, weak correlated activity (eg, postsynaptic neurons firing before the presynaptic cell) leads to LTD. Because associativity is a critical component, LTP and LTD have become leading candidate mechanisms underlying learning and memory. They can be elicited at glutamatergic synapses of the mesolimbic reward system and are modulated by **dopamine**. The **dopamine** receptors dictate the rules of synaptic plasticity. In D<sub>1</sub>R-expressing cells, a surge of **dopamine** favors LTP of excitatory afferents but blocks LTD. Conversely in D<sub>2</sub>R-expressing neurons, **dopamine** release concomitant to glutamate transmission leads to the depression of the latter and inhibits LTP. Drugs of abuse therefore interfere with LTP and LTD at sites of convergence of **dopamine** and glutamate projections, leading to drug-evoked synaptic plasticity. Exposure to an addictive drug thus typically triggers a potentiation of excitatory afferents onto D<sub>1</sub>R-expressing neurons. **Dopamine** also potentiates GABA<sub>A</sub> receptor-mediated inhibition of the GABA neurons in the VTA and the ventral pallidum (VP), both primary targets of the medium spiny neurons of the nucleus accumbens. As a consequence, the excitability of **dopamine** neurons is increased, the synaptic calcium sources altered, and the rules for subsequent LTP inverted. In the nucleus accumbens, drug-evoked synaptic plasticity appears with some delay on D<sub>1</sub> receptor-expressing neurons, which are the ones projecting back to the VTA to control the activity of the GABA neurons as well as to the VP. Manipulations in mice that prevent or reverse drug-evoked plasticity in vivo also have effects on persistent changes of drug-associated behavioral sensitization or cue-induced drug seeking, providing more direct evidence for a causal role of synaptic plasticity in drug-adaptive behavior. The strengthening of the projection from the orbitofrontal cortex to the dorsal striatum may be a neural correlate of compulsion in those animals that self-stimulate the VTA **dopamine** neurons or take a drug even when punished. Together, a circuit model of staged drug-evoked synaptic plasticity is emerging, whereby various symptoms are caused by changes in specific projections, eventually combining into addiction.

Non-substance-dependent disorders, such as pathologic gambling and compulsive shopping, share many clinical features of addiction. Several lines of arguments suggest that they also share the underlying neurobiological mechanisms. This conclusion is supported by the clinical observation that, as an adverse effect of **dopamine** agonist medication, patients with Parkinson disease may become pathologic gamblers. Other patients may develop a compulsion for recreational activities, such as shopping, binge eating, or hypersexuality. Although large-scale studies are not yet available, an estimated one in seven parkinsonian patients develops an addiction-like behavior when receiving **dopamine** agonists (see [Chapter 28](#)).

Large individual differences exist also in vulnerability to substance-related addiction. Whereas one person may become “hooked” after a few doses, others may be able to use a drug occasionally during their entire lives without ever having difficulty in stopping. Even in the case of drugs that induce dependence in all subjects, only a percentage of users progress to addiction. For example, a retrospective analysis shows that after several decades of **cocaine** abuse, only 20% become addicted. With cannabis, the fraction is only 10%, while heroin leads to approximately 30% of users becoming addicts. A similar percentage for **cocaine** is also observed in rats and mice that have extended access to the drug. With **dopamine** neuron self-stimulation, the fraction of mice that resist punishment is approximately 50%. Recent studies in rats suggest that impulsivity or excessive anxiety may be crucial traits that represent a risk for addiction. The transition to addiction is determined by a combination of environmental and genetic factors. Heritability of addiction, as determined by comparing monozygotic with dizygotic twins, is relatively modest for cannabinoids but higher for **cocaine**. It is of interest that the relative risk for addiction (addiction liability) of a drug (see [Table 32-1](#)) correlates with its heritability, suggesting that the neurobiologic basis of addiction common to all drugs is what is being inherited. Further genomic analysis indicates that numerous, perhaps even hundreds of alleles need to function in combination to produce the phenotype. However, identification of the genes involved remains elusive. Although some substance-specific candidate genes have been identified (eg, **alcohol** dehydrogenase, nicotinic **acetylcholine** receptor subunits), current research focuses on genes implicated in the neurobiologic mechanisms common to all addictive drugs. An appealing idea is the contribution of epigenetics as a determinant of addiction vulnerability. This scenario is supported by the observation that the fraction of transition to compulsion in genetically homogeneous mice is similar to that observed in humans. **Cocaine** regulates posttranslational modifications of histones, DNA methylation, and signaling via noncoding RNAs, which eventually may have an impact on behavior. The cellular mechanism involved and the relationship to synaptic plasticity are currently under investigation.

Some drugs of abuse do not lead to addiction. This is the case for substances that alter perception without causing sensations of reward and euphoria, such as psychedelics and dissociative anesthetics (see [Table 32–1](#)). Unlike addictive drugs, which primarily target the mesolimbic [dopamine](#) system, these agents primarily target cortical and thalamic circuits. Lysergic acid diethylamide (LSD), for example, activates the serotonin 5-HT<sub>2A</sub> receptor in the prefrontal cortex, acutely enhancing glutamatergic transmission onto pyramidal neurons for the duration of the presence of the drug. These excitatory afferents mainly come from the thalamus and carry sensory information of varied modalities, which may constitute a link to enhanced perception. Phencyclidine (PCP) and [ketamine](#) produce a feeling of separation of mind and body (which is why they are called dissociative anesthetics) and, at higher doses, stupor and coma. The principal mechanism of action is a use-dependent inhibition of glutamate receptors of the NMDA type. High doses of [dextromethorphan](#), an over-the-counter cough suppressant, can also elicit a dissociative state. This effect is mediated by a rather nonselective action on serotonin reuptake, and opioid, [acetylcholine](#), and NMDA receptors.

The classification of NMDA antagonists as nonaddictive drugs was based on early assessments, which, in the case of PCP, have recently been questioned. Animal research shows that PCP can increase mesolimbic [dopamine](#) concentrations and has some reinforcing properties in rodents. [Ketamine](#) also increases [dopamine](#) and leads to weak reinforcement but not to long-lasting adaptation, because NMDA receptor blockage precludes the induction of drug-evoked synaptic plasticity. Addiction liability is thus believed to be low, but not zero. Concurrent effects on both thalamocortical and mesolimbic systems also exist for other addictive drugs. Psychosis-like symptoms can be observed with cannabinoids, amphetamines, and [cocaine](#), which may reflect their effects on thalamocortical structures. For example, cannabinoids, in addition to their documented effects on the mesolimbic [dopamine](#) system, also enhance excitation in cortical circuits through presynaptic inhibition of GABA release.

Hallucinogens and NMDA antagonists, even if they do not produce dependence or addiction, can still have long-term effects. Flashbacks of altered perception can occur years after LSD use. Moreover, chronic use of PCP may lead to an irreversible schizophrenia-like psychosis.

## BASIC PHARMACOLOGY OF DRUGS OF ABUSE

Since all addictive drugs increase [dopamine](#) concentrations in the target structures of the mesolimbic projections, we classify them based on the underlying cellular mechanism (see [Table 32–1](#) and [Figure 32–2](#)). The first group includes [nicotine](#), which through its ionotropic receptor stimulates [dopamine](#) neurons. The second group comprises [cocaine](#), [amphetamines](#), and [ecstasy](#), which all bind to monoamine transporters and lead to increased [dopamine](#) levels independent of their effect on neuron firing. The third group contains [opioids](#), [cannabinoids](#), [γ-hydroxybutyric acid \(GHB\)](#), and [benzodiazepines](#), which exert their action through G<sub>i/o</sub> protein-coupled receptors and ionotropic receptors and cause disinhibition of [dopamine](#) neurons. [Alcohol](#), which has several molecular targets, increases [dopamine](#) through a still unknown mechanism. Drugs such as [psychedelics](#) do not increase [dopamine](#), are not addictive, and are classified based on their molecular target.

### DRUGS THAT EXCITE DOPAMINE NEURONS

#### NICOTINE

In terms of numbers affected, [nicotine](#) addiction exceeds all other forms of addiction, touching more than 50% of all adults in some countries. [Nicotine](#) exposure occurs primarily through smoking of tobacco, which causes associated diseases that are responsible for many preventable deaths. The chronic use of chewing tobacco and snuff tobacco is also addictive.

[Nicotine](#) is a selective agonist of the nicotinic [acetylcholine](#) receptor (nAChR) that is normally activated by [acetylcholine](#) (see [Chapters 6](#) and [7](#)). Based on [nicotine](#)'s enhancement of cognitive performance and the association of Alzheimer dementia with a loss of ACh-releasing neurons from the nucleus basalis of Meynert, nAChRs are believed to play an important role in many cognitive processes. The rewarding effect of [nicotine](#) requires involvement of the VTA, in which nAChRs are expressed on [dopamine](#) neurons. When [nicotine](#) excites projection neurons, [dopamine](#) is released in the nucleus accumbens and the prefrontal cortex, thus fulfilling the [dopamine](#) requirement of addictive drugs. α4β2-containing channels in the VTA are the nAChRs mediating the rewarding effects of [nicotine](#). This statement is based on the observation that knockout mice deficient for the β2 subunit lose interest in self-administering [nicotine](#), and that in these mice, this behavior can be restored through an in vivo transfection of the β2 subunits in neurons of the VTA. Electrophysiologic evidence suggests that homomeric nAChRs made exclusively of α7 subunits also contribute to the reinforcing effects of [nicotine](#). These receptors are mainly expressed on synaptic terminals of excitatory afferents projecting onto the [dopamine](#) neurons. They

also contribute to nicotine-evoked **dopamine** release and the long-term changes induced by the drugs related to addiction (eg, long-term synaptic potentiation of excitatory inputs).

**Nicotine** withdrawal is mild compared with opioid withdrawal and involves irritability and problems sleeping. However, **nicotine** is among the most addictive drugs (relative risk 4), and relapse after attempted cessation is very common.

### Treatment

Treatments for **nicotine** addiction include **nicotine** itself in forms that are slowly absorbed and several other drugs. **Nicotine** that is chewed, inhaled, or transdermally delivered can be substituted for the **nicotine** in cigarettes, thus slowing the pharmacokinetics and eliminating the many complications associated with the toxic substances found in tobacco smoke. Recently, two partial agonists of  $\alpha 4\beta 2$ -containing nAChRs have been characterized: the plant-extract **cytisine** and its synthetic derivative **varenicline**. Both work by occupying nAChRs on **dopamine** neurons of the VTA, thus preventing **nicotine** from exerting its action. **Varenicline** may impair the capacity to drive and has been associated with suicidal ideation. The antidepressant **bupropion** is approved for **nicotine** cessation therapy. It is most effective when combined with behavioral therapies.

Many countries have banned smoking in public places to create smoke-free environments. This important step not only reduces passive smoking and the hazards of secondhand smoke but also the risk that ex-smokers will be exposed to smoke, which as a contextual cue, may trigger relapse.

## DRUGS THAT INTERFERE WITH DOPAMINE REUPTAKE

### Cocaine

The prevalence of **cocaine** abuse remains a major public health problem worldwide. **Cocaine** is highly addictive (relative risk = 5), and its use is associated with a number of complications.

**Cocaine** is an alkaloid found in the leaves of *Erythroxylum coca*, a shrub indigenous to the Andes. For more than 100 years, it has been extracted and used in clinical medicine, mainly as a local anesthetic and to dilate pupils in ophthalmology. Sigmund Freud famously proposed its use to treat depression and **alcohol** dependence, but addiction quickly brought an end to these ideas.

**Cocaine** hydrochloride is a water-soluble salt that can be injected or absorbed by any mucosal membrane (eg, nasal snorting). When heated in an alkaline solution, it is transformed into the free base, “crack **cocaine**,” which can then be smoked. Inhaled crack **cocaine** is rapidly absorbed in the lungs and penetrates swiftly into the brain, producing an almost instantaneous “rush.”

In the peripheral nervous system, **cocaine** inhibits voltage-gated sodium channels, thus blocking initiation and conduction of action potentials (see **Chapter 26**). This mechanism, underlying its effect as a local anesthetic, seems responsible for neither the acute rewarding nor the addictive effects. In the central nervous system, **cocaine** blocks the uptake of **dopamine**, noradrenaline, and serotonin through their respective transporters. The block of the **dopamine transporter (DAT)**, which increases **dopamine** concentrations in the nucleus accumbens, has been implicated in the rewarding effects of **cocaine** (**Figure 32–4**). In fact, the rewarding effects of **cocaine** are abolished in mutant mice with a cocaine-insensitive DAT. The activation of the sympathetic nervous system results mainly from blockage of the **norepinephrine** transporter (NET) and leads to an acute increase in arterial pressure, tachycardia, and often, ventricular arrhythmias. Users typically lose their appetite, are hyperactive, and sleep little. **Cocaine** exposure increases the risk for intracranial hemorrhage, ischemic stroke, myocardial infarction, and seizures. **Cocaine** overdose may lead to hyperthermia, coma, and death. In the 1970s, when crack-cocaine appeared in the USA, it was suggested that the drug is particularly harmful to the fetus in addicted pregnant women. The term “crack-baby” was used to describe a specific syndrome of the newborn, and the mothers faced harsh legal consequences. The follow-up of the children, now adults, does not confirm a drug-specific handicap in cognitive performance. Moreover, in this population, the percentage of drug-users is comparable to controls matched for socioeconomic environment.

### FIGURE 32–4

Mechanism of action of **cocaine** and **amphetamine** on synaptic terminal of **dopamine** (DA) neurons. **Left:** **Cocaine** inhibits the **dopamine** transporter (DAT), decreasing DA clearance from the synaptic cleft and causing an increase in extracellular DA concentration. **Right:** Since **amphetamine** (Amph) is a substrate of the DAT, it competitively inhibits DA transport. In addition, once in the cell, **amphetamine** interferes with the vesicular monoamine transporter (VMAT) and impedes the filling of synaptic vesicles. As a consequence, vesicles are depleted and cytoplasmic DA increases. This leads to a

Source: Todd W. Vanderah:  
Basic & Clinical Pharmacology, Sixteenth Edition  
Copyright © McGraw Hill. All rights reserved.

Susceptible individuals may become dependent and addicted after only a few exposures to [cocaine](#). Although a withdrawal syndrome is reported, it is not as strong as that observed with opioids. Tolerance may develop, but in some users, a reverse tolerance is observed; that is, they become sensitized to small doses of [cocaine](#). This behavioral sensitization is in part context-dependent. Cravings are very strong and underlie the very high addiction liability of [cocaine](#). To date, no specific antagonist is available, and the management of intoxication remains supportive. Developing a pharmacologic treatment for [cocaine](#) addiction is a top priority.

## AMPHETAMINES

Amphetamines are a group of synthetic, indirect-acting sympathomimetic drugs that cause the release of endogenous biogenic amines, such as [dopamine](#) and [norepinephrine](#) (see [Chapters 6](#) and [9](#)). [Amphetamine](#), [methamphetamine](#), and their many derivatives exert their effects by reversing the action of biogenic amine transporters at the plasma membrane. Amphetamines are substrates of these transporters and are taken up into the cell (see [Figure 32-4](#)). Once in the cell, amphetamines interfere with the vesicular monoamine transporter (VMAT; see [Figure 6-4](#)), depleting synaptic vesicles of their neurotransmitter content. As a consequence, levels of [dopamine](#) (or other transmitter amine) in the cytoplasm increase and quickly become sufficient to cause release into the synapse by reversal of the plasma membrane DAT. Normal vesicular release of [dopamine](#) consequently decreases (because synaptic vesicles contain less transmitter), whereas nonvesicular release increases. Similar mechanisms apply for other biogenic amines (serotonin and [norepinephrine](#)).

Together with GHB and ecstasy, amphetamines are often referred to as “club drugs” because they are increasingly popular in the club scene. They are often produced in small clandestine laboratories, which makes their precise chemical identification difficult. They differ from ecstasy chiefly in the context of use: intravenous administration and “hard-core” addiction are far more common with amphetamines, especially [methamphetamine](#). In general, amphetamines lead to elevated catecholamine levels that increase arousal and reduce sleep, whereas the effects on the [dopamine](#) system mediate euphoria but may also cause abnormal movements and precipitate psychotic episodes. Effects on serotonin transmission may play a role in the hallucinogenic and anorexic functions as well as in the hyperthermia often caused by amphetamines.

Unlike many other abused drugs, amphetamines are neurotoxic. The exact mechanism is not known, but neurotoxicity depends on the NMDA receptor and affects mainly serotonin and [dopamine](#) neurons.

Amphetamines are typically taken initially in pill form by abusers, but can also be smoked or injected. Heavy users often progress rapidly to intravenous administration. Within hours after oral ingestion, amphetamines increase alertness and cause euphoria, agitation, and confusion. Bruxism (tooth grinding) and skin flushing may occur. Effects on heart rate may be minimal with some compounds (eg, [methamphetamine](#)), but with increasing dosage these agents often lead to tachycardia and dysrhythmias. Hypertensive crisis and vasoconstriction may lead to stroke. Spread of HIV and hepatitis infection in inner cities has been closely associated with needle sharing by intravenous users of [methamphetamine](#).

With chronic use, [amphetamine](#) tolerance may develop, leading to dose escalation. Withdrawal consists of dysphoria, drowsiness (in some cases, insomnia), and general irritability.

Ecstasy is the name of a class of drugs that includes a large variety of derivatives of the amphetamine-related compound methylenedioxyamphetamine (MDMA). MDMA was originally used in some forms of psychotherapy, but no medically useful effects were documented. This is perhaps not surprising, because the main effect of ecstasy appears to be to foster feelings of intimacy and empathy without impairing intellectual capacities. Today, MDMA and its many derivatives are often produced in small quantities in ad hoc laboratories and distributed at parties or “raves,” where it is taken orally. Ecstasy therefore is the prototypic **designer drug** and, as such, is increasingly popular.

Similar to the amphetamines, MDMA causes release of biogenic amines by reversing the action of their respective transporters. It has a preferential affinity for the **serotonin transporter (SERT)** and therefore most strongly increases the extracellular concentration of serotonin. This release is so profound that there is a marked intracellular depletion for 24 hours after a single dose. With repetitive administration, serotonin depletion may become permanent, which has triggered a debate on its neurotoxicity. Although direct proof from animal models for neurotoxicity remains weak, several studies report long-term cognitive impairment in heavy users of MDMA.

In contrast, there is a wide consensus that MDMA has several *acute* adverse effects, in particular hyperthermia, which along with dehydration (eg, caused by an all-night dance party) may be fatal. Other complications include serotonin syndrome (mental status change, autonomic hyperactivity, and neuromuscular abnormalities; see [Chapter 16](#)) and seizures. Following warnings about the dangers of MDMA, some users have attempted to compensate for hyperthermia by drinking excessive amounts of water, causing water intoxication involving severe hyponatremia, seizures, and even death.

Withdrawal is marked by a mood “offset” characterized by depression lasting up to several weeks. There have also been reports of increased aggression during periods of abstinence in chronic MDMA users.

Taken together, the evidence for irreversible damage to the brain, although not completely convincing, implies that even occasional recreational use of MDMA cannot be considered safe.

## DRUGS THAT DISINHIBIT DOPAMINE NEURONS

### OPIOIDS

Opioids may have been the first drug abused in human history and are still among the most commonly used for nonmedical purposes.

#### Pharmacology & Clinical Aspects

As described in [Chapter 31](#), opioids comprise a large family of endogenous and exogenous agonists at three G protein-coupled receptors: the  $\mu$ -,  $\kappa$ -, and  $\delta$ -opioid receptors. Although all three receptors couple to inhibitory G proteins (ie, they all inhibit adenylyl cyclase and activate  $K^+$  channels), they have distinct, sometimes even opposing effects, mainly because of the cell type-specific expression throughout the brain. In the VTA, for example,  $\mu$ -opioid receptors are selectively expressed on GABA neurons (which they inhibit), whereas  $\kappa$ -opioid receptors are expressed on and inhibit **dopamine** neurons. This may explain why  $\mu$ -opioid agonists cause euphoria, whereas  $\kappa$  agonists induce dysphoria.

In line with the latter observations, the rewarding effects of **morphine** are absent in knockout mice lacking  $\mu$  receptors but persist when either of the other opioid receptors are ablated. In the VTA,  $\mu$  opioids cause an inhibition of GABAergic inhibitory interneurons, which leads to a disinhibition of **dopamine** neurons, particularly those that project to the medial shell of the nucleus accumbens.

The most commonly abused  $\mu$  opioids include **morphine**, **heroin** (diacetylmorphine, which is rapidly metabolized to **morphine**), **codeine**, and **oxycodone**. The very potent synthetic opioid **fentanyl** (which within minutes saturates opioid receptors at a dose 100× lower than **morphine**) has become a widely abused drug because of its rapid onset and ease of distribution. Because of its pharmacokinetic properties it is among the most dangerous drugs and accounts for many deaths by overdose. **Meperidine** (also known as **pethidine**) is commonly abused among health professionals. All of these drugs induce strong tolerance and dependence, which increases the risk of transition to addiction by negative reinforcement. Positive and negative reinforcing effects of opioids both depend on  $\mu$  receptors. In genetically modified mice lacking this receptor, no withdrawal is observed once chronic opioid exposure is terminated. In humans, the withdrawal syndrome may be very severe (except for **codeine**) and includes intense dysphoria, nausea or vomiting, muscle aches, lacrimation, rhinorrhea, mydriasis, piloerection, sweating, diarrhea, yawning, and tremor. Beyond the withdrawal syndrome, which usually lasts no longer than a few days, some individuals who have received opioids as analgesics to

treat acute pain develop addiction. Despite this fact, opioid addiction has become a major public health issue in some countries, particularly the USA and Canada. The reason for this epidemic has been identified as careless, widespread chronic prescription of pain killers such as **oxycodone** to patients, who eventually switched to heroin or other illicit opioids. The relative risk of addiction is 4 out of 5 on a scale of 1 (nonaddictive) to 5 (highly addictive).

## Treatment

The opioid antagonist **naloxone** reverses the effects of a dose of **morphine** or heroin within minutes. This may be lifesaving in the case of an overdose, given typically IV or IM, but also as a nasal spray that can be applied by nonmedical personnel (see **Chapters 31** and **58**). **Naloxone** administration also provokes an acute withdrawal (precipitated abstinence) syndrome in a dependent person, which limits compliance. The half-life of **naloxone** is shorter than **morphine** (1 h and 2–4 h, respectively), which is why repeated administrations may be necessary.

In treating opioid addiction, a longer-acting opioid (eg, **methadone**, **buprenorphine**, **extended-release morphine sulfate**) is often substituted for the shorter-acting, more rewarding opioid (eg, heroin). For substitution therapy, **methadone** is given orally once daily, facilitating supervised intake. The use of a partial agonist (**buprenorphine**) and the much longer half-life (**methadone**, extended-release **morphine sulfate**, and **buprenorphine**) may also have some beneficial effects (eg, weaker drug sensitization, which typically requires intermittent exposures), but it is essential to realize that abrupt termination of **methadone** administration also precipitates a withdrawal syndrome; that is, the subject on substitution therapy remains dependent. Levomethadone, a preparation containing only the active enantiomer, has similar kinetics and effects as **methadone**, but lower side effects, particularly when cardiac repolarization is perturbed (long QT interval in the electrocardiogram). The use of **buprenorphine** may be limited by the withdrawal syndrome observed at the beginning of the therapy. Some countries (eg, Canada, Denmark, Netherlands, United Kingdom, Switzerland) allow substitution of medical heroin for street heroin. A follow-up of a cohort of addicts who received heroin injections in a controlled setting and had access to counseling indicates that addicts under heroin substitution have an improved health status and are better integrated in society. The current opioid crisis in the USA has become a leading cause of death in young adults and more than 2 million individuals are dependent.

## CANNABINOIDS

Endogenous cannabinoids that act as neurotransmitters include 2-arachidonyl glycerol (2-AG) and anandamide, both of which bind to CB<sub>1</sub> receptors (see also **Chapter 63**). These very lipid-soluble compounds are released at the postsynaptic somatodendritic membrane, and diffuse through the extracellular space to bind at presynaptic CB<sub>1</sub> receptors, where they inhibit the release of either glutamate or GABA. Because of this backward signaling, endocannabinoids are called retrograde messengers. In the hippocampus, the release of endocannabinoids from pyramidal neurons selectively affects inhibitory transmission and may contribute to the induction of synaptic plasticity during learning and memory formation.

Exogenous cannabinoids, eg, in **marijuana**, which when smoked contains thousands of organic and inorganic chemical compounds, exert their pharmacologic effects through active substances, including  $\Delta^9$ -**tetra-hydrocannabinol (THC)**, a powerful psychoactive substance. Like opioids, THC causes disinhibition of **dopamine** neurons, mainly by presynaptic inhibition of GABA neurons in the VTA. The half-life of THC is about 4 hours. The onset of effects of THC after smoking marijuana occurs within minutes and reaches a maximum after 1–2 hours. The most prominent effects are euphoria and relaxation. Users also report feelings of well-being, grandiosity, and altered perception of passage of time. Dose-dependent perceptual changes (eg, visual distortions), drowsiness, diminished coordination, and memory impairment may occur. Cannabinoids can also create a dysphoric state and, in rare cases following the use of very high doses, eg, in **hashish**, result in visual hallucinations, depersonalization, and frank psychotic episodes. Additional effects of THC, eg, increased appetite, attenuation of nausea, decreased intraocular pressure, and relief of chronic pain, have led to the use of cannabinoids in medical therapeutics. The justification of medicinal use of marijuana was comprehensively examined more than 20 years ago. Today, medical use of botanical marijuana has been legalized in 25 states and the District of Columbia. Nevertheless this continues to be a controversial issue, mainly because of the fear that cannabinoids may serve as a gateway to the consumption of “hard” drugs or cause schizophrenia in individuals with a predisposition.

Chronic exposure to marijuana leads to dependence, which is revealed by a distinctive, but mild and short-lived withdrawal syndrome that includes restlessness, irritability, mild agitation, insomnia, nausea, and cramping. The relative risk for addiction is 2.

The synthetic  $\Delta^9$ -THC analog **dronabinol** is a US Food and Drug Administration (FDA)-approved cannabinoid agonist currently marketed in the USA and some European countries. **Nabilone**, an older commercial  $\Delta^9$ -THC analog, was recently reintroduced in the USA to treat chemotherapy-induced

www.konkur.in  
emesis. **Cannabidiol (CBD)** is an active ingredient in marijuana, with low addiction liability, that is legal in all states and most western countries. It may benefit some forms of epilepsy, anxiety, insomnia, and chronic pain. Major side effects include nausea, fatigue, and enhanced blood thinning (particularly in patients receiving anticoagulants). CBD is a low-affinity agonist at CB1/CB2 receptors, but it also binds to other (orphan) GPCRs and can affect serotonin and opioid signaling. **Nabiximols** (trade name Sativex) is a botanical drug obtained by standard extraction. Its active principles are  $\Delta^9$ -THC and CBD. Initially only marketed in the United Kingdom, it is now widely available to treat symptoms of multiple sclerosis. In the USA, nabiximols is in phase III testing for cancer pain. The cannabinoid system will likely emerge as an essential drug target in the future because of its apparent involvement in several therapeutically desirable effects.

## GAMMA-HYDROXYBUTYRIC ACID

Gamma-hydroxybutyric acid (GHB, or sodium oxybate for its salt form) is produced during the metabolism of GABA, but the function of this endogenous agent is unknown at present. The pharmacology of GHB is complex because there are two distinct binding sites. The protein that contains a high-affinity binding site (1  $\mu\text{M}$ ) for GHB has been cloned, but its involvement in the cellular effects of GHB at pharmacologic concentrations remains unclear. The low-affinity binding site (1 mM) has been identified as the GABA<sub>B</sub> receptor. In mice that lack GABA<sub>B</sub> receptors, even very high doses of GHB have no effect; this suggests that GABA<sub>B</sub> receptors are the sole mediators of GHB's pharmacologic action.

GHB was first synthesized in 1960 in France and introduced as a general anesthetic. Because of its narrow safety margin and its addictive potential, it is not available in the USA for this purpose. Sodium oxybate (GHB sodium salt) can, however, be prescribed to treat narcolepsy and to decrease daytime sleepiness and episodes of cataplexy through a mechanism unrelated to the reward system. Before causing sedation and coma, GHB causes euphoria, enhanced sensory perceptions, a feeling of social closeness, and amnesia. These properties have made it a popular "club drug" that goes by colorful street names such as "liquid ecstasy," "grievous bodily harm," or "date rape drug." As the latter name suggests, GHB has been used in date rapes because it is odorless and can be readily dissolved in beverages. It is rapidly absorbed after ingestion and reaches a maximal plasma concentration 20–30 minutes after ingestion of a 10–20 mg/kg dose. The elimination half-life is about 30 minutes and leaves the recipient amnesic for events during the drug's duration of action.

Although GABA<sub>B</sub> receptors are expressed on all neurons of the VTA, GABA neurons are much more sensitive to GHB than are dopamine neurons (Figure 32–5). This is reflected by the EC<sub>50</sub>s, which differ by about one order of magnitude, as a result of the difference in coupling efficiency of the GABA<sub>B</sub> receptor and the potassium channels responsible for the hyperpolarization. Because GHB is a weak agonist, only GABA neurons are inhibited at the concentrations typically obtained with recreational use. This feature may underlie the reinforcing effects of GHB and the basis for addiction to the drug. At higher doses, however, GHB also hyperpolarizes dopamine neurons, eventually completely inhibiting dopamine release. Such an inhibition of the VTA may in turn preclude its activation by other addictive drugs and may explain why GHB might have some usefulness as an "anticraving" compound, particularly in the treatment of alcoholism.

### FIGURE 32–5

Disinhibition of dopamine (DA) neurons in the ventral tegmental area (VTA) through drugs that act via G<sub>i</sub>o-coupled receptors. **Top:** Opioids target  $\mu$ -opioid receptors (MORs) that in the VTA are located exclusively on  $\gamma$ -aminobutyric acid (GABA) neurons. MORs are expressed on the presynaptic terminal of these cells and the somatodendritic compartment of the postsynaptic cells. Each compartment has distinct effectors (*insets*). G protein- $\beta\gamma$ -mediated inhibition of voltage-gated calcium channels (VGCC) is the major mechanism in the presynaptic terminal. Conversely, in dendrites MORs activate K channels. Together the pre- and postsynaptic mechanisms reduce transmitter release and suppress activity, ultimately taking away the inhibition by the GABA neurons. **Middle:**  $\Delta^9$ -tetrahydrocannabinol (THC) and other cannabinoids mainly act through presynaptic inhibition. **Bottom:** Gamma-hydroxybutyric acid (GHB) targets GABA<sub>B</sub> receptors, which are located on both cell types. However, GABA neurons are more sensitive to GHB than are DA neurons, leading to disinhibition at concentrations typically obtained with recreational use. CB<sub>1</sub>R, cannabinoid receptors.

## BENZODIAZEPINES

Benzodiazepines are commonly prescribed as anxiolytics and sleep medications. They represent a definite risk for abuse, which has to be weighed against their beneficial effects. Some persons abuse benzodiazepines for their euphoriant effects, but most often, abuse occurs concomitant with other drugs, eg, to attenuate anxiety during withdrawal from opioids.

Benzodiazepine dependence is very common, and diagnosis of addiction is probably often missed. Withdrawal from benzodiazepines occurs within days of stopping the medication and varies as a function of the half-life of elimination. Symptoms include irritability, insomnia, phonophobia and photophobia, depression, muscle cramps, and even seizures. Typically, these symptoms taper off within 1–2 weeks.

Benzodiazepines are positive modulators of the GABA<sub>A</sub> receptor, increasing both single-channel conductance and open-channel probability. GABA<sub>A</sub> receptors are pentameric structures consisting of  $\alpha$ ,  $\beta$ , and  $\gamma$  subunits (see [Chapter 22](#)). GABA receptors on [dopamine](#) neurons of the VTA lack  $\alpha 1$ , a subunit isoform that is present in GABA neurons nearby (ie, interneurons). Because of this difference, unitary synaptic currents in interneurons are larger than those in [dopamine](#) neurons, and when this difference is amplified by benzodiazepines, interneurons fall silent. GABA is no longer released, and benzodiazepines lose their effect on [dopamine](#) neurons, ultimately leading to disinhibition of the [dopamine](#) neurons. The rewarding effects of benzodiazepines are, therefore, mediated by  $\alpha 1$ -containing GABA<sub>A</sub> receptors expressed on VTA neurons. Receptors containing  $\alpha 5$  subunits seem to be required for tolerance to the sedative effects of benzodiazepines, and studies in humans link  $\alpha 2\beta 3$ -containing receptors to [alcohol](#) dependence (the GABA<sub>A</sub> receptor is also a target of [alcohol](#); see following text). Taken together, a picture is emerging linking GABA<sub>A</sub> receptors that contain the  $\alpha 1$  subunit isoform to their addiction liability. By extension,  $\alpha 1$ -sparing compounds, which at present remain experimental and are not approved for human use, may eventually be preferred to treat anxiety disorders because of their reduced risk of induced addiction.

**Barbiturates**, which preceded benzodiazepines as the most commonly abused sedative-hypnotics (after ethanol), are now rarely prescribed to outpatients and therefore constitute a less common prescription drug problem than they did in the past. Street sales of barbiturates, however, continue. Management of barbiturate withdrawal and addiction is similar to that of benzodiazepines.

## DRUGS WITH MULTIPLE MECHANISMS OF ACTION

**Alcohol** (ethanol, see [Chapter 23](#)) is regularly used by most of the population in many Western countries. Although only a minority becomes dependent and addicted, abuse is a severe public health problem because of the social costs and many diseases associated with alcoholism.

### Pharmacology

The pharmacology of **alcohol** is complex, and no single receptor mediates all of its effects. On the contrary, **alcohol** alters the function of several receptors and cellular functions, including GABA<sub>A</sub> receptors, Kir3/GIRK channels, **adenosine** reuptake (through the equilibrative nucleoside transporter, ENT1), the glycine receptor, NMDA receptor, and 5-HT<sub>3</sub> receptor. They are all, with the exception of ENT1, either ionotropic receptors or ion channels. It is not clear which of these targets is responsible for the increase of **dopamine** release from the mesolimbic reward system. The inhibition of ENT1 is probably not responsible for the rewarding effects (ENT1 knockout mice drink more than controls) but seems to be involved in **alcohol** dependence through an accumulation of **adenosine**, stimulation of **adenosine** A<sub>2</sub> receptors, and ensuing enhanced CREB signaling.

Dependence becomes apparent 6–12 hours after cessation of heavy drinking as a withdrawal syndrome that may include tremor (mainly of the hands), nausea and vomiting, excessive sweating, agitation, and anxiety. In some individuals, this is followed by visual, tactile, and auditory hallucinations 12–24 hours after cessation. Generalized seizures may manifest after 24–48 hours. Finally, 48–72 hours after cessation, an **alcohol** withdrawal delirium (delirium tremens) may become apparent in which the person hallucinates, is disoriented, and shows evidence of autonomic instability. Delirium tremens is associated with 5–15% mortality.

### Treatment

Treatment of ethanol withdrawal is supportive and relies on **benzodiazepines**, taking care to use compounds such as **oxazepam** and **lorazepam**, which are not as dependent on oxidative hepatic metabolism as most other benzodiazepines. In patients in whom monitoring is not reliable and liver function is adequate, a longer-acting benzodiazepine such as **chlordiazepoxide** is preferred.

As in the treatment of all chronic drug abuse problems, heavy reliance is placed on psychosocial approaches to **alcohol** addiction. This is perhaps even more important for the alcoholic patient because of the ubiquitous presence of **alcohol** in many social contexts.

The pharmacologic treatment of **alcohol** addiction is limited, although several compounds, with different goals, have been used. Therapy is discussed in [Chapter 23](#).

## INHALANTS

Inhalant abuse is defined as recreational exposure to chemical vapors, such as **nitrites**, **ketones**, and aliphatic and aromatic **hydrocarbons**. These substances are present in a variety of household and industrial products that are inhaled by “sniffing,” “huffing,” or “bagging.” Sniffing refers to inhalation from an open container, huffing to the soaking of a cloth in the volatile substance before inhalation, and bagging to breathing in and out of a paper or plastic bag filled with fumes. It is common for novices to start with sniffing and progress to huffing and bagging as addiction develops. Inhalant abuse is particularly prevalent in children and young adults.

The exact mechanism of action of most volatile substances remains unknown. Altered function of ionotropic receptors and ion channels throughout the central nervous system has been demonstrated for a few. Nitrous oxide, for example, binds to NMDA receptors, and fuel additives enhance GABA<sub>A</sub> receptor function. Most inhalants produce euphoria; increased excitability of the VTA has been documented for toluene and may underlie its addiction risk. Other substances, such as amyl nitrite (“poppers”), primarily produce smooth muscle relaxation and enhance erection but are not addictive. With chronic exposure to the aromatic hydrocarbons (eg, benzene, toluene), toxic effects can be observed in many organs, including white matter lesions in the central nervous system. Management of overdose remains supportive.

## NON-ADDICTIVE DRUGS OF ABUSE

### LSD, Mescaline, & Psilocybin

LSD, mescaline, and psilocybin are commonly called psychedelics because of their ability to alter consciousness, so one senses stimuli that are not

present. They induce, often in an unpredictable way, perceptual symptoms, including shape and color distortion. Psychosis-like manifestations (depersonalization, hallucinations, distorted time perception) have led some to classify these drugs as psychotomimetics. They also produce somatic symptoms (dizziness, nausea, paresthesias, and blurred vision). Some users have reported intense reexperiencing of perceptual effects (flashbacks) up to several years after the last drug exposure.

Psychedelics differ from most other drugs described in this chapter in that they induce neither dependence nor addiction. However, repetitive exposure still leads to rapid tolerance (also called tachyphylaxis). Animals do not self-administer hallucinogens, suggesting that they are not rewarding to them. Additional studies show that these drugs also fail to stimulate **dopamine** release, further supporting the idea that only drugs that activate the mesolimbic **dopamine** system are addictive. Instead, hallucinogens increase glutamate release in the cortex, presumably by enhancing excitatory afferent input via presynaptic serotonin receptors (eg, 5-HT<sub>2A,B</sub>) from the thalamus. Resolution of the 3D structure of an LSD-bound 5-HT<sub>2B</sub> receptor reveals an unusual attachment mode, explaining the slow kinetics of the molecule.

LSD is an ergot alkaloid. After synthesis, blotter paper or sugar cubes are sprinkled with the liquid and allowed to dry. When LSD is swallowed, psychoactive effects typically appear after 30 minutes and last 6–12 hours. During this time, subjects have impaired ability to make rational judgments and understand common dangers, which puts them at risk for accidents and personal injury.

In adults, a typical dose is 20–30 mcg. LSD is not considered neurotoxic, but like most ergot alkaloids, it may lead to strong contractions of the uterus that can induce abortion (see [Chapter 16](#)).

The main molecular target of LSD and other hallucinogens is the 5-HT<sub>2A</sub> receptor. This receptor couples to G proteins of the G<sub>q</sub> type and generates inositol trisphosphate (IP<sub>3</sub>), leading to a release of intracellular calcium. Although hallucinogens, and LSD in particular, have been proposed for several therapeutic indications, efficacy remains elusive pending the outcome of ongoing clinical studies (for historical reasons often being carried out in Switzerland) for cluster headache, depression, and **alcohol** use disorder.

## **KETAMINE & PHENCYCLIDINE (PCP)**

**Ketamine** and PCP were developed as general anesthetics (see [Chapter 25](#)), but only **ketamine** is still used for this application, and more recently as an antidepressant (see [Chapter 30](#)). Both drugs, along with others, are now classified as “club drugs” and sold under names such as “angel dust,” “Hog,” and “Special K.” They owe their effects to their use-dependent, noncompetitive antagonism of the NMDA receptor. The effects of these substances became apparent when patients undergoing surgery reported unpleasant vivid dreams and hallucinations after anesthesia. **Ketamine** and PCP are white crystalline powders in their pure forms, but on the street they are also sold as liquids, capsules, or pills, which can be snorted, ingested, injected, or smoked. Psychedelic effects last for about 1 hour and also include increased blood pressure, impaired memory function, and visual alterations. At high doses, unpleasant out-of-body and near-death experiences have been reported. Although **ketamine** and PCP do not cause dependence and addiction (relative risk = 1), chronic exposure, particularly to the latter, may lead to long-lasting psychosis closely resembling schizophrenia, which may persist beyond drug exposure. Surprisingly, intravenous administration of **ketamine** can eliminate episodes of depression within hours (see [Chapter 30](#)), in strong contrast to selective serotonin reuptake inhibitors and other antidepressants, which usually take weeks to act.

The antidepressive mechanism is believed to involve the antagonism of NMDA receptors. An alternate explanation may involve hydroxynorketamine, a metabolite of **ketamine**, that targets AMPA receptors to exert the antidepressant effect. Recent findings suggest that **ketamine** dampens the NMDA receptor dependent burst activity of neurons of the lateral habenula, which leads to a weak disinhibition of the ventral tegmental area. Additional work implicates a disinhibitory circuit in the anterior cingulate cortex. While one **ketamine** preparation (eg, **esketamine**, the S-enantiomer, introduced in Germany in 1997 as an anesthetic) has received FDA approval to treat depression in adults, a limitation may be the transient nature of the effect, which wears off within days even with repetitive administration.

## **CLINICAL PHARMACOLOGY OF DEPENDENCE & ADDICTION**

No single pharmacologic treatment (even in combination with behavioral interventions) efficiently eliminates addiction. This is not to say that addiction is irreversible. Pharmacologic interventions may in fact, be useful at all stages of the disease. This is particularly true in the case of a massive overdose, in which reversal of drug action may be a lifesaving measure. However, FDA-approved antagonists are available only for opioids and benzodiazepines.

Pharmacologic interventions may also alleviate the withdrawal syndrome, particularly after opioid exposure. On the assumption that withdrawal reflects—at least in part—hyperactivity of central adrenergic systems, the  $\alpha_2$ -adrenoceptor agonist **clonidine** (also used as a centrally active antihypertensive drug; see [Chapter 11](#)) has been used with some success to attenuate withdrawal. Today, most clinicians prefer to manage opioid withdrawal by very slowly tapering the administration of long-acting opioids.

Another widely accepted treatment is substitution of a legally available agonist that acts at the same receptor as the abused drug. This approach has been approved for opioids and **nicotine**. For example, heroin addicts may receive **methadone** to replace heroin; smoking addicts may receive **nicotine** continuously via a transdermal patch system to replace smoking. In general, a rapid-acting substance is replaced with one that acts or is absorbed more slowly. Some substitution therapies employ a partial agonist (eg, **buprenorphine**), which, however, may trigger withdrawal. Substitution treatments are largely justified by the benefits of reducing associated health risks, the reduction of drug-associated crime, and better social integration. Although dependence persists, the goal is, with the support of behavioral interventions, to motivate drug users to gradually reduce the dose and become abstinent.

The biggest challenge is the treatment of addiction itself. Several approaches have been proposed, but all remain experimental. One approach is to pharmacologically reduce cravings. The  $\mu$ -opioid receptor antagonist and partial agonist **naltrexone** is FDA-approved for this indication in opioid and **alcohol** addiction. Its effect is modest and may involve a modulation of endogenous opioid systems.

Clinical trials are currently being conducted with a number of drugs, including the high-affinity GABA<sub>B</sub>-receptor agonist **baclofen**, and initial results have shown a significant reduction of craving. This effect may be mediated by the inhibition of the **dopamine** neurons of the VTA, which is possible at **baclofen** concentrations obtained by oral administration because of its very high affinity for the GABA<sub>B</sub> receptor.

**Rimonabant** is an inverse agonist of the CB<sub>1</sub> receptor that behaves like an antagonist of cannabinoids. It was developed for smoking cessation and to facilitate weight loss. Because of frequent adverse effects—most notably severe depression carrying a substantial risk of suicide—this drug is no longer used clinically. It was initially used in conjunction with diet and exercise for obese patients (body mass index above 30 kg/m<sup>2</sup>). While the cellular mechanism of rimonabant remains to be elucidated, data in rodents convincingly demonstrate that this compound can reduce self-administration in naive as well as drug-experienced animals.

While still experimental, the emergence of a circuit model for addiction has prompted interest in neuromodulatory interventions, such as deep brain stimulation (DBS) or transcranial magnetic stimulation (TMS). Inspired by optogenetic “treatments” in rodent models of addiction, novel protocols have been proposed for DBS in the nucleus accumbens or TMS of the prefrontal cortex. Case studies seem to confirm the potential of such approaches, but controlled clinical studies are lacking.

### SUMMARY Drugs Used to Treat Dependence and Addiction

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>OPIOID RECEPTOR ANTAGONIST</b>				
• <b>Naloxone</b>	Nonselective antagonist of opioid receptors	Reverses the acute effects of opioids; can precipitate severe abstinence syndrome	Opioid overdose	Effect much shorter than <b>morphine</b> (1–2 h); therefore several injections required
• <b>Naltrexone</b>	Antagonist of opioid receptors	Blocks effects of illicit opioids	Treatment of alcoholism, opioid addiction	Half-life 10 h (oral); 5–10 days (depot injection)

### SYNTHETIC OPIOID

• <b>Methadone</b>	Slow-acting agonist of $\mu$ -opioid receptor	Acute effects similar to <b>morphine</b> (see text)	Substitution therapy for opioid addicts	High oral bioavailability • half-life highly variable among individuals (range 4–130 h) • <i>Toxicity</i> : Respiratory depression, constipation, miosis, tolerance, dependence, arrhythmia, and withdrawal symptoms
• <b>Levomethadone</b>	“Enantiopure” <b>methadone</b> containing only the left-enantiomer of the molecule	Similar to <b>morphine</b> and <b>methadone</b> , but at half the dose of the latter	Substitution therapy	Less toxic compared to racemic <b>methadone</b> , particularly related to cardiac adverse effects (long QT interval)
• <b>Morphine sulphate</b>	A salt containing <b>morphine</b> sulfate pentahydrate	Slow-release version with a longer action than <b>morphine</b>	Substitution therapy	

#### PARTIAL $\mu$ -OPIOID RECEPTOR AGONIST

• <b>Buprenorphine</b>	Partial agonist at $\mu$ -opioid receptors	Attenuates acute effects of <b>morphine</b>	Oral substitution therapy for opioid addicts	Long half-life (40 h) • formulated together with <b>naloxone</b> to avoid illicit IV injections
------------------------	--	---	--	---

#### NICOTINIC RECEPTOR PARTIAL AGONIST

• <b>Varenicline</b>	Partial agonist of nicotinic <b>acetylcholine</b> receptor of the $\alpha 4\beta 2$ -type	Occludes “rewarding” effects of smoking • heightened awareness of colors	Smoking cessation	<i>Toxicity</i> : Nausea and vomiting, seizures, psychiatric changes
----------------------	---	--	-------------------	--

• *Cytisine*: Natural analog (extracted from *laburnum* flowers) of **varenicline**

#### BENZODIAZEPINES

• <b>Oxazepam</b> , others	Positive modulators of the GABA <sub>A</sub> receptors, increase frequency of channel opening	Enhances GABAergic synaptic transmission; attenuates withdrawal symptoms (tremor, hallucinations, anxiety) in alcoholics • prevents withdrawal seizures	Delirium tremens	Half-life 4–15 h • pharmacokinetics not affected by decreased liver function
----------------------------	---	---	------------------	--

• **Lorazepam**: Alternate to **oxazepam** with similar properties

• <b>Acamprosate</b>	Antagonist of NMDA glutamate receptors	May interfere with forms of synaptic plasticity that depend on NMDA receptors	Treatment of alcoholism • effective only in combination with counseling	<i>Toxicity:</i> Allergic reactions, arrhythmia, and low or high blood pressure, headaches, insomnia, and impotence • hallucinations, particularly in elderly patients
<b>CANNABINOID RECEPTOR INVERSE AGONIST</b>				
• <b>Rimonabant</b>	CB <sub>1</sub> receptor inverse agonist	Decreases neurotransmitter release at GABAergic and glutamatergic synapses	Approved in Europe from 2006 to 2008 to treat obesity, then withdrawn because of major side effects • smoking cessation has never been approved, but remains an off-label indication	<i>Toxicity:</i> Major depression, including increased risk of suicide

### CASE STUDY ANSWER

When found by his parents, the patient was having visual hallucinations of colorful insects. Hallucinations are often caused by a cannabis overdose, especially when hashish is ingested. The slower kinetics of oral cannabis are more difficult to control compared to smoking marijuana. The poor learning performance may be due to the interference of exogenous cannabis with endocannabinoids that fine-tune synaptic transmission and plasticity. While probably not fulfilling the criteria for addiction at present, the patient is at risk as epidemiologic studies show that drug abuse typically begins in late adolescence. The fact that he is not yet using other drugs is a positive sign.

## Chapter 33: Agents Used in Cytopenias; Hematopoietic Growth Factors

James L. Zehnder; Lacrisha J. Go

### CASE STUDY

#### CASE STUDY

A 25-year-old woman who has been on a strict vegan diet for the past 2 years presents with increasing numbness and paresthesias in her extremities, generalized weakness, a sore tongue, and gastrointestinal discomfort. Physical examination reveals a pale woman with diminished vibration sensation, diminished spinal reflexes, and extensor plantar reflexes (Babinski sign). Examination of her oral cavity reveals atrophic glossitis, in which the tongue appears deep red in color and abnormally smooth and shiny due to atrophy of the lingual papillae. Laboratory testing reveals a macrocytic anemia based on a hematocrit of 30% (normal for women, 37–48%), a hemoglobin concentration of 9.4 g/dL, an erythrocyte mean cell volume (MCV) of 123 fL (normal, 84–99 fL), an erythrocyte mean cell hemoglobin concentration (MCHC) of 34% (normal, 31–36%), and a low reticulocyte count. Further laboratory testing reveals a normal serum folate concentration and a serum vitamin B<sub>12</sub> (cobalamin) concentration of 98 pg/mL (normal, 250–1100 pg/mL). Once megaloblastic anemia was identified, why was it important to measure serum concentrations of both folic acid and cobalamin? Should this patient be treated with oral or parenteral vitamin B<sub>12</sub>?

Hematopoiesis, the production from undifferentiated stem cells of circulating erythrocytes, platelets, and leukocytes, is a remarkable process that produces more than 200 billion new blood cells per day in the normal person and even greater numbers of cells in persons with conditions that cause loss or destruction of blood cells.<sup>\*</sup> In adults, the hematopoietic machinery resides primarily in the bone marrow and requires a constant supply of three essential nutrients—**iron**, **vitamin B<sub>12</sub>**, and **folic acid**—as well as the presence of **hematopoietic growth factors**, proteins that regulate the proliferation and differentiation of hematopoietic cells. Inadequate supplies of either the essential nutrients or the growth factors result in deficiency of functional blood cells. **Anemia**, a deficiency in oxygen-carrying erythrocytes, is the most common deficiency and several forms are easily treated. Sickle cell anemia, a condition resulting from a genetic alteration in the hemoglobin molecule, is common but is not easily treated. It is discussed in the Box: Sickle Cell Disease and [Hydroxyurea](#). **Thrombocytopenia** and **neutropenia** are not rare, and some forms are amenable to drug therapy. In this chapter, we first consider the treatment of anemia due to deficiency of iron, vitamin B<sub>12</sub>, or folic acid; we then turn to the medical use of hematopoietic growth factors to combat anemia, thrombocytopenia, and neutropenia, and to support stem cell transplantation.

Sickle cell disease is a genetic cause of hemolytic anemia, a form of anemia due to increased erythrocyte *destruction*, instead of the reduced mature erythrocyte *production* seen with iron, folic acid, and vitamin B<sub>12</sub> deficiency. Patients with sickle cell disease are homozygous for the aberrant  $\beta$ -hemoglobin S (*HbS*) allele (substitution of valine for glutamic acid at amino acid 6 of  $\beta$ -globin) or heterozygous for HbS and a second mutated  $\beta$ -hemoglobin gene such as hemoglobin C (*HbC*) or  $\beta$ -thalassemia. Sickle cell disease has an increased prevalence in individuals of African descent because the heterozygous trait confers resistance to malaria.

In the majority of patients with sickle cell disease, anemia is not the primary presenting problem; the anemia is generally well compensated even though such individuals have a chronically low hematocrit (20–30%), a low serum hemoglobin level (7–10 g/dL), and an elevated reticulocyte count. Instead, the primary problem is that deoxygenated HbS chains form polymeric structures that dramatically change erythrocyte shape, reduce deformability, and elicit membrane permeability changes that further promote hemoglobin polymerization. Abnormal erythrocytes aggregate in the microvasculature—where **oxygen** tension is low and hemoglobin is deoxygenated—and cause veno-occlusive damage. In the musculoskeletal system, this results in characteristic, extremely severe bone and joint pain. In the cerebral vascular system, it causes ischemic stroke. Damage to the spleen increases the risk of infection, particularly by encapsulated bacteria such as *Streptococcus pneumoniae*. In the pulmonary system, there is an increased risk of infection, and in adults, an increase in embolism and pulmonary hypertension. Supportive treatment includes analgesics, antibiotics, pneumococcal vaccination, and blood transfusions. In addition, the cancer chemotherapeutic drug **hydroxyurea** (hydroxycarbamide) reduces veno-occlusive events. It is approved in the United States for treatment of adults with recurrent sickle cell crises and approved in Europe in adults and children with recurrent vaso-occlusive events. As an anticancer drug used in the treatment of chronic and acute myelogenous leukemia, **hydroxyurea** inhibits ribonucleotide reductase and thereby depletes deoxynucleoside triphosphate and arrests cells in the S phase of the cell cycle (see [Chapter 54](#)). In the treatment of sickle cell disease, **hydroxyurea** acts through poorly defined pathways to increase the production of fetal hemoglobin  $\gamma$  (HbF), which interferes with the polymerization of HbS. Clinical trials have shown that **hydroxyurea** decreases painful crises in adults and children with severe sickle cell disease. Its adverse effects include hematopoietic depression, gastrointestinal effects, and teratogenicity in pregnant women. More recently, **voxelotor**, an oral drug that binds HbS and reduces sickling by increasing its affinity for **oxygen**, has received accelerated approval from the FDA.

## AGENTS USED IN ANEMIAS

### IRON

#### Basic Pharmacology

Iron deficiency is the most common cause of chronic anemia. Like other forms of chronic anemia, iron deficiency anemia leads to pallor, fatigue, dizziness, exertional dyspnea, and other generalized symptoms of tissue hypoxia. The cardiovascular adaptations to chronic anemia—tachycardia, increased cardiac output, vasodilation—can worsen the condition of patients with underlying cardiovascular disease.

Iron forms the nucleus of the iron-porphyrin heme ring, which together with globin chains forms hemoglobin. Hemoglobin reversibly binds **oxygen** and provides the critical mechanism for **oxygen** delivery from the lungs to other tissues. In the absence of adequate iron, small erythrocytes with insufficient hemoglobin are formed, giving rise to **microcytic hypochromic anemia**. Iron-containing heme is also an essential component of myoglobin, cytochromes, and other proteins with diverse biologic functions.

#### Pharmacokinetics

Free inorganic iron is extremely toxic, but iron is required for essential proteins such as hemoglobin; therefore, evolution has provided an elaborate system for regulating iron absorption, transport, and storage ([Figure 33–1](#)). The system uses specialized transport, storage, ferrireductase, and ferroxidase proteins whose concentrations are controlled by the body's demand for hemoglobin synthesis and adequate iron stores ([Table 33–1](#)). A peptide called **hepcidin**, produced primarily by liver cells, serves as a key central regulator of the system. Nearly all of the iron used to support

hematopoiesis is reclaimed from catalysis of the hemoglobin in senescent or damaged erythrocytes. Normally, only a small amount of iron is lost from the body each day, so dietary requirements are small and easily fulfilled by the iron available in a wide variety of foods. However, in special populations with either increased iron requirements (eg, growing children, pregnant women) or increased losses of iron (eg, menstruating women), iron requirements can exceed normal dietary supplies, and iron deficiency can develop.

FIGURE 33-1

Absorption, transport, and storage of iron. Intestinal epithelial cells actively absorb inorganic iron via the divalent metal transporter 1 (DMT1) and heme iron via the heme carrier protein 1 (HCP1). Iron that is absorbed or released from absorbed heme iron in the intestine (1) is actively transported into the blood by ferroportin (FP) and stored as ferritin (F). In the blood, iron is transported by transferrin (Tf) to erythroid precursors in the bone marrow for synthesis of hemoglobin (Hgb) in red blood cells (RBC) (2); or to hepatocytes for storage as ferritin (3). The transferrin-iron complex binds to transferrin receptors (TfR) in erythroid precursors and hepatocytes and is internalized. After release of iron, the TfR-Tf complex is recycled to the plasma membrane and Tf is released. Macrophages that phagocytize senescent erythrocytes (RBC) reclaim the iron from the RBC hemoglobin and either export it or store it as ferritin (4). Hepatocytes use several mechanisms to take up iron and store the iron as ferritin. High hepatic iron stores increase hepcidin synthesis, and hepcidin inhibits ferroportin; low hepatocyte iron and increased erythroferrone inhibits hepcidin and enhances iron absorption via ferroportin. Ferrous iron ( $\text{Fe}^{2+}$ ), blue diamonds, squares; ferric iron ( $\text{Fe}^{3+}$ ), red; DB, duodenal cytochrome B; F, ferritin. Iron distribution in normal adults.<sup>1</sup>

	Iron Content (mg)	
	Men	Women
Hemoglobin	3050	1700
Myoglobin	430	300
Enzymes	10	8
Transport (transferrin)	8	6
Storage (ferritin and other forms)	750	300
Total	4248	2314

<sup>1</sup>Values are based on data from various sources and assume that normal men weigh 80 kg and have a hemoglobin level of 16 g/dL and that normal women weigh 55 kg and have a hemoglobin level of 14 g/dL.

### A. Absorption

The average American diet contains 10–15 mg of elemental iron daily. A normal individual absorbs 5–10% of this iron, or about 0.5–1 mg daily. Iron is absorbed in the duodenum and proximal jejunum, although the more distal small intestine can absorb iron if necessary. Iron absorption increases in response to low iron stores or increased iron requirements. Total iron absorption increases to 1–2 mg/d in menstruating women and may be as high as 3–4 mg/d in pregnant women.

Iron is available in a wide variety of foods but is especially abundant in meat. The iron in meat protein can be efficiently absorbed, because heme iron in meat hemoglobin and myoglobin can be absorbed intact without first having to be dissociated into elemental iron (see [Figure 33-1](#)). Iron in other foods, especially vegetables and grains, is often tightly bound to organic compounds and is much less available for absorption. Nonheme iron in foods and iron in inorganic iron salts and complexes must be reduced by a ferrireductase to ferrous iron ( $\text{Fe}^{2+}$ ) before it can be absorbed by intestinal mucosal cells.

Iron crosses the luminal membrane of the intestinal mucosal cell by two mechanisms: active transport of ferrous iron by the divalent metal transporter DMT1, and absorption of iron complexed with heme (see [Figure 33-1](#)). Together with iron split from absorbed heme, the newly absorbed iron can be actively transported into the blood across the basolateral membrane by a transporter known as ferroportin and oxidized to ferric iron ( $\text{Fe}^{3+}$ ) by the ferroxidase hephaestin. The liver-derived hepcidin inhibits intestinal cell iron release by binding to ferroportin and triggering its internalization and destruction. Excess iron is stored in intestinal epithelial cells as ferritin, a water-soluble complex consisting of a core of ferric hydroxide covered by a shell of a specialized storage protein called **apoferritin**.

### B. Transport

Iron is transported in the plasma bound to **transferrin**, a  $\beta$ -globulin that can bind two molecules of ferric iron (see [Figure 33-1](#)). The transferrin-iron complex enters maturing erythroid cells by a specific receptor mechanism. Transferrin receptors—integral membrane glycoproteins present in large numbers on proliferating erythroid cells—bind and internalize the transferrin-iron complex through the process of receptor-mediated endocytosis. In

endosomes, the ferric iron is released, reduced to ferrous iron, and transported by DMT1 into the cytoplasm, where it is funneled into hemoglobin synthesis or stored as ferritin. The transferrin-transferrin receptor complex is recycled to the cell membrane, where the transferrin dissociates and returns to the plasma. This process provides an efficient mechanism for supplying the iron required by developing red blood cells.

Increased erythropoiesis is associated with an increase in the number of transferrin receptors on developing erythroid cells and a reduction in hepatic hepcidin release. Iron store depletion and iron deficiency anemia are associated with an increased concentration of serum transferrin.

### C. Storage

In addition to the storage of iron in intestinal mucosal cells, iron is also stored, primarily as ferritin, in macrophages in the liver, spleen, and bone, and in parenchymal liver cells (see [Figure 33-1](#)). The mobilization of iron from macrophages and hepatocytes is primarily controlled by hepcidin regulation of ferroportin activity. Low hepcidin concentrations result in iron release from these storage sites; high hepcidin concentrations inhibit iron release. Ferritin is detectable in serum. Since the ferritin present in serum is in equilibrium with storage ferritin in reticuloendothelial tissues, the serum ferritin level can be used to estimate total body iron stores.

### D. Elimination

There is no mechanism for excretion of iron. Small amounts are lost in the feces by exfoliation of intestinal mucosal cells, and trace amounts are excreted in bile, urine, and sweat. These losses account for no more than 1 mg of iron per day. Because the body's ability to excrete iron is so limited, regulation of iron balance must be achieved by changing intestinal absorption and storage of iron in response to the body's needs. As noted below, impaired regulation of iron absorption leads to serious pathology.

## Clinical Pharmacology

### A. Indications for the Use of Iron

The only clinical indication for the use of iron preparations is the treatment or prevention of iron deficiency anemia. This manifests as a hypochromic, microcytic anemia in which the erythrocyte mean cell volume (MCV) and the mean cell hemoglobin concentration are low ([Table 33-2](#)). Iron deficiency is commonly seen in populations with increased iron requirements. These include infants, especially premature infants; children during rapid growth periods; pregnant and lactating women; and patients with chronic kidney disease who lose erythrocytes at a relatively high rate during hemodialysis and also form them at a high rate as a result of treatment with the erythrocyte growth factor erythropoietin (see below). Inadequate iron absorption also can cause iron deficiency. This is seen after gastrectomy and in patients with severe small bowel disease that results in generalized malabsorption.

**Distinguishing features of the nutritional anemias.**

<b>Nutritional Deficiency</b>	<b>Type of Anemia</b>	<b>Laboratory Abnormalities</b>
Iron	Microcytic, hypochromic with MCV <80 fL and MCHC <30%	Low SI <30 mcg/dL with increased TIBC, resulting in a % transferrin saturation (SI/TIBC) of <10%; low serum ferritin level (<20 mcg/L)
Folic acid	Macrocytic, normochromic with MCV >100 fL and normal or elevated MCHC	Low serum folic acid (<4 ng/mL)
Vitamin B <sub>12</sub>	Same as folic acid deficiency	Low serum cobalamin (<100 pmol/L) accompanied by increased serum homocysteine (>13 μmol/L), and increased serum (>0.4 μmol/L) and urine (>3.6 μmol/mol creatinine) methylmalonic acid

MCV, mean cell volume; MCHC, mean cell hemoglobin concentration; SI, serum iron; TIBC, transferrin iron-binding capacity.

The most common cause of iron deficiency in adults is blood loss. Menstruating women lose about 30 mg of iron with each menstrual period; women with heavy menstrual bleeding may lose much more. Thus, many premenopausal women have low iron stores or even iron deficiency. In men and postmenopausal women, the most common site of blood loss is the gastrointestinal tract. Patients with unexplained iron deficiency anemia should be evaluated for occult gastrointestinal bleeding.

**B. Treatment**

Iron deficiency anemia is treated with oral or parenteral iron preparations. Oral iron corrects the anemia just as rapidly and completely as parenteral iron in most cases if iron absorption from the gastrointestinal tract is normal. An exception is the high requirement for iron of patients with advanced chronic kidney disease who are undergoing hemodialysis and treatment with erythropoietin; for these patients, parenteral iron administration is preferred.

**1. Oral iron therapy**

A wide variety of oral iron preparations is available. Because ferrous iron is most efficiently absorbed, ferrous salts should be used. Ferrous sulfate, ferrous gluconate, and ferrous fumarate are all effective and inexpensive and are recommended for the treatment of most patients.

Different iron salts provide different amounts of elemental iron, as shown in Table 33-3. In an iron-deficient individual, about 50–100 mg of iron can be incorporated into hemoglobin daily, and about 25% of oral iron given as ferrous salt can be absorbed. Therefore, 200–400 mg of elemental iron should be given daily to correct iron deficiency most rapidly. Patients unable to tolerate such large doses of iron can be given lower daily doses of iron, which results in slower but still complete correction of iron deficiency. Treatment with oral iron should be continued for 3–6 months after correction of the cause of the iron loss. This corrects the anemia and replenishes iron stores.

## Some commonly used oral iron preparations.

Preparation	Tablet Size	Elemental Iron per Tablet	Usual Adult Dosage for Treatment of Iron Deficiency (Tablets per Day)
Ferrous sulfate, hydrated	325 mg	65 mg	2–4
Ferrous sulfate, desiccated	200 mg	65 mg	2–4
Ferrous gluconate	325 mg	36 mg	3–4
Ferrous fumarate	325 mg	106 mg	2–3

Common adverse effects of oral iron therapy include nausea, epigastric discomfort, abdominal cramps, constipation, and diarrhea. These effects are usually dose-related and often can be overcome by lowering the daily dose of iron or by taking the tablets immediately after or with meals, without dairy. Some patients have less severe gastrointestinal adverse effects with one iron salt than another and benefit from changing preparations. Patients taking oral iron commonly develop black stools; this has no clinical significance in itself but may obscure the diagnosis of continued gastrointestinal blood loss.

## 2. Parenteral iron therapy

Parenteral therapy should be reserved for patients with documented iron deficiency who are unable to tolerate or absorb oral iron and for patients with extensive chronic anemia who cannot be maintained with oral iron alone, or require rapid repletion. This includes patients with advanced chronic renal disease requiring hemodialysis and treatment with erythropoietin, various postgastrectomy conditions and previous small bowel resection, inflammatory bowel disease involving the proximal small bowel, and malabsorption syndromes.

The challenge with parenteral iron therapy is that parenteral administration of inorganic free ferric iron produces serious dose-dependent toxicity, which severely limits the dose that can be administered. However, when the ferric iron is formulated as a colloid containing particles with a core of iron oxyhydroxide surrounded by a core of carbohydrate, bioactive iron is released slowly from the stable colloid particles. In the United States, the three traditional forms of parenteral iron are **iron dextran**, **sodium ferric gluconate complex**, and **iron sucrose**. Two newer preparations are also available (see below).

**Iron dextran** is a stable complex of ferric oxyhydroxide and **dextran** polymers containing 50 mg of elemental iron per milliliter of solution. It can be given by deep intramuscular injection or by intravenous infusion, although the intravenous route is used most commonly. Intravenous administration eliminates the local pain and tissue staining that often occur with the intramuscular route and allows delivery of the entire dose of iron necessary to correct the iron deficiency at one time. Adverse effects of intravenous iron **dextran** therapy include headache, light-headedness, fever, arthralgias, nausea and vomiting, back pain, flushing, urticaria, bronchospasm, and, rarely, anaphylaxis and death. Owing to the risk of a hypersensitivity reaction, a small test dose of iron **dextran** should always be given before full intramuscular or intravenous doses are given. Patients with a strong allergy history and patients who have had a prior reaction to parenteral iron are more likely to have hypersensitivity reactions to treatment with parenteral iron **dextran**. The iron **dextran** formulations used clinically are distinguishable as high-molecular-weight and low-molecular-weight forms. In the United States, the INFED preparation is a low-molecular-weight form while Dexferrum is a high-molecular-weight form. Clinical data—primarily from observational studies—indicate that the risk of anaphylaxis is largely associated with high-molecular-weight formulations.

**Sodium ferric gluconate complex** and **iron-sucrose complex** are alternative parenteral iron preparations. **Ferric carboxymaltose** is a colloidal iron preparation embedded within a carbohydrate polymer. **Ferumoxytol** is a superparamagnetic iron oxide nanoparticle coated with carbohydrate. The carbohydrate shell is removed in the reticuloendothelial system, allowing the iron to be stored as ferritin, or released to transferrin.

**Ferumoxytol** may interfere with magnetic resonance imaging (MRI) studies. Thus if imaging is needed, MRI should be performed prior to **ferumoxytol**

therapy or alternative imaging modality used if needed soon after dosing. The US Food and Drug Administration (FDA) has issued a black box warning about risk of potentially fatal allergic reactions associated with the use of **ferumoxytol**.

For patients treated chronically with parenteral iron, it is important to monitor iron storage levels to avoid the serious toxicity associated with iron overload. Unlike oral iron therapy, which is subject to the regulatory mechanism provided by the intestinal uptake system, parenteral administration—which bypasses this regulatory system—can deliver more iron than can be safely stored. Iron stores can be estimated on the basis of serum concentrations of ferritin and the transferrin saturation, which is the ratio of the total serum iron concentration to the total iron-binding capacity (TIBC).

## Clinical Toxicity

### A. Acute Iron Toxicity

Acute iron toxicity is seen almost exclusively in young children who accidentally ingest iron tablets. As few as 10 tablets of any of the commonly available oral iron preparations can be lethal in young children. Adult patients taking oral iron preparations should be instructed to store tablets in child-proof containers out of the reach of children. Children who are poisoned with oral iron experience necrotizing gastroenteritis with vomiting, abdominal pain, and bloody diarrhea followed by shock, lethargy, and dyspnea. Subsequently, improvement is often noted, but this may be followed by severe metabolic acidosis, coma, and death. Urgent treatment is necessary. **Whole bowel irrigation** (see **Chapter 58**) should be performed to flush out unabsorbed pills. **Deferoxamine**, a potent iron-chelating compound, can be given intravenously to bind iron that has already been absorbed and to promote its excretion in urine and feces. Activated charcoal, a highly effective adsorbent for most toxins, does **not** bind iron and thus is ineffective. Appropriate supportive therapy for gastrointestinal bleeding, metabolic acidosis, and shock must also be provided.

### B. Chronic Iron Toxicity

Chronic iron toxicity (iron overload), also known as **hemochromatosis**, results when excess iron is deposited in the heart, liver, pancreas, and other organs. It can lead to organ failure and death. It most commonly occurs in patients with inherited hemochromatosis, a disorder characterized by excessive iron absorption, and in patients who receive many red cell transfusions over a long period of time (eg, individuals with  $\beta$ -thalassemia).

Chronic iron overload in the absence of anemia is most efficiently treated by intermittent phlebotomy. About one unit of blood can be removed every week until all of the excess iron is removed. Iron chelation therapy using parenteral **deferoxamine** or the oral iron chelators **deferasirox** or **deferiprone** (see **Chapter 57**) is less efficient, and more complicated, expensive, and hazardous, but sometimes the only option for patients with iron overload that cannot be managed by phlebotomy. This is often the case for many individuals with inherited and acquired causes of refractory anemia such as thalassemia major, sickle cell anemia, aplastic anemia, etc. **Deferiprone** has rarely been associated with agranulocytosis; thus weekly complete blood count monitoring is required.

## VITAMIN B<sub>12</sub>

Vitamin B<sub>12</sub> (cobalamin) serves as a cofactor for several essential biochemical reactions in humans. Deficiency of vitamin B<sub>12</sub> leads to megaloblastic anemia (see **Table 33-2**), gastrointestinal symptoms, and neurologic abnormalities. Although deficiency of vitamin B<sub>12</sub> due to an inadequate supply in the diet is unusual, deficiency of B<sub>12</sub> in adults—especially older adults—due to inadequate absorption of dietary vitamin B<sub>12</sub> is a relatively common and easily treated disorder.

### Chemistry

Vitamin B<sub>12</sub> consists of a porphyrin-like ring with a central cobalt atom attached to a nucleotide. Various organic groups may be covalently bound to the cobalt atom, forming different cobalamins. Deoxyadenosylcobalamin and methylcobalamin are the active forms of the vitamin in humans.

**Cyanocobalamin** and **hydroxocobalamin** (both available for therapeutic use) and other cobalamins found in food sources are converted to the active forms. The ultimate source of vitamin B<sub>12</sub> is from microbial synthesis; the vitamin is not synthesized by animals or plants. The chief dietary source of vitamin B<sub>12</sub> is microbially derived vitamin B<sub>12</sub> in meat (especially liver), eggs, and dairy products. Vitamin B<sub>12</sub> is sometimes called **extrinsic factor** to differentiate it from **intrinsic factor**, a protein secreted by the stomach that is required for gastrointestinal uptake of dietary vitamin B<sub>12</sub>.

The average American diet contains 5–30 mcg of vitamin B<sub>12</sub> daily, 1–5 mcg of which is usually absorbed. The vitamin is avidly stored, primarily in the liver, with an average adult having a total vitamin B<sub>12</sub> storage pool of 3000–5000 mcg. Only trace amounts of vitamin B<sub>12</sub> are normally lost in urine and stool. Because the normal daily requirements of vitamin B<sub>12</sub> are only about 2 mcg, it would take about 5 years for all of the stored vitamin B<sub>12</sub> to be exhausted and for megaloblastic anemia to develop if B<sub>12</sub> absorption were stopped. Vitamin B<sub>12</sub> is absorbed after it complexes with **intrinsic factor**, a glycoprotein secreted by the parietal cells of the gastric mucosa. Intrinsic factor combines with the vitamin B<sub>12</sub> that is liberated from dietary sources in the stomach and duodenum, and the intrinsic factor-vitamin B<sub>12</sub> complex is subsequently absorbed in the distal ileum by a highly selective receptor-mediated transport system. Vitamin B<sub>12</sub> deficiency in humans most often results from malabsorption of vitamin B<sub>12</sub> due either to lack of intrinsic factor or to loss or malfunction of the absorptive mechanism in the distal ileum. Nutritional deficiency is rare but may be seen in strict vegetarians after many years without meat, eggs, or dairy products.

Once absorbed, vitamin B<sub>12</sub> is transported to the various cells of the body bound to a family of specialized glycoproteins, transcobalamin I, II, and III. Excess vitamin B<sub>12</sub> is stored in the liver.

### Pharmacodynamics

Two essential enzymatic reactions in humans require vitamin B<sub>12</sub> (Figure 33–2). In one, methylcobalamin serves as an intermediate in the transfer of a methyl group from *N*<sup>5</sup>-methyltetrahydrofolate to homocysteine, forming methionine (see Figure 33–2A; Figure 33–3, section 1). Without vitamin B<sub>12</sub>, conversion of the major dietary and storage folate—*N*<sup>5</sup>-methyltetrahydrofolate—to tetrahydrofolate, the precursor of folate cofactors, cannot occur. As a result, vitamin B<sub>12</sub> deficiency leads to deficiency of folate cofactors necessary for several biochemical reactions involving the transfer of one-carbon groups. In particular, the depletion of tetrahydrofolate prevents synthesis of adequate supplies of the deoxythymidylate (dTMP) and purines required for DNA synthesis in rapidly dividing cells, as shown in Figure 33–3, section 2. The accumulation of folate as *N*<sup>5</sup>-methyltetrahydrofolate and the associated depletion of tetrahydrofolate cofactors in vitamin B<sub>12</sub> deficiency have been referred to as the “**methylfolate trap**.” This is the biochemical step whereby vitamin B<sub>12</sub> and folic acid metabolism are linked, and it explains why the megaloblastic anemia of vitamin B<sub>12</sub> deficiency can be partially corrected by ingestion of large amounts of folic acid. Folic acid can be reduced to dihydrofolate by the enzyme dihydrofolate reductase (see Figure 33–3, section 3) and thereby serve as a source of the tetrahydrofolate required for synthesis of the purines and dTMP required for DNA synthesis.

Vitamin B<sub>12</sub> deficiency causes the accumulation of homocysteine due to reduced formation of methylcobalamin, which is required for the conversion of homocysteine to methionine (see Figure 33-3, section 1). The increase in serum homocysteine can be used to help establish a diagnosis of vitamin

The other reaction that requires vitamin B<sub>12</sub> is isomerization of methylmalonyl-CoA to succinyl-CoA by the enzyme methylmalonyl-CoA mutase (see Figure 33–2B). In vitamin B<sub>12</sub> deficiency, this conversion cannot take place and the substrate, methylmalonyl-CoA, as well as methylmalonic acid accumulate. The increase in serum and urine concentrations of methylmalonic acid can be used to support a diagnosis of vitamin B<sub>12</sub> deficiency (see Table 33–2). In the past, it was thought that abnormal accumulation of methylmalonyl-CoA causes the neurologic manifestations of vitamin B<sub>12</sub> deficiency. However, newer evidence implicates the disruption of the methionine synthesis pathway as the cause of neurologic problems. Whatever the biochemical explanation for neurologic damage, the important point is that administration of folic acid in the setting of vitamin B<sub>12</sub> deficiency will not prevent neurologic manifestations even though it will largely correct the anemia caused by the vitamin B<sub>12</sub> deficiency.

### Clinical Pharmacology

Vitamin B<sub>12</sub> is used to treat or prevent deficiency. The most characteristic clinical manifestation of vitamin B<sub>12</sub> deficiency is megaloblastic, macrocytic anemia (see Table 33–2), often with associated mild or moderate leukopenia or thrombocytopenia (or both), and a characteristic hypercellular bone marrow with an accumulation of megaloblastic erythroid and other precursor cells. The neurologic syndrome associated with vitamin B<sub>12</sub> deficiency usually begins with paresthesias in peripheral nerves and weakness that progresses to spasticity, ataxia, and other central nervous system dysfunctions. Correction of vitamin B<sub>12</sub> deficiency arrests the progression of neurologic disease, but it may not fully reverse neurologic symptoms that have been present for several months. Although most patients with neurologic abnormalities caused by vitamin B<sub>12</sub> deficiency have megaloblastic anemia when first evaluated, occasional patients have few if any hematologic abnormalities.

Once a diagnosis of megaloblastic anemia is made, it must be determined whether vitamin B<sub>12</sub> or folic acid deficiency is the cause. Other megaloblastic anemia causes are rare. This can usually be accomplished by measuring serum levels of the **vitamins**. The Schilling test, which measures absorption and urinary excretion of radioactively labeled vitamin B<sub>12</sub>, can be used to further define the mechanism of vitamin B<sub>12</sub> malabsorption when this is found to be the cause of the megaloblastic anemia.

The most common causes of vitamin B<sub>12</sub> deficiency are pernicious anemia, partial or total gastrectomy, and conditions that affect the distal ileum, such as malabsorption syndromes, inflammatory bowel disease, or small bowel resection. Strict vegans eating a diet free of meat and dairy products may become B<sub>12</sub> deficient.

**Pernicious anemia** results from defective secretion of intrinsic factor by the gastric mucosal cells. Patients with pernicious anemia have gastric atrophy and fail to secrete intrinsic factor (as well as hydrochloric acid). These patients frequently have autoantibodies to intrinsic factor. Historically, the Schilling test demonstrated diminished absorption of radioactively labeled vitamin B<sub>12</sub>, which is corrected when intrinsic factor is administered with radioactive B<sub>12</sub>, since the vitamin can then be normally absorbed. This test is now rarely performed due to use of radioactivity in the assay.

Vitamin B<sub>12</sub> deficiency also occurs when the region of the distal ileum that absorbs the vitamin B<sub>12</sub>-intrinsic factor complex is damaged, as when the ileum is involved with inflammatory bowel disease or when the ileum is surgically resected. In these situations, radioactively labeled vitamin B<sub>12</sub> is not absorbed in the Schilling test, even when intrinsic factor is added. Rare cases of vitamin B<sub>12</sub> deficiency in children have been found to be secondary to congenital deficiency of intrinsic factor or to defects of the receptor sites for vitamin B<sub>12</sub>-intrinsic factor complex located in the distal ileum.

Alternatives to the Schilling test include testing for intrinsic factor antibodies and testing for elevated homocysteine and methylmalonic acid levels (see Figure 33–2) to make a diagnosis of pernicious anemia with high sensitivity and specificity.

Almost all cases of vitamin B<sub>12</sub> deficiency are caused by malabsorption of the vitamin; therefore, parenteral injections of vitamin B<sub>12</sub> are required for therapy. For patients with potentially reversible diseases, the underlying disease should be treated after initial treatment with parenteral vitamin B<sub>12</sub>.

Vitamin B<sub>12</sub> for parenteral injection is available as [cyanocobalamin](#) or [hydroxocobalamin](#). [Hydroxocobalamin](#) is preferred because it is more highly protein-bound and therefore remains longer in the circulation. Initial therapy should consist of 100–1000 mcg of vitamin B<sub>12</sub> intramuscularly daily or every other day for 1–2 weeks to replenish body stores. Maintenance therapy consists of 100–1000 mcg intramuscularly once a month for life. If neurologic abnormalities are present, maintenance therapy injections should be given every 1–2 weeks for 6 months before switching to monthly injections. Oral vitamin B<sub>12</sub>-intrinsic factor mixtures and liver extracts should not be used to treat vitamin B<sub>12</sub> deficiency; however, oral doses of 1000 mcg of vitamin B<sub>12</sub> daily are usually sufficient to treat patients with pernicious anemia who refuse or cannot tolerate the injections. After pernicious anemia is in remission following parenteral vitamin B<sub>12</sub> therapy, the vitamin can be administered intranasally as a spray or gel.

## FOLIC ACID

Reduced forms of folic acid are required for essential biochemical reactions that provide precursors for the synthesis of amino acids, purines, and DNA. Folate deficiency is relatively common, even though the deficiency is easily corrected by administration of folic acid. The consequences of folate deficiency go beyond the problem of anemia because folate deficiency is implicated as a cause of congenital malformations in newborns and may play a role in vascular disease (see Box: [Folic Acid Supplementation: A Public Health Dilemma](#)).

### Folic Acid Supplementation: A Public Health Dilemma

Starting in January 1998, all products made from enriched grains in the United States and Canada were required to be supplemented with folic acid. These rulings were issued to reduce the incidence of congenital neural tube defects (NTDs). Epidemiologic studies show a strong correlation between maternal folic acid deficiency and the incidence of NTDs such as spina bifida and anencephaly. The requirement for folic acid supplementation is a public health measure aimed at the significant number of women who do not receive prenatal care and are not aware of the importance of adequate folic acid ingestion for preventing birth defects in their infants. Observational studies from countries that supplement grains with folic acid have found that supplementation is associated with a significant (20–25%) reduction in NTD rates. Observational studies also suggest that rates of other types of congenital anomalies (heart and orofacial) have fallen since supplementation began.

There may be an added benefit for adults. *N*<sup>5</sup>-Methyl-tetrahydrofolate is required for the conversion of homocysteine to methionine ([Figure 33–2](#); [Figure 33–3](#), section 1). Impaired synthesis of *N*<sup>5</sup>-methyltetrahydrofolate results in elevated serum concentrations of homocysteine. Data from several sources suggest a positive correlation between elevated serum homocysteine and occlusive vascular diseases such as ischemic heart disease and stroke. Clinical data suggest that the folate supplementation program has improved the folate status and reduced the prevalence of hyperhomocysteinemia in a population of middle-aged and older adults who did not use vitamin supplements. There is also evidence that adequate folic acid protects against several cancers, including colorectal, breast, and cervical cancer.

Although the potential benefits of supplemental folic acid during pregnancy are compelling, the decision to require folic acid in grains was controversial. As described in the text, ingestion of folic acid can partially or totally correct the anemia caused by vitamin B<sub>12</sub> deficiency. However, folic acid supplementation does not prevent the potentially irreversible neurologic damage caused by vitamin B<sub>12</sub> deficiency. People with pernicious anemia and other forms of vitamin B<sub>12</sub> deficiency are usually identified because of signs and symptoms of anemia, which typically occur before neurologic symptoms. Some opponents of folic acid supplementation were concerned that increased folic acid intake in the general population would mask vitamin B<sub>12</sub> deficiency and increase the prevalence of neurologic disease in the elderly population. To put this in perspective, approximately 4000 pregnancies, including 2500 live births, in the United States each year are affected by NTDs. In contrast, it is estimated that more than 10% of the elderly population in the United States, or several million people, are at risk for the neuropsychiatric complications of vitamin B<sub>12</sub> deficiency. In acknowledgment of this controversy, the FDA kept its requirements for folic acid supplementation at a somewhat low level. There is also concern based on observational and prospective clinical trials that high folic acid levels can increase the risk of some diseases, such as colorectal cancer, for which folic acid may exhibit a bell-shaped curve. Further research is needed to more accurately define the optimal level of folic acid fortification in food and recommendations for folic acid supplementation in different populations and age groups.

Folic acid (pteroylglutamic acid) is composed of a heterocycle (pteridine), *p*-aminobenzoic acid, and glutamic acid (Figure 33–4). Various numbers of glutamic acid moieties are attached to the pteroyl portion of the molecule, resulting in monoglutamates, triglutamates, or polyglutamates. Folic acid undergoes reduction, catalyzed by the enzyme dihydrofolate reductase (“folate reductase”), to give dihydrofolic acid (see Figure 33–3, section 3). Tetrahydrofolate is subsequently transformed to folate cofactors possessing one-carbon units attached to the 5-nitrogen, to the 10-nitrogen, or to both positions (see Figure 33–3). Folate cofactors are interconvertible by various enzymatic reactions and serve the important biochemical function of donating one-carbon units at various levels of oxidation. In most of these, tetrahydrofolate is regenerated and becomes available for reutilization.

## Pharmacokinetics

The average American diet contains 500–700 mcg of folates daily, 50–200 mcg of which is usually absorbed, depending on metabolic requirements. Pregnant women may absorb as much as 300–400 mcg of folic acid daily. Various forms of folic acid are present in a wide variety of plant and animal tissues; the richest sources are yeast, liver, kidney, and green vegetables. Normally, 5–20 mg of folates is stored in the liver and other tissues. Folates are excreted in the urine and stool and are also destroyed by catabolism, so serum levels fall within a few days when intake is diminished. Because body stores of folates are relatively low and daily requirements high, folic acid deficiency and megaloblastic anemia can develop within 1–6 months after the intake of folic acid stops, depending on the patient’s nutritional status and the rate of folate utilization.

Unaltered folic acid is readily and completely absorbed in the proximal jejunum. Dietary folates, however, consist primarily of polyglutamate forms of *N*<sup>5</sup>-methyltetrahydrofolate. Before absorption, all but one of the glutamyl residues of the polyglutamates must be hydrolyzed by the enzyme  $\alpha$ -1-glutamyl transferase (“conjugase”) within the brush border of the intestinal mucosa. The monoglutamate *N*<sup>5</sup>-methyltetrahydrofolate is subsequently transported into the bloodstream by both active and passive transport and is then widely distributed throughout the body. Inside cells, *N*<sup>5</sup>-methyltetrahydrofolate is converted to tetrahydrofolate by the demethylation reaction that requires vitamin B<sub>12</sub> (see Figure 33–3, section 1).

## Pharmacodynamics

Tetrahydrofolate cofactors participate in one-carbon transfer reactions. As described earlier in the discussion of vitamin B<sub>12</sub>, one of these essential reactions produces the dTMP needed for DNA synthesis. In this reaction, the enzyme thymidylate synthase catalyzes the transfer of the one-carbon unit of *N*<sup>5</sup>, *N*<sup>10</sup>-methylenetetrahydrofolate to deoxyuridine monophosphate (dUMP) to form dTMP (see Figure 33–3, section 2). Unlike all the other enzymatic reactions that use folate cofactors, in this reaction the cofactor is oxidized to dihydrofolate, and for each mole of dTMP produced, 1 mole of

tetrahydrofolate is consumed. In rapidly proliferating tissues, considerable amounts of tetrahydrofolate are consumed in this reaction, and continued DNA synthesis requires continued regeneration of tetrahydrofolate by reduction of dihydrofolate, catalyzed by the enzyme dihydrofolate reductase. The tetrahydrofolate thus produced can then reform the cofactor  $N^5, N^{10}$ -methylene tetrahydrofolate by the action of serine transhydroxymethylase and thus allow for the continued synthesis of dTMP. The combined catalytic activities of dTMP synthase, dihydrofolate reductase, and serine transhydroxymethylase are referred to as the *dTMP synthesis cycle*. Enzymes in the dTMP cycle are the targets of two anticancer drugs: **methotrexate** inhibits dihydrofolate reductase, and a metabolite of 5-fluorouracil inhibits thymidylate synthase (see [Chapter 54](#)).

Cofactors of tetrahydrofolate participate in several other essential reactions.  $N^5$ -Methylene tetrahydrofolate is required for the vitamin B<sub>12</sub>-dependent reaction that generates methionine from homocysteine (see [Figure 33–2A](#); [Figure 33–3](#), section 1). In addition, tetrahydrofolate cofactors donate one-carbon units during the de novo synthesis of essential purines. In these reactions, tetrahydrofolate is regenerated and can reenter the tetrahydrofolate cofactor pool.

## Clinical Pharmacology

Folate deficiency results in a megaloblastic anemia that is microscopically indistinguishable from the anemia caused by vitamin B<sub>12</sub> deficiency (see above). However, folate deficiency does not cause the characteristic neurologic syndrome seen in vitamin B<sub>12</sub> deficiency. In patients with megaloblastic anemia, folate status is assessed with assays for serum folate or for red blood cell folate. Red blood cell folate levels are often of greater diagnostic value than serum levels, because serum folate levels tend to be labile and do not necessarily reflect tissue levels.

Folic acid deficiency is often caused by inadequate dietary intake of folates. Patients with **alcohol** dependence and patients with liver disease can develop folic acid deficiency because of poor diet and diminished hepatic storage of folates. Pregnant women and patients with hemolytic anemia have increased folate requirements and may become folic acid-deficient, especially if their diets are marginal. Evidence implicates maternal folic acid deficiency in the occurrence of fetal neural tube defects. (See Box: [Folic Acid Supplementation: A Public Health Dilemma](#).) Patients with malabsorption syndromes also frequently develop folic acid deficiency. Patients who require renal dialysis are at risk of folic acid deficiency because folates are removed from the plasma during the dialysis procedure.

Folic acid deficiency can be caused by drugs. **Methotrexate** and, to a lesser extent, **trimethoprim** and **pyrimethamine**, inhibit dihydrofolate reductase and may result in a deficiency of folate cofactors and ultimately in megaloblastic anemia. Long-term therapy with **phenytoin** also can cause folate deficiency, but it only rarely causes megaloblastic anemia.

Parenteral administration of folic acid is rarely necessary, since oral folic acid is well absorbed even in patients with malabsorption syndromes. A dose of 1 mg folic acid orally daily is sufficient to reverse megaloblastic anemia, restore normal serum folate levels, and replenish body stores of folates in almost all patients. Therapy should be continued until the underlying cause of the deficiency is removed or corrected. Therapy may be required indefinitely for patients with malabsorption or dietary inadequacy. Folic acid supplementation to prevent folic acid deficiency should be considered in high-risk patients, including pregnant women, patients with **alcohol** dependence, hemolytic anemia, liver disease, or certain skin diseases, and patients on renal dialysis.

## HEMATOPOIETIC GROWTH FACTORS

The hematopoietic growth factors are glycoprotein hormones that regulate the proliferation and differentiation of hematopoietic progenitor cells in the bone marrow. The first growth factors to be identified were called *colony-stimulating factors* because they could stimulate the growth of colonies of various bone marrow progenitor cells in vitro. Many of these growth factors have been purified and cloned, and their effects on hematopoiesis have been extensively studied. Quantities of these growth factors sufficient for clinical use are produced by recombinant DNA technology.

Of the known hematopoietic growth factors, **erythropoietin (epoetin alfa and epoetin beta)**, **granulocyte colony-stimulating factor (G-CSF)**, **granulocyte-macrophage colony-stimulating factor (GM-CSF)**, **interleukin 11 (IL-11)**, and thrombopoietin receptor agonists (**romiplostim** and **eltrombopag**) are currently in clinical use.

The hematopoietic growth factors and drugs that mimic their action have complex effects on the function of a wide variety of cell types, including nonhematologic cells. Their usefulness in other areas of medicine, particularly as potential anticancer and anti-inflammatory drugs, is being

## ERYTHROPOIETIN

### Chemistry & Pharmacokinetics

Erythropoietin, a 34- to 39-kDa glycoprotein, was the first human hematopoietic growth factor to be isolated. It was originally purified from the urine of patients with severe anemia. Recombinant human erythropoietin (rHuEPO, epoetin alfa) is produced in a mammalian cell expression system. After intravenous administration, erythropoietin has a serum half-life of 4–13 hours in patients with chronic renal failure. It is not cleared by dialysis. It is measured in international units (IU). Darbepoetin alfa is a modified form of erythropoietin that is more heavily glycosylated as a result of changes in amino acids. Darbepoetin alfa has a twofold to threefold longer half-life than epoetin alfa. Methoxy polyethylene glycol-epoetin beta is an isoform of erythropoietin covalently attached to a long polyethylene glycol polymer. This long-lived recombinant product is administered as a single intravenous or subcutaneous dose at 2-week or monthly intervals, whereas epoetin alfa is generally administered three times a week and darbepoetin is administered weekly.

### Pharmacodynamics

Erythropoietin stimulates erythroid proliferation and differentiation by interacting with erythropoietin receptors on red cell progenitors. The erythropoietin receptor is a member of the JAK/STAT superfamily of cytokine receptors that use protein phosphorylation and transcription factor activation to regulate cellular function (see [Chapter 2](#)). Erythropoietin also induces release of reticulocytes from the bone marrow. Endogenous erythropoietin is produced primarily in the kidney. In response to tissue hypoxia, more erythropoietin is produced through an increased rate of transcription of the erythropoietin gene. This results in correction of the anemia, provided that the bone marrow response is not impaired by red cell nutritional deficiency (especially iron deficiency), primary bone marrow disorders (see below), or bone marrow suppression from drugs or chronic diseases.

Normally, an inverse relationship exists between the hematocrit or hemoglobin level and the serum erythropoietin level. Nonanemic individuals have serum erythropoietin levels of less than 20 IU/L. As the hematocrit and hemoglobin levels fall and anemia becomes more severe, the serum erythropoietin level rises exponentially. Patients with moderately severe anemia usually have erythropoietin levels in the 100–500 IU/L range, and patients with severe anemia may have levels of thousands of IU/L. The most important exception to this inverse relationship is in the anemia of chronic renal failure. In patients with renal disease, erythropoietin levels are usually low because the kidneys cannot produce the growth factor. These are the patients most likely to respond to treatment with exogenous erythropoietin. In most primary bone marrow disorders (aplastic anemia, leukemias, myeloproliferative and myelodysplastic disorders, etc) and most nutritional and secondary anemias, endogenous erythropoietin levels are high, so there is less likelihood of a response to exogenous erythropoietin (but see below).

### Clinical Pharmacology

The availability of erythropoiesis-stimulating agents (ESAs) has had a significant positive impact for patients with several types of anemia ([Table 33–4](#)). The ESAs consistently improve the hematocrit and hemoglobin level, often eliminate the need for transfusions, and reliably improve quality of life indices. The ESAs are used routinely in patients with anemia secondary to chronic kidney disease. In patients treated with an ESA, an increase in reticulocyte count is usually observed in about 10 days and an increase in hematocrit and hemoglobin levels in 2–6 weeks. Dosages of ESAs are adjusted to maintain a target hemoglobin up to, but not exceeding, 10–12 g/dL. To support the increased erythropoiesis, nearly all patients with chronic kidney disease require oral or parenteral iron supplementation. Folate supplementation may also be necessary in some patients.

## Clinical uses of hematopoietic growth factors and agents that mimic their actions.

Hematopoietic Growth Factor	Clinical Condition Being Treated or Prevented	Recipients
Erythropoietin, darbepoetin alfa	Anemia	Patients with chronic renal failure HIV-infected patients treated with <a href="#">zidovudine</a> Cancer patients treated with myelosuppressive cancer chemotherapy Patients scheduled to undergo elective, noncardiac, nonvascular surgery
Granulocyte colony-stimulating factor (G-CSF; <a href="#">filgrastim</a> ) and granulocyte-macrophage colony-stimulating factor (GM-CSF; <a href="#">sargramostim</a> )	Neutropenia	Cancer patients treated with myelosuppressive cancer chemotherapy Patients with severe chronic neutropenia Patients recovering from bone marrow transplantation
	Stem cell or bone marrow transplantation	Patients with nonmyeloid malignancies or other conditions being treated with stem cell or bone marrow transplantation
	Mobilization of peripheral blood progenitor cells (PBPCs)	Donors of stem cells for allogeneic or autologous transplantation
Interleukin-11 (IL-11, <a href="#">oprelvekin</a> )	Thrombocytopenia	Patients with nonmyeloid malignancies who receive myelosuppressive cancer chemotherapy
<a href="#">Romiplostim</a> , <a href="#">eltrombopag</a>	Thrombocytopenia	Patients with idiopathic thrombocytopenic purpura

An alternative approach to treatment of chronic kidney disease anemia may become available in the future as a result of research that led to the Nobel Prize in Physiology or Medicine in 2019. Studies of the response to hypoxia resulted in the identification of a DNA-regulating factor that was named hypoxia-inducible factor (HIF). It was found that HIF was inactivated at normal [oxygen](#) levels by a set of enzymes called prolyl hydroxylases (PHDs) and when not inactivated (in hypoxic conditions), increased erythropoiesis. Small molecule PHD inhibitors have been discovered that increase hemoglobin; one such, **roxadustat**, has already been banned by professional sport authorities. This drug is in clinical trials for the treatment of kidney disease anemia.

In selected patients, erythropoietin is also used to reduce the need for red blood cell transfusion in patients undergoing myelosuppressive cancer chemotherapy who have a hemoglobin level of less than 10 g/dL, and for selected patients with low-risk myelodysplastic syndromes and anemia requiring red blood cell transfusion. Patients who have disproportionately low serum erythropoietin levels for their degree of anemia are most likely to respond to treatment. Patients with endogenous erythropoietin levels of less than 100 IU/L have the best chance of response, although patients with erythropoietin levels between 100 and 500 IU/L respond occasionally. Methoxy polyethylene glycol-epoetin beta should not be used for treatment of anemia caused by cancer chemotherapy because a clinical trial found significantly more deaths among patients receiving this form of erythropoietin.

Erythropoietin is one of the drugs commonly used illegally by endurance athletes to enhance performance. Other methods such as autologous transfusion of red cells or use of androgens also have been used to increase hemoglobin. "Blood doping" constitutes a serious health risk to athletes, is considered a form of cheating, and is universally banned and routinely tested for in athletic events.

The most common adverse effects of erythropoietin are hypertension and thrombotic complications. ESAs increase the risk of serious cardiovascular events, thromboembolic events, stroke, and mortality in clinical studies when given to support hemoglobin levels greater than 11 g/dL. In addition, a meta-analysis of 51 placebo-controlled trials of ESAs in cancer patients reported an increased rate of all-cause mortality and venous thrombosis in those receiving an ESA. Based on the accumulated evidence, it is recommended that the hemoglobin level not exceed 11 g/dL in patients with chronic kidney disease receiving an ESA, and that ESAs be used conservatively in cancer patients (eg, when hemoglobin levels are <10 g/dL) and with the lowest dose needed to avoid transfusion. It is further recommended that ESAs not be used when a cancer therapy is being given with curative intent.

Allergic reactions to ESAs have been infrequent. There have been a small number of cases of pure red cell aplasia (PRCA) accompanied by neutralizing antibodies to erythropoietin. PRCA was most commonly seen in dialysis patients treated subcutaneously for a long period with a particular form of epoetin alfa (Eprex with a polysorbate 80 stabilizer rather than human serum albumin) that is not available in the United States. After regulatory agencies required that Eprex be administered intravenously rather than subcutaneously, the rate of ESA-associated PRCA diminished. However, rare cases have still been seen with all ESAs administered subcutaneously for long periods to patients with chronic kidney disease.

## MYELOID GROWTH FACTORS

### Chemistry & Pharmacokinetics

**G-CSF** and **GM-CSF**, the two myeloid growth factors currently available for clinical use, were originally purified from cultured human cell lines (see Table 33–4). Recombinant human G-CSF (**rHuG-CSF**; **filgrastim**) is produced in a bacterial expression system. It is a nonglycosylated peptide of 175 amino acids, with a molecular weight of 18 kDa. **Tbo-filgrastim** is similar to **filgrastim**, with minor structural differences and equivalent activity. Recombinant human GM-CSF (**rHuGM-CSF**; **sargramostim**) is produced in a yeast expression system. It is a partially glycosylated peptide of 127 amino acids, comprising three molecular species with molecular weights of 15,500, 15,800, and 19,500. These preparations have serum half-lives of 2–7 hours after intravenous or subcutaneous administration. **Pegfilgrastim**, a covalent conjugation product of **filgrastim** with a form of polyethylene glycol, has a much longer serum half-life than recombinant G-CSF, and it can be injected once per myelosuppressive chemotherapy cycle instead of daily for several days. **Lenograstim**, used widely in Europe, is a glycosylated form of recombinant G-CSF.

### Pharmacodynamics

The myeloid growth factors stimulate proliferation and differentiation by interacting with specific receptors found on myeloid progenitor cells. Like the erythropoietin receptor, these receptors are members of the JAK/STAT superfamily (see Chapter 2). G-CSF stimulates proliferation and differentiation of progenitors already committed to the neutrophil lineage. It also activates the phagocytic activity of mature neutrophils and prolongs their survival in the circulation. G-CSF also has a remarkable ability to mobilize hematopoietic stem cells and increase their concentration in peripheral blood. This biologic effect underlies a major advance in transplantation—the use of **peripheral blood stem cells (PBSCs)** rather than bone marrow stem cells for autologous and allogeneic hematopoietic stem cell transplantation (see below).

GM-CSF has broader biologic actions than G-CSF. It is a multipotential hematopoietic growth factor that stimulates proliferation and differentiation of early and late granulocytic progenitor cells as well as erythroid and megakaryocyte progenitors. Like G-CSF, GM-CSF also stimulates the function of mature neutrophils. GM-CSF acts together with interleukin-2 to stimulate T-cell proliferation and appears to be a locally active factor at the site of inflammation. GM-CSF mobilizes peripheral blood stem cells, but it is significantly less efficacious and more toxic than G-CSF in this regard.

### Clinical Pharmacology

#### A. Cancer Chemotherapy-Induced Neutropenia

Neutropenia is a common adverse effect of the cytotoxic drugs used to treat cancer and increases the risk of serious infection in patients receiving chemotherapy. Unlike the treatment of anemia and thrombocytopenia, transfusion of neutropenic patients with granulocytes collected from donors is rarely performed with limited success. The introduction of G-CSF in 1991 represented a milestone in the treatment of chemotherapy-induced neutropenia. This growth factor dramatically accelerates the rate of neutrophil recovery after dose-intensive myelosuppressive chemotherapy. It reduces the duration of neutropenia and usually raises the nadir count, the lowest neutrophil count seen following a cycle of chemotherapy.

www.kobility.com  
The utility of G-CSF to increase neutrophil counts after myelosuppressive chemotherapy is nearly universal, but its impact on clinical outcomes is more variable. Many, but not all, clinical trials and meta-analyses have shown that G-CSF reduces episodes of febrile neutropenia, requirements for broad-spectrum antibiotics, infections, and days of hospitalization. Clinical trials have not shown improved survival in cancer patients treated with G-CSF. Clinical guidelines for the use of G-CSF after cytotoxic chemotherapy recommend reserving G-CSF for patients at high risk for febrile neutropenia based on age, medical history, and disease characteristics; patients receiving dose-intensive chemotherapy regimens that carry a greater than 20% risk of causing febrile neutropenia; patients with a prior episode of febrile neutropenia after cytotoxic chemotherapy; patients at high risk for febrile neutropenia; and patients who are unlikely to survive an episode of febrile neutropenia. **Pegfilgrastim** is an alternative to G-CSF for prevention of chemotherapy-induced febrile neutropenia. **Pegfilgrastim** can be administered once per chemotherapy cycle, and it may shorten the period of severe neutropenia slightly more than G-CSF.

Like G-CSF and **pegfilgrastim**, GM-CSF also reduces the duration of neutropenia after cytotoxic chemotherapy. It has been more difficult to show that GM-CSF reduces the incidence of febrile neutropenia, probably because GM-CSF itself can induce fever. In the treatment of chemotherapy-induced neutropenia, G-CSF 5 mcg/kg daily or GM-CSF 250 mcg/m<sup>2</sup> daily is usually started within 24–72 hours after completing chemotherapy and is continued until the absolute neutrophil count is greater than 10,000 cells/ $\mu$ L. **Pegfilgrastim** is given as a single dose of 6 mg.

The utility and safety of the myeloid growth factors in the postchemotherapy supportive care of patients with acute myeloid leukemia (AML) have been the subject of a number of clinical trials. Because leukemic cells arise from progenitors whose proliferation and differentiation are normally regulated by hematopoietic growth factors, including GM-CSF and G-CSF, there was concern that myeloid growth factors could stimulate leukemic cell growth and increase the rate of relapse. The results of randomized clinical trials suggest that both G-CSF and GM-CSF are safe following induction and consolidation treatment of myeloid and lymphoblastic leukemia. There has been no evidence that these growth factors reduce the rate of remission or increase relapse rate. On the contrary, the growth factors accelerate neutrophil recovery and reduce infection rates and days of hospitalization. Both G-CSF and GM-CSF have FDA approval for treatment of patients with AML.

## B. Other Applications

G-CSF and GM-CSF have also proved to be effective in treating neutropenia associated with **congenital neutropenia, cyclic neutropenia, myelodysplasia, and aplastic anemia**. Many patients with these disorders respond with a prompt and sometimes dramatic increase in neutrophil count. In some cases, this results in a decrease in the frequency of infections. Because neither G-CSF nor GM-CSF stimulates the formation of erythrocytes and platelets, they are sometimes combined with other growth factors for treatment of pancytopenia.

The myeloid growth factors play an important role in **autologous stem cell transplantation** for patients undergoing high-dose chemotherapy. High-dose chemotherapy with autologous stem cell support is increasingly used to treat patients with tumors that are resistant to standard doses of chemotherapeutic drugs. The high-dose regimens produce extreme myelosuppression; the myelosuppression is then counteracted by reinfusion of the patient's own hematopoietic stem cells (which are collected prior to chemotherapy). The administration of G-CSF or GM-CSF early after autologous stem cell transplantation reduces the time to engraftment and to recovery from neutropenia in patients receiving stem cells obtained either from bone marrow or from peripheral blood. These effects are seen in patients being treated for lymphoma or for solid tumors. G-CSF and GM-CSF are also used to support patients who have received allogeneic bone marrow transplantation for treatment of hematologic malignancies or bone marrow failure states. In this setting, the growth factors speed the recovery from neutropenia without increasing the incidence of acute graft-versus-host disease.

Perhaps the most important role of the myeloid growth factors in transplantation is for mobilization of peripheral blood stem cells. Stem cells collected from peripheral blood have nearly replaced bone marrow as the hematopoietic preparation used for autologous and allogeneic transplantation. The cells can be collected in an outpatient setting with a procedure that avoids much of the risk and discomfort of bone marrow collection, including the need for general anesthesia. In addition, there is evidence that PBSC transplantation results in more rapid engraftment of all hematopoietic cell lineages and in reduced rates of graft failure or delayed platelet recovery.

G-CSF is the cytokine most commonly used for PBSC mobilization because of its increased efficacy and reduced toxicity compared with GM-CSF. To mobilize stem cells for autologous transplantation, donors are given 5–10 mcg/kg daily subcutaneously for 4 days. On the fifth day, they undergo leukapheresis. The success of PBSC transplantation depends on transfusion of adequate numbers of stem cells. CD34, an antigen present on early progenitor cells and absent from later, committed, cells, is used as a marker for the requisite stem cells. The goal is to infuse at least  $5 \times 10^6$  CD34 cells/kg; this number of CD34 cells usually results in prompt and durable engraftment of all cell lineages. It may take several separate leukaphereses to collect enough CD34 cells, especially from older patients and patients who have been exposed to radiation therapy or chemotherapy.

For patients with multiple myeloma or non-Hodgkin lymphoma who respond suboptimally to G-CSF alone, the novel hematopoietic stem cell mobilizer **plerixafor** can be added to G-CSF. **Plerixafor** is a bicyclam molecule originally developed as an anti-HIV drug because of its ability to inhibit the CXC chemokine receptor 4 (CXCR4), a co-receptor for HIV entry into CD4+ T lymphocytes (see [Chapter 49](#)). Early clinical trials of **plerixafor** revealed a remarkable ability to increase CD34 cells in peripheral blood. **Plerixafor** mobilizes CD34 cells by preventing chemokine stromal cell-derived factor-1 $\alpha$  (CXCL12) from binding to CXCR4 and directing the CD34 cells to “home” to the bone marrow. **Plerixafor** is administered by subcutaneous injection after 4 days of G-CSF treatment and 11 hours prior to leukapheresis; it can be used with G-CSF for up to 4 continuous days. **Plerixafor** is eliminated primarily by the renal route and must be dose-adjusted for patients with renal impairment. The drug is well tolerated; the most common adverse effects associated with its use are injection site reactions, gastrointestinal disturbances, dizziness, fatigue, and headache.

## Toxicity

Although the three growth factors have similar effects on neutrophil counts, G-CSF and **pegfilgrastim** are used more frequently than GM-CSF because they are better tolerated. G-CSF and **pegfilgrastim** can cause bone pain, which clears when the drugs are discontinued. GM-CSF can cause more severe side effects, particularly at higher doses. These include fever, malaise, arthralgias, myalgias, and a capillary leak syndrome characterized by peripheral edema and pleural or pericardial effusions. Allergic reactions may occur but are infrequent. Splenic rupture is a rare but serious complication of the use of G-CSF for PBSC mobilization.

## MEGAKARYOCYTE GROWTH FACTORS

Patients with thrombocytopenia have a high risk of hemorrhage. Although platelet transfusion is commonly used to treat thrombocytopenia, this procedure can cause adverse reactions in the recipient; furthermore, a significant number of patients fail to exhibit the expected increase in platelet count. **Thrombopoietin (TPO)** and **IL-11** both appear to be key endogenous regulators of platelet production. A recombinant form of IL-11 was the first agent to gain FDA approval for treatment of thrombocytopenia. Recombinant human thrombopoietin and a pegylated form of a shortened human thrombopoietin protein underwent extensive clinical investigation in the 1990s. However, further development was abandoned after autoantibodies to the native thrombopoietin formed in healthy human subjects and caused thrombocytopenia. Efforts shifted to investigation of novel, nonimmunogenic agonists of the thrombopoietin receptor, which is known as **MPL**. Three thrombopoietin agonists (**romiplostim**, **eltrombopag**, and **avatrombopag**) are approved for treatment of thrombocytopenia. **Fostamatinib** is a tyrosine kinase inhibitor prodrug. The active metabolite targets the SYK kinase in the signaling pathway downstream from the B cell receptor and the Fc receptor in the reticuloendothelial system.

## Chemistry, Pharmacokinetics, & Pharmacodynamics

**Interleukin-11** is a 65- to 85-kDa protein produced by fibroblasts and stromal cells in the bone marrow. **Oprelvekin**, the recombinant form of IL-11 approved for clinical use (see [Table 33-4](#)), is produced by expression in *Escherichia coli*. The half-life of IL-11 is 7–8 hours when the drug is injected subcutaneously. Interleukin-11 acts through a specific cell surface cytokine receptor to stimulate the growth of multiple lymphoid and myeloid cells. It acts synergistically with other growth factors to stimulate the growth of primitive megakaryocytic progenitors and, most importantly, increases the number of peripheral platelets and neutrophils.

**Romiplostim** is a thrombopoietin agonist peptide covalently linked to antibody fragments that serve to extend the peptide’s half-life. The MPL-binding peptide has no sequence homology with human thrombopoietin, and there is no evidence in animal or human studies that the MPL-binding peptide or **romiplostim** induces antibodies to thrombopoietin. After subcutaneous administration, **romiplostim** is eliminated by the reticuloendothelial system with an average half-life of 3–4 days. Its half-life is inversely related to the serum platelet count; it has a longer half-life in patients with thrombocytopenia and a shorter half-life in patients whose platelet counts have recovered to normal levels. **Romiplostim** is approved for therapy of patients with chronic immune thrombocytopenia who have had an inadequate response to other therapies. **Romiplostim** has high affinity for the human MPL receptor and results in a dose-dependent increase in platelet count. **Romiplostim** is administered once weekly by subcutaneous injection.

**Eltrombopag** is an orally active small nonpeptide thrombopoietin agonist molecule approved for therapy of patients with chronic immune thrombocytopenia who have had an inadequate response to other therapies, and for treatment of thrombocytopenia in patients with hepatitis C to allow initiation of interferon therapy. Following oral administration, peak **eltrombopag** levels are observed in 2–6 hours and the half-life is 26–35 hours. **Eltrombopag** is excreted primarily in the feces. **Eltrombopag** interacts with the transmembrane domain of the MPL receptor and, similarly to

**Avatrombopag** is an orally active thrombopoietin agonist approved for treatment of thrombocytopenia in adult patients with chronic liver disease to increase platelet count to greater than 50,000 prior to procedures, and to treat patients with chronic immune thrombocytopenia who have had an inadequate response to other therapies. The dose in liver disease is 60 mg orally/d for 5 days in patients with a platelet count of less than 40k, and 50 mg/d for 5 days for patients with a platelet count of 40 to less than 50k, 10–13 days prior to the procedure. In clinical studies, the platelet count increased beginning on day 4 post-dose, peaking day 10–13, and returning to baseline values by 4–5 weeks. For patients with immune thrombocytopenia with inadequate response to prior therapy, the starting dose is 20 mg/d.

**Fostamatinib** is an orally active prodrug approved for use in patients with chronic immune thrombocytopenia who have had an inadequate response to other therapies. The active metabolite, R406, is an SYK tyrosine kinase inhibitor which blocks B-cell activation Fc signaling pathways, decreasing antibody-mediated platelet removal from circulation. R406 is metabolized by CYP3A4, and strong CYP3A4 inhibitors such as **ketoconazole** increase drug effect. The starting dose is 100 mg twice daily.

## Clinical Pharmacology

Interleukin-11 is approved for the secondary prevention of thrombocytopenia in patients receiving cytotoxic chemotherapy for treatment of nonmyeloid cancers. Clinical trials show that it reduces the number of platelet transfusions required by patients who experience severe thrombocytopenia after a previous cycle of chemotherapy. Although IL-11 has broad stimulatory effects on hematopoietic cell lineages in vitro, it does not appear to have significant effects on the leukopenia caused by myelosuppressive chemotherapy. Interleukin-11 is given by subcutaneous injection at a dose of 50 mcg/kg daily. It is started 6–24 hours after completion of chemotherapy and continued for 14–21 days or until the platelet count passes the nadir and rises to more than 50,000/ $\mu$ L.

In patients with chronic immune thrombocytopenia who failed to respond adequately to previous treatment with steroids, immunoglobulins, or splenectomy, **romiplostim**, **eltrombopag**, **avatrombopag**, or **fostamatinib** can be used to significantly increase platelet count in most patients. All drugs are used at the minimal dose required to maintain platelet counts of greater than 50,000/ $\mu$ L.

## Toxicity

The most common adverse effects of IL-11 are fatigue, headache, dizziness, and cardiovascular effects. The cardiovascular effects include anemia (due to hemodilution), dyspnea (due to fluid accumulation in the lungs), and transient atrial arrhythmias. Hypokalemia also has been seen in some patients. All of these adverse effects appear to be reversible.

**Eltrombopag** is potentially hepatotoxic and liver function must be monitored, particularly when used in patients with hepatitis C. Portal vein thrombosis also has been reported with **eltrombopag**, **romiplostim**, and **avatrombopag** in the setting of chronic liver disease. In patients with myelodysplastic syndromes, **romiplostim** increases the blast count and risk of progression to acute myeloid leukemia. Marrow fibrosis has been observed with thrombopoietin agonists but is generally reversible when the drug is discontinued. Rebound thrombocytopenia has been observed following discontinuation of TPO agonists. Reported toxicities with **fostamatinib** include diarrhea, hypertension, hepatic toxicity, and neutropenia.

## SUMMARY Agents Used in Anemias and Hematopoietic Growth Factors

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>IRON</b>				
• Ferrous sulfate	Required for biosynthesis of heme and heme-containing	Adequate supplies required for normal heme synthesis • deficiency results in	Iron deficiency, which manifests as microcytic anemia • oral preparation	Complicated endogenous system for absorbing, storing, and transporting iron • <i>Toxicity:</i> Acute overdose results in necrotizing gastroenteritis, abdominal

proteins, including hemoglobin and myoglobin	inadequate heme production	pain, bloody diarrhea, shock, lethargy, and dyspnea • chronic iron overload results in hemochromatosis, with damage to the heart, liver, pancreas, and other organs • organ failure and death can ensue
--	----------------------------	---

- *Ferrous gluconate and ferrous fumarate: Oral iron preparations*

• *Iron dextran, iron sucrose complex, sodium ferric gluconate complex, ferric carboxymaltose, and ferumoxytol: Parenteral preparations can cause pain, hypersensitivity reactions*

### IRON CHELATORS

<ul style="list-style-type: none"> <li>• <b>Deferoxamine</b> (see also <a href="#">Chapters 57 and 58</a>)</li> </ul>	Chelates excess iron	Reduces toxicity associated with acute or chronic iron overload	Acute iron poisoning; inherited or acquired hemochromatosis	Preferred route of administration is IM or SC • <i>Toxicity:</i> Rapid IV administration may cause hypotension • neurotoxicity and increased susceptibility to certain infections have occurred with long-term use
---	----------------------	---	---	--

- *Deferasirox: Orally administered iron chelator for treatment of hemochromatosis*

### VITAMIN B<sub>12</sub>

<ul style="list-style-type: none"> <li>• <b>Cyanocobalamin</b></li> <li>• <b>Hydroxocobalamin</b></li> </ul>	Cofactor required for essential enzymatic reactions that form tetrahydrofolate, convert homocysteine to methionine, and metabolize L-methylmalonyl-CoA	Adequate supplies required for amino acid and fatty acid metabolism, and DNA synthesis	Vitamin B <sub>12</sub> deficiency, which manifests as megaloblastic anemia and is the basis of pernicious anemia; <b>hydroxocobalamin</b> is also used as a cyanide antidote (see <a href="#">Chapter 58</a> )	Parenteral vitamin B <sub>12</sub> is required for pernicious anemia and other malabsorption syndromes • <i>Toxicity:</i> No toxicity associated with excess vitamin B <sub>12</sub>
--	--	--	---	--

### FOLIC ACID

<ul style="list-style-type: none"> <li>• <b>Folacin</b> (pteroylglutamic acid)</li> </ul>	Precursor of an essential donor of methyl groups used for synthesis of amino acids,	Adequate supplies required for essential biochemical reactions involving amino acid	Folic acid deficiency, which manifests as megaloblastic anemia, and prevention of congenital neural tube defects	Oral; well-absorbed; need for parenteral administration is rare • <i>Toxicity:</i> Folic acid is not toxic in overdose, but large amounts can partially compensate for vitamin B <sub>12</sub> deficiency and put people with unrecognized B <sub>12</sub> deficiency at risk of
---	---	---	--	--

purines, and  
deoxynucleotidemetabolism, and  
purine and DNA  
synthesisneurologic consequences of vitamin B<sub>12</sub>  
deficiency, which are not compensated by  
folic acid**ERYTHROCYTE-STIMULATING AGENTS**

• Epoetin alfa	Agonist of erythropoietin receptors expressed by red cell progenitors	Stimulates erythroid proliferation and differentiation, and induces the release of reticulocytes from the bone marrow	Anemia, especially anemia associated with chronic renal failure, HIV infection, cancer, and prematurity • prevention of the need for transfusion in patients undergoing certain types of elective surgery	IV or SC administration 1–3 times per week • <i>Toxicity</i> : Hypertension, thrombotic complications, and, very rarely, pure red cell aplasia • to reduce the risk of serious cerebrovascular events, hemoglobin levels should be maintained <12 g/dL
----------------	---	---	---	---

• *Darbepoetin alfa*: Long-acting glycosylated form administered weekly

• *Methoxy polyethylene glycol-epoetin beta*: Long-acting form administered 1–2 times per month

**MYELOID GROWTH FACTORS**

• Granulocyte colony-stimulating factor (G-CSF; <a href="#">filgrastim</a> )	Stimulates G-CSF receptors expressed on mature neutrophils and their progenitors	Stimulates neutrophil progenitor proliferation and differentiation • activates phagocytic activity of mature neutrophils and extends their survival • mobilizes hematopoietic stem cells	Neutropenia associated with congenital neutropenia, cyclic neutropenia, myelodysplasia, and aplastic anemia • secondary prevention of neutropenia in patients undergoing cytotoxic chemotherapy • mobilization of peripheral blood cells in preparation for autologous and allogeneic stem cell transplantation	Daily SC administration • <i>Toxicity</i> : Bone pain • rarely, splenic rupture
--	--	--	---	---

• *Pegfilgrastim*: Long-acting form of [filgrastim](#) that is covalently linked to a type of polyethylene glycol

• *Tbo-filgrastim*: Similar to [filgrastim](#)

• *GM-CSF ([sargramostim](#))*: Myeloid growth factor that acts through a distinct GM-CSF receptor to stimulate proliferation and differentiation of early and late granulocytic progenitor cells, and erythroid and megakaryocyte progenitors; clinical uses are similar to those of G-CSF, but it is more likely than G-CSF to cause fever, arthralgia, myalgia, and capillary leak syndrome

• *Plerixafor*: Antagonist of CXCR4 used in combination with G-CSF for mobilization of peripheral blood cells prior to autologous transplantation in patients with multiple myeloma or non-Hodgkin lymphoma who responded suboptimally to G-CSF alone

**MEGAKARYOCYTE GROWTH FACTORS**

• Oprelvekin (interleukin-11; IL-11)	Recombinant form of an endogenous	Stimulates growth of multiple lymphoid and	Secondary prevention of thrombocytopenia in patients undergoing cytotoxic chemotherapy	Daily SC injection • <i>Toxicity</i> : Fatigue, headache, dizziness, anemia, fluid accumulation in the lungs, and transient

circulating platelets  
and neutrophils

for nonmyeloid cancers

atrial arrhythmias

• **Romiplostim:** Subcutaneously administered thrombopoietin agonist approved for treatment of chronic immune thrombocytopenia with insufficient response to corticosteroids, intravenous immunoglobulin, or splenectomy

• **Eltrombopag:** Orally active thrombopoietin agonist approved for treatment of chronic immune thrombocytopenia with insufficient response to corticosteroids, intravenous immunoglobulin, or splenectomy; and for treatment of thrombocytopenia in hepatitis C to allow the use of interferon-based therapies

• **Avatrombopag:** Orally active thrombopoietin agonist approved for treatment of chronic immune thrombocytopenia with insufficient response to corticosteroids, intravenous immunoglobulin, or splenectomy; and for treatment of thrombocytopenia in patients with chronic liver disease to increase platelet count prior to procedures

#### KINASE INHIBITOR

• **Fostamatinib:** Orally active tyrosine kinase inhibitor, decreases signaling through Fc and B cell receptors; results in decreased antibody-mediated platelet destruction

PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
Avatrombopag	Doptelet
Darbepoetin alfa	Aranesp
Deferasirox	Exjade
Deferoxamine	Generic, Desferal
Eltrombopag	Promacta
Epoetin alfa	Erythropoietin (EPO), Epogen, Procrit
Epoetin beta (Methoxy polyethylene glycol-epoetin beta)	Mircera
Filgrastim (G-CSF)	Neupogen, Granix
Folic acid (folacin, pteroylglutamic acid)	Generic
Iron	
Oral: See <a href="#">Table 33-3</a> .	
Iron <a href="#">dextran</a> (parenteral)	INFeD, Dexferrum
Sodium ferric gluconate complex (parenteral)	Ferrlecit
Iron <a href="#">sucrose</a> (parenteral)	Venofer
Ferric carboxymaltose (parenteral)	Injectafer
<a href="#">Ferumoxytol</a> (parenteral)	Feraheme
Oprelvekin (IL-11)	Neumega
<a href="#">Pegfilgrastim</a>	Neulasta
<a href="#">Plerixafor</a>	Mozobil
<a href="#">Romiplostim</a>	Nplate
<a href="#">Sargramostim</a> (GM-CSF)	Leukine
Vitamin B <sub>12</sub>	
Oral, parenteral	Generic <a href="#">cyanocobalamin</a> or <a href="#">hydroxocobalamin</a>
Nasal	Nascobal, CaloMist

### CASE STUDY ANSWER

This patient's megaloblastic anemia appears to be due to vitamin B<sub>12</sub> (cobalamin) deficiency secondary to inadequate dietary B<sub>12</sub>. It is important to measure serum concentrations of both folic acid and cobalamin because megaloblastic anemia can result from deficiency of either nutrient. It is especially important to diagnose vitamin B<sub>12</sub> deficiency because this deficiency, if untreated, can lead to irreversible neurologic damage. Folate supplementation, which can compensate for vitamin B<sub>12</sub>-derived anemia, does not prevent B<sub>12</sub>-deficiency neurologic damage. To correct this patient's vitamin B<sub>12</sub> deficiency, she would probably be treated parenterally with cobalamin because of her neurologic symptoms, followed by oral supplementation to maintain her body stores of vitamin B<sub>12</sub>.

## Chapter 34: Drugs Used in Disorders of Coagulation

James L. Zehnder

### CASE STUDY

#### CASE STUDY

A 25-year-old woman presents to the emergency department complaining of acute onset of shortness of breath and pleuritic pain. She had been in her usual state of health until 2 days prior when she noted that her left leg was swollen and red. Her only medication was oral contraceptives. Family history was significant for a history of “blood clots” in multiple members of the maternal side of her family. Physical examination demonstrates an anxious woman with stable vital signs. The left lower extremity demonstrates erythema and edema and is tender to touch. Oxygen saturation by fingertip pulse oximeter while breathing room air is 87% (normal >90%). Ultrasound reveals a deep vein thrombosis in the left lower extremity; chest computed tomography scan confirms the presence of pulmonary emboli. Laboratory blood tests indicate elevated D-dimer levels. What therapy is indicated acutely? What are the long-term therapy options? How long should she be treated? Should this individual use oral contraceptives?

*Hemostasis* refers to the finely regulated dynamic process of maintaining fluidity of the blood, repairing vascular injury, and limiting blood loss while avoiding vessel occlusion (thrombosis) and inadequate perfusion of vital organs. Either extreme—excessive bleeding or thrombosis—represents a breakdown of the hemostatic mechanism. Common causes of dysregulated hemostasis include hereditary or acquired defects in the clotting mechanism and secondary effects of infection or cancer. Atrial fibrillation is associated with stasis of blood in the atria, formation of clots, and increased risk of occlusive stroke. Because of the high prevalence of chronic atrial fibrillation, especially in the older population, use of anticoagulants is common. Guidelines for the use of oral anticoagulants (**CHA<sub>2</sub>DS<sub>2</sub>-VASC** score, see January C et al reference) are based on various risk factors (congestive heart failure, hypertension, age, diabetes, history of stroke, vascular disease, and sex). The drugs used to inhibit thrombosis and to limit abnormal bleeding are the subjects of this chapter.

### MECHANISMS OF BLOOD COAGULATION

The vascular endothelial cell layer lining blood vessels has an anticoagulant phenotype, and circulating blood platelets and clotting factors do not normally adhere to it to an appreciable extent. In the setting of vascular injury, the endothelial cell layer rapidly undergoes a series of changes resulting in a more procoagulant phenotype. Injury exposes reactive subendothelial matrix proteins such as collagen and von Willebrand factor, which results in platelet adherence and activation, and secretion and synthesis of vasoconstrictors and platelet-recruiting and activating molecules. Thus, **thromboxane A<sub>2</sub> (TXA<sub>2</sub>)** is synthesized from arachidonic acid within platelets and is a platelet activator and potent vasoconstrictor. Products secreted from platelet granules include **adenosine diphosphate (ADP)**, a powerful inducer of platelet aggregation, and **serotonin (5-HT)**, which stimulates aggregation and vasoconstriction. Activation of platelets results in a conformational change in the  $\alpha_{IIb}\beta_{III}$  integrin (IIb/IIIa) receptor, enabling it to bind fibrinogen, which cross-links adjacent platelets, resulting in aggregation and formation of a platelet plug (Figure 34-1). Simultaneously, the coagulation system cascade is activated, resulting in **thrombin** generation and a fibrin clot, which stabilizes the platelet plug (see below). Knowledge of the hemostatic mechanism is important for diagnosis of bleeding disorders. Patients with defects in the formation of the primary platelet plug (defects in primary hemostasis, eg, platelet function defects, von Willebrand disease) typically bleed from surface sites (gingiva, skin, heavy menses) with injury. In contrast, patients with defects in the clotting mechanism (secondary hemostasis, eg, hemophilia A) tend to bleed into deep tissues (joints, muscle, retroperitoneum), often with no apparent inciting event, and bleeding may recur unpredictably.

Thrombus formation at the site of the damaged vascular wall (EC, endothelial cell) and the role of platelets and clotting factors. Platelet membrane receptors include the glycoprotein (GP) Ia receptor, binding to collagen (C); GP Ib receptor, binding von Willebrand factor (vWF); and GP IIb/IIIa, which binds fibrinogen and other macromolecules. Antiplatelet prostacyclin (PGI<sub>2</sub>) is released from the endothelium. Aggregating substances released from the degranulating platelet include adenosine diphosphate (ADP), thromboxane A<sub>2</sub> (TXA<sub>2</sub>), and serotonin (5-HT). Production of factor Xa by intrinsic and extrinsic pathways is detailed in Figure 34–2.

The platelet is central to normal hemostasis and thromboembolic disease, and is the target of many therapies discussed in this chapter. Platelet-rich thrombi (**white thrombi**) form in the high flow rate and high shear force environment of arteries. Occlusive arterial thrombi cause serious disease by producing downstream ischemia of extremities or vital organs, and they can result in limb amputation or organ failure. Venous clots tend to be more fibrin-rich, contain large numbers of trapped red blood cells, and are recognized pathologically as **red thrombi**. Deep venous thrombi (DVT) can cause severe swelling and pain of the affected extremity, but the most feared consequence is pulmonary embolism (PE). This occurs when part or all of the clot breaks off from its location in the deep venous system and travels as an embolus through the right side of the heart and into the pulmonary arterial circulation. Occlusion of a large pulmonary artery by an embolic clot can precipitate acute right heart failure and sudden death. In addition lung ischemia or infarction will occur distal to the occluded pulmonary arterial segment. Such emboli usually arise from the deep venous system of the proximal lower extremities or pelvis. Although all thrombi are mixed, the platelet nidus dominates the arterial thrombus and the fibrin tail dominates the venous thrombus.

## BLOOD COAGULATION CASCADE

Blood coagulates due to the transformation of soluble fibrinogen into insoluble fibrin by the enzyme **thrombin**. Several circulating proteins interact in a cascading series of limited proteolytic reactions (Figure 34–2). At each step, a clotting factor zymogen undergoes limited proteolysis and becomes an active protease (eg, factor VII is converted to factor VIIa). Each protease factor activates the next clotting factor in the sequence, culminating in the formation of **thrombin** (factor IIa). Several of these factors are targets for drug therapy (Table 34–1).

FIGURE 34–2

A model of blood coagulation. With tissue factor (TF), factor VII forms an activated complex (VIIa-TF) that catalyzes the activation of factor IX to factor IXa. Activated factor XIa also catalyzes this reaction. Tissue factor pathway inhibitor inhibits the catalytic action of the VIIa-TF complex. The cascade proceeds as shown, resulting ultimately in the conversion of fibrinogen to fibrin, an essential component of a functional clot. The two major anticoagulant drugs, **heparin** and **warfarin**, have very different actions. **Heparin**, acting in the blood, directly activates anticlotting factors, specifically **antithrombin**, which inactivates the factors enclosed in rectangles. **Warfarin**, acting in the liver, inhibits the synthesis of the factors enclosed in circles. Proteins C and S exert anticlotting effects by inactivating activated factors Va and VIIIa.

Clotting in Vivo

Blood clotting factors and drugs that affect them.<sup>1</sup>

Component or Factor	Common Synonym	Target for the Action of:
I	Fibrinogen	
II	Prothrombin	Heparin, dabigatran (IIa); warfarin (synthesis)
III	Tissue thromboplastin	
IV	Calcium	
V	Proaccelerin	
VII	Proconvertin	Warfarin (synthesis)
VIII	Antihemophilic factor (AHF)	
IX	Christmas factor, plasma thromboplastin component (PTC)	Warfarin (synthesis)
X	Stuart-Prower factor	Heparin, rivaroxaban, apixaban, edoxaban (Xa); warfarin (synthesis)
XI	Plasma thromboplastin antecedent (PTA)	
XII	Hageman factor	
XIII	Fibrin-stabilizing factor	
Proteins C and S		Warfarin (synthesis)
Plasminogen		Thrombolytic enzymes, aminocaproic acid

<sup>1</sup>See Figure 34-2 and text for additional details.

**Thrombin** has a central role in hemostasis and has many functions. In clotting, **thrombin** proteolytically cleaves small peptides from fibrinogen, allowing fibrinogen to polymerize and form a fibrin clot. **Thrombin** also activates many upstream clotting factors, leading to more **thrombin** generation, and activates factor XIII, a transaminase that cross-links the fibrin polymer and stabilizes the clot. **Thrombin** is a potent platelet activator and mitogen. **Thrombin** also exerts *anticoagulant* effects by activating the protein C pathway, which attenuates the clotting response (see Figure 34-2). It should therefore be apparent that the response to vascular injury is a complex and precisely modulated process that ensures that under normal circumstances, repair of vascular injury occurs without thrombosis and downstream ischemia—that is, the response is proportionate and reversible. Eventually vascular remodeling and repair occur with reversion to the quiescent resting anticoagulant endothelial cell phenotype.

### Initiation of Clotting: The Tissue Factor-VIIa Complex

The main initiator of blood coagulation in vivo is the tissue factor (TF) VIIa pathway (see Figure 34-2). Tissue factor is a transmembrane protein located outside the vasculature but not normally expressed in an active form within vessels. The exposure of TF on damaged

endothelium or to blood that has extravasated into tissue binds TF to factor VIIa. This complex, in turn, activates factors X and IX. Factor Xa along with factor Va forms the prothrombinase complex on activated cell surfaces, which catalyzes the conversion of prothrombin (factor II) to **thrombin** (factor IIa). **Thrombin**, in turn, activates upstream clotting factors, primarily factors V, VIII, and XI, resulting in amplification of **thrombin** generation. The TF-factor VIIa-catalyzed activation of factor Xa is regulated by tissue factor pathway inhibitor (TFPI). Thus after initial activation of factor X to Xa by TF-VIIa, further propagation of the clot occurs by feedback amplification of **thrombin** through the intrinsic pathway factors VIII and IX. (This provides an explanation for why patients with deficiency of factor VIII or IX—hemophilia A and hemophilia B, respectively—have a severe bleeding disorder.)

It is also important to note that the coagulation mechanism in vivo does not occur in solution, but is localized to activated *cell surfaces* expressing anionic phospholipids such as phosphatidylserine, and is mediated by  $\text{Ca}^{2+}$  bridging between the anionic phospholipids and  $\gamma$ -carboxyglutamic acid residues of the clotting factors. This is the basis for using calcium chelators such as ethylenediamine tetraacetic acid (EDTA) or citrate to prevent blood from clotting in a test tube.

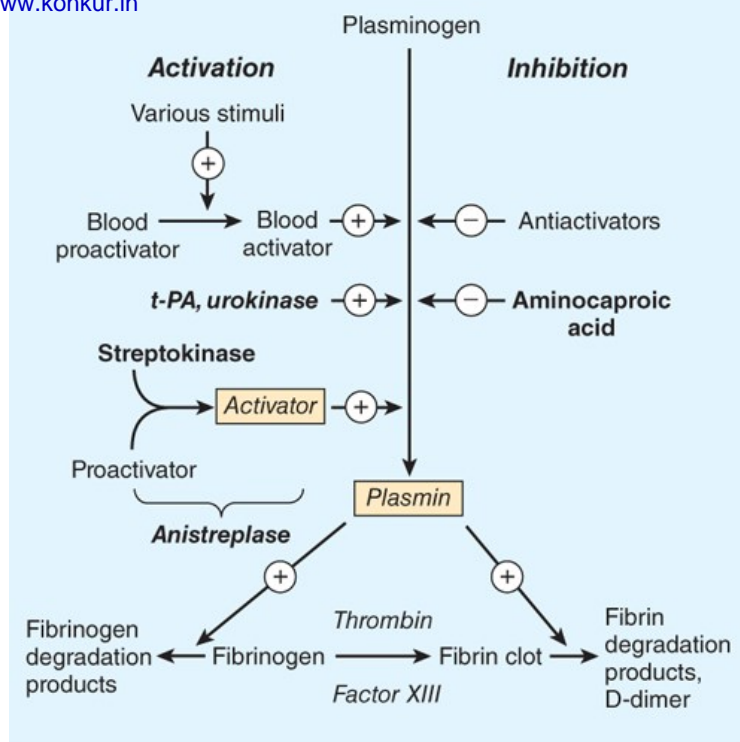

**Antithrombin (AT)** is an endogenous anticoagulant and a member of the serine protease inhibitor (serpin) family; it inactivates the serine proteases IIa, IXa, Xa, XIa, and XIIa. The endogenous anticoagulants **protein C** and **protein S** attenuate the blood clotting cascade by proteolysis of the two cofactors Va and VIIIa. From an evolutionary perspective, it is of interest that factors V and VIII have an identical overall domain structure and considerable homology, consistent with a common ancestor gene; likewise the serine proteases are descendants of a trypsin-like common ancestor. Thus, the TF-VIIa initiating complex, serine proteases, and cofactors each have their own lineage-specific attenuation mechanism (see [Figure 34-2](#)). Defects in natural anticoagulants result in an increased risk of venous thrombosis. The most common defect in the natural anticoagulant system is a mutation in factor V (factor V Leiden), which results in resistance to inactivation by the protein C/protein S mechanism.

## Fibrinolysis

Fibrinolysis refers to the process of fibrin digestion by the fibrin-specific protease, plasmin. The fibrinolytic system is similar to the coagulation system in that the precursor form of the serine protease plasmin circulates in an inactive form as plasminogen. In response to injury, endothelial cells synthesize and release tissue plasminogen activator (t-PA), which converts plasminogen to plasmin ([Figure 34-3](#)). Plasmin remodels the thrombus and limits its extension by proteolytic digestion of fibrin.

**FIGURE 34-3**

Schematic representation of the fibrinolytic system. Plasmin is the active fibrinolytic enzyme. Several clinically useful activators are shown on the left in bold. Anistreplase is a combination of streptokinase and the proactivator plasminogen. Aminocaproic acid (*right*) inhibits the activation of plasminogen to plasmin and is useful in some bleeding disorders. t-PA, tissue plasminogen activator.

Source: Todd W. Vanderah:  
Basic & Clinical Pharmacology, Sixteenth Edition  
Copyright © McGraw Hill. All rights reserved.

Both plasminogen and plasmin have specialized protein domains (kringles) that bind to exposed lysines on the fibrin clot and impart clot specificity to the fibrinolytic process. It should be noted that this clot specificity is only observed at *physiologic* levels of t-PA. At the *pharmacologic* levels of t-PA used in thrombolytic therapy, clot specificity is lost and a systemic lytic state is created, with attendant increase in bleeding risk. As in the coagulation cascade, there are negative regulators of fibrinolysis: endothelial cells synthesize and release plasminogen activator inhibitor (PAI), which inhibits t-PA; in addition  $\alpha_2$  antiplasmin circulates in the blood at high concentrations and under physiologic conditions will rapidly inactivate any plasmin that is not clot-bound. However, this regulatory system is overwhelmed by therapeutic doses of plasminogen activators.

If the coagulation and fibrinolytic systems are pathologically activated, the hemostatic system may careen out of control, leading to generalized intravascular clotting and bleeding. This process is called **disseminated intravascular coagulation (DIC)** and may follow massive tissue injury, advanced cancers, obstetric emergencies such as abruptio placentae or retained products of conception, or bacterial sepsis. The treatment of DIC is to control the underlying disease process; if this is not possible, DIC is often fatal.

Regulation of the fibrinolytic system is useful in therapeutics. Increased fibrinolysis is effective therapy for thrombotic disease. **Tissue plasminogen activator, urokinase, and streptokinase** all activate the fibrinolytic system (see Figure 34-3). Conversely, decreased fibrinolysis protects clots from lysis and reduces the bleeding of hemostatic failure. **Aminocaproic acid** is a clinically useful inhibitor of fibrinolysis. **Heparin** and the oral anticoagulant drugs do not affect the fibrinolytic mechanism.

## BASIC PHARMACOLOGY OF THE ANTICOAGULANT DRUGS

The ideal anticoagulant drug would prevent pathologic thrombosis and limit reperfusion injury yet allow a normal response to vascular injury and limit bleeding. Theoretically this could be accomplished by preservation of the TF-VIIa initiation phase of the clotting mechanism with attenuation of the secondary intrinsic pathway propagation phase of clot development. At this time such a drug does not exist; all anticoagulants and fibrinolytic drugs have an increased bleeding risk as their principal toxicity.

### INDIRECT THROMBIN INHIBITORS

The indirect **thrombin** inhibitors are so-named because their antithrombotic effect is exerted by their interaction with a separate protein, **antithrombin**. **Unfractionated heparin (UFH)**, also known as **high-molecular-weight (HMW) heparin**, **low-molecular-weight (LMW) heparin**, and the synthetic pentasaccharide **fondaparinux** bind to **antithrombin** and enhance its inactivation of factor Xa (Figure 34-4). Unfractionated **heparin** and to a lesser extent **LMW heparin** also enhance **antithrombin's** inactivation of **thrombin**.

FIGURE 34-4

Differences between low-molecular-weight (LMW) heparins and high-molecular-weight **heparin** (unfractionated **heparin**). **Fondaparinux** is a small pentasaccharide fragment of **heparin**. Activated **antithrombin III (AT III)** degrades **thrombin**, factor X, and several other factors. Binding of these drugs to AT III can increase the catalytic action of AT III 1000-fold. The combination of AT III with unfractionated **heparin** increases degradation of both factor Xa and **thrombin**. Combination with **fondaparinux** or **LMW heparin** more selectively increases degradation of Xa.

## HEPARIN

### Chemistry & Mechanism of Action

**Heparin** is a heterogeneous mixture of sulfated mucopolysaccharides. It binds to endothelial cell surfaces and a variety of plasma proteins. Its biologic activity is dependent upon the endogenous anticoagulant **antithrombin**. **Antithrombin** inhibits clotting factor proteases, especially **thrombin** (IIa), IXa, and Xa, by forming equimolar stable complexes with them. In the absence of **heparin**, these reactions are slow; in the presence of **heparin**, they are accelerated 1000-fold. Only about a third of the molecules in commercial **heparin** preparations have an accelerating effect because the remainder lack the unique pentasaccharide sequence needed for high-affinity binding to **antithrombin**. The active **heparin** molecules bind tightly to **antithrombin** and cause a conformational change in this inhibitor. The conformational change of **antithrombin** exposes its active site for more rapid interaction with the proteases (the activated clotting factors). **Heparin** functions as a cofactor for the antithrombin-protease reaction without being consumed. Once the antithrombin-protease complex is formed, **heparin** is released intact for renewed binding to more **antithrombin**.

The **antithrombin** binding region of commercial unfractionated **heparin** consists of repeating sulfated disaccharide units composed of D-glucosamine-L-iduronic acid and D-glucosamine-D-glucuronic acid. High-molecular-weight fractions of **heparin** with high affinity for **antithrombin** markedly inhibit blood coagulation by inhibiting all three factors, especially **thrombin** and factor Xa. Unfractionated **heparin** has a molecular weight range of 5000–30,000 Da. In contrast, the shorter-chain, low-molecular-weight fractions of **heparin** inhibit activated factor X but have less effect on **thrombin** than the HMW species. Nevertheless, numerous studies have demonstrated that LMW heparins such as **enoxaparin**, **dalteparin**, and **tinzaparin** are effective in several thromboembolic conditions. In fact, these LMW heparins—in comparison with UFH—have equal efficacy, increased bioavailability from the subcutaneous site of injection, and less frequent dosing requirements (once or twice daily is sufficient).

USP **heparin** is harmonized to the World Health Organization International Standard (IS) unit dose. **Enoxaparin** is obtained from the same sources as regular UFH, but doses are specified in milligrams. **Fondaparinux** also is specified in milligrams. **Dalteparin**, **tinzaparin**, and **danaparoid** (an LMW heparinoid containing heparan sulfate, dermatan sulfate, and chondroitin sulfate), on the other hand, are specified in anti-factor Xa units.

### Clinical Pharmacology

**Heparin** is indicated for prevention and treatment of venous thromboembolic disease, arterial thrombosis, and prevention of thrombosis in arterial or

cardiac surgery. Heparin may be administered parenterally or subcutaneous, but not intramuscular injection). The drug is extensively bound by plasma proteins. The elimination of heparin is complex, with the saturable protein binding phase followed by dose-dependent elimination with a half-life of 30 minutes to 2 hours.

### Monitoring of Heparin Effect

Close monitoring of the **activated partial thromboplastin time (aPTT or PTT)** is necessary in patients receiving UFH. Levels of UFH may also be determined by **protamine** titration (therapeutic levels 0.2–0.4 unit/mL) or anti-Xa units (therapeutic levels 0.3–0.7 unit/mL). Weight-based dosing of the LMW heparins results in predictable pharmacokinetics and plasma levels in patients with normal renal function. Therefore, LMW heparin levels are not generally measured except in the setting of renal insufficiency, obesity, and pregnancy. LMW heparin levels can be determined by anti-Xa units. For **enoxaparin**, peak therapeutic levels should be 0.5–1 unit/mL for twice-daily dosing, determined 4 hours after administration, and approximately 1.5 units/mL for once-daily dosing.

### Toxicity

#### A. Bleeding and Miscellaneous Effects

The major adverse effect of heparin is bleeding. This risk can be decreased by scrupulous patient selection, careful control of dosage, and close monitoring. Elderly women and patients with renal failure are more prone to hemorrhage. Heparin is of animal origin and should be used cautiously in patients with allergy. Increased loss of hair and reversible alopecia have been reported. Long-term heparin therapy is associated with osteoporosis and spontaneous fractures. Heparin accelerates the clearing of postprandial lipemia by causing the release of lipoprotein lipase from tissues, and long-term use is associated with mineralocorticoid deficiency.

#### B. Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is a systemic hypercoagulable state that occurs in 1–4% of individuals treated with UFH. Surgical patients are at greatest risk. The reported incidence of HIT is lower in pediatric populations outside the critical care setting; it is relatively rare in pregnant women. The risk of HIT may be higher in individuals treated with UFH of bovine origin compared with porcine heparin and is lower in those treated exclusively with LMW heparin.

Morbidity and mortality in HIT are related to thrombotic events. Venous thrombosis occurs most commonly, but occlusion of peripheral or central arteries is not infrequent. If an indwelling catheter is present, the risk of thrombosis is increased in that extremity. Skin necrosis has been described, particularly in individuals treated with **warfarin** in the absence of a direct **thrombin** inhibitor, presumably due to acute depletion of the vitamin K-dependent anticoagulant protein C occurring in the presence of high levels of procoagulant proteins and an active hypercoagulable state.

The following points should be considered in all patients receiving heparin: Platelet counts should be performed frequently; thrombocytopenia appearing in a time frame consistent with an immune response to heparin should be considered suspicious for HIT; and any new thrombus occurring in a patient receiving heparin therapy should raise suspicion of HIT. Patients who develop HIT are treated by discontinuance of heparin and administration of the direct **thrombin** inhibitor **argatroban**.

### Contraindications

Heparin is contraindicated in patients with HIT, hypersensitivity to the drug, active bleeding, hemophilia, significant thrombocytopenia, purpura, severe hypertension, intracranial hemorrhage, infective endocarditis, active tuberculosis, ulcerative lesions of the gastrointestinal tract, threatened abortion, visceral carcinoma, or advanced hepatic or renal disease. Heparin should be avoided in patients who have recently had surgery of the brain, spinal cord, or eye; and in patients who are undergoing lumbar puncture or regional anesthetic block. Despite the apparent lack of placental transfer, heparin should be used in pregnant women only when clearly indicated.

### Administration & Dosage

The indications for the use of heparin are described in the section on clinical pharmacology. A plasma concentration of heparin of 0.2–0.4 unit/mL (by protamine titration) or 0.3–0.7 unit/mL (anti-Xa units) is considered to be the therapeutic range for treatment of venous thromboembolic disease. This

concentration generally corresponds to a PTT of 1.5–2.5 times baseline. However, the use of the PTT for **heparin** monitoring is problematic. There is no standardization scheme for the PTT as there is for the prothrombin time (PT) and its international normalized ratio (INR) in **warfarin** monitoring. The PTT in seconds for a given **heparin** concentration varies between different reagent/instrument systems. Thus, if the PTT is used for monitoring, the laboratory should determine the clotting time that corresponds to the therapeutic range by **protamine** titration or anti-Xa activity, as listed above.

In addition, some patients have a prolonged baseline PTT due to factor deficiency or inhibitors (which could increase bleeding risk) or lupus anticoagulant (which is generally not associated with bleeding risk but may be associated with thrombosis risk). Using the PTT to assess **heparin** effect in such patients is problematic. An alternative is to use anti-Xa activity to assess **heparin** concentration, a test now widely available on automated coagulation instruments. This approach measures **heparin** concentration; however, it does not provide the global assessment of intrinsic pathway integrity of the PTT.

The following strategy is recommended: prior to initiating anticoagulant therapy of any type, the integrity of the patient's hemostatic system should be assessed by a careful history of prior bleeding events, as well as baseline PT and PTT. If there is a prolonged clotting time, the cause of this (deficiency or inhibitor) should be determined prior to initiating therapy, and treatment goals stratified to a risk-benefit assessment. In high-risk patients measuring both the PTT and anti-Xa activity may be useful. When *intermittent* **heparin** administration is used, the aPTT or anti-Xa activity should be measured 6 hours after the administered dose to maintain prolongation of the aPTT to 2–2.5 times that of the control value. However, LMW **heparin** therapy is the preferred option in this case, as no monitoring is required in most patients.

Continuous intravenous administration of **heparin** is accomplished via an infusion pump. After an initial bolus injection of 80–100 units/kg, a continuous infusion of about 15–22 units/kg per hour is required to maintain the anti-Xa activity in the range of 0.3–0.7 units/mL. Low-dose prophylaxis is achieved with subcutaneous administration of **heparin**, 5000 units every 8–12 hours. Because of the danger of hematoma formation at the injection site, **heparin** must never be administered intramuscularly.

Prophylactic **enoxaparin** is given subcutaneously in a dosage of 30 mg twice daily or 40 mg once daily. Full-dose **enoxaparin** therapy is 1 mg/kg subcutaneously every 12 hours. This corresponds to a therapeutic anti-factor Xa level of 0.5–1 unit/mL. Selected patients may be treated with **enoxaparin** 1.5 mg/kg once a day, with a target anti-Xa level of 1.5 units/mL. The prophylactic dosage of **dalteparin** is 5000 units subcutaneously once a day; therapeutic dosing is 200 units/kg once a day for venous disease or 120 units/kg every 12 hours for acute coronary syndrome. LMW **heparin** should be used with caution in patients with renal insufficiency or body weight greater than 150 kg. Measurement of the anti-Xa level is useful to guide dosing in these individuals.

The synthetic pentasaccharide molecule **fondaparinux** avidly binds **antithrombin** with high specific activity, resulting in efficient inactivation of factor Xa. **Fondaparinux** has a long half-life of 15 hours, allowing for once-daily dosing by subcutaneous administration. **Fondaparinux** is effective in the prevention and treatment of venous thromboembolism and does not appear to cross-react with pathologic HIT antibodies in most individuals.

#### Reversal of Heparin Action

Excessive anticoagulant action of **heparin** is treated by discontinuance of the drug. If bleeding occurs, administration of a specific antagonist such as **protamine sulfate** is indicated. **Protamine** is a highly basic, positively charged peptide that combines with negatively charged **heparin** as an ion pair to form a stable complex devoid of anticoagulant activity. For every 100 units of **heparin** remaining in the patient, 1 mg of **protamine** sulfate is given intravenously; the rate of infusion should not exceed 50 mg in any 10-minute period. Excess **protamine** must be avoided; it also has an anticoagulant effect. Neutralization of LMW **heparin** by **protamine** is incomplete. Limited experience suggests that 1 mg of **protamine** sulfate may be used to partially neutralize 1 mg of **enoxaparin**. **Protamine** will not reverse the activity of **fondaparinux**. Excess **danaparoid** can be removed by plasmapheresis.

## WARFARIN & OTHER COUMARIN ANTICOAGULANTS

### Chemistry & Pharmacokinetics

The clinical use of the coumarin anticoagulants began with the discovery of an anticoagulant substance formed in spoiled sweet clover silage, which caused hemorrhagic disease in cattle. At the behest of local farmers, a chemist at the University of Wisconsin identified the toxic agent as bishydroxycoumarin. Dicumarol, a synthesized derivative, and its congeners, most notably **warfarin** (Wisconsin Alumni Research Foundation, with “-arin” from coumarin added; Figure 34–5), were initially used as rodenticides. In the 1950s, **warfarin** (under the brand name Coumadin) was introduced as an anticoagulant agent in humans. **Warfarin** is one of the most commonly prescribed drugs.

**Warfarin** is generally administered as the sodium salt and has 100% oral bioavailability. Over 99% of racemic **warfarin** is bound to plasma **albumin**, which may contribute to its small volume of distribution (the **albumin** space), its long half-life in plasma (36 hours), and the lack of urinary excretion of unchanged drug. **Warfarin** used clinically is a racemic mixture composed of equal amounts of two enantiomorphs. The levorotatory *S*-warfarin is four times more potent than the dextrorotatory *R*-warfarin. This observation is useful in understanding the stereoselective nature of several drug interactions involving **warfarin**.

### Mechanism of Action

Coumarin anticoagulants block the  $\gamma$ -carboxylation of several glutamate residues in prothrombin and factors VII, IX, and X as well as the endogenous anticoagulant proteins C and S (see [Figure 34-2](#) and [Table 34-1](#)). The blockade results in incomplete coagulation factor molecules that are biologically inactive. The protein carboxylation reaction is coupled to the oxidation of vitamin K. The vitamin must then be reduced to reactivate it. **Warfarin** prevents reductive metabolism of the inactive vitamin K epoxide back to its active **hydroquinone** form ([Figure 34-6](#)). Mutational change of the gene for the responsible enzyme, vitamin K epoxide reductase (*VKORC1*), can give rise to genetic resistance to **warfarin** in humans and rodents.

FIGURE 34-6

Vitamin K cycle—metabolic interconversions of vitamin K associated with the synthesis of vitamin K-dependent clotting factors. Vitamin K<sub>1</sub> or K<sub>2</sub> is activated by reduction to the **hydroquinone** form (KH<sub>2</sub>). Stepwise oxidation to vitamin K epoxide (KO) is coupled to prothrombin carboxylation by the enzyme carboxylase. The reactivation of vitamin K epoxide is the warfarin-sensitive step (**warfarin**). The R on the vitamin K molecule represents a 20-carbon phytyl side chain in vitamin K<sub>1</sub> and a 30- to 65-carbon polyprenyl side chain in vitamin K<sub>2</sub>.

There is an 8- to 12-hour delay in the action of **warfarin**. Its anticoagulant effect results from a balance between partially inhibited synthesis and unaltered degradation of the four vitamin K-dependent clotting factors. The resulting inhibition of coagulation is dependent on their degradation half-lives in the circulation. These half-lives are 6, 24, 40, and 60 hours for factors VII, IX, X, and II, respectively. Importantly, protein C has a short half-life similar to factor VIIa. Thus the immediate effect of **warfarin** is to deplete the procoagulant factor VII and anticoagulant protein C, which can paradoxically create a transient hypercoagulable state due to residual activity of the longer half-life procoagulants in the face of protein C depletion (see below). For this reason in patients with active hypercoagulable states, such as acute DVT or PE, UFH or LMW **heparin** is always used to achieve immediate anticoagulation until adequate warfarin-induced depletion of the procoagulant clotting factors is achieved. The duration of this overlapping therapy is generally 5–7 days.

### Toxicity

**Warfarin** crosses the placenta readily and can cause a hemorrhagic disorder in the fetus. Furthermore, fetal proteins with  $\gamma$ -carboxyglutamate residues found in bone and blood may be affected by **warfarin**; the drug can cause a serious birth defect characterized by abnormal bone formation. Thus, **warfarin** should never be administered during pregnancy. Cutaneous necrosis with reduced activity of protein C sometimes occurs during the first weeks of therapy in patients who have inherited deficiency of protein C. Rarely, the same process causes frank infarction of the breast, fatty tissues, intestine, and extremities. The pathologic lesion associated with the hemorrhagic infarction is venous thrombosis, consistent with a hypercoagulable state due to warfarin-induced depletion of protein C.

### Administration & Dosage

Treatment with **warfarin** should be initiated with standard doses of 5–10 mg. The initial adjustment of the prothrombin time takes about 1 week, which usually results in a maintenance dosage of 5–7 mg/d. The **prothrombin time (PT)** should be increased to a level representing a reduction of prothrombin activity to 25% of normal and maintained there for long-term therapy. When the activity is less than 20%, the **warfarin** dosage should be reduced or omitted until the activity rises above 20%. Inherited polymorphisms in *CYP2C9* and *VKORC1* have significant effects on **warfarin** dosing; however, algorithms incorporating genomic information to predict initial **warfarin** dosing were no better than standard clinical algorithms in two of three large randomized trials examining this issue (see [Chapter 5](#)).

$\text{www.konkur.in}$  prothrombin time/mean of normal prothrombin time for lab)<sup>ISI</sup>, where the ISI exponent refers to the International Sensitivity Index and is dependent on the specific reagents and instruments used for the determination. The ISI serves to relate measured prothrombin times to a World Health Organization reference standard thromboplastin; thus the prothrombin times performed on different properly calibrated instruments with a variety of thromboplastin reagents should give the same INR results for a given sample. For most reagent and instrument combinations in current use, the ISI is close to 1, making the INR roughly the ratio of the patient prothrombin time to the mean normal prothrombin time. The recommended INR for prophylaxis and treatment of thrombotic disease is 2–3. Patients with some types of artificial heart valves (eg, tilting disk) or other medical conditions increasing thrombotic risk have a recommended range of 2.5–3.5. While a prolonged INR is widely used as an indication of integrity of the coagulation system in liver disease and other disorders, it has been validated only in patients in steady state on chronic [warfarin](#) therapy.

Occasionally patients exhibit [warfarin](#) resistance, defined as progression or recurrence of a thrombotic event while in the therapeutic range. These individuals may have their INR target raised (which is accompanied by an increase in bleeding risk) or be changed to an alternative form of anticoagulation (eg, daily injections of LMW [heparin](#) or one of the newer oral anticoagulants). [Warfarin](#) resistance is most commonly seen in patients with advanced cancers, typically of gastrointestinal origin (Trousseau syndrome). LMW [heparin](#) is superior to [warfarin](#) in preventing recurrent venous thromboembolism in patients with cancer.

### Drug Interactions

The coumarin anticoagulants often interact with other drugs and with disease states. These interactions can be broadly divided into pharmacokinetic and pharmacodynamic effects ([Table 34–2](#)). Pharmacokinetic mechanisms for drug interaction with [warfarin](#) mainly involve cytochrome P450 CYP2C9 enzyme induction, enzyme inhibition, and reduced plasma protein binding. Pharmacodynamic mechanisms for interactions with [warfarin](#) are synergism (impaired hemostasis, reduced clotting factor synthesis, as in hepatic disease), competitive antagonism (vitamin K), and an altered physiologic control loop for vitamin K (hereditary resistance to oral anticoagulants).

Pharmacokinetic and pharmacodynamic drug and body interactions with oral anticoagulants.

<sup>1</sup>Stereoselectively inhibits the oxidative metabolism of the S-warfarin enantiomorph of racemic warfarin.

The most serious interactions with warfarin are those that increase the anticoagulant effect and the risk of bleeding. The most dangerous of these interactions are the pharmacokinetic interactions with the mostly obsolete pyrazolones phenylbutazone and sulfinpyrazone. These drugs not only augment the hypoprothrombinemia but also inhibit platelet function and may induce peptic ulcer disease (see Chapter 36). The mechanisms for their hypoprothrombinemic interaction are a stereoselective inhibition of oxidative metabolic transformation of S-warfarin (the more potent isomer) and displacement of albumin-bound warfarin, increasing the free fraction. For this and other reasons, neither phenylbutazone nor sulfinpyrazone is in common use in the United States. Metronidazole, fluconazole, and trimethoprim-sulfamethoxazole also stereoselectively inhibit the metabolic transformation of S-warfarin, whereas amiodarone, disulfiram, and cimetidine inhibit metabolism of both enantiomorphs of warfarin (see Chapter 4).

Aspirin, hepatic disease, and hyperthyroidism augment warfarin's effects— aspirin by its effect on platelet function and the latter two by increasing the

turnover rate of clotting factors. The third-generation cephalosporins eliminate the bacteria in the intestinal tract that produce vitamin K and, like [warfarin](#), also directly inhibit vitamin K epoxide reductase.

Barbiturates and [rifampin](#) cause a marked *decrease* of the anticoagulant effect by induction of the hepatic enzymes that transform racemic [warfarin](#). Cholestyramine binds [warfarin](#) in the intestine and reduces its absorption and bioavailability.

Pharmacodynamic reductions of anticoagulant effect occur with increased vitamin K intake (increased synthesis of clotting factors), the diuretics [chlorthalidone](#) and [spironolactone](#) (clotting factor concentration), hereditary resistance (mutation of vitamin K reactivation cycle molecules), and hypothyroidism (decreased turnover rate of clotting factors).

Drugs with *no* significant effect on anticoagulant therapy include ethanol, phenothiazines, benzodiazepines, [acetaminophen](#), opioids, [indomethacin](#), and most antibiotics.

#### Reversal of [Warfarin](#) Action

Excessive anticoagulant effect and bleeding from [warfarin](#) can be reversed by stopping the drug and administering oral or parenteral vitamin K<sub>1</sub> ([phytonadione](#)), fresh-frozen plasma, prothrombin complex concentrates, and recombinant factor VIIa (rFVIIa). A four-factor concentrate containing factors II, VII, IX, and X (Prothrombin Complex Concentrate, [Human]; Kcentra) (4F PCC) is available. The disappearance of excessive effect is not correlated with plasma [warfarin](#) concentrations but rather with reestablishment of normal activity of the clotting factors. A modest excess of anticoagulant effect without bleeding may require no more than cessation of the drug. The [warfarin](#) effect can be rapidly reversed in the setting of severe bleeding with the administration of prothrombin complex or rFVIIa coupled with intravenous vitamin K. It is important to note that due to the long half-life of [warfarin](#), a single dose of vitamin K or rFVIIa may not be sufficient.

## ORAL DIRECT FACTOR Xa INHIBITORS

Oral Xa inhibitors, including [rivaroxaban](#), [apixaban](#), [edoxaban](#), and [betrixaban](#), represent a newer class of oral anticoagulant drugs that require no monitoring. Along with oral direct [thrombin](#) inhibitors (discussed below) this class of direct oral anticoagulant (DOAC) drugs is increasingly used in antithrombotic pharmacotherapy.

#### Pharmacology

[Rivaroxaban](#), [apixaban](#), [edoxaban](#), and [betrixaban](#) inhibit factor Xa in the final common pathway of clotting (see [Figure 34-2](#)). These drugs are given as fixed doses and do not require monitoring. They have a rapid onset of action and shorter half-lives than [warfarin](#).

[Rivaroxaban](#) has high oral bioavailability when taken with food. Following an oral dose, the peak plasma level is achieved within 2–4 hours; the drug is extensively protein-bound. It is a substrate for the cytochrome P450 system and the P-glycoprotein transporter. Drugs inhibiting both CYP3A4 and P-glycoprotein (eg, [ketoconazole](#)) result in increased [rivaroxaban](#) effect. One third of the drug is excreted unchanged in the urine and the remainder is metabolized and excreted in the urine and feces. The drug half-life is 5–9 hours in patients age 20–45 years and is increased in the elderly and in those with impaired renal or hepatic function.

[Apixaban](#) has an oral bioavailability of 50% and prolonged absorption, resulting in a half-life of 12 hours with chronic dosing. The drug is a substrate of the cytochrome P450 system and P-glycoprotein and is excreted in the urine and feces. As with [rivaroxaban](#), drugs inhibiting both CYP3A4 and P-glycoprotein, as well as impairment of renal or hepatic function, result in increased drug effect.

[Edoxaban](#) is a once-daily Xa inhibitor with a 62% oral bioavailability. Peak drug concentrations occur 1–2 hours after dosage and are not affected by food. The drug half-life is 10–14 hours. [Edoxaban](#) does not induce CYP450 enzymes. No dose reduction is required with concurrent use of P-glycoprotein inhibitors. [Edoxaban](#) is primarily excreted unchanged in the urine.

[Betrixaban](#) is also a once daily Xa inhibitor with oral bioavailability of 34% and half-life of 19–27 hours; peak levels are achieved in 3–4 hours, and are reduced up to 70% if taken with food. Dose reduction is required if used with P-glycoprotein inhibitors and in renal failure. The drug is primarily excreted by the liver and should be used with caution in patients with liver disease.

**Rivaroxaban** is approved for prevention of embolic stroke in patients with atrial fibrillation without valvular heart disease; prevention of venous thromboembolism following hip or knee surgery or acutely ill medical patients at risk for VTE; treatment of venous thromboembolic disease (VTE); risk reduction of cardiovascular events (MI, stroke, cardiovascular death) in patients with coronary artery disease (CAD); and risk reduction of thrombotic events in patients with peripheral arterial disease (PAD). The prophylactic dosage is 10 mg orally per day for 35 days for hip replacement or 12 days for knee replacement. For treatment of DVT/PE the dosage is 15 mg twice daily for 3 weeks followed by 20 mg/d. The dose for risk reduction of cardiovascular events in CAD and PAD is 2.5 mg twice daily, along with **aspirin**, 70–100 mg daily. Depending on clinical presentation and risk factors, patients with VTE are treated for 3–6 months; **rivaroxaban** is also approved for extended therapy (10 mg once daily) in selected patients to reduce recurrence risk at the treatment dose. Pediatric dosing is weight-based. Dose reduction is recommended for creatine clearance of 15–50 mL/min in AF, and use avoided in patients with creatinine clearance of <15 mL/min. Combined use of P-glycoprotein inhibitors and CYP3A inhibitors increases drug exposure; combined use of p-glycoprotein and CYP3A diminishes drug effect. **Apixaban** is approved for prevention of stroke in nonvalvular atrial fibrillation, for prevention of VTE following hip or knee surgery, and for treatment and long-term prevention of VTE. The dosage for atrial fibrillation is 5 mg twice daily; the dose for VTE is 10 mg twice a day for the first week, followed by 5 mg twice a day. The prophylactic dose for prevention of VTE following hip or knee surgery or long-term prevention of VTE following initial therapy is 2.5 mg twice a day. The recommended duration of therapy in hip and knee replacement is the same as for **rivaroxaban**. Combined use of P-glycoprotein inhibitors and CYP3A inhibitors increases drug exposure; combined use of p-glycoprotein and CYP3A diminishes drug effect. **Edoxaban** is approved for prevention of stroke in nonvalvular atrial fibrillation, and to treat VTE following treatment with **heparin** or LMWH for 5–10 days. The dose for atrial fibrillation and VTE treatment is 60 mg once daily. For patients with creatinine clearance of 15–50 mL/min, the dose is 30 mg once daily. **Edoxaban** is contraindicated in patients with atrial fibrillation and creatinine clearance >95 mL/min, due to the increased rate of ischemic stroke in this group compared with patients taking **warfarin**. **Betrixaban** is approved for prophylaxis of VTE. The recommended dosage is an initial single dose of 160 mg, followed by 80 mg once daily, taken at the same time each day with food (with dose reductions for severe renal impairment or concomitant P-glycoprotein inhibitor use). The recommended duration of treatment is 35 to 42 days.

#### Assessment of and Reversal of Anti-Xa Drug Effect

Measurement of anti-Xa drug effect is not needed in most situations but can be accomplished by anti-Xa assays calibrated for the drug in question.

**Andexanet alfa** is a factor Xa “decoy” molecule without procoagulant activity that competes for binding to anti-Xa drugs. In clinical trials involving **apixaban** and **rivaroxaban**, andexanet given by IV infusion results in rapid decrease in anti-Xa effect. The drug was FDA-approved in 2018 for reversal of life-threatening bleeding in patients treated with **apixaban** or **rivaroxaban**. The dosing strategy takes into account the dose of **apixaban** or **rivaroxaban** used, and time since the last dose. Low dose is 400 mg IV at a rate of 30 mg/min, followed by 4 mg/min for up to 120 min; high dose is 800 mg bolus given at 30 mg/min followed by 8 mg/min for up to 120 minutes. Thrombotic complications have been reported, as well as cardiac arrest and sudden death. Four-factor concentrate may be considered as an alternative approach to life-threatening bleeding on anti-Xa drugs.

## DIRECT THROMBIN INHIBITORS

The direct **thrombin** inhibitors (DTIs) exert their anticoagulant effect by directly binding to the active site of **thrombin**, thereby inhibiting **thrombin**'s downstream effects. This is in contrast to indirect **thrombin** inhibitors such as **heparin** and LMW **heparin** (see above), which act through **antithrombin**.

**Hirudin** and **bivalirudin** are large, bivalent DTIs that bind at the catalytic or active site of **thrombin** as well as at a substrate recognition site.

**Argatroban** and **melagatran** are small molecules that bind only at the **thrombin** active site. One oral **thrombin** inhibitor (**dabigatran**) is available.

## PARENTERAL DIRECT THROMBIN INHIBITORS

Leeches have been used for bloodletting since the age of Hippocrates. More recently, surgeons have used medicinal leeches (*Hirudo medicinalis*) to prevent thrombosis in the fine vessels of reattached digits. **Hirudin** is a specific, irreversible **thrombin** inhibitor from leech saliva that for a time was available in recombinant form as **lepirudin**. Its action is independent of **antithrombin**, which means it can reach and inactivate fibrin-bound **thrombin** in thrombi. Lepirudin has little effect on platelets or the bleeding time. Like **heparin**, it must be administered parenterally and is monitored by aPTT. Lepirudin was approved by the US Food and Drug Administration (FDA) for use in patients with thrombosis related to heparin-induced thrombocytopenia (HIT). Lepirudin is excreted by the kidney and should be used with great caution in patients with renal insufficiency as no antidote exists. Up to 40% of patients who receive long-term infusions develop an antibody directed against the thrombin-lepirudin complex. These antigen-antibody complexes are not cleared by the kidney and may result in an enhanced anticoagulant effect. Some patients re-exposed to the drug

**Bivalirudin**, another bivalent inhibitor of **thrombin**, is administered intravenously, with a rapid onset and offset of action. The drug has a short half-life with clearance that is 20% renal and the remainder metabolic. **Bivalirudin** is FDA-approved for use in percutaneous coronary angioplasty and in patients with heparin-induced thrombocytopenia (HIT) who require coronary interventions.

**Argatroban** is a small molecule **thrombin** inhibitor that is FDA-approved for use in patients with HIT with or without thrombosis and coronary angioplasty in patients with HIT. It, too, has a short half-life, is given by continuous intravenous infusion, and is monitored by aPTT. Its clearance is not affected by renal disease but is dependent on liver function; dose reduction is required in patients with liver disease. Patients on **argatroban** will demonstrate elevated INRs, rendering the transition to **warfarin** challenging (ie, the INR will reflect contributions from both **warfarin** and **argatroban**). (INR is discussed in detail in the section on **warfarin** administration.) A nomogram is supplied by the manufacturer to assist in this transition.

## ORAL DIRECT THROMBIN INHIBITOR

Advantages of oral direct **thrombin** inhibition include predictable pharmacokinetics and bioavailability, which allow for fixed dosing and predictable anticoagulant response and make routine coagulation monitoring unnecessary. Similar to the direct oral anti-Xa drugs described above, the rapid onset and offset of action of these agents allow for immediate anticoagulation.

**Dabigatran etexilate mesylate** is the only FDA-approved oral direct **thrombin** inhibitor. Dabigatran is approved for reduction in risk of stroke and systemic embolism with nonvalvular atrial fibrillation, treatment of VTE following 5–7 days of initial **heparin** or LMWH therapy, reduction of the risk of recurrent VTE, and VTE prophylaxis following hip or knee replacement surgery.

### Pharmacology

Dabigatran and its metabolites are direct **thrombin** inhibitors. Following oral administration, dabigatran etexilate mesylate, a prodrug, is converted to dabigatran. The oral bioavailability is 3–7% in normal volunteers. The drug is a substrate for the P-glycoprotein efflux pump; P-glycoprotein inhibitors such as **ketoconazole** should be avoided in patients with impaired renal function. The half-life of the drug in normal volunteers is 12–17 hours. Renal impairment results in prolonged drug clearance.

### Administration & Dosage

For prevention of stroke and systemic embolism in nonvalvular atrial fibrillation, the dosage is 150 mg twice daily for patients with creatinine clearance greater than 30 mL/min. For decreased creatinine clearance of 15–30 mL/min, the dosage is 75 mg twice daily. No monitoring is required.

### Assessment of & Reversal of Antithrombin Drug Effect

As with any anticoagulant drug, the primary toxicity of dabigatran is bleeding. Dabigatran will prolong the PTT, **thrombin** time, and ecarin clotting time, which can be used to estimate drug effect if necessary. (The ecarin clotting time [ECT] is another clotting test based on the use of a protein isolated from viper venom.) **Idarucizumab** is a humanized monoclonal antibody Fab fragment that binds to dabigatran and reverses the anticoagulant effect. This reversing drug is approved for use in situations requiring emergent surgery or for life-threatening bleeding. The recommended dose is 5 g given intravenously. If bleeding recurs, a second dose may be given. The drug is primarily excreted by the kidneys. The half-life in patients with normal renal function is approximately 1 hour. As discussed above for reversing anti-Xa therapy, reversal of dabigatran exposes patients to the underlying thrombotic disease they are being treated for, and use should be restricted to those with life-threatening bleeding or surgery.

### Summary of the Direct Oral Anticoagulant Drugs

The direct oral anticoagulant drugs have consistently shown equivalent antithrombotic efficacy and lower bleeding rates when compared with traditional **warfarin** therapy. In addition, these drugs offer the advantages of rapid therapeutic effect, no monitoring requirement, and fewer drug interactions in comparison with **warfarin**, which has a narrow therapeutic window, is affected by diet and many drugs, and requires monitoring for dosage optimization. However, the short half-life of the newer anticoagulants has the important consequence that patient noncompliance will quickly lead to loss of anticoagulant effect and risk of thromboembolism. Given the convenience of once- or twice-daily oral dosing, lack of a monitoring requirement, and fewer drug and dietary interactions documented thus far, the new direct oral anticoagulants represent a significant advance in the prevention and therapy of thrombotic disease.

# BASIC PHARMACOLOGY OF THE FIBRINOLYTIC DRUGS

Fibrinolytic drugs rapidly lyse thrombi by catalyzing the formation of the serine protease **plasmin** from its precursor zymogen, plasminogen (see [Figure 34–3](#)). These drugs create a generalized lytic state when administered intravenously. Thus, both protective hemostatic thrombi and target thromboemboli are broken down. The Box: [Thrombolytic Drugs for Acute Myocardial Infarction](#) describes the use of these drugs in one major application.

## Thrombolytic Drugs for Acute Myocardial Infarction

The paradigm shift in 1980 on the causation of acute myocardial infarction to acute coronary occlusion by a thrombus created the rationale for thrombolytic therapy of this common lethal disease. At that time—and for the first time—intravenous thrombolytic therapy for acute myocardial infarction in the European Cooperative Study Group trial was found to reduce mortality. Later studies, with thousands of patients in each trial, provided enough statistical power for the 20% reduction in mortality to be considered statistically significant. Although the standard of care in areas with adequate facilities and experience in percutaneous coronary intervention (PCI) now favors catheterization and placement of a stent, thrombolytic therapy is still very important where PCI is not readily available.

The proper selection of patients for thrombolytic therapy is critical. The diagnosis of acute myocardial infarction is made clinically and is confirmed by electrocardiography. Patients with ST-segment elevation and bundle branch block on electrocardiography have the best outcomes. All trials to date show the greatest benefit for thrombolytic therapy *when it is given early, within 6 hours* after symptomatic onset of acute myocardial infarction.

Thrombolytic drugs reduce the mortality of acute myocardial infarction. The early and appropriate use of any thrombolytic drug probably transcends possible advantages of a particular drug.

## Pharmacology

**Streptokinase** is a protein (but not an enzyme in itself) synthesized by streptococci that combines with the proactivator plasminogen. This enzymatic complex catalyzes the conversion of inactive plasminogen to active plasmin. **Urokinase** is a human enzyme synthesized by the kidney that directly converts plasminogen to active plasmin. Plasmin itself cannot be used because naturally occurring inhibitors (antiplasmins) in plasma prevent its effects. However, the absence of inhibitors for urokinase and the streptokinase-proactivator complex permits their use clinically. Plasmin formed inside a thrombus by these activators is protected from plasma antiplasmins; this allows it to lyse the thrombus from within.

Plasminogen can also be activated endogenously by **tissue plasminogen activators (t-PAs)**. These activators preferentially activate plasminogen that is bound to fibrin, which (in theory) confines fibrinolysis to the formed thrombus and avoids systemic activation. Recombinant human t-PA is manufactured as **alteplase**. **Retepase** is another recombinant human t-PA from which several amino acid sequences have been deleted, and it has a longer half-life. **Tenecteplase** is a genetically engineered form of t-PA that has increased fibrin-binding affinity and a longer half-life, and it can be given as a single intravenous bolus. **Retepase** and **tenecteplase** are as effective as **alteplase** and have simpler dosing schemes because of their longer half-lives.

## Indications & Dosage

Administration of fibrinolytic drugs by the intravenous route is indicated in cases of **pulmonary embolism with hemodynamic instability**, severe **deep venous thrombosis** such as the superior vena caval syndrome, and **ascending thrombophlebitis** of the iliofemoral vein with severe lower extremity edema. These drugs are also given intra-arterially, especially for peripheral vascular disease.

Thrombolytic therapy in the management of **acute myocardial infarction** requires careful patient selection, the use of a specific thrombolytic agent, and the benefit of adjuvant therapy. Streptokinase is administered by intravenous infusion of a loading dose of 250,000 units, followed by 100,000 units/h for 24–72 hours. Patients with antistreptococcal antibodies can develop fever, allergic reactions, and therapeutic resistance. Urokinase requires a loading dose of 300,000 units given over 10 minutes and a maintenance dose of 300,000 units/h for 12 hours. **Alteplase** (t-PA) is given as a 15-mg bolus followed by 0.75 mg/kg (up to 50 mg) over 30 minutes and then 0.5 mg/kg (up to 35 mg) over 60 minutes. **Retepase** is given as two 10-unit

bolus injections, the second administered 30 minutes after the first injection. **Tenecteplase** is given as a single intravenous bolus ranging from 30 to 50 mg depending on body weight. **Alteplase** has also been approved for use in acute ischemic stroke within 3 hours of symptom onset. In patients without hemorrhagic infarct or other contraindications, this therapy has been demonstrated to provide better outcomes in several randomized clinical trials. The recommended dose is 0.9 mg/kg, not to exceed 90 mg, with 10% given as a bolus and the remainder during a 1-hour infusion. Streptokinase has been associated with increased bleeding risk in acute ischemic stroke when given at a dose of 1.5 million units, and its use is not recommended in this setting.

## BASIC PHARMACOLOGY OF ANTIPLATELET AGENTS

Platelet function is regulated by three categories of substances. The first group consists of agents generated outside the platelet that interact with platelet membrane receptors, eg, catecholamines, **collagen**, **thrombin**, and prostacyclin. The second category contains agents generated within the platelet that interact with membrane receptors, eg, ADP, prostaglandin D<sub>2</sub>, prostaglandin E<sub>2</sub>, and serotonin. A third group comprises agents generated within the platelet that act within the platelet, eg, prostaglandin endoperoxides and thromboxane A<sub>2</sub>, the cyclic nucleotides cAMP and cGMP, and calcium ion. From this list of agents, several targets for platelet inhibitory drugs have been identified (see **Figure 34–1**): inhibition of prostaglandin synthesis (**aspirin**), inhibition of ADP-induced platelet aggregation (**clopidogrel**, **prasugrel**, **ticlopidine**), and blockade of glycoprotein IIb/IIIa (GP IIb/IIIa) receptors on platelets (**abciximab**, **tirofiban**, and **eptifibatide**). **Dipyridamole** and **cilostazol** are additional antiplatelet drugs.

### ASPIRIN

The prostaglandin **thromboxane A<sub>2</sub>** is an arachidonate product that causes platelets to change shape, release their granules, and aggregate (see **Chapter 18**). Drugs that antagonize this pathway interfere with platelet aggregation in vitro and prolong the bleeding time in vivo. **Aspirin** is the prototype of this class of drugs.

As described in **Chapter 18**, **aspirin** inhibits the synthesis of thromboxane A<sub>2</sub> by irreversible acetylation of the enzyme cyclooxygenase. Other salicylates and nonsteroidal anti-inflammatory drugs also inhibit cyclooxygenase but have a shorter duration of inhibitory action because they cannot acetylate cyclooxygenase; that is, their action is reversible.

In 2014, following a review of the available data, the FDA reversed course and concluded that **aspirin** for *primary* prophylaxis (patients without a history of myocardial infarction or stroke) was not supported by the available data but did carry significant bleeding risk. A 2019 recommendation by the American College of Cardiology and American Heart Association recommended low dose **aspirin** (75–100 mg/d) be considered for primary prevention in adults 40–70 years of age with high risk of atherosclerotic cardiovascular disease and no increased bleeding risk. In contrast, meta-analysis of many published trials of **aspirin** and other antiplatelet agents have demonstrated the utility of **aspirin** in the *secondary* prevention of vascular events among patients with a history of vascular events.

### THIENOPYRIDINES: TICLOPIDINE, CLOPIDOGREL, & PRASUGREL

**Ticlopidine**, **clopidogrel**, and **prasugrel** reduce platelet aggregation by inhibiting the ADP pathway of platelets. These drugs irreversibly block the ADP P2Y<sub>12</sub> receptor on platelets. Unlike **aspirin**, these drugs have no effect on prostaglandin metabolism. Use of **ticlopidine**, **clopidogrel**, or **prasugrel** to prevent thrombosis is now considered standard practice in patients undergoing placement of a coronary stent. As the indications and adverse effects of these drugs are different, they will be considered individually.

**Ticlopidine** is approved for prevention of stroke in patients with a history of a transient ischemic attack (TIA) or thrombotic stroke, and in combination with **aspirin** for prevention of coronary stent thrombosis. Adverse effects of **ticlopidine** include nausea, dyspepsia, and diarrhea in up to 20% of patients, hemorrhage in 5%, and, most seriously, leukopenia in 1%. The leukopenia is detected by regular monitoring of the white blood cell count during the first 3 months of treatment. Development of thrombotic thrombocytopenic purpura has also been associated with the ingestion of **ticlopidine**. The dosage of **ticlopidine** is 250 mg twice daily orally. Because of the significant side effect profile, the use of **ticlopidine** for stroke prevention should be restricted to those who are intolerant of or have failed **aspirin** therapy. Dosages of **ticlopidine** less than 500 mg/d may be efficacious with fewer adverse effects.

**Clopidogrel** is approved for patients with unstable angina or non-ST-elevation acute myocardial infarction (NSTEMI) in combination with **aspirin**; for

patients with ST-elevation myocardial infarction (STEMI); or recent myocardial infarction, stroke, or established peripheral arterial disease. For NSTEMI, the dosage is a 300-mg loading dose orally followed by 75 mg daily of **clopidogrel**, with a daily **aspirin** dosage of 75–325 mg. For patients with STEMI, the dosage is 75 mg daily of **clopidogrel** orally, in association with **aspirin** as above; and for recent myocardial infarction, stroke, or peripheral vascular disease, the dosage is 75 mg/d.

**Clopidogrel** has fewer adverse effects than **ticlopidine** and is rarely associated with neutropenia. Thrombotic thrombocytopenic purpura has been reported. Because of its superior adverse effect profile and dosing requirements, **clopidogrel** is frequently preferred over **ticlopidine**. The antithrombotic effects of **clopidogrel** are dose-dependent; within 5 hours after an oral loading dose of 300 mg, 80% of platelet activity will be inhibited. The maintenance dosage of **clopidogrel** is 75 mg/d, which achieves maximum platelet inhibition. The duration of the antiplatelet effect is 7–10 days. **Clopidogrel** is a prodrug that requires activation via the cytochrome P450 enzyme isoform CYP2C19. Depending on the single nucleotide polymorphism (SNP) inheritance pattern in CYP2C19, individuals may be poor metabolizers of **clopidogrel**, and these patients may be at increased risk of cardiovascular events due to inadequate drug effect. The FDA has recommended CYP2C19 genotyping to identify such patients and advises prescribers to consider alternative therapies in poor metabolizers (see **Chapter 5**). Drugs that impair CYP2C19 function, such as **omeprazole**, should be used with caution.

**Prasugrel**, similar to **clopidogrel**, is approved for patients with acute coronary syndromes. The drug is given orally as a 60-mg loading dose and then 10 mg/d in combination with **aspirin** as outlined for **clopidogrel**. The Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with **Prasugrel** (TRITON-TIMI38) compared **prasugrel** with **clopidogrel** in a randomized, double-blind trial with **aspirin** and other standard therapies managed with percutaneous coronary interventions. This trial showed a reduction in the primary composite cardiovascular endpoint (cardiovascular death, nonfatal stroke, or nonfatal myocardial infarction) for **prasugrel** in comparison with **clopidogrel**. However, the major and minor bleeding risk was increased with **prasugrel**. **Prasugrel** is contraindicated in patients with history of TIA or stroke because of increased bleeding risk. In contrast to **clopidogrel**, cytochrome P450 genotype status is not an important factor in **prasugrel** pharmacology.

**Ticagrelor** is a newer type of ADP inhibitor (cyclopentyl triazolopyrimidine) and is also approved for oral use in combination with **aspirin** in patients with acute coronary syndromes. **Cangrelor** is a *parenteral* P2Y<sub>12</sub> inhibitor approved for IV use in coronary interventions in patients without previous ADP P2Y<sub>12</sub> inhibitor therapy.

**Vorapaxar** is a platelet protease receptor 1 (PAR-1) antagonist indicated for reduction of recurrent events in patients with history of MI or peripheral arterial disease. **Vorapaxar** has a long half-life with 50% inhibition of platelet aggregation remaining 1 month after cessation of therapy. Dosing is 2.08 mg orally daily. Peak concentrations occur 1–2 hours following a 2.08 mg dose.

### Aspirin & Clopidogrel Resistance

The reported incidence of resistance to these drugs varies greatly, from less than 5% to 75%. In part this variation reflects the definition of resistance (recurrent thrombosis while on antiplatelet therapy versus in vitro testing), methods by which drug response is measured, and patient compliance. Several methods for testing **aspirin** and **clopidogrel** resistance in vitro are now FDA-approved. However, the measures of drug resistance vary considerably by testing method. These tests may be useful in selected patients to assess compliance or identify patients at increased risk of recurrent thrombotic events. However, their utility in routine clinical decision making outside of clinical trials remains controversial. A randomized prospective trial found no benefit over standard therapy when information obtained from monitoring antiplatelet drug effect was used to alter therapy.

## BLOCKADE OF PLATELET GLYCOPROTEIN IIB/IIIa RECEPTORS

The platelet GP IIb/IIIa (integrin  $\alpha_{IIb}\beta_{III}$ ) receptor functions as a receptor mainly for fibrinogen and vitronectin but also for fibronectin and von Willebrand factor. Activation of this receptor complex is the final common pathway for platelet aggregation. Ligands for GP IIb/IIIa contain an Arg-Gly-Asp (RGD) sequence motif important for ligand binding, and thus RGD constitutes a therapeutic target. There are approximately 50,000 copies of this complex on the surface of each platelet. Persons lacking this receptor have a bleeding disorder, Glanzmann's thrombasthenia.

The GP IIb/IIIa antagonists are used in patients with acute coronary syndromes. These drugs target the platelet GP IIb/IIIa receptor complex shown in **Figure 34–1**. **Abciximab**, a chimeric monoclonal antibody that binds to and blocks the IIb/IIIa and vitronectin (integrin  $\alpha_{v}\beta_{III}$ ) receptors in a non-RGD-dependent manner, was the first agent approved in this class of drugs. It has been approved for use in percutaneous coronary interventions in

combination with **aspirin** and **heparin**. **Eptifibatid** is a cyclic peptide derived from rattlesnake venom that contains a variation of the RGD motif (KGD)

www.konkur.in  
www.konkur.in is used for use in acute coronary syndromes and percutaneous interventions in combination with [aspirin](#) and [heparin](#). [Tirofiban](#) is a peptidomimetic inhibitor with the RGD sequence motif approved for use in non-ST-elevation acute coronary syndromes. [Eptifibatid](#) and [tirofiban](#) inhibit ligand binding to the IIb/IIIa receptor by their occupancy of the receptor but do not block the vitronectin receptor. Because of their short half-lives, they must be given by continuous infusion.

## ADDITIONAL ANTIPLATELET-DIRECTED DRUGS

[Dipyridamole](#) is a vasodilator that also inhibits platelet function by inhibiting [adenosine](#) uptake and cGMP phosphodiesterase activity. [Dipyridamole](#) by itself has little or no beneficial effect. Therefore, therapeutic use of this agent is primarily in combination with [aspirin](#) to prevent cerebrovascular ischemia. It may also be used in combination with [warfarin](#) for primary prophylaxis of thromboemboli in patients with prosthetic heart valves. A combination of [dipyridamole](#) complexed with 25 mg of [aspirin](#) is now available for secondary prophylaxis of cerebrovascular disease.

[Cilostazol](#) is a phosphodiesterase inhibitor that promotes vasodilation and inhibition of platelet aggregation. [Cilostazol](#) is used primarily to treat intermittent claudication.

# CLINICAL PHARMACOLOGY OF DRUGS USED TO PREVENT CLOTTING

## VENOUS THROMBOSIS

### Risk Factors

#### A. Inherited Disorders

The inherited disorders characterized by a tendency to form thrombi (thrombophilia) derive from either quantitative or qualitative abnormalities of the natural anticoagulant system. Deficiencies (loss of function mutations) in the natural anticoagulants [antithrombin](#), protein C, and protein S account for approximately 15% of selected patients with juvenile or recurrent thrombosis and 5–10% of unselected cases of acute venous thrombosis. Additional causes of thrombophilia include gain of function mutations such as the factor V Leiden mutation and the prothrombin 20210 mutation, elevated clotting factor and cofactor levels, and hyperhomocysteinemia that together account for the greater number of hypercoagulable patients. Although loss of function mutations are less common, they are associated with the greatest thrombosis risk. Some patients have multiple inherited risk factors or combinations of inherited and acquired risk factors as discussed below. These individuals are at higher risk for recurrent thrombotic events and are often considered candidates for lifelong therapy.

#### B. Acquired Disease

The increased risk of thromboembolism associated with atrial fibrillation and with the placement of mechanical heart valves has long been recognized. Similarly, prolonged bed rest, high-risk surgical procedures, and the presence of cancer are clearly associated with an increased incidence of deep venous thrombosis and embolism. Antiphospholipid antibody syndrome is another important acquired risk factor. Drugs may function as synergistic risk factors in concert with inherited risk factors. For example, women who have the factor V Leiden mutation and take oral contraceptives have a synergistic increase in risk.

### Antithrombotic Management

#### A. Prevention

Primary prevention of venous thrombosis reduces the incidence of and mortality rate from pulmonary emboli. [Heparin](#) and [warfarin](#) may be used to prevent venous thrombosis. Subcutaneous administration of low-dose unfractionated [heparin](#), LMW [heparin](#), or [fondaparinux](#) provides effective prophylaxis. [Warfarin](#) is also effective but requires laboratory monitoring of the prothrombin time.

#### B. Treatment of Established Disease

Treatment for established venous thrombosis may be initiated with direct oral anticoagulants alone. Alternatively, patients may be treated with unfractionated or LMW [heparin](#) for the first 5–7 days, with an overlap with [warfarin](#). Once therapeutic effects of [warfarin](#) have been established,

therapy with [warfarin](#) is continued for 6 weeks to 6 months or longer, depending on the clinical presentation of the patient. In general, patients who have a provoked event (eg, VTE in the postoperative setting with no other risk factors) would be treated on the shorter end of the spectrum, whereas an individual with recurrent VTE or multiple risk factors might be treated indefinitely. Superficial thrombi confined to the calf veins respond well to short courses of LMW [heparin](#).

[Warfarin](#) readily crosses the placenta. It can cause hemorrhage at any time during pregnancy as well as developmental defects in the fetus when administered during the first trimester. Therefore, venous thromboembolic disease in pregnant women is generally treated with [heparin](#), best administered by subcutaneous injection.

## ARTERIAL THROMBOSIS

Activation of platelets is considered an essential process for arterial thrombosis. Thus, treatment with platelet-inhibiting drugs such as [aspirin](#) and [clopidogrel](#) or [ticlopidine](#) is indicated in patients with TIAs and strokes or unstable angina and acute myocardial infarction. As discussed above, [prasugrel](#) and [ticagrelor](#) are alternatives to [clopidogrel](#) for patients with acute coronary syndromes managed with percutaneous coronary interventions. In angina and infarction, these drugs are often used in conjunction with  $\beta$  blockers, calcium channel blockers, and fibrinolytic drugs.

## DRUGS USED IN BLEEDING DISORDERS

### VITAMIN K

Vitamin K confers biologic activity upon prothrombin and factors VII, IX, and X by participating in their postribosomal modification. Vitamin K is a fat-soluble substance found primarily in leafy green vegetables. The dietary requirement is low because the vitamin is additionally synthesized by bacteria that colonize the human intestine. Two natural forms exist: [vitamins K<sub>1</sub>](#) and [K<sub>2</sub>](#). Vitamin [K<sub>1</sub>](#) ([phytonadione](#); see [Figure 34–5](#)) is found in food. Vitamin [K<sub>2</sub>](#) (menaquinone) is found in human tissues and is synthesized by intestinal bacteria.

[Vitamins K<sub>1</sub>](#) and [K<sub>2</sub>](#) require bile salts for absorption from the intestinal tract. Vitamin [K<sub>1</sub>](#) is available clinically in oral and parenteral forms. Onset of effect is delayed for 6 hours but the effect is complete by 24 hours when treating depression of prothrombin activity caused by excess [warfarin](#) or vitamin K deficiency. Intravenous administration of vitamin [K<sub>1</sub>](#) should be slow, as rapid infusion can produce dyspnea, chest and back pain, and even death. Vitamin K repletion is best achieved with intravenous or oral administration because its bioavailability after subcutaneous administration is erratic. Vitamin [K<sub>1</sub>](#) is currently administered to all newborns to prevent the hemorrhagic disease of vitamin K deficiency, which is especially common in premature infants.

*The water-soluble salt of vitamin K<sub>3</sub> (menadione) should never be used in therapeutics.* It is particularly ineffective in the treatment of [warfarin](#) overdosage. Vitamin K deficiency frequently occurs in hospitalized patients in intensive care units because of poor diet, parenteral nutrition, recent surgery, multiple antibiotic therapy, and uremia. Severe hepatic failure results in diminished protein synthesis and a hemorrhagic diathesis that is unresponsive to vitamin K.

## PLASMA FRACTIONS

### Sources & Preparations

Deficiencies in plasma coagulation factors can cause bleeding ([Table 34–3](#)). Spontaneous bleeding occurs when factor activity is less than 5–10% of normal. Factor VIII deficiency (**classic hemophilia**, or **hemophilia A**) and factor IX deficiency (**Christmas disease**, or **hemophilia B**) account for most of the heritable coagulation defects. Concentrated plasma fractions and recombinant protein preparations are available for the treatment of these deficiencies. Administration of plasma-derived, heat- or detergent-treated factor concentrates and recombinant factor concentrates are the standard treatments for prevention and treatment of bleeding associated with hemophilia. Lyophilized factor VIII concentrates are prepared from large pools of plasma. Transmission of viral diseases such as hepatitis B and C and HIV is reduced or eliminated by pasteurization and by extraction of plasma with solvents and detergents. However, this treatment does not remove other potential causes of transmissible diseases such as prions. For this reason, recombinant clotting factor preparations are recommended whenever possible for factor replacement. The best use of these therapeutic materials requires diagnostic specificity of the deficient factor and quantitation of its activity in plasma. Recently, several longer-acting factor VIII and IX

preparations have been developed. **Eloctate** is a factor VIII-Fc domain conjugate that prolongs the factor VIII half-life and allows twice-weekly dosing in many cases. **Idelvion** is a factor IX-albumin conjugate with a half-life of 100 hours (native factor IX has a half-life of 16 hours) and is FDA-approved for prophylaxis or treatment of bleeding in hemophilia B patients, offering the possibility of once-weekly dosing in the case of Idelvion. Intermediate purity factor VIII concentrates (as opposed to recombinant or high purity concentrates) contain significant amounts of von Willebrand factor. **Humate-P** is a factor VIII concentrate that is approved by the FDA for the treatment of bleeding associated with von Willebrand disease. **Vonicog alfa** is a recombinant von Willebrand factor product approved for treatment and control of bleeding in adults with von Willebrand disease. Fresh frozen plasma is used for factor deficiencies for which no recombinant form of the protein is available. A four-factor plasma replacement preparation containing vitamin K-dependent factors II, VII, IX, and X (**4F PCC**, Kcentra) is available for rapid reversal of **warfarin** in bleeding patients.

TABLE 34-3

**Therapeutic products for the treatment of coagulation disorders.<sup>1</sup>**

---

Factor	Deficiency State	Hemostatic Levels	Half-Life of Infused Factor	Replacement Source
I	Hypofibrinogenemia	1 g/dL	4 days	Cryoprecipitate, FFP
II	Prothrombin deficiency	30–40%	3 days	Prothrombin complex concentrates (intermediate purity factor IX concentrates)
V	Factor V deficiency	20%	1 day	FFP
VII	Factor VII deficiency	30%	4–6 hours	FFP Prothrombin complex concentrates (intermediate purity factor IX concentrates), Recombinant factor VIIa
VIII	Hemophilia A	30–50% 100% for major bleeding or trauma	12 hours	Recombinant factor VIII products Plasma-derived high purity concentrates Cryoprecipitate <sup>2</sup> Some patients with mild deficiency will respond to DDAVP
IX	Hemophilia B Christmas disease	30–50% 100% for major bleeding or trauma	24 hours	Recombinant factor IX products Plasma-derived high purity concentrates
X	Stuart-Prower defect	25%	36 hours	FFP Prothrombin complex concentrates
XI	Hemophilia C	30–50%	3 days	FFP
XII	Hageman defect	Not required		Treatment not necessary
von Willebrand	von Willebrand disease	30%	Approximately 10 hours	Intermediate purity factor VIII concentrates that contain von Willebrand factor Type I patients respond to DDAVP Cryoprecipitate <sup>2</sup>
XIII	Factor XIII deficiency	5%	6 days	FFP Cryoprecipitate

FFP, fresh frozen plasma; DDAVP, 1-deamino-8-D-arginine [vasopressin](#).

<sup>1</sup>For [warfarin](#) overdose or coumarin rodenticide poisoning, a four-factor concentrate (II, VII, IX, X) is available. [Antithrombin](#) concentrates are available for patients with thrombosis in the setting of [antithrombin](#) deficiency. Activated protein C concentrates were approved for treatment of sepsis but withdrawn from the market in 2011 following publication of a study demonstrating no benefit in sepsis and increased bleeding risk.

<sup>2</sup>Cryoprecipitate should be used to treat bleeding in the setting of factor VIII deficiency and von Willebrand disease only in an emergency in which pathogen-inactivated products are not available.

www.kopkila.com and B patients are given factor VIII and IX replacement, respectively, as prophylaxis to prevent bleeding, and in higher doses to treat bleeding events or to prepare for surgery.

**Desmopressin acetate** increases the factor VIII activity of patients with mild hemophilia A or von Willebrand disease. It can be used in preparation for minor surgery such as tooth extraction without any requirement for infusion of clotting factors if the patient has a documented adequate response. High-dose intranasal **desmopressin** (see [Chapter 37](#)) is available and has been shown to be efficacious and well tolerated by patients.

Freeze-dried concentrates of plasma containing prothrombin, factors IX and X, and varied amounts of factor VII (Proplex, etc) are commercially available for treating deficiencies of these factors (see [Table 34–3](#)). Each unit of factor IX per kilogram of body weight raises its activity in plasma 1.5%. **Heparin** is often added to inhibit coagulation factors activated by the manufacturing process. However, addition of **heparin** does not eliminate all thromboembolic risk.

Some preparations of factor IX concentrate contain *activated* clotting factors, which has led to their use in treating patients with inhibitors or antibodies to factor VIII or factor IX. Two products are available expressly for this purpose: **Autoplex** (with factor VIII correctional activity) and **FEIBA** (Factor Eight Inhibitor Bypass Activity). These products are not uniformly successful in arresting hemorrhage, and the factor IX inhibitor titers often rise after treatment with them. Acquired inhibitors of coagulation factors may also be treated with porcine factor VIII (for factor VIII inhibitors) and recombinant activated factor VII. Recombinant activated factor VII (**NovoSeven**) increasingly is being used to treat coagulopathy associated with liver disease and major blood loss in trauma and surgery. These recombinant and plasma-derived factor concentrates are very expensive, and the indications for them are very precise. Therefore, close consultation with a hematologist knowledgeable in this area is essential.

**Cryoprecipitate** is a plasma protein fraction obtainable from whole blood. It is used to treat deficiencies or qualitative abnormalities of fibrinogen, such as that which occurs with disseminated intravascular coagulation and liver disease. A single unit of cryoprecipitate contains 300 mg of fibrinogen.

Cryoprecipitate may also be used for patients with factor VIII deficiency and von Willebrand disease if **desmopressin** is not indicated and a pathogen-inactivated, recombinant, or plasma-derived product is not available. The concentration of factor VIII and von Willebrand factor in cryoprecipitate is not as great as that found in the concentrated plasma fractions. Moreover, cryoprecipitate is not treated in any manner to decrease the risk of viral exposure. For infusion, the frozen cryoprecipitate unit is thawed and dissolved in a small volume of sterile citrate-saline solution and pooled with other units. Rh-negative women with potential for childbearing should receive only Rh-negative cryoprecipitate because of possible contamination of the product with Rh-positive blood cells.

## RECOMBINANT FACTOR VIIa

Recombinant factor VIIa is approved for treatment of inherited or acquired hemophilia A or B with inhibitors, treatment of bleeding associated with invasive procedures in congenital or acquired hemophilia, or factor VII deficiency. In the European Union, the drug is also approved for treatment of Glanzmann thrombasthenia.

Factor VIIa initiates activation of the clotting pathway by activating factor IX and factor X in association with tissue factor (see [Figure 34–2](#)). The drug is given by bolus injection. For hemophilia A or B with inhibitors and bleeding, the dosage is 90 mg/kg every 2 hours until hemostasis is achieved, and then continued at 3- to 6-hour intervals until stable. For congenital factor VII deficiency, the recommended dosage is 15–30 mg/kg every 4–6 hours until hemostasis is achieved.

Factor VIIa has been widely used for off-label indications, including bleeding with trauma, surgery, intracerebral hemorrhage, and **warfarin** toxicity. A major concern of off-label use has been the possibility that thrombotic events may be increased. A recent study examined rates of thromboembolic events in 35 placebo-controlled trials where factor VIIa was administered for nonapproved indications. This study found an increase in arterial, but not venous, thrombotic events, particularly among elderly individuals.

## ORPHAN DRUGS FOR TREATMENT OF RARE HEREDITARY COAGULATION DISORDERS

Orphan drug status is a designation given by the FDA to promote development of therapies for rare disorders (see [Chapter 1](#)).

Factor XIII is a transaminase that crosslinks fibrin within a clot, thereby stabilizing it. Congenital factor XIII deficiency is a rare bleeding disorder.

**Recombinant factor XIII A-subunit** is FDA-approved for prevention of bleeding in patients with factor XIII deficiency.

**Factor X concentrate** is a plasma-derived factor X preparation that is FDA-approved for control of bleeding in patients with factor X deficiency and for perioperative management of patients with mild factor X deficiency.

**Protein C concentrate** is a plasma-derived protein C preparation approved for treatment of life-threatening thrombosis or purpura fulminans, a life-threatening disorder involving thrombosis in skin and systemic circulation.

**Recombinant antithrombin** is FDA-approved for prevention of perioperative and peripartum thromboembolic events in patients with hereditary antithrombin deficiency.

**Emicizumab** is a novel bispecific monoclonal antibody to factor IXa and factor X that replaces the function of factor VIII. Clinical studies have shown a dramatic reduction in bleeding events in hemophilia patients with or without Factor VIII inhibitors. The drug is FDA-approved to prevent or reduce the frequency of bleeding episodes in adult and pediatric patients with hemophilia A (congenital factor VIII deficiency) with or without factor VIII inhibitors. The dose is 3 mg/kg subcutaneously daily for 1 week (loading dose), followed by 1.5 mg/kg every week, 3 mg/kg biweekly or 6 mg/kg monthly. The bioavailability is 80–90% after subcutaneous injection, and the half-life is approximately 27 days. Thrombosis has been reported in patients also receiving prothrombin complex concentrates. **Emicizumab** will interfere with standard PTT and PTT-based factor assays. Chromogenic factor VIII assays using bovine components are available to assess endogenous factor VIII levels in patient treated with **emicizumab**.

## FIBRINOLYTIC INHIBITORS: AMINOCAPROIC ACID

Aminocaproic acid (EACA), which is chemically similar to the amino acid lysine, is a synthetic inhibitor of fibrinolysis. It competitively inhibits plasminogen activation (see [Figure 34–3](#)). It is rapidly absorbed orally and is cleared from the body by the kidney. The usual oral dosage of EACA is 6 g four times a day. When the drug is administered intravenously, a 5-g loading dose should be infused over 30 minutes to avoid hypotension.

**Tranexamic acid** is an analog of aminocaproic acid and has the same properties. It is administered orally with a 15-mg/kg loading dose followed by 30 mg/kg every 6 hours.

Clinical uses of EACA are as adjunctive therapy in hemophilia, as therapy for bleeding from fibrinolytic therapy, and as prophylaxis for rebleeding from intracranial aneurysms. Treatment success has also been reported in patients with postsurgical gastrointestinal bleeding and postprostatectomy bleeding and bladder hemorrhage secondary to radiation- and drug-induced cystitis. Adverse effects of the drug include intravascular thrombosis from inhibition of plasminogen activator, hypotension, myopathy, abdominal discomfort, diarrhea, and nasal stuffiness. The drug should not be used in patients with disseminated intravascular coagulation or genitourinary bleeding of the upper tract, eg, kidney and ureters, because of the potential for excessive clotting.

## DRUGS REMOVED FROM MARKET FOR LACK OF EFFICACY OR SAFETY: APROTININ & ACTIVATED PROTEIN C

Aprotinin is a serine protease inhibitor (serpin) that inhibits fibrinolysis by free plasmin and may have other antihemorrhagic effects as well. It also inhibits the plasmin-streptokinase complex in patients who have received that thrombolytic agent. Aprotinin was shown to reduce bleeding—by as much as 50%—from many types of surgery, especially that involving extracorporeal circulation for open-heart procedures and liver transplantation. However, clinical trials and internal data from the manufacturer suggested that use of the drug was associated with an increased risk of renal failure, heart attack, and stroke. A prospective trial was initiated in Canada but halted early because of concerns that use of the drug was associated with increased mortality. The drug was removed from the market in 2007.

**Drotrecogin alfa** is a recombinant form of activated protein C that was initially approved by the FDA in 2001 for reduction of mortality in adults with sepsis associated with acute organ dysfunction and high mortality. The drug was voluntarily withdrawn from the market in 2011 after a follow-up study showed no survival benefit in sepsis.

PREPARATIONS AVAILABLE

Abciximab

ReoPro

Alteplase recombinant [t-PA]

Activase

Aminocaproic acid

Generic, Amicar

Anisindione

Miradon (outside the USA)

Antihemophilic factor [factor VIII, AHF]

Alphanate, Bioclote, Helixate, Hemofil M, Koate-HP, Kogenate, Monoclote, Recombinate, others

Anti-inhibitor coagulant complex

Autoplex T, Feiba VH Immuno

Antithrombin III

ATryn, Thrombate III

Apixaban

Eliquis

Argatroban

Generic

Betrixaban

Bevyxxa

Bivalirudin

Generic, Angiomax

Cilostazol

Generic, Pletal

Clopidogrel

Generic, Plavix

Coagulation factor VIIa recombinant

NovoSeven

Dabigatran

Pradaxa

Dalteparin

Fragmin

Danaparoid

Orgaran

Desirudin

Iprivask

Dipyridamole

Generic, Persantine

Edoxaban

Sayvasa

Emicizumab

Hemlibra

Enoxaparin (low-molecular-weight heparin)

Generic, Lovenox

Eptifibatide

Integrilin

Factor VIIa: see Coagulation factor VIIa recombinant

Factor VIII: see Antihemophilic factor

Factor IX complex, human	AlphaNine SD, Bebulin VH, BeneFix, Konyne 80, Mononine, Profilnine SD, Proplex T, Proplex SX-T
Factor X complex, human Four-factor prothrombin complex concentrate (II, VII, IX, X)	Coagadex Kcentra
Fondaparinux	Generic, Arixtra
Heparin sodium	Generic, Liquaemin
Prasugrel	Effient
Protamine	Generic
Retepase	Retavase
Rivaroxaban	Xarelto
Streptokinase	Streptase
Tenecteplase	TNKase
Ticlopidine	Generic, Ticlid
Tinzaparin	Innohep
Tirofiban	Aggrastat
Tranexamic acid	Generic, Cyklokapron, Lysteda
Urokinase	Abbokinase, Kinlytic
Vitamin K	Generic, various
Vorapaxar	Zontivity
Warfarin	Generic, Coumadin

### CASE STUDY ANSWER

This patient has pulmonary embolism secondary to a deep venous thrombosis. Options for treating this patient include unfractionated **heparin** or low-molecular-weight **heparin** followed by **warfarin**, with INR goal of 2–3; parenteral anticoagulation for 5–7 days followed by **edoxaban** or dabigatran; or **rivaroxaban**, **apixaban**, or **edoxaban** alone without monitoring. As this situation can be considered a provoked event given the history of oral contraceptive use, the recommended duration of therapy would be 3–6 months depending on individual risk factors and preferences. The patient should be counseled to use an alternative form of contraception.

Mary J. Malloy; John P. Kane

### CASE STUDY

#### CASE STUDY

A 52-year-old woman was told at age 19 that her “cholesterol” was elevated. Diet and exercise were advised, but she had gained weight, she did no regular exercise, and her diet was high in fat and simple CHO. At her first visit, her direct LDL was 155 mg/dL, triglycerides 458, and HDL 40. Her Lp(a) was not elevated. BMI 30, A1c 6.4, free T4 normal, and ALT about twice the normal. She had no symptoms of coronary or peripheral vascular disease, but a coronary calcium score was greater than zero. Physical examination was normal aside from her obesity that was mostly abdominal. Specific dietary and exercise advice were given. Her mother has T2D and is overweight. Her father survived an MI at age 47. He had no apparent risk factors other than “high cholesterol.” Both parents take a statin. At the end of the visit, 20 mg of **rosuvastatin** and marine omega 3 fatty acids were prescribed. The patient returned after 3 months. She had lost 6 pounds, was fully compliant with diet, and was gradually increasing her exercise. Her LDL was 97, triglycerides 340, HDL 45, A1c 5.8, and ALT unchanged. How would you manage this patient?

Plasma lipids are transported in complexes called **lipoproteins**. Metabolic disorders that involve elevations in any lipoprotein species are termed **hyperlipoproteinemia** or **hyperlipidemia**. **Hyperlipemia** denotes increased levels of triglycerides.

The major clinical sequelae of hyperlipidemia are acute pancreatitis and atherosclerosis. The former occurs in patients with marked hyperlipemia. Control of triglycerides can prevent recurrent attacks of this life-threatening disease.

Atherosclerosis is the leading cause of death for both genders in the USA and other Western countries. Lipoproteins that contain **apolipoprotein (apo) B-100** convey lipids into the artery wall. These are **low-density (LDL)**, **intermediate-density (IDL)**, **very-low-density (VLDL)**, and **lipoprotein(a) (Lp[a])**. Remnant lipoproteins formed during the catabolism of chylomicrons that contain the B-48 protein (apo B-48) can also enter the artery wall, contributing to atherosclerosis.

Cellular components in atherosclerotic plaques (atheromas) include foam cells, which are transformed macrophages, and smooth muscle cells filled with **cholesteryl esters**. These cellular alterations result from endocytosis of modified lipoproteins via at least four species of **scavenger receptors**. Chemical modifications of lipoproteins by free radicals create ligands for these receptors. The atheroma grows with the accumulation of foam cells, **collagen**, fibrin, and calcium. Whereas such lesions can slowly occlude coronary vessels, clinical symptoms are more frequently precipitated by rupture of unstable atheromatous plaques, leading to activation of platelets and formation of occlusive thrombi.

Although treatment of hyperlipidemia can cause slow physical regression of plaques, the well-documented reduction in acute coronary events that follows vigorous lipid-lowering treatment is attributable chiefly to mitigation of the inflammatory activity of macrophages and is evident within 2–3 months after starting therapy.

**High-density lipoproteins (HDL)** exert several *anti*atherogenic effects. They participate in retrieval of cholesterol from the artery wall and inhibit the oxidation of atherogenic lipoproteins. Low levels of HDL (hypoalphalipoproteinemia) are associated with atherosclerotic disease and thus are a potential target for intervention.

Cigarette smoking is a major risk factor for coronary disease. It is associated with reduced levels of HDL, impairment of cholesterol retrieval, cytotoxic effects on the endothelium, increased oxidation of lipoproteins, and stimulation of thrombogenesis. Diabetes, also a major risk factor, is another source of oxidative stress. Hypertension contributes significantly to atherosclerotic vascular disease.

Normal coronary arteries can dilate in response to ischemia, increasing delivery of oxygen to the myocardium. This process is mediated by nitric oxide, acting on smooth muscle cells of the arterial media. The release of nitric oxide from the vascular endothelium is impaired by atherogenic lipoproteins, thus aggravating ischemia. Reducing levels of atherogenic lipoproteins and inhibiting their oxidation restores endothelial function.

Because atherogenesis, a dynamic process, is multifactorial, therapy should be directed toward all modifiable risk factors. Quantitative angiographic trials have demonstrated net regression of plaques during aggressive lipid-lowering therapy. Primary and secondary prevention trials have shown significant reduction in mortality from new coronary events and in all-cause mortality.

## PATHOPHYSIOLOGY OF HYPERLIPOPROTEINEMIA

### NORMAL LIPOPROTEIN METABOLISM

#### Structure

Lipoproteins have hydrophobic core regions containing cholesteryl esters and triglycerides surrounded by unesterified cholesterol, phospholipids, and apoproteins. Certain lipoproteins contain very high-molecular-weight B proteins that exist in two forms: **B-48**, formed in the intestine and found in chylomicrons and their remnants; and **B-100**, synthesized in liver and found in **VLDL**, **VLDL remnants (IDL)**, **LDL** (formed from VLDL), and **Lp(a) lipoproteins**. HDL consist of at least 20 discrete molecular species containing apolipoprotein A-I (apo A-I). About 100 other proteins are known to be distributed variously among the HDL species, exhibiting antioxidant, antimicrobial, anti-inflammatory, and molecular signaling activities. They also transport microRNAs. Twelve HDL species are recognized in the ovary and six in cerebrospinal fluid.

#### ACRONYMS

<b>Apo</b>	Apolipoprotein
<b>CETP</b>	Cholesteryl ester transfer protein
<b>CK</b>	Creatine kinase
<b>HDL</b>	High-density lipoproteins
<b>HMG-CoA</b>	3-Hydroxy-3-methylglutaryl-coenzyme A
<b>IDL</b>	Intermediate-density lipoproteins
<b>LCAT</b>	Lecithin:cholesterol acyltransferase
<b>LDL</b>	Low-density lipoproteins
<b>Lp(a)</b>	Lipoprotein(a)
<b>LPL</b>	Lipoprotein lipase
<b>PCSK9</b>	Proprotein convertase subtilisin/kexin type 9
<b>PPAR</b>	Peroxisome proliferator-activated receptor
<b>VLDL</b>	Very-low-density lipoproteins

### A. Chylomicrons

Chylomicrons are formed in the intestine and carry **triglycerides** of dietary origin, **unesterified cholesterol**, and **cholesteryl esters**. They transit the thoracic duct to the bloodstream.

Triglycerides are removed from the chylomicrons in extrahepatic tissues through a pathway shared with VLDL that involves hydrolysis by the **lipoprotein lipase (LPL)** system. Decrease in particle diameter occurs as triglycerides are depleted. Surface lipids and small apoproteins are transferred to HDL. The resultant chylomicron remnants are taken up by receptor-mediated endocytosis into hepatocytes.

### B. Very-Low-Density Lipoproteins

VLDL are secreted by liver and export triglycerides to peripheral tissues (Figure 35-1). VLDL triglycerides are hydrolyzed by LPL, yielding free fatty acids for storage in adipose tissue and for oxidation in tissues such as cardiac and skeletal muscle. Depletion of triglycerides produces remnants (IDL), some of which undergo endocytosis directly into hepatocytes. The remainder are converted to LDL by further removal of triglycerides mediated by hepatic lipase. This process explains the “beta shift” phenomenon, the increase of LDL (beta-lipoprotein) in serum as hypertriglyceridemia subsides. Increased levels of LDL can also result from increased secretion of VLDL and from decreased LDL catabolism.

FIGURE 35-1

Metabolism of lipoproteins of hepatic origin. The heavy arrows show the primary pathways. Nascent VLDL are secreted via the Golgi apparatus. They acquire additional apo C lipoproteins and apo E from HDL. Very-low-density lipoproteins (VLDL) are converted to VLDL remnants (IDL) by lipolysis via lipoprotein lipase in the vessels of peripheral tissues. In the process, C apolipoproteins and a portion of the apo E are given back to high-density lipoproteins (HDL). Some of the VLDL remnants are converted to LDL by further loss of triglycerides and loss of apo E. A major pathway for LDL degradation involves the endocytosis of LDL by LDL receptors in the liver and the peripheral tissues, for which apo B-100 is the ligand. Dark color denotes cholesteryl esters; light color denotes triglycerides; the asterisk denotes a functional ligand for LDL receptors; triangles indicate apo E; circles and squares represent C apolipoproteins. FFA, free fatty acid; RER, rough endoplasmic reticulum. (Adapted with permission from Rosenberg RN, Prusiner S, DiMauro S, et al: *The Molecular and Genetic Basis of Neurological Disease*, 2nd ed. Philadelphia, PA: Butterworth-Heinemann; 1997.)

### C. Low-Density Lipoproteins

LDL is synthesized chiefly in hepatocytes and other cells after receptor-mediated endocytosis. Cholesteryl esters from LDL are hydrolyzed, yielding free cholesterol for the synthesis of cell membranes. Cells also obtain cholesterol by synthesis via a pathway involving the formation of mevalonic acid by HMG-CoA reductase. Production of this enzyme and of LDL receptors is transcriptionally regulated by the content of cholesterol in the cell. Normally, about 70% of LDL is removed from plasma by hepatocytes. Even more cholesterol is delivered to the liver via IDL and chylomicrons. Unlike other cells, hepatocytes can eliminate cholesterol by secretion in bile and by conversion to bile acids.

#### D. Lp(a) Lipoprotein

Lp(a) is formed from LDL and the (a) protein, linked by a disulfide bridge. The (a) protein is highly homologous with plasminogen but is not activated by tissue plasminogen activator. It occurs in a number of isoforms of different molecular weights. Levels of Lp(a) vary from nil to over 2000 nM/L and are determined chiefly by genetic factors. Lp(a) is found in atherosclerotic plaques and also contributes to coronary disease by inhibiting thrombolysis. It is associated with aortic stenosis. Levels are elevated in certain inflammatory states. The risk of coronary disease is strongly related to the level of Lp(a) and is partially mitigated by [aspirin](#). A common variant (14399M) in the coding region is associated with elevated levels.

#### E. High-Density Lipoproteins

The apoproteins of HDL are secreted largely by the liver and intestine. Much of the lipid comes from the surface monolayers of chylomicrons and VLDL during lipolysis. HDL also acquires cholesterol from peripheral tissues, protecting the cholesterol homeostasis of cells. Free cholesterol is chiefly exported from the cell membrane by a transporter, ABCA1, acquired by a small particle termed prebeta-1 HDL, and then esterified by lecithin:cholesterol acyltransferase (LCAT), leading to the formation of larger HDL species. Cholesterol is also exported by the ABCG1 transporter and the scavenger receptor, SR-BI, to large HDL particles. The cholesteryl esters are transferred to VLDL, IDL, LDL, and chylomicron remnants with the aid of cholesteryl ester transfer protein (CETP). Much of the cholesteryl ester thus transferred is ultimately delivered to the liver by endocytosis of the acceptor lipoproteins. HDL can also deliver cholesteryl esters directly to the liver via SR-BI that does not involve endocytosis of the lipoproteins. At the population level, HDL cholesterol (HDL-C) levels relate inversely to atherosclerosis risk. Among individuals, the capacity to accept exported cholesterol can vary widely at identical levels of HDL-C. The ability of peripheral tissues to export cholesterol via the transporter mechanism and the acceptor capacity of HDL are emerging as major determinants of coronary atherosclerosis.

## LIPOPROTEIN DISORDERS

Lipoprotein disorders are detected by measuring lipids in serum after a 10-hour fast. Risk of heart disease increases with concentrations of the atherogenic lipoproteins, is inversely related to levels of HDL-C, and is modified by other risk factors. Evidence from clinical trials suggests that an LDL cholesterol (LDL-C) of about 50 mg/dL is optimal for patients with coronary or peripheral arterial disease. Ideally, triglycerides should be below 120 mg/dL. Although LDL-C is still the primary target of treatment, reducing the levels of VLDL and IDL also is important. The lipoproteins involved in each disorder are shown in [Table 35-1](#). Diagnosis of a primary disorder usually requires further clinical and genetic data as well as ruling out secondary hyperlipidemias ([Table 35-2](#)). Because measurement of plasma triglycerides commonly focuses on constituent glycerol, patients with a rare condition, glycerol kinase deficiency, can be erroneously identified as having hypertriglyceridemia. This can be excluded by ultracentrifugation.

The primary hyperlipoproteinemias and their treatment.

Disorder	Manifestations	Diet + Single Drug	Drug Combination
Primary chylomicronemia (familial lipoprotein lipase, cofactor deficiency; others)	Chylomicrons, VLDL increased	Dietary management; omega-3 fatty acids, fibrate, or <b>niacin</b> (Apo C-III antisense)	Fibrate plus <b>niacin</b>
Familial hypertriglyceridemia	VLDL increased; chylomicrons may be increased	Dietary management; omega-3 fatty acids, fibrate, <b>niacin</b> , statin	Two or three of the individual drugs
Familial combined hyperlipoproteinemia	VLDL predominantly increased	Omega-3 fatty acids, statin, fibrate	Statin plus omega-3 fatty acids or Fibrate
	LDL predominantly increased	Statin or <b>ezetimibe</b>	Statin plus <b>ezetimibe</b>
	VLDL, LDL increased	Statin, omega-3 fatty acids, fibrate	Statin plus omega-3 fatty acids or Fibrate
Familial dysbetalipoproteinemia	VLDL remnants, chylomicron remnants increased	Statin, fibrate	Statin plus fibrate <sup>1</sup>
Familial hypercholesterolemia			
Heterozygous	LDL increased	Statin, <b>ezetimibe</b> , resin, or PCSK9 MAB	Two or three of the individual drugs
Homozygous	LDL increased	Statin, <b>ezetimibe</b> , <b>lomitapide</b> , PCSK9 MAB, evinacumab	Combinations of several single agents
Familial ligand-defective apo B-100	LDL increased	Statin, PCSK9 MAB, <b>ezetimibe</b>	Two or three of the single agents
Lp(a) hyperlipoproteinemia	Lp(a) increased	<b>Niacin</b> , PCSK9 MAB	

<sup>1</sup>Select pharmacologically compatible statin or bempedoic acid (see text).

## Secondary causes of hyperlipoproteinemia.

Hypertriglyceridemia	Hypercholesterolemia
Diabetes mellitus	Hypothyroidism
Alcohol ingestion	Early nephrosis
Severe nephrosis	Resolving lipemia
Estrogens	Immunoglobulin-lipoprotein complex disorders
Uremia	Anorexia nervosa
HIV infection	Cholestasis
Myxedema	Hypopituitarism
Glycogen storage disease	Corticosteroid excess
Hypopituitarism	Androgen overdose
Acromegaly	
Immunoglobulin-lipoprotein complex disorders	
Lipodystrophy	
Protease inhibitors, <a href="#">tacrolimus</a> , <a href="#">sirolimus</a> , other drugs	

Phenotypes of abnormal lipoprotein distribution are described in this section. Drugs mentioned for use in these conditions are described in the following section on basic and clinical pharmacology.

## THE PRIMARY HYPERTRIGLYCERIDEMIAS

Hypertriglyceridemia is associated with increased risk of coronary disease. Chylomicrons, VLDL, and IDL are found in atherosclerotic plaques. These patients tend to have cholesterol-rich VLDL of small particle diameter and small, dense LDL. Hypertriglyceridemic patients with coronary disease or risk equivalents should be treated aggressively. Patients with triglycerides above 700 mg/dL should be treated to prevent acute pancreatitis because the LPL clearance mechanism is saturated at about this level.

Hypertriglyceridemia is an important component of the **metabolic syndrome**, which also includes [insulin](#) resistance, hypertension, and abdominal obesity. Reduced levels of HDL-C are usually observed due to transfer of cholesteryl esters to triglyceride-rich lipoproteins. Hyperuricemia is frequently present. [Insulin](#) resistance occurs in most patients. Management frequently requires the use of [metformin](#), another antidiabetic agent, or both (see [Chapter 41](#)). The severity of hypertriglyceridemia of any cause is increased in the presence of the metabolic syndrome, type 2 diabetes, or the ingestion of [alcohol](#).

### Primary Chylomicronemia (Familial Chylomicronemia Syndrome)

Chylomicrons are not present in the serum of normal individuals who have fasted 10 hours. The recessive traits of genetically compromised LPL, its

cofactor Apo C-II, and the LMF1, CREB3L3, or GPIIIBP1 proteins are usually associated with severe lipemia (1000 mg/dL of triglycerides or higher when the patient is consuming a typical American diet). Mutations in Apo A-V can usually affect lipolysis in both the homozygous and heterozygous states. Familial chylomicronemia might not be diagnosed until an attack of acute pancreatitis occurs or a woman becomes pregnant. Patients may have eruptive xanthomas, hepatosplenomegaly, hypersplenism, lipemia retinalis, and lipid-laden foam cells in bone marrow, liver, and spleen. The lipemia is increased by **estrogens** because they stimulate VLDL production. Although these patients have a predominant chylomicronemia, they may also have elevated VLDL, presenting with a pattern called *mixed lipemia*. Deficiency of lipolytic activity can be diagnosed after intravenous injection of **heparin**. A presumptive diagnosis is made by demonstrating a pronounced decrease in triglycerides 72 hours after elimination of dietary fat. Marked restriction of dietary fat, weight control, exercise, and abstention from **alcohol** are the basis of effective long-term treatment of chylomicronemia and all hypertriglyceridemias. A fibrate, **niacin**, or marine omega-3 fatty acids may be of some benefit if VLDL levels are increased. Apo C-III antisense, available in Europe as volanesorsen, is a potential adjunct to therapy. Plasmapheresis may contribute to the rapid reduction of triglycerides in the setting of acute pancreatitis.

### Familial Hypertriglyceridemia

The primary hypertriglyceridemias probably reflect a variety of genetic determinants. Variants in a large number of genes have been implicated as causative in patients with hypertriglyceridemia, for which a polygenic risk score has been developed. Many patients have central obesity with **insulin** resistance. Impaired removal of triglyceride-rich lipoproteins with overproduction of VLDL can result in mixed lipemia. Eruptive xanthomas, lipemia retinalis, epigastric pain, and pancreatitis are variably present depending on the severity of the lipemia. Treatment is primarily dietary. Marine omega-3 fatty acids, especially EPA only, may be helpful for patients with coronary artery disease or who are at high risk. Some patients require treatment with a statin if LDL is elevated, and a fibrate may be needed if triglycerides are consistently greater than 500 mg/dL. If **insulin** resistance is not present, **niacin** may be helpful. **Metformin** is useful in patients with **insulin** resistance.

### Familial Combined Hyperlipoproteinemia (FCH)

The genetic basis of FCH is undetermined but probably involves multiple loci. In this very common disorder, which is associated with an increased incidence of coronary disease, individuals may have elevated levels of VLDL, LDL, or both, and the pattern may change with time. An elevated level of Apo B-100 is a constant feature. FCH involves an approximate doubling in VLDL secretion and appears to be transmitted as a dominant trait. Triglycerides can be increased by factors noted above. Elevations of cholesterol and triglycerides are generally moderate. Diet alone does not normalize lipid levels. A statin alone, or in combination with **niacin** or fenofibrate, is often required to treat these patients. When fenofibrate is combined with a statin, either **pravastatin** or **rosuvastatin** is recommended because neither is metabolized via CYP3A4. Marine omega-3 fatty acids may be useful.

### Familial Dysbetalipoproteinemia

In this disorder, remnants of chylomicrons and VLDL accumulate and levels of LDL are decreased. Because remnants are rich in cholesteryl esters, the level of total cholesterol may be as high as that of triglycerides. Diagnosis is confirmed by the absence of the  $\epsilon 3$  and  $\epsilon 4$  alleles of apo E, the  $\epsilon 2/\epsilon 2$  genotype. Other rare apo E isoforms that lack receptor ligand properties can also be associated with this disorder. Patients often develop tuberous or tuberoeruptive xanthomas, or characteristic planar xanthomas of the palmar creases. They tend to be obese, and some have impaired glucose tolerance. These factors, as well as hypothyroidism, can increase the lipemia. Coronary and peripheral atherosclerosis occurs with increased frequency. Weight loss, together with decreased fat, cholesterol, and **alcohol** consumption, may be sufficient. Statins are often effective because they increase hepatic LDL receptors that participate in remnant removal. A fibrate is sometimes needed to control the condition.

## THE PRIMARY HYPERCHOLESTEROLEMIAS

### LDL Receptor-Deficient Familial Hypercholesterolemia (FH)

This is a common autosomal dominant trait. Although levels of LDL tend to increase throughout childhood, the diagnosis can often be made on the basis of elevated umbilical cord blood cholesterol. In most heterozygotes, cholesterol levels range from 260 to 400 mg/dL. Triglycerides are usually normal. Tendon xanthomas are often present. Arcus corneae and xanthelasma may also be present. Coronary disease tends to occur prematurely. In homozygous FH, which can lead to coronary disease in childhood, levels of cholesterol can range from 500 to over 1000 mg/dL. Early tuberous, tendinous, and planar xanthomas occur, and aortic stenosis is common.

www.konkur.in  
 Individuals have combined heterozygosity for alleles producing nonfunctional and kinetically impaired LDL receptors. In heterozygous patients, LDL can be normalized with reductase inhibitors or combined drug regimens (Figure 35-2). Homozygotes and those with combined heterozygosity whose receptors retain even minimal function may partially respond to combinations of niacin, ezetimibe, and reductase inhibitors. Lomitapide, a small molecule inhibitor of microsomal triglyceride transfer protein (MTP), and monoclonal antibodies directed at PCSK9 also have some effectiveness. Evinacumab, a monoclonal antibody against ANGPTL3, is very effective because its mechanism of action does not depend on LDL receptor function. LDL apheresis is a definitive treatment in medication-refractory patients.

FIGURE 35-2

Sites of action of HMG-CoA reductase inhibitors, PCSK9 MAB, niacin, ezetimibe, and resins used in treating hyperlipidemias. Low-density lipoprotein (LDL) receptors are increased by treatment with resins and HMG-CoA reductase inhibitors. PCSK9 MAB decreases destruction of LDL receptors by PCSK9. VLDL, very-low-density lipoproteins; R, LDL receptor; L, lysosome.

#### Familial Ligand-Defective Apolipoprotein B-100

Defects in the domain of apo B-100 that binds to the LDL receptor impair the endocytosis of LDL, leading to hypercholesterolemia of moderate severity. Tendon xanthomas may occur. Response to reductase inhibitors is variable. Upregulation of LDL receptors in liver does not increase uptake of ligand-defective LDL particles. Fibrates or niacin may have beneficial effects by reducing VLDL production.

#### PCSK9 Gain of Function

The receptor chaperone PCSK9 normally conducts the receptor to the lysosome for degradation (see Figure 35-2). Gain-of-function mutations in PCSK9 are associated with elevated levels of LDL-C and are managed with a PCSK9 antibody.

The RAP1 gene product facilitates the uptake in hepatocytes of the LDL receptor and its associated LDL particle, enhancing the removal of LDL from plasma. Rare defective variants lead to increased LDL, clinically resembling homozygous FH. Statins and bile acid sequestrants may be effective. A similar mechanism for an Apolipoprotein E variant (Leu 167 del) has been described.

#### CYP7a Deficiency

Decreased catabolism of cholesterol to bile acids and accumulation of cholesterol in hepatocytes result from loss of function mutations in CYP7a. LDL in plasma is increased with downregulation of LDL receptors. LDL is moderately elevated in heterozygous patients. Homozygous patients have higher LDL levels, sometimes elevated triglycerides, early coronary disease, increased risk of gallstones, and are resistant to statins. The addition of [niacin](#) to a statin results in a significant reduction in lipid levels.

#### Familial Combined Hyperlipoproteinemia (FCH)

As described above, some persons with FCH have only an elevation in LDL necessitating treatment with a statin.

#### Lp(a) Hyperlipoproteinemia

This genetic disorder, which is associated with increased atherogenesis and arterial thrombus formation, is determined chiefly by alleles that dictate increased production of the (a) protein moiety. Lp(a) can be secondarily elevated in patients with severe nephrosis and certain other inflammatory states. [Niacin](#) reduces levels of Lp(a) in many patients, and an (a) antisense will be available soon. Reduction of levels of LDL-C below 100 mg/dL decreases the risk of atherosclerosis attributable to Lp(a), and the administration of low-dose [aspirin](#) may reduce the risk of thrombus. PCSK9 MABs also reduce levels of Lp(a) by about 25%.

#### Cholesteryl Ester Storage Disease

Individuals lacking activity of lysosomal acid lipase (LAL) accumulate cholesteryl esters in liver and macrophages leading to hepatomegaly with subsequent fibrosis, and atherosclerosis. They have elevated levels of LDL-C, low levels of HDL-C, and often modest hypertriglyceridemia. Rarely, a fatal totally ablative form, Wolman disease, occurs in infancy. A recombinant replacement enzyme therapy, **sebelipase alfa** given intravenously weekly or every other week, effectively restores the hydrolysis of cholesteryl esters in liver, normalizing plasma lipoprotein levels.

#### Phytosterolemia

The ABCG5 and ABCG8 half-transporters act together in enterocytes and hepatocytes to export phytosterols into the intestinal lumen and bile, respectively. Homozygous or combined heterozygous ablative mutations in either transporter result in elevated levels of LDL enriched in phytosterols, tendon and tuberous xanthomas, and accelerated atherosclerosis. Many techniques for quantitation of cholesterol include phytosterols and can misdiagnose this disorder. [Ezetimibe](#) is the specific therapeutic.

#### HDL DEFICIENCY

Rare genetic disorders, including Tangier disease and LCAT (lecithin:cholesterol acyltransferase) deficiency, are associated with extremely low levels of HDL. Familial hypoalphalipoproteinemia is a more common disorder with levels of HDL usually below 35 mg/dL in men and 45 mg/dL in women, most commonly attributable to mutations in the *ABCA1* gene. These patients tend to have premature atherosclerosis, and the low HDL may be the only identified risk factor. Paradoxically, HDL levels above 90 mg/dL are associated with increased atherosclerotic vascular disease in population studies. This risk relationship is associated in some cases with variants in the *SCARB-1* gene.

Management of HDL deficiency includes special attention to avoidance or treatment of other risk factors. [Niacin](#) increases HDL in many of these patients but the effect on clinical outcome is unknown. Reductase inhibitors and fibric acid derivatives exert lesser effects. Aggressive reduction of LDL and VLDL is indicated.

In the presence of hypertriglyceridemia, HDL is low because of exchange of cholesteryl esters from HDL into triglyceride-rich lipoproteins. Treatment of hypertriglyceridemia increases HDL.

Before primary disorders can be diagnosed, secondary causes of the lipid phenotype must be considered. The more common conditions are summarized in [Table 35–2](#). The lipoprotein abnormality usually resolves if the underlying disorder can be treated successfully. These secondary entities can also amplify a primary genetic disorder.

## DIETARY MANAGEMENT OF HYPERLIPOPROTEINEMIA

Dietary measures are initiated first, unless the patient has evident coronary or peripheral vascular disease, and may obviate the need for drugs. Patients with genetic hypercholesterolemias always require drug therapy in addition to diet. Cholesterol, and saturated and *trans*-fats are the principal factors that increase LDL.

Total fat, [sucrose](#), and, especially, fructose increase VLDL. [Alcohol](#) can cause significant hypertriglyceridemia by increasing hepatic secretion of VLDL. Synthesis and secretion of VLDL are increased by excess calories. During weight loss, LDL and VLDL levels may be much lower than can be maintained during neutral caloric balance. The conclusion that diet suffices for management can be made only after weight has stabilized for at least 1 month.

General recommendations include limiting total calories from fat to 20–25% of daily intake, saturated fats to less than 7%, and cholesterol to less than 200 mg/d. Reductions in serum cholesterol range from 10% to 20% on this regimen. Complex carbohydrates and fiber are recommended, and *cis*-monounsaturated fats should predominate. Weight reduction, caloric restriction, and avoidance of [alcohol](#) are especially important for patients with elevated triglycerides.

The effect of dietary fats on hypertriglyceridemia is dependent on the disposition of double bonds in the fatty acids. Omega-3 fatty acids found in fish oils activate peroxisome proliferator-activated receptor- $\alpha$  (PPAR- $\alpha$ ) and can induce profound reduction of triglycerides in some patients. They also have anti-inflammatory and antithrombotic activities. Omega-3 fatty acids are available as a prescription medication containing both docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) from marine sources (Lovaza). An EPA-only prescription preparation (icosapent ethyl, Vascepa) is also available and has been shown to reduce elevated triglycerides and remnant lipoproteins, and cardiovascular events. It reduces levels of apolipoprotein C-III, which is an inhibitor of lipoprotein lipase.

Patients with primary chylomicronemia and some with mixed lipemia must consume a diet severely restricted in total fat (10–20 g/d, of which 5 g should be vegetable oils rich in essential fatty acids), and fat-soluble [vitamins](#) should be given.

Homocysteine, which initiates proatherogenic changes in endothelium, can be reduced in many patients by restriction of total protein intake to the amount required for amino acid replacement. Supplementation with folic acid plus other B [vitamins](#), and administration of [betaine](#), a methyl donor, is indicated in severe homocysteinemia. Reduction of high levels of homocysteine is especially important in individuals with elevated levels of Lp(a). It liberates the (a) protein from ApoB-100, increasing thrombosis. Consumption of red meat should be minimized to reduce the production by the intestinal biome of trimethyl amine oxide, a compound injurious to arteries.

## BASIC & CLINICAL PHARMACOLOGY OF DRUGS USED IN HYPERLIPIDEMIA

The decision to use drug therapy for hyperlipidemia is based on the specific metabolic defect and its potential for causing atherosclerosis or pancreatitis. Suggested regimens for the principal lipoprotein disorders are presented in [Table 35–1](#). Experience to date suggests that the available hypolipidemic drugs can be used in various combinations with appropriate safety monitoring. Diet should be continued to achieve the full potential of the drug regimen. These drugs generally should be avoided in pregnant and lactating women and those likely to become pregnant. All drugs that alter plasma lipoprotein concentrations potentially require adjustment of doses of anticoagulants. Children with heterozygous FH may be treated with a resin or reductase inhibitor, the latter usually after about 8 years of age when myelination of the central nervous system is essentially complete. The decision to treat a child should be based on levels of LDL and other atherogenic lipoproteins, other risk factors including the family history, and the child's age. Children with homozygous FH or chylomicronemia syndrome must be treated at the time of diagnosis.

### REDUCTASE INHIBITORS: “STATINS”

[www.konkur.in](http://www.konkur.in)  
**fluvastatin, pravastatin, simvastatin, rosuvastatin, and pitavastatin** belong to this class. Their principal effect is the reduction of LDL. Other effects include decreased oxidative stress and vascular inflammation with increased stability of atherosclerotic lesions. Emerging effects include inhibition of certain viruses, mitigation of NAFLD and irritable bowel disease, and retardation of the replication of cancer cells in hepatocellular carcinoma. It has become standard practice to initiate high-dose statin therapy immediately after acute coronary syndromes, regardless of lipid levels.

FIGURE 35-3

Inhibition of HMG-CoA reductase. **Top:** The HMG-CoA intermediate that is the immediate precursor of mevalonate, a critical compound in the synthesis of cholesterol. **Bottom:** The structure of **lovastatin** and its active form, showing the similarity to the normal HMG-CoA intermediate (shaded areas).

## Chemistry & Pharmacokinetics

**Lovastatin** and **simvastatin** are inactive lactone prodrugs that are hydrolyzed in the gastrointestinal tract to the active  $\beta$ -hydroxyl derivatives, whereas **pravastatin** has an open, active lactone ring. **Atorvastatin**, **fluvastatin**, and **rosuvastatin** are fluorine-containing congeners that are active as given. Absorption of the ingested doses of the reductase inhibitors varies from 40% to 75% with the exception of **fluvastatin**, which is almost completely absorbed. All have high first-pass extraction by the liver. Most of the absorbed dose is excreted in the bile; 5–20% is excreted in the urine. Plasma half-lives of these drugs range from 1 to 3 hours except for **atorvastatin** (14 hours), **pitavastatin** (12 hours), and **rosuvastatin** (19 hours).

## Mechanism of Action

HMG-CoA reductase mediates the first committed step in sterol biosynthesis. The active forms of the reductase inhibitors are structural analogs of the HMG-CoA intermediate (see [Figure 35-3](#)) that is formed by HMG-CoA reductase in the synthesis of mevalonate. These analogs cause partial inhibition of the enzyme and thus may impair the synthesis of isoprenoids such as ubiquinone and dolichol, and the prenylation of proteins. It is not known whether this has biologic significance. However, statins clearly induce an increase in high-affinity LDL receptors. This effect increases both the fractional catabolic rate of LDL and the liver's extraction of LDL precursors (VLDL remnants) from the blood, thus reducing LDL (see [Figure 35-2](#)). Because of marked first-pass hepatic extraction, the major effect is on the liver. Preferential activity in liver of some congeners appears to be attributable to tissue-specific differences in uptake. Modest decreases in plasma triglycerides and small increases in HDL also occur.

Clinical trials involving many of the statins have demonstrated significant reduction of new coronary events and atherothrombotic stroke. Mechanisms other than reduction of lipoprotein levels also appear to be involved. The availability of isoprenyl groups from the HMG-CoA pathway for prenylation of proteins is reduced by statins, resulting in reduced prenylation of Rho and Rab proteins. Prenylated Rho activates Rho kinase, which mediates a number of mechanisms in vascular biology. The observation that reduction in new coronary events occurs more rapidly than changes in morphology

of arterial plaques suggests that these pleiotropic effects may be important. Likewise, decreased prenylation of Rab reduces the accumulation of A $\beta$  protein in neurons, possibly mitigating the manifestations of Alzheimer disease.

### Therapeutic Uses & Dosage

Statins are useful alone or in combinations with [ezetimibe](#), PCSK9 MABs, resins, [niacin](#), or bempedoic acid in reducing levels of LDL. If VLDL levels are also elevated, a fibrate may be useful.

Because cholesterol synthesis occurs predominantly at night, reductase inhibitors—except [atorvastatin](#), [rosuvastatin](#), and [pitavastatin](#)—should be given in the evening. Absorption generally (with the exception of [pravastatin](#) and [pitavastatin](#)) is enhanced by food. Daily doses of [lovastatin](#) vary from 10 to 80 mg. [Pravastatin](#) is nearly as potent on a mass basis as [lovastatin](#) with a maximum recommended daily dose of 80 mg. [Simvastatin](#) is twice as potent and is given in doses of 5–80 mg daily. Because of increased risk of myopathy with the 80-mg/d dose, the US Food and Drug Administration (FDA) issued labeling for scaled dosing of [simvastatin](#) and combined [ezetimibe/simvastatin](#). [Pitavastatin](#) is given in doses of 1–4 mg daily. [Fluvastatin](#) appears to be about half as potent as [lovastatin](#) on a mass basis and is given in doses of 10–80 mg daily. [Atorvastatin](#) is given in doses of 10–80 mg/d, and [rosuvastatin](#) at 5–40 mg/d. The dose-response curves of [pravastatin](#) and especially of [fluvastatin](#) tend to level off in the upper part of the dosage range in patients with moderate to severe hypercholesterolemia. Those of other statins are somewhat more linear. Starting doses should be lower in patients of North Asian ancestry.

### Toxicity

Elevations of serum aminotransferase (AST/ALT) activity (up to three times normal) occur in some patients. This is often intermittent and usually not associated with other evidence of hepatic toxicity. Therapy may be continued in such patients in the absence of symptoms if AST and ALT are monitored and stable. In some patients, who may have underlying liver disease or a history of [alcohol](#) abuse, levels may exceed three times normal. This finding portends more severe hepatic toxicity. These patients may present with malaise, anorexia, and precipitous decreases in LDL. Medication should be discontinued immediately, and also in asymptomatic patients whose AST/ALT activity is persistently elevated to more than three times normal. These agents should be used with caution and in reduced dosage in patients with hepatic parenchymal disease. Severe hepatic disease may preclude their use. In general, AST and ALT activity should be measured at baseline, at 1–2 months, and then every 12 months (if stable). Monitoring of liver enzymes should be more frequent if the patient is taking other drugs that have potential interactions with the statin. Excess intake of [alcohol](#) tends to increase hepatotoxic effects of statins.

Fasting plasma glucose levels tend to increase minimally with statin treatment in some patients. A relatively small number develop [insulin](#) resistance of varying degree that responds to conventional treatment. Long-term studies have shown a small but significant increase in the incidence of type 2 diabetes in statin-treated patients, many of whom had findings of prediabetes before treatment.

Minor increases in creatine kinase (CK) activity in plasma are observed in some patients receiving statins, frequently associated with heavy physical activity. Rarely, patients may have marked elevations in CK activity, often accompanied by generalized discomfort or weakness in skeletal muscles. If the drug is not discontinued, rhabdomyolysis with myoglobinuria can occur, leading to renal injury. Myopathy may occur with monotherapy, but there is an increased incidence in patients also receiving certain other drugs. Genetic variation in an anion transporter (OATP1B1 protein) is associated with severe myopathy and rhabdomyolysis induced by statins. Variants in the gene (*SLCO1B1*) coding for this protein, which is involved in metabolism of statins can be assessed to identify some individuals intolerant of the drug (see [Chapter 5](#)).

The catabolism of [lovastatin](#), [simvastatin](#), and [atorvastatin](#) proceeds chiefly through CYP3A4, whereas that of [fluvastatin](#) and [rosuvastatin](#), and to a lesser extent [pitavastatin](#), is mediated by CYP2C9. [Pravastatin](#) is catabolized through other pathways, including sulfation. The 3A4-dependent reductase inhibitors tend to accumulate in plasma in the presence of drugs that inhibit or compete for the 3A4 cytochrome. These include the macrolide antibiotics, [cyclosporine](#), [ketoconazole](#) and its congeners, some HIV protease inhibitors, [tacrolimus](#), [nefazodone](#), fibrates, [paroxetine](#), [venlafaxine](#), and others (see [Chapters 4](#) and [67](#)). Concomitant use of reductase inhibitors with [amiodarone](#) or [verapamil](#) also increases risk of myopathy.

Drugs such as [phenytoin](#), [griseofulvin](#), barbiturates, [rifampin](#), and thiazolidinediones increase expression of CYP3A4 and can reduce the plasma concentrations of the 3A4-dependent reductase inhibitors. Inhibitors of CYP2C9 such as [ketoconazole](#) and its congeners, [metronidazole](#), [sulfonpyrazone](#), [amiodarone](#), and [cimetidine](#) may increase plasma levels of [fluvastatin](#) and [rosuvastatin](#). [Pravastatin](#) and [rosuvastatin](#) appear to be the statins of choice for use with [verapamil](#), the [ketoconazole](#) group of antifungal agents, macrolides, and [cyclosporine](#). Doses should be kept low and the

patients monitored frequently. Plasma levels of **lovastatin**, **simvastatin**, and **atorvastatin** may be elevated in patients ingesting large amounts of grapefruit juice daily.

All statins undergo glycosylation, thus creating a potential interaction with **gemfibrozil**. Fenofibrate is preferred in combination with a statin.

Creatine kinase activity should be measured in patients receiving potentially interacting drug combinations. If muscle pain or weakness appears, CK should be measured immediately and the drug discontinued if activity is elevated significantly over baseline. The myopathy usually reverses promptly upon cessation of therapy. If the association is unclear, the patient can be rechallenged under close surveillance. Myopathy in the absence of elevated CK can occur. Rarely, hypersensitivity syndromes have been reported that include a lupus-like disorder, dermatomyositis, peripheral neuropathy, and autoimmune myopathy. The latter presents as severe pain and weakness in proximal muscles that does not remit when the statin is discontinued. It is HMG-CoA reductase antibody positive and requires immunosuppressive treatment.

Statins may be temporarily discontinued in the event of serious illness, trauma, or major surgery to minimize the potential for liver and muscle toxicity.

Use of **red yeast rice**, a fermentation product that contains statin activity, is not recommended because the statin content is variable and some preparations contain a nephrotoxin, citrinin.

## FIBRIC ACID DERIVATIVES (FIBRATES)

**Gemfibrozil** and **fenofibrate** decrease levels of VLDL and, in some patients, LDL as well. Another fibrate, **bezafibrate**, is not available in the USA.

### Chemistry & Pharmacokinetics

**Gemfibrozil** is absorbed quantitatively from the intestine and is tightly bound to plasma proteins. It undergoes enterohepatic circulation and readily passes the placenta. The plasma half-life is 1.5 hours. Seventy percent is eliminated through the kidneys, mostly unmodified. The liver modifies some of the drug to hydroxymethyl, carboxyl, or quinol derivatives. Fenofibrate is an isopropyl ester that is hydrolyzed completely in the intestine. Its plasma half-life is 20 hours. Sixty percent is excreted in the urine as the glucuronide, and about 25% in feces.

**Gemfibrozil**

**Fenofibrate**

### Mechanism of Action

Fibrates function primarily as ligands for the nuclear transcription receptor PPAR- $\alpha$ . They transcriptionally up-regulate LPL, apo A-I, and apo A-II, and they down-regulate apo C-III, an inhibitor of lipolysis. A major effect is an increase in oxidation of fatty acids in liver and striated muscle (Figure 35-4). They increase lipolysis of lipoprotein triglyceride via LPL. Intracellular lipolysis in adipose tissue is decreased. Levels of VLDL decrease, in part as a result of decreased secretion by the liver. Only modest reductions of LDL occur in most patients. In others, especially those with combined hyperlipidemia, LDL often increases as triglycerides are reduced. HDL cholesterol increases moderately. Part of this apparent increase is a consequence of lower triglyceride in plasma, resulting in reduction in the exchange of triglycerides into HDL in place of cholesteryl esters.

Hepatic and peripheral effects of fibrates. These effects are mediated by activation of peroxisome proliferator-activated receptor- $\alpha$ , which decreases the secretion of VLDL and increases its peripheral metabolism. LPL, lipoprotein lipase; VLDL, very-low-density lipoproteins.

Source: Todd W. Vanderah:  
Basic & Clinical Pharmacology, Sixteenth Edition  
Copyright © McGraw Hill. All rights reserved.

### Therapeutic Uses & Dosage

Fibrates are useful to prevent pancreatitis in severe hypertriglyceridemias in which VLDL predominates, and in dysbetalipoproteinemia. They also may be of benefit in treating the hypertriglyceridemia that results from treatment with antiviral protease inhibitors. The usual dose of **gemfibrozil** is 600 mg orally once or twice daily. The dosage of fenofibrate as Tricor is one to three 48-mg tablets (or a single 145-mg tablet) daily. Dosages of other preparations vary. Absorption of **gemfibrozil** is improved when the drug is taken with food. Although useful to reduce triglycerides, the data on their ability to mitigate cardiovascular disease are varied, but increasingly positive in the presence of T2D and the metabolic syndrome. Fibrates can be used in combination with other lipid-lowering agents. Fenofibrate is the fibrate of choice for use in combination with a statin.

### Toxicity

Rare adverse effects of fibrates include rashes, gastrointestinal symptoms, myopathy, arrhythmias, hypokalemia, and high blood levels of aminotransferases or alkaline phosphatase. A few patients show decreases in white blood count or hematocrit. Both fibrates may potentiate the action of anticoagulants, and their doses should be adjusted. Rhabdomyolysis has occurred rarely. Fibrates should be avoided in patients with hepatic or renal dysfunction. However, they may have therapeutic value in patients with non-alcoholic fatty liver disease. There appears to be a modest increase in the risk of cholesterol gallstones, reflecting an increase in the cholesterol content of bile. Therefore, fibrates should be used with caution in patients with biliary tract disease or in those at higher risk such as women, obese patients, and Native Americans.

### NIACIN (NICOTINIC ACID)

Historically, combination therapy including **niacin** has been associated with regression of atherosclerotic coronary lesions in three angiographic trials and with extension of lifespan in one large trial in which patients received **niacin** alone. Response to **niacin** is individual and highly variable.

In its role as a vitamin, **niacin** (vitamin B<sub>3</sub>) is converted in the body to the amide, which is incorporated into **niacinamide** adenine dinucleotide (NAD), which in turn has a critical role in energy metabolism. In pharmacologic doses, it has important effects on lipid metabolism, including mitochondrial activity. It is excreted in the urine unmodified and as several metabolites. One, *N*-methyl nicotinamide, creates a draft on methyl groups that can occasionally result in erythrocyte macrocytosis, similar to deficiency of folate or vitamin B<sub>12</sub>.

#### Mechanism of Action

**Niacin** inhibits VLDL secretion, in turn decreasing production of LDL (see [Figure 35–2](#)). It increases clearance of VLDL via the LPL pathway. Excretion of neutral sterols is increased acutely as cholesterol is mobilized from tissue pools. The catabolic rate for HDL is decreased. Fibrinogen levels are reduced, and levels of tissue plasminogen activator appear to increase. **Niacin** inhibits the intracellular lipase of adipose tissue via receptor-mediated signaling, possibly reducing VLDL production by decreasing the flux of free fatty acids to the liver.

#### Therapeutic Uses & Dosage

In combination with a resin and/or reductase inhibitor, **niacin** can contribute to further reduction of LDL cholesterol. These combinations are also indicated in some cases of nephrosis. In severe mixed lipemia, **niacin** often produces marked reduction of triglycerides, an effect enhanced by marine omega-3 fatty acids. It is useful in some patients with combined hyperlipidemia and in those with dysbetalipoproteinemia. **Niacin** is clearly the most effective agent for increasing HDL and reduces Lp(a) in many patients.

For treatment of heterozygous FH, 2–4 g of **niacin** daily is usually required; more than this should not be given. For other types of hypercholesterolemia and for hypertriglyceridemia, 1.5–3.5 g daily is often sufficient. Crystalline **niacin** should be given in divided doses with meals, starting with 100 mg two or three times daily and increasing gradually. Several extended-release **niacin** preparations are available.

#### Toxicity

Most persons experience a harmless cutaneous vasodilation and sensation of warmth after each dose when **niacin** is started or the dose increased. Taking 81–325 mg of **aspirin** 30 minutes beforehand blunts this prostaglandin-mediated effect. Tachyphylaxis to flushing usually occurs within a few days at doses of 1.5–3 g daily. Patients should be warned to expect the flush and understand that it is a harmless side effect. Pruritus, rashes, dry skin or mucous membranes, and acanthosis nigricans have been reported. The latter requires the discontinuance of **niacin** because of its association with **insulin** resistance. Some patients experience nausea and abdominal discomfort. Many can continue the drug at reduced dosage, with antacids not containing aluminum. **Niacin** should be avoided in patients with significant peptic disease.

Reversible elevations in aminotransferases up to twice normal may occur, usually not associated with liver toxicity. However, liver function should be monitored at baseline and at appropriate intervals. Rarely, true hepatotoxicity may occur, and the drug should be discontinued. The association of severe hepatic dysfunction, including acute necrosis, with the use of over-the-counter sustained-release preparations of **niacin** has been reported. Carbohydrate tolerance may be moderately impaired, especially in obese patients, and **insulin** resistance may increase. Hyperuricemia occurs in some patients and occasionally precipitates gout. Red cell macrocytosis can occur and is usually not an indication for discontinuing treatment. Significant platelet deficiency occurs rarely and is reversible. Rarely, **niacin** is associated with arrhythmias, mostly atrial, and with macular edema, both requiring cessation of treatment. Patients should be instructed to report blurring of distance vision. **Niacin** may potentiate the action of antihypertensive agents, requiring adjustment of their dosages. Birth defects have been reported in offspring of animals given very high doses.

## BILE ACID–BINDING RESINS

**Colestipol**, **cholestyramine**, and **colesevelam** are useful only for isolated increases in LDL. In patients who also have hypertriglyceridemia, VLDL levels may be further increased during treatment with resins.

#### Chemistry & Pharmacokinetics

The bile acid-binding agents are large polymeric cationic exchange resins that are insoluble in water. They bind bile acids in the intestinal lumen and prevent their absorption. The resin itself is not absorbed.

Bile acids, metabolites of cholesterol, are normally efficiently reabsorbed in the jejunum and ileum (see [Figure 35–2](#)). Excretion is increased up to tenfold when resins are given, resulting in enhanced conversion of cholesterol to bile acids in liver via  $7\alpha$ -hydroxylation, which is normally controlled by negative feedback by bile acids. Decreased activation of the FXR receptor by bile acids may result in a modest increase in plasma triglycerides but can also improve glucose metabolism in patients with diabetes. The latter effect is due to increased secretion of the incretin glucagon-like peptide-1 from the intestine, thus increasing [insulin](#) secretion. Increased uptake of LDL and IDL from plasma results from up-regulation of LDL receptors, particularly in liver. Therefore, the resins are without effect in patients with homozygous familial hypercholesterolemia who have no functioning receptors but may be useful in those with some residual receptor function and in patients with receptor-defective combined heterozygous states.

### Therapeutic Uses & Dosage

The resins are used in treatment of patients with primary hypercholesterolemia, producing approximately 20% reduction in LDL cholesterol in maximal dosage. If resins are used to treat LDL elevations in persons with combined hyperlipidemia, they may cause an increase in VLDL, requiring the addition of a second agent such as a fibrate or [niacin](#). Resins are also used in combination with other drugs to achieve further hypocholesterolemic effect (see below). They may be helpful in relieving pruritus in patients who have cholestasis and bile salt accumulation. Because the resins bind digitalis glycosides, they may be useful in digitalis toxicity.

[Colestipol](#) and cholestyramine are available as granular preparations. A gradual increase of dosage from 4 or 5 g/d to 20 g/d is recommended. Total dosages of 30–32 g/d may be needed for maximum effect. The usual dosage for a child is 10–20 g/d. Granular resins are mixed with juice or water and allowed to hydrate for 1 minute. [Colestipol](#) is also available in 1-g tablets that must be swallowed whole, with a maximum dose of 16 g daily. [Colesevelam](#) is available in 625-mg tablets and as a suspension (1875-mg or 3750-mg packets). The maximum dose is six tablets or 3750 mg as suspension, daily. Resins should be taken in two or three doses with meals.

### Toxicity

Common complaints are constipation and bloating, usually relieved by increasing dietary fiber. Resins should be avoided in patients with diverticulitis. Gastric discomfort and diarrhea are occasionally reported. In patients who have preexisting bowel disease or cholestasis, steatorrhea may occur. Malabsorption of vitamin K occurs rarely, leading to hypoprothrombinemia. Prothrombin time should be measured frequently in patients who are taking resins and anticoagulants. Malabsorption of folic acid has been reported rarely. Increased formation of gallstones, particularly in obese persons, was an anticipated adverse effect but has rarely occurred in practice.

Absorption of certain drugs, including those with neutral or cationic charge as well as anions, may be impaired by the resins. These include digitalis glycosides, thiazides, [warfarin](#), [tetracycline](#), thyroxine, iron salts, [pravastatin](#), [fluvastatin](#), [ezetimibe](#), folic acid, phenylbutazone, [aspirin](#), and ascorbic acid, among others. In general, additional medication (except [niacin](#)) should be given 1 hour before or at least 2 hours after the resin to ensure adequate absorption. [Colesevelam](#) does not bind [digoxin](#), [warfarin](#), or reductase inhibitors.

## INHIBITORS OF INTESTINAL STEROL ABSORPTION

[Ezetimibe](#) inhibits intestinal absorption of phytosterols and cholesterol. Added to statin therapy, it provides an additional effect, decreasing LDL levels and further reducing the dimensions of atherosclerotic plaques.

### Chemistry & Pharmacokinetics

[Ezetimibe](#) is readily absorbed and conjugated in the intestine to an active glucuronide, reaching peak blood levels in 12–14 hours. It undergoes enterohepatic circulation, and its half-life is 22 hours. Approximately 80% of the drug is excreted in feces. Plasma concentrations are substantially increased when it is administered with fibrates and reduced when it is given with cholestyramine. Other resins may also decrease its absorption. There are no significant interactions with [warfarin](#) or [digoxin](#).

Ezetimibe

### Mechanism of Action

**Ezetimibe** selectively inhibits intestinal absorption of cholesterol and phytosterols. A transport protein, NPC1L1, is the target of the drug. It is effective in the absence of dietary cholesterol because it also inhibits reabsorption of cholesterol excreted in the bile.

### Therapeutic Uses & Dosage

A daily dose of 10 mg is used. Average reduction in LDL cholesterol with **ezetimibe** alone in patients with primary hypercholesterolemia is about 18%, with minimal increases in HDL cholesterol. It is the drug of choice for patients with phytosterolemia. **Ezetimibe** is synergistic with reductase inhibitors, producing decrements as great as 25% in LDL cholesterol beyond that achieved with the reductase inhibitor alone.

### Toxicity

**Ezetimibe** does not appear to be a substrate for cytochrome P450 enzymes. Experience to date reveals a low incidence of reversible impaired hepatic function with a small increase in incidence when given with a reductase inhibitor. Myositis has been reported rarely.

## INHIBITION OF MICROSOMAL TRIGLYCERIDE TRANSFER PROTEIN

Microsomal triglyceride transfer protein (MTP) plays an essential role in the addition of triglycerides to nascent VLDL in liver, and to chylomicrons in the intestine. Its inhibition decreases VLDL secretion and consequently the accumulation of LDL in plasma. An MTP inhibitor, **lomitapide**, is available but is restricted to patients with homozygous FH. It causes accumulation of triglycerides in the liver in some individuals. Elevations in transaminases can occur. Patients must maintain a low-fat diet to avoid steatorrhea and should take steps to minimize deficiency of essential fat-soluble nutrients. **Lomitapide** is given orally in gradually increasing doses of 5 to 60 mg once daily 2 hours after the evening meal. No more than 30 mg should be given with a 3A4 inhibitor. It is available only through a restricted risk evaluation and mitigation strategy (REMS) program.

## PCSK9 INHIBITION

Development of inhibitors of proprotein convertase subtilisin/kexin type 9 (PCSK9) followed on the observation that loss of function mutations result in very low levels of LDL and no apparent morbidity.

### Pharmacokinetics and Mode of Action

The PCSK9 protein binds the LDL receptor at the hepatic cell surface, conducting it to destruction in the lysosome (see [Figure 35-2](#)). The binding is dependent on heparan sulfate proteoglycans, providing a potential venue for small molecule inhibition of PCSK9 activity by heparan analogs. Humanized antibodies to PCSK9 (**evolocumab**, **alirocumab**) block interaction with the LDL receptor, allowing the receptor to recycle to the cell surface. LDL reductions of up to 70% at the highest doses have been achieved with these agents. Triglycerides and apo B-100 are reduced, and Lp(a) levels decrease by about 25%.

### Therapeutic Uses and Dosage

Use of these agents is restricted to patients who have familial hypercholesterolemia or clinical atherosclerotic cardiovascular disease who require

given alone, or with a statin, bempedoic acid, and/or ezetimibe if needed to reach the patient's LDL goal.

www.konkur.in

Both are given as subcutaneous injections. **Evolocumab** is given as 140 mg every 14 days or 420 mg monthly. **Alirocumab** is given as 75 or 150 mg every 14 days or 300 mg monthly.

### Toxicity

Rarely, hypersensitivity reactions have occurred. Local reactions at the injection site, as well as upper respiratory and flu-like symptoms, have been observed.

## RNAi INHIBITOR of PCSK9

Inclisiran, a small siRNA now approved, reduces LDL-C about 50% and reduces plasma levels of PCSK9. It is given twice yearly.

## ATP CITRATE LYASE INHIBITION

Bempedoic acid, an oral inhibitor of ATP citrate lyase, inhibits cholesterol synthesis in the liver in the HMG-CoA reductase pathway at a site proximal to that of statins. It acts alone, and contributes additional reduction of LDL synthesis when given with a statin. Because its activity is restricted to liver, it is not expected to cause myopathy. Potential side effects include hyperuricemia and tendon rupture.

## ANGIOPOIETIN-LIKE-3 INHIBITOR

A monoclonal antibody, evinacumab, binds to angiotensin-like-3, an inhibitor of lipoprotein lipase and endothelial lipase. Restricted to patients with homozygous familial hypercholesterolemia, it reduces LDL an additional 49% on average when added to other treatments for this disease.

## AGENTS UNDER DEVELOPMENT

### Antisense Oligonucleotide Inhibitors of Lp(a)

A significant dose-dependent reduction of the Lp(a) lipoprotein and its burden of oxidized lipids is achieved with an antisense oligonucleotide (**pelacarsen**). Reduction of Lp(a) decreases proinflammatory activation of circulating monocytes. Very few side effects have been observed to date. Clinical trials are proceeding. Another antisense and an siRNA targeting Lp(a) are also in development.

### Antisense Oligonucleotide Inhibitor of Apo C-III

This agent (**volanesorsen**) is approved in the European Union but not in the USA. It exerts a significant reduction of the very high levels of triglycerides in patients with familial chylomicronemia syndrome. Thrombocytopenia was observed in some patients.

### CETP Inhibitor

Inhibition of CETP leads to accumulation of mature HDL particles and diminution of the transport of cholesteryl esters to liver. The accumulation of large HDL particles does not have the anticipated cardioprotective effect. Thus far no drug in this class has been approved.

## TREATMENT WITH DRUG COMBINATIONS

Combined drug therapy is useful when LDL and VLDL levels are both elevated, and when levels of either are not at goal with a single agent. The lowest effective doses should be used in combination therapy and the patient monitored more closely for evidence of toxicity. In combinations that include resins, the other agent (with the exception of **niacin**) should be separated temporally to ensure absorption.

### SUMMARY Drugs Used in Dyslipidemia

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>STATINS</b>				
<ul style="list-style-type: none"> <li>Atorvastatin, simvastatin, rosuvastatin, pitavastatin</li> </ul>	Inhibit HMG-CoA reductase	Reduce cholesterol synthesis and up-regulate low-density lipoprotein (LDL) receptors on hepatocytes • modest reduction in triglycerides	Elevated LDL • atherosclerotic vascular disease (primary and secondary prevention) • acute coronary syndromes	Oral • duration 12–24 h • <i>Toxicity</i> : Myopathy, hepatic dysfunction • <i>Interactions</i> : CYP-dependent metabolism (3A4, 2C9) interacts with CYP inhibitors/competitors
<ul style="list-style-type: none"> <li>Fluvastatin, pravastatin, lovastatin: Similar but somewhat less efficacious</li> </ul>				
<b>FIBRATES</b>				
<ul style="list-style-type: none"> <li>Fenofibrate, gemfibrozil</li> </ul>	Peroxisome proliferator-activated receptor-alpha (PPAR- $\alpha$ ) agonists	Decrease secretion of very-low-density lipoproteins (VLDL) • increase lipoprotein lipase activity • increase high-density lipoproteins (HDL)	Hypertriglyceridemia	Oral • duration 3–24 h • <i>Toxicity</i> : Low incidence of myopathy, hepatic dysfunction
<b>BILE ACID SEQUESTRANTS</b>				
<ul style="list-style-type: none"> <li>Colestipol</li> </ul>	Binds bile acids in gut • prevents reabsorption • increases cholesterol catabolism • up-regulates LDL receptors	Decreases LDL	Elevated LDL, digitalis toxicity, pruritus	Oral • taken with meals • not absorbed • <i>Toxicity</i> : Constipation, bloating • interferes with absorption of some drugs and <b>vitamins</b>
<ul style="list-style-type: none"> <li>Cholestyramine, colesevelam: Similar to <i>colestipol</i></li> </ul>				
<b>STEROL ABSORPTION INHIBITOR</b>				
<ul style="list-style-type: none"> <li>Ezetimibe</li> </ul>	Blocks sterol transporter NPC1L1 in intestine brush border	Inhibits reabsorption of cholesterol excreted in bile • decreases LDL and phytosterols	Elevated LDL, phytosterolemia	Oral • duration 24 h • <i>Toxicity</i> : Low incidence of hepatic dysfunction, myositis
<b>NIACIN</b>				
	Decreases catabolism of apo AI • reduces VLDL secretion from liver	Increases HDL • decreases lipoprotein(a) [Lp(a)], LDL	Elevated VLDL, Lp(a)	Oral • large doses • <i>Toxicity</i> : Gastric irritation, flushing, low incidence of hepatic toxicity • may reduce glucose tolerance, may induce elevated uric acid, thrombocytopenia Rarely macular edema
<ul style="list-style-type: none"> <li>Extended-release <i>niacin</i>: Similar to regular <i>niacin</i></li> </ul>				

## PCSK9 HUMANIZED MONOCLONAL ANTIBODIES

• <b>Evolocumab</b>	Complexes PCSK9	Inhibits catabolism of LDL receptor	Familial hypercholesterolemia • incomplete response to other drug therapy	Parenteral • <i>Toxicity</i> : injection site reactions, Uncommon nasopharyngitis, flu-like symptoms, rarely myalgia
• <i>Alirocumab: Similar to evolocumab</i>				
• <b>Bempedoic Acid</b>	Inhibits cholesterol biosynthesis in liver	Reduces cholesterol synthesis, upregulates LDL receptors	Elevated LDL	Oral • duration 20 h; <i>Toxicity</i> : hyperuricemia, tendon rupture

## PREPARATIONS AVAILABLE

GENERIC NAME	TRADE NAMES
<b>Alirocumab</b>	Praluent
<b>Atorvastatin</b>	Generic, Lipitor
<b>Bempedoic acid</b>	Nexletol
<b>Cholestyramine</b>	Generic, Prevalite, Questran
<b>Colesevelam</b>	Welchol
<b>Colestipol</b>	Generic, Colestid
<b>Evolocumab</b>	Repatha
<b>Evinacumab</b>	Evkeeza
<b>Ezetimibe</b>	Generic, Zetia
<b>Fenofibrate</b>	Generic, Antara, Lofibra, Tricor
<b>Fluvastatin</b>	Generic, Lescol, Lescol XL
<b>Gemfibrozil</b>	Generic, Lopid
<b>Inclisiran</b>	Leqvio
<b>Lomitapide</b>	Juxtapid

Lovastatin	Generic, Altoprev, Mevacor
Niacin, nicotinic acid, vitamin B <sub>3</sub>	Generic only
Omega-3 fatty acids–marine	Lovaza, Vascepa
Pitavastatin	Livalo
Pravastatin	Generic, Pravachol
Rosuvastatin	Generic, Crestor
Simvastatin	Generic, Zocor
<b>COMBINATION TABLETS</b>	
Ezetimibe/simvastatin	Vytorin
Bempedoic acid/ezetimibe	Nexlizet
Rosuvastatin/ezetimibe	Roszet

### CASE STUDY ANSWER

It is likely that her diagnosis is familial combined hyperlipidemia (FCH), with elevations in LDL and VLDL each contributing to risk of CVD, as are her obesity and prediabetes. It is likely that she also has hepatic steatosis based on her elevated ALT and features of the metabolic syndrome. Because of the evidence of early structural coronary disease (elevated calcium score), her FCH diagnosis, her low HDL, and her father's premature CAD, her goal LDL is in the 50-mg/dL range. She opted to add **ezetimibe** rather than increase the statin dose. After 2 months, her LDL was 58, and triglycerides were 305 mg/dL. Fenofibrate was added, resulting after 3 months in triglycerides of 95, LDL 53, and HDL 49 mg/dL. Four months later, her triglycerides are 92 and LDL 54 mg/dL. Continued diet, exercise, and weight reduction have reduced her A1c to 5.6 and ALT is normal. If her A1c increases, **metformin** should be considered. She will pause her fibrate and monitor her triglycerides.

## Chapter 36: Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout

T. Kevin Kafaja; Sana Anwar; Daniel E. Furst

### CASE STUDY

#### CASE STUDY

A 48-year-old man presents with complaints of bilateral morning stiffness in his wrists and knees and pain in these joints on exercise. On physical examination, the joints are slightly swollen. The rest of the examination is unremarkable. His laboratory findings are also negative except for slight anemia, elevated erythrocyte sedimentation rate, and positive rheumatoid factor. With the diagnosis of rheumatoid arthritis, he is started on a regimen of [naproxen](#), 220 mg twice daily (bid). After 1 week, the dosage is increased to 440 mg bid. His symptoms are reduced at this dosage, but he complains of significant heartburn that is not controlled by antacids. He is then switched to [celecoxib](#), 200 mg bid, and on this regimen his joint symptoms and heartburn resolve. Two years later, he returns with increased joint symptoms. His hands, wrists, elbows, feet, and knees are all now involved and appear swollen, warm, and tender. He is given oral [methotrexate](#) weekly and his disease decreases by about 20%, but he continues to have multiple tender and swollen joints and morning stiffness that lasts 2 hours. What therapeutic options should be considered at this time? What are the possible complications?

<b>TNF</b>	Tumor necrosis factor

## THE IMMUNE RESPONSE

The immune response occurs when immunologically competent cells are activated in response to foreign organisms or antigenic substances liberated during the acute or chronic inflammatory response. The chronic inflammation involves the release of eicosanoids, lipoxygenases, leukotrienes, multiple cytokines and chemokines, and a very complex interplay of immunoactive cells including eosinophils, neutrophils, dendritic cells, lymphocytes and their subsets, and macrophages. These are further elucidated in [Chapters 18](#) and [55](#).

The whole range of autoimmune diseases (eg, RA, vasculitis, SLE) and inflammatory conditions (eg, gout) derive from abnormalities in this cascade.

The cell damage associated with inflammation acts on cell membranes to release leukocyte lysosomal enzymes; arachidonic acid is then liberated from precursor compounds, and various eicosanoids are synthesized (see [Chapter 18](#)). The lipoxygenase pathway of arachidonate metabolism yields leukotrienes, which have a powerful chemotactic effect on eosinophils, neutrophils, and macrophages and promote bronchoconstriction and

reactive molecules such as hydrogen peroxide and hydroxyl radicals. The interaction of these substances with arachidonic acid results in the generation of chemotactic substances, thus perpetuating the inflammatory process.

## THERAPEUTIC STRATEGIES

The treatment of patients with inflammation involves two primary goals: first, the relief of symptoms and the maintenance of function, which are usually the major continuing complaints of the patient. For this first goal, both NSAIDs and disease-modifying drugs (DMARDs) are needed. For a second goal, slowing or arrest of the tissue-damaging processes is desirable. For the second goal, DMARDs are absolutely necessary.

To monitor the effects of these medications in RA, SLE, vasculitis, JIA, PMS/DMS, AS, PSA, gout, etc., multiple validated combined indices have been developed and are used to define response. Examples include the Disease Activity Score in 28 joints (DAS28) in RA, SLE Disease Activity Index 2K (SLEDAI-2K) in SLE, Ankylosing Spondylitis Disease Activity Score (ASDAS) in ankylosing spondylitis, etc. These indices often combine measures of joint and muscle tenderness and swelling, patient response, and laboratory data.

## NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDs)

Salicylates and other similar agents used to treat rheumatic disease share the capacity to suppress the signs and symptoms of inflammation including pain. These drugs also exert antipyretic effects.

Since [aspirin](#), the original NSAID, has a number of adverse effects, many other NSAIDs have been developed to improve [aspirin](#)'s efficacy profile and decrease its toxicity.

### Chemistry & Pharmacokinetics

The NSAIDs are grouped in several chemical classes, as shown in [Figure 36–1](#). This chemical diversity yields a broad range of pharmacokinetic characteristics ([Table 36–1](#)). Although there are many differences in the kinetics of NSAIDs, they have some general properties in common. All but one of the NSAIDs are weak organic acids as given; the exception, [nabumetone](#), is a ketone prodrug that is metabolized to the acidic active drug.

TABLE 36–1

**Pharmacokinetic properties of some nonsteroidal anti-inflammatory drugs.**

Drug	Half-Life (hours)	CYP Metabolism	Recommended Anti-inflammatory Dosage
Aspirin <sup>1</sup>	0.25	Yesa	1200–1500 mg tid
Salicylic Acid <sup>2</sup>	1.9–12	Yesb,c,d,e,f,g	See footnote <sup>2</sup>
Celecoxib	11.2	Yesc,b	100–200 mg bid
Diclofenac	1.9–2.3	Yesb,c,g	50–75 mg bid
Diflunisal	8–12	No	250–500 mg bid
Etodolac	6.4	No	300–500 mg bid
Flurbiprofen	3.8	Yesc	300 mg tid
Ibuprofen	2	Yesc	600 mg qid
Indomethacin	4–5	Yesi	25–50 mg tid
Ketoprofen	2.1 ± 1.2	No	75 mg tid
Meloxicam	20	Yesc,g	7.5–15 mg qd
Nabumetone <sup>3</sup>	22.5–29.8	Yesj	1000–2000 mg qd
Naproxen	12–17	Yesc,j	375–750 mg bid
Oxaprozin	54.9	No	1200–1800 mg qd
Piroxicam	50	Yesc	20 mg qd
Sulindac <sup>4</sup>	16.4	Yes	150–200 mg bid
Tolmetin	1–2	No	200–600 mg tid

bid, twice daily; tid three times daily; qd, once daily; qid, four times daily.

<sup>1</sup>Aspirin is rapidly hydrolyzed to salicylic acid and is undetectable 1–2 hours after dosing.

<sup>2</sup>Major anti-inflammatory metabolite of aspirin;  $t_{1/2}$  is dose-dependent.

<sup>3</sup>Nabumetone is a prodrug; half-life, protein binding,  $T_{max}$ , clearance, and urinary excretion are for its active metabolite, 6MNA.

<sup>4</sup>Sulindac is a prodrug; half-life, protein binding,  $T_{max}$ , and urinary excretion are for its active sulfide metabolite.

<sup>a</sup>CYP2C19 inducer; <sup>b</sup>CYP2C8 substrate; <sup>c</sup>CYP2C9 substrate; <sup>d</sup>CYP2C19 substrate; <sup>e</sup>CYP2D6 substrate; <sup>f</sup>CYP2E1 substrate; <sup>g</sup>CYP3A4 substrate; <sup>h</sup>CYP2D6 inhibitor;

FIGURE 36-1

Chemical structures of some NSAIDs.

Most of these drugs are well absorbed, and food does not substantially change their bioavailability. Most of the NSAIDs are highly metabolized, some by phase I followed by phase II mechanisms and others by direct glucuronidation (phase II) alone. NSAID metabolism proceeds, in large part, by way of the CYP3A or CYP2C families of P450 enzymes in the liver (see [Chapter 4](#)). While renal excretion is the most important route for final elimination, nearly all undergo varying degrees of biliary excretion and reabsorption (enterohepatic circulation). In fact, the degree of lower gastrointestinal (GI) tract irritation correlates with the amount of enterohepatic circulation. Most of the NSAIDs are highly protein-bound (~98%), usually to [albumin](#). Most of the NSAIDs (eg, [ibuprofen](#), [ketoprofen](#)) are racemic mixtures, while one, [naproxen](#), is provided as a single enantiomer and a few have no chiral center (eg, [diclofenac](#)).

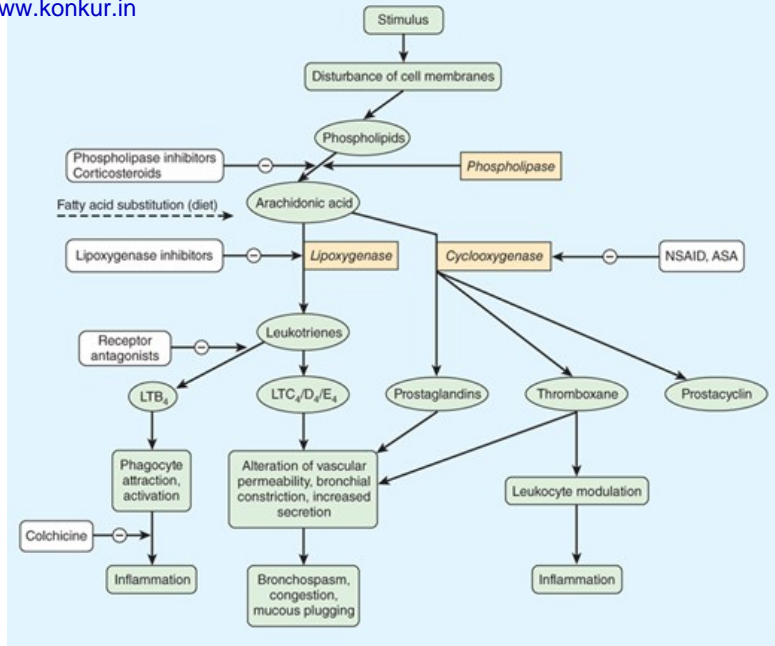

All NSAIDs can be found in synovial fluid after repeated dosing. Drugs with short half-lives remain in the joints longer than would be predicted from their serum half-lives, while drugs with longer half-lives disappear from the synovial fluid at a rate proportionate to their serum half-lives.

## Pharmacodynamics

NSAID anti-inflammatory activity is mediated chiefly through inhibition of prostaglandin biosynthesis ([Figure 36-2](#)). Various NSAIDs have additional possible mechanisms of action, including inhibition of chemotaxis, downregulation of IL-1 production, decreased production of free radicals and superoxide, and interference with calcium-mediated intracellular events. [Aspirin](#) irreversibly acetylates and blocks platelet COX, while the non-COX-selective NSAIDs are reversible inhibitors.

FIGURE 36-2

Selectivity for COX-1 versus COX-2 is variable and incomplete for the older NSAIDs, but drugs that are selective *in vitro* COX-2 inhibitors have been synthesized. The selective COX-2 inhibitors do not affect platelet function at their usual doses. The *in vivo* efficacy of COX-2-selective drugs equals that of the older NSAIDs, while GI safety may be improved. On the other hand, selective COX-2 inhibitors increase the incidence of edema, hypertension, and possibly myocardial infarction.

The NSAIDs decrease the sensitivity of vessels to bradykinin and histamine, affect lymphokine production from T lymphocytes, and reverse the vasodilation of inflammation. To varying degrees, all newer NSAIDs are analgesic, anti-inflammatory, and antipyretic, and all (except the COX-2-selective agents and the nonacetylated salicylates) inhibit platelet aggregation. NSAIDs are all gastric irritants and can be associated with GI ulcers and bleeding as well, although as a group, the newer agents tend to cause less GI irritation than [aspirin](#). Nephrotoxicity, reported for all NSAIDs, is due in part to interference with the autoregulation of renal blood flow, which is modulated by prostaglandins. Hepatotoxicity also can occur with any NSAID.

Although these drugs effectively inhibit inflammation, there is no evidence that—in contrast to drugs such as [methotrexate](#), biologics, and other DMARDs—they alter the course of any arthritic disorder. Several NSAIDs (including [aspirin](#)) reduce the incidence of colon cancer when taken chronically. Several large epidemiologic studies have shown a 50% reduction in relative risk for this neoplasm when the drugs are taken for 5 years or longer.

Although not all NSAIDs are approved by the FDA for the whole range of rheumatic diseases, most are probably effective in RA, seronegative spondyloarthropathies (SpAs—eg, PsA, arthritis associated with inflammatory bowel disease), OA, localized musculoskeletal syndromes (eg, sprains and strains, low back pain), and gout (except [tolmetin](#), which appears to be ineffective in gout).

Adverse effects are generally quite similar for all of the NSAIDs:

1. **Central nervous system:** Headaches, tinnitus, dizziness, and rarely aseptic meningitis.
2. **Cardiovascular:** Fluid retention, hypertension, edema, and rarely myocardial infarction and congestive heart failure (CHF).
3. **Gastrointestinal:** Abdominal pain, dyspepsia, nausea, vomiting, and rarely ulcers or bleeding.
4. **Hematologic:** Rare thrombocytopenia, neutropenia, or even aplastic anemia.
5. **Hepatic:** Abnormal liver function test results and rare liver failure.

7. **Skin:** Rashes, all types, pruritus.
8. **Renal:** Renal insufficiency, renal failure, hyperkalemia, and proteinuria.

## ASPIRIN

**Aspirin** is now rarely used as an anti-inflammatory medication and will be reviewed only in terms of its antiplatelet effects (ie, doses of 81–325 mg once daily, qd). **Mechanism of Action:** **Aspirin** irreversibly inhibits platelet COX such that **aspirin**'s antiplatelet effect lasts 8–10 days (the life of the platelet). **Pharmacokinetics:** Salicylic acid is a simple organic acid with a  $pK_a$  of 3.0. **Aspirin** (acetylsalicylic acid; ASA) has a  $pK_a$  of 3.5 (see [Table 1–3](#)).

**Aspirin** is absorbed as such and is rapidly hydrolyzed (serum half-life 15 minutes) to acetic acid and salicylate by esterases in tissue and blood ([Figure 36–3](#), [Table 36–1](#)). Salicylate is nonlinearly bound to **albumin**. Alkalinization of the urine increases the rate of excretion of free salicylate and its water-soluble conjugates. **Clinical Use and Dosing:** **Aspirin** decreases the incidence of transient ischemic attacks, unstable angina, coronary artery thrombosis with myocardial infarction, and thrombosis after coronary bypass grafting (see [Chapter 34](#)). **Ticagrelor** and **aspirin** are similar in efficacy in reducing risk for MI, stroke, and cardiovascular death. Coadministration of 2.5 mg bid **rivaroxaban** and 100 mg qd **aspirin** may also be effective in reducing MI, stroke, and cardiovascular death compared to **aspirin** alone. However, it is associated with a greater risk for major bleeding. Coadministration of 75 mg **clopidogrel** (initial dose of 300 mg) and 75 mg **aspirin** may be more effective in reducing recurrent ischemic stroke compared to **aspirin** alone, but it is associated with a higher risk for major hemorrhage (1% rising to 5%). Low-dose **aspirin** is efficacious in preventing preterm preeclampsia and is recommended by the American College of Obstetricians and Gynecologists for women with a history of preeclampsia.

**Adverse Effects:** In addition to the common side effects listed above, **aspirin**'s main adverse effects at antithrombotic doses are gastric upset (intolerance) and gastric and duodenal ulcers. Hepatotoxicity, asthma, rashes, GI bleeding, and renal toxicity rarely if ever occur at antithrombotic doses. The antiplatelet action of **aspirin** contraindicates its use by patients with hemophilia. Long-term low-dose **aspirin** usage in patients with type 2 diabetes increases risk for GI bleeding.

## NONACETYLATED SALICYLATES

These drugs include magnesium choline salicylate, sodium salicylate, and salicyl salicylate. All nonacetylated salicylates are effective anti-inflammatory drugs, and they do not inhibit platelet aggregation. Although rarely used, they may be preferable when COX inhibition is undesirable such as in

## COX-2 SELECTIVE INHIBITORS

COX-2 selective inhibitors, or coxibs, were developed in an attempt to inhibit prostaglandin synthesis by the COX-2 isozyme induced at sites of inflammation without affecting the action of the constitutively active “housekeeping” COX-1 isozyme found in the GI tract, kidneys, and platelets. COX-2 inhibitors at usual doses have no impact on platelet aggregation, which is mediated by thromboxane produced by the COX-1 isozyme. In contrast, they do inhibit COX-2-mediated prostacyclin synthesis in the vascular endothelium and so are not cardioprotective. Recommended doses of COX-2 inhibitors cause renal toxicities similar to those associated with traditional NSAIDs.

### Celecoxib

**Mechanism of Action:** Celecoxib, a benzenesulfonamide, is a selective COX-2 inhibitor, about 10–20 times more selective for COX-2 than COX-1.

**Pharmacokinetics:** Refer to Table 36–1. **Indications and Dosage:** Celecoxib is indicated for the treatment of OA, RA, JRA, and AS. The usual dosage is 100–200 mg bid. Celecoxib at 400 mg/d has also shown efficacy as an adjunctive therapy for improving schizophrenic symptoms, most likely due to suspected neuroinflammation in the disorder. **Adverse Effects:** Celecoxib at usual doses is associated with fewer endoscopic ulcers than most other NSAIDs and is noninferior to naproxen and ibuprofen for most toxicities. It may have a minor effect on platelet aggregation. It interacts occasionally with warfarin and also increases plasma concentrations of both lithium and fluconazole, as would be expected of a drug metabolized by CYP2C9.

Celecoxib

### Etodolac

**Mechanism of Action:** Etodolac is a racemic acetic acid derivative whose mechanism of action has been described as relatively COX-2 selective.

**Pharmacokinetics:** Etodolac has an intermediate half-life and is metabolized principally through glucuronidation as well as inhibiting the Wnt pathway (see Table 36–1). **Indications and Dosage:** Etodolac is indicated for the treatment of OA, RA, and JRA. The recommended dosage is 300 mg bid–tid or 500 mg bid initially, then 600 mg/d. **Adverse Effects:** Etodolac may be associated with fewer clinical GI symptoms than nonselective NSAIDs. One report associates etodolac with an increased incidence of acute pancreatitis. Otherwise, this drug has the same spectrum of adverse events as other NSAIDs (see above).

### Meloxicam

**Mechanism of Action:** Meloxicam is an enolcarboxamide related to piroxicam and is a relatively selective COX-2 inhibitor, particularly at 7.5 mg/d. Similarly, while meloxicam inhibits synthesis of thromboxane A<sub>2</sub>, even at subtherapeutic doses, its blockade of thromboxane A<sub>2</sub> does not reach levels that result in decreased in vivo platelet function (see common adverse effects listed above). **Pharmacokinetics:** Refer to Table 36–1. **Indications and Dosage:** The drug is indicated in OA, RA, and JRA patients. Dosage is 7.5–15 mg/d. **Adverse Effects:** Meloxicam is associated with fewer clinical GI symptoms and complications than piroxicam, diclofenac, and naproxen. Other adverse effects are listed above.

## NONSELECTIVE COX INHIBITORS

**Mechanism of Action:** **Diclofenac** is a phenylacetic acid derivative that is a relatively nonselective COX inhibitor. **Pharmacokinetics:** See [Table 36–1](#). Coadministration of **voriconazole** may increase the toxicity of **diclofenac**, as **voriconazole** is a CYP2C9 inhibitor. **Indications and Dosage:** See [Table 36–1](#) for dosing information. **Diclofenac** is indicated for OA, RA, and AS. Off-label use has included biliary colic, corneal abrasions, gout, migraine, and post-episiotomy pain. It is available as sodium, potassium, and epolamine salts, as well as combined in preparations with **misoprostol** and **omeprazole**—both of which decrease GI injury. Other preparations include a 0.1% ophthalmic solution, a 1% topical gel, a 3% topical gel, and a rectal suppository form. The 1% gel is available over the counter and is indicated for OA pain and muscular pain, given as 2 g applied locally every 4–6 hours. In Europe, **diclofenac** is also available as an oral **mouthwash** and for intramuscular administration. **Adverse Effects:** GI ulceration may occur less frequently than with some other NSAIDs. Elevation of serum aminotransferases occurs more commonly with this drug than with other NSAIDs. Adverse effects are the common toxicities listed above.

## Diflunisal

**Mechanism of Action:** **Diflunisal** is a difluorophenyl derivative of salicylic acid and is a nonselective COX inhibitor. It is rarely used today. **Pharmacokinetics:** Like salicylic acid, **diflunisal** is subject to capacity-limited metabolism. Although **diflunisal** is derived from salicylic acid, it is not metabolized to salicylic acid or salicylate and retains the fluorine atoms, resulting in its longer half-life (see [Table 36–1](#)). It undergoes enterohepatic recycling. **Indications and Dosage:** **Diflunisal** is indicated for OA, RA, and pain at the usual dosage of 500 mg bid. **Adverse Effects:** **Diflunisal** at 1000 mg bid inhibits platelet aggregation and may cause fecal blood loss but has no effect on bleeding time. Its antiplatelet effect is also reversible and minimal in comparison to those induced by **aspirin** and **piroxicam**. Common adverse effects are listed above.

## Flurbiprofen

**Mechanism of Action:** **Flurbiprofen** is a propionic acid derivative whose (S)(+) enantiomer inhibits COX nonselectively. **Pharmacokinetics:** See [Table 36–1](#). It demonstrates enterohepatic circulation with extensive hepatic metabolism. Its (S)(+) and (R)(–) enantiomers are metabolized differently and undergo minimal chiral conversion, unlike other propionic acid derivatives. **Indications and Dosage:** See [Table 36–1](#) for dosing. **Flurbiprofen** is approved for OA and RA; it is also used for postoperative analgesia and ophthalmic indications. **Flurbiprofen** is available orally and as a sodium salt in topical ophthalmic formulation for inhibition of intraoperative miosis. Intravenous **flurbiprofen**, lozenge, and oral spray are available in Europe. **Adverse Effects:** Although its adverse effect profile is similar to that of other NSAIDs in most ways, **flurbiprofen** is also rarely associated with cogwheel rigidity, ataxia, tremor, and myoclonus.

## Ibuprofen

**Mechanism of Action:** **Ibuprofen** is a simple phenylpropionic acid derivative and a nonselective COX inhibitor (see [Figure 36–1](#)). **Pharmacokinetics:** Refer to [Table 36–1](#). It is available in oral, topical, and intravenous forms. **Indications and Dosage:** Oral **ibuprofen** is indicated for OA, RA, and JRA. It is available over the counter as 200-mg tablets. In doses of 2400 mg/d, **ibuprofen** is equivalent to 4 g of **aspirin** in anti-inflammatory effect. At  $\leq 1600$  mg/d, it is analgesic but not anti-inflammatory. Oral and IV **ibuprofen** are effective in closing patent ductus arteriosus in preterm infants, with much the same efficacy and safety as indomethacin—but it may cause higher bilirubin levels. Pre-emptive 400–600 mg **ibuprofen** can effectively manage postoperative pain, decrease TNF- $\alpha$  and IL-1 $\beta$ , and reduce opioid consumption. A topical cream preparation is absorbed into fascia and muscle. It can cause “compensated hypogonadism” with decreased **testosterone** production and secondary increased LH/FSH, resulting in normal **testosterone** levels but a stressed system, hypothetically resulting in long-term effects (not proven). **Adverse Effects:** In comparison to **indomethacin**, **ibuprofen** decreases urine output less and also causes less fluid retention. The drug is relatively contraindicated in individuals with nasal polyps, angioedema, and bronchospastic reactivity to **aspirin**. Aseptic meningitis, particularly in patients with SLE, has been reported. Rare hematologic effects include agranulocytosis and aplastic anemia. The concomitant administration of **ibuprofen** and **aspirin** antagonizes the irreversible platelet inhibition induced by **aspirin**, limiting the cardioprotective effect of **aspirin**. Common adverse effects are listed above.

## Indomethacin

**Mechanism of Action:** **Indomethacin**, introduced in 1963, is an indole derivative (see [Figure 36–1](#)) and a potent nonselective COX inhibitor that may also inhibit phospholipase A and C, reduce neutrophil migration, and decrease T-cell and B-cell proliferation. **Pharmacokinetics:** Refer to [Table 36–1](#). **Dosage:** See [Table 36–1](#) for dosing information. The drug is recommended for OA, RA, AS., bursitis/tendonitis, and acute gouty

arthritic. Dosage of 50–70 mg tid may be increased to 25 mg or 50 mg, up to 200 mg/d. **Indomethacin** accelerates closure of patent ductus arteriosus. **Indomethacin** has been tried in reactive arthritis, Sweet syndrome, JRA, pleurisy, nephrotic syndrome, tocolysis, diabetes insipidus, urticarial vasculitis, post-episiotomy pain, prophylaxis of heterotopic ossification in arthroplasty, and COVID-19. An ophthalmic preparation is available in Canada and is efficacious for conjunctival inflammation and to reduce pain after traumatic corneal abrasion. Gingival inflammation is reduced after administration of **indomethacin** oral rinse. Epidural injections produce a degree of pain relief similar to that achieved with methylprednisone in postlaminectomy syndrome. **Indomethacin** is also available in a rectal formulation. New low-dose **indomethacin** (20 and 40 mg) capsules containing submicroscopic particles provides analgesic efficacy in acute postoperative pain. **Adverse Effects:** At usual dosages, **indomethacin** has the common adverse effects listed above. The GI effects may include obstruction, ulcerative colitis, and regional ileitis. Headache is experienced by 11.7% of patients. **Indomethacin** can aggravate depression, epilepsy, and parkinsonism. It is rarely associated with corneal deposits and retinal disturbances decrease it.

## Nabumetone

**Mechanism of Action:** **Nabumetone** is the only nonacid NSAID in current use and resembles **naproxen** in structure (see [Figure 36–1](#)). It is a nonselective COX inhibitor. **Pharmacokinetics:** See [Table 36–1](#). **Nabumetone** is given as a ketone prodrug; 35% of a 1000-mg dose is converted to its active naphthylacetic acid metabolite. Renal impairment results in a doubling of its half-life and a 30% increase in the area under the curve. **Indications and Dosage:** The recommended starting dose for OA and RA (eg, 1500–2000 mg/d) often needs to be exceeded, and this is a very expensive NSAID. **Adverse Effects:** Its adverse effects are very similar to those of other NSAIDs. While diarrhea, dyspepsia, and abdominal pain are experienced by 12–14% of patients, the incidence of GI ulceration is lower than that seen with most other NSAIDs.

## Naproxen

**Mechanism of Action:** **Naproxen** is a naphthyl-propionic acid derivative and is a nonselective COX inhibitor. **Pharmacokinetics:** see [Table 36–1](#). **Naproxen** is the only NSAID marketed as a single enantiomer. **Naproxen**'s free fraction is significantly higher in women than in men, but half-life is similar in both sexes (see [Table 36–1](#)). **Indications and Dosage:** See [Table 36–1](#) for dosing information. **Naproxen** is effective for OA, RA, AS, pain, and bursitis/tendonitis. It is also used to treat JIA, acute gout, and migraine. It is available as a slow-release formulation, oral suspension, over the counter (as 220-mg tablets), with **sumatriptan** (for migraine), as a topical preparation, and as an ophthalmic solution. **Adverse Effects:** Common adverse effects include pressure sensations, nausea, dizziness, and somnolence. The incidence of upper GI bleeding in over-the-counter use is low but still double that of over-the-counter **ibuprofen** (perhaps due to a dose effect). On the other hand, **naproxen** has a more favorable cardiovascular risk profile than **ibuprofen**. Rare cases of allergic pneumonitis, leukocytoclastic vasculitis, and pseudoporphyria as well as the common NSAID-associated adverse effects have been noted. It is contraindicated in patients with hepatic impairment.

## Oxaprozin

**Mechanism of Action:** **Oxaprozin**, another propionic acid-derivative NSAID, is a nonselective COX inhibitor. **Pharmacokinetics:** **Oxaprozin** has a long half-life of 50–60 hours and is given once daily (see [Table 36–1](#)) and does not reach peak plasma levels for 3 hours despite not undergoing significant enterohepatic circulation. **Indications and Dosage:** See [Table 36–1](#) for dosing information. It is used to treat OA, RA, and JRA. **Adverse Effects:** Its adverse effect profile is like that of other propionic acid derivatives.

## Piroxicam

**Mechanism of Action:** **Piroxicam**, an enolcarboxamide derivative (see [Figure 36–1](#)), is a nonselective COX inhibitor that at high concentration also inhibits polymorphonuclear leukocyte migration, decreases **oxygen** radical production, and inhibits lymphocyte function. **Pharmacokinetics:** **Piroxicam** undergoes extensive enterohepatic circulation as indicated by its long half-life of 57 hours, so once-daily dosing is appropriate (see [Table 36–1](#)). Steady-state levels are reached within 7–12 days. **Indications and Dosage:** The recommended dosage for OA and RA is 20 mg qd. **Adverse Effects:** At dosages higher than 20 mg/d, **piroxicam** increases the incidence of peptic ulcer and bleeding (relative risk up to 9.5). See common adverse effects listed above.

## Sulindac

**Mechanism of Action:** **Sulindac** is a sulfoxide nonselective prodrug whose active metabolite is a nonselective COX inhibitor. **Pharmacokinetics:**

[www.konkur.in](http://www.konkur.in) Sulindac is reversibly metabolized to the active sulfide metabolite and has enterohepatic cycling; this prolongs the duration of action to 12–16 hours (see [Table 36–1](#)). Its metabolite has less effect on renal prostaglandins and thus has been used when renal function is somewhat compromised.

**Indications and Dosage:** See [Table 36–1](#) for dosing information. It is used to treat OA, RA, AS, bursitis/tendonitis, and acute gouty arthritis. **Sulindac** may suppress familial intestinal polyposis. **Adverse Effects:** **Sulindac** shares the usual NSAID adverse effect profile. As noted above, it is sometimes used in the face of moderate renal compromise. Rare severe adverse reactions include thrombocytopenia, agranulocytosis, and nephrotic syndrome. It is sometimes associated with cholestatic liver damage, pancreatitis, and aseptic meningitis in patients with SLE and mixed connective tissue disease. Coadministration of dimethyl sulfoxide (DMSO) may cause peripheral neuropathy.

## Tolmetin

**Mechanism of Action:** **Tolmetin** is a pyrrole alkanolic acid derivative (see [Figure 36–1](#)) and a nonselective COX inhibitor. It is rarely used today.

**Pharmacokinetics:** It has a short half-life of 1–2 hours and reaches peak plasma concentrations within 0.5–1 hour. Refer to [Table 36–1](#). **Indications and Dosage:** See [Table 36–1](#) for dosing information. **Tolmetin** is indicated for OA, RA, and JRA and is apparently not effective in gout. **Adverse Effects:** Nausea occurs in 11% of patients, and acute interstitial nephritis has been observed. Common adverse effects are listed above.

## Other NSAIDs

**Meclofenamate** and **tenoxicam** are rarely used and are not reviewed here.

## CHOICE OF NSAID

All NSAIDs, including **aspirin**, are about equally efficacious with a few exceptions—tolmetin seems not to be effective for gout, and **aspirin** is less effective than other NSAIDs (eg, **indomethacin**) for AS. Therefore, NSAIDs tend to be differentiated on the basis of toxicity and cost-effectiveness. For example, some surveys suggest that **indomethacin** and **tolmetin** are the NSAIDs associated with the greatest toxicity, while **salsalate**, **aspirin**, and **ibuprofen** are least toxic. The selective COX-2 inhibitors were not included in these surveys.

For patients with renal insufficiency, nonacetylated salicylates may be best. **Diclofenac** and **sulindac** are associated with more liver function test abnormalities than other NSAIDs. The relatively expensive selective COX-2 inhibitor **celecoxib** is probably safest for patients at high risk for GI bleeding but may have a higher risk of cardiovascular toxicity. **Celecoxib** or a nonselective NSAID plus **omeprazole** or **misoprostol** may be appropriate in patients at highest risk for GI bleeding; in this subpopulation of patients, they are cost-effective despite their high acquisition costs.

The choice of an NSAID thus requires a balance of efficacy, cost-effectiveness, safety, and numerous personal factors (eg, other drugs also being used, concurrent illness, compliance, medical insurance coverage), so that there is no best NSAID for all patients. There may, however, be one or two best NSAIDs for a specific person.

## DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

RA is a progressive immunologic disease that causes significant systemic effects, shortens life, and reduces mobility and quality of life. Interest has centered on finding treatments that might arrest—or at least slow—this progression by modifying the disease itself. The effects of disease-modifying therapies may take 2 weeks to 6 months to become clinically evident. These therapies include conventional synthetic (cs) and biologic (b) disease-modifying antirheumatic drugs (recently designated **csDMARDs** and **bDMARDs**, respectively). The conventional synthetic agents include small molecule drugs such as **methotrexate**, **azathioprine**, **chloroquine** and **hydroxychloroquine**, **cyclophosphamide**, **cyclosporine**, **leflunomide**, **mycophenolate mofetil**, and **sulfasalazine**. **Tofacitinib**, although marketed as a biologic, is actually a small molecule targeted synthetic DMARD (tsDMARD). Gold salts, which were once extensively used, are no longer recommended because of their significant toxicities and questionable efficacy. Nevertheless, they have found limited use for RA in Canada. Biologics are large molecule therapeutic agents, usually proteins, that are often produced by recombinant DNA technology. The bDMARDs approved for RA include a T-cell–modulating biologic (**abatacept**), a B-cell cytotoxic agent (**rituximab**), anti-IL-6 receptor antibodies (**tocilizumab** and **sarilumab**), IL-1–inhibiting agents (**anakinra**, **rilonacept**, **canakinumab**), and the TNF- $\alpha$ –blocking agents (five drugs). bDMARDs are further divided into biological original (or legacy) products and biosimilar DMARDs (boDMARDs and bsDMARDs, respectively).

The small-molecule DMARDs and biologics are discussed alphabetically, independent of origin.

**Mechanism of Action:** Abatacept is a soluble fusion protein composed of the Fc region of human immunoglobulin G1 (IgG1) fused to the extracellular domain of human cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4). Abatacept is designed to inhibit T-cell activation by binding to ligands CD80 and CD86 on antigen-presenting cells (APCs), ultimately blocking CD80 and CD86 interaction with CD28 on T cells. **Pharmacokinetics:** Abatacept is given by subcutaneous or intravenous administration. The bioavailability of abatacept following subcutaneous administration relative to intravenous administration was 79%. Mean estimates for systemic clearance were 0.28 mL/h/kg, volume of distribution was 0.11 L/kg, and terminal half-life was 14.3 days, with comparability between subcutaneous and intravenous administration. **Indications and Dosage:** Abatacept can be used as monotherapy or in combination with methotrexate or another csDMARD in rheumatoid arthritis, PsA, and polyarthritic JIA in patients 2 years of age and older, plus for the prophylaxis of acute graft-versus-host disease (aGVHD), in combination with a calcineurin inhibitor and methotrexate, and in adults and pediatric patients ( $\geq 2$  years of age) undergoing hematopoietic stem cell transplantation (HSCT). Abatacept has also been used in SLE, primary Sjögren syndrome, type 1 diabetes, inflammatory bowel disease, Takayasu arteritis, psoriasis vulgaris, and dermatomyositis. Dosing for abatacept is weight adjusted. Intravenous doses are 500 mg monthly if  $\leq 25$  to 59 kg, going from 500 mg and maximizing at 1000 mg for those weighing 100 kg. Subcutaneous doses are also weight based, ranging from 50 mg SC weekly (if 10 to  $< 25$  kg) and maximizing at 125 mg for those weighing 50 kg or more. Methotrexate plus abatacept in early rapidly progressive RA was superior to methotrexate alone to achieve minimal disease activity as early as 2 months, significantly inhibiting radiographic progression at 1 and 2 years. By Bysome measures, abatacept prevented patients from progressing from undifferentiated inflammatory arthritis to rheumatoid arthritis. Abatacept has been associated with a decreased risk of cardiovascular disease and increased HDL compared to TNF inhibitors in RA patients. **Adverse Effects:** There is an increased risk of infection (as with other biologics), predominantly of the upper respiratory and urinary tract, as well as headache, nasopharyngitis, and nausea. Concomitant use with TNF inhibitors or other biologics is probably associated with increased serious infections. All patients should be screened for latent tuberculosis and viral hepatitis before starting, although the risk of latent tuberculosis activation may be slightly less with this drug than with other biologics. Live vaccines should be avoided for up to 3 months after discontinuation of abatacept. Infusion-related reactions, hypersensitivity reactions, and anaphylaxis are reported rarely. Anti-abatacept antibody formation is  $< 5\%$  and does not appear to affect clinical outcomes. There is controversy about whether abatacept increases cancer risk overall, but the weight of evidence is against this association except for a possible increased risk of lymphomas.

## ANIFROLUMAB

**Mechanism of action:** Anifrolumab is a humanized IgG1k monoclonal antibody that binds to subunit 1 of the type 1 IFN receptor, IFNAR, and inhibits formation of the IFN/IFNAR complex. Anifrolumab antagonizes the receptor responsible for cellular signaling induced by IFN- $\alpha$  (predominant in SLE pathogenesis), IFN- $\beta$ , IFN- $\epsilon$ , IFN- $\kappa$ , and IFN- $\omega$ . Anifrolumab corrects defects in the innate and adaptive immune system by altering protein expression, reversal of cytopenias, and normalization of immune cell population, especially in patients with high type 1 IFN gene-dominant disease, such as is probably true for SLE. **Pharmacokinetics:** Anifrolumab can be administered SC and IV. Anifrolumab serum half-life was 18.5 days for the 300 mg dose and serum concentration dropped below the in vitro effective threshold by 84 days post-dose. Clearance was mostly through the RES system. **Indication and Dosage:** Anifrolumab is one of the three anti-type-1 interferon agents under investigation for the potential treatment for SLE. The US Food and Drug Administration (FDA) approved the drug for nonrenal lupus in June 2021. Phase 2 studies in renal lupus were equivocal, but further studies are ongoing. The anifrolumab dose is 150–300 mg IV every 4 weeks, as higher doses (eg, 1000 mg) resulted in more infections. **Adverse Effects:** The most common adverse effects included upper respiratory tract infection, bronchitis, sinusitis, arthralgia, nasopharyngitis, infusion-related reactions, and UTI. Long-term adverse effects are still under investigation.

## APREMILAST

**Mechanism of Action:** Apremilast is a selective small molecule inhibitor of the enzyme phosphodiesterase 4 (PDE4), hindering the conversion of cyclic AMP to AMP. The inhibition of PDE4 leads to increased intracellular cAMP and decreased production of proinflammatory cytokines including CXCL9 and CXCL10, IFN- $\gamma$ , TNF- $\alpha$ , and IL-2, -8, -12, and -23. **Pharmacokinetics:** The bioavailability of apremilast is 73%, and its terminal half-life is approximately 6–9 hours. It is 70% metabolized by CYP3A4, thus leading to many potential drug–drug interactions. Elimination is 58% by the kidneys and 39% by the feces, and dose adjustments are recommended if creatinine clearance (CrCl) is  $\leq 30$  mL/min. **Indications and Dosage:** Apremilast is given orally, gradually increasing the dose over the first 5 days until the recommended dose of 30 mg bid is reached. It is indicated for plaque psoriasis (in candidates for phototherapy or systemic therapy), psoriatic arthritis, and oral ulcers associated with Behçet disease. **Adverse Effects:** Apremilast's principal adverse effects are gastrointestinal (diarrhea, nausea), but upper abdominal pain, vomiting, upper respiratory tract infections, arthralgia, weight loss, headaches, mood disorders, and suicidal ideation are reported rarely.

**Mechanism of Action:** Azathioprine is a csDMARD and is metabolized to 6-MP and then to its major active metabolite, 6-thioguanine (6-TG). 6-TG suppresses inosinic acid synthesis, ultimately suppressing B- and T-cell function, immunoglobulin production, and IL-2 secretion (see Chapter 55).  
**Pharmacokinetics:** Azathioprine can be given orally or subcutaneously. Its metabolism is bimodal in humans, with rapid metabolizers clearing the drug four times faster than slow metabolizers. **Indications and Dosage:** Azathioprine is approved for active rheumatoid arthritis (2 mg/kg/day orally). It is used to prevent kidney transplant rejection in combination with other immunosuppressives. Controlled or open trials show efficacy in psoriatic arthritis, reactive arthritis, polymyositis, SLE (including nephritis), autoimmune hepatitis, maintenance of remission in vasculitis, Behçet disease, IgG4-related disease, and inflammatory myopathies. **Adverse Effects:** Azathioprine suppresses the bone marrow, causes GI disturbances, is carcinogenic, and increases infection risk. Polymorphism of *NUDT15* is strongly associated with azathioprine-induced leukopenia, as is TPMT homozygosity (0.3% of the population).

## BARICITINIB

**Mechanism of Action:** Baricitinib is an anti-inflammatory, targeted, synthetic small molecule (tsDMARD) that in vitro, selectively, and reversibly inhibits JAK1 and JAK3 more than JAK2 and also inhibits the JAK-STAT signaling pathway **Pharmacokinetics:** Baricitinib has an absolute bioavailability of 79%. The elimination half-life is approximately 12 hours. About 10% is metabolized via CYP3A4, so drug interactions are not usually significant. It is excreted mainly by the kidneys, so it should be used cautiously if at all in patients whose glomerular filtration rate is <60 mL/min/1.73 m<sup>2</sup>. **Indications and Dosage:** Baricitinib is approved for RA in TNF- $\alpha$  inadequate responders. In a randomized controlled trial, baricitinib was more effective than adalimumab for ACR20 response at 12 weeks. The FDA-approved dose of baricitinib for RA is 2 mg daily in the USA, and its efficacy at this dose is controversial; in Europe, 2 and 4 mg daily are used. It can be used as monotherapy or in combination with methotrexate or other csDMARDs (eg, leflunomide, hydroxychloroquine). A recent phase 2 trial demonstrated efficacy of baricitinib 4 mg daily for patients with active, drug-resistant SLE. It has also been approved in alopecia areata and used in atopic dermatitis and psoriasis. **Adverse Effects:** Baricitinib increases the risk of infection and of herpes virus reactivation. It falls under the FDA “black box” warning for VTE, DVT, and PE, although the data are not strong. Patients should be screened for active and latent tuberculosis prior to initiation of treatment. Lymphoma and other malignancies have been observed. A large study of patients receiving baricitinib found no association with major cardiovascular events, arterial thrombotic events, or congestive heart failure. Gastrointestinal perforations also have been reported, and baricitinib should be used with caution in patients with a history of diverticulitis. Neutropenia, lymphopenia, anemia, liver enzyme elevation, and lipid elevation also have been associated with baricitinib.

## BELIMUMAB

**Mechanism of Action:** Belimumab is a fully human IgG1 monoclonal antibody that selectively inhibits soluble B-lymphocyte stimulator protein (BLyS) from binding to B cells. **Pharmacokinetics:** Belimumab has a distribution half-life of 1.75 days and a terminal half-life of 19.4 days. **Indications and Dosage:** Belimumab is indicated for the treatment of patients aged  $\geq 5$  years with SLE or adult active lupus nephritis on background standard of care (SOC) therapy. A recent trial of rituximab followed by belimumab in refractory SLE demonstrated decreased neutrophil extracellular traps (NET), decreased ANA, and improved lupus disease activity states. It has not been tested in combination with other bDMARDs or cyclophosphamide. Belimumab is administered as an intravenous infusion of 10 mg/kg at weeks 0, 2, and 4, and every 4 weeks thereafter or 200 mg SC weekly. **Adverse Effects:** The most common adverse effects of belimumab are nausea, diarrhea, pyrexia, insomnia, extremity pain, migraine, and respiratory tract infections. As with other bDMARDs, there is an increase in serious infection risk. Importantly, depression and suicide have been reported. Infusion reactions occur, including rare anaphylaxis.

## RISANKIZUMAB

**Mechanism of action:** Risankizumab is a humanized Ig G1 monoclonal antibody that selectively targets and binds to the p19 subunit of the IL-23 receptor complex and subsequently inhibits the IL-23-dependent proinflammatory effect. **Pharmacokinetics:** Risankizumab can be administered subcutaneously and intravenously. Risankizumab exhibits linear pharmacokinetics when administered intravenously (0.01 mg/kg to 1200 mg) or subcutaneously (0.25 mg/kg 300 mg), with a long terminal half-life of 28 days. Peak plasma concentration after SC dosing was reached 3–14 days after dosing, with an estimated bioavailability of 89%. **Indication and Dosage:** Risankizumab is approved for the treatment of moderate to severe plaque psoriasis at a dose of 150 mg administered subcutaneously at weeks 0 and 4, and every 12 weeks thereafter. It is also approved for PSA. **Adverse**

**Effects:** The most common side effects include fatigue, arthralgia, nasopharyngitis, headache, skin rashes, and local injection reactions; less common

## CALCINEURIN INHIBITORS: CYCLOSPORINE, TACROLIMUS, AND VOCLOSPORIN

**Mechanism of Action:** Cyclosporine (CSA) and voclosporin (VOCLO) act by binding to cyclophilin-1 while tacrolimus (TAC) binds FK506 binding protein (FKBP), all of which result in inhibition of calcineurin. This selective inhibition impairs the transcription of TNF- $\alpha$ , IL-2, IL-3, IL-4, CD40L, granulocyte-macrophage colony-stimulating factor, interferon- $\gamma$ , and other cytokines in T-cells. Thus, these drugs interfere with T-cell activation, proliferation, and differentiation. Voclosporin also inhibits p-glycoprotein as well as organic anion transporting polypeptides 1B1 and 1B3 (see Chapter 55). **Pharmacokinetics:** Cyclosporine and tacrolimus absorption are low and erratic (~3–5%), as is that of voclosporin (about 8%), although a microemulsion formulation of cyclosporine provides 20–30% bioavailability. CSA and TOC are available for oral and IV use. Voclosporin is only oral. All are metabolized by CYP3A4 and therefore are subject to a large number of potential drug interactions (see Chapters 55 and 67). Grapefruit juice increases cyclosporine bioavailability by as much as 62%. The mean terminal half-lives are approximately 30 hours (24.9–36.5 hours). VOCLO has nonlinear kinetics at low doses so that it produces calcineurin inhibition at one-tenth the usual dose of cyclosporine. This means lower tissue concentrations and lower renal and cardiac toxicity, while cyclosporine may be more effective in diseases like psoriasis (in which it reaches higher tissue concentrations). **Indications and Dosage:** Cyclosporine 3–5 mg/kg/day in two divided doses and TAC 2–4 mg qd are clinically active and retard bony erosions in severe and active RA. VOCLO is indicated for SLE nephritis at doses of 23.7 mg bid (tabs are 7.9 mg so three tabs bid) with mycophenolate and/or steroids. CSA and TAC may also be useful in SLE (including nephritis), plaque psoriasis, allogenic post-organ transplant rejection, polymyositis, dermatomyositis, clinically amyopathic dermatomyositis, granulomatous polyangiitis, adult-onset Still disease, JIA, steroid-refractory ulcerative colitis, and refractory eye involvement in Behçet disease. **Adverse Effects:** Leukopenia, thrombocytopenia, and anemia are predictable. High doses can be cardiotoxic, neurotoxic, and nephrotoxic, and they can induce hypertension. Voclosporin may be less reno- and cardiotoxic than CSA. Metabolic abnormalities, hepatotoxicity, life-threatening bacterial, viral, and fungal infections, and malignancies can occur for all three. Bladder cancer is very rare (not reported for VOCLO) but must be looked for, up to 5 years after usage. Sterility has been reported.

## CHLOROQUINE AND HYDROXYCHLOROQUINE

**Mechanism of Action:** Chloroquine and hydroxychloroquine are nonbiologic drugs used for malaria (see Chapter 52) and in rheumatic diseases. They suppress T-lymphocyte responses to mitogens, inhibit leukocyte chemotaxis, stabilize lysosomal enzyme processing by Fc receptor, inhibit DNA and RNA synthesis, and interfere with type 1 IFN through effects on TLR7 and 9. **Pharmacokinetics:** Antimalarials are rapidly absorbed and 50% plasma protein bound, but they are extensively tissue bound, particularly to melanin-containing tissue such as the retina. The drugs are deaminated in the liver and have long and variable plasma elimination half-lives (40–50 days) because of a high volume of distribution, an extended mean residence time (HCQ 1300 hours and CQ 900 hours), and renal clearance. **Indications and Dosage:** Antimalarials are approved for RA (not very effective), systemic lupus erythematosus, chronic discoid lupus erythematosus, JIA, and Sjögren syndrome. They do not alter erosions at their usual dose, and it takes 3–6 months to obtain a clinical response. Antimalarials are used commonly in SLE as they decrease mortality, skin manifestations, serositis, and joint pain in this disease. They have been used in Sjögren syndrome. Based on systematic literature reviews and population-based cohorts, antimalarials reduce the risk of cardiovascular disease in rheumatic disease patients. Although their efficacy in thrombophlebitis in SLE is unclear, they do improve the lipid profile in RA and SLE and prolong pregnancy in threatened preterm delivery. **Adverse Effects:** Dosing was  $\leq 6$  mg/kg/d for hydroxychloroquine or  $\leq 2.5$  mg/kg/d for chloroquine. At these doses, retinopathy is <1% for up to 5 years and <2% for up to 10 years, and 1% per year thereafter. A baseline ophthalmologic exam and annual screenings after 5 years are recommended, using ocular CT imaging. Other toxicities include dyspepsia, nausea, vomiting, abdominal pain, rashes, weakness from myopathy, cardiomyopathy, cardiac conduction defects, neuromyotoxicity, cytopenias, nightmares, and conduction disorders. These drugs are relatively safe in pregnancy.

## CYCLOPHOSPHAMIDE (CYC)

**Mechanism of Action:** Cyclophosphamide is a csDMARD. Its major metabolite, phosphoramidate mustard, cross-links DNA to prevent cell replication (see Chapter 54). It thereby suppresses T- and B-cell function by 30–40%. T-cell suppression correlates with clinical response in the rheumatic diseases. Its pharmacokinetics and toxicities are discussed in Chapter 54. **Indications and Dosage:** Cyclophosphamide is available for oral and intravenous use. It is indicated principally for systemic lupus erythematosus (nephritis and central nervous system lupus), vasculitis, ssc, and possibly myositis. Oral dosing is 2 mg/kg/day while IV monthly CYC is 0.5 (low dose) to 1.0 (high dose) g/m<sup>2</sup>. A meta-analysis of seven randomized controlled studies showed equal remission rates after low-dose IV compared to high-dose IV cyclophosphamide, with lower infection rates (in SLE nephritis). The Scleroderma Lung Study (SLS) demonstrated a modest but significant benefit for cyclophosphamide in forced vital capacity dyspnea, skin thickening,

and health-related quality of life at 18–24 months. **Adverse Effects:** The most common adverse effects include dyspepsia, nausea, vomiting, neutropenia, thrombocytopenia, infections, and sterility—and in the long term, both skin and bladder cancers.

## INTERLEUKIN-1 INHIBITORS

**Introduction:** IL-1 $\alpha$  plays a major role in the pathogenesis of several inflammatory and autoimmune diseases including RA. IL-1 $\alpha$ , IL-1 $\beta$ , and IL-1 receptor antagonist (IL-1RA) are other members of the IL-1 family. Three IL-1 inhibitor drugs are marketed.

### Anakinra

**Mechanism of Action:** **Anakinra** is the oldest drug in this family. **Anakinra** is a recombinant form of human interleukin 1 (IL-1) receptor antagonist (IL-1Ra). It blocks the effect of IL-1 $\alpha$  and IL-1 $\beta$  on IL-1 receptors, hence decreasing the immune response in inflammatory diseases.

**Pharmacokinetics:** **Anakinra**'s absolute bioavailability is 95%, and its median (range) half-life is 5.7 (3.1–28.2) hours and is given SC daily.

**Indications and Dosage:** See [Table 36–2A](#). Although **anakinra** is approved for the treatment of active RA, it is rarely used for RA. The recommended dose in the treatment of RA is 100 mg qd; for CAPS it is weight based and maximizes at 8 mg/kg per day. Reduction to every-other-day dosing is recommended if CrCl <30 mL/min. Multiple trials and a meta-analysis showed that **anakinra**, by targeting hyperinflammation, reduces mortality risk of hospitalized non-intubated patients with COVID-19 without increasing the risk of adverse effects. **Adverse Events:** See below.

TABLE 36–2A

**FDA-approved and Off-label Use of H1 Inhibitors (“cases only” denote case reports; rest are studies of varying credibility)**

	FDA Approved	Off Label Uses	Off-Label Uses
<b>Anakinra</b>	Deficiency of IL-1 RA antagonist Rheumatoid arthritis	Adult Onset Still’s Disease Auto-inflammatory Hearing Loss (cases only) Behcet’s Syndrome (cases only) CAPS (FACS, Mukel-Wells, NOMID) Congestive Heart Failure CVA (subarachnoid hemorr; Cerebral Thromobsus- a few cases) Dilated Cardiomyopathy (cases only) Dry Eye Syndrome (Topical) Giant cell Arteritis (cases only) Gout Hidradenitis Suppurativa	Hyper IgD (cases only) Kawasaki Syndrome (cases only) Myocarditis (cases only) Osteoarthritis Pericardtis Pulmonary Silicosis (cases only) Pyogenic arthritis, pyoderma gangrenosum Acne (PAPA) (cases only) Pustular Psoriasis Pyoderma Gangrenosum Schnitzler Syndrome (cases only) Systemic Onset JIA Takayasu Arteritis (cases only) TRAPS (cases only)

### Canakinumab

**Mechanism of Action:** **Canakinumab** is a human IgG<sub>1</sub>/ $\kappa$  monoclonal antibody against IL-1 $\beta$ . It forms a complex with IL-1 $\beta$ , preventing its binding to IL-1 receptors. **Pharmacokinetics:** **Canakinumab** given subcutaneously has a bioavailability of 66% (less than **anakinra**) and a 26-day mean terminal half-life. **Indications and Dosage:** see [Table 36–2B](#). In a 10,061-patient, randomized, double-blind trial of **canakinumab** versus placebo in patients with previous myocardial infarction and elevated CRP, **canakinumab** lowered recurrent MIs, decreased the incidence and deaths from lung cancer, and improved osteoarthritis pain (all statistically significant). The recommended dose for patients with SJIA who weigh more than 7.5 kg is 4 mg/kg every 4

CAPS, Cryopyrin-Associated Periodic Syndromes; DM, diabetes mellitus; EMA, European Registration Authority; FACS, Familial cold auto-inflammatory syndrome; FMF, Familal Mediterranean Fever; IgD, Immunoglobulin D; JIA, Juvenile Inflammatory Arthritis; MI, Myocardial Infarction; PAPA, Pyogenic Arthritis Pyoderma Gangrenosum Acne

**Rilonacept**

**Mechanism of Action:** **Rilonacept** is a recombinant form of the ligand-binding domain of the IL-1 receptor. It binds mainly to IL-1β and with lower affinity to IL-1 and a 23-fold lower affinity for IL-1RA. **Rilonacept** thus neutralizes IL-1β and prevents its attachment to IL-1 receptors.

**Pharmacokinetics:** **Rilonacept** bioavailability is 50% (less than **anakinra**), and it has an approximate elimination half-life of 1 week (154–184 hours).

**Indications and Dosage:** see **Table 36–2B**. **Rilonacept** is approved to treat the familial cold autoinflammatory syndrome (FCAS) and Muckle-Wells syndrome (MWS), which are CAPS subtypes, in patients 12 years or older. **Rilonacept** is also used to treat gout and has been shown to treat recurrent pericarditis. The subcutaneous dose of **rilonacept** for CAPS is age dependent. **Adverse Effects:** see below.

**Adverse Effects of Interleukin 1 Inhibitors**

The most common adverse effects of the above IL-1 inhibitors are injection-site reactions (up to 40%) and upper respiratory tract infections. Serious infections including TBC and opportunistic or fungal infections occur very rarely. Headache, abdominal pain, nausea, diarrhea, arthralgia, and flu-like illness all have been reported, as have hypersensitivity reactions. Patients taking IL-1 inhibitors may experience neutrophilia, a physiologic result of inhibiting IL-1 and not an AE; rare transient neutropenia requires neutrophil monitoring.

**GUSELKUMAB**

**Mechanism of Action:** **Guselkumab** is a fully human monoclonal IgG1λ antibody that selectively binds to the p19 subunit of IL-23 with high affinity and inhibits its interaction with the IL-23 receptor, secondarily reducing C-reactive protein (CRP), serum amyloid A (SAA), IL-6, and Th17 effector cytokines (IL-17A, IL-17F and IL-22) in active psoriatic arthritis. **Pharmacokinetics:** **Guselkumab** reaches maximum concentration in approximately 5.5 days (Tmax) after a single 100-mg subcutaneous injection. The bioavailability is 49% after a single 100-mg subcutaneous injection with a volume

**Guselkumab** is indicated for the treatment of adult active plaque psoriasis patients at 100 mg, by subcutaneous injection at 0 and 4 weeks, and every 8 weeks thereafter. **Adverse Effects:** The most common side effect of **guselkumab** is upper respiratory infections (nasopharyngitis). Other side effects include headaches, injection-site reactions, arthralgia, diarrhea, and gastroenteritis. Evaluation for tuberculosis prior to starting treatment with **guselkumab** is needed.

## IXEKIZUMAB

**Mechanism of Action:** **Ixekizumab** is a human IgG4- $\kappa$  monoclonal antibody that binds to the IL-17A cytokine (found particularly in psoriasis and psoriatic arthritis) and IL17A/F heterodimers. **Pharmacokinetics:** **Ixekizumab** is given subcutaneously. Its peak plasma concentration is reached 4 days after the dose. The mean elimination half-life is 13 days. **Indications and Dosage:** **Ixekizumab** is indicated for adults with moderate to severe plaque psoriasis and adults with PsA. The loading dose for psoriasis is 160 mg subcutaneously followed by 80 mg every 2 weeks to week 12, then 80 mg every 4 weeks. For adults with psoriatic arthritis the recommended dose is 160 mg at week 0, followed by 80 mg every 4 weeks. It can be administered alone or in combination with a csDMARD. Randomized controlled trials have shown efficacy of **ixekizumab** for radiographic axial spondyloarthritis.

**Adverse Effects:** Infection is a common side effect, with upper respiratory tract infections being the most common. Tuberculosis should be evaluated prior to starting therapy. **Ixekizumab** may cause or exacerbate inflammatory bowel disease.

## JANUS KINASE INHIBITORS

While Janus kinase and tyrosine kinase inhibitors (specifically **baricitinib**, **tofacitinib**, and **upadacitinib**) are part of a family of medications, there are some differences amongst them. This will be an overview of the commonalities among these drugs, while specific differences will be discussed for each medication. **Mechanism of Action:** these drugs, at concentrations related to their clinical indications used doses in rheumatic diseases, have some apparent differences in mechanisms of action (see [Table 36-3](#)). It should be noted that the effect of these drugs in the tissues, where concentrations may be very different, cannot automatically be extrapolated from these apparent differences in serum concentration-derived mechanisms.

**Pharmacokinetics:** These three drugs have a number of similarities (see [Table 36-3](#)) and a few differences. The differences will be mentioned within the specific sections below. **Indications and Uses:** The FDA-approved uses of **baricitinib**, **tofacitinib**, and **upadacitinib** are listed in [Table 36-3](#), as are the published off-label uses of these drugs. **Adverse Effects:** For all these medications, there is an increase in infections, particularly upper respiratory infections with cough, headache, fever, etc. Headache and cough are also found without infection. Herpes zoster, particularly, is increased when using JAK inhibitors, although it is rarely disseminated. While there are no data specifically associated with tuberculous, fungal, or opportunistic infections when using JAK inhibitors, these may occur in this patient population independent of these drugs. It is not known whether this propensity is related to the JAK inhibitors, disease activity, or concomitant medications. Nevertheless, all patients should be screened for latent tuberculosis before starting therapy. JAK inhibitors are associated with dose-dependent increases in total cholesterol and LDL, although the relevance to ASCVD is unclear. Lipid levels should be carefully followed and, when appropriate, treated. All JAK inhibitors have a “black box warning” from the FDA relating to increased venous thrombotic events (VTEs), deep-vein thrombosis (DVT), pulmonary emboli (PE), major adverse cardiovascular events (MACE), and cancer. These basically originated from a large, FDA-mandated postmarketing study using **tofacitinib** in patients with high cardiovascular risk. This study was interpreted as showing an increased risk for these events after **tofacitinib** at all doses. Upon closer examination, this was a dose-response effect, with 10 mg BID being associated while 5 mg BID was not. Rare events of these sorts had been found in the registration studies, and a few such events were also found for **baricitinib** and **upadacitinib**. One can speculate that the rare events in the preregistration studies resulted in the “black box” warning. When using these drugs, one should observe high-risk patients closely, but an appropriate clinical decision with patient input is more appropriate than complete prohibition. GI perforations, initially thought associated with JAK inhibitors, were found principally in patients with a history of diverticulitis, and on corticosteroids. Nevertheless, caution should be exercised in those with histories of diverticulitis. While animal studies indicated teratogenicity and possible infertility, these animal findings used markedly supertherapeutic dosing, and no increased teratogenicity or infertility in humans has thus far been found. Elevated liver function tests, rare lymphomas, and rare neutropenia, lymphopenia, and anemia have been documented for all three JAK inhibitors.

Janus Kinase Inhibitors

	Baricitinib	Tofacitinib	Upadacitinib
Bioavailability(%)	79	94	76%(ER vs IR)
Metabolism(%)	CYP3A4-10	CYP3A4-70	Unchanged-79%; CYP3A4-<13%

Protein Binding(%)	50	94	52
Terminal T ½(hrs)	12.5	3	9-14
FDA Approved	Alopecia areata, Rheumatoid Arthritis(1)	Ankylosing Spondylitis Alopecia areaata Juvenile Inflamm. Arthritis Psoriatic Arthritis Rheumatoid Arthritis(2) Ulcerative Colitis	Ankylosing Spndylitis Atopic Dermatitis Psoriatic Arthritis Rheumatoid Arthritis(2) Ulcerative Colitis
Used	Atopic dermatitis, (COVID19) Systemic Lupus Erythem. psoriasis	Systemic Lupus Erythem.	Alopecia areata

CYP, liver metabolizing enzyme classification; T ½, terminal half life in serum-- (1) -in TNFa and [methotrexate](#) incomplete responders/resisten; t(2) as in (1) plus conventional synthetic DMARD incomplete responders/resistent

ER, extended release; IR, immediate release.

### Baricitinib

**Mechanism of Action:** [Baricitinib](#) is an anti-inflammatory, targeted, synthetic small molecule (tsDMARD) that, in vitro, selectively and reversibly inhibits JAK1 and JAK3 more than JAK2 and also inhibits the JAK-STAT signaling pathway **Pharmacokinetics:** See [Table 36-3](#). Only about 10% of [baricitinib](#) is metabolized via CYP3A4, so drug interactions are not usually significant. It is excreted mainly by the kidneys, so it should be used cautiously if at all in patients whose glomerular filtration rate is <60 mL/min/1.73 m<sup>2</sup>. **Indications and Dosage:** see [Table 36-3](#). In a randomized controlled trial, [baricitinib](#) was more effective than [adalimumab](#) for ACR20 response at 12 weeks. The FDA-approved dose of [baricitinib](#) for RA is 2 mg daily in the USA, and its efficacy at this dose is controversial; in Europe, 2 and 4 mg daily are used. It can be used as monotherapy or in combination with [methotrexate](#) or other csDMARDs (eg, [leflunomide](#), [hydroxychloroquine](#)). **Adverse Effects:** See introduction. A large study of patients receiving [baricitinib](#) found no association with major cardiovascular events, arterial thrombotic events, or congestive heart failure.

### Tofacitinib

**Mechanism of Action:** [Tofacitinib](#) is a targeted synthetic small molecule (tsDMARD) that selectively inhibits all members of the Janus kinase (JAK; see [Chapter 2](#)) family to varying degrees. At therapeutic doses, [tofacitinib](#) exerts its effect mainly by inhibiting JAK 1, 2, and 3, hence interrupting the JAK-STAT signaling pathway. This pathway plays a major role in the pathogenesis of autoimmune diseases including RA. The JAK3/JAK1 complex is responsible for signal transduction from the common chain receptor (IL-2RG) for IL-2, -4, -7, -9, -15, and -21, which subsequently blocks phosphorylation, as well as transcription of several genes that are crucial for the differentiation, proliferation, and function of NK cells and T and B lymphocytes. In addition, JAK1 (in combination with other JAKs) controls signal transduction from IL-6 and interferon receptors. RA patients receiving

**tofacitinib** rapidly reduce C-reactive protein concentrations. **Pharmacokinetics:** Patients taking CYP enzyme inhibitors and those with moderate hepatic or renal impairment require dose reduction to 5 mg once daily. **Tofacitinib** demonstrates high protein binding compared with the other JAK inhibitors indicates that dialysis may be less effective than for **Baricitinib** or **upadacitinib**. It should not be given to patients with severe hepatic disease. **Indications and Dosage:** See introduction to this section and **Table 36–3**. **Tofacitinib** can be used as monotherapy or in combination with other csDMARDs, including **methotrexate**. The recommended dose of **tofacitinib** in the treatment of RA and PsA is 5 mg twice daily (not 10 mg bid). In 2016, the FDA approved extended-release (XR) **tofacitinib** citrate 11-mg tablets for once-daily treatment. Its use at 10 mg bid in ulcerative colitis is being reconsidered. **Adverse Effects:** See introduction. **Tofacitinib** has thus far not been used with potent immunosuppressants (eg, **azathioprine**, **cyclosporine**) or biologic bDMARDs (except in one small case series). **Tofacitinib** increases the risk of EBV in renal transplant patients, particularly in combination with **prednisone**. A ~5000-patient study in RA patients at risk for cardiac disease demonstrated that, compared to TNF inhibitors, 10-mg bid dosing increased risk for cardiac events, thromboses, pulmonary emboli, and nonmelanotic skin cancers, while 5 mg bid did not demonstrate any of these risks except for nonmelanotic skin cancers. Lymphoma and other malignancies have been reported.

## Upadacitinib

**Mechanism of Action:** **Upadacitinib** is a small, second-generation Janus kinase selective inhibitor inhibiting JAK 1 and 2 > 3 at usual therapeutic doses, thereby blocking the processes that lead to inflammation in RA and other immune-mediated inflammatory diseases.

**Pharmacokinetics:** See **Table 36–3**. **Upadacitinib** is 79% excreted unchanged in the urine and feces. With little CYP metabolism, drug interactions are unlikely. **Indications and Dosage:** See **Table 36–3**. The recommended daily dosage is 15 mg. One RCT indicated that it was more effective than **abatacept**. **Adverse Effects:** See **Table 36–3**. Serious infections can be seen in patients administered 30 mg in randomized controlled trials. The use of **upadacitinib** with biologic DMARDs is not recommended, and it should be discontinued before administration of a live attenuated vaccine.

## LEFLUNOMIDE

**Mechanism of Action:** **Leflunomide**, another csDMARD, is rapidly converted to its active metabolite, A77 1726, in the intestines and plasma. A77 1726 inhibits dihydroorotate dehydrogenase, leading to decreased ribonucleic acid synthesis and arrest of cells in the G<sub>1</sub> phase of cell growth. **Leflunomide** therefore inhibits T-cell proliferation, reduces B-cell antibody production, increases IL-10 receptor mRNA, decreases IL-8 receptor mRNA, and decreases TNF- $\alpha$ -dependent NF- $\kappa$ B activation. **Pharmacokinetics:** **Leflunomide** oral tablets are 80% absorbed with a mean plasma half-life of 19 days for both parent drug and its active metabolite. It undergoes enterohepatic recirculation. Cholestyramine decreases half-life to about 1 day.

**Indications and Dosage:** **Leflunomide** equals **methotrexate** in efficacy in RA, including inhibition of bony erosions. **Methotrexate** plus **leflunomide** more than doubled the ACR 20 response in patients receiving **methotrexate** alone (46.2% versus 19.5%). In lupus nephritis, **cyclophosphamide** and **leflunomide** were comparably effective, and **leflunomide** was relatively safe. **Leflunomide** has been used in giant cell arteritis, Takayasu arteritis, dermatomyositis, and myasthenia gravis. **Adverse Effects:** Diarrhea occurs in 25%, although only 3–5% discontinue the drug secondary to diarrhea. Diarrhea and liver function test abnormalities are reduced by decreasing the **leflunomide** dose. Mitochondrial dysfunction may be responsible for **leflunomide**'s hepatotoxicity. Leukopenia and thrombocytopenia occur rarely. Mild alopecia, weight gain, and increased blood pressure occur. A meta-analysis found no evidence of the previously reported increased in respiratory adverse events, either infectious or noninfectious.

## MESALAMINE

**Mechanism of Action:** **Mesalamine**, an aminosalicylate (5-aminosalicylic acid), is hypothesized to have a topical anti-inflammatory effect on colonic epithelial cells, decreasing the synthesis of prostaglandins and leukotrienes. Other potential mechanisms include reducing the activity of NF- $\kappa$ B, and inhibition of TNF, thereby inhibiting the cellular functions of mucosal lymphocytes, macrophages, and natural killer cells. **Pharmacokinetics:** **Mesalamine** is rapidly metabolized in the intestinal mucosal wall and the liver with an absorption of 20–30% and metabolism to inactive metabolites. **Mesalamine**'s mean elimination half-life is ~25 hours. **Indications and Dosage:** **Mesalamine** is indicated for the treatment of ulcerative colitis. It has been used, off label, in Crohn disease. **Mesalamine** can be supplemented with other drugs such as topical or oral glucocorticoids, oral 5-ASA, **budesonide** multimatrix, or a TNF $\alpha$  inhibitor. **Adverse Effects:** The most common effects are diarrhea, headache, nausea, abdominal pain, dyspepsia, vomiting, and rash. Renal impairment, including interstitial nephritis, nephrotic syndrome, and renal failure, can be seen and must be carefully monitored.

## METHOTREXATE (MTX)

**Methotrexate** is a very important csDMARD used in a wide variety of conditions (see [Chapters 54](#) and [55](#)). **Mechanism of Action:** Low-dose **methotrexate** inhibits amino-imidazole-carboxamide-ribonucleotide (AICAR) transformylase and thymidylate synthetase. This ultimately leads to extracellular AMP accumulation, which inhibits inflammation, suppressing neutrophil, macrophage, dendritic cell, and lymphocyte function. It secondarily affects polymorphonuclear chemotaxis. MTX directly inhibits proliferation and stimulates apoptosis while its effects on dihydrofolate reductase are relatively minor at rheumatic disease doses. **Pharmacokinetics:** **Methotrexate** is administered orally, subcutaneously, or intramuscularly. It is approximately 70% absorbed after oral administration. MTX and a less active metabolite are polyglutamated and then retained in cells for prolonged periods. MTX serum half-life is 6–9 hours, although **hydroxychloroquine** can reduce **methotrexate** clearance. **Methotrexate** is excreted principally in the urine but up to 30% may be excreted in the bile. **Indications and Dosage:** **Methotrexate** oral treatment begins with 7.5 mg weekly and is increased to 15–25 mg weekly. While there is an increased effect up to 30–35 mg weekly, there is also increased toxicity. It decreases the rate of appearance of new erosions in RA. It effectively decreases skin involvement in SSC. Some evidence supports its use in JIA, psoriasis, psoriatic arthritis, peripheral joint disease in AS (not axial disease), granulomatosis with polyangiitis (formerly Wegener granulomatosis), polymyositis, giant cell arteritis, SLE, and vasculitis. Response in RA is predicted by seronegativity, high baseline disease activity, high anxiety scores, and genetic factors. **Adverse Effects:** Nausea and stomatitis are the most common toxicities. Other side effects such as leukopenia, anemia, GI ulceration, and alopecia result from inhibiting cellular proliferation. Dose-related liver enzyme elevations occur frequently. Stomatitis and GI and liver function test abnormalities can be reduced by leucovorin or folic acid, although this may decrease **methotrexate** efficacy by 10–18%. **Methotrexate** toxicity in RA is increased in patients who have increased mutations in cytochrome P450 genes (*CYP20A1*, *CYP39A1*), solute carrier genes (*SLC22A2*, *SLC7A7*), and the mitochondrial aldehyde dehydrogenase gene (*ALDH2*). **Methotrexate** is contraindicated in pregnancy.

## MYCOPHENOLATE MOFETIL

**Mechanism of Action:** **Mycophenolate** mofetil (MMF), a csDMARD, is converted to mycophenolic acid (MPA), the active form of the drug. The active product inhibits inosine monophosphate dehydrogenase (IMPDH), leading to suppression of T- and B-lymphocyte proliferation. Downstream, it interferes with leukocyte adhesion to endothelial cells through inhibition of E-selectin, P-selectin, and intercellular adhesion molecule.

**Pharmacokinetics:** MMF's pharmacokinetics and toxicities are discussed in [Chapter 55](#). **Indications and Dosage:** MMF is indicated in renal and nonrenal SLE (possibly including neuropsychiatric manifestations). It is supplied as 500-mg tablets when used as **mycophenolate** mofetil and 375 mg as mycophenolic acid; 375 mg of the acid is equivalent to 500 mg of **mycophenolate** mofetil. As **mycophenolate** mofetil, dosing is 1000–1500 mg bid and is effective for interstitial lung disease and skin thickening in scleroderma. It has been used in vasculitis, Takayasu arteritis, granulomatous polyangiitis, polymyositis, and dermatomyositis. There is no convincing evidence that MMF is effective in RA. **Adverse Effects:** MMF is associated with GI symptoms (nausea, dyspepsia, abdominal pain), hepatotoxicity, hematologic effects (leukopenia, thrombocytopenia, anemia), and serious infections. It is very rarely associated with malignancy. It is contraindicated in pregnancy.

## RITUXIMAB (RTX)

**Mechanism of Action:** **Rituximab** is a chimeric monoclonal antibody biologic agent (bDMARD) that targets CD20 B-lymphocytes (see [Chapter 55](#)) through cell-mediated and complement-dependent cytotoxicity and stimulation of cell apoptosis. Depletion of B lymphocytes reduces inflammation by decreasing the presentation of antigens to T-lymphocytes and inhibiting the secretion of proinflammatory cytokines. **Rituximab** rapidly depletes peripheral B-cells (uncorrelated with efficacy or toxicity) and synovial tissue B-cell counts, which do correlate with response in RA.

**Pharmacokinetics:** For rheumatoid arthritis, **rituximab** is given as two intravenous infusions of 1000 mg, separated by 2 weeks. Repeated courses remain effective. For induction therapy in GPA and microscopic polyangiitis, it is given IV, 375 mg/m<sup>2</sup> once weekly for 4 doses. Pretreatment with **acetaminophen**, an antihistamine, and an H<sub>2</sub> blocker, given 30 minutes prior to infusion decreases the incidence and severity of infusion reactions.

**Indications and Dosage:** RTX plus **methotrexate** treats RA, and RTX with glucocorticoids is approved for GPA and microscopic polyangiitis. In the rheumatic diseases (although different from oncologic practice), RTX is given as 1000 mg with 100 mg methylprednisone infused over several hours. A single course consists of two doses given 2 weeks apart, and courses are given every 6 months, although spacing of doses has varied from every 4 months to every 9 months (or even longer when disease control is achieved). Trials have used single doses and lower doses (as low as 200 mg) after remission was achieved in RA. RA-interstitial lung disease (ILD) was stabilized or improved in an observational study. It has been used for CD20-positive B-cell non-Hodgkin lymphoma (NHL), chronic lymphocytic leukemia (CLL), pemphigus vulgaris, refractory lupus nephritis, Sjögren syndrome, idiopathic inflammatory myositis (including with ILD), IgG4-related disease, and systemic sclerosis. **Adverse Effects:** About 30% of patients develop rash (usually not requiring discontinuation) with the first RTX dose, but rash incidence progressively decreases with each course of therapy thereafter. Urticaria or anaphylactic reactions can occur, as can fatal Stevens-Johnson syndrome. Very low IgG/IgM concentrations may be associated with infection, and IgG/IgM concentrations should be monitored. Serious and even fatal bacterial, fungal, and viral infections have been reported rarely.

www.konkur.in associated with reactivation of hepatitis B, so ongoing treatment of hepatitis B is appropriate and monitoring for several months after treatment termination is necessary. **Rituximab** has not been associated with activation of tuberculosis or the de novo occurrence of lymphoma or other tumors (see [Chapter 55](#)).

## SARILUMAB

**Mechanism of Action:** IL-6 is a proinflammatory cytokine active in the pathogenesis of RA. **Sarilumab** is an IL-6 receptor antagonist bDMARD that binds to both soluble and membrane-bound IL-6 receptors, thus inhibiting IL-6-mediated signaling. **Pharmacokinetics:** **Sarilumab** has a concentration-dependent half-life of 8–10 days with an estimated absolute bioavailability of 80%. **Indications and Dosage:** **Sarilumab** is effective in rheumatoid arthritis, either as monotherapy or in combination with [methotrexate](#) or other csDMARDs. **Sarilumab** monotherapy appears to be superior to [adalimumab](#) monotherapy in RA patients. The recommended dosage is 200 mg once every 2 weeks, administered subcutaneously. **Adverse Effects:** The most common adverse effect of [sarilumab](#) is infection. **Sarilumab** may result in neutropenia, thrombocytopenia, and anemia. Transaminitis >1.5 times higher than normal can occur and should be monitored. Elevated triglycerides and LDL have been reported, and lipids should be tested regularly and treated if abnormal. Perforation with diverticulitis has been reported, although careful studies attribute most of this adverse event to the concomitant use of corticosteroids. Nevertheless, patients with diverticulitis should not be given [sarilumab](#). Malignancies have been observed.

## SECUKINUMAB

**Mechanism of Action:** **Secukinumab** is a human IgG<sub>1</sub> monoclonal antibody bDMARD that selectively binds to the IL-17A cytokine, inhibiting its interaction with the IL-17A receptor. IL-17A is involved in normal inflammatory and immune responses. **Pharmacokinetics:** **Secukinumab** is available as a prefilled SC injection or as lyophilized powder for SC injection. Pharmacokinetics are linear, and elimination half-life is 22–31 days. Bioavailability ranged from 55% to 77% following the SC dose of 150 or 300 mg. **Indications and Dosage:** **Secukinumab** is indicated for moderate to severe plaque psoriasis, or, psoriatic arthritis, ankylosing spondylitis, and nonradiographic axial spondyloarthritis (nr-axSpA) and has been shown to be effective in Ra. An initial loading dose is weekly 300 mg SC for weeks 0–4, followed by 150–300 mg SC monthly. **Sarilumab** can be used with or without MTX. **Adverse Effects:** As for any of these biologics, infection is a common side effect (28.7%). Nasopharyngitis occurs in about 12%. TB status should be evaluated prior to therapy. **Secukinumab** may cause or exacerbate inflammatory bowel disease.

## SULFASALAZINE

**Mechanism of Action:** **Sulfasalazine**, a csDMARD, is metabolized to sulfapyridine (which may be its active moiety in RA) and 5-aminosalicylic acid (see [Chapter 62](#) and [Figure 62–8](#)). Some authorities believe that the parent compound, [sulfasalazine](#), also has an effect. 5-aminosalicylic acid is thought to be the active moiety in inflammatory bowel disease, acting by inhibiting the proinflammatory NK-KBs signaling pathway and inhibiting T-cell response to concanavalin and B-cell proliferation, secondarily suppressing the production of IgM and IgG in vitro. Production and release of [sulfasalazine](#) and its metabolites also inhibits inflammatory cytokine monocytes/macrophages (eg, IL-1, -6, -8, -11, -12), growth-related gene protein and TNF in vitro. **Pharmacokinetics:** Only 5–13% of orally administered [sulfasalazine](#) is absorbed. **Sulfasalazine** undergoes enterohepatic recirculation. Sulfapyridine is nearly completely absorbed, and its inherited slow acetylator phenotype accounts for most of [sulfasalazine](#)'s toxicity. Lack of intact colon or use of antibiotics will increase its toxicity, and genetic phenotype can help guide therapy. 5-aminosalicylic acid remains unabsorbed. Some [sulfasalazine](#) is excreted unchanged in the urine, whereas sulfapyridine is excreted after hepatic acetylation and hydroxylation. **Sulfasalazine**'s half-life is 6–17 hours. **Indications and Dosage:** **Sulfasalazine**, 2–3 g/day, is effective in RA and reduces radiologic disease progression. It has also been used in reactive arthritis, JIA, inflammatory bowel disease (FDA approved for ulcerative colitis but not for Crohn disease), gastrointestinal Behçet disease, and HLA-B27-positive anterior uveitis with AS. It decreases platelet aggregation. **Adverse Effects:** Approximately 30% of patients using [sulfasalazine](#) discontinue the drug because of toxicity. Common adverse effects include nausea, vomiting, headache, and rash. The most serious skin hypersensitivity reaction is toxic epidermal necrosis. Hemolytic anemia and methemoglobinemia also occur rarely, Neutropenia occurs in 1–5% of patients, and even agranulocytosis has been documented (particularly in HLA-B 08.01 and HLA-AN 31.01 patients). Pulmonary toxicity and positive double-stranded DNA (dsDNA) are occasionally seen, but drug-induced lupus is rare. Reversible infertility occurs in men, but [sulfasalazine](#) does not affect fertility in women. The drug appears relatively safe in pregnancy.

## TNF- $\alpha$ -BLOCKING AGENTS

TNF- $\alpha$  appears to be particularly important in the inflammatory process associated with rheumatoid arthritis. TNF- $\alpha$  affects cellular function via activation of specific membrane-bound TNF receptors (TNFR<sub>1</sub>, TNFR<sub>2</sub>). Five legacy bDMARDs interfering with TNF- $\alpha$  have been approved for the treatment of RA and other rheumatic diseases (Figure 36-4). Biosimilar biologics (bsDMARDs) with lower costs are available in many countries and, at least hypothetically, should decrease cost. The efficacy, toxicity, and immunogenicity of the biosimilars have been found to be equivalent to those of the legacy compounds. TNF- $\alpha$  inhibitors have many adverse effects in common, and these will be treated similarly, with comments for exceptions (see below).

FIGURE 36-4

Structures of TNF- $\alpha$  antagonists used in rheumatoid arthritis. C<sub>H</sub>, constant heavy chain; C<sub>L</sub>, constant light chain; F<sub>C</sub>, complex immunoglobulin region; V<sub>H</sub>, variable heavy chain; V<sub>L</sub>, variable light chain. Red regions, human derived; blue regions, mouse derived; green regions, polyethylene glycol (PEG).

## Adalimumab

**Mechanism of Action:** Adalimumab is a fully human, IgG, anti-TNF monoclonal antibody. This compound complexes with both soluble and membrane-bound TNF and prevents interaction with p55 and p75 cell surface TNF receptors, downregulating macrophage and T-cell function.

**Pharmacokinetics:** Adalimumab SC has a half-life of 10–20 days. Absolute bioavailability is 64%. MTX inhibits adalimumab clearance. **Indications and Dosage:** The compound is approved for RA, AS, PsA, JIA, uveitis, hidradenitis suppurativa, plaque psoriasis, Crohn disease, and ulcerative colitis. It decreases the rate of formation of new erosions in RA in both reports and case series. Adalimumab has also been used in Behçet disease, sarcoidosis, and noninfectious uveitis. The usual dose in RA, PsA, and AS is 40 mg every other week, but it is frequently increased to 40 mg weekly (despite the increased cost). In psoriasis, 80 mg is given at week 0, 40 mg at week 1, and then 40 mg every 20 weeks. The initial dose in inflammatory bowel disease is higher: patients receive 160 mg at week 0, 80 mg 2 weeks later, and 40-mg maintenance treatment beyond 8 weeks if they are in remission by that time. Adalimumab dosage depends on body weight in patients with JIA or uveitis. **Adverse Effects:** Adalimumab increases the risk of serious infections—in particular latent TB reactivation, deep fungal infections, worsening or initiation of multiple sclerosis/neurologic diseases, and heart failure. Other uncommon to rare adverse effects include headache, rash, possibly lymphoma, and lupus-like syndrome.

**Mechanism of Action:** Certolizumab is a recombinant, humanized antibody Fab fragment conjugated to polyethylene glycol (PEG) with specificity for human TNF- $\alpha$ . Certolizumab neutralizes membrane-bound and soluble TNF- $\alpha$  in a dose-dependent manner. Additionally, certolizumab does not contain an F<sub>c</sub> region and does not fix complement or cause antibody-dependent cell-mediated cytotoxicity in vitro. **Pharmacokinetics:** Certolizumab is given subcutaneously and has a half-life of 14 days. **Methotrexate** decreases the appearance of anti-certolizumab antibodies. To a very large degree, it does not cross into breast milk or cross the placenta. **Indications and Dosage:** Certolizumab is FDA approved in RA, Crohn disease, plaque psoriasis, PsA, and AS as well as in nonradiographic axial spondyloarthritis. It can be used as monotherapy or in combination with csDMARDs. A trial in moderate to severe MTX-incomplete-responder RA patients comparing **adalimumab** plus MTX to certolizumab plus MTX showed ACR20 responses at 3 months and achievement of low disease activity at 2 years that were comparable for both treatments. Unfortunately, confounding factors prevent definitive conclusions from this trial. Certolizumab has no to minimal placental transfer from mothers to the fetus, thus suggesting it as a good TNF inhibitor during pregnancy. It also has low to minimal transfer from plasma to breast milk. The usual dose for RA is 400 mg initially and at weeks 2 and 4, followed by 200 mg every other week, or 400 mg every 4 weeks.

## Etanercept

**Mechanism of action:** **Etanercept** is a recombinant fusion protein consisting of two soluble TNF p75 receptor moieties linked to the F portion of human IgG (see [Figure 36-4](#)); it binds TNF and molecules and also inhibits lymphotoxin. **Pharmacokinetics:** After subcutaneous administration, the drug is slowly absorbed, with peak concentrations at 72 hours. **Indications and Dosage:** **Etanercept** is approved for the treatment of RA, juvenile chronic arthritis, psoriasis, PsA, and AS. It can be used as monotherapy. However, **ustekinumab** (an IL-12 and 23 inhibitor) receiving **methotrexate**. **Etanercept** decreases the rate of formation of new erosions relative to **methotrexate** alone. It is also being used in other rheumatic syndromes including granulomatosis with polyangiitis (Wegener granulomatosis). **Ustekinumab** was superior to high-dose **etanercept** over a 12-week period in psoriasis. In nonradiographic axial spondylarthritis, **etanercept** decreased sacroiliac MRI erosions compared with placebo. **Etanercept** is usually given as 50 mg weekly in RA. In psoriasis, 50 mg is given twice weekly for 12 weeks. **Adverse Effects:** Common adverse effects include viral, bacterial, or fungal infections, as well as injection-site reactions. Other rare adverse effects include GI problems, skin rashes, lupus-like syndrome, pancytopenia, and lymphoma.

## Golimumab

**Mechanism of Action:** **Golimumab** is a human monoclonal antibody with a high affinity for soluble and membrane-bound TNF- $\alpha$ . **Golimumab** effectively reduces the inflammatory effects produced by TNF- $\alpha$  seen in diseases such as RA, PsA (2 years or older), UC, and ankylosing spondylitis. **Pharmacokinetics:** **Golimumab** is administered subcutaneously or intravenously and has a half-life of approximately 14 days. **Indications and Dosage:** **Golimumab** with **methotrexate** treats moderately to severely active RA. It is used in PsA, AS, and moderate to severe ulcerative colitis. Concomitant **methotrexate** increases **golimumab** serum levels and decreases anti-golimumab antibodies. The recommended dose for RA, PsA, and AS is 50 mg given every 4 weeks or 2 mg/kg at weeks 0 and 4, and then every 8 weeks. A higher dose of **golimumab** is used to treat ulcerative colitis: 200 mg initially at week 0 followed by 100 mg at week 2 and every 4 weeks thereafter. **Adverse Effects:** Adverse effects (typical of all TNF inhibitors) include severe infections (including fungal infections and reactivation of tuberculosis), new onset or exacerbation of CHF, lupus-like syndrome, and worsening or new-onset demyelinated disorders.

## Infliximab

**Mechanism of Action:** **Infliximab** (see [Figure 36-4](#)) is a *E. coli*-derived chimeric (25% mouse, 75% human) IgG monoclonal antibody that binds and inhibits membrane-bound TNF. Its mechanism of action is probably the same as that of **adalimumab**. **Pharmacokinetics:** The terminal half-life of **infliximab** is 9–12 days. After intermittent therapy, **infliximab** elicits human antichimeric antibodies in up to 62% of patients. Concurrent therapy with **methotrexate** markedly decreases the prevalence of human antichimeric antibodies by 29% at 10 mg. **Infliximab** treats RA, AS, PsA, Crohn disease, ulcerative colitis, pediatric inflammatory bowel disease, and psoriasis. It is being used off-label in other diseases, including granulomatosis with polyangiitis (Wegener granulomatosis), giant cell arteritis, Behçet disease, and uveitis sarcoidosis. In RA, **infliximab** plus **methotrexate** decreases the rate of formation of new erosions. **Infliximab** is given as an intravenous infusion with induction at 0, 2, and 6 weeks and maintenance infusions every 8 weeks thereafter. Dose range is 3–5 mg/kg, and the usual frequency is every 8 weeks. Although it is recommended that **methotrexate** be used in conjunction with **infliximab**, several other csDMARDs, including antimalarials, **azathioprine**, **leflunomide**, and **cyclosporine**, can be used in conjunction with this drug. **Infliximab** is also used as monotherapy. **Adverse Effects of TNF- $\alpha$ -Blocking Agents:** TNF- $\alpha$ -blocking agents increase the risk of

bacterial infections. Macrophage-dependent infections (including tuberculosis and fungal and other opportunistic infections) are increased, although they remain very low. Activation of latent tuberculosis is lower with **etanercept** than with TNF- $\alpha$ -blocking agents. Nevertheless, all patients should be screened for latent or active tuberculosis before starting TNF- $\alpha$ -blocking agents. The use of TNF- $\alpha$ -blocking agents is also associated with increased risk of HBV reactivation; screening for HBV is important. TNF- $\alpha$ -blocking agents increase the risk for lymphoma and skin cancers, including melanoma, which necessitates periodic skin examination, especially in high-risk patients. The FDA has placed a black box warning on all anti-TNF agents regarding possible association with malignancies, especially lymphomas. A low incidence of newly formed dsDNA and antinuclear antibodies is well documented after TNF inhibitors, but clinical lupus is extremely rare, and the presence of such antibodies does not contraindicate their use. Rare cases of leukopenia, neutropenia, thrombocytopenia, and pancytopenia also have been reported. The precipitating drug should be discontinued.

## TOCILIZUMAB

**Mechanism of Action:** The bDMARD **tocilizumab** (TCZ) binds to soluble and membrane-bound IL-6 receptors, similar to **sarilumab** but with different affinities. It, too, inhibits IL-6–mediated signaling. **Pharmacokinetics:** TCZ is available as IV and SC formulations. The half-life of TCZ is 11 days (4 mg/kg) to 13 days (8 mg/kg). It stimulates CYP 450, which may be clinically relevant for drugs such as **cyclosporine** or **warfarin**, and dosage adjustment of these medications may be needed. **Indications and Dosage:** TCZ is available for rheumatoid arthritis, systemic sclerosis–associated interstitial lung disease, and giant cell arteritis (GCA) as well as active systemic JIA in patients >2 years old. TCZ can be used in combination with csDMARDs or as monotherapy in RA. It is clinically superior to **adalimumab** in **methotrexate** incomplete responders. In GCA, TCZ 162 mg subcutaneously every 1–2 weeks, combined with a 26-week **prednisone** taper, was effective to sustain glucocorticoid-free remission. In a phase 3 trial in patients with systemic sclerosis–associated interstitial lung disease, TCZ 162 mg was administered SC once every week. In the USA, RA dosing starts at 4 mg/kg IV and may be increased up to 8 mg/kg (maximum 800 mg). A clinical study successfully treated adult patients with COVID-19 pneumonia at a dose of 8 mg/kg IV. In Europe, the starting dose is 8 mg/kg with the same maximum dose. Subcutaneous dosing is 162 mg every 1–2 weeks. **Adverse Effects:** The most common adverse reactions are upper respiratory tract infections, headache, hypertension, and elevated liver enzymes. Serious infections including tuberculosis (prescreening requirement) and fungal, viral, and other opportunistic infections and thrombocytopenia occur occasionally, and lipids should be monitored. GI perforation has been reported when using **tocilizumab** or TNF inhibitors in patients with diverticulitis, although this is probably associated with glucocorticoid use, rather than TCZ per se. The manufacturer recommends discontinuing **tocilizumab** therapy if the ALT or AST reach 5 times the ULN, ANC <500 cells/mm<sup>3</sup>, or platelets <50,000 cells/mm<sup>3</sup> (more closely associated with corticosteroids than TCZ or TNF inhibitors). Demyelinating disorders including multiple sclerosis are rarely associated with **tocilizumab** use. Fewer than 1% of patients treated with **tocilizumab** develop anaphylactic reactions. Anti-tocilizumab antibodies develop in 2% of the patients, and these can be associated with hypersensitivity reactions requiring discontinuation.

## USTEKINUMAB

**Mechanism of Action:** **Ustekinumab** is a fully human IgG monoclonal IL-12 and IL-23 antagonist at the p-40 protein subunit. **Ustekinumab** prevents the binding of the p40 subunit of both IL-12 and IL-23 to IL-12R $\beta$ 1, which is found on the surface of CD4 T cells and NK cells and suppresses the formation of proinflammatory TH1 and TH17 cells. **Pharmacokinetics:** **Ustekinumab**'s bioavailability is 57% following SC injection; time to peak plasma concentration is 7–13.5 days and elimination half-life is 21 days. **Indications and Dosage:** **Ustekinumab** is indicated for treatment of adult patients with PsA as monotherapy or in combination with **methotrexate**. Other indications include plaque psoriasis, UC, and Crohn disease. It is used as an off-label treatment for giant cell arteritis, Behçet disease, SLE, pyoderma gangrenosum, Takayasu arteritis, lichen planus, synovitis, pustulosis, and atopic dermatitis. **Ustekinumab** was not effective in axial spondylarthritis. **Ustekinumab** is used at 45 or 90 mg >100 kg at 0 and 4 weeks and is followed by maintenance doses of 45–90 mg once every 12 weeks. IV infusion as a 260- to 520-mg initial dose followed by 90 mg SC is available for Crohn disease and UC. **Adverse Effects:** Upper respiratory tract infection is the most common side effect, but rare severe infection, malignancy, cryptogenic organizing pneumonia, interstitial or eosinophilic pneumonia, and reversible posterior leukoencephalopathy syndrome have been reported. **Ustekinumab** should be discontinued  $\geq$ 15 weeks before live vaccines are administered and can be resumed 2 weeks after.

## COMBINATION THERAPY WITH DMARDs

The 2015 ACR guidelines for the treatment of rheumatoid arthritis strongly recommend the use of combination traditional DMARDs (eg, **methotrexate**, **hydroxychloroquine**, **azathioprine**) or addition of TNF inhibitors, non-TNF biologics, or small molecules for patients with RA and moderate or high disease activity refractory to DMARD monotherapy. Combinations of DMARDs can be designed rationally on the basis of complementary mechanisms of action, nonoverlapping pharmacokinetics, and nonoverlapping toxicities. When added to **methotrexate** background therapy, **cyclosporine**,

hydroxychloroquine, hydroxychloroquine, leflunomide, infliximab, adalimumab, rituximab, and etanercept have all shown improved efficacy. Triple therapy with methotrexate, sulfasalazine, and hydroxychloroquine appears to be as effective, clinically, as etanercept and methotrexate, but radiologic outcomes may not be as good. In contrast, azathioprine or sulfasalazine plus methotrexate results in no additional therapeutic benefit. Other combinations have occasionally been used. While it might be anticipated that combination therapy could result in more toxicity, this is often not the case. Combination therapy for patients not responding adequately to monotherapy is now the rule in the treatment of RA.

## BIOSIMILARS

Biosimilars are biologic medications that are very similar in properties and actions to existing biologic medications, ie, they are designed to be generic versions of the original biologic molecule. These drugs offer a potential reduction in cost of bDMARDs thereby improving accessibility of these medications to patients. Thus far, these drugs appear to have the same efficacy and toxicity as the legacy compounds and the same degree of immunogenicity.

## GLUCOCORTICOID DRUGS (LIMITED TO RHEUMATIC DISEASES)

The general pharmacology of corticosteroids, including mechanism of action, pharmacokinetics, and other applications, as discussed in [Chapter 39](#). **Indications:** Corticosteroids are chronically used in 30–70% of RA patients. Their effects are prompt and dramatic, and they are capable of slowing the appearance of new bone erosions. Corticosteroids may be administered for certain serious extra-articular manifestations of RA such as pericarditis or eye involvement or during periods of exacerbation. When prednisone is required for long-term therapy of RA, the dosage should not exceed 7.5 mg daily, and gradual reduction of the dose should be encouraged. Even doses as low as 2.8 mg prednisone daily over more than 5 years are associated with severe infections. Alternate-day corticosteroid therapy is usually unsuccessful in RA. Other rheumatic diseases in which the corticosteroids' potent anti-inflammatory effects may be useful include vasculitis, SLE, polyangiitis with granulomatosis, PA, giant cell arteritis, sarcoidosis, and gout. Intra-articular corticosteroids are often helpful to alleviate painful symptoms for up to several months. A recent approach uses delayed-release prednisone for the treatment of early morning stiffness and pain in RA. By releasing a pulse of prednisone between 2:00 AM and 4:00 AM, the circadian inflammatory cytokine are decreased. At low doses of 3–5 mg prednisone, the adrenal-pituitary axis does not seem to be impacted. Adrenal function generally recovers by the slow tapering of glucocorticoids, although symptoms independent of adrenal insufficiency may occur at dose as low as 1 mg daily prednisone. **Adverse Effects:** Adverse effect seen are both dose- and time-dependent: weight gain and epistaxis at >5 mg daily; glaucoma, depression, and hypertension at >7.8 mg daily. Prolonged use of corticosteroids leads to serious and disabling toxic effects as described in [Chapter 39](#). Many of these adverse effects occur at doses below 7.5 mg prednisone equivalent daily, and some data show 3 mg or fewer daily. Prednisone can cause effects when used over prolonged periods. Most common adverse effect on long-term glucocorticoids include osteoporosis, myopathy, osteonecrosis, hyperglycemia, Cushing syndrome, life-threatening infections, fluid retention, impaired wound healing, skin thinning and atrophy, increased risk of cataract, glaucoma, gastric ulcer, and depression.

## OTHER ANALGESICS

**Acetaminophen** (also known as **paracetamol**) is one of the most important drugs used in the treatment of mild to moderate pain when an anti-inflammatory effect is not necessary. **Phenacetin** (acetophenetidin), a prodrug that is metabolized to acetaminophen, is more toxic and should not be used.

## ACETAMINOPHEN

**Mechanism of Action:** Acetaminophen is the active metabolite of phenacetin and is responsible for its analgesic effect. It is a weak COX-1 and COX-2 inhibitor in peripheral tissues. Its antinociceptive effects are also due to interactions with the endogenous opioid, cannabinoid, and serotonergic systems. Acetaminophen is antipyretic but possesses no significant anti-inflammatory effects. **Pharmacokinetics:** Acetaminophen is administered orally and is also available for IV injection. After oral administration peak blood concentrations are usually reached in 30–60 minutes. Acetaminophen is poorly bound to plasma proteins and is partially metabolized by hepatic microsomal enzymes to the inactive sulfate and glucuronide (see [Figure 4–5](#)). Less than 5% is excreted unchanged. In large doses, a minor but highly reactive metabolite (*N*-acetyl-*p*-benzoquinone) is important because it is toxic to both liver and kidney (see [Chapter 4](#)). The half-life of acetaminophen is 2–3 hours and is relatively unaffected by renal function. With toxic doses or liver disease, the half-life may be increased twofold or more.

**Indications and Dosage:** **Acetaminophen** is said to be equivalent to **aspirin** as an analgesic and antipyretic agent. It does not affect uric acid levels and lacks platelet-inhibiting effects. The drug is useful in mild to moderate pain such as headache, myalgia, postpartum pain, and other circumstances in which **aspirin** is an effective analgesic. **Acetaminophen** alone is inadequate therapy for inflammatory conditions such as RA. For mild analgesia, **acetaminophen** is the preferred drug in patients allergic to **aspirin**, when salicylates are poorly tolerated. It is preferable to **aspirin** in patients with hemophilia, in those with a history of peptic ulcer, and in those in whom bronchospasm is precipitated by **aspirin**. Unlike **aspirin**, **acetaminophen** does not antagonize the effects of uricosuric agents. Recently, **acetaminophen** has been combined with an NSAID for better pain management; however, this can potentiate the gastrointestinal toxicity of the NSAID. Acute pain and fever may be effectively treated with 325–500 mg four times daily and proportionately less for children. Dosing in adults is recommended not to exceed 4 g/d in most cases. **Adverse Effects:** In therapeutic doses, a mild reversible increase in hepatic enzymes may occasionally occur. With larger doses, dizziness, excitement, and disorientation may occur. Ingestion of 15 g of **acetaminophen** may be fatal, death being caused by severe hepatotoxicity with centrilobular necrosis, sometimes associated with acute renal tubular necrosis (see **Chapters 4** and **58**). Present data indicate that even 4 g **acetaminophen** is associated with increased liver function test abnormalities. Early symptoms of hepatic damage include nausea, vomiting, diarrhea, and abdominal pain. Cases of renal damage without hepatic damage have occurred, even after usual doses of **acetaminophen**. High doses of **acetaminophen** can promote oxidative stress and damage cells in the brain. For overdose, in addition to supportive therapy, one should provide sulfhydryl groups in the form of **acetylcysteine** to neutralize the toxic metabolites (see **Chapter 58**). Hemolytic anemia, methemoglobinemia, anaphylaxis, and serious skin reactions are very rare adverse events. Interstitial nephritis and papillary necrosis—serious complications of phenacetin—have *not* occurred. Caution is necessary in patients with any type of liver disease, significant **alcohol** consumption, or malnutrition (prolonged fasting, anorexia).

## KETOROLAC

**Mechanism of Action:** **Ketorolac** is an analgesic NSAID that decreases inflammation by inhibiting the cyclooxygenase (COX) enzyme; unlike the NSAIDs discussed earlier, it is used almost exclusively as an analgesic. **Pharmacokinetics:** It can be administered intravenously, intramuscularly, intranasally, orally, or as an ophthalmic; it has a half-life of 5–6 hours. **Ketorolac** is partly metabolized by the liver and about 90% is excreted by the kidneys, with 60% unchanged. **Indications and Dosage:** It can be used as an adjuvant with opioids, other nonopioid analgesics, local anesthetics, and other NSAIDs for pain relief. The recommended initial dose is 30 mg IV, 60 mg IM, or one 15.75-mg spray in each nostril, then 15–30 mg given every 6–8 hours and a maximum daily dose of 120 mg. The initial dose should not be administered orally; an IV or IM dose should be given first, then 10 mg PO every 6 hours. All doses should be halved in those older than 65, with a body mass less than 50 kg, or with renal impairment. **Adverse Effects:** Toxicities are similar to those of other NSAIDs (see page 676), although renal toxicity is more common with chronic use. It has less toxicity than **morphine**, but its use should not exceed 5 days.

## TRAMADOL

**Mechanism of Action:** **Tramadol** is a centrally acting synthetic analgesic with a weak affinity for  $\mu$ -opioid receptors (see **Chapter 31**). It also acts on serotonin (5-HT) and **norepinephrine** receptors by reuptake inhibition. **Indications and Dosage:** **Tramadol** is used in the treatment of acute and chronic pain but does not have significant anti-inflammatory effects. The dose is up to 300mg a day with an elimination half-life of about 6 hours. **Adverse Effects:** **Tramadol** has fewer side effects and lower addiction potential than classic opioids. **Tramadol**'s most common side effects include nausea, vomiting, vertigo, dizziness, tiredness, sedation, dry mouth, constipation and sweating which tends to occur during the initial treatment period. Other adverse effects include serotonin syndrome, seizures, exacerbated anticoagulant effect, and angioedema.

## DRUGS USED IN GOUT

Gout is a metabolic disease characterized by recurrent episodes of acute arthritis due to deposits of monosodium urate in joints and cartilage. Uric acid renal calculi, tophi, and interstitial nephritis also may occur. Adverse cardiovascular outcomes are becoming more evident as well. Gout is usually associated with a high serum uric acid level (hyperuricemia), a poorly soluble substance that is the major end product of purine metabolism. In most mammals, uricase converts acid to the more soluble allantoin; uricase is absent in humans. While clinical gouty episodes are associated with

The treatment of gout aims to relieve acute gouty attacks and prevent recurrent gouty episodes and urate lithiasis. Therapies for acute gout are based on our current understanding of the pathophysiologic events that occur in this disease (Figure 36-5). Clinical gout is dependent on a macromolecular complex of proteins, called NLRP3, which regulates the activation of IL-1. Urate crystals activate NLRP3, resulting in release of prostaglandins and lysosomal enzymes by synoviocytes. Attracted by these chemotactic mediators, polymorphonuclear leukocytes migrate into the joint space and amplify the ongoing inflammatory process. In the later phases of the attack, increased numbers of mononuclear phagocytes (macrophages) appear, ingest the urate crystals, and release more inflammatory mediators.

FIGURE 36-5

Pathophysiologic events in a gouty joint. Synoviocytes phagocytose urate crystals and then secrete inflammatory mediators, which attract and activate polymorphonuclear leukocytes (PMN) and mononuclear phagocytes (MNP) (macrophages). Drugs active in gout inhibit crystal phagocytosis and polymorphonuclear leukocyte and macrophage release of inflammatory mediators. PG, prostaglandin; IL-1, interleukin-1; LTB<sub>4</sub>, leukotriene B<sub>4</sub>.

Before starting chronic urate-lowering therapy for gout, patients in whom hyperuricemia is associated with gout and urate lithiasis must be clearly distinguished from individuals with only hyperuricemia. The efficacy of long-term drug treatment in an asymptomatic hyperuricemic person is unproven. Although there are data suggesting a clear relationship between the degree of uric acid elevation and the likelihood of clinical gout, in some individuals, uric acid levels may be elevated up to two standard deviations above the mean for a lifetime without adverse consequences. Many different agents have been used for the treatment of acute and chronic gout. However, nonadherence to these drugs is exceedingly common; adherence has been documented to be 18–26% in younger patients. Providers should be aware of compliance as an important issue.

## ALLOPURINOL

**Mechanism of Action:** Xanthine oxidase is responsible for the conversion of xanthine and hypoxanthine to uric acid. **Allopurinol** is a purine analogue that inhibits this enzyme, resulting in a fall in the plasma urate level and a decrease in the overall urate burden. The result of xanthine oxidase inhibition is a build-up of its substrates, the more soluble xanthine and hypoxanthine. **Pharmacokinetics:** The structure of **allopurinol**, an isomer of hypoxanthine, is shown in Figure 36-7. **Allopurinol** is approximately 80% absorbed after oral administration and has a terminal serum half-life of 1–2 hours. **Allopurinol** is metabolized by xanthine oxidase to alloxanthine (oxypurinol) with a half-life of 15 hours, which also inhibits xanthine oxidase; its duration of action is >24 hours so that **allopurinol** is given only once a day. It is renally cleared. **Indications and Dosage:** **Allopurinol** is often the first-line agent for the treatment of chronic gout in the period between attacks, and it tends to prolong the intercritical period. Therapy is continued for years if not for life. When initiating **allopurinol**, **colchicine** or an NSAID should be used until steady state serum uric acid is normalized or decreased to <6 mg/dL in patients with gout and <5 mg/dL in patients with tophaceous gout, and an NSAID or **colchicine** should be continued for 6 months or longer. Thereafter, **colchicine** or the NSAID can be cautiously stopped while continuing **allopurinol** therapy. The recommended initial dosage of **allopurinol** is 100 mg/d. It should be titrated upward by 100 mg/d every 2–5 weeks until serum uric acid <6 mg/dL or 800 mg/d is reached. For those with chronic kidney disease, the initial dose should not be >50 mg/d and the titrations should be of 50 mg/d. **Adverse Effects:** In addition to precipitating gout (the

concomitant use of **colchicine** or NSAID), GI intolerance (including nausea, vomiting, and diarrhea), peripheral neuritis, necrotizing vasculitis, bone marrow suppression, and aplastic anemia may rarely occur. Hepatic toxicity and interstitial nephritis have been reported. A current tenant allergic skin reaction characterized by pruritic lesions occurs in 3% of patients. Isolated cases of exfoliative dermatitis have been reported. In very rare cases, **allopurinol** has become bound to the lens, resulting in cataracts. **Allopurinol** hypersensitivity syndrome (AHS) is very rare but can be lethal. AHS is characterized by Stevens-Johnson syndrome and toxic epidermal necrolysis, eosinophils leukocytes, fever, hepatitis, and renal failure. These symptoms typically occur within 2–4 weeks after starting therapy, and the FDA recommends **allopurinol** to be stopped at the first sign of a rash. Factors that increase the risk for AHAS are higher starting doses; renal dysfunction; concomitant use of diuretics, **amoxicillin**, or **ampicillin**; and HLA-B 5801 genotype. The FDA recommends that patients of Han Chinese, Korean, or Thai descent should be screened for the HLA-B 5801 genotype (because of the high prevalence in these populations), and **allopurinol** should not be used with a positive test. When chemotherapeutic purines (eg, **azathioprine**) are given concomitantly with **allopurinol**, dosage must be reduced by 75%. **Allopurinol** may also increase the effect of **cyclophosphamide**. **Allopurinol** inhibits the metabolism of **probenecid** and oral anticoagulants and may increase hepatic iron concentration. **Allopurinol** should not be stopped during flare since it may worsen the attack recovery and may take longer. Safety in children and during pregnancy has not been established.

## COLCHICINE

Although NSAIDs, corticosteroids, or **colchicine** are now first-line drugs for acute gout, **colchicine** was the primary treatment for many years. It can be taken with or without food and is sometimes given in combination with NSAIDs. **Colchicine** is an alkaloid isolated from the autumn crocus, *Colchicum autumnale*. Its structure is shown in **Figure 36–6**. **Mechanism of Action:** **Colchicine** relieves the pain and inflammation of gouty arthritis in 12–24 hours without altering urate metabolism or excretion and without other analgesic effects. By binding to the intracellular protein tubulin, it prevents polymerization into microtubules, resulting in inhibition of leukocyte migration and phagocytosis. It also disrupts the function of caspase-1-activating cryopyrin inflammasome (thus decreasing the formation of IL-1 $\beta$  and IL-18), inhibits the formation of leukotriene B<sub>4</sub>, decreases the levels of IFN- $\alpha$  and IL-6, and decreases TNF- $\alpha$  receptor expression on macrophages. Several of **colchicine**'s adverse effects are produced by its inhibition of tubulin polymerization and cell mitosis. **Pharmacokinetics:** **Colchicine** is absorbed readily after oral administration, reaches peak plasma levels within 2 hours, and is eliminated with a serum half-life of 9 hours. It is not removed by hemodialysis because it is extensively bound to tissues (and has a large volume of distribution); thus, dose reduction in these gout patients is recommended. **Indications and Dosage:** **Colchicine** is indicated for acute gout and is also used between attacks (the “intercritical period”) for prolonged prophylaxis (at low doses) of flares during urate-lowering treatment initiation. It prevents attacks of acute Mediterranean fever and may have a mild beneficial effect in sarcoid arthritis and in hepatic cirrhosis. **Colchicine** is also used to treat pseudogout, Behçet disease, epidermolysis bullosa acquisita, leukocytoclastic vasculitis, Sweet syndrome, pericarditis, pleurisy, and coronary artery disease, probably due to its anti-inflammatory effect. It is no longer used intravenously. In prophylaxis (the most common use), the dosage of **colchicine** is 0.6 mg one to two times a daily, starting 12 hours after an acute attack. For termination of a gouty attack, a regimen of 1.2 mg followed by a single 0.6-mg oral dose an hour later was as effective as higher-dose regimens, and adverse events were less frequent. ACR guidelines suggest administering **colchicine** within 36 hours of a gouty attack, due to its decreased efficacy after this time. Dose reductions are recommended for patients with renal or hepatic impairment, and in those taking cytochrome P450 3A4 or P-glycoprotein inhibitors. In 2009, the FDA asked that IV cytochrome be removed from the US market because of possible severe adverse effects. In 2015, generic **colchicine** again became available in the USA (following a few years when only a branded form was available). **Adverse Effects:** **colchicine** often causes diarrhea and may occasionally cause nausea, vomiting, and abdominal pain. CNS symptoms such as fatigue and headache also are observed. Hepatic necrosis, increase in LFTs, pharyngolaryngeal pain, acute renal failure, disseminated intravascular coagulation, and seizures also have been observed. **Colchicine** may rarely cause hair loss and bone marrow depression, as well as peripheral neuritis, myopathy, rhabdomyolysis, and even death. The more severe adverse events have been associated with the intravenous administration of **colchicine**, although these effects can also occur (very rarely) after oral use.

## FEBUXOSTAT

**Mechanism of Action:** **Febuxostat** is a potent and selective nonpurine inhibitor of xanthine oxidase (Figure 36-7), thereby reducing the formation of xanthine and uric acid without affecting other enzymes in the purine or pyrimidine metabolic pathway. **Pharmacokinetics:** **Febuxostat** is more than 80% absorbed following oral administration. Maximum concentration is achieved in approximately 1 hour, and although it has a half-life of 4–8 hours, once-daily dosing is effective. **Febuxostat** is extensively metabolized in the liver. The drug and its inactive metabolites appear in the urine, with <5% appearing as unchanged drug. **Indications and Dosage:** **Febuxostat** is approved at doses of 40 or 80 mg daily to treat chronic hyperuricemia in gout patients, with a target of serum uric acid level of <6.0 mg/dL. Although 80–120 mg was more effective than 300 mg daily **allopurinol** as urate-lowering therapy, 300 mg **allopurinol** daily does not reflect the actual dosing regimens used in clinical practice. The urate-lowering effect is similar to that of **allopurinol**, regardless of the cause of hyperuricemia (overproduction or underexcretion). **Febuxostat** and **allopurinol** both appear renoprotective over long treatment periods, although adherence issues cloud most results. **Febuxostat** may be tried in patients with a prior hypersensitivity reaction to **allopurinol**; however, a reaction with **febuxostat** may still occur. Unlike **allopurinol**, **febuxostat** appears safe in patients with moderate chronic kidney disease. However, there are no data for the safety of **febuxostat** in patients with severe renal impairment. It is primarily considered an alternative for those who are intolerant or did not respond to **allopurinol**. Because there was concern for cardiovascular events in the original phase 3 trials, the FDA approved only 40-mg and 80-mg daily doses (not the 120-mg dose used in some trials). **Adverse Effects:** Initial concerns about increased MACE when using **febuxostat** have not been born out. As with **allopurinol**, prophylactic treatment with **colchicine** or NSAIDs should be

started at the beginning of therapy to avoid gout flares. The most frequent treatment-related adverse events are liver function abnormalities, diarrhea, headache, and nausea. **Febuxostat** is well tolerated in patients with a history of **allopurinol** intolerance. Rashes can occur but are dose dependent.

FIGURE 36-7

Inhibition of uric acid synthesis by **allopurinol** occurs because **allopurinol** and alloxanthine inhibit xanthine oxidase. (Reproduced with permission from Meyers FH, Jawetz E, Goldfien A: *Review of Medical Pharmacology*, 7th ed. McGraw Hill, 1980.)

## NSAIDs IN GOUT

**Mechanism of Action:** In addition to inhibiting prostaglandin synthase, NSAIDs inhibit urate crystal phagocytosis and reduce inflammation and pain in acute gout flare. **Pharmacokinetics:** **Aspirin** is not used because it causes renal retention of uric acid at lower doses ( $\leq 2.6$  g/d); it is uricosuric at doses  $> 3.6$  g/d. **Indications and Dosage:** All NSAIDs except **aspirin**, salicylates, and **tolmetin** have been successfully used to treat acute gouty episodes. **Oxaprozin**, which also lowers serum uric acid, is hypothetically a good choice and all NSAIDs appear to be as effective and safe as the older drugs like **indomethacin**. **Adverse Effects:** Side effects associated with NSAID use include gastrointestinal, cardiovascular, and renal events. Selective COX-2 inhibitors have been associated with fewer adverse effects than other NSAIDs.

## PEGLOTICASE

**Mechanism of Action:** **Pegloticase** is a recombinant mammalian urate oxidase (uricase) that is covalently attached to a methoxy polyethylene glycol (mPEG) to prolong the circulating half-life and diminish immunogenic responses. Urate oxidase enzyme, absent in humans and some higher primates, converts uric acid to allantoin. Allantoin is highly soluble and can be easily eliminated by the kidneys. **Pharmacokinetics:** It is a rapidly acting drug, achieving a peak effect (decline in uric acid level) within 24–72 hours. The serum half-life ranges from 6 to 14 days. Several studies have shown earlier clearance of PEG-uricase (mean of 11 days vs 16 days) due to antibody production. **Indications and Dosage:** **Pegloticase** monotherapy and with **methotrexate** are FDA approved as urate-lowering therapy in symptomatic gout and effectively decrease tophi. **Pegloticase** lowers urate levels for up to 21 days after a single IV infusion at doses of 4–12 mg, allowing for IV dosing every 2 weeks. **Pegloticase** should not be used for asymptomatic hyperuricemia. The recommended dose for **pegloticase** is 8 mg IV every 2 weeks. To prevent infusion reactions, patients should be premedicated with a corticosteroid and antihistamine. **Adverse Effects:** Gout flare can occur during treatment with **pegloticase**, especially during the first 3–6 months of treatment, requiring prophylaxis with NSAIDs or **colchicine**. When used with **methotrexate**, most allergic reactions are abrogated, and efficacy is increased. **Mycophenolate** mofetil has also been used for the same purpose. Nephrolithiasis, arthralgia, muscle spasm, headache, anemia, and nausea may occur. Other less frequent side effects include upper respiratory tract infection, urinary tract infection, peripheral edema, and diarrhea. There is some concern for hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency because the formation of hydrogen peroxide by uricase is feared; therefore, **pegloticase** should be avoided in these patients.

## PROBENECID AND LESINURAD

**Probenecid** and **lesinurad** (the latter withdrawn in the USA in 2019) are uricosuric drugs employed to decrease the body pool of urate in patients with tophaceous gout or in those with increasingly frequent gouty attacks. In a patient who excretes large amounts of uric acid, the uricosuric agents should not be used. **Sulfinpyrazone**, another uricosuric agent, has been discontinued in the USA. Other novel uricosuric agents in development include verinurad and arhalofenate. **Mechanism of Action:** **Probenecid** inhibits active transport sites for reabsorption and secretion in the proximal renal tubule so that net reabsorption of uric acid in the proximal tubule is decreased. Because **aspirin** in doses of <2.6 g daily causes net retention of uric acid by inhibiting the secretory transporter, it should not be used for analgesia in patients with gout. The secretion of other weak acids (eg, penicillin) also is reduced by uricosuric agents. As the urinary excretion of uric acid increases, the urate pool decreases, although the plasma concentration may not be greatly reduced. In patients who respond favorably, tophaceous deposits of urate are reabsorbed, with relief of arthritis and remineralization of bone. With the ensuing increase in uric acid excretion, a predisposition to the formation of renal stones is augmented rather than decreased; therefore, high urine volume should be maintained and at least early in treatment, the urine pH should be kept above 6.0 by the administration of alkali. **Pharmacokinetics:** **Probenecid** is an organic acid (see [Figure 36–6](#)) and acts at the anion transport sites of the renal tubule (see [Chapter 15](#)). **Probenecid** is completely reabsorbed by the renal tubules and is metabolized slowly with a terminal serum half-life of 5–8 hours. **Indications and Dosage:** Uricosuric therapy should be initiated in gouty patients with underexcretion of uric acid when **allopurinol** or **febuxostat** is contraindicated or when tophi are present. Therapy should not be started until 2–3 weeks after an acute attack. **Probenecid** can be used as monotherapy or in combination with a xanthine oxidase inhibitor (eg, **allopurinol** or **febuxostat**). **Probenecid** is usually started at a dosage of 0.5 g orally daily in divided doses, progressing to 1 g daily after 1 week. It is essential to maintain a large urine volume to minimize the possibility of stone formation. **Adverse Effects:** Organic acids cause GI irritation. A rash may appear after the use of **probenecid**, as may nephrotic syndrome. **Probenecid** may rarely cause aplastic anemia.

## GLUCOCORTICOIDS IN GOUT

**Mechanism of Action:** As described in [Chapter 39](#), corticosteroids decrease activation, proliferation, and survival of various inflammatory cells. Additionally, they decrease the migration of neutrophils, and they inhibit prostaglandins and proinflammatory cytokines such as IL-1 $\beta$ . **Indications and Dosage:** Corticosteroids are a good alternative for patients in whom NSAIDs or **colchicine** are contraindicated and in those with renal impairment or chronic kidney disease. Corticosteroids are sometimes used in the treatment of severe symptomatic gout by oral, intra-articular, systemic, or subcutaneous routes. The most commonly used oral corticosteroid is **prednisone**. The recommended oral dose is 30–50 mg/d for 1–2 days, tapered over 7–10 days; a **methylprednisolone** dose pack also may be prescribed. Intra-articular injection of 10 mg (small joints), 30 mg (wrist, ankle, elbow), and 40 mg (knee) of **triamcinolone** acetonide or **methylprednisolone** can be given if the patient is unable to take oral medications. Joint infection should be ruled out, if possible, before administration of corticosteroids. **Adverse Effects:** Common side effects include immune system suppression (very rare if given for <7 days), mood changes, fluid retention, and increased appetite, blood pressure, and glucose levels.

## INTERLEUKIN-1 INHIBITORS IN GOUT

**Mechanism of Action:** As described previously, **canakinumab**, **anakinra**, and **rilonacept** inhibit the IL-1 receptor pathway. IL-1 $\beta$  is the main proinflammatory cytokine responsible for the crystal-induced inflammation of gout. However, these agents are not yet FDA approved for the treatment of gout. Although the data are limited, these agents may provide a promising treatment option for acute gout in patients with contraindications to, or who are refractory to, traditional therapies. All three IL-1 inhibitors are administered subcutaneously, and the 2012 ACR guidelines recommend **anakinra** 100 mg/day for 3 consecutive days or **canakinumab** 150 mg as a single dose for the treatment of acute gout. These medications are also being evaluated as therapies for prevention of gout flares while initiating urate-lowering therapy.

### PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
NONSTEROIDAL ANTI-INFLAMMATORY DRUGS	

Aspirin, acetylsalicylic acid	Generic, others
Bromfenac	Various
Celecoxib	Generic, Celebrex
Choline salicylate	Various
Diclofenac	Generic, Voltaren, others
Diffunisal	Generic, others
Etodolac	Generic, others
Fenoprofen	Generic, others
Flurbiprofen	Generic, others, Ocufer (ophthalmic)
Ibuprofen	Generic, Advil (OTC), Nuprin (OTC), others
Indomethacin	Generic, Indocin
Ketoprofen	Generic, others
Magnesium salicylate	Doan's Pills, Magan, Mobidin
Meclofenamate sodium	Generic
Mefenamic acid	Generic, others
Meloxicam	Generic, others
Nabumetone	Generic
Naproxen	Generic (OTC), others, Aleve (OTC)
Oxaprozin	Generic, others
Piroxicam	Generic, others
Salicylsalicylic acid	Generic, others
Sodium salicylate	Generic
Sodium thiosalicylate	Generic, others
Sulindac	Generic, others
Tolmetin	Generic, others
<b>DISEASE-MODIFYING ANTIRHEUMATIC DRUGS</b>	

Abatacept	Orencia
Adalimumab	Humira
Anakinra	Kineret
Auranofin	Ridaura
Aurothioglucose	Solganal
Baricitinib	Olumiant
Belimumab	Benlysta
Canakinumab	Ilaris
Certolizumab	Cimzia
Cyclophosphamide	Generic, Cytoxan
Cyclosporine	Generic, Sandimmune
Etanercept	Enbrel
Gold sodium thiomalate	Generic, Aurolate
Golimumab	Simponi
Infliximab	Remicade
Leflunomide	Generic, Arava
Methotrexate	Generic, Rheumatrex
Mycophenolate mofetil	Generic, Cellcept
Rituximab	Rituxan
Sarilumab	Kevzara
Sulfasalazine	Generic, Azulfidine
Tocilizumab	Actemra
Tofacitinib	Xeljanz
Ustekinumab	Stelara
<b>ACETAMINOPHEN AND OTHER ANALGESICS</b>	
Acetaminophen	Generic, Tylenol, Tempra, Panadol, Acephen, others

Tramadol

Generic, Ultram

**DRUGS USED IN GOUT**

Allopurinol

Generic, Zyloprim

Colchicine

Generic,\* Colchrys, Colcrys

Febuxostat

Uloric

Pegloticase

Krystexxa

Probenecid

Generic

Sulfinpyrazone\*

Generic, Anturane

\*Outside the United States.

**CASE STUDY ANSWER**

This patient had good control of his symptoms for 1 year but now has a prolonged flare, probably denoting worsening disease (not just a temporary flare). In addition to physical findings and measurement of acute-phase reactants such as sedimentation rate or C-reactive protein, it would be wise to get hand and feet radiographs to document whether he has developed joint damage. Assuming such damage is found, the appropriate approach would be either a combination of nonbiologic DMARDs (eg, adding [sulfasalazine](#) and [hydroxychloroquine](#)) or adding a biologic medication, usually a TNF inhibitor followed by non-TNF biologics or JAK inhibitors. Follow-up should be every 1–3 months to gauge response and toxicity. Adverse events requiring caution are an increased risk of infection, possible appearance of lymphoma, and rare liver function test or hematologic abnormalities. Importantly, close follow-up should ensue, including changing medications every 3–6 months if needed, until full disease control is achieved.

## Chapter 37: Hypothalamic & Pituitary Hormones

Roger K. Long; Hakan Cakmak

### CASE STUDY

#### CASE STUDY

A 10-year-old girl (height 126 cm, 3rd percentile; weight 36 kg, approximately 65th percentile) presents with short stature. Review of her growth chart demonstrates normal birth weight and length and growth velocity until a markedly decreased growth velocity over the past 2 years, resulting in a decrease in height percentile from the 50th to the 3rd. Review of history reveals headaches, increased urination and drinking, and dizziness with febrile illnesses. Physical examination demonstrates short stature, mild generalized obesity, a bitemporal visual field defect, and no breast development. The patient is diagnosed with a suprasellar craniopharyngioma. After complete surgical resection, laboratory evaluations demonstrate growth hormone (GH) deficiency and a delayed bone age of 18 months. The patient is treated with recombinant human GH at a dose of 40 mcg/kg per day subcutaneously. After 1 year of treatment, her height velocity has increased from 4 cm/year to 10 cm/year. How does GH stimulate growth in children? What other hormone deficiencies are suggested by the patient's history and physical examination? What other hormone replacements will this patient likely require?

The control of metabolism, growth, and reproduction is mediated by a combination of neural and endocrine systems located in the hypothalamus and pituitary gland. The pituitary weighs about 0.6 g and rests at the base of the brain in the bony sella turcica near the optic chiasm and the cavernous sinuses. The pituitary consists of an anterior lobe (adenohypophysis) and a posterior lobe (neurohypophysis) (Figure 37-1). It is connected to the overlying hypothalamus by a stalk of neurosecretory fibers and blood vessels, including a portal venous system that drains the hypothalamus and perfuses the anterior pituitary. The portal venous system carries small regulatory hormones (Figure 37-1, Table 37-1) from the hypothalamus to the anterior pituitary.

#### FIGURE 37-1

The hypothalamic-pituitary endocrine system. Hormones released from the anterior pituitary stimulate the production of hormones by a peripheral endocrine gland, the liver, or other tissues, or act directly on target tissues. Prolactin and the hormones released from the posterior pituitary (**vasopressin** and **oxytocin**) act directly on target tissues. Hypothalamic factors regulate the release of anterior pituitary hormones. ACTH, adrenocorticotropin; ADH, antidiuretic hormone [**vasopressin**]; CRH, corticotropin-releasing hormone; DA, **dopamine**; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; PRL, prolactin; SST, somatostatin; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

Links between hypothalamic, anterior pituitary, and target organ hormone or mediator.<sup>1</sup>

Anterior Pituitary Hormone	Hypothalamic Hormone	Target Organ	Primary Target Organ Hormone or Mediator
Growth hormone (GH, somatotropin)	Growth hormone-releasing hormone (GHRH) (+), Somatostatin (-)	Liver, bone, muscle, kidney, and others	Insulin-like growth factor-I (IGF-I)
Thyroid-stimulating hormone (TSH)	Thyrotropin-releasing hormone (TRH) (+)	Thyroid	Thyroxine, triiodothyronine
Adrenocorticotropic hormone (ACTH)	Corticotropin-releasing hormone (CRH) (+)	Adrenal cortex	Cortisol
Follicle-stimulating hormone (FSH) Luteinizing hormone (LH)	Gonadotropin-releasing hormone (GnRH) (+) <sup>2</sup>	Gonads	Estrogen, progesterone, testosterone
Prolactin (PRL)	Dopamine (-)	Breast	—

<sup>1</sup>All of these hormones act through G protein-coupled receptors except GH and PRL, which act through JAK/STAT receptors.

<sup>2</sup>Endogenous GnRH, which is released in pulses, stimulates LH and FSH release. When administered continuously as a drug, GnRH and its analogs inhibit LH and FSH release through down-regulation of GnRH receptors.

(+), stimulant; (-), inhibitor.

The posterior lobe hormones are synthesized in the hypothalamus and transported via the neurosecretory fibers in the stalk of the pituitary to the posterior lobe; from there they are released into the circulation.

Drugs that mimic or block the effects of hypothalamic and pituitary hormones have pharmacologic applications in three primary areas: (1) as replacement therapy for hormone deficiency states; (2) as antagonists for diseases caused by excess production of pituitary hormones; and (3) as diagnostic tools for identifying endocrine abnormalities.

## ANTERIOR PITUITARY HORMONES & THEIR HYPOTHALAMIC REGULATORS

All the hormones produced by the anterior pituitary except prolactin are key participants in hormonal systems in which they regulate the production of hormones and autocrine-paracrine factors by endocrine glands and other peripheral tissues. In these systems, the secretion of the pituitary hormone is under the control of one or more hypothalamic hormones. Each hypothalamic-pituitary-endocrine gland system or axis provides multiple opportunities for complex neuroendocrine regulation of growth and development, metabolism, and reproductive function.

### ANTERIOR PITUITARY & HYPOTHALAMIC HORMONE RECEPTORS

The anterior pituitary hormones can be classified according to hormone structure and the types of receptors that they activate. **Growth hormone (GH)** and **prolactin (PRL)**, single-chain protein hormones with significant homology, form one group. Both hormones activate receptors of the JAK/STAT superfamily (see [Chapter 2](#)). Three pituitary hormones—**thyroid-stimulating hormone (TSH, thyrotropin)**, **follicle-stimulating hormone (FSH)**, and **luteinizing hormone (LH)**—are dimeric proteins that activate G protein-coupled receptors (see [Chapter 2](#)). TSH, FSH, and LH share a common  $\alpha$  subunit. Their  $\beta$  subunits, though somewhat similar to each other, differ enough to confer receptor specificity. Finally, **adrenocorticotropic hormone (ACTH)**, a peptide cleaved from a larger precursor, pro-opiomelanocortin (POMC), represents a third category. POMC can be cleaved into various other biologically active peptides like  $\alpha$ -melanocyte-stimulating hormone (MSH) and  $\beta$ -endorphin (see [Chapter 31](#)). Like TSH, LH, and FSH, ACTH acts through a G protein-coupled receptor. A unique feature of the ACTH receptor (also known as the melanocortin 2 receptor) is that a transmembrane protein, melanocortin 2 receptor accessory protein, is essential for normal ACTH receptor trafficking and signaling.

<b>ACTH</b>	Adrenocorticotropic hormone ( <b>corticotropin</b> )
<b>ADH</b>	Antidiuretic hormone ( <b>vasopressin</b> )
<b>CRH</b>	Corticotropin-releasing hormone
<b>FSH</b>	Follicle-stimulating hormone
<b>GH</b>	Growth hormone
<b>GHRH</b>	Growth hormone-releasing hormone
<b>GnRH</b>	Gonadotropin-releasing hormone
<b>hCG</b>	Human chorionic gonadotropin
<b>hMG</b>	Human menopausal gonadotropin
<b>IGF</b>	Insulin-like growth factor
<b>LH</b>	Luteinizing hormone
<b>PRL</b>	Prolactin
<b>rhGH</b>	Recombinant human growth hormone
<b>SST</b>	Somatostatin
<b>TRH</b>	Thyrotropin-releasing hormone
<b>TSH</b>	Thyroid-stimulating hormone (thyrotropin)

TSH, FSH, LH, and ACTH share similarities in the regulation of their release from the pituitary. Each is under the control of a distinctive hypothalamic peptide that stimulates their production by acting on G protein-coupled receptors (see [Table 37-1](#)). TSH release is regulated by **thyrotropin-releasing hormone (TRH)**, whereas the release of LH and FSH (known collectively as gonadotropins) is stimulated by pulses of **gonadotropin-releasing hormone (GnRH)**. ACTH release is stimulated by **corticotropin-releasing hormone (CRH)**. An important regulatory feature shared by these four structurally related hormones is that they and their hypothalamic releasing factors are subject to feedback inhibitory regulation by the hormones whose production they control. TSH and TRH production are inhibited by the two key thyroid hormones, thyroxine and triiodothyronine (see [Chapter 38](#)). Gonadotropin and GnRH production is inhibited in women by estrogen and **progesterone**, and in men by **testosterone** and other androgens. ACTH and CRH production are inhibited by cortisol. Feedback regulation is critical to the physiologic control of thyroid, adrenal cortical, and gonadal function and is also important in pharmacologic treatments that affect these systems.

The hypothalamic hormonal control of GH and prolactin differs from the regulatory systems for TSH, FSH, LH, and ACTH. The hypothalamus secretes two hormones that regulate GH; **growth hormone-releasing hormone (GHRH)** stimulates GH production, whereas the peptide **somatostatin (SST)** inhibits GH production. GH and its primary peripheral mediator, **insulin-like growth factor I (IGF-I)**, also provide feedback to inhibit GH release. Prolactin production is inhibited by the catecholamine **dopamine** acting through the D<sub>2</sub> subtype of **dopamine** receptors. The hypothalamus

does not produce a hormone that specifically stimulates prolactin secretion, although TRH can stimulate prolactin release, particularly when TRH

Whereas all the pituitary and hypothalamic hormones described previously are available for use in humans, only a few are of major clinical importance. Because of the greater ease of administration of target endocrine gland hormones or their synthetic analogs, the related hypothalamic and pituitary hormones are used infrequently as treatments. However, many of them (TRH, TSH, CRH, ACTH, GnRH, GHRH) are used for specialized diagnostic testing. These agents are described in [Tables 37-2](#) and [37-3](#) and are not discussed further in this chapter. In contrast, GH, SST, LH, FSH, GnRH, and [dopamine](#) or analogs of these hormones are commonly used and are described in the following text.

TABLE 37-2

**Clinical uses of hypothalamic hormones and their analogs.**

Hypothalamic Hormone	Clinical Uses
Growth hormone-releasing hormone (GHRH)	Used rarely as a diagnostic test for GH and GHRH sufficiency
Thyrotropin-releasing-hormone (TRH, protirelin)	May be used to diagnose TRH or TSH deficiencies; not currently available for clinical use in the United States
Corticotropin-releasing hormone (CRH)	Used rarely to distinguish Cushing disease from ectopic ACTH secretion
Gonadotropin-releasing hormone (GnRH)	May be used in a single dose to assess initiation of puberty (pubertal gonadotropin response) May be used in pulses to treat infertility caused by GnRH deficiency
	Analogues used in long-acting formulations to inhibit gonadal function in children with precocious puberty, in some transgender/gender variant early pubertal adolescents (to block endogenous puberty), in men with prostate cancer and women undergoing assisted reproductive technology (ART) or women who require ovarian suppression for a gynecologic disorder
<a href="#">Dopamine</a>	<a href="#">Dopamine</a> agonists (eg, <a href="#">bromocriptine</a> , <a href="#">cabergoline</a> ) used for treatment of hyperprolactinemia

**Diagnostic uses of thyroid-stimulating hormone and adrenocorticotropin.**

Hormone	Diagnostic Use
Thyroid-stimulating-hormone (TSH; thyrotropin)	In patients who have been treated surgically for thyroid carcinoma, to test for cancer recurrence by assessing TSH-stimulated radioactive iodine uptake and serum thyroglobulin level (see <a href="#">Chapter 38</a> )
Adrenocorticotropin (ACTH)	In patients suspected of adrenal insufficiency, either central (CRH/ACTH deficiency) or peripheral (cortisol deficiency), in particular in suspected cases of congenital adrenal hyperplasia (see <a href="#">Figure 39-1</a> and <a href="#">Chapter 39</a> )

**GROWTH HORMONE (SOMATOTROPIN)**

Growth hormone, an anterior pituitary hormone, is required during childhood and adolescence for attainment of normal adult size and has important effects throughout postnatal life on lipid and carbohydrate metabolism, and on lean body mass and bone density. Its growth-promoting effects are primarily mediated via IGF-I (also known as somatomedin C). Individuals with congenital or acquired deficiency of GH during childhood or early adolescence have an adult height potential significantly lower than their midparental target adult height and have disproportionately increased body fat and decreased muscle mass. Adults with GH deficiency also have disproportionately low lean body mass, as well as bone mineral density and perceive a lower quality of life.

**Chemistry & Pharmacokinetics****A. Structure**

Growth hormone is a 191-amino-acid peptide with two sulfhydryl bridges. Its structure closely resembles that of prolactin. In the past, medicinal GH was isolated from the pituitaries of human cadavers. However, this form of GH was found to be contaminated with prions that could cause Creutzfeldt-Jakob disease. For this reason, it is no longer used. [Somatotropin](#), the recombinant form of GH, has a 191-amino-acid sequence that is identical with the predominant native form of human GH.

**B. Absorption, Metabolism, and Excretion**

Circulating endogenous GH has a half-life of approximately 20 minutes and is predominantly cleared by the liver. Recombinant human GH (rhGH) is administered subcutaneously six to seven times per week. Peak levels occur in 2–4 hours, and active blood levels persist for approximately 36 hours. Weekly subcutaneous dosing with efficacy comparable to daily administration is available with recombinant human GH derivatives that are modified to extend duration action with an added albumin-binding moiety or a transiently linked inert protective carrier.

**Pharmacodynamics**

Growth hormone mediates its effects via cell surface receptors of the JAK/STAT cytokine receptor superfamily. The hormone has two distinct GH receptor binding sites. Dimerization of two GH receptors is stimulated by a single GH molecule and activates signaling cascades mediated by receptor-associated JAK tyrosine kinases and STATs (see [Chapter 2](#)). The hormone has complex effects on growth, body composition, and carbohydrate, protein, and lipid metabolism. The growth-promoting effects are mediated principally, but not solely, through an increase in the production of IGF-I. Much of the circulating IGF-I is produced by the liver. Growth hormone also stimulates production of IGF-I in bone, cartilage, muscle, kidney, and other tissues, where it has autocrine or paracrine roles. It stimulates longitudinal bone growth until the epiphyseal plates fuse—near the end of puberty. In both children and adults, GH has anabolic effects in muscle and catabolic effects in adipose cells that shift the balance of body mass to an increase in muscle mass and a reduction in adiposity. The direct and indirect effects of GH on carbohydrate metabolism are mixed, in part because GH and IGF-I have opposite effects on [insulin](#) sensitivity. Growth hormone reduces [insulin](#) sensitivity, which results in mild hyperinsulinemia and increased blood glucose levels, whereas IGF-I has insulin-like effects on glucose transport. In patients who are unable to respond to growth hormone because of severe

www.konkur.in  
resistance (caused by GH receptor mutations, post-receptor signaling mutations, or GH antibodies), the administration of recombinant human IGF-I may cause hypoglycemia because of its insulin-like effects.

## Clinical Pharmacology

### A. Growth Hormone Deficiency

Growth hormone deficiency can have a genetic basis, be associated with midline developmental defect syndromes (eg, septo-optic dysplasia), or be acquired as a result of damage to the pituitary or hypothalamus by a traumatic event (including breech or traumatic delivery), intracranial tumors, infection, infiltrative or hemorrhagic processes, or irradiation. Neonates with isolated GH deficiency are typically of normal size at birth because prenatal growth is not GH-dependent. In contrast, IGF-I is essential for normal prenatal and postnatal growth. Through poorly understood mechanisms, IGF-I expression and postnatal growth become GH-dependent during the first year of life. In childhood, GH deficiency typically presents as short stature, often with mild adiposity. Another early sign of GH deficiency is hypoglycemia due to the loss of the counter-regulatory hormonal response of GH to hypoglycemia; young children are at a greater risk for this condition due to their high sensitivity to [insulin](#). Criteria for diagnosis of GH deficiency usually include (1) a subnormal height velocity for age and (2) a subnormal serum GH response following provocative testing with at least two GH secretagogues. [Clonidine](#) ( $\alpha_2$ -adrenergic agonist), [levodopa](#) (dopaminergic agonist), and exercise are factors that increase GHRH levels.

[Arginine](#) and insulin-induced hypoglycemia cause diminished SST, which increases GH release. The mechanisms by which [glucagon](#) stimulates GH secretion remain unclear. [Macimorelin](#), an orally administered ghrelin receptor agonist, is approved for GH stimulation testing in adults. If therapy with rhGH is initiated at an early age, many children with short stature due to GH deficiency will achieve an adult height within their midparental target height range.

In the past, it was believed that adults with GH deficiency do not exhibit a significant syndrome. However, more detailed studies suggest that adults with GH deficiency often have generalized obesity, reduced muscle mass, asthenia, diminished bone mineral density, dyslipidemia, lower quality-of-life assessments, and reduced cardiac output. Growth hormone-deficient adults who have been treated with GH experience reversal of many of these manifestations.

### B. Growth Hormone Treatment of Pediatric Patients with Short Stature

Although the greatest improvement in growth occurs in patients with GH deficiency, exogenous GH has some effect on height in children with short stature caused by conditions other than GH deficiency. Growth hormone has been approved for several conditions ([Table 37-4](#)) and has been used experimentally or off-label in many others. Prader-Willi syndrome is an autosomal dominant genetic disease associated with growth failure, obesity, and carbohydrate intolerance. In children with Prader-Willi syndrome and growth failure, GH treatment decreases body fat and increases lean body mass, linear growth, and energy expenditure.

## Clinical uses of recombinant human growth hormone.

Primary Therapeutic Objective	Clinical Condition
Growth	Growth failure in pediatric patients associated with:
	Growth hormone deficiency
	Chronic renal insufficiency pre-transplant
	Noonan syndrome
	Prader-Willi syndrome
	Short stature homeobox-containing gene (SHOX) deficiency
	Turner syndrome
	Small-for-gestational-age with failure to catch up by age 2 years
	Idiopathic short stature
Improved metabolic state, increased lean body mass, sense of well-being	Growth hormone deficiency in adults
Increased lean body mass, weight, and physical endurance	Wasting in patients with HIV infection
Improved gastrointestinal function	Short bowel syndrome in patients who are also receiving specialized nutritional support

Growth hormone treatment has also been shown to have a strong beneficial effect on final height of girls with Turner syndrome (45 X karyotype and variants). In clinical trials, GH treatment has been shown to increase adult height in girls with Turner syndrome by 10–15 cm (4–6 inches). Because girls with Turner syndrome also have either absent or rudimentary ovaries, GH must be judiciously combined with gonadal steroids to achieve maximal height. Other conditions of pediatric growth failure for which GH treatment is approved include chronic renal insufficiency pre-transplant, and small-for-gestational-age at birth with failure of catch-up growth, in which the child's height remains more than 2 standard deviations below normal at 2 years of age.

A controversial but approved use of GH is for children with idiopathic short stature (ISS). This is a heterogeneous population that has in common no identifiable cause of the short stature. ISS is clinically defined as having a height at least 2.25 standard deviations below normal for children of the same age and a predicted adult height that is <2.25 standard deviations below the mean (<59 inches in females, and <63 inches in males). In this group of children, many years of GH therapy result in an average increase in adult height of 4–7 cm (1.57–2.76 inches) at a cost of \$5000–\$40,000 per year. The complex issues involved in the cost-risk-benefit relationship of this use of GH are important because an estimated 400,000 children in the United States fit the diagnostic criteria for ISS.

Treatment of children with short stature should be carried out by specialists experienced in GH administration. Dose requirements vary with the condition being treated, with GH-deficient children typically being most responsive. Children must be observed closely for slowing of growth velocity, which could indicate a need to increase the dosage or the possibility of epiphyseal plate fusion or intercurrent problems such as hypothyroidism or malnutrition.

Growth hormone affects many organ systems and also has a net anabolic effect. It has been tested in a number of conditions that are associated with a severe catabolic state and is approved for the treatment of wasting in patients with AIDS. In 2004, GH was approved for treatment of patients with short bowel syndrome who are dependent on total parenteral nutrition (TPN). After intestinal resection or bypass, the remaining functional intestine in many patients undergoes extensive adaptation that allows it to adequately absorb nutrients. However, other patients fail to adequately adapt and develop a malabsorption syndrome. Growth hormone has been shown to increase intestinal growth and improve its function in experimental animals. Benefits of GH treatment for patients with short bowel syndrome and dependence on TPN have mostly been short-lived in the clinical studies that have been published to date.

Growth hormone is a popular component of “anti-aging” programs. Serum levels of GH normally decline with aging; anti-aging programs claim that injection of GH or administration of drugs purported to increase GH release are effective anti-aging remedies. These claims are largely unsubstantiated. In contrast, studies in mice and the nematode *Caenorhabditis elegans* have clearly demonstrated that analogs of human GH and IGF-I consistently shorten life span and that loss-of-function mutations in the signaling pathways for the GH and IGF-I analogs lengthen life span. Another use of GH is by athletes for a purported increase in muscle mass and athletic performance. Growth hormone is one of the drugs banned by the International Olympic Committee.

### Toxicity & Contraindications

Children generally tolerate growth hormone treatment well. Adverse events are rare and include pseudotumor cerebri, slipped capital femoral epiphysis, progression of scoliosis, edema, hyperglycemia, and increased risk of asphyxiation in severely obese patients with Prader-Willi syndrome and upper airway obstruction or sleep apnea. Patients with Turner syndrome have an increased risk of otitis media while taking GH. In children with GH deficiency, periodic evaluation of the other anterior pituitary hormones may reveal concurrent deficiencies, which also require treatment (ie, with hydrocortisone, levothyroxine, or gonadal hormones). Pancreatitis, gynecomastia, and nevus growth have occurred in patients receiving GH. Adults tend to have more adverse effects from GH therapy. Peripheral edema, myalgias, and arthralgias (especially in the hands and wrists) occur commonly but remit with dosage reduction. Carpal tunnel syndrome can occur. Growth hormone treatment increases the activity of cytochrome P450 isoforms, which may reduce the serum levels of drugs metabolized by that enzyme system (see Chapter 4). There has been no increased incidence of malignancy among patients receiving GH therapy, but such treatment is contraindicated in a patient with a known active malignancy. Growth hormone treatment does not increase mortality rate in children. However, mortality rates are elevated for children with history of prior malignancy or serious non-GH-deficient medical conditions, and doubled in critically ill patients. The long-term health effects of GH treatment in childhood are unknown. The results from the Safety and Appropriateness of GH in Europe (SAGHE) study are inconsistent. A higher all-cause mortality (mostly due to cardiovascular disease) was found in the GH treatment group in the French arm of the study, but no long-term risks of GH treatment were observed in the study arm from other regions of Europe—including no increased mortality in Sweden when adjusting for birth parameters. A large, prospective, postmarketing observational study (GeNeSIS) revealed no increased risk of mortality or primary cancer.

### MECASERMIN

A small number of children with growth failure have severe IGF-I deficiency that is not responsive to exogenous GH. Causes include mutations in the GH receptor and in the GH receptor signaling pathway, neutralizing antibodies to GH, and IGF-I gene defects. In 2005, the US Food and Drug Administration (FDA) approved two forms of recombinant human IGF-I (rhIGF-I) for treatment of severe IGF-I deficiency that is not responsive to GH: **mecasermin** and **mecasermin** rinfabate. **Mecasermin** is rhIGF-I alone, while **mecasermin** rinfabate is a complex of rhIGF-I and recombinant human insulin-like growth factor-binding protein-3 (rhIGFBP-3). This binding protein significantly increases the circulating half-life of rhIGF-I. Normally, the great majority of the circulating IGF-I is bound to IGFBP-3, which is produced principally by the liver under the control of GH. Due to a patent settlement, **mecasermin** rinfabate is not available for short stature-related indications. **Mecasermin** is administered subcutaneously twice daily at a low starting dosage and increased weekly as tolerated up to a maximum twice-daily dose. The growth response rate to rhIGF-I is lower than that observed during GH treatment of GH-deficient children: a growth velocity of 8–9 cm per year compared with 9–14 cm per year, respectively. During the first year of rhIGF-I treatment, height velocity increases by approximately 4–5 cm per year and height standard deviation score (SDS) increases by only 0.5 after 2 years of treatment.

The most important adverse effect observed with **mecasermin** is hypoglycemia. To avoid hypoglycemia, the prescribing instructions require consumption of a carbohydrate-containing meal or snack within 20 minutes of **mecasermin** administration. Cases of intracranial hypertension, telecanthus, acromegaly, lipohypertrophy, and asymptomatic elevation of liver enzymes have been reported.

Antagonists of GH are used to reverse the effects of GH-producing cells (somatotrophs) in the anterior pituitary that form GH-secreting tumors. Hormone-secreting pituitary adenomas occur most commonly in adults. In adults, GH-secreting adenomas cause acromegaly, which is characterized by abnormal growth of cartilage and bone tissue, and many organs including skin, muscle, heart, liver, and the gastrointestinal tract. When a GH-secreting adenoma occurs before the long bone epiphyses close, it leads to a rare condition, gigantism. Larger pituitary adenomas produce greater amounts of GH and also can impair visual and central nervous system function by encroaching on nearby brain structures, ie, optic nerve chiasm. The initial therapy of choice for GH-secreting adenomas is endoscopic transsphenoidal surgery. Medical therapy with GH antagonists is indicated when surgical resection is not possible or GH hypersecretion persists after surgery as determined by elevated IGF-I levels or GH not suppressible to <1 mcg/L. These agents include somatostatin analogs and **dopamine** receptor agonists, which reduce the production of GH, and the GH receptor antagonist **pegvisomant**, which prevents GH from activating GH signaling pathways. Radiation therapy is reserved for patients with inadequate response to surgical and medical therapies.

**Somatostatin Analogs**

Somatostatin, a 14-amino-acid peptide (Figure 37-2), is found in the hypothalamus, other parts of the central nervous system, the pancreas, and other sites in the gastrointestinal tract. It functions primarily as an inhibitory paracrine factor and inhibits the release of GH, TSH, **glucagon**, **insulin**, and gastrin. Somatostatin is rapidly cleared from the circulation, with a half-life of 1–3 minutes. The kidney appears to play an important role in its metabolism and excretion.

FIGURE 37-2

**Above:** Amino acid sequence of somatostatin. **Below:** Sequence of the synthetic analog, **octreotide**.

Source: Todd W. Vanderah:  
 Basic & Clinical Pharmacology, Sixteenth Edition  
 Copyright © McGraw Hill. All rights reserved.

Somatostatin has limited therapeutic usefulness because of its short duration of action and multiple effects in many secretory systems. A series of longer-acting somatostatin analogs that retain biologic activity have been developed. **Octreotide**, the most widely used somatostatin analog (see Figure 37-2), is 45 times more potent than somatostatin in inhibiting GH release but only twice as potent in reducing **insulin** secretion. Because of this relatively reduced effect on pancreatic beta cells, hyperglycemia rarely occurs during treatment. The plasma elimination half-life of subcutaneous **octreotide** is about 80 minutes, 30 times longer than that of somatostatin.

**Octreotide**, 50–200 mcg given subcutaneously every 8 hours, reduces symptoms caused by a variety of hormone-secreting tumors: acromegaly, carcinoid tumor, gastrinoma, glucagonoma, insulinoma, VIPoma, and ACTH-secreting tumor. Other therapeutic use indications include diarrhea—secretory, HIV associated, diabetic, chemotherapy, or radiation induced—and portal hypertension. Somatostatin receptor scintigraphy, using radiolabeled **octreotide**, is useful in localizing neuroendocrine tumors having somatostatin receptors and helps predict the response to **octreotide** therapy. **Octreotide** is also useful for the acute control of bleeding from esophageal varices.

**Octreotide** acetate injectable long-acting suspension is a slow-release microsphere formulation. It may be instituted after a brief course of shorter-acting **octreotide** has been demonstrated to be effective and tolerated. Injections into alternate gluteal muscles are repeated at 4-week intervals in doses of 10–40 mg.

Adverse effects of **octreotide** therapy include nausea, vomiting, abdominal cramps, flatulence, and steatorrhea with bulky bowel movements. Biliary sludge and gallstones may occur after 1 year of use in 20–30% of patients, up to 50% at 5 years of therapy. However, the yearly incidence of symptomatic gallstones is about 1%. Cardiac effects include sinus bradycardia (25%) and conduction disturbances (10%). Pain at the site of injection is common, especially with the long-acting **octreotide** suspension. Vitamin B<sub>12</sub> deficiency may occur with long-term use of **octreotide**.

A long-acting formulation of **lanreotide**, another octapeptide somatostatin analog, is approved for treatment of acromegaly. **Lanreotide** appears to have effects comparable to those of **octreotide** in reducing GH levels and normalizing IGF-I concentrations. **Pasireotide** is a somatostatin analog with greater affinity for the somatostatin receptor 5 than the other analogs. After 12 months of treatment with a long-acting formulation of **pasireotide**, there was greater biochemical control of acromegaly than with long-acting **octreotide** (31.3% versus 19.2%). However, submaximal dosing of the **octreotide** may have impacted the comparison. Long-acting somatostatin analogs may cause shrinkage of GH-secreting pituitary adenomas in some patients. An oral formulation of **octreotide** may be used for long-term maintenance treatment in those patients who tolerated and responded to long-acting somatostatin analogs.

### **Pegvisomant**

**Pegvisomant** is a GH receptor antagonist used to treat acromegaly. It is the polyethylene glycol (PEG) derivative of a mutant GH, B2036. Pegylation reduces its clearance and improves its overall clinical effectiveness. Like native GH, **pegvisomant** has two GH receptor binding sites. However, one of its GH receptor binding sites has increased affinity for the GH receptor, whereas its second GH receptor binding site has reduced affinity. This differential receptor affinity blocks native GH bindings as it allows the initial step (GH receptor dimerization) but prevents the conformational changes required for signal transduction. In clinical trials, **pegvisomant** was administered subcutaneously to patients with acromegaly; daily treatment for 12 months or longer reduced serum levels of IGF-I into the normal range in 97%. **Pegvisomant** does not inhibit GH secretion and may lead to increased GH levels and possible adenoma growth, so monitoring includes measurements of IGF-I and yearly MRIs of the pituitary. No serious problems have been observed; however, increases in liver enzymes without liver failure have been reported.

## **THE GONADOTROPINS (FOLLICLE-STIMULATING HORMONE & LUTEINIZING HORMONE) & HUMAN CHORIONIC GONADOTROPIN**

The gonadotropins are produced by gonadotroph cells, which constitute 7–15% of the cells in the pituitary. These hormones serve complementary functions in the reproductive process. In women, the principal function of FSH is to stimulate ovarian follicle development. Both FSH and LH are needed for ovarian steroidogenesis. In the ovary, LH stimulates androgen production by theca cells in the follicular stage of the menstrual cycle, whereas FSH stimulates the conversion of androgens to **estrogens** by granulosa cells. In the luteal phase of the menstrual cycle, estrogen and **progesterone** production is primarily under the control first of LH and then, if pregnancy occurs, under the control of human chorionic gonadotropin (hCG). Human chorionic gonadotropin is a placental glycoprotein nearly identical with LH; its actions are mediated through LH receptors.

In men, FSH is the primary regulator of spermatogenesis, whereas LH is the main stimulus for **testosterone** synthesis in Leydig cells. FSH helps maintain high local androgen concentrations in the vicinity of developing sperm by stimulating the production of androgen-binding protein in Sertoli cells. FSH also stimulates the conversion by Sertoli cells of **testosterone** to estrogen that is also required for spermatogenesis.

FSH and hCG are available in several pharmaceutical forms. They are used in states of infertility to stimulate spermatogenesis in men and to induce follicle development and ovulation in women. Their most common clinical use is for the controlled ovarian stimulation that is the cornerstone of assisted reproductive technologies such as in vitro fertilization (IVF, see below).

### **Chemistry & Pharmacokinetics**

All three hormones—FSH, LH, and hCG—are heterodimers that share an identical  $\alpha$  subunit in addition to a distinct  $\beta$  subunit that confers receptor specificity. The  $\beta$  subunits of hCG and LH are nearly identical, and hCG is typically used to obtain LH activity due to its longer half-life. All the gonadotropin preparations are administered by subcutaneous or intramuscular injection, usually on a daily basis. Half-lives vary by preparation and route of injection from 10 to 40 hours.

The first commercial gonadotropin product containing both FSH and LH was extracted from the urine of postmenopausal women. This purified extract of FSH and LH is known as **menotropin**, or human menopausal gonadotropin (**hMG**). From the early 1960s, these preparations were used for the stimulation of follicle development in women. The early extraction techniques were very crude, requiring around 30 L of urine to manufacture enough hMG needed for a single treatment cycle. These initial preparations were also contaminated with other proteins; less than 5% of the proteins present were bioactive. The FSH-to-LH bioactivity ratio of these early preparations was 1:1. As purity improved, it was necessary to add hCG in order to maintain this ratio of bioactivity.

#### B. Follicle-Stimulating Hormone

Three forms of purified FSH are available. **Urofollitropin**, also known as uFSH, is a purified preparation of human FSH extracted from the urine of postmenopausal women. Virtually all the LH activity has been removed through a form of immune-affinity chromatography that uses anti-hCG antibodies. Urofollitropin was withdrawn from the United States market in 2015. Two recombinant forms of FSH (**rFSH**) are also available: **follitropin alfa** and **follitropin beta**. The amino acid sequences of these two products are identical to that of human FSH. They differ from each other and urofollitropin in the composition of carbohydrate side chains. The rFSH preparations have a shorter half-life than preparations derived from human urine but stimulate estrogen secretion and follicle development at least as efficiently and, in some studies, more efficiently. Compared with urine-derived gonadotropins, rFSH preparations have little protein contamination and much less batch-to-batch variability, and they may cause less local tissue reaction. The rFSH preparations are considerably more expensive.

#### C. Luteinizing Hormone

**Lutropin alfa**, the first and only recombinant form of human LH, was introduced in the United States in 2004 but withdrawn in 2012. When given by subcutaneous injection, it has a half-life of about 10 hours. Lutropin has only been approved for use in combination with follitropin alfa for stimulation of follicular development in infertile hypogonadotropic hypogonadal women with profound LH deficiency (<1.2 IU/L). In hypogonadotropic hypogonadal women, the use of follitropin alfa and lutropin combination to stimulate follicle development fell out of favor due to cost and could not replace hMG, which has FSH and LH activity. Lutropin has not been used to induce ovulation due to its shorter half-life.

#### D. Human Chorionic Gonadotropin

Human chorionic gonadotropin is produced by the human placenta and excreted into the urine, whence it can be extracted and purified. It is a glycoprotein consisting of a 92-amino-acid  $\alpha$  subunit virtually identical to that of FSH, LH, and TSH, and a  $\beta$  subunit of 145 amino acids that resembles that of LH except for the presence of a carboxyl terminal sequence of 30 amino acids not present in LH. **Choriogonadotropin alfa** (rhCG) is a recombinant form of hCG. Because of its greater consistency in biologic activity, rhCG is packaged and dosed on the basis of weight rather than units of activity. All of the other gonadotropins, including rFSH, are packaged and dosed on the basis of units of activity. Both the hCG preparation that is purified from human urine and rhCG can be administered by subcutaneous or intramuscular injection.

#### Pharmacodynamics

The gonadotropins and hCG exert their effects through G protein-coupled receptors. LH and FSH have complex effects on reproductive tissues in both sexes. In women, these effects change over the time course of a menstrual cycle as a result of a complex interplay among concentration-dependent effects of the gonadotropins, cross-talk of LH, FSH, and gonadal steroids, and the influence of other ovarian hormones. A coordinated pattern of FSH and LH secretion during the menstrual cycle (see [Figure 40-1](#)) is required for normal follicle development, ovulation, and pregnancy.

During the first 8 weeks of pregnancy, the **progesterone** and estrogen required to maintain pregnancy are produced by the ovarian corpus luteum. For the first few days after ovulation, the corpus luteum is maintained by maternal LH. However, as maternal LH concentration falls owing to increasing concentrations of **progesterone** and estrogen, the corpus luteum will continue to function only if the role of maternal LH is taken over by hCG produced by syncytiotrophoblast cells in the placenta.

#### Clinical Pharmacology

The gonadotropins are used to induce follicle development and ovulation in women with anovulation that is secondary to hypogonadotropic hypogonadism, polycystic ovary syndrome, and other causes. Because of the high cost of gonadotropins and the need for close monitoring during their administration, they are generally reserved for anovulatory women who fail to respond to other less complicated forms of treatment (eg, [clomiphene](#); see [Chapter 40](#)). Gonadotropins are also used for **controlled ovarian stimulation** in assisted reproductive technology procedures. Currently, a number of different protocols use gonadotropins in ovulation induction and controlled ovulation stimulation, and new protocols are continually being developed to improve the rates of success and to decrease the two primary risks of ovulation induction: multiple pregnancies and the **ovarian hyperstimulation syndrome (OHSS)**; see below).

Although the details differ, all of these protocols are based on the complex physiology that underlies a normal menstrual cycle. Like a menstrual cycle, controlled ovulation stimulation is discussed in relation to a cycle that begins on the first day of a menstrual bleed ([Figure 37-3](#)). Shortly after the first day (usually on day 2), daily injections with one of the FSH preparations (hMG or rFSH) are begun and continued for approximately 9–12 days. In women with hypogonadotropic hypogonadism, follicle development requires treatment with a combination of FSH and LH because these women do not produce the basal level of LH that is required for normal follicle development. The dose and duration of gonadotropin treatment are based on the response as measured by the serum [estradiol](#) concentration and by ultrasound evaluation of ovarian follicle development. When exogenous gonadotropins are used to stimulate follicle development, there is risk of a premature endogenous surge in LH owing to the rapidly increasing serum [estradiol](#) levels. To prevent this, gonadotropins are almost always administered in conjunction with a drug that blocks the effects of endogenous GnRH—either continuous administration of a GnRH agonist, which down-regulates GnRH receptors, or a GnRH receptor antagonist (see below and [Figure 37-3](#)).

FIGURE 37-3

Controlled ovarian stimulation in preparation for an assisted reproductive technology such as in vitro fertilization. Follicular phase: Follicle development is stimulated with gonadotropin injections that begin about 2 days after menses begin. When the follicles are ready, as assessed by ultrasound measurement of follicle size, final oocyte maturation is induced by an injection of hCG. Luteal phase: Shortly thereafter oocytes are retrieved and fertilized in vitro. The recipient's luteal phase is supported with injections of [progesterone](#). To prevent a premature luteinizing-hormone surge, endogenous LH secretion is inhibited with either a GnRH agonist or a GnRH antagonist. In most protocols, the GnRH agonist is started midway through the preceding luteal cycle.

Copyright © McGraw Hill. All rights reserved.

When appropriate follicular growth has occurred, the gonadotropin and the GnRH agonist or GnRH antagonist injections are discontinued and hCG (3300–10,000 IU) is administered subcutaneously to induce final oocyte maturation and, in ovulation induction protocols, ovulation. The hCG administration is followed by timed intercourse or intrauterine insemination in ovulation induction and by oocyte retrieval in assisted reproductive technology procedures. Because use of GnRH agonists or antagonists during the follicular phase of ovulation induction suppresses endogenous LH production, it is important to provide exogenous hormonal support of the luteal phase. In clinical trials, exogenous [progesterone](#), hCG, or a

www.konkai.in  
combination of the two have been effective at providing adequate luteal support. However, **progesterone** is preferred for luteal support because hCG carries a higher risk of OHSS in patients with high follicular response to gonadotropins.

#### B. Male Infertility

Most of the signs and symptoms of hypogonadism in males (eg, delayed puberty, retention of prepubertal secondary sex characteristics after puberty) can be adequately treated with exogenous androgen; however, treatment of infertility in hypogonadal men requires the activity of both LH and FSH. For many years, conventional therapy has consisted of initial treatment for 8–12 weeks with injections of 1000–2500 IU hCG several times per week. After the initial phase, hMG is injected at a dose of 75–150 IU three times per week. In men with hypogonadal hypogonadism, it takes an average of 4–6 months of such treatment for sperm to appear in the ejaculate in up to 90% of patients, but often not at normal levels. Even if pregnancy does not occur spontaneously, the number of sperm is often sufficient that pregnancy can be achieved by insemination with the patient's semen (intrauterine insemination) or with the help of an assisted reproductive technique such as in vitro fertilization with or without intracytoplasmic sperm injection (ICSI), in which a single sperm is injected directly into a mature oocyte that has been retrieved after controlled ovarian stimulation of a female partner. With the advent of ICSI, the minimum threshold of spermatogenesis required for pregnancy is greatly lowered.

#### C. Outdated Uses

Chorionic gonadotropin is approved for the treatment of prepubertal cryptorchidism. Prepubertal boys were treated with intramuscular injections of hCG for 2–6 weeks. However, this clinical use is no longer supported because the long-term efficacy of hormonal treatment of cryptorchidism (~20%) is much lower than the long-term efficacy of surgical treatment (>95%), and because of concerns that early childhood treatment with hCG treatment has a negative impact on germ cells in addition to increasing the risk of precocious puberty.

In the United States, chorionic gonadotropin has a black box warning against its use for increasing weight loss. The use of hCG plus severe calorie restriction for weight loss was popularized by a publication in the 1950s claiming that the hCG selectively mobilizes body fat stores. This practice continues today, despite a preponderance of scientific evidence from placebo-controlled trials that hCG does not provide any weight loss benefit beyond the weight loss associated with severe calorie restriction alone.

#### Toxicity & Contraindications

In women treated with gonadotropins and hCG, the two most serious complications are **OHSS** and **multiple pregnancies**. Stimulation of the ovary during ovulation induction often leads to uncomplicated ovarian enlargement that usually resolves spontaneously. However, OHSS may occur and can be associated with ovarian enlargement, hypovolemia, ascites, liver dysfunction, pulmonary edema, electrolyte imbalance, and thromboembolic events. Although OHSS is often self-limited, with spontaneous resolution within a few days, severe disease may require hospitalization and intensive care. Triggering the final oocyte maturation with hCG carries the risk of inducing OHSS. GnRH agonists also induce this final oocyte maturation by promoting the release of endogenous gonadotropin stores from the hypophysis and can be used as an alternative to hCG. Use of the GnRH agonist trigger dramatically reduces the risk of OHSS, owing to the short half-life of the GnRH agonist–induced endogenous LH surge.

The probability of multiple pregnancies is increased when ovulation induction and assisted reproductive technologies are used. In ovulation induction, the risk of a multiple pregnancy is estimated to be 5–10%, whereas the percentage of multiple pregnancies in the general population is closer to 1%. Multiple pregnancies carry an increased risk of complications, such as gestational diabetes, preeclampsia, preterm labor, and premature birth. For in vitro fertilization procedures, the risk of a multiple pregnancy is determined primarily by the number of embryos transferred to the patient. A strong trend in recent years has been to transfer single embryos to avoid multiple pregnancy.

Other reported adverse effects of gonadotropin treatment are headache, depression, edema, precocious puberty, and (rarely) production of antibodies to hCG. In men treated with gonadotropins, the risk of gynecomastia is directly correlated with the level of **testosterone** produced in response to treatment.

#### GONADOTROPIN-RELEASING HORMONE & ITS ANALOGS

Gonadotropin-releasing hormone is secreted by neurons in the hypothalamus. It travels through the hypothalamic-pituitary venous portal plexus to the anterior pituitary, where it binds to G protein-coupled receptors on the plasma membranes of gonadotrophs. *Pulsatile* GnRH secretion is required

to stimulate the gonadotrophs to produce and release LH and FSH.

www.konkur.in

Sustained *nonpulsatile* administration of GnRH or GnRH analogs *inhibits* the release of FSH and LH by the pituitary in both women and men, resulting in hypogonadotropic hypogonadism. GnRH agonists are used to induce gonadal suppression in children with central precocious puberty, in early adolescents who are transgender or gender diverse, and in men with prostate cancer. They are also used in women who are undergoing assisted reproductive technology procedures or who have a gynecologic problem (like endometriosis) that is benefited by ovarian suppression.

## Chemistry & Pharmacokinetics

### A. Structure

GnRH is a decapeptide found in all mammals. **Gonadorelin** is an acetate salt of synthetic human GnRH. Substitution of amino acids at the 6 position or replacement of the C-terminal glycine-amide produces synthetic agonists. Both modifications make them more potent and longer-lasting than native GnRH and **gonadorelin**. Such analogs of GnRH include **goserelin**, **buserelin**, **histrelin**, **leuprolide**, **nafarelin**, and **triptorelin**.

### B. Pharmacokinetics

**Gonadorelin** can be administered intravenously or subcutaneously. Other GnRH agonists can be administered subcutaneously, intramuscularly, via nasal spray (**nafarelin**), or as a subcutaneous implant. The half-life of intravenous **gonadorelin** is 4 minutes, and the half-lives of subcutaneous and intranasal GnRH analogs are approximately 3 hours. The duration of clinical uses of GnRH agonists varies from a few days for controlled ovarian stimulation to a number of years for treatment of metastatic prostate cancer. Therefore, preparations have been developed with a range of durations of action from several hours (for daily administration) to 1, 3, 6, or 12 months (depot forms).

## Pharmacodynamics

The physiologic actions of GnRH exhibit complex dose-response relationships that change dramatically from the fetal period through the end of puberty. This is not surprising in view of the complex role that GnRH plays in normal reproduction, particularly in female reproduction. Pulsatile GnRH release occurs and is responsible for stimulating LH and FSH production during the fetal and neonatal period. Subsequently, from the age of 2 years until the onset of puberty, GnRH secretion falls off and the pituitary simultaneously exhibits very low sensitivity to GnRH. Just before puberty, an increase in the frequency and amplitude of GnRH release occurs and then, in early puberty, pituitary sensitivity to GnRH increases, which is due in part to the effect of increasing concentrations of gonadal steroids. In females, it usually takes several months to a year after the onset of puberty for the hypothalamic-pituitary system to produce an LH surge and ovulation. By the end of puberty, the system is well established so that menstrual cycles proceed at relatively constant intervals. The amplitude and frequency of GnRH pulses vary in a regular pattern through the menstrual cycle with the highest amplitudes occurring during the luteal phase and the highest frequency occurring late in the follicular phase. Lower pulse frequencies favor FSH secretion, whereas higher pulse frequencies favor LH secretion. Gonadal steroids as well as the peptide hormones activin, inhibin, and follistatin have complex modulatory effects on the gonadotropin response to GnRH.

In the pharmacologic use of GnRH and its analogs, pulsatile intravenous administration of **gonadorelin** every 1–4 hours stimulates FSH and LH secretion. Continuous administration of **gonadorelin** or its longer-acting analogs produces a biphasic response. During the first 7–10 days, an agonist effect results in increased concentrations of gonadal hormones in males and females; this initial phase is referred to as a *flare*. After this period, the continued presence of GnRH results in an inhibitory action that manifests as a drop in the concentration of gonadotropins and gonadal steroids (ie, hypogonadotropic hypogonadal state). The inhibitory action is due to a combination of receptor down-regulation and changes in the signaling pathways activated by GnRH.

## Clinical Pharmacology

The GnRH agonists are occasionally used for stimulation of gonadotropin production. They are used far more commonly for suppression of gonadotropin release.

### A. Stimulation

In the current era of widespread availability of gonadotropins and assisted reproductive technology, the use of pulsatile GnRH administration to treat infertility is uncommon. Although pulsatile GnRH is less likely than gonadotropins to cause multiple pregnancies and OHSS, the inconvenience and cost associated with continuous use of an intravenous pump and difficulties obtaining native GnRH (**gonadorelin**) are barriers to pulsatile GnRH. When this approach is used, a portable battery-powered programmable pump and intravenous tubing deliver pulses of **gonadorelin** every 90 minutes.

**Gonadorelin** or a GnRH agonist analog (eg, **leuprolide**) can be used to initiate an LH surge and ovulation in women with infertility who are undergoing ovulation induction with gonadotropins. Traditionally, hCG has been used to initiate ovulation in this situation. However, **gonadorelin** or a GnRH agonist is less likely to cause OHSS compared with hCG.

### 2. Male infertility

It is possible to use pulsatile **gonadorelin** for infertility in men with hypothalamic hypogonadotropic hypogonadism. A portable pump infuses **gonadorelin** intravenously every 90 minutes. Serum **testosterone** levels and semen analyses must be done regularly. At least 3–6 months of pulsatile infusions are required before significant numbers of sperm are seen. As described above, treatment of hypogonadotropic hypogonadism is more commonly done with hCG and hMG or their recombinant equivalents.

### 3. Diagnosis of LH responsiveness

GnRH may be useful in determining whether delayed puberty in a hypogonadotropic adolescent is due to constitutional delay or to hypogonadotropic hypogonadism. The LH response (but not the FSH response) to a single dose of GnRH may distinguish between these two conditions; however, there can be significant individual overlap in the LH response between the two groups. Serum LH levels are measured before and at several times after an intravenous or subcutaneous bolus of GnRH. An increase in serum LH with a peak that is  $>5\text{--}8$  mIU/mL suggests early pubertal status. An impaired LH response suggests hypogonadotropic hypogonadism due to either pituitary or hypothalamic disease, but it does not rule out constitutional delay of puberty.

## B. Suppression of Gonadotropin Production

### 1. Controlled ovarian stimulation

In the controlled ovarian stimulation that provides multiple mature oocytes for assisted reproductive technologies such as in vitro fertilization, it is critical to suppress an endogenous LH surge that could prematurely trigger ovulation. This suppression is achieved by daily subcutaneous injections of **leuprolide** or daily nasal applications of **nafarelin**. For **leuprolide**, treatment is commonly initiated with 1 mg daily for about 10 days until menstrual bleeding occurs. At that point, the dose is reduced to 0.5 mg daily until hCG is administered (see **Figure 37-3**). For **nafarelin**, the beginning dosage is generally 400 mcg twice a day, which is decreased to 200 mcg when menstrual bleeding occurs.

### 2. Endometriosis

Endometriosis is defined as the presence of estrogen-sensitive endometrium outside the uterus that results in cyclical abdominal pain in premenopausal women. The pain of endometriosis is often reduced by abolishing exposure to the cyclical changes in the concentrations of estrogen and **progesterone** that are a normal part of the menstrual cycle. The ovarian suppression induced by continuous treatment with a GnRH agonist greatly reduces estrogen and **progesterone** concentrations and prevents cyclical changes. The preferred duration of treatment with a GnRH agonist is limited to 6 months because ovarian suppression beyond this period can result in decreased bone mineral density. When relief of pain from treatment with a GnRH agonist supports continued therapy for more than 6 months, the addition of add-back therapy (estrogen or progestins) reduces or eliminates GnRH agonist-induced bone mineral loss and provides symptomatic relief without reducing the efficacy of pain relief. **Leuprolide** and **goserelin** are administered as depot preparations that provide 1 or 3 months of continuous GnRH agonist activity. **Nafarelin** is administered twice daily as a nasal spray at a dose of 0.2 mg per spray.

### 3. Uterine leiomyomata (uterine fibroids)

Uterine leiomyomata are benign, estrogen-sensitive, smooth muscle tumors in the uterus that can cause menorrhagia, with associated anemia and pelvic pain. Treatment for 3–6 months with a GnRH agonist reduces fibroid size and, when combined with supplemental iron, improves anemia. The effects of GnRH agonists are temporary, with gradual recurrent growth of leiomyomas to previous size within several months after cessation of treatment. GnRH agonists have been used widely for preoperative treatment of uterine leiomyomas, for both myomectomy and hysterectomy. GnRH agonists have been shown to improve hematologic parameters, shorten hospital stay, and decrease blood loss, operating time, and postoperative pain when given for 3 months preoperatively.

### 4. Prostate cancer

Androgen deprivation therapy is the primary therapy for prostate cancer. Combined antiandrogen therapy with continuous GnRH agonist and an androgen receptor antagonist is as effective as surgical castration in reducing serum **testosterone** concentrations and effects. **Leuprolide**, **goserelin**, **histrelin**, **buserelin**, and **triptorelin** are approved for this indication. The preferred formulation is one of the long-acting depot forms that provide 1, 3, 4, 6, or 12 months of active drug therapy. During the first 7–10 days of GnRH analog therapy, serum **testosterone** levels increase because of the agonist action of the drug; this can precipitate pain in patients with bone metastases, and tumor growth and neurologic symptoms in patients with vertebral metastases. It can also temporarily worsen symptoms of urinary obstruction. Such tumor flares can usually be avoided with the concomitant administration of an androgen receptor antagonist (**flutamide**, **bicalutamide**, or **nilutamide**) (see **Chapter 40**). Within about 2 weeks, serum **testosterone** levels fall to the hypogonadal range.

#### 5. *Central precocious puberty*

Continuous administration of a GnRH agonist is indicated for treatment of central precocious puberty (onset of secondary sex characteristics before 7–8 years in girls or 9 years in boys). Before embarking on treatment with a GnRH agonist, one must confirm central precocious puberty by demonstrating a pubertal gonadotropin response to GnRH or a “test dose” of a GnRH analog. Treatment is indicated in a child whose final height would be otherwise significantly compromised (as evidenced by a significantly advanced bone age) or in whom the early development of pubertal secondary sexual characteristics or menses causes significant emotional distress. While central precocious puberty is most often idiopathic, it is important to rule out central nervous system pathology with MRI imaging of the hypothalamic-pituitary area.

Treatment is most commonly carried out with either every-month or every-3-months intramuscular or every-6-months subcutaneous depot injection of **leuprolide** acetate or with a once-yearly implant of **histrelin** acetate. Daily subcutaneous regimens and multiple daily nasal spray regimens of GnRH agonists also are available but are not recommended due to poor adherence. Treatment with a GnRH agonist is generally continued long enough to optimize adult height and allow pubertal development that is concurrent with peers. Typically, treatment is continued until age 11 in females and age 12 in males.

#### 6. *Other*

The gonadal suppression provided by continuous GnRH agonist treatment is used in the management of advanced breast and ovarian cancer. In addition, clinical practice guidelines recommend the use of continuous GnRH agonist administration in early pubertal transgender adolescents to block endogenous puberty prior to subsequent treatment with cross-gender gonadal hormones.

#### **Toxicity**

**Gonadorelin** can cause headache, light-headedness, nausea, and flushing. Local swelling often occurs at subcutaneous injection sites. Generalized hypersensitivity dermatitis has occurred after long-term subcutaneous administration. Rare acute hypersensitivity reactions include bronchospasm and anaphylaxis. Sudden pituitary apoplexy and blindness have been reported following administration of GnRH to a patient with a gonadotropin-secreting pituitary tumor.

Continuous treatment of women with a GnRH analog (**leuprolide**, **nafarelin**, **goserelin**) causes the typical symptoms of menopause, which include hot flashes, sweats, and headaches. Depression, diminished libido, generalized pain, vaginal dryness, and breast atrophy also may occur. Ovarian cysts may develop within the first month of therapy due to its flare effect on gonadotropin secretion and generally resolve after an additional 6 weeks. Reduced bone mineral density and osteoporosis may occur with prolonged use, so patients should be monitored with bone densitometry before repeated treatment courses. Depending on the condition being treated with the GnRH agonist, it may be possible to ameliorate the signs and symptoms of the hypoestrogenic state without losing clinical efficacy by adding back a small dose of a progestin alone or in combination with a low dose of an estrogen. Contraindications to the use of GnRH agonists in women include pregnancy and breast-feeding.

In men treated with continuous GnRH agonist administration, adverse effects include hot flashes and sweats, edema, gynecomastia, decreased libido, decreased hematocrit, reduced bone density, asthenia, and injection site reactions. GnRH analog treatment of children is generally well tolerated. However, temporary exacerbation of precocious puberty may occur during the first few weeks of therapy. **Nafarelin** nasal spray may cause or aggravate sinusitis.

#### **GnRH RECEPTOR ANTAGONISTS**

Four synthetic decapeptides that function as competitive antagonists of GnRH receptors are available for clinical use. **Ganirelix**, **cetorelix**, **degarelix**, and **organelix** inhibit the secretion of FSH and LH in a dose-dependent manner. **Ganirelix** and **cetorelix** are approved for use in controlled

ovarian stimulation procedures, whereas **degarelix** and **abarelix** are approved for men with advanced prostate cancer. More recently, orally active nonpeptide GnRH-receptor antagonists (eg, **elagolix**, **relugolix**, **linzagolix**) were introduced to clinical practice for the management of moderate to severe pain associated with endometriosis and of moderate to severe pain/abnormal uterine bleeding symptoms of uterine fibroids in women of reproductive age.

### Pharmacokinetics

**Ganirelix** and **cetorelix** are absorbed rapidly after subcutaneous injection. Administration of 0.25 mg daily maintains GnRH antagonism. Alternatively, a single 3.0-mg dose of **cetorelix** suppresses LH secretion for 96 hours. **Degarelix** therapy is initiated with 240 mg administered as two subcutaneous injections. Maintenance dosing is with an 80-mg subcutaneous injection every 28 days. **Elagolix** rapidly suppressed LH, FSH, **estradiol**, and **progesterone** in a dose-dependent manner when administered orally at doses of 150 mg once daily or 100–400 mg twice daily in premenopausal women.

### Clinical Pharmacology

#### A. Suppression of Gonadotropin Production

##### 1. Controlled ovarian stimulation

**Ganirelix** and **cetorelix** are approved for preventing the LH surge during controlled ovarian stimulation. They offer several advantages over continuous treatment with a GnRH agonist. Because GnRH antagonists produce an immediate antagonist effect, their use can be delayed until day 6–8 of the in vitro fertilization cycle (see **Figure 37–3**), and thus the duration of administration is shorter. They also appear to have a less suppressive effect on the ovarian response to gonadotropin stimulation, which permits a decrease in the total duration and dose of gonadotropin. On the other hand, because their antagonist effects reverse more quickly after their discontinuation, adherence to the treatment regimen is critical.

##### 2. Endometriosis and uterine leiomyoma

In 2018, the FDA approved **elagolix** tablets for the management of moderate to severe pain associated with endometriosis. **Elagolix** and other nonpeptide GnRH-receptor antagonist with and without low-dose hormone add-back therapy are undergoing phase III clinical trial for heavy menstrual bleeding and pain associated with uterine leiomyoma.

##### 3. Advanced prostate cancer

**Degarelix** and **abarelix** are approved for the treatment of symptomatic advanced prostate cancer. These GnRH antagonists reduce concentrations of gonadotropins and androgens more rapidly than GnRH agonists and avoid the **testosterone** surge seen with GnRH agonist therapy.

### Toxicity

When used for controlled ovarian stimulation, **ganirelix** and **cetorelix** are well tolerated. The most common adverse effects are nausea and headache. **Elagolix** is also well tolerated in women with endometriosis or uterine leiomyoma with most adverse effects (eg, hot flush, night sweats, headache, mood swings) being of mild to moderate severity. During the treatment of men with prostate cancer, **degarelix** causes injection-site reactions and increases in liver enzymes. Like continuous treatment with a GnRH agonist, **degarelix** and **abarelix** lead to signs and symptoms of androgen deprivation, including hot flushes and weight gain.

## PROLACTIN

Prolactin is a 198-amino-acid peptide hormone produced in the anterior pituitary. Its structure resembles that of GH. Prolactin is the principal hormone responsible for lactation. Milk production is stimulated by prolactin when appropriate circulating levels of **estrogens**, progestins, corticosteroids, and **insulin** are present. A deficiency of prolactin—which can occur in rare states of pituitary deficiency—is manifested by failure to lactate. No preparation of prolactin is available for use in prolactin-deficient patients.

In pituitary stalk section from surgery or head trauma, stalk compression due to a sellar mass, or rare cases of hypothalamic destruction, prolactin levels may be elevated as a result of impaired transport of **dopamine** (prolactin-inhibiting hormone) to the pituitary. Much more commonly, prolactin is elevated as a result of prolactin-secreting adenomas. In addition, a number of drugs elevate prolactin levels. These include antipsychotic and gastrointestinal motility drugs that are known **dopamine** receptor antagonists, **estrogens**, and opiates. Hyperprolactinemia causes hypogonadism, which manifests with infertility, oligomenorrhea or amenorrhea, and galactorrhea in premenopausal women, and with loss of libido, erectile

dysfunction and infertility in men. In the case of large tumors (macroadenomas), hyperprolactinemia can be associated with symptoms of a pituitary mass, including visual changes due to compression of the optic nerves. The hypogonadism and infertility associated with hyperprolactinemia result from inhibition of GnRH release. For patients with symptomatic hyperprolactinemia, inhibition of prolactin secretion can be achieved with **dopamine** agonists, which act in the pituitary to inhibit prolactin release.

## DOPAMINE AGONISTS

Adenomas that secrete excess prolactin usually retain the sensitivity to inhibition by **dopamine** exhibited by normal pituitary lactotrophs, prolactin-secreting cells. **Bromocriptine** and **cabergoline** are ergot derivatives (see **Chapters 16** and **28**) with a high affinity for **dopamine** D<sub>2</sub> receptors.

**Quinagolide**, a drug approved in Europe, is a nonergot agent with similarly high D<sub>2</sub> receptor affinity. The chemical structure and pharmacokinetic features of ergot alkaloids are presented in **Chapter 16**.

**Dopamine** agonists suppress prolactin release very effectively in patients with hyperprolactinemia and GH release is reduced in patients with acromegaly, although not as effectively as somatostatin analogs. **Bromocriptine** has also been used in Parkinson disease to improve motor function and reduce **levodopa** requirements (see **Chapter 28**). Newer, nonergot D<sub>2</sub> agonists used in Parkinson disease (**pramipexole** and **ropinirole**; see **Chapter 28**) have been reported to interfere with lactation, but they are not approved for use in hyperprolactinemia.

### Pharmacokinetics

All available **dopamine** agonists are active as oral preparations, and all are eliminated by metabolism. They can also be absorbed systemically after vaginal insertion of tablets to avoid nausea due to oral administration. **Cabergoline**, with a half-life of approximately 65 hours, has the longest duration of action. **Quinagolide** has a half-life of about 20 hours, whereas the half-life of **bromocriptine** is about 7 hours. After vaginal administration, serum levels peak more slowly.

### Clinical Pharmacology

#### A. Hyperprolactinemia

A **dopamine** agonist is the standard first-line treatment for hyperprolactinemia. These drugs shrink pituitary prolactin-secreting tumors, lower circulating prolactin levels, and restore ovulation in approximately 70% of women with microadenomas and 30% of women with macroadenomas (**Figure 37-4**). **Cabergoline** is initiated at 0.25 mg twice weekly orally or vaginally. It can be increased gradually, according to serum prolactin determinations, up to a maximum of 1 mg twice weekly. **Bromocriptine** is generally taken daily after the evening meal at the initial dose of 1.25 mg; the dose is then increased as tolerated. Most patients require 2.5–7.5 mg daily. Long-acting oral **bromocriptine** formulations (Parlodel SRO) and intramuscular formulations (Parlodel LAR) are available outside the United States.

#### FIGURE 37-4

Results from a clinical trial of **cabergoline** in women with hyperprolactinemia and anovulation. **(A)** The dashed line indicates the upper limit of normal serum prolactin concentrations. **(B)** Complete success was defined as pregnancy or at least two consecutive menses with evidence of ovulation at least once. Partial success was two menstrual cycles without evidence of ovulation or just one ovulatory cycle. The most common reasons for withdrawal from the trial were nausea, headache, dizziness, abdominal pain, and fatigue. (Data from Webster J, Piscitelli G, Polli A, Ferrari CI, Ismail I, Scanlon MF: A comparison of **cabergoline** and **bromocriptine** in the treatment of hyperprolactinemic amenorrhea. **Cabergoline** Comparative Study Group, *N Engl J Med* 1994 Oct 6;331(14):904-909.)

Basic & Clinical Pharmacology, Sixteenth Edition  
Copyright © McGraw Hill. All rights reserved.

### B. Physiologic Lactation

**Dopamine** agonists were used in the past to prevent breast engorgement when breast-feeding was not desired. Their use for this purpose has been discouraged because of toxicity (see [Toxicity & Contraindications](#)).

### C. Acromegaly

A **dopamine** agonist alone or in combination with pituitary surgery, radiation therapy, or somatostatin analog administration can be used to treat acromegaly. The doses required are higher than those used to treat hyperprolactinemia. For example, patients with acromegaly require 20–30 mg/d of **bromocriptine** and seldom respond adequately to **bromocriptine** alone unless the pituitary tumor secretes prolactin as well as GH.

### Toxicity & Contraindications

**Dopamine** agonists can cause nausea, headache, light-headedness, orthostatic hypotension, and fatigue. Psychiatric manifestations occasionally occur, even at lower doses, and may take months to resolve. Erythromelalgia occurs rarely. High dosages of ergot-derived preparations can cause cold-induced peripheral digital vasospasm. Pulmonary infiltrates have occurred with chronic high-dosage therapy. **Cabergoline** treatment at high doses for Parkinson disease is associated with higher risk of valvular heart disease, but probably not at the lower dose used for hyperprolactinemia. **Cabergoline** appears to cause nausea less often than **bromocriptine**. Vaginal administration can reduce nausea, but may cause local irritation.

**Dopamine** agonist therapy during the early weeks of pregnancy has not been associated with an increased risk of spontaneous abortion or congenital malformations. Although there has been a longer experience with the safety of **bromocriptine** during early pregnancy, there is growing evidence that **cabergoline** is also safe in women with macroadenomas who must continue a **dopamine** agonist during pregnancy. In patients with small pituitary adenomas, **dopamine** agonist therapy is discontinued upon conception because the risk of growth of microadenomas during pregnancy is low (2.7%). Patients with macroadenomas require vigilance, as the risk for tumor progression is high (22.9%) and such patients often require a **dopamine** agonist

throughout pregnancy. There have been rare reports of stroke or coronary thrombosis in postpartum women taking [bromocriptine](#) to suppress postpartum lactation.

## POSTERIOR PITUITARY HORMONES

The two posterior pituitary hormones—[vasopressin](#) and [oxytocin](#)—are synthesized in neuronal cell bodies in the hypothalamus and transported via their axons to the posterior pituitary, where they are stored and then released into the circulation. Each has limited but important clinical uses.

### OXYTOCIN

[Oxytocin](#) is a peptide hormone secreted by the posterior pituitary. [Oxytocin](#) stimulates muscular contractions in the uterus and myoepithelial contractions in the breast. Thus, it is involved in parturition and the letdown of milk. During the second half of pregnancy, uterine smooth muscle shows an increase in the expression of [oxytocin](#) receptors and becomes increasingly sensitive to the stimulant action of endogenous [oxytocin](#).

### Chemistry & Pharmacokinetics

#### A. Structure

[Oxytocin](#) is a 9-amino-acid peptide with an intrapeptide disulfide cross-link ([Figure 37-5](#)). Its amino acid sequence differs from that of [vasopressin](#) at positions 3 and 8.

FIGURE 37-5

Posterior pituitary hormones and [desmopressin](#). (Reproduced with permission from Ganong WF: *Review of Medical Physiology*, 21st ed. New York, NY: McGraw Hill; 2003.)

#### B. Absorption, Metabolism, and Excretion

[Oxytocin](#) is administered intravenously for initiation and augmentation of labor. It also can be administered intramuscularly for control of postpartum bleeding. [Oxytocin](#) is not bound to plasma proteins and is rapidly eliminated by the kidneys and liver, with a circulating half-life of 5 minutes.

### Pharmacodynamics

[Oxytocin](#) acts through G protein-coupled receptors and the phosphoinositide-calcium second-messenger system to contract uterine smooth muscle.

www.konkur.in stimulates the release of prostaglandins and leukotrienes that augment uterine contraction. In small doses **oxytocin** increases both the frequency and the force of uterine contractions. At higher doses, it produces sustained contraction.

**Oxytocin** also causes contraction of myoepithelial cells surrounding mammary alveoli, which leads to milk letdown. Without oxytocin-induced contraction, normal lactation cannot occur. At high concentrations, **oxytocin** has weak antidiuretic and pressor activity due to activation of **vasopressin** receptors.

## Clinical Pharmacology

**Oxytocin** is used to induce labor for conditions requiring expedited vaginal delivery such as uncontrolled maternal diabetes, worsening preeclampsia, intrauterine infection, or ruptured membranes after 34 gestational weeks. It is also used to augment protracted labor. **Oxytocin** can also be used in the immediate postpartum period to stop vaginal bleeding due to uterine atony.

Before delivery, **oxytocin** is usually administered intravenously via an infusion pump with appropriate fetal and maternal monitoring. For induction of labor, an initial infusion rate of 0.5–2 mU/min is increased every 30–60 minutes until a physiologic contraction pattern is established. The maximum infusion rate is 20 mU/min. For postpartum uterine bleeding, 10–40 units are added to 1 L of 5% **dextrose**, and the infusion rate is titrated to control uterine atony. Alternatively, 10 units of **oxytocin** can be administered by intramuscular injection.

During the antepartum period, **oxytocin** induces uterine contractions that transiently reduce placental blood flow to the fetus. The **oxytocin** challenge test measures the fetal heart rate response to a standardized **oxytocin** infusion and provides information about placental circulatory reserve. An abnormal response, seen as late decelerations in the fetal heart rate, may indicate fetal hypoxia and may warrant immediate cesarean delivery.

## Toxicity & Contraindications

When **oxytocin** is used judiciously, serious toxicity is rare. The toxicity that does occur is due either to excessive stimulation of uterine contractions or to inadvertent activation of **vasopressin** receptors. Excessive stimulation of uterine contractions before delivery can cause fetal distress, placental abruption, or uterine rupture. These complications can be detected early by means of standard fetal monitoring. High concentrations of **oxytocin** with activation of **vasopressin** receptors can cause excessive fluid retention, or water intoxication, leading to hyponatremia, heart failure, seizures, and death. Bolus injections of **oxytocin** can cause hypotension. To avoid hypotension, **oxytocin** is administered intravenously as dilute solutions at a controlled rate.

Contraindications to **oxytocin** include fetal distress, fetal malpresentation, placental abruption, and other predispositions for uterine rupture, including previous extensive uterine surgery.

## OXYTOCIN ANTAGONIST

**Atosiban** is an antagonist of the **oxytocin** receptor that has been approved outside the United States as a treatment (tocolysis) for preterm labor. Atosiban is a modified form of **oxytocin** that is administered by intravenous infusion for 2–48 hours. In a small number of published clinical trials, atosiban appears to be as effective as  $\beta$ -adrenoceptor-agonist tocolytics and to produce fewer adverse effects. In 1998, however, the FDA decided not to approve atosiban based on concerns about efficacy and safety.

## VASOPRESSIN (ANTIDIURETIC HORMONE, ADH)

**Vasopressin** is a peptide hormone released by the posterior pituitary in response to rising plasma tonicity or falling blood pressure. It possesses antidiuretic and vasopressor properties. A deficiency of this hormone results in central diabetes insipidus (DI) (see **Chapters 15** and **17**). Central DI is caused by a variety of acquired conditions, including tumors, trauma, and neurosurgical procedures, as well as congenital conditions that result in decreased neurons of the hypothalamic/posterior pituitary axis and loss of **vasopressin** secretion.

## Chemistry & Pharmacokinetics

### A. Structure

**Vasopressin** is a nonapeptide with a 6-amino-acid ring and a 3-amino-acid side chain. The residue at position 8 is **arginine** in humans and in most other

mammals except pigs and related species, whose **vasopressin** contains lysine at position 8 (see [Figure 37–5](#)). **Desmopressin** acetate (DDAVP, 1-desamino-8-D-arginine **vasopressin**) is a long-acting synthetic analog of **vasopressin** with minimal pressor activity and an antidiuretic-to-pressor ratio 4000 times that of **vasopressin**. **Desmopressin** is modified at position 1 and contains a D-amino acid at position 8. Like **vasopressin** and **oxytocin**, **desmopressin** has a disulfide linkage between positions 1 and 6.

### B. Absorption, Metabolism, and Excretion

**Vasopressin** is administered by intravenous or intramuscular injection. The half-life of circulating **vasopressin** is approximately 15 minutes, with renal and hepatic metabolism via reduction of the disulfide bond and peptide cleavage.

**Desmopressin** can be administered intravenously, subcutaneously, intranasally, or orally. The half-life of circulating **desmopressin** is 1.5–2.5 hours. Nasal **desmopressin** is available as a unit dose spray that delivers 10 mcg per spray; it is also available with a calibrated nasal tube that can be used to deliver a more precise dose. Nasal bioavailability of **desmopressin** is 3–4%, whereas oral bioavailability is less than 1%.

### Pharmacodynamics

**Vasopressin** activates two subtypes of G protein-coupled receptors (see [Chapter 17](#)).  $V_1$  receptors are found on vascular smooth muscle cells and mediate vasoconstriction via the coupling protein  $G_q$  and phospholipase C.  $V_2$  receptors are found on renal tubule cells and reduce diuresis through increased water permeability and water resorption in the collecting tubules via  $G_s$  and adenylyl cyclase. Extrarenal  $V_2$ -like receptors regulate the release of coagulation factor VIII and von Willebrand factor, which increases platelet aggregation.

### Clinical Pharmacology

**Desmopressin** is the treatment of choice for pituitary diabetes insipidus. The dosage of **desmopressin** is 10–40 mcg in two to three divided doses as a nasal spray or, as an oral tablet, 0.1–0.2 mg two to three times daily. Enteral absorption of **desmopressin** is decreased by 50% when taken with meals, so fasting administration may be required if there is poor response to oral dosing. The dosage by subcutaneous injection is 1–4 mcg every 12–24 hours as needed for polyuria, polydipsia, or hypernatremia. **Vasopressin** as intermittent subcutaneous injection or low-dose infusion may be used to treat diabetes insipidus with close monitoring of urine output for dose adjustments. **Vasopressin** infusion is effective in some cases of esophageal variceal bleeding and colonic diverticular bleeding and may be used as a second-line agent in refractory vasodilatory shock. Bedtime **desmopressin** therapy, by intranasal, oral, or sublingual administration, ameliorates nocturnal enuresis by decreasing nocturnal urine production. **Desmopressin** is also used for the treatment of coagulopathy in uremia, hemophilia A, and von Willebrand disease (see [Chapter 34](#)).

### Toxicity & Contraindications

Headache, nausea, abdominal cramps, agitation, and allergic reactions occur rarely with use. Overdosage may cause water intoxication due to impaired ability to excrete free water from the kidneys, which results in hyponatremia that can progress to coma and/or seizures. **Vasopressin**, but not **desmopressin**, can cause vasoconstriction and ischemia and should be used cautiously in patients with coronary artery disease. Nasal insufflation of **desmopressin** may be less effective when nasal congestion is present.

## VASOPRESSIN RECEPTOR ANTAGONISTS

There are two subtypes of receptors for **vasopressin**: the  $V_{1a}$  and  $V_{1b}$ , and the  $V_2$  receptors. The  $V_2$  receptor mediates the antidiuretic response of **vasopressin** by promoting free water reabsorption in renal collecting tubules. The  $V_{1a}$  and  $V_{1b}$  receptors primarily affect vasoconstriction and adrenocorticotrophic hormone release, respectively. A group of nonpeptide antagonists of **vasopressin** receptors has been developed for use in patients with euvolemic or hypervolemic hyponatremia, which is often associated with elevated concentrations of **vasopressin**. **Conivaptan** has high affinity for both  $V_{1a}$  and  $V_2$  receptors. **Tolvaptan** has a 30-fold higher affinity for  $V_2$  than for  $V_1$  receptors. In several clinical trials, both agents promote the excretion of free water, restoration of serum sodium concentration, relieve symptoms, and reduce objective signs of hyponatremia and heart failure. **Conivaptan**, administered intravenously, and **tolvaptan**, given orally, are approved by the FDA for treatment of persistent hyponatremia that cannot be maintained above 120 mEq/L or in patients with persistent neurologic symptoms. **Tolvaptan** treatment duration is limited to 30 days due to [Telgram: @pharm\\_1k](#), including life-threatening liver failure, and requires regular monitoring of ALT, AST, and bilirubins. Several other selective

## SUMMARY Hypothalamic & Pituitary Hormones<sup>1</sup>

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>GROWTH HORMONE (GH)</b>				
<ul style="list-style-type: none"> <li>• <b>Somatropin</b></li> </ul>	Recombinant form of human GH • acts through GH receptors to increase production of IGF-I	Restores normal growth and metabolic GH effects in GH-deficient individuals • increases final adult height in some children with short stature not due to GH deficiency	Replacement in GH deficiency • increased final adult height in children with certain conditions associated with short stature (see <a href="#">Table 37-4</a> ) • wasting in HIV infection • short bowel syndrome	SC injection • <i>Toxicity:</i> Pseudotumor cerebri, slipped capital femoral epiphysis, edema, hyperglycemia, progression of scoliosis, risk of asphyxia in severely obese patients with Prader-Willi syndrome and upper airway obstruction or sleep apnea
<ul style="list-style-type: none"> <li>• <i>Somapacitan, lonapegsomatropin: weekly formulation of <a href="#">somatropin</a></i></li> </ul>				
<b>IGF-I AGONIST</b>				
<ul style="list-style-type: none"> <li>• <b>Mecasermin</b></li> </ul>	Recombinant form of IGF-I that stimulates IGF-I receptors	Improves growth and metabolic IGF-I effects in individuals with IGF-I deficiency due to severe GH resistance	Replacement in IGF-I deficiency that is not responsive to exogenous GH	SC injection • <i>Toxicity:</i> Hypoglycemia, intracranial hypertension, lipohypertrophy, tonsillar hypertrophy, increased liver enzymes
<b>SOMATOSTATIN ANALOGS</b>				
<ul style="list-style-type: none"> <li>• <b>Octreotide</b></li> </ul>	Agonist at somatostatin receptors	Inhibits production of GH and, to a lesser extent, of TSH, <a href="#">glucagon</a> , <a href="#">insulin</a> , and gastrin	Acromegaly and several other hormone-secreting tumors • acute control of bleeding from esophageal varices • refractory diarrhea	SC or IV injection • oral • long-acting formulation injected IM monthly • <i>Toxicity:</i> Transient gastrointestinal disturbances, gallstones, bradycardia, cardiac conduction problems
<ul style="list-style-type: none"> <li>• <i>Lanreotide: Similar to <a href="#">octreotide</a>; available as a monthly SC injection formulation for acromegaly</i></li> </ul>				
<ul style="list-style-type: none"> <li>• <i>Pasireotide: available as a monthly IM injection for acromegaly and Cushing disease (also SC dosing); frequent hyperglycemia</i></li> </ul>				
<b>GH RECEPTOR ANTAGONIST</b>				
<ul style="list-style-type: none"> <li>• <b>Pegvisomant</b></li> </ul>	Blocks GH receptors	Ameliorates effects of excess GH production	Acromegaly	SC injection • <i>Toxicity:</i> Increased liver enzymes • need to monitor for pituitary adenoma growth

**GONADOTROPINS: FOLLICLE-STIMULATING HORMONE (FSH) ANALOGS**

• Follitropin alfa	Activates FSH receptors	Mimics effects of endogenous FSH	Controlled ovarian stimulation • infertility due to hypogonadotropic hypogonadism in men	SC injection • <i>Toxicity</i> : Ovarian hyperstimulation syndrome and multiple pregnancies in women • gynecomastia in men • headache, depression, edema in both sexes
--------------------	-------------------------	----------------------------------	--	--

• *Follitropin beta*: A recombinant product with the same peptide sequence as follitropin alfa but differs in its carbohydrate side chains

• *Urofollitropin*: Human FSH purified from the urine of postmenopausal women

• *Menotropins* (hMG): Extract of the urine of postmenopausal women; contains both FSH and LH activity

**GONADOTROPINS: LUTEINIZING HORMONE (LH) ANALOGS**

• Human chorionic gonadotropin (hCG)	Agonist at LH receptors	Mimics effects of endogenous LH	Initiation of final oocyte maturation and ovulation during controlled ovarian stimulation • male hypogonadotropic hypogonadism	IM or SC injection • <i>Toxicity</i> : Ovarian hyperstimulation syndrome • headache, depression, edema in both sexes
--------------------------------------	-------------------------	---------------------------------	--	--

• *Choriogonadotropin alfa*: Recombinant form of hCG

• *Lutropin*: Recombinant form of human LH

• *Menotropins* (hMG): Extract of the urine of postmenopausal women that contains both FSH and LH activity

**GONADOTROPIN-RELEASING HORMONE (GnRH) ANALOGS**

• <i>Leuprolide</i>	Agonist at GnRH receptors	Increased LH and FSH secretion with intermittent administration • reduced LH and FSH secretion with prolonged continuous administration	Ovarian suppression • controlled ovarian stimulation • central precocious puberty • block of endogenous puberty in some transgender/gender variant early pubertal adolescents • advanced prostate cancer	Administered IV, SC, IM, or intranasally • depot formulations are available • <i>Toxicity</i> : Headache, light-headedness, nausea, injection site reactions • symptoms of hypogonadism with continuous treatment
---------------------	---------------------------	---	--	---

• *Gonadorelin*: Synthetic human GnRH

• Other GnRH analogs: *Goserelin*, *buserelin*, *histrelin*, *nafarelin*, and *triptorelin*

**GONADOTROPIN-RELEASING HORMONE (GnRH) RECEPTOR ANTAGONISTS**

• <i>Ganirelix</i>	Blocks GnRH receptors	Reduces endogenous production of LH and FSH	Prevention of premature LH surge during controlled ovarian stimulation	SC injection • <i>Toxicity</i> : Nausea, headache
--------------------	-----------------------	---	--	---

• *Cetrorelix*: Similar to *ganirelix*, approved for controlled ovarian stimulation

- *Degarelix and abarelix: Approved for advanced prostate cancer*

### DOPAMINE AGONISTS

• Bromocriptine	Activates dopamine D <sub>2</sub> receptors	Suppresses pituitary secretion of prolactin and, less effectively, GH • dopaminergic effects on CNS motor control and behavior	Treatment of hyperprolactinemia • acromegaly • Parkinson disease (see Chapter 28)	Administered orally or, for hyperprolactinemia, vaginally • <i>Toxicity:</i> Gastrointestinal disturbances, orthostatic hypotension, headache, psychiatric disturbances, vasospasm and pulmonary infiltrates in high doses
-----------------	---	--	---	---

- *Cabergoline: Another ergot derivative with similar effects*

<b>OXYTOCIN</b>	Activates oxytocin receptors	Increased uterine contractions	Induction and augmentation of labor • control of uterine hemorrhage after delivery	IV infusion or IM injection • <i>Toxicity:</i> Fetal distress, placental abruption, uterine rupture, fluid retention, hypotension
-----------------	------------------------------	--------------------------------	--	---

### OXYTOCIN RECEPTOR ANTAGONIST

• Atosiban	Blocks oxytocin receptors	Decreased uterine contractions	Tocolysis for preterm labor (not available in the USA)	IV infusion • <i>Toxicity:</i> Concern about increased rates of infant death; not FDA approved
------------	---------------------------	--------------------------------	--	--

### VASOPRESSIN RECEPTOR AGONISTS

• Desmopressin	Relatively selective vasopressin V <sub>2</sub> receptor agonist	Acts in the kidney collecting duct cells to decrease the excretion of water • acts on extrarenal V <sub>2</sub> receptors to increase factor VIII and von Willebrand factor	Central diabetes insipidus • primary nocturnal enuresis • hemophilia A and von Willebrand disease	Oral, IV, SC, sublingual, or intranasal • <i>Toxicity:</i> Gastrointestinal disturbances, headache, hyponatremia, allergic reactions
----------------	--	---	---	--

- *Vasopressin: Available for treatment of diabetes insipidus and sometimes used to control bleeding from esophageal varices*

### VASOPRESSIN RECEPTOR ANTAGONIST

• Conivaptan	Antagonist of vasopressin V <sub>1a</sub> and V <sub>2</sub> receptors	Increased renal excretion of water in conditions associated with increased vasopressin	Hyponatremia in hospitalized patients	IV infusion • <i>Toxicity:</i> Infusion site reactions
--------------	--	--	---------------------------------------	--

- *Tolvaptan: Similar but more selective for vasopressin V<sub>2</sub> receptors; oral administration; indications: autosomal dominant polycystic kidney disease and hyponatremia; treatment course initiated in the hospital and limited to 30 days due to risk of hepatotoxicity*

**PREPARATIONS AVAILABLE**

GENERIC NAME	AVAILABLE AS
<b>GROWTH FACTOR AGONISTS &amp; ANTAGONISTS</b>	
Lanreotide acetate	Somatuline Depot
Lonapegsomatropin	Skytrofa
Mecasermin	Increlex
Octreotide acetate	Bynfezia, Mycapssa, Sandostatin, Sandostatin LAR Depot
Pasireotide	Signifor, Signifor LAR
Pegvisomant	Somavert
Somapacitan	Sogroya
Somatropin	Genotropin, Humatrope, Norditropin, Nutropin, Omnitrope, Saizen, Serostim, Zomacton, Zorbtive
<b>GONADOTROPIN AGONISTS &amp; ANTAGONISTS</b>	
Abarelix	Plenaxis*
Cetrorelix acetate	Cetrotide
Choriogonadotropin alfa (rhCG)	Ovidrel
Chorionic gonadotropin (hCG)	Pregnyl, Novarel
Degarelix	Firmagon
Elagolix	Orilissa
Follitropin alfa (rFSH)	Gonal-f
Follitropin beta (rFSH)	Follistim
Ganirelix acetate	Antagon, Fyremadel
Gonadorelin hydrochloride (GnRH)	Factrel

Goserelin acetate	Zoladex
Histrelin acetate	Supprelin LA, Vantas
Leuprolide acetate	Eligard, Lupron, Fensolvi
Menotropins (hMG)	Menopur
Nafarelin acetate	Synarel
Triptorelin pamoate	Trelstar, Trelstar LA, Trelstar Depot, Triptodur
<b>PROLACTIN ANTAGONISTS (DOPAMINE AGONISTS)</b>	
Bromocriptine mesylate	Parlodel, Cycloset
Cabergoline	Dostinex
<b>OXYTOCIN</b>	
Oxytocin	Pitocin
<b>VASOPRESSIN AGONISTS AND ANTAGONISTS</b>	
Conivaptan HCl	Vaprisol
Desmopressin acetate	DDAVP, Nocdurna, Noctiva, Stimite
Tolvaptan	Samsca, Jynarque
Vasopressin	Pitressin
<b>OTHER</b>	
Corticotropin ovine triflutate	Acthrel
Corticotropin	H.P. Acthar Gel
ACTH	Cortrosyn, Cosyntropin
Thyrotropin alfa	Thyrogen

\*Withdrawn from the USA.

While growth hormone (GH) may have some direct growth-promoting effects, it is thought to mediate skeletal growth principally through production of insulin-like growth factor I (IGF-I) at the epiphyseal plate, which acts mainly in an autocrine/paracrine manner. IGF-I may also promote statural growth through endocrine mechanisms. This patient is at risk for multiple hypothalamic/pituitary deficiencies due to the location of her tumor and effects of treatments on the hypothalamus and pituitary. She may have ACTH/cortisol and TSH/thyroid hormone deficiencies and thus may require supplementation with [hydrocortisone](#) and [levothyroxine](#), in addition to supplementation with GH. She should be evaluated for the presence of central diabetes insipidus in light of her increased urination and fluid intake and, if present, treated with [desmopressin](#), a V<sub>2</sub> [vasopressin](#) receptor-selective analog. The patient likely has gonadotropin deficiency and will not initiate puberty spontaneously. She should be evaluated if she manifests delayed puberty in the future and provided increasing doses of [estradiol](#) to mimic puberty.

## Chapter 38: Thyroid & Antithyroid Drugs

Betty J. Dong

### CASE STUDY

#### CASE STUDY

JP is a 33-year-old woman who presents with complaints of fatigue requiring daytime naps, weight gain, cold intolerance, and muscle weakness for the last few months. These complaints are new since she used to always feel “hot,” noted difficulty sleeping, and could eat anything that she wanted without gaining weight. She also would like to become pregnant in the near future. Because of poor medication adherence to **methimazole** and **propranolol**, she received radioactive **iodine** (RAI) therapy, developed hypothyroidism, and was started on **levothyroxine** 100 mcg daily. Other medications include calcium carbonate three times daily to “protect her bones” and **omeprazole** for “heartburn.” On physical examination, her blood pressure is 130/89 mm Hg with a pulse of 50 bpm. Her weight is 136 lb (61.8 kg), an increase of 10 lb (4.5 kg) in the last year. Her thyroid gland is not palpable and her reflexes are delayed. Laboratory findings include a thyroid-stimulating hormone (TSH) level of 24.9  $\mu$ IU/mL (normal 0.45–4.12  $\mu$ IU/mL) and a free thyroxine level of 8 pmol/L (normal 10–18 pmol/L). Evaluate the management of her past history of hyperthyroidism and assess her current thyroid status. Identify your treatment recommendations to maximize control of her current thyroid status.

### THYROID PHYSIOLOGY

The normal thyroid gland secretes sufficient amounts of the thyroid hormones—**triiodothyronine (T<sub>3</sub>)** and **tetraiodothyronine (T<sub>4</sub>, thyroxine)**—to normalize growth and development, body temperature, and energy levels. <sup>†</sup> These hormones contain 59% and 65% (respectively) **iodine** as an essential part of the molecule. **Calcitonin**, the second type of thyroid hormone, is important in the regulation of calcium metabolism and is discussed in [Chapter 42](#).

#### Iodide Metabolism

The recommended daily adult iodide ( $I^-$ )<sup>†</sup> intake is 150 mcg (200 mcg during pregnancy and lactation and up to 250 mcg for children).

Iodide, ingested from food, water, or medication, is rapidly absorbed and enters an extracellular fluid pool. The thyroid gland removes about 75 mcg a day from this pool for hormone synthesis, and the balance is excreted in the urine. If iodide intake is increased, the fractional **iodine** uptake by the thyroid is diminished.

#### Biosynthesis of Thyroid Hormones

Once taken up by the thyroid gland, iodide undergoes a series of enzymatic reactions that incorporate it into active thyroid hormone (see [Figure 38–1](#)). The first step is the transport of iodide into the thyroid gland by an intrinsic follicle cell basement membrane protein called the sodium/iodide symporter (NIS). This can be inhibited by large doses of iodides as well as anions—eg, thiocyanate ( $SCN^-$ ), pertechnetate ( $TcO_4^-$ ), and perchlorate ( $ClO_4^-$ ). At the apical cell membrane a second  $I^-$  transport enzyme called pendrin controls the flow of iodide across the membrane. Pendrin is also found in the cochlea of the inner ear. If pendrin is deficient or absent (SLC26A4 mutation), a hereditary syndrome of goiter and deafness, called **Pendred syndrome (PDS)**, ensues. At the apical cell membrane, iodide is oxidized by thyroidal peroxidase (TPO) to **iodine**, in which form it rapidly iodinates tyrosine residues within the thyroglobulin molecule to form **monoiodotyrosine (MIT)** and **diiodotyrosine (DIT)**. This process is called

**Iodide organification.** Thyroidal peroxidase is strongly blocked by high levels of intrathyroidal iodide and more persistently blocked by thioamide drugs. Gene expression of TPO is stimulated by thyroid-stimulating hormone (TSH).

FIGURE 38-1

Biosynthesis of thyroid hormones. The sites of action of various drugs that interfere with thyroid hormone biosynthesis are shown. (Reproduced with permission from Gardner DG, Shoback D: Greenspan's Basic & Clinical Endocrinology, 8th ed. New York, NY: McGraw Hill; 2007.)

Two molecules of DIT combine within the thyroglobulin molecule to form L-thyroxine ( $T_4$ ). One molecule of MIT and one molecule of DIT combine to form  $T_3$ . In addition to thyroglobulin, other proteins within the gland may be iodinated, but these iodoproteins do not have hormonal activity.

Thyroxine,  $T_3$ , MIT, and DIT are released from thyroglobulin by exocytosis and proteolysis of thyroglobulin at the apical colloid border. The MIT and DIT are then deiodinated within the gland, and the iodine is reutilized. This process of proteolysis is also blocked by high levels of intrathyroidal iodide. The ratio of  $T_4$  to  $T_3$  within thyroglobulin is approximately 5:1, so that most of the hormone released is thyroxine. Eighty percent of  $T_3$  circulating in the blood is derived from peripheral metabolism of thyroxine and the rest from direct thyroid secretion (see below, Figure 38-2).

## Transport of Thyroid Hormones

Thyroxine and T<sub>3</sub> in plasma are reversibly bound to protein, primarily thyroxine-binding globulin (TBG). Only about 0.04% of total T<sub>4</sub> and 0.4% of T<sub>3</sub> exist in the free form (as FT<sub>4</sub> and FT<sub>3</sub>). Many physiologic and pathologic states and drugs affect T<sub>4</sub>, T<sub>3</sub>, and thyroid transport. However, the actual levels of free hormone generally remain normal, reflecting feedback control.

## Peripheral Metabolism of Thyroid Hormones

The primary pathway for the peripheral metabolism of thyroxine is deiodination by three 5'-deiodinase enzymes (D1, D2, D3). Deiodination of T<sub>4</sub> may occur by monodeiodination of the outer ring, producing 3,5,3'-triiodothyronine (T<sub>3</sub>), which is three to four times more potent than T<sub>4</sub>. The D1 enzyme is responsible for about 24% of the circulating T<sub>3</sub> while 64% of peripheral T<sub>3</sub> is generated by D2, which also regulates T<sub>3</sub> levels in the brain and pituitary. D3 deiodination produces metabolically inactive 3,3',5'-triiodothyronine (reverse T<sub>3</sub> [rT<sub>3</sub>]) (see [Figure 38-2](#)). The low serum levels of T<sub>3</sub> and rT<sub>3</sub> in normal individuals are due to the high metabolic clearances of these two compounds.

Drugs such as [amiodarone](#), iodinated contrast media, β blockers, and corticosteroids, as well as severe illness or starvation, inhibit the 5'-deiodinase necessary for the conversion of T<sub>4</sub> to T<sub>3</sub>, resulting in low T<sub>3</sub> and high rT<sub>3</sub> levels in the serum. A polymorphism in the D2 gene can reduce T<sub>3</sub> activation and impair thyroid hormone response. The pharmacokinetics of thyroid hormones are listed in [Table 38-1](#).

## Summary of thyroid hormone kinetics.

Variable	T <sub>4</sub>	T <sub>3</sub>
Volume of distribution	10 L	40 L
Extrathyroidal pool	800 mcg	54 mcg
Daily production	75 mcg	25 mcg
Fractional turnover per day	10%	60%
Metabolic clearance per day	1.1 L	24 L
Half-life (biologic)	7 days	1 day
Serum levels		
Total	4.8–10.4 mcg/dL	59–156 ng/dL
	(62–134 nmol/L)	(09–2.4 nmol/L)
Free	0.8–1.4 ng/dL	169–371 pg/dL
	(10–18 pmol/L)	(2.6–5.7 pmol/L)
Amount bound	99.96%	99.6%
Biologic potency	1	4
Oral absorption	70%	95%

## Evaluation of Thyroid Function

Tests used to evaluate thyroid function are listed in [Table 38-2](#).

Typical adult values for thyroid function tests.

Name of Test	Normal Value <sup>1</sup>	Results in Hypothyroidism	Results in Hyperthyroidism
Total thyroxine (T <sub>4</sub> )	4.8–10.4 mcg/dL (62–134 nmol/L)	Low	High
Total triiodothyronine (T <sub>3</sub> )	59–156 ng/dL (0.9–2.4 nmol/L)	Normal or low	High
Free T <sub>4</sub> (FT <sub>4</sub> )	0.8–1.4 ng/dL (10–18 pmol/L)	Low	High
Free T <sub>3</sub> (FT <sub>3</sub> )	169–371 ng/dL (2.6–5.7 pmol/L)	Low	High
Thyrotropic hormone (TSH)	0.45–4.12 μIU/mL (0.45–4.12 mIU/L)	High <sup>2</sup>	Low
<sup>123</sup> I uptake at 24 hours	5–35%	Low	High
Antithyroglobulin antibodies (Tg-Ab)	<200 IU/mL	Often present	Usually present
Thyroperoxidase antibodies (ATPO)	≤100 WHO units	Often present	Usually present
Isotope scan with <sup>123</sup> I or <sup>99m</sup> TcO <sub>4</sub>	Normal pattern	Test not indicated	Diffusely enlarged gland
Fine-needle aspiration (FNA) biopsy	Normal pattern	Test not indicated	Test not indicated
Serum thyroglobulin	Women: 1.5–38.5 mcg/L Men: 1.4–29.2 mcg/L	Test not indicated	Test not indicated
TSH receptor-stimulating antibody or thyroid-stimulating immunoglobulin (TSI)	Negative <140% of baseline	Test not indicated	Elevated in Graves disease

<sup>1</sup>Results may vary with different laboratories.

<sup>2</sup>Exception is central hypothyroidism.

### A. Thyroid-Pituitary Relationships

Control of thyroid function via thyroid-pituitary feedback is also discussed in [Chapter 37](#). Hypothalamic cells secrete thyrotropin-releasing hormone (TRH) ([Figure 38-3](#)). TRH is secreted into capillaries of the pituitary portal venous system, and in the pituitary gland, TRH stimulates the synthesis and release of thyrotropin (thyroid-stimulating hormone, TSH). TSH in turn stimulates an adenylyl cyclase-mediated mechanism in the thyroid cell to

the action of TSH and in the hypothalamus to inhibit the synthesis and secretion of TRH. Other hormones or drugs may also affect the release of TRH or TSH.

FIGURE 38-3

The hypothalamic-pituitary-thyroid axis. Acute psychosis or prolonged exposure to cold may activate the axis. Hypothalamic thyroid-releasing hormone (TRH) stimulates pituitary thyroid-stimulating hormone (TSH) release, while somatostatin and dopamine inhibit it. TSH stimulates  $T_4$  and  $T_3$  synthesis and release from the thyroid, and they in turn inhibit both TRH and TSH synthesis and release. Small amounts of iodide are necessary for hormone production, but large amounts inhibit  $T_3$  and  $T_4$  production and release. H, hypothalamus; AP, anterior pituitary.

## B. Autoregulation of the Thyroid Gland

The thyroid gland also regulates its uptake of iodide and thyroid hormone synthesis by intrathyroidal mechanisms that are independent of TSH. These mechanisms are primarily related to the level of iodine in the blood. Large doses of iodine inhibit iodide organification (Wolff-Chaikoff block; see Figure 38-1). In certain disease states (eg, Hashimoto thyroiditis), this can inhibit thyroid hormone synthesis and result in hypothyroidism. Hyperthyroidism can result from the loss of the Wolff-Chaikoff block in susceptible individuals (eg, multinodular goiter).

## C. Abnormal Thyroid Stimulators

In Graves disease (see below), lymphocytes secrete a TSH receptor–stimulating antibody (TSH-R Ab [stim]), also known as thyroid-stimulating immunoglobulin (TSI). This immunoglobulin binds to the TSH receptor and stimulates the gland in the same fashion as TSH itself. The duration of its effect, however, is much longer than that of TSH. TSH receptors, stimulated by high levels of TSH-R Ab [stim], and insulin-like growth factor 1 receptor (IGF-1R) are also found in orbital fibrocytes, and can cause ophthalmopathy.

\*This chapter is dedicated to Dr. Francis S. Greenspan, co-author, mentor, colleague, and friend who will be sorely missed by his many colleagues and by his patients for his kindness, generosity, and expert care as chief of the UCSF Thyroid Clinic.

†In this chapter, the term *iodine* denotes all forms of the element; the term *iodide* denotes only the ionic form,  $I^-$ .

## BASIC PHARMACOLOGY OF THYROID & ANTITHYROID DRUGS

### THYROID HORMONES

#### Chemistry

The structural formulas of thyroxine and triiodothyronine as well as reverse triiodothyronine ( $rT_3$ ) are shown in [Figure 38-2](#). All of these naturally occurring molecules are levo (L) isomers. The synthetic dextro (D) isomer of thyroxine, dextrothyroxine, has approximately 4% of the biologic activity of the L-isomer as evidenced by its lesser ability to suppress TSH secretion and correct hypothyroidism.

#### Pharmacokinetics

Thyroxine is absorbed best in the duodenum and ileum; its absorption is modified by intraluminal factors such as food, drugs, gastric acidity, and intestinal flora. Oral bioavailability of current tablet preparations of L-thyroxine averages 70–80% (see [Table 38-1](#)) and is improved with the Tirosint formulations (see below). In contrast,  $T_3$  is almost completely absorbed (95%).  $T_4$  and  $T_3$  absorption appear unaffected by mild hypothyroidism but may be impaired in severe myxedema with ileus. These factors are important in switching from oral to parenteral therapy. For parenteral use, the intravenous route is preferred for both hormones.

In patients with hyperthyroidism, the metabolic clearances of  $T_4$  and  $T_3$  are increased and the half-lives decreased; the opposite is true in patients with hypothyroidism. Drugs that induce hepatic microsomal enzymes (eg, [rifampin](#), [phenobarbital](#), [carbamazepine](#), [phenytoin](#), tyrosine kinase inhibitors, HIV protease inhibitors) increase the metabolism of both  $T_4$  and  $T_3$  ([Table 38-3](#)). Despite this change in clearance, the normal hormone concentration is maintained in the majority of euthyroid patients due to compensatory hyperfunction of the thyroid. However, patients dependent on  $T_4$  replacement medication may require higher dosages to maintain clinical effectiveness. A similar compensation occurs when changes in binding sites occur. When TBG sites are increased by pregnancy, [estrogens](#), or oral contraceptives, levels of bound hormones increase initially, causing reductions in its rate of elimination until the normal free to bound hormone concentration is restored. Thus, the concentration of total and bound hormone will increase, but the concentration of free hormone and the steady-state elimination will remain normal. The reverse occurs when reduced thyroid binding sites occur.

TABLE 38-3

#### Drug effects and thyroid function.

Drug Effect	Drugs
<b>Change in thyroid hormone synthesis</b>	
Inhibition of TRH or TSH secretion without induction of hypothyroidism or hyperthyroidism	<a href="#">Bexarotene</a> , <a href="#">dopamine</a> , <a href="#">bromocriptine</a> , <a href="#">cabergoline</a> , <a href="#">levodopa</a> , corticosteroids, somatostatin, <a href="#">octreotide</a> , <a href="#">metformin</a> , interleukin-6, heroin
Inhibition of thyroid hormone synthesis or	Iodides (including <a href="#">amiodarone</a> ), <a href="#">lithium</a> , aminoglutethimide, thioamides, <a href="#">ethionamide</a> , tyrosine kinase

release with the induction of hypothyroidism (or occasionally hyperthyroidism)	inhibitors (eg, <a href="#">sunitinib</a> , <a href="#">sorafenib</a> , <a href="#">imatinib</a> ), HIV protease inhibitors
<b>Alteration of thyroid hormone transport and serum total T<sub>3</sub> and T<sub>4</sub> levels, but usually no modification of FT<sub>4</sub> or TSH</b>	
Increased TBG	<a href="#">Estrogens</a> , <a href="#">tamoxifen</a> , <a href="#">raloxifene</a> , heroin, <a href="#">methadone</a> , <a href="#">mitotane</a> , 5-fluorouracil, <a href="#">perphenazine</a>
Decreased TBG	Androgens, anabolic steroids, glucocorticoids, <a href="#">danazol</a> , L-asparaginase, nicotinic acid
Displacement of T <sub>3</sub> and T <sub>4</sub> from TBG with transient hyperthyroxinemia	Salicylates, fenclofenac, mefenamic acid, intravenous <a href="#">furosemide</a> , <a href="#">heparin</a>
<b>Alteration of T<sub>4</sub> and T<sub>3</sub> metabolism with modified serum T<sub>3</sub> and T<sub>4</sub> levels but not TSH levels (unless receiving thyroxine replacement therapy)</b>	
Increased hepatic metabolism, enhanced degradation of thyroid hormone	<a href="#">Nicardipine</a> , <a href="#">phenytoin</a> , <a href="#">carbamazepine</a> , <a href="#">primidone</a> , <a href="#">phenobarbital</a> , <a href="#">rifampin</a> , <a href="#">rifabutin</a> , tyrosine kinase inhibitors (eg, <a href="#">sunitinib</a> , <a href="#">sorafenib</a> , <a href="#">imatinib</a> ), <a href="#">sertraline</a> , <a href="#">quetiapine</a>
Inhibition of 5' -deiodinase with decreased T <sub>3</sub> , increased rT <sub>3</sub>	lopanoic acid, ipodate, <a href="#">amiodarone</a> , β blockers, corticosteroids, <a href="#">propylthiouracil</a> , flavonoids, interleukin-6
<b>Other interactions</b>	
Interference with T <sub>4</sub> absorption from the gut	Oral bisphosphonates, cholestyramine, <a href="#">colesevelam</a> , <a href="#">colestipol</a> , chromium picolinate, charcoal, <a href="#">ciprofloxacin</a> , proton pump inhibitors, <a href="#">sucralfate</a> , Kayexalate, <a href="#">raloxifene</a> , <a href="#">sevelamer</a> hydrochloride, aluminum hydroxide, ferrous sulfate, calcium carbonate, bran/fiber, soy, coffee, <a href="#">orlistat</a>
Induction of autoimmune thyroid disease with hypothyroidism or hyperthyroidism	Interferon-α, interleukin-2, interferon-β, <a href="#">lithium</a> , <a href="#">amiodarone</a> , tyrosine kinase inhibitors (eg, <a href="#">sunitinib</a> , <a href="#">sorafenib</a> , <a href="#">imatinib</a> ), immune checkpoint inhibitors (eg, <a href="#">ipilimumab</a> , <a href="#">nivolumab</a> , <a href="#">pembrolizumab</a> , <a href="#">atezolizumab</a> , <a href="#">cemiplimab</a> , <a href="#">avelumab</a> , <a href="#">durvalumab</a> )
<b>Effect of thyroid function on drug effects</b>	
Anticoagulation	Lower doses of <a href="#">warfarin</a> required in hyperthyroidism, higher doses in hypothyroidism
Glucose control	Increased hepatic glucose production and glucose intolerance in hyperthyroidism; impaired <a href="#">insulin</a> action and glucose disposal in hypothyroidism
Cardiac drugs	Higher doses of <a href="#">digoxin</a> required in hyperthyroidism; lower doses in hypothyroidism
Sedatives; analgesics	Increased sedative and respiratory depressant effects from sedatives and opioids in hypothyroidism; converse in hyperthyroidism

## Mechanism of Action

A model of thyroid hormone action is depicted in [Figure 38–4](#), which shows the free forms of thyroid hormones, T<sub>4</sub> and T<sub>3</sub>, dissociated from thyroid-binding proteins, entering the cell by the active transporters (eg, monocarboxylate transporter 8 [MCT8], MCT10, and organic anion transporting polypeptide [OATP1C1]). Transporter mutations can result in a clinical syndrome of mental retardation, myopathy, and low serum T<sub>4</sub> levels (Allan-

Herndon-Dudley syndrome). Within the cell,  $T_4$  is converted to  $T_3$  by 5'-deiodinase, and the  $T_3$  enters the nucleus, where  $T_3$  binds to a specific  $T_3$  thyroid receptor protein, a member of the *c-erb* oncogene family. (This family also includes the steroid hormone receptors and receptors for vitamins A and D.) The  $T_3$  receptor exists in two forms,  $\alpha$  and  $\beta$ . Differing concentrations of receptors in different tissues (eg,  $\alpha$  receptors in the brain and  $\beta$  receptors in the liver) may account for variations in  $T_3$  effect on these tissues. Mutations in both  $\alpha$  and  $\beta$  genes have been associated with generalized thyroid hormone resistance. Cigarette smoking and environmental agents (eg, polychlorinated biphenyls) also may interfere with receptor action.

**FIGURE 38-4**

Model of the interaction of  $T_3$  with the  $T_3$  receptor. **(A) Inactive phase**—the unliganded  $T_3$  receptor dimer bound to the thyroid hormone response element (TRE) along with corepressors acts as a suppressor of gene transcription. **(B) Active phase**— $T_3$  and  $T_4$  circulate bound to thyroid-binding proteins (TBPs). The free hormones are transported into the cell by a specific transport system. Within the cytoplasm,  $T_4$  is converted to  $T_3$  by 5'-deiodinase (5'DI);  $T_3$  then moves into the nucleus. There it binds to the ligand-binding domain of the thyroid receptor (TR) monomer. This promotes disruption of the TR homodimer and heterodimerization with retinoid X receptor (RXR) on the TRE, displacement of corepressors, and binding of coactivators. The TR-coactivator complex activates gene transcription, which leads to alteration in protein synthesis and cellular phenotype. TR-LBD,  $T_3$  receptor ligand-binding domain; TR-DBD,  $T_3$  receptor DNA-binding domain; RXR-LBD, retinoid X receptor ligand-binding domain; RXR-DBD, retinoid X receptor DNA-binding domain;  $T_3$ , triiodothyronine;  $T_4$ , tetraiodothyronine, L-thyroxine. Most of the effects of thyroid on metabolic processes appear to be mediated by activation of nuclear receptors that lead to increased formation of RNA and subsequent protein synthesis, eg, increased formation of Na<sup>+</sup>/K<sup>+</sup>-ATPase. This is consistent with the observation that the action of thyroid is evident in vivo with a time lag of hours or days after its administration.

Large numbers of thyroid hormone receptors are found in the most hormone-responsive tissues (pituitary, liver, kidney, heart, skeletal muscle, lung, and intestine), while few receptor sites occur in hormone-unresponsive tissues (spleen, testes). The brain, which lacks an anabolic response to T<sub>3</sub>, contains an intermediate number of receptors. In congruence with their biologic potencies, the affinity of the receptor site for T<sub>4</sub> is about 10 times lower than that for T<sub>3</sub>. Under some conditions, the number of nuclear receptors may be altered to preserve body homeostasis. For example, starvation lowers both circulating T<sub>3</sub> hormone and cellular T<sub>3</sub> receptors.

### Effects of Thyroid Hormones

The thyroid hormones are responsible for optimal growth, development, function, and maintenance of all body tissues. Excess or inadequate amounts result in the signs and symptoms of hyperthyroidism or hypothyroidism, respectively (Table 38-4). Since T<sub>3</sub> and T<sub>4</sub> are qualitatively similar, they may be considered as one hormone in the discussion that follows.

## Manifestations of thyrotoxicosis and hypothyroidism.

System	Thyrotoxicosis	Hypothyroidism
Skin and appendages	Warm, moist skin; sweating; heat intolerance; fine, thin hair; Plummer's nails; pretibial dermatopathy (Graves disease)	Pale, cool, puffy, yellowish skin, face, and hands; dry and brittle hair; brittle nails
Eyes, face	Retraction of upper lid with wide stare; periorbital edema; exophthalmos; diplopia (Graves disease)	Drooping of eyelids; periorbital edema; loss of temporal aspects of eyebrows; puffy, nonpitting facies; large tongue, hoarseness
Cardiovascular system	Decreased peripheral vascular resistance; increased heart rate, stroke volume, cardiac output, pulse pressure; high-output heart failure; increased inotropic and chronotropic effects; arrhythmias; angina	Increased peripheral vascular resistance; decreased heart rate, stroke volume, cardiac output, pulse pressure; low-output heart failure; ECG: bradycardia, prolonged PR interval, flat T wave, low voltage; pericardial effusion
Respiratory system	Dyspnea; hypoventilation; decreased vital capacity	Pleural effusions; hypoventilation and CO <sub>2</sub> retention; sleep apnea
Gastrointestinal system	Increased appetite; increased frequency of bowel movements; hypoproteinemia	Decreased appetite; decreased frequency of bowel movements, constipation; ascites
Central nervous system	Nervousness; hyperkinesia; emotional lability, agitation	Lethargy/fatigue; general slowing of mental processes; neuropathies; weakness and muscle cramps
Musculoskeletal system	Weakness and muscle fatigue; increased deep tendon reflexes; tremors; hypercalcemia; osteoporosis	Stiffness and muscle fatigue; carpal tunnel syndrome; decreased deep tendon reflexes; increased alkaline phosphatase, LDH, AST
Renal system	Mild polyuria; increased renal blood flow; increased glomerular filtration rate	Impaired water excretion; decreased renal blood flow; decreased glomerular filtration rate
Hematopoietic system	Increased erythropoiesis; anemia <sup>1</sup>	Decreased erythropoiesis; anemia <sup>1</sup>
Reproductive system	Menstrual irregularities; amenorrhea; infertility; increased gonadal steroid metabolism	Menorrhagia; infertility; decreased libido; impotence; oligospermia; decreased gonadal steroid metabolism
Metabolic system	Increased basal metabolic rate; negative nitrogen balance; hyperglycemia; increased free fatty acids; decreased total cholesterol and triglycerides; increased hormone degradation; increased requirements for fat- and water-soluble vitamins; increased drug metabolism; decreased warfarin requirement	Decreased basal metabolic rate; slight positive nitrogen balance; delayed degradation of insulin with increased sensitivity; increased total cholesterol and triglycerides; hyponatremia; decreased hormone degradation; decreased requirements for fat- and water-soluble vitamins; decreased drug metabolism; increased warfarin requirement

<sup>1</sup>The anemia of hyperthyroidism is usually normochromic and caused by increased red blood cell turnover. The anemia of hypothyroidism may be normochromic, hyperchromic, or hypochromic and may be due to decreased production rate, decreased iron absorption, decreased folic acid absorption, or to autoimmune pernicious anemia. AST, aspartate aminotransferase; LDH, lactic dehydrogenase.

as well as potentiation of the secretion and action of growth hormone. Thyroid deprivation in early life results in irreversible mental retardation and dwarfism—typical of congenital cretinism.

Effects on growth and calorogenesis are accompanied by a pervasive influence on metabolism of drugs as well as carbohydrates, fats, proteins, and **vitamins**. Many of these changes are dependent upon or modified by activity of other hormones. Conversely, the secretion and degradation rates of virtually all other hormones, including catecholamines, cortisol, **estrogens**, **testosterone**, and **insulin**, are affected by thyroid status.

Many of the manifestations of thyroid hyperactivity resemble sympathetic nervous system overactivity (especially in the cardiovascular system), although catecholamine levels are not increased. Changes in catecholamine-stimulated adenylyl cyclase activity as measured by cAMP are found with changes in thyroid activity. Thyroid hormone increases the numbers of  $\beta$  receptors and enhances amplification of the  $\beta$ -receptor signal. Other clinical symptoms reminiscent of excessive **epinephrine** activity (and partially alleviated by adrenoceptor antagonists) include lid lag and retraction, tremor, excessive sweating, anxiety, and nervousness. The opposite constellation of effects appears in hypothyroidism (see [Table 38–4](#)).

## Thyroid Preparations

See the Preparations Available section at the end of this chapter for a list of available preparations. These preparations may be synthetic (**levothyroxine**, **liothyronine**, liotrix) or of animal origin (desiccated thyroid).

Thyroid hormones are not effective and can be detrimental in the management of obesity, abnormal vaginal bleeding, or depression if thyroid hormone levels are normal. A review of  $T_3$  co-administered with antidepressants showed some promising depression benefits only when combined with tricyclics, but further confirmation of its optimal use is required.

Synthetic **levothyroxine** ( $T_4$ ) is the preparation of choice for thyroid replacement and suppression therapy because of its stability, content uniformity, low cost, lack of allergenic foreign protein, easy laboratory measurement of serum levels, long half-life (7 days) permitting once-daily to weekly administration, and long term safety. Generic  $T_4$  preparations provide comparable efficacy and are more cost-effective than branded preparations. Although some recommend that patients remain on a consistent  $T_4$  preparation between refills to avoid changes in bioavailability, a recent study between generics found otherwise. In addition, generic  $T_4$  preparations are FDA approved with the expectation that they are substitutable. Compared with the tablet formulation, a branded soft gel capsule and solution (Tirosint, Tirosint-SOL) provided faster, more complete dissolution; provided 98% bioavailability; was less affected by gastric pH or coffee; and produced lower TSH levels. According to the American Thyroid Association guidelines, these newer formulations may be considered in persons allergic to tablet excipients.

Although **liothyronine** ( $T_3$ ) is three to four times more potent than **levothyroxine**, it is not generally recommended for routine replacement therapy because of its shorter half-life (24 hours,) necessitating multiple daily doses, and difficulty in monitoring its adequacy of replacement by conventional laboratory tests. In addition,  $T_4$  is converted intracellularly to  $T_3$  by deiodinase enzymes producing both hormones so that  $T_3$  administration is usually unnecessary. However, emerging evidence suggests that genetic defects/polymorphisms in D2 enzymes (Thr92Ala-DIO2) in some hypothyroid patients produce insufficient  $T_3$  levels on  $T_4$  alone, leading to continued hypothyroid symptoms. Use  $T_3$  cautiously in persons with cardiac disease due to risk of cardiotoxicity from significant elevations in peak  $T_3$  levels.  $T_3$  is best reserved for short-term TSH suppression or combined with **levothyroxine** in those with confirmed unresponsiveness to  $T_4$  alone.

The use of desiccated thyroid (DTE) versus synthetic preparations is never justified due to disadvantages of protein antigenicity, product instability, variable hormone concentrations, limited FDA oversight, and difficulty in laboratory monitoring despite its lower cost. DTE treatment results in a much higher serum  $T_3/T_4$  ratio, and the potential for toxic peak  $T_3$  levels. Nevertheless, one randomized, double-blind study found no difference in hormone levels achieved between Armour DTE,  $T_4$ , or  $T_3$ , with some patients preferring  $T_3$ . Similarly, another large study also found that patients were more satisfied with DTE rather than  $T_4$  or  $T_4$  plus  $T_3$ . Significant amounts of  $T_3$  found in some thyroid extracts may produce significant and toxic elevations in  $T_3$  levels. Exact equi-effective doses have not been determined. Approximate equivalences suggested between preparations are desiccated thyroid 60 mg (1 grain) to 80–100 mcg of **levothyroxine**, and to 37.5 mcg of **liothyronine**. Any dosage conversions should be re-titrated based on laboratory and clinical response.

A consensus statement that provides guidance on adding T<sub>3</sub>, desiccated thyroid, or the more expensive fixed-dose combination of T<sub>4</sub> plus T<sub>3</sub> therapy (Liotrix) is available.

The shelf life of synthetic hormone preparations is about 2 years, particularly if they are stored in dark bottles to minimize spontaneous deiodination. The shelf life of desiccated thyroid is unknown with certainty, but its potency is better preserved if it is kept dry.

## ANTITHYROID AGENTS

Reduction of thyroid activity and hormone effects is accomplished by agents that interfere with the production of thyroid hormones, modify the tissue response to thyroid hormones, or cause glandular destruction by radiation or surgery. Goitrogens are agents that suppress secretion of T<sub>3</sub> and T<sub>4</sub> to subnormal levels and thereby increase TSH, which in turn produces glandular enlargement (goiter). The antithyroid compounds used clinically include the thioamides, iodides, and radioactive iodine.

## THIOAMIDES

The thioamides **methimazole** and **propylthiouracil** are major drugs for treatment of thyrotoxicosis. In the United Kingdom, **carbimazole**, which is converted to **methimazole** in vivo, is widely used. **Methimazole** is about 10 times more potent than **propylthiouracil** and is the drug of choice in adults and children. Due to a black box warning about severe hepatitis, **propylthiouracil** should be reserved for use only during the first trimester of pregnancy, in thyroid storm, and in those experiencing adverse reactions to **methimazole** (not agranulocytosis or hepatitis). The chemical structures of these compounds are shown in Figure 38-5. The thiocarbamide group is essential for antithyroid activity.

FIGURE 38-5

Structure of thioamides. The thiocarbamide moiety is shaded in color.

## Pharmacokinetics

**Methimazole** is completely absorbed but at variable rates. It is readily concentrated by the thyroid gland and has a volume of distribution similar to that of **propylthiouracil**. Excretion is slower than with **propylthiouracil**; 65–70% of a dose is recovered in the urine in 48 hours.

**Propylthiouracil** is rapidly absorbed, reaching peak serum levels after 1 hour. The bioavailability of 50–80% may be due to incomplete

absorption or a large first-pass effect in the liver. The volume of distribution approximates total body water with accumulation in the thyroid gland. The majority of **propylthiouracil** is excreted within 24 hours by the kidney as the inactive glucuronide.

The short plasma half-life of these agents (1.5 hours for **propylthiouracil** and 6 hours for **methimazole**) has little influence on the duration of the antithyroid action or the dosing interval because both agents are concentrated in the thyroid gland. For **propylthiouracil**, giving the drug every 6–8 hours is reasonable since a single 100 mg dose can inhibit **iodine** organification by 60% for 7 hours. A single 30-mg dose of **methimazole** exerts an antithyroid effect for longer than 24 hours, so a single daily dose is effective in the management of mild to severe hyperthyroidism.

Both thioamides cross the placental barrier into the fetal thyroid, so caution is required when using these drugs in pregnancy. Both thioamides are classified by the FDA as pregnancy category D (see **Chapter 59**) due to the risk of fetal hypothyroidism. **Propylthiouracil** is preferable during the first trimester of pregnancy because it is more strongly protein-bound and, therefore, crosses the placenta less readily. In addition, **methimazole** has been, albeit rarely, associated with congenital malformations. Low concentrations of both thioamides found in breast milk are considered safe to use in the nursing infant.

### Pharmacodynamics

The thioamides act by multiple mechanisms. The major action is to prevent hormone synthesis by inhibiting the thyroid peroxidase-catalyzed reactions and blocking **iodine** organification. In addition, they block coupling of the iodotyrosines. They do not block uptake of iodide by the gland. **Propylthiouracil**, but not **methimazole**, also inhibits the peripheral deiodination of  $T_4$  and  $T_3$  (see **Figure 38–1**). Since the synthesis rather than the release of hormones is affected, the onset of these agents is slow, often requiring 3–4 weeks before  $T_4$  stores are depleted.

### Toxicity

Adverse reactions to the thioamides occur in 3–12% of treated patients. Most reactions occur early, especially nausea and gastrointestinal distress. An altered sense of taste or smell may occur with **methimazole**. The most common adverse effect is a maculopapular pruritic rash (4–6%), at times accompanied by systemic signs such as fever. Rare adverse effects include an urticarial rash, vasculitis, a lupus-like reaction, lymphadenopathy, hypoprothrombinemia, exfoliative dermatitis, polyserositis, and acute arthralgia. An increased risk of severe hepatitis, sometimes fatal, is reported with **propylthiouracil** (black box warning), so it should be avoided in children and adults unless no other options are available. Cholestatic jaundice is more common with **methimazole** than **propylthiouracil**. Asymptomatic elevations in transaminase levels can also occur.

The most dangerous complication is agranulocytosis (granulocyte count  $<500$  cells/mm<sup>3</sup>), an infrequent but potentially fatal adverse reaction. It occurs in 0.1–0.5% of patients taking thioamides, but the risk appears increased in older patients and usually within the first 90 days in those receiving more than 40 mg/d of **methimazole**. The reaction is usually rapidly reversible when the drug is discontinued, but broad-spectrum antibiotic therapy may be necessary for complicating infections. Colony-stimulating factors (eg, G-CSF; see **Chapter 33**) may hasten recovery of the granulocytes. The cross-sensitivity between **propylthiouracil** and **methimazole** is about 50%; therefore, switching drugs in patients with severe reactions should be avoided.

## ANION INHIBITORS

Monovalent anions such as perchlorate ( $\text{ClO}_4^-$ ), pertechnetate ( $\text{TcO}_4^-$ ), and thiocyanate ( $\text{SCN}^-$ ) can block uptake of iodide by the gland through competitive inhibition of the iodide transport mechanism. Since these effects are overcome by large doses of iodides, their effectiveness is somewhat unpredictable.

The major clinical use for potassium perchlorate is to block thyroidal reuptake of  $\text{I}^-$  in patients with iodide-induced hyperthyroidism (eg, amiodarone-induced hyperthyroidism). However, potassium perchlorate is rarely used clinically because due to risk of aplastic anemia.

## IODIDES

Prior to the introduction of the thioamides in the 1940s, iodides were the major antithyroid agents; today they are rarely used alone.

### Pharmacodynamics

Iodides have several actions on the thyroid. They inhibit organification and hormone release, and they decrease the size and vascularity of the hyperplastic gland. In susceptible individuals, iodides can induce hyperthyroidism (Jod-Basedow phenomenon) or precipitate hypothyroidism.

In pharmacologic doses (>6 mg/d), the major action of iodides is to inhibit hormone release, possibly through inhibition of thyroglobulin proteolysis. Improvement in thyrotoxic symptoms occurs rapidly—within 2–7 days—hence the value of iodide therapy in thyroid storm. In addition, iodides decrease the vascularity, size, and fragility of a hyperplastic gland, making the drugs valuable as preoperative preparation for surgery.

### Clinical Use of Iodide

Disadvantages of iodide therapy include an increase in intraglandular stores of **iodine**, which can delay onset of thioamide therapy or prevent use of radioactive **iodine** therapy for several weeks thereafter. Therefore, avoid iodides if radioactive **iodine** treatment seems likely and do not administer unless thioamide have begun. If iodides are administered alone, the gland can escape from the iodide block in 2–8 weeks, causing severe exacerbation of thyrotoxicosis in an iodine-enriched gland. Avoid chronic use of iodides in pregnancy due to placenta passage and the risk of fetal goiter. In radiation emergencies involving release of radioactive **iodine** isotopes, the thyroid-blocking effects of potassium iodide can protect the gland from subsequent damage if administered before radiation exposure.

### Toxicity

Adverse reactions to **iodine** (iodism) are uncommon and in most cases reversible upon discontinuance. They include acneiform rash (similar to that of bromism), swollen salivary glands, mucous membrane ulcerations, conjunctivitis, rhinorrhea, drug fever, metallic taste, bleeding disorders, and rarely, anaphylactoid reactions.

## RADIOACTIVE IODINE

<sup>131</sup>I is the only isotope used for treatment of thyrotoxicosis. (Others are used for diagnosis.) Administered orally in solution as sodium <sup>131</sup>I, it is rapidly absorbed, concentrated by the thyroid, and incorporated into storage follicles. Its therapeutic effect depends on emission of  $\beta$  rays with an effective half-life of 5 days and a penetration range of 400–2000  $\mu\text{m}$ . Within a few weeks after administration, destruction of thyroid parenchyma is evident by epithelial swelling and necrosis, follicular disruption, edema, and leukocyte infiltration. Advantages of radioiodine include easy administration, effectiveness, low expense, and absence of pain. Fears of radiation-induced genetic damage, leukemia, and neoplasia have not materialized after more than 50 years of clinical experience with radioiodine therapy for hyperthyroidism. Avoid radioactive **iodine** in pregnant women or nursing mothers, since it crosses the placenta to destroy the fetal thyroid gland and is secreted in breast milk.

## ADRENOCEPTOR-BLOCKING AGENTS

Beta blockers without intrinsic sympathomimetic activity (eg, **metoprolol**, **propranolol**, **atenolol**) are effective therapeutic adjuncts in the management of thyrotoxicosis since many of these symptoms mimic those associated with sympathetic stimulation. **Propranolol** has been the  $\beta$  blocker most widely studied and used in the therapy of thyrotoxicosis. Beta blockers cause clinical improvement of hyperthyroid symptoms but do not typically alter thyroid hormone levels. **Propranolol** at doses greater than 160 mg/d may also reduce  $T_3$  levels approximately 20% by inhibiting the peripheral conversion of  $T_4$  to  $T_3$ .

## CLINICAL PHARMACOLOGY OF THYROID & ANTITHYROID DRUGS

### HYPOTHYROIDISM

Hypothyroidism is a syndrome resulting from deficiency of thyroid hormones and a reversible slowing of all body functions (see [Table 38–4](#)). In infants and children, there is striking retardation of growth and development that results in dwarfism and irreversible mental retardation.

The etiology and pathogenesis of hypothyroidism are summarized in [Table 38–5](#). Hypothyroidism can occur with or without thyroid enlargement (goiter). The laboratory diagnosis of hypothyroidism in the adult is easily confirmed by findings of a low free thyroxine and elevated serum TSH levels (see [Table 38–2](#)).

**Etiology and pathogenesis of hypothyroidism.**

Cause	Pathogenesis	Goiter	Degree of Hypothyroidism
Hashimoto thyroiditis	Autoimmune destruction of thyroid	Present early, absent later	Mild to severe
Drug-induced <sup>1</sup>	Blocked hormone formation <sup>2</sup>	Present	Mild to moderate
Dyshormonogenesis	Impaired synthesis of T <sub>4</sub> due to enzyme deficiency	Present	Mild to severe
Radiation, <sup>131</sup> I, X-ray, thyroidectomy	Destruction or removal of gland	Absent	Severe
Congenital (cretinism)	Athyreosis or ectopic thyroid, iodine deficiency; TSH receptor-blocking antibodies	Absent or present	Severe
Secondary (TSH deficit)	Pituitary or hypothalamic disease	Absent	Mild

<sup>1</sup>Iodides, lithium, fluoride, thioamides, aminosalicic acid, phenylbutazone, amiodarone, perchlorate, ethionamide, thiocyanate, cytokines (interferons, interleukins), bexarotene, tyrosine kinase inhibitors, etc. See Table 38-3.

<sup>2</sup>See Table 38-3 for specific pathogenesis.

The most common cause of hypothyroidism in the United States at this time is probably Hashimoto thyroiditis, an immunologic disorder in genetically predisposed individuals. In this condition, there is evidence of humoral immunity in the presence of antithyroid antibodies and lymphocyte sensitization to thyroid antigens. Genetic mutations as discussed previously and certain medications also can cause hypothyroidism (see Table 38-5).

**MANAGEMENT OF HYPOTHYROIDISM**

Except for drug-induced hypothyroidism, which is managed in some cases by simply removing the offending agent, the general strategy of replacement therapy is appropriate. The most satisfactory preparation is levothyroxine, administered as either a branded or less costly generic preparation. Switching among three generics in a large claims database in persons with residual thyroid function was not associated with clinically significant changes in TSH level. Multiple trials have documented that combination levothyroxine plus liothyronine is not superior to levothyroxine alone, although some patients remain symptomatic on thyroxine alone. Genetic variations in deiodinases or hormone transporters may account for some of this lack of efficacy.

There is some variability in the absorption of thyroxine; dosage will also vary depending on age and weight. Infants and children require more T<sub>4</sub> per kilogram of body weight than adults. The average dosage for an infant aged 1–6 months old is 10–15 mcg/kg per day, whereas the average adult dosage is about 1.7 mcg/kg per day (0.8 mcg/lb per day) or 125 mcg/d. Older adults (>65 years of age) may require less thyroxine (1.6 mcg/kg or 0.7 mcg/lb per day) for replacement as body mass declines. In patients requiring post-thyroidectomy suppression therapy for thyroid cancer, the average daily dosage of T<sub>4</sub> is 2.2 mcg/kg or 1 mcg/lb. Higher thyroxine requirements have also been reported in persons following bariatric surgery and with other malabsorptive disorders (eg, atrophic gastritis, *Helicobacter pylori* gastritis, celiac disease, lactose intolerance); thyroxine doses may be reduced following treatment of these disorders.

Since interactions with certain foods (eg, bran, soy, coffee) and drugs (see Table 38-3) can impair its absorption, thyroxine is optimally administered (eg, 30–60 minutes before meals, 4 hours after meals, or at bedtime) to maintain TSH within an therapeutic range of 0.5–2.5

mIU/L. Its long half-life of 7 days permits once-daily dosing. Children require monitoring for normal growth and development. Measure serum TSH and free thyroxine levels before any dosage changes to avoid transient serum alterations. Steady-state thyroxine levels in the bloodstream are not achieved until 6–8 weeks after a consistent dose of thyroxine. Thus, dosage changes need to be adjusted slowly.

In younger patients or those with very mild disease, full replacement therapy can be started immediately. In older patients (>50 years) without cardiac disease, **levothyroxine** can be started at a dosage of 50 mcg/d. In long-standing hypothyroidism and in older patients with underlying cardiac disease, it is imperative to start with smaller dosages of **levothyroxine**, 12.5–25 mcg/d for 2 weeks, before increasing by 12.5–25 mcg/d every 2 weeks until euthyroidism or drug toxicity occurs. In cardiac patients, the heart is very sensitive to the level of circulating thyroxine, and if angina pectoris or cardiac arrhythmia develops, it is essential to stop or reduce the thyroxine dosage immediately.

Thyroxine toxicity correlates with the hormone level. In children, restlessness, insomnia, and accelerated bone maturation and growth may be signs of thyroxine toxicity. In adults, increased nervousness, heat intolerance, episodes of palpitation and tachycardia, or unexplained weight loss may be the presenting symptoms. If these symptoms are present, it is important to monitor serum TSH and FT<sub>4</sub> levels (see [Table 38–2](#)), which will determine whether the symptoms are due to excess thyroxine blood levels. Chronic overtreatment with T<sub>4</sub>, particularly in elderly patients, can increase the risk of atrial fibrillation and accelerated osteoporosis.

### Special Problems in Management of Hypothyroidism

#### A. Myxedema and Coronary Artery Disease

Since myxedema frequently occurs in older persons, it is often associated with underlying coronary artery disease. In this situation, the low levels of circulating thyroid hormone actually protect the heart against increasing demands that could result in angina pectoris, atrial fibrillation, or myocardial infarction. Correction of myxedema must be done cautiously to avoid provoking these cardiac events. If coronary artery surgery is indicated, it should be done first, prior to correction of the myxedema by thyroxine administration.

#### B. Myxedema Coma

Myxedema coma is an end state of untreated hypothyroidism. It is associated with progressive weakness, stupor, hypothermia, hypoventilation, hypoglycemia, hyponatremia, water intoxication, shock, and death.

Myxedema coma is a medical emergency. The patient should be treated in the intensive care unit, since tracheal intubation and mechanical ventilation may be required. Associated illnesses such as infection or heart failure must be managed with appropriate therapy. It is important to give all preparations intravenously, because patients with myxedema coma absorb drugs poorly from other routes. Administer intravenous fluids cautiously to avoid excessive water intake. These patients have large pools of empty T<sub>3</sub> and T<sub>4</sub> binding sites that must be filled before there is adequate free thyroxine to affect tissue metabolism. Accordingly, the treatment of choice in myxedema coma is to give a loading dose of **levothyroxine** intravenously—usually 300–400 mcg initially, followed by 50–100 mcg daily. Intravenous T<sub>3</sub> 5–20 mcg initially, followed by 2.5–10 mcg every 8 hours, also can be added but may be more cardiotoxic and more difficult to monitor. Lower T<sub>4</sub> and T<sub>3</sub> doses can be considered for smaller or older patients, or those with concomitant cardiac disease or arrhythmias. Intravenous **hydrocortisone** is indicated if there is associated adrenal or pituitary insufficiency but is probably not necessary in most patients with primary myxedema. Use opioids and sedatives with extreme caution.

#### C. Hypothyroidism and Pregnancy

Hypothyroid women frequently have anovulatory cycles and are therefore relatively infertile until restoration of the euthyroid state. This has led to the widespread use of thyroid hormone for infertility, although there is no evidence for its usefulness in infertile euthyroid patients. In a pregnant hypothyroid patient receiving thyroxine, it is extremely important that the daily dose of thyroxine is adequate because early development of the fetal brain depends on maternal thyroxine. In many hypothyroid patients, an increase in the thyroxine dose (about 25–30%) is required to normalize the serum TSH level during pregnancy. It is reasonable to counsel women to take one extra dose of their current thyroxine tablet twice a week separated by several days as soon as they are pregnant. Administer thyroxine apart from prenatal **vitamins** and calcium by at least 4 hours to avoid reducing T<sub>4</sub> absorption. Because the elevated maternal TBG levels result in elevated total T<sub>4</sub> levels, adequate maternal thyroxine dosages warrant maintenance of

TSH between 0.1 and 3.0 mIU/L (eg, first trimester, 0.1–2.5 mIU/L; second trimester, 0.2–3.0 mIU/L; third trimester, 0.3–3.0 mIU/L) and the total T<sub>4</sub> at or

#### D. Subclinical Hypothyroidism

Subclinical hypothyroidism, defined as an elevated TSH level and normal thyroid hormone levels, occurs in 4–10% of the general population and up to 20% in women older than age 50. **Levothyroxine** administration should be individualized based on the risks and benefits of treatment. The consensus of most expert thyroid organizations concluded that thyroid hormone therapy might be considered for patients with TSH levels >10 mIU/L despite conflicting beneficial outcomes, while close TSH monitoring is appropriate for those with lower TSH elevations.

#### E. Drug-Induced Hypothyroidism

Drug-induced hypothyroidism (see [Table 38–3](#)) is satisfactorily managed with **levothyroxine** therapy if the offending agent cannot be stopped. In the case of amiodarone-induced hypothyroidism, **levothyroxine** therapy may be necessary even after its discontinuance due to **amiodarone**'s very long half-life.

## HYPERTHYROIDISM

Hyperthyroidism (thyrotoxicosis) is the clinical syndrome that occurs when tissues are exposed to high levels of thyroid hormone (see [Table 38–4](#)).

### GRAVES DISEASE

The most common form of hyperthyroidism is Graves disease, or diffuse toxic goiter. The presenting signs and symptoms of Graves disease are set forth in [Table 38–4](#).

#### Pathophysiology

Graves disease is an autoimmune disorder in which a defect in suppressor T lymphocytes stimulates B lymphocytes to synthesize antibodies (TSH-R Ab [stim]) to thyroidal antigens. The TSH-R Ab [stim] binds and activates the TSH receptor in the thyroid cell membrane and stimulates growth and biosynthetic activity of the thyroid cell. Genetics, the postpartum state, cigarette smoking, and physical and emotional stress increase TSH-R Ab [stim] development. A genetic predisposition is suggested by a high frequency of HLA-B8 and HLA-DR3 in Caucasians, HLA-Bw46 and HLA-B5 in Chinese, and HLA-B17 in African Americans. Spontaneous remission is rare, so some patients require years of antithyroid therapy.

#### Laboratory Diagnosis

In most patients with hyperthyroidism,  $T_3$ ,  $T_4$ ,  $FT_4$ , and  $FT_3$  are elevated and TSH is suppressed (see [Table 38–2](#)). Radioiodine uptake is typically markedly elevated as well. Antithyroglobulin, thyroid peroxidase, and TSH-R Ab [stim] antibodies are usually present.

#### Management of Graves Disease

The three primary methods for controlling hyperthyroidism include antithyroid drug therapy, destruction of the gland with radioactive **iodine**, and surgical thyroidectomy. None of these methods alters the underlying pathogenesis of the disease.

#### A. Antithyroid Drug Therapy

Drug therapy is most useful in young patients with small glands and mild disease. **Methimazole** (preferred) or **propylthiouracil** administration is continued until spontaneous remission occurs. This is the only therapy that leaves the thyroid gland intact, often requiring a long period of treatment and observation (12–18 months). However, once therapy is stopped, a high rate (50–60%) of relapse may occur.

**Methimazole** is preferable to **propylthiouracil** (except in pregnancy and thyroid storm) because it has a lower risk of serious liver injury and can be administered once daily, improving adherence. Antithyroid drug therapy is usually begun with divided doses, shifting to maintenance therapy with single daily doses when the patient becomes clinically euthyroid. However, mild to moderately severe thyrotoxicosis can often be controlled with an initial single dose of 20–40 mg of **methimazole** administered for 4–8 weeks to normalize hormone levels. Maintenance therapy requires 5–15 mg once

daily. Alternatively, administer [propylthiouracil](#) 100–150 mg every 6 or 8 hours until the patient is euthyroid, then follow with gradual reduction of the dose to the maintenance level of 50–150 mg once daily. In addition to inhibiting [iodine](#) organification, [propylthiouracil](#) also inhibits the conversion of  $T_4$  to  $T_3$ , so it brings the level of activated thyroid hormone down more quickly than does [methimazole](#). The best clinical guide to remission is reduction in the size of the goiter. Laboratory tests most useful in monitoring the course of therapy are serum  $FT_3$ ,  $FT_4$ , and TSH levels.

Adverse reactions to antithyroid drugs have been described above. A minor rash without systemic symptoms can often be controlled by antihistamine therapy. Because the more severe reaction of agranulocytosis is often preceded by sore throat and a high fever, patients receiving antithyroid drugs must be instructed to discontinue the drug and seek immediate medical attention if these symptoms develop and persist. White blood cell counts with a differential and a throat culture are indicated in such cases, followed by appropriate antibiotic therapy. Stop therapy if significant elevations in transaminases (two to three times the upper limit of normal) occur.

#### B. Thyroidectomy

A near-total thyroidectomy is the treatment of choice for patients with very large glands or multinodular goiters. Patients are treated with antithyroid drugs until euthyroid (about 6 weeks). In addition, for 10–14 days prior to surgery, they receive saturated solution of potassium iodide, 5 drops twice daily, to diminish vascularity of the gland and simplify surgery. About 80–90% of patients will require thyroid supplementation following near-total thyroidectomy.

#### C. Radioactive Iodine

Radioiodine therapy (RAI) utilizing  $^{131}I$  is the preferred treatment for most patients over 21 years of age. In patients without heart disease, the therapeutic dose can be given immediately in a range of 80–120  $\mu Ci/g$  of estimated thyroid weight corrected for uptake. In patients with underlying heart disease or severe thyrotoxicosis and in elderly patients, it is desirable to treat with antithyroid drugs (preferably [methimazole](#)) until the patient is euthyroid. Stop the [methimazole](#) for 2–3 days before RAI is administered so as not to interfere with RAI retention, but it can be restarted 3–5 days later and then gradually tapered over 4–6 weeks as thyroid function normalizes. Iodides should be avoided to ensure maximal  $^{131}I$  uptake. Six to 12 weeks following the administration of RAI, the gland will shrink in size and the patient will usually become euthyroid or hypothyroid. A second dose may be required 3 months post-RAI if there is insufficient response. Hypothyroidism occurs in about 80% of patients following RAI. Serum  $FT_4$  and TSH levels should be monitored regularly. When hypothyroidism develops, prompt replacement with oral [levothyroxine](#), 50–150 mcg daily, should be started.

#### D. Adjuncts to Antithyroid Therapy

During the acute phase of thyrotoxicosis,  $\beta$ -adrenoceptor–blocking agents without intrinsic sympathomimetic activity are appropriate additions in symptomatic patients aged 60 years or older, in those with heart rates  $>90$  beats/min, and in those with cardiovascular disease. [Propranolol](#), 20–40 mg orally every 6 hours, or [metoprolol](#), 25–50 mg orally every 6–8 hours, will control tachycardia, hypertension, and atrial fibrillation. Beta-adrenoceptor–blocking agents are gradually withdrawn as serum thyroxine levels return to normal. [Diltiazem](#), 90–120 mg three or four times daily, can be used to control tachycardia in patients in whom  $\beta$  blockers are contraindicated, eg, those with asthma. Dihydropyridine calcium channel blockers may not be as effective as [diltiazem](#) or [verapamil](#). Adequate nutrition and vitamin supplements are essential. Barbiturates accelerate  $T_4$  breakdown (by hepatic enzyme induction) and may be helpful both as sedatives and to lower  $T_4$  levels. Bile acid sequestrants (eg, cholestyramine) can also rapidly lower  $T_4$  levels by increasing the fecal excretion of  $T_4$ .

### TOXIC UNINODULAR GOITER & TOXIC MULTINODULAR GOITER

These forms of hyperthyroidism occur often in older women with nodular goiters. Free thyroxine is moderately elevated or occasionally normal, but  $FT_3$  or  $T_3$  is strikingly elevated. Single toxic adenomas can be managed either with surgical excision of the adenoma or with radioiodine therapy. Toxic multinodular goiter is usually associated with a large goiter and is best treated by preparation with [methimazole](#) (preferable) or [propylthiouracil](#) followed by subtotal thyroidectomy.

### SUBACUTE THYROIDITIS

During the acute phase of a viral infection of the thyroid gland, there is destruction of thyroid parenchyma with transient release of stored thyroid hormones. A similar state may occur in patients with Hashimoto thyroiditis and with some drug-induced dysfunction (eg, immune checkpoint inhibitors, **amiodarone**) before the onset of hypothyroidism. These episodes of transient thyrotoxicosis have been termed *spontaneously resolving hyperthyroidism*. Supportive therapy is usually all that is necessary, such as  $\beta$ -adrenoceptor–blocking agents without intrinsic sympathomimetic activity (eg, **propranolol**) for tachycardia and **aspirin** or nonsteroidal anti-inflammatory drugs to control local pain and fever. Corticosteroids may be necessary in severe cases to control the inflammation.

## SPECIAL PROBLEMS

### Thyroid Storm

Thyroid storm, or thyrotoxic crisis, is sudden acute exacerbation of all of the symptoms of thyrotoxicosis, presenting as a life-threatening syndrome. Vigorous management is mandatory. **Propranolol**, 60–80 mg orally every 4 hours, or intravenous **propranolol**, 1–2 mg slowly every 5–10 minutes to a total of 10 mg, or **esmolol**, 50–100 mg/kg per min, is helpful to control the severe cardiovascular manifestations. If  $\beta$  blockers are contraindicated by the presence of severe heart failure or asthma, hypertension and tachycardia may be controlled with **diltiazem**, 90–120 mg orally three or four times daily or 5–10 mg/h by intravenous infusion (asthmatic patients only). Release of thyroid hormones from the gland is blocked by the administration of saturated solution of potassium iodide, 5 drops orally every 6 hours starting 1 hour after giving thioamides. Hormone synthesis is reduced by the administration of **propylthiouracil**, 500–1000 mg as a loading dose, followed by 250 mg orally every 4 hours. If the patient is unable to take **propylthiouracil** by mouth, a rectal formulation\* can be prepared and administered in a dosage of 400 mg every 6 hours as a retention enema. **Methimazole** may also be prepared for rectal administration in a dose of 60–80 mg daily. **Hydrocortisone**, 50 mg intravenously every 6 hours, will protect the patient against shock and will block the conversion of  $T_4$  to  $T_3$ , rapidly reducing the level of thyroactive material in the blood.

Supportive therapy is essential to control fever, heart failure, and any underlying disease process that may have precipitated the acute storm. In rare situations, where the above methods are not adequate to control the problem, oral bile acid sequestrants (eg, cholestyramine), plasmapheresis, or peritoneal dialysis has been used to lower the levels of circulating thyroxine.

### Ophthalmopathy

Ophthalmopathy is attributed to the presence of TSH receptors and insulin-like growth factor 1 receptor (IGF-1R) in orbital fibrocytes. Although severe ophthalmopathy is rare, it is difficult to treat. A 15–20% risk of aggravating severe eye disease may occur following RAI, especially in those who smoke. Management requires effective treatment of the thyroid disease, usually by total surgical excision or  $^{131}\text{I}$  ablation of the gland plus anti-inflammatory therapies (see below). In addition, local therapy may be necessary, eg, elevation of the head to diminish periorbital edema and artificial tears to relieve corneal drying due to exophthalmos. Smoking cessation is necessary to prevent progression of the ophthalmopathy. For severe, acute inflammatory reaction, **prednisone**, 60–100 mg orally daily for about a week and then 60–100 mg every other day, tapering the dose over 6–12 weeks, may be effective. **Teprotumumab** (Tepezza), a monoclonal antibody given once every three weeks for total of eight IV infusions, significantly reduces eye bulges, pain and swelling, and double vision. If the aforementioned therapy fails or is contraindicated, irradiation of the posterior orbit, using well-collimated high-energy X-ray therapy, will frequently result in marked improvement of the acute process. Threatened loss of vision is an indication for surgical decompression of the orbit. Eyelid or eye muscle surgery may be necessary to correct residual problems after the acute process has subsided.

### Dermopathy

Dermopathy or pretibial myxedema will often respond to topical corticosteroids applied to the involved area and covered with an occlusive dressing.

### Thyrotoxicosis during Pregnancy

Ideally, women in the childbearing period with severe disease should have definitive therapy with  $^{131}\text{I}$  or subtotal thyroidectomy *prior* to pregnancy in order to avoid an acute exacerbation of the disease during pregnancy or following delivery. If thyrotoxicosis does develop during pregnancy, RAI is contraindicated due to its placenta passage and injury to the fetal thyroid. During the first trimester, **propylthiouracil** (lower teratogenic risks than **methimazole**) is given but to avoid the risk of liver damage, PTU is changed to **methimazole** for the remainder of the pregnancy. **Propylthiouracil** must be kept to the minimum dosage necessary for control of the disease (ie, <300 mg/d) to avoid inhibiting the function of the fetal thyroid gland.

Alternatively, a subtotal thyroidectomy can be safely performed during the mid-trimester. It is essential to give the patient a thyroid supplement during

### Neonatal Graves Disease

Graves disease may occur in the newborn infant, due either to passage of maternal TSH-R Ab [stim] through the placenta, stimulating the thyroid gland of the neonate, or to genetic transmission of the trait to the fetus. Laboratory studies reveal an elevated free  $T_4$ , a markedly elevated  $T_3$ , and a low TSH—in contrast to the normal infant, in whom TSH is elevated at birth. TSH-R Ab [stim] is usually found in the serum of both the child and the mother.

If caused by maternal TSH-R Ab [stim], the disease is usually self-limited and subsides over a period of 4–12 weeks, coinciding with the fall in the infant's TSH-R Ab [stim] level. However, treatment is necessary because of the severe metabolic stress the infant experiences. Therapy includes [propylthiouracil](#) at a dosage of 5–10 mg/kg daily in divided doses at 8-hour intervals; Lugol solution (8 mg of iodide per drop), one drop every 8 hours; and [propranolol](#), 2 mg/kg daily in divided doses. Careful supportive therapy is essential. If the infant is very ill, oral [prednisone](#), 2 mg/kg daily in divided doses, will help block conversion of  $T_4$  to  $T_3$ . These medications are gradually reduced as the clinical picture improves and can be discontinued by 6–12 weeks.

### SUBCLINICAL HYPERTHYROIDISM

Subclinical hyperthyroidism is defined as a suppressed TSH level (below the normal range) in conjunction with normal thyroid hormone levels. Cardiac toxicity (eg, atrial fibrillation), especially in older persons and those with underlying cardiac disease, is of greatest concern. The consensus of thyroid experts agree that hyperthyroidism treatment is appropriate in those with TSH less than 0.1 mIU/L, while close monitoring of the TSH level is appropriate for those with less TSH suppression.

### Amiodarone-Induced Thyrotoxicosis

In addition to those patients who develop hypothyroidism caused by [amiodarone](#), approximately 3% of patients receiving this drug will develop hyperthyroidism instead. Two types of amiodarone-induced thyrotoxicosis have been reported: iodine-induced (type I), which often occurs in persons with underlying thyroid disease (eg, multinodular goiter, Graves disease); and an inflammatory thyroiditis (type II) that occurs in patients without thyroid disease due to leakage of thyroid hormone into the circulation. Treatment of type I requires therapy with thioamides, while type II responds best to glucocorticoids. Since it is not always possible to differentiate between the two types, thioamides and glucocorticoids are often co-administered together. Even if [amiodarone](#) is stopped, rapid improvement does not occur due to its long half-life.

### NONTOXIC GOITER

Nontoxic goiter is a syndrome of thyroid enlargement without excessive thyroid hormone production. Enlargement of the thyroid gland is often due to TSH stimulation from inadequate thyroid hormone synthesis. The most common cause of nontoxic goiter worldwide is iodide deficiency, but in the United States, it is Hashimoto thyroiditis. Other causes include germ-line or acquired mutations in genes involved in hormone synthesis, dietary goitrogens, and neoplasms (see below).

Goiter due to iodide deficiency is best managed by prophylactic administration of iodide. The optimal daily iodide intake is 150–200 mcg. Iodized salt and iodate used as preservatives in flour and bread are excellent sources of [iodine](#) in the diet. In areas where it is difficult to introduce iodized salt or iodate preservatives, a solution of iodized poppy-seed oil has been administered intramuscularly to provide a long-term source of inorganic [iodine](#).

Goiter due to ingestion of dietary goitrogens is treated by elimination of the goitrogen or by adding sufficient thyroxine to shut off TSH stimulation. Similarly, in Hashimoto thyroiditis and dysmorphogenesis, adequate thyroxine therapy—150–200 mcg/d orally—will suppress pituitary TSH and result in slow regression of the goiter as well as correction of hypothyroidism.

### THYROID NEOPLASMS

Neoplasms of the thyroid gland may be benign (adenomas) or malignant. The primary diagnostic test is a fine-needle aspiration biopsy and cytologic examination. Benign lesions may be monitored for growth or symptoms of local obstruction, which would mandate surgical excision. [Levothyroxine](#) therapy is not recommended for the suppression of benign nodules, especially in iodine-sufficient areas. Management of thyroid carcinoma requires a [Levothyroxine](#) therapy, postoperative radioiodine therapy in selected instances, and lifetime replacement with [levothyroxine](#). The evaluation for

recurrence of some thyroid malignancies often involves withdrawal of thyroxine replacement for 4–6 weeks—accompanied by the development of hypothyroidism. Tumor recurrence is likely if there is a rise in serum thyroglobulin (ie, a tumor marker) or a positive  $^{131}\text{I}$  scan when TSH is elevated. Alternatively, administration of recombinant human TSH (Thyrogen) can produce comparable TSH elevations without discontinuing thyroxine and avoiding hypothyroidism. Recombinant human TSH is administered intramuscularly once daily for 2 days. A rise in serum thyroglobulin or a positive  $^{131}\text{I}$  scan will indicate a recurrence of the thyroid cancer.

### SUMMARY Drugs Used in the Management of Thyroid Disease

Subclass, Drug	Mechanism of Action and Effects	Indications	Pharmacokinetics, Toxicities, Interactions
<b>THYROID PREPARATIONS</b>			
<ul style="list-style-type: none"> <li>Levothyroxine (<math>\text{T}_4</math>)</li> <li>Liothyronine (<math>\text{T}_3</math>)</li> </ul>	Activation of nuclear receptors results in gene expression with RNA formation and protein synthesis	Hypothyroidism	See <a href="#">Table 38-1</a> • maximum effect seen after 6–8 weeks of therapy • <i>Toxicity</i> : See <a href="#">Table 38-4</a> for symptoms of thyroid excess
<b>ANTITHYROID AGENTS</b>			
<b>THIOAMIDES</b>			
<ul style="list-style-type: none"> <li>Methimazole</li> <li>Propylthiouracil (PTU)</li> </ul>	Inhibit thyroid peroxidase reactions • block iodine organification • inhibit peripheral deiodination of $\text{T}_4$ to $\text{T}_3$ (primarily PTU)	Hyperthyroidism	Oral • duration of action: 24 h (methimazole), 6–8 h (PTU) • delayed onset of action • <i>Toxicity</i> : Nausea, gastrointestinal distress, rash, agranulocytosis, hepatitis (PTU black box), hypothyroidism, teratogenicity (methimazole > PTU)
<b>IODIDES</b>			
<ul style="list-style-type: none"> <li>Lugol solution</li> <li>Potassium iodide</li> </ul>	Inhibit organification and hormone release • reduce the size and vascularity of the gland	Preparation for surgical thyroidectomy	Oral • acute onset within 2–7 days • <i>Toxicity</i> : Rare (see text)
<b>BETA BLOCKERS</b>			
<ul style="list-style-type: none"> <li>Propranolol, other <math>\beta</math> blockers lacking partial agonist activity</li> </ul>	Inhibition of $\beta$ adrenoreceptors • inhibit $\text{T}_4$ to $\text{T}_3$ conversion (only propranolol)	Hyperthyroidism, especially thyroid storm • adjunct to control tachycardia, hypertension, and atrial fibrillation	Onset within hours • duration of 4–6 h (oral propranolol) • <i>Toxicity</i> : bronchospasm, AV blockade, hypotension, bradycardia
<b>MONOCLONAL ANTIBODY</b>			
<ul style="list-style-type: none"> <li>Teprotumumab</li> </ul>	Inhibits insulin-like growth factor receptor type 1 (IGF-1R)	Proptosis, redness, swelling, double vision, from thyroid-	• Onset before completion of eight total infusions • T1/2 20 days • <i>Toxicity</i> : infusion reactions, muscle cramps, nausea,

**RADIOACTIVE IODINE  $^{131}\text{I}$  (RAI)**

Radiation destruction of thyroid parenchyma

Hyperthyroidism • patients should be euthyroid or on  $\beta$  blockers before RAI • avoid in pregnancy and in nursing mothers

Oral • half-life 5 days • onset in 6–12 weeks • maximum effect in 3–6 months • *Toxicity*: Sore throat, sialitis, hypothyroidism

## PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
<b>THYROID AGENTS</b>	
Oral <b>levothyroxine</b> (T <sub>4</sub> )	Generic (also IV), Eltroxin, Euthyrox, Levoxyl, Levo-T, Levolet*, Novothyrox, Synthroid (IV also), Thyquidity, Tirosint, Tirosint-SOL, Unithroid
Oral <b>liothyronine</b> (T <sub>3</sub> )	Generic, Cytomel, Triostat (IV)
Oral Liotrix (a 4:1 ratio of T <sub>4</sub> :T <sub>3</sub> )	Thyrolar
Oral Thyroid desiccated (USP)	Generic, Armour, Nature-Throid, Westhroid
<b>ANTITHYROID AGENTS</b>	
Radioactive <b>iodine</b> ( <sup>131</sup> I) sodium	Iodotope, Sodium Iodide I 131 Therapeutic
Oral <b>methimazole</b>	Generic, Northyx, Tapazole
Potassium iodide	
Oral solution (SSKI)	ThyroShield
Oral solution (Lugol solution)	Lugol solution
Oral potassium iodide tablets	IOSAT, Pima, Thyro-Block, ThyroSafe
Oral <b>propylthiouracil</b> [PTU]	Generic
<b>Teprotumumab</b>	Tepezza (IV)
<b>DIAGNOSTIC AGENT</b>	
Thyrotropin; recombinant human TSH	Thyrogen

\* Not available in the United States.

The initial **methimazole** treatment was appropriate and preferable to **propylthiouracil** because of its longer duration of action allowing once-daily dosing and its improved safety profile. JP presents with the typical signs and symptoms of hypothyroidism following RAI despite **levothyroxine** replacement. Either radioactive **iodine** or thyroidectomy are reasonable and effective strategies for definitive treatment of her hyperthyroidism, especially before becoming pregnant to avoid an acute hyperthyroid exacerbation during pregnancy or following delivery. Her hypothyroid symptoms should have been easily corrected by the addition of **levothyroxine** dosed correctly at 1.7 mcg/kg/day or 100 mcg daily. Because she is young and has no cardiac disease, full replacement doses were appropriate to start. However, her elevated TSH level indicates inadequate **levothyroxine** replacement which may be related to nonadherence, or concomitant calcium and **omeprazole** co-administration. For optimal absorption, **levothyroxine** should be taken orally 30–60 minutes before meals (eg, empty stomach) or at bedtime, and separated by 4 hours from her calcium administration. Lower thyroxine doses may also be sufficient if her **omeprazole** is stopped. Once-weekly thyroxine injections may be effective in those with ongoing nonadherence. Thyroid function tests should be monitored after 6–8 weeks of therapy, obtained before thyroxine administration to avoid transient hormone alterations, and the dosage adjusted to achieve a normal TSH level and resolution of hypothyroid symptoms.

\*To prepare a water suspension **propylthiouracil** enema, grind eight 50-mg tablets and suspend the powder in 90 mL of sterile water.

## Chapter 39: Adrenocorticosteroids & Adrenocortical Antagonists

George P. Chrousos

### CASE STUDY

#### CASE STUDY

A 19-year-old man complains of anorexia, fatigue, dizziness, and weight loss of 8 months' duration. The examining physician discovers postural hypotension and moderate vitiligo (depigmented areas of skin) and obtains routine blood tests. She finds hyponatremia, hyperkalemia, and acidosis and suspects Addison disease. She performs a standard ACTH 1–24 stimulation test, which reveals an insufficient plasma cortisol response, which is compatible with primary adrenal insufficiency. The diagnosis of autoimmune Addison disease is made, and the patient must start replacement of the hormones he cannot produce himself. How should this patient be treated? What precautions should he take?

The natural adrenocortical hormones are steroid molecules produced and released by the adrenal cortex. Deficiency of the adrenocortical hormones results in the signs and symptoms of **Addison disease**. Excess production causes **Cushing syndrome**. Both natural and synthetic corticosteroids are used for the diagnosis and treatment of disorders of adrenal function. They are also used—more often and in much larger doses—for treatment of a variety of inflammatory, immunologic, and hematologic disorders.

Secretion of adrenocortical steroids, especially the glucocorticoids, is controlled by the pituitary release of **corticotropin (ACTH)** (see [Chapter 37](#)). **Corticotropin** is derived from a larger protein synthesized in the pituitary, **pro-opiomelanocortin (POMC)**. Secretion of the salt-retaining hormone aldosterone is primarily under the influence of circulating angiotensin and potassium. **Corticotropin** has some actions that do not depend on its effect on adrenocortical secretion. However, its pharmacologic value as an anti-inflammatory agent and its use in testing adrenal function depend on its secretory action. Its pharmacology is reviewed only briefly here.

Inhibitors of the synthesis or antagonists of the action of the adrenocortical steroids are important in the treatment of several conditions. These agents are described at the end of this chapter.

### ADRENOCORTICOSTEROIDS

The adrenal cortex releases a large number of steroids into the circulation. Some have minimal biologic activity and function primarily as precursors, and there are some for which no function has been established. The hormonal steroids may be classified as those having important effects on intermediary metabolism and immune function (**glucocorticoids**), those having principally salt-retaining activity (**mineralocorticoids**), and those having **androgenic** or **estrogenic** activity (see [Chapter 40](#)). In humans, the major glucocorticoid is **cortisol** and the most important mineralocorticoid is **aldosterone**. Quantitatively, dehydroepiandrosterone (DHEA) in its sulfated form (DHEAS) is the major adrenal androgen. However, DHEA and two other adrenal androgens, androstenedione and androstenediol, are weak androgens and androstenediol is a potent estrogen. Androstenedione can be converted to **testosterone** and **estradiol** in extra-adrenal tissues ([Figure 39–1](#)). Adrenal androgens constitute the major endogenous precursors of estrogen in women after menopause and in younger patients in whom ovarian function is deficient or absent.

FIGURE 39–1

Outline of major pathways in adrenocortical hormone biosynthesis. The major secretory products are underlined. Pregnenolone is the major precursor of corticosterone and aldosterone, and 17-hydroxypregnenolone is the major precursor of cortisol. The enzymes and cofactors for the

reactions progressing down each column are shown on the left and across columns at the top of the figure. When a particular enzyme is deficient,

## THE NATURALLY OCCURRING GLUCOCORTICOID; CORTISOL (HYDROCORTISONE)

### Pharmacokinetics

Cortisol (also called **hydrocortisone**, compound F) exerts a wide range of physiologic effects, including regulation of intermediary metabolism, cardiovascular function, growth, and immunity. Its synthesis and secretion are tightly regulated by the central nervous system, which is very sensitive to negative feedback by the circulating cortisol and exogenous (synthetic) glucocorticoids. Cortisol is synthesized from cholesterol (as shown in [Figure 39-1](#)). The mechanisms controlling its secretion are discussed in [Chapter 37](#).

The rate of secretion follows a circadian rhythm ([Figure 39-2](#)) governed by pulses of ACTH that peak in the early morning hours and after meals. In plasma, cortisol is bound to circulating proteins. **Corticosteroid-binding globulin (CBG)**, an  $\alpha_2$  globulin synthesized by the liver, binds about 90% of the circulating hormone under normal circumstances. The remainder is free (about 5–10%) or loosely bound to **albumin** (about 5%) and is available to exert its effect on target cells. When plasma cortisol levels exceed 20–30 mcg/dL, CBG is saturated, and the concentration of free cortisol rises rapidly. CBG is increased in pregnancy, with estrogen administration, and in hyperthyroidism. It is decreased by hypothyroidism, genetic defects in synthesis, and protein deficiency states. **Albumin** has a large capacity but low affinity for cortisol, and for practical purposes albumin-bound cortisol should be considered free. Synthetic corticosteroids such as **dexamethasone** are largely bound to **albumin** rather than CBG.

FIGURE 39-2

Circadian variation in plasma cortisol throughout the 24-hour day (**upper panel**). The sensitivity of tissues to glucocorticoids is also circadian but inverse to that of cortisol, with low sensitivity in the late morning and high sensitivity in the evening and early night (**lower panel**). The sensitivity of tissues to glucocorticoids is inversely related to that of glucocorticoid receptor (GR) acetylation by the transcription factor CLOCK; the acetylated receptor has decreased transcriptional activity.

Basic & Clinical Pharmacology, Sixteenth Edition  
Copyright © McGraw Hill. All rights reserved.

The half-life of cortisol in the circulation is normally about 60–90 minutes; it may be increased when [hydrocortisone](#) (the pharmaceutical preparation of cortisol) is administered in large amounts or when stress, hypothyroidism, or liver disease is present. Only 1% of cortisol is excreted unchanged in the urine as free cortisol; about 20% of cortisol is converted to [cortisone](#) by 11-hydroxysteroid dehydrogenase in the kidney and other tissues with mineralocorticoid receptors (see below) before reaching the liver. Most cortisol is metabolized in the liver. About one-third of the cortisol produced daily is excreted in the urine as dihydroxy ketone metabolites and is measured as 17-hydroxysteroids (see [Figure 39–3](#) for carbon numbering). Many cortisol metabolites are conjugated with glucuronic acid or sulfate at the C<sub>3</sub> and C<sub>21</sub> hydroxyls, respectively, in the liver; they are then excreted in the urine.

FIGURE 39–3

Chemical structures of several glucocorticoids. The acetonide-substituted derivatives (eg, [triamcinolone](#) acetonide) have increased surface activity and are useful in dermatology. [Dexamethasone](#) is identical to [betamethasone](#) except for the configuration of the methyl group at C<sub>16</sub>: in [betamethasone](#) it is beta (projecting *up* from the plane of the rings); in [dexamethasone](#) it is alpha.

Basic & Clinical Pharmacology, Sixteenth Edition  
Copyright © McGraw Hill. All rights reserved.

In some species (eg, the rat), corticosterone is the major glucocorticoid. It is less firmly bound to protein and therefore metabolized more rapidly. The pathways of its degradation are similar to those of cortisol.

## Pharmacodynamics

### A. Mechanism of Action

Most of the known effects of the glucocorticoids are mediated by widely distributed intracellular glucocorticoid receptors. These proteins are members of the superfamily of nuclear receptors, which includes steroid, sterol (vitamin D), thyroid, retinoic acid, and many other receptors with unknown or nonexistent ligands (orphan receptors). All these receptors interact with the promoters of—and regulate the transcription of—target genes (Figure 39–4). In the absence of the hormonal ligand, glucocorticoid receptors are primarily cytoplasmic, in oligomeric complexes with chaperone heat-shock proteins (hsp). The most important of these are two molecules of hsp90, although other proteins (eg, hsp40, hsp70, FKBP5) also are involved. Free hormone from the plasma and interstitial fluid enters the cell and binds to the receptor, inducing conformational changes that allow it to dissociate from the heat shock proteins and dimerize. The dimeric ligand-bound receptor complex then is actively transported into the nucleus, where it interacts with DNA and nuclear proteins. As a homodimer, it binds to **glucocorticoid receptor elements (GREs)** in the promoters of responsive genes. The GRE is composed of two palindromic sequences that bind to the hormone receptor dimer.

FIGURE 39–4

A model of the interaction of a steroid, S (eg, cortisol), and its receptor, R, and the subsequent events in a target cell. The steroid is present in the blood in bound form on the corticosteroid-binding globulin (CBG) but enters the cell as the free molecule. The intracellular receptor is bound to stabilizing proteins, including two molecules of heat-shock protein 90 (hsp90) and several others including FKBP5, denoted as “X” in the figure. This receptor complex is incapable of activating transcription. When the complex binds a molecule of cortisol, an unstable complex is created and the hsp90 and associated molecules are released. The steroid-receptor complex is now able to dimerize, enter the nucleus, bind to a glucocorticoid response element (GRE) on the regulatory region of the gene, and regulate transcription by RNA polymerase II and associated transcription factors. A variety of regulatory factors (not shown) may participate in facilitating (coactivators) or inhibiting (corepressors) the steroid response. The resulting mRNA is edited and exported to the cytoplasm for the production of protein that brings about the final hormone response. An alternative to the steroid-receptor complex interaction with a GRE is an interaction with and altering the function of other transcription factors, such as NF- $\kappa$ B in the nucleus of cells.

Source: Todd W. Vanderah:  
Basic & Clinical Pharmacology, Sixteenth Edition  
Copyright © McGraw Hill. All rights reserved.

In addition to binding to GREs, the ligand-bound receptor also forms complexes with and influences the function of other transcription factors, such as AP1 and nuclear factor kappa-B (NF- $\kappa$ B), which act on non-GRE-containing promoters, to contribute to the regulation of transcription of their responsive genes. These transcription factors have broad actions on the regulation of growth factors, proinflammatory cytokines, etc, and to a great extent mediate the anti-growth, anti-inflammatory, and immunosuppressive effects of glucocorticoids.

Two genes for the corticoid receptor have been identified: one encoding the classic glucocorticoid receptor (**GR**) and the other encoding the mineralocorticoid receptor (**MR**). Alternative splicing of human glucocorticoid receptor pre-mRNA generates two highly homologous isoforms termed hGR $\alpha$  and hGR $\beta$ . Human GR $\alpha$  is the classic ligand-activated glucocorticoid receptor, which, in the hormone-bound state, modulates the expression of glucocorticoid-responsive genes. In contrast, hGR $\beta$  does not bind glucocorticoids and is transcriptionally inactive. However, hGR $\beta$  is able to inhibit the effects of hormone-activated hGR $\alpha$  on glucocorticoid-responsive genes, playing the role of a physiologically relevant endogenous inhibitor of glucocorticoid action. It was recently shown that the two hGR alternative transcripts have eight distinct translation initiation sites—ie, in a human cell there may be up to 16 GR $\alpha$  and GR $\beta$  isoforms, which may form up to 256 homodimers and heterodimers with different transcriptional and possibly nontranscriptional activities. This variability suggests that this important class of steroid receptors has complex stochastic activities. In addition, rare mutations in hGR may result in partial glucocorticoid resistance. Affected individuals have increased ACTH secretion because of reduced pituitary feedback and additional endocrine abnormalities (see below).

The prototype GR isoform is composed of about 800 amino acids and can be divided into three functional domains (see [Figure 2-6](#)). The glucocorticoid-binding domain is located at the carboxyl terminal of the molecule. The DNA-binding domain is located in the middle of the protein and contains nine **cysteine** residues. This region folds into a “two-finger” structure stabilized by zinc ions connected to cysteines to form two tetrahedrons. This part of the molecule binds to the GREs that regulate glucocorticoid action on glucocorticoid-regulated genes. The zinc fingers represent the basic structure by which the DNA-binding domain recognizes specific nucleic acid sequences. The amino terminal domain is involved in the transactivation activity of the receptor and increases its specificity.

The interaction of glucocorticoid receptors with GREs or other transcription factors is facilitated or inhibited by several families of proteins called steroid receptor *coregulators*, divided into *coactivators* and *corepressors*. The coregulators do this by serving as bridges between the receptors and other nuclear proteins and by expressing enzymatic activities such as histone acetylase or deacetylase, which alter the conformation of nucleosomes and the transcribability of genes.

www.ck12.org and 20% of expressed genes in a cell are regulated by glucocorticoids. The number and affinity of receptors for the hormone, the complement of transcription factors and coregulators, and post-transcription events determine the relative specificity of these hormones' actions in various cells. The effects of glucocorticoids are due mainly to proteins synthesized from mRNA transcribed from their target genes.

Some of the effects of glucocorticoids can be attributed to their binding to mineralocorticoid receptors. Indeed, MRs bind aldosterone and cortisol with similar affinity. A mineralocorticoid effect of the higher levels of cortisol is avoided in some tissues (eg, kidney, colon, salivary glands) by expression of 11 $\beta$ -hydroxysteroid dehydrogenase type 2, the enzyme responsible for biotransformation to its 11-keto derivative (**cortisone**), which has minimal action on aldosterone receptors.

The GR also interacts with other regulators of cell function. One such molecule is CLOCK/BMAL-1, a transcription factor dimer expressed in all tissues and generating the circadian rhythm of cortisol secretion (see **Figure 39-2**) at the suprachiasmatic nucleus of the hypothalamus. CLOCK is an acetyltransferase that acetylates the hinge region of the GR, neutralizing its transcriptional activity and thus rendering target tissues resistant to glucocorticoids. As shown in **Figure 39-2**, lower panel, the glucocorticoid target tissue sensitivity rhythm generated is in reverse phase to that of circulating cortisol concentrations, explaining the increased sensitivity of the organism to evening administration of glucocorticoids. The activated GR also interacts with NF- $\kappa$ B, a regulator of production of cytokines and other molecules involved in inflammation. This explains the circadian variability of the inflammatory reaction, which is enhanced in the evening and early night and suppressed in the morning.

Prompt effects such as initial feedback suppression of pituitary ACTH occur in minutes and are too rapid to be explained on the basis of gene transcription and protein synthesis. It is not known how these effects are mediated. Among the proposed mechanisms are direct effects on cell membrane receptors for the hormone or nongenomic effects of the classic hormone-bound glucocorticoid receptor. The putative membrane receptors might be entirely different from the known intracellular receptors. For example, recent studies implicate G protein-coupled membrane receptors in the response of glutamatergic neurons to glucocorticoids in rats. Furthermore, all steroid receptors (except the MRs) have been shown to have palmitoylation motifs that allow enzymatic addition of palmitate and increased localization of the receptors in the vicinity of plasma membranes. Such receptors are available for direct interactions with, and effects on, various membrane-associated or cytoplasmic proteins without the need for entry into the nucleus and induction of transcriptional actions.

#### B. Physiologic Effects

The glucocorticoids have widespread effects because they influence the function of most cells in the body. The major metabolic consequences of glucocorticoid secretion or administration are due to direct actions of these hormones in the cell. However, some important effects are the result of homeostatic responses by **insulin** and **glucagon**. Although many of the effects of glucocorticoids are dose-related and become magnified when large amounts are administered for therapeutic purposes, there are also other effects—called *permissive* effects—without which many normal functions become deficient. For example, the response of vascular and bronchial smooth muscle to catecholamines is diminished in the absence of cortisol and restored by physiologic amounts of this glucocorticoid. Similarly, the lipolytic responses of fat cells to catecholamines, ACTH, and growth hormone are attenuated in the absence of glucocorticoids.

#### C. Metabolic Effects

The glucocorticoids have important dose-related effects on carbohydrate, protein, and fat metabolism. The same effects are responsible for some of the serious adverse effects associated with their use in therapeutic doses. Glucocorticoids stimulate and are required for gluconeogenesis and glycogen synthesis in the fasting state. They stimulate phosphoenolpyruvate carboxykinase, glucose-6-phosphatase, and glycogen synthase and the release of amino acids in the course of muscle catabolism.

Glucocorticoids increase serum glucose levels and thus stimulate **insulin** release but inhibit the uptake of glucose by muscle cells, while they stimulate hormone-sensitive lipase and thus lipolysis. The increased **insulin** secretion stimulates lipogenesis and to a lesser degree inhibits lipolysis, leading to a net increase in fat deposition combined with increased release of fatty acids and glycerol into the circulation.

The net results of these actions are most apparent in the fasting state, when the supply of glucose from gluconeogenesis, the release of amino acids from muscle catabolism, the inhibition of peripheral glucose uptake, and the stimulation of lipolysis all contribute to maintenance of an adequate glucose supply to the brain.

Although glucocorticoids stimulate RNA and protein synthesis in the liver, they have catabolic and antianabolic effects in lymphoid and connective tissue, muscle, peripheral fat, and skin. Supraphysiologic amounts of glucocorticoids lead to decreased muscle mass and weakness, and thinning of the skin. Catabolic and antianabolic effects on bone are the cause of osteoporosis in Cushing syndrome and impose a major limitation in the long-term therapeutic use of glucocorticoids. In children, glucocorticoids reduce growth. This effect may be partially prevented by administration of growth hormone in high doses, but this use of growth hormone is not recommended except in extreme situations.

#### **E. Anti-Inflammatory and Immunosuppressive Effects**

Glucocorticoids dramatically reduce the manifestations of inflammation. This is due to their profound effects on the concentration, distribution, and function of peripheral leukocytes and to their suppressive effects on inflammatory cytokines and chemokines, and on other small molecule mediators of inflammation. Inflammation, regardless of its cause, is characterized by the extravasation and infiltration of leukocytes into the affected tissue. These events are mediated by a complex series of interactions of white cell adhesion molecules with those on endothelial cells and are inhibited by glucocorticoids. After a single dose of a short-acting glucocorticoid, the concentration of neutrophils in the circulation increases while the lymphocytes (T and B cells), monocytes, eosinophils, and basophils decrease. The changes are maximal at 6 hours and are dissipated in 24 hours. The increase in neutrophils is due both to increased influx into the blood from the bone marrow and to decreased migration from the blood vessels, leading to a reduction in the number of cells at the site of inflammation. The reduction in circulating lymphocytes, monocytes, eosinophils, and basophils is primarily the result of their movement from the vascular bed to lymphoid tissue.

Glucocorticoids also inhibit the functions of tissue macrophages as well as dendritic and other antigen-presenting cells. The ability of these cells to respond to antigens and mitogens is reduced. The effect on macrophages is particularly marked and limits their ability to phagocytose and kill microorganisms and to produce tumor necrosis factor  $\alpha$ , interleukin 1, metalloproteinases, and plasminogen activator. Both macrophages and lymphocytes produce less interleukin 12 and interferon- $\gamma$ , important inducers of TH1 cell activity, and cellular immunity.

In addition to their effects on leukocyte function, glucocorticoids influence the inflammatory response by inhibiting phospholipase A<sub>2</sub> and thus reduce the synthesis of arachidonic acid, the precursor of prostaglandins and leukotrienes, and of platelet-activating factor. Finally, glucocorticoids reduce expression of cyclooxygenase 2, the inducible form of this enzyme, in inflammatory cells, thus reducing the amount of enzyme available to produce prostaglandins (see [Chapters 18](#) and [36](#)).

Glucocorticoids cause vasoconstriction when applied directly to the skin, possibly by suppressing mast cell degranulation. They also decrease capillary permeability by reducing the amount of histamine released by basophils and mast cells.

The anti-inflammatory and immunosuppressive effects of glucocorticoids are largely due to the actions described above. In humans, complement activation is unaltered, but its effects are inhibited. Antibody production can be reduced by large doses of steroids, although it is unaffected by moderate doses (eg, 20 mg/d of [prednisone](#)).

The anti-inflammatory and immunosuppressive effects of these agents are widely useful therapeutically but are also responsible for some of their most serious adverse effects (see text that follows).

#### **F. Other Effects**

Glucocorticoids have important effects on the nervous system. Adrenal insufficiency causes marked slowing of the alpha rhythm of the electroencephalogram and is associated with depression. Increased amounts of glucocorticoids often produce behavioral disturbances in humans: initially insomnia and euphoria and subsequently depression. Large doses of glucocorticoids may increase intracranial pressure (pseudotumor cerebri).

Glucocorticoids given chronically suppress the pituitary release of ACTH, growth hormone, thyroid-stimulating hormone, and luteinizing hormone.

Large doses of glucocorticoids have been associated with the development of peptic ulcer, possibly by suppressing the local immune response against *Helicobacter pylori*. They also promote fat redistribution in the body, with increase of visceral, facial, nuchal, and supraclavicular fat, and they appear to antagonize the effect of vitamin D on calcium absorption. The glucocorticoids also have important effects on the hematopoietic system. In addition to their effects on leukocytes, they increase the number of platelets and red blood cells.

Cortisol deficiency results in impaired renal function (particularly glomerular filtration), augmented [vasopressin](#) secretion, and diminished ability to excrete a water load.

Glucocorticoids have important effects on the development of the fetal lungs. Indeed, the structural and functional changes in the lungs near term, including the production of pulmonary surface-active material required for air breathing (surfactant), are stimulated by glucocorticoids.

Recently, glucocorticoids were found to have direct effects on the epigenetic regulation of specific target genes by altering the activities of DNA methyltransferases and other enzymes participating in epigenesis. This is of particular importance in the prenatal treatment of pregnant mothers or treatment of young infants and children, when the epigenetic effects of glucocorticoids may be long term or even permanent. These effects may predispose these patients to behavioral or somatic disorders, such as depression or obesity and metabolic syndrome.

## SYNTHETIC CORTICOSTEROIDS

Glucocorticoids have become important agents for use in the treatment of many inflammatory, immunologic, hematologic, and other disorders. This has stimulated the development of many synthetic steroids with anti-inflammatory and immunosuppressive activity.

## PHARMACOKINETICS

Pharmaceutical steroids are usually synthesized from cholic acid obtained from cattle or steroid sapogenins found in plants. Further modifications of these steroids have led to the marketing of a large group of synthetic steroids with special characteristics that are pharmacologically and therapeutically important ([Table 39-1](#); see [Figure 39-3](#)).

Some commonly used natural and synthetic corticosteroids for general use. (See Table 61-4 for dermatologic corticosteroids.)

Agent	Activity <sup>1</sup>			Equivalent Oral Dose (mg)	Forms Available
	Anti-Inflammatory	Topical	Salt-Retaining		
<b>Short- to medium-acting glucocorticoids</b>					
Hydrocortisone (cortisol)	1	1	1	20	Oral, injectable, topical
Cortisone	0.8	0	0.8	25	Oral
Prednisone	4	0	0.3	5	Oral
Prednisolone	5	4	0.3	5	Oral, injectable
Methylprednisolone	5	5	0.25	4	Oral, injectable
Meprednisone <sup>2</sup>	5		0	4	Oral, injectable
<b>Intermediate-acting glucocorticoids</b>					
Triamcinolone	5	53	0	4	Oral, injectable, topical
Paramethasone <sup>2</sup>	10		0	2	Oral, injectable
Fluprednisolone <sup>2</sup>	15	7	0	1.5	Oral
<b>Long-acting glucocorticoids</b>					
Betamethasone	25–40	10	0	0.6	Oral, injectable, topical
Dexamethasone	30	10	0	0.75	Oral, injectable, topical
<b>Mineralocorticoids</b>					
Fludrocortisone	10	0	250	2	Oral
Desoxycorticosterone acetate <sup>2</sup>	0	0	20		Injectable, pellets

<sup>1</sup>Potency relative to hydrocortisone.

<sup>2</sup>Outside the United States.

<sup>3</sup>Triamcinolone acetonide: Up to 100.

The metabolism of the naturally occurring adrenal steroids has been discussed above. The synthetic corticosteroids (see Table 39-1) are in most cases rapidly and almost completely absorbed when given by mouth. Although they are transported and metabolized in a fashion similar to that of the

Alterations in the glucocorticoid molecule influence its affinity for glucocorticoid and mineralocorticoid receptors as well as its protein-binding affinity, side chain stability, rate of elimination, and metabolic products. Halogenation at the 9 position, unsaturation of the  $\Delta 1-2$  bond of the A ring, and methylation at the 2 or 16 position prolong the half-life by more than 50%. The  $\Delta 1$  compounds are excreted in the free form. In some cases, the agent given is a prodrug; for example, **prednisone** is rapidly converted to the active product **prednisolone** in the body.

## PHARMACODYNAMICS

The actions of the synthetic steroids are similar to those of cortisol (see above). They bind to the specific intracellular receptor proteins and produce the same effects but have different ratios of glucocorticoid to mineralocorticoid potency (Table 39–1).

## CLINICAL PHARMACOLOGY

### A. Diagnosis and Treatment of Disturbed Adrenal Function

#### 1. Adrenocortical insufficiency

##### a. CHRONIC (ADDISON DISEASE)

Chronic adrenocortical insufficiency is characterized by weakness, fatigue, weight loss, hypotension, hyperpigmentation, and inability to maintain the blood glucose level during fasting. In such individuals, minor noxious, traumatic, or infectious stimuli may produce acute adrenal insufficiency with circulatory shock and even death.

In primary adrenal insufficiency, about 20–30 mg of **hydrocortisone** must be given daily, with increased amounts during periods of stress. Although **hydrocortisone** has some mineralocorticoid activity, this must be supplemented by an appropriate amount of a salt-retaining hormone such as **fludrocortisone**. Synthetic glucocorticoids that are long-acting and devoid of salt-retaining activity should not be administered as hormone substitution to these patients.

##### b. ACUTE

When acute adrenocortical insufficiency is suspected, treatment must be instituted immediately. Therapy consists of large amounts of parenteral **hydrocortisone** in addition to correction of fluid and electrolyte abnormalities and treatment of precipitating factors.

**Hydrocortisone** sodium succinate or phosphate in doses of 100 mg intravenously is given every 8 hours until the patient is stable. The dose is then gradually reduced, achieving maintenance dosage within 5 days.

The administration of salt-retaining hormone is resumed when the total **hydrocortisone** dosage has been reduced to less than 50 mg/d.

#### 2. Adrenocortical hypo- and hyperfunction

##### a. CONGENITAL ADRENAL HYPERPLASIA

This group of disorders is characterized by specific defects in the synthesis of cortisol. In pregnancies at high risk for congenital adrenal hyperplasia, fetuses can be protected from genital abnormalities by administration of **dexamethasone** to the mother.

The most common defect is a decrease in or lack of P450c21 (21 $\alpha$ -hydroxylase) activity.\* As can be seen in Figure 39–1, this would lead to a reduction in cortisol synthesis and secretion and thus produce a compensatory increase in ACTH release. The adrenal becomes hyperplastic and produces abnormally large amounts of precursors such as 17-hydroxyprogesterone that can be diverted to the androgen pathway, which leads to virilization and can result in ambiguous genitalia in the female fetus. Metabolism of this compound in the liver leads to pregnanetriol, which is characteristically excreted into the urine in large amounts in this disorder and can be used to make the diagnosis and to monitor efficacy of glucocorticoid substitution. However, the most reliable method of detecting this disorder is the increased response of plasma 17-hydroxyprogesterone to ACTH stimulation.

If the defect is in 11-hydroxylation, large amounts of deoxycorticosterone are produced, and because this steroid has mineralocorticoid activity, hypertension with or without hypokalemic alkalosis may ensue. When 17-hydroxylation is defective in the adrenals and gonads, hypogonadism also is present. However, increased amounts of 11-deoxycorticosterone are formed, and the signs and symptoms associated with mineralocorticoid excess—such as hypertension and hypokalemia—also are observed.

When first seen, the infant with congenital adrenal hyperplasia may be in acute adrenal crisis and should be treated as described above, using appropriate electrolyte solutions and an intravenous preparation of **hydrocortisone** in stress doses. Once the patient is stabilized, oral **hydrocortisone**, 12–18 mg/m<sup>2</sup> per day in two unequally divided doses (two thirds in the morning, one third in late afternoon) is begun. The dosage is adjusted to allow normal growth and bone maturation and to prevent androgen excess. Alternate-day therapy with **prednisone** has also been used to achieve greater ACTH suppression without increasing growth inhibition. **Fludrocortisone**, 0.05–0.2 mg/d, should also be administered by mouth, with added salt to maintain normal blood pressure, plasma renin activity, and electrolytes.

#### b. CUSHING SYNDROME

Cushing syndrome is usually the result of bilateral adrenal hyperplasia secondary to an ACTH-secreting pituitary adenoma (Cushing disease) but occasionally is due to tumors or nodular hyperplasia of the adrenal gland or ectopic production of ACTH by other nonadrenocortical tumors. The manifestations are those associated with the chronic presence of excessive glucocorticoids. When glucocorticoid hypersecretion is marked and prolonged, a rounded, plethoric face and trunk obesity are striking in appearance. Protein loss may be significant and includes muscle wasting; thinning, purple striae, and easy bruising of the skin; poor wound healing; and osteoporosis. Other serious disturbances include mental disorders, hypertension, and diabetes. This disorder is treated by surgical removal of the tumor producing ACTH or cortisol, irradiation of the pituitary tumor, or resection of one or both adrenals. These patients must receive large doses of cortisol during and after the surgical procedure. Doses of up to 300 mg of soluble **hydrocortisone** may be given as a continuous intravenous infusion on the day of surgery. The dose must be reduced slowly to normal replacement levels, since rapid reduction in dose may produce withdrawal symptoms, including nausea, vomiting, fever, and joint pain. If adrenalectomy has been performed, long-term maintenance is similar to that outlined above for adrenal insufficiency.

#### c. PRIMARY GENERALIZED GLUCOCORTICOID RESISTANCE (CHROUSOS SYNDROME)

This rare sporadic or familial genetic condition is usually due to inactivating mutations of the glucocorticoid receptor gene. The hypothalamic-pituitary-adrenal (HPA) axis hyperfunctions in an attempt to compensate for the defect, and the increased production of ACTH leads to high circulating levels of cortisol and cortisol precursors such as corticosterone and 11-deoxycorticosterone with mineralocorticoid activity, as well as of adrenal androgens. These increased levels may result in hypertension with or without hypokalemic alkalosis and hyperandrogenism expressed as virilization and precocious puberty in children and acne, hirsutism, male pattern baldness, and menstrual irregularities (mostly oligo-amenorrhea and hypofertility) in women. The therapy of this syndrome is high doses of synthetic glucocorticoids such as **dexamethasone** with no inherent mineralocorticoid activity. These doses are titrated to normalize the production of cortisol, cortisol precursors, and adrenal androgens.

#### d. ALDOSTERONISM

Primary aldosteronism usually results from the excessive production of aldosterone by an adrenal adenoma. However, it may also result from abnormal secretion by hyperplastic glands or from a malignant adrenal tumor. The clinical findings of hypertension, weakness, and tetany are related to the continued renal loss of potassium, which leads to hypokalemia, alkalosis, and elevation of serum sodium concentrations. Recently, aldosteronism was found to be a more frequent cause of hypertension than originally thought, with a rate higher than 20%. This syndrome can also be produced in disorders of adrenal steroid biosynthesis by excessive secretion of deoxycorticosterone, corticosterone, or 18-hydroxycorticosterone—all compounds with inherent mineralocorticoid activity.

In contrast to patients with secondary aldosteronism (see text that follows), these patients have low (suppressed) levels of plasma renin activity and angiotensin II. When treated with **fludrocortisone** (0.2 mg twice daily orally for 3 days) or deoxycorticosterone acetate (20 mg/d intramuscularly for 3 days—but not available in the United States), patients fail to retain sodium and the secretion of aldosterone is not significantly reduced. When the disorder is mild, it may escape detection if only serum potassium levels are used for screening. However, it may be detected by an increased ratio of plasma aldosterone to renin. Patients generally improve when treated with **spironolactone** or **eplerenone**, steroidal aldosterone receptor-blocking agents, and the response to these agents is of diagnostic and therapeutic value. Recently, nonsteroidal compounds with aldosterone receptor-mediated antagonist activity were added to our armamentarium. One of these, finerenone is already in the market.

### 3. Use of glucocorticoids for diagnostic purposes

It is sometimes necessary to suppress the production of ACTH to identify the source of a particular hormone or to establish whether its production is influenced by the secretion of ACTH. In these circumstances, it is advantageous to use a very potent substance such as **dexamethasone** because the use of small quantities reduces the possibility of confusion in the interpretation of hormone assays in blood or urine. For example, if complete suppression is achieved by the use of 50 mg of cortisol, the urinary 17-hydroxycorticosteroids will be 15–18 mg/24 h, since one-third of the dose given will be reconverted in urine as 17-hydroxycorticosteroid. If an equivalent dose of 1.5 mg of **dexamethasone** is used, suppression will again be complete

but the urinary excretion will be only 0.5 mg/24 h and blood levels will be low.  
[www.konkur.in](http://www.konkur.in)

The **dexamethasone suppression test** is used for the diagnosis of Cushing syndrome and has also been used in the differential diagnosis of depressive psychiatric states. As a screening test, 1 mg **dexamethasone** is given orally at 11 PM, and a plasma sample is obtained the following morning. In normal individuals, the morning cortisol concentration is usually <2 mcg/dL, whereas in Cushing syndrome the level is usually >5 mcg/dL. The results are not reliable in the patient with depression, anxiety, concurrent illness, and other stressful conditions or in the patient who is receiving a medication that enhances the catabolism of **dexamethasone** in the liver. To distinguish between hypercortisolism due to anxiety, depression, and alcoholism (pseudo-Cushing syndrome) and bona fide Cushing syndrome, a combined test is carried out, consisting of **dexamethasone** (0.5 mg orally every 6 hours for 2 days) followed by a standard corticotropin-releasing hormone (CRH) test (1 mg/kg given as a bolus intravenous infusion 2 hours after the last dose of **dexamethasone**).

In patients in whom the diagnosis of Cushing syndrome has been established clinically and confirmed by a finding of elevated free cortisol in the urine, suppression with large doses of **dexamethasone** will help to distinguish patients with Cushing disease from those with steroid-producing tumors of the adrenal cortex or with the ectopic ACTH syndrome. **Dexamethasone** is given in a dosage of 0.5 mg orally every 6 hours for 2 days, followed by 2 mg orally every 6 hours for 2 days, and the urine is then assayed for cortisol or its metabolites (Liddle test); or **dexamethasone** is given as a single dose of 8 mg at 11 PM, and the plasma cortisol is measured at 8 AM the following day. In patients with Cushing disease, the suppressant effect of **dexamethasone** usually produces a 50% reduction in hormone levels. In patients in whom suppression does not occur, the ACTH level will be low in the presence of a cortisol-producing adrenal tumor and elevated in patients with an ectopic ACTH-producing tumor.

#### **B. Corticosteroids and Stimulation of Lung Maturation in the Fetus**

Lung maturation in the fetus is regulated by the fetal secretion of cortisol. Treatment of the mother with large doses of glucocorticoid reduces the incidence of respiratory distress syndrome in infants delivered prematurely. When delivery is anticipated before 34 weeks of gestation, intramuscular **betamethasone**, 12 mg, followed by an additional dose of 12 mg 18–24 hours later, is commonly used. **Betamethasone** is chosen because maternal protein binding and placental metabolism of this corticosteroid is less than that of cortisol, allowing increased transfer across the placenta to the fetus. A study of more than 10,000 infants born at 23–25 weeks of gestation indicated that exposure to exogenous corticosteroids before birth reduced the death rate and evidence of neurodevelopmental impairment.

#### **C. Corticosteroids and Nonadrenal Disorders**

The synthetic analogs of cortisol are useful in the treatment of a diverse group of diseases generally unrelated to any known disturbance of adrenal function (Table 39–2). The usefulness of corticosteroids in these disorders is a function of their ability to suppress inflammatory and immune responses and to alter leukocyte function, as previously described (see also Chapter 55). These agents are useful in disorders in which host response is the cause of the major manifestations of the disease. A good example of this is the therapy of patients with severe COVID-19, in whom high doses of a synthetic glucocorticoid decreased mortality by approximately 30%. In instances in which the inflammatory or immune response is important in controlling the pathologic process, therapy with corticosteroids may be dangerous but justified to prevent irreparable damage from an inflammatory response—if used in conjunction with specific therapy for the disease process.

## Some therapeutic indications for the use of glucocorticoids in nonadrenal disorders.

Disorder	Examples
Allergic reactions	Angioneurotic edema, asthma, bee stings, contact dermatitis, drug reactions, allergic rhinitis, serum sickness, urticaria
Collagen-vascular disorders	Giant cell arteritis, lupus erythematosus, scleroderma, mixed connective tissue syndromes, polymyositis, rheumatoid arthritis, temporal arteritis
Eye diseases	Acute uveitis, allergic conjunctivitis, choroiditis, optic neuritis
Gastrointestinal diseases	Inflammatory bowel disease, nontropical sprue, subacute hepatic necrosis
Hematologic disorders	Acquired hemolytic anemia, acute allergic purpura, leukemia, lymphoma, autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, multiple myeloma
Systemic inflammation	Acute respiratory distress syndrome (sustained therapy with moderate dosage accelerates recovery and decreases mortality)
Infections	Acute respiratory distress syndrome, sepsis, COVID-19
Inflammatory conditions of bones and joints	Arthritis, bursitis, tenosynovitis
Nausea and vomiting	A large dose of <a href="#">dexamethasone</a> reduces emetic effects of chemotherapy and general anesthesia
Neurologic disorders	Cerebral edema (large doses of <a href="#">dexamethasone</a> are given to patients following brain surgery to minimize cerebral edema in the postoperative period), multiple sclerosis
Organ transplants	Prevention and treatment of rejection (immunosuppression)
Pulmonary diseases	Aspiration pneumonia, bronchial asthma, prenatal prevention of infant respiratory distress syndrome, sarcoidosis
Renal disorders	Nephrotic syndrome
Skin diseases	Atopic dermatitis, dermatoses, lichen simplex chronicus (localized neurodermatitis), mycosis fungoides, pemphigus, psoriasis, seborrheic dermatitis, xerosis
Thyroid diseases	Malignant exophthalmos, subacute thyroiditis
Miscellaneous	Hypercalcemia, mountain sickness

Since corticosteroids are not usually curative, the pathologic process may progress while clinical manifestations are suppressed. Therefore, chronic systemic therapy with these drugs should be undertaken with great care and only when the seriousness of the disorder warrants their use and when less hazardous measures have been exhausted.

In general, attempts should be made to bring the disease process under control using medium- to intermediate-acting glucocorticoids such as [prednisone](#) and [prednisolone](#) (Table 39-1), as well as all ancillary measures possible to keep the dose low. Where possible, alternate-day therapy (beginning on the following text). Therapy should not be decreased or stopped abruptly. When prolonged therapy is anticipated, it is helpful to

obtain chest x-rays and a tuberculin test, since glucocorticoid therapy can reactivate dormant tuberculosis. The presence of diabetes, peptic ulcer, osteoporosis, and psychological disturbances should be taken into consideration, and cardiovascular function should be assessed.

Treatment for transplant rejection is a very important application of glucocorticoids. The efficacy of these agents is based on their ability to reduce antigen expression from the grafted tissue, delay revascularization, and interfere with the sensitization of cytotoxic T lymphocytes and the generation of primary antibody-forming cells.

## Toxicity

The benefits obtained from glucocorticoids vary considerably. Use of these drugs must be carefully weighed in each patient against their widespread effects. The major undesirable effects of glucocorticoids are the result of their hormonal actions, which lead to the clinical picture of iatrogenic Cushing syndrome (see later in text).

When glucocorticoids are used for short periods (<2 weeks), it is unusual to see serious adverse effects even with moderately large doses. However, insomnia, behavioral changes (primarily hypomania), and acute peptic ulcers are occasionally observed even after only a few days of treatment. Acute pancreatitis is a rare but serious acute adverse effect of high-dose glucocorticoids.

### A. Metabolic Effects

Most patients who are given daily doses of 100 mg of **hydrocortisone** or more (or the equivalent amount of synthetic steroid) for longer than 2 weeks undergo a series of changes that have been termed **iatrogenic Cushing syndrome**. The rate of development is a function of the dosage and the genetic background of the patient. In the face, rounding, puffiness, fat deposition, and plethora usually appear (moon facies). Similarly, fat tends to be redistributed from the extremities to the trunk, the back of the neck, and the supraclavicular fossae. There is an increased growth of fine hair over the face, thighs, and trunk. Steroid-induced punctate acne may appear, and insomnia and increased appetite are noted. In the treatment of dangerous or disabling disorders, these changes may not require cessation of therapy. However, the underlying metabolic changes accompanying them can be very serious by the time they become obvious. The continuing breakdown of protein and diversion of amino acids to glucose production increase the need for **insulin** and over time result in weight gain; visceral fat deposition; myopathy and muscle wasting; thinning of the skin, with striae and bruising; hyperglycemia; and eventually osteoporosis, diabetes, and aseptic necrosis of the hip. Wound healing also is impaired under these circumstances. When diabetes occurs, it is treated with diet and **insulin**. These patients are often resistant to **insulin** but rarely develop ketoacidosis. In general, patients treated with corticosteroids should be on high-protein and potassium-enriched diets and should receive adequate doses of vitamin D.

### B. Other Complications

Other serious adverse effects of glucocorticoids include peptic ulcers and their consequences. The clinical findings associated with certain disorders, particularly bacterial and mycotic infections, may be masked by the corticosteroids, and patients must be carefully monitored to avoid serious mishap when large doses are used. Severe myopathy is more frequent in patients treated with long-acting glucocorticoids. The administration of such compounds has been associated with nausea, dizziness, and weight loss in some patients. These effects are treated by changing drugs, reducing dosage, and increasing potassium and protein intake.

Hypomania or acute psychosis may occur, particularly in patients receiving very large doses of corticosteroids. Long-term therapy with intermediate- and long-acting steroids is associated with depression and the development of posterior subcapsular cataracts. Psychiatric follow-up and periodic slit-lamp examination are indicated in such patients. Increased intraocular pressure is common, and glaucoma may be induced. Benign intracranial hypertension also occurs. In dosages of 45 mg/m<sup>2</sup> per day or more of **hydrocortisone** equivalent, growth retardation occurs in children. Medium-, intermediate-, and long-acting glucocorticoids have greater growth-suppressing potency than the natural steroid at equivalent doses.

When given in larger than physiologic amounts, steroids such as **cortisone** and **hydrocortisone**, which have mineralocorticoid effects in addition to glucocorticoid effects, cause some sodium and fluid retention and loss of potassium. In patients with normal cardiovascular and renal function, this leads to a hypokalemic, hypochloremic alkalosis and eventually to a rise in blood pressure. In patients with hypoproteinemia, renal disease, or liver disease, edema also may occur. In patients with heart disease, even small degrees of sodium retention may lead to heart failure. These effects can be minimized by using synthetic non-salt-retaining steroids, sodium restriction, and judicious amounts of potassium supplements.

When corticosteroids are administered for more than 2 weeks, adrenal suppression may occur. If treatment extends over weeks to months, the patient should be given appropriate supplementary therapy at times of minor stress (twofold dosage increases for 24–48 hours) or severe stress (up to tenfold dosage increases for 48–72 hours) such as accidental trauma or major surgery. If corticosteroid dosage is to be reduced, it should be tapered slowly. If therapy is to be stopped, the reduction process should be quite slow when the dose reaches replacement levels. It may take 2–12 months for the hypothalamic-pituitary-adrenal axis to function acceptably, and cortisol levels may not return to normal for another 6–9 months. The glucocorticoid-induced suppression is not a pituitary problem, and treatment with ACTH does not reduce the time required for the return of normal function.

If the dosage is reduced too rapidly in patients receiving glucocorticoids for a certain disorder, the symptoms of the disorder may reappear or increase in intensity. However, patients without an underlying disorder (eg, patients cured surgically of Cushing disease) also develop symptoms with rapid reductions in corticosteroid levels. These symptoms include anorexia, nausea or vomiting, weight loss, lethargy, headache, fever, joint or muscle pain, and postural hypotension. Although many of these symptoms may reflect true glucocorticoid deficiency, they may also occur in the presence of normal or even elevated plasma cortisol levels, suggesting glucocorticoid dependence.

## Contraindications & Cautions

### A. Special Precautions

Patients receiving glucocorticoids must be monitored carefully for the development of hyperglycemia, glycosuria, sodium retention with edema or hypertension, hypokalemia, peptic ulcer, osteoporosis, and hidden infections.

The dosage should be kept as low as possible, and intermittent administration (eg, alternate-day) should be used when satisfactory therapeutic results can be obtained on this schedule. Even patients maintained on relatively low doses of corticosteroids may require supplementary therapy at times of stress, such as when surgical procedures are performed or intercurrent illnesses or accidents occur.

### B. Contraindications

Glucocorticoids must be used with great caution in patients with peptic ulcer, heart disease or hypertension with heart failure, certain infectious illnesses such as varicella and tuberculosis, psychoses, diabetes, osteoporosis, or glaucoma.

## Selection of Drug & Dosage Schedule

Glucocorticoid preparations differ with respect to relative anti-inflammatory and mineralocorticoid effect, duration of action, cost, and dosage forms available (Table 39-1), and these factors should be taken into account in selecting the drug to be used.

### A. ACTH versus Adrenocortical Steroids

In patients with normal adrenals, ACTH was used in the past to induce the endogenous production of cortisol to obtain similar effects. However, except when an increase in androgens is desirable, the use of ACTH as a therapeutic agent has been abandoned. Instances in which ACTH was claimed to be more effective than glucocorticoids were probably due to the administration of smaller amounts of corticosteroids than were produced by the dosage of ACTH.

### B. Dosage

In determining the dosage regimen to be used, the physician must consider the seriousness of the disease, the amount of drug likely to be required to obtain the desired effect, and the duration of therapy. In some diseases, the amount required for maintenance of the desired therapeutic effect is less than the dose needed to obtain the initial effect, and the lowest possible dosage for the needed effect should be determined by gradually lowering the dose until a small increase in signs or symptoms is noted.

When it is necessary to maintain continuously elevated plasma corticosteroid levels to suppress ACTH, a slowly absorbed parenteral preparation or small oral doses at frequent intervals are required. The opposite situation exists with respect to the use of corticosteroids in the treatment of inflammatory and allergic disorders. The same total quantity given in a few doses may be more effective than that given in many smaller doses or in a

Severe autoimmune conditions involving vital organs must be treated aggressively, and undertreatment is as dangerous as overtreatment. To minimize the deposition of immune complexes and the influx of leukocytes and macrophages, 1 mg/kg per day of **prednisone** in divided doses is required initially. This dosage is maintained until the serious manifestations respond. The dosage can then be gradually reduced.

When large doses are required for prolonged periods of time, alternate-day administration of the compound may be tried. When used in this manner, very large amounts (eg, 100 mg of **prednisone**) can sometimes be administered with less marked adverse effects because there is a recovery period between each dose. The transition to an alternate-day schedule can be made after the disease process is under control. It should be done gradually and with additional supportive measures between doses.

When selecting a drug for use in large doses, a medium- or intermediate-acting synthetic steroid with no or little mineralocorticoid effect is advisable. If possible, it should be given as a single morning dose.

### C. Special Dosage Forms

Local therapy, such as topical preparations for skin disease, ophthalmic forms for eye disease, intra-articular injections for joint disease, inhaled steroids for asthma, and **hydrocortisone** enemas for ulcerative colitis, provides a means of delivering large amounts of steroid to the diseased tissue with reduced systemic effects.

**Beclomethasone** dipropionate and several other glucocorticoids—primarily **budesonide**, **flunisolide**, and **mometasone** furoate, administered as inhaled aerosols—have been found to be extremely useful in the treatment of asthma (see [Chapter 20](#)).

**Beclomethasone** dipropionate, **triamcinolone** acetonide, **budesonide**, **flunisolide**, **fluticasone**, and others are available as nasal sprays for the topical treatment of allergic rhinitis. They are effective at doses (one or two sprays one, two, or three times daily) that in most patients result in plasma levels that are too low to influence adrenal function or have any other systemic effects.

Corticosteroids incorporated in ointments, creams, lotions, and sprays are used extensively in dermatology. These preparations are discussed in more detail in [Chapter 61](#).

Recently, new timed-release **hydrocortisone** tablets were developed for the replacement treatment of Addisonian and congenital adrenal hyperplasia patients. These tablets produce plasma cortisol levels that are similar to those secreted normally in a circadian fashion.

For therapeutic reasons, new timed-release **prednisone** tablets were developed for the therapy of patients with rheumatoid arthritis.

## MINERALOCORTICIDS (ALDOSTERONE, DEOXYCORTICOSTERONE, FLUDROCORTISONE)

The most important mineralocorticoid in humans is aldosterone. However, small amounts of 11-deoxycorticosterone (11-DOC) also are formed and released. Although the amount is normally insignificant, 11-DOC was of some importance therapeutically in the past. Its actions, effects, and metabolism are qualitatively similar to those described below for aldosterone. **Fludrocortisone**, a synthetic corticosteroid, is the most commonly prescribed salt-retaining hormone.

### Aldosterone

Aldosterone is synthesized mainly in the zona glomerulosa of the adrenal cortex. Its structure and synthesis are illustrated in [Figure 39-1](#). The rate of aldosterone secretion is subject to several influences. ACTH produces a moderate stimulation of its release, but this effect is not sustained for more than a few days in the normal individual. The quantities of aldosterone produced by the adrenal cortex and its plasma concentrations are insufficient to participate in any significant feedback control of ACTH secretion.

Without ACTH, aldosterone secretion falls to about half the normal rate, indicating that other factors, eg, angiotensin, are able to maintain and perhaps regulate its secretion (see [Chapter 17](#)). Independent variations between cortisol and aldosterone secretion can also be demonstrated by means of lesions in the nervous system such as decerebration, which decreases the secretion of cortisol while increasing the secretion of aldosterone.

### A. Physiologic and Pharmacologic Effects

Aldosterone and other steroids with mineralocorticoid properties promote the reabsorption of sodium from the distal part of the distal convoluted renal tubule and from the cortical collecting tubules, loosely coupled to the excretion of potassium and hydrogen ion. Sodium reabsorption in the sweat and salivary glands, in the gastrointestinal mucosa, and across cell membranes in general also is increased. Excessive levels of aldosterone produced by tumors or overdosage with synthetic mineralocorticoids lead to hypokalemia, metabolic alkalosis, increased plasma volume, and hypertension.

Mineralocorticoids act by binding to the mineralocorticoid receptor in the cytoplasm of target cells, especially principal cells of the distal convoluted and collecting tubules of the kidney. The drug-receptor complex activates a series of events similar to those described above for the glucocorticoids and illustrated in [Figure 39–4](#). It is of interest that this receptor has the same affinity for cortisol, which is present in much higher concentrations in the extracellular fluid. The specificity for mineralocorticoids in the kidney appears to be conferred, at least in part, by the presence—in the kidney—of the enzyme 11 $\beta$ -hydroxysteroid dehydrogenase type 2, which converts cortisol to [cortisone](#). The latter has low affinity for the receptor and is inactive as a mineralocorticoid or glucocorticoid in the kidney. The major effect of activation of the aldosterone receptor is increased expression of Na<sup>+</sup>/K<sup>+</sup>-ATPase and the epithelial sodium channel (ENaC).

## B. Metabolism

Aldosterone is secreted at the rate of 100–200 mcg/d in normal individuals with a moderate dietary salt intake. The plasma level in men (resting supine) is about 0.007 mcg/dL. The half-life of aldosterone injected in tracer quantities is 15–20 minutes, and it does not appear to be firmly bound to serum proteins.

The metabolism of aldosterone is similar to that of cortisol, about 50 mcg/24 h appearing in the urine as conjugated tetrahydroaldosterone. Approximately 5–15 mcg/24 h is excreted free or as the 3-oxo glucuronide.

## 11-Deoxycorticosterone (11-DOC)

11-DOC, which also serves as a precursor of aldosterone (see [Figure 39–1](#)), is normally secreted in amounts of about 200 mcg/d. Its half-life when injected into the human circulation is about 70 minutes. Estimates of its concentration in plasma are approximately 0.03 mcg/dL. The control of its secretion differs from that of aldosterone in that the secretion of 11-DOC is primarily under the control of ACTH. Although the response to ACTH is enhanced by dietary sodium restriction, due to adaptations, a low-salt diet does not increase 11-DOC secretion. The secretion of DOC may be markedly increased in abnormal conditions such as adrenocortical carcinoma and congenital adrenal hyperplasia with reduced P450c11 or P450c17 activity.

## Fludrocortisone

This compound, a potent steroid with both glucocorticoid and mineralocorticoid activity, is the most widely used mineralocorticoid. Oral doses of 0.1 mg two to seven times weekly have potent salt-retaining activity and are used in the treatment of adrenocortical insufficiency associated with mineralocorticoid deficiency. These dosages are too small to have important anti-inflammatory or antigrowth effects.

## ADRENAL ANDROGENS

The adrenal cortex secretes large amounts of DHEA and smaller amounts of androstenedione and [testosterone](#). Although these androgens are thought to contribute to the normal maturation process, they do not stimulate or support major androgen-dependent pubertal changes in humans. Studies suggest that DHEA and its sulfate might have other important physiologic actions. If that is correct, these results are probably due to the peripheral conversion of DHEA to more potent androgens or to [estrogens](#) and interaction with androgen and estrogen receptors, respectively. Additional effects may be exerted through an interaction with the GABA<sub>A</sub> and glutamate receptors in the brain or with a nuclear receptor in several central and peripheral sites. The therapeutic use of DHEA in humans has been explored, but the substance has already been adopted with uncritical enthusiasm by members of the sports drug and the vitamin and food supplement cultures.

The results of a placebo-controlled trial of DHEA in patients with systemic lupus erythematosus have been reported as well as those of a study of DHEA replacement in women with adrenal insufficiency. In both studies a small beneficial effect was seen, with some improvement of the disease in the former and an added sense of well-being in the latter. The androgenic or estrogenic actions of DHEA could explain the effects of the compound in both situations. In contrast, there is no evidence to support DHEA use to increase muscle strength or improve memory.

## ANTAGONISTS OF ADRENOCORTICAL AGENTS

### SYNTHESIS INHIBITORS & GLUCOCORTICOID ANTAGONISTS

Inhibitors of steroid synthesis act at several different steps, and one glucocorticoid antagonist acts at the receptor level.

#### AMINOGLUTETHIMIDE

Aminoglutethimide (Figure 39-5) blocks the conversion of cholesterol to pregnenolone (see Figure 39-1) and causes a reduction in the synthesis of all hormonally active steroids. It has been used in conjunction with **dexamethasone** or **hydrocortisone** to reduce or eliminate estrogen production in patients with carcinoma of the breast. In a dosage of 1 g/d it was well tolerated; however, with higher dosages, lethargy and skin rash were common effects. The use of aminoglutethimide in breast cancer patients has now been supplanted by **tamoxifen** or by another class of drugs, the aromatase inhibitors (see Chapters 40 and 54). Aminoglutethimide can be used in conjunction with **metyrapone** or **ketoconazole** to reduce steroid secretion in patients with Cushing syndrome due to adrenocortical cancer who do not respond to **mitotane**.

FIGURE 39-5

Some adrenocortical blockers. Because of their toxicity, some of these compounds are no longer available in the United States.

Source: Todd W. Vanderah:  
Basic & Clinical Pharmacology, Sixteenth Edition  
Copyright © McGraw Hill. All rights reserved.

Aminoglutethimide also apparently increases the clearance of some steroids. It has been shown to enhance the metabolism of **dexamethasone**, reducing its half-life from 4-5 hours to 2 hours.

#### KETOCONAZOLE

**Ketoconazole**, an antifungal imidazole derivative (see Chapter 48), is a potent and rather nonselective inhibitor of adrenal and gonadal steroid synthesis. This compound inhibits the cholesterol side-chain cleavage, P450c17, C17,20-lyase, 3 $\beta$ -hydroxysteroid dehydrogenase, and P450c11

enzymes required for steroid hormone synthesis. The sensitivity of the P450 enzymes to this compound in mammalian tissues is much lower than that needed to treat fungal infections, so that its inhibitory effects on steroid biosynthesis are seen only at high doses.

**Ketoconazole** has been used in the treatment of patients with Cushing syndrome due to several causes. Dosages of 200–1200 mg/d have caused a reduction in hormone levels and clinical improvement in some patients. This drug has some hepatotoxicity and should be started at 200 mg/d and slowly increased by 200 mg/d every 2–3 days up to a total daily dose of 1000 mg.

## ETOMIDATE

**Etomidate** [R-1-(1-ethylphenyl)imidazole-5-ethyl ester] is used for induction of general anesthesia and sedation. At subhypnotic doses of 0.1 mg/kg per hour this drug inhibits adrenal steroidogenesis at the level of 11 $\beta$ -hydroxylase and has been used as the only parenteral medication available in the treatment of severe Cushing syndrome.

## METYRAPONE

**Metyrapone** (see [Figure 39–5](#)) is a relatively selective inhibitor of steroid 11-hydroxylation, interfering with cortisol and corticosterone synthesis. In the presence of a normal pituitary gland, there is a compensatory increase in pituitary ACTH release and adrenal 11-deoxycortisol secretion. This response is a measure of the capacity of the anterior pituitary to produce ACTH and has been adapted for clinical use as a diagnostic test. Although the toxicity of **metyrapone** is much lower than that of **mitotane** (see text that follows), the drug may produce transient dizziness and gastrointestinal disturbances. This agent has not been widely used in the treatment of Cushing syndrome. However, in doses of 0.25 g twice daily to 1 g four times daily, **metyrapone** can reduce cortisol production to normal levels in some patients with endogenous Cushing syndrome. Thus, it may be useful in the management of severe manifestations of cortisol excess while the cause of this condition is being determined or in conjunction with radiation or surgical treatment. **Metyrapone** is the only adrenal-inhibiting medication that can be administered to pregnant women with Cushing syndrome. The major adverse effects observed are salt and water retention and hirsutism resulting from diversion of the 11-deoxycortisol precursor to DOC and androgen synthesis.

**Metyrapone** is commonly used in tests of adrenal function. The blood levels of 11-deoxycortisol and the urinary excretion of 17-hydroxycorticoids are measured before and after administration of the compound. Normally, there is a twofold or greater increase in the urinary 17-hydroxycorticoid excretion. A dosage of 300–500 mg every 4 hours for six doses is often used, and urine collections are made on the day before and the day after treatment. In patients with Cushing syndrome, a normal response to **metyrapone** indicates that the cortisol excess is not the result of a cortisol-secreting adrenal carcinoma or adenoma, since secretion by such tumors produces suppression of ACTH and atrophy of normal adrenal cortex.

Pituitary function may also be tested by administering **metyrapone**, 2–3 g orally at midnight and by measuring the level of ACTH or 11-deoxycortisol in blood drawn at 8 AM or by comparing the excretion of 17-hydroxycorticosteroids in the urine during the 24-hour periods preceding and following administration of the drug. In patients with suspected or known lesions of the pituitary, this procedure is a means of estimating the ability of the gland to produce ACTH. **Metyrapone** has been withdrawn from the market in the United States but is available on a compassionate basis.

## TRILOSTANE

Trilostane is a 3 $\beta$ -17 hydroxysteroid dehydrogenase inhibitor that interferes with the synthesis of adrenal and gonadal hormones and is comparable to aminoglutethimide. Trilostane's adverse effects are predominantly gastrointestinal; adverse effects occur in about 50% of patients with both trilostane and aminoglutethimide. There is no cross-resistance or crossover of side effects between these compounds. Trilostane is not available in the United States.

## ABIRATERONE

Abiraterone is the newest of the steroid synthesis inhibitors to be approved. It blocks 17 $\alpha$ -hydroxylase (P450c17) and 17,20-lyase (see [Figure 39–1](#)), and it predictably reduces synthesis of cortisol in the adrenal and gonadal steroids in the gonads. A compensatory increase occurs in ACTH and aldosterone synthesis, but this can be prevented by concomitant administration of **dexamethasone**. Abiraterone is an orally active steroid prodrug and is approved for the treatment of refractory prostate cancer.

## MIFEPRISTONE (RU-486)

The search for a glucocorticoid receptor antagonist finally succeeded in the early 1980s with the development of the 11 $\beta$ -aminophenyl-substituted 19-norsteroid called RU-486, later named **mifepristone**. Unlike the enzyme inhibitors previously discussed, **mifepristone** is a pharmacologic antagonist at the steroid receptor. This compound has strong antiprogestin activity and initially was proposed as a contraceptive-contragestive agent. High doses of **mifepristone** exert antiglucocorticoid activity by blocking the glucocorticoid receptor, since **mifepristone** binds to it with high affinity, causing (1) some stabilization of the hsp-glucocorticoid receptor complex and inhibition of the dissociation of the RU-486-bound glucocorticoid receptor from the hsp chaperone proteins; and (2) alteration of the interaction of the glucocorticoid receptor with coregulators, favoring the formation of a transcriptionally inactive complex in the cell nucleus. The result is inhibition of glucocorticoid receptor activation.

The mean half-life of **mifepristone** is 20 hours. This is longer than that of many natural and synthetic glucocorticoid agonists. (**Dexamethasone** has a half-life of 4–5 hours.) Less than 1% of the daily dose is excreted in the urine, suggesting a minor role of kidneys in the clearance of the compound. The long plasma half-life of **mifepristone** results from extensive and strong binding to plasma proteins. Less than 5% of the compound is found in the free form when plasma is analyzed by equilibrium dialysis. **Mifepristone** can bind to **albumin** and  $\alpha_1$ -acid glycoprotein, but it has no affinity for corticosteroid-binding globulin.

In humans, **mifepristone** causes generalized glucocorticoid resistance. Given orally to several patients with Cushing syndrome due to ectopic ACTH production or adrenal carcinoma, it was able to reverse the cushingoid phenotype, eliminate carbohydrate intolerance, normalize blood pressure, correct thyroid and gonadal hormone suppression, and ameliorate the psychological sequelae of hypercortisolism in these patients. At present, this use of **mifepristone** can only be recommended for inoperable patients with ectopic ACTH secretion or adrenal carcinoma who have failed to respond to other therapeutic manipulations. Its pharmacology and use in women as a **progesterone** antagonist are discussed in **Chapter 40**.

## MITOTANE

**Mitotane** (see **Figure 39–5**), a drug related to the DDT class of insecticides, has a nonselective cytotoxic action on the adrenal cortex in dogs and to a lesser extent in humans. This drug is administered orally in divided doses up to 12 g daily. About one third of patients with adrenal carcinoma show a reduction in tumor mass. In 80% of patients, the toxic effects are sufficiently severe to require dose reduction. These include diarrhea, nausea, vomiting, depression, somnolence, and skin rashes. The drug has been withdrawn from the market in the United States but is available on a compassionate basis.

## MINERALOCORTICOID ANTAGONISTS

In addition to agents that interfere with aldosterone synthesis (see above), there are steroids that compete with aldosterone for its receptor and decrease its effect peripherally. **Progesterone** is mildly active in this respect.

**Spirolactone** is a 7 $\alpha$ -acetylthiospirolactone. Its onset of action is slow, and the effects last for 2–3 days after the drug is discontinued. It is used in the treatment of primary aldosteronism in dosages of 50–100 mg/d. This agent reverses many of the manifestations of aldosteronism. It has been useful in establishing the diagnosis in some patients and in ameliorating the signs and symptoms when surgical removal of an adenoma is delayed. When used diagnostically for the detection of aldosteronism in hypokalemic patients with hypertension, dosages of 400–500 mg/d for 4–8 days—with an adequate intake of sodium and potassium—restore potassium levels to or toward normal. **Spirolactone** is also useful in preparing these patients for surgery. Dosages of 300–400 mg/d for 2 weeks are used for this purpose and may reduce the incidence of cardiac arrhythmias.

**Spirolactone**

**Spironolactone** is also an androgen antagonist and as such is sometimes used in the treatment of hirsutism and acne in women. Dosages of 50–200 mg/d cause a reduction in the density, diameter, and rate of growth of facial hair in patients with idiopathic hirsutism or hirsutism secondary to androgen excess. The effect can usually be seen in 2 months and becomes maximal in about 6 months.

**Spironolactone** as a diuretic is discussed in [Chapter 15](#). The drug has benefits in heart failure greater than those predicted from its diuretic effects alone (see [Chapter 13](#)). Adverse effects reported for **spironolactone** include hyperkalemia, cardiac arrhythmia, menstrual abnormalities, gynecomastia, sedation, headache, gastrointestinal disturbances, and skin rashes.

**Eplerenone**, another aldosterone antagonist, is approved for the treatment of hypertension and heart failure (see [Chapters 11, 13, and 15](#)). Like **spironolactone**, **eplerenone** has also been found to reduce mortality in heart failure. This aldosterone receptor antagonist is somewhat more selective than **spironolactone** and has no reported effects on androgen receptors. The standard dosage in hypertension is 50–100 mg/d. The most common toxicity is hyperkalemia, but this is usually mild.

**Drospirenone**, a progestin, is an oral contraceptive (see [Chapter 40](#)) and also antagonizes the effects of aldosterone.

**Finerenone**, a novel nonsteroidal aldosterone antagonist, is approved for the treatment of hypertension and heart failure. It differs from both steroidal agents with respect to physicochemical, pharmacodynamic, and pharmacokinetic properties. It has beneficial anti-inflammatory, anti-remodeling, and antifibrotic properties in the kidneys, heart, and vasculature. At this time, there are several nonsteroidal MRAs under development and clinical assessment; of these, only esaxerenone and finerenone are approved for treatment globally. Compared with steroidal compounds, finerenone more potently inhibits MR co-regulator recruitment and fibrosis and distributes more evenly between the heart and kidneys.

#### PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
<b>GLUCOCORTICOIDS FOR ORAL &amp; PARENTERAL USE*</b>	
Betamethasone	Celestone
Betamethasone sodium phosphate	Generic, Celestone Phosphate
Budesonide	Generic, Entocort EC
Cortisone	Generic
Dexamethasone	Generic, Decadron
Dexamethasone sodium phosphate	Generic
Hydrocortisone (cortisol)	Generic, Cortef
Hydrocortisone acetate	Generic
Hydrocortisone sodium phosphate	Hydrocortone
Hydrocortisone sodium succinate	Generic, Solu-Cortef, others

Methylprednisolone	Generic, Medrol
Methylprednisolone acetate	Generic, Depo-Medrol
Methylprednisolone sodium succinate	Generic, Solu-Medrol, others
Prednisolone	Generic, Prelone, others
Prednisolone acetate	Generic, Flo-Pred
Prednisolone sodium phosphate	Generic, Hydeltrasol
Prednisone	Generic, Deltasone, Prednicot
Triamcinolone acetonide	Generic, Kenalog, Azmacort
Triamcinolone hexacetonide	Aristospan
<b>MINERALOCORTICIDS</b>	
Fludrocortisone acetate	Generic, Florinef Acetate, Cortineff Acetate
<b>ADRENAL STEROID INHIBITORS</b>	
Abiraterone	Zytiga
Ketoconazole	Generic, Nizoral
Etomidate	Amidate
Mifepristone	Mifeprex, Korlym
Mitotane	Lysodren

\*Glucocorticoids for respiratory use: See [Chapter 20](#). Glucocorticoids for dermatologic use: See [Chapter 61](#). Glucocorticoids for gastrointestinal use: See [Chapter 62](#).

### CASE STUDY ANSWER

The patient should be placed on replacement oral [hydrocortisone](#) at 10 mg/m<sup>2</sup> per day and [fludrocortisone](#) at 75 mcg/d. He should be given a MedicAlert bracelet and instructions for increased treatment at two times standard glucocorticoid dosage for 24 hours for minor stress and 10 times replacement of [hydrocortisone](#) for major stress over 48 hours.

## Chapter 40: The Gonadal Hormones & Inhibitors

George P. Chrousos

### CASE STUDY

#### CASE STUDY

A 25-year-old woman with menarche at 13 years and menstrual periods until about 1 year ago complains of hot flushes, skin and vaginal dryness, weakness, poor sleep, and scanty and infrequent menstrual periods of a year's duration. She visits her gynecologist, who obtains plasma levels of follicle-stimulating hormone and luteinizing hormone, both of which are moderately elevated. She is diagnosed with premature ovarian failure, and estrogen and **progesterone** replacement therapy is recommended. A dual-energy absorptiometry scan (DEXA) reveals a bone density t-score of <2.5 SD, ie, frank osteoporosis. How should the ovarian hormones she lacks be replaced? What extra measures should she take for her osteoporosis while receiving treatment?

## THE OVARY (ESTROGENS, PROGESTINS, OTHER OVARIAN HORMONES, ORAL CONTRACEPTIVES, INHIBITORS & ANTAGONISTS, & OVULATION-INDUCING AGENTS)

The ovary has important gametogenic functions that are integrated with its hormonal activity. In the human female, the gonad is relatively quiescent during childhood, the period of rapid growth and maturation. At puberty, the ovary begins a 30- to 40-year period of cyclic function called the **menstrual cycle** because of the regular episodes of bleeding that are its most obvious manifestation. It then fails to respond to gonadotropins secreted by the anterior pituitary gland, and the cessation of cyclic bleeding that occurs is called **menopause**.

The mechanism responsible for the onset of ovarian function at the time of puberty is thought to be neural in origin, because the immature gonad can be stimulated by gonadotropins already present in the pituitary and because the pituitary is responsive to exogenous **hypothalamic gonadotropin-releasing hormone (GnRH)**. Despite extensive research in the field, the mechanism of puberty initiation still remains an enigma. Pulsatile pituitary gonadotropin secretion under the guidance of GnRH definitely constitutes a *sine qua non* for pubertal onset. However, the secretion of GnRH in the human hypothalamus is regulated by kisspeptin and its receptor, as well as by permissive or opposing signals mediated by neurokinin B and dynorphin acting on their respective receptors. These three supra-GnRH regulators compose the **Kisspeptin, Neurokinin B, and Dynorphin neuron (KNDy) system**, a key player in pubertal onset and progression. Recently, makorin ring finger protein 3 (MKRN3) was also implicated in pubertal onset by contributing to the regulation of the KNDy system. However, the inhibitory (gamma-amino butyric acid, neuropeptide Y, and RFamide-related peptide-3) and stimulatory (glutamate) signals acting upstream of KNDy call into question the primary role of MKRN3 as the gatekeeper of puberty. Recently, epigenetic mechanisms involving derepression of genes, such as that of kisspeptin, have been implicated in pubertal onset. Ultimately, withdrawal of a childhood-related inhibitory effect upon hypothalamic arcuate nucleus neurons allows these neurons to produce GnRH in pulses with the appropriate amplitude, which stimulate the release of **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)** (see [Chapter 37](#)). At first, small amounts of the latter two hormones are released during the night, and the limited quantities of ovarian estrogen secreted in response start to cause breast development. Subsequently, FSH and LH are secreted throughout the day and night, causing secretion of higher amounts of estrogen and leading to further breast enlargement, alterations in fat distribution, and a growth spurt that culminates in epiphyseal closure in the long bones. The change of ovarian function at puberty is called **gonadarche**.

#### ACRONYMS

<b>CBG</b>	Corticosteroid-binding globulin (transcortin)
<b>DHEA</b>	Dehydroepiandrosterone
<b>DHEAS</b>	Dehydroepiandrosterone sulfate
<b>ERE</b>	Estrogen response element
<b>FSH</b>	Follicle-stimulating hormone
<b>GnRH</b>	Gonadotropin-releasing hormone
<b>HDL</b>	High-density lipoprotein
<b>HRT</b>	Hormone replacement therapy (also called HT)
<b>LDL</b>	Low-density lipoprotein
<b>LH</b>	Luteinizing hormone
<b>PRE</b>	Progesterone response element
<b>SERM</b>	Selective estrogen receptor modulator
<b>SHBG</b>	Sex hormone-binding globulin
<b>TBG</b>	Thyroxine-binding globulin

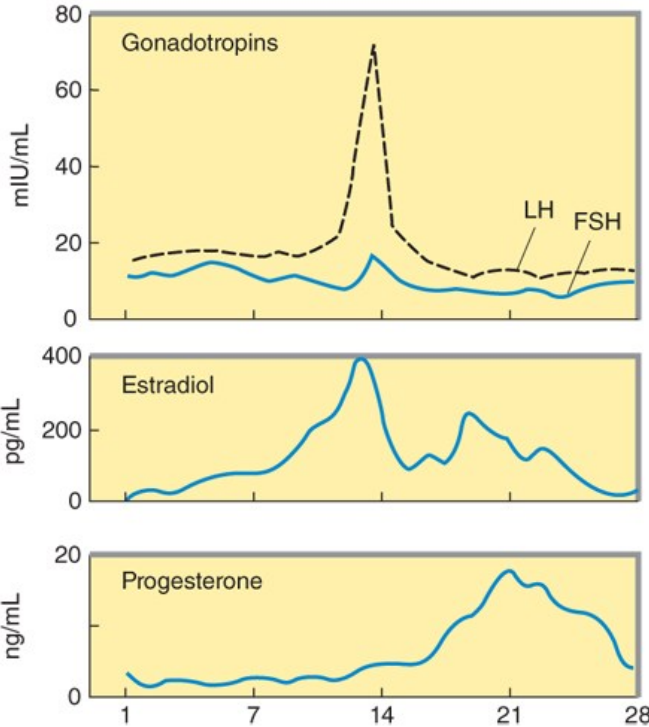

A year or so after gonadarche, sufficient estrogen is produced to induce endometrial changes and periodic bleeding (**menarche**). After the first few irregular cycles, which may be anovulatory, normal cyclic function is established.

At the beginning of each cycle, a variable number of follicles (vesicular follicles), each containing an ovum, begin to enlarge in response to FSH. After 5 or 6 days, one follicle, called the dominant follicle, begins to develop more rapidly. The outer theca and inner granulosa cells of this follicle multiply and, under the influence of LH, synthesize and release **estrogens** at an increasing rate. The **estrogens** appear to inhibit FSH release and may lead to regression of the smaller, less mature follicles. The mature dominant ovarian follicle consists of an ovum surrounded by a fluid-filled antrum lined by granulosa and theca cells. The estrogen secretion reaches a peak just before midcycle, and the granulosa cells begin to secrete **progesterone**. These changes stimulate the brief surge in LH and FSH release that precedes and causes ovulation. When the follicle ruptures, the ovum is released into the abdominal cavity near the opening of the uterine tube.

Following the above events, the cavity of the ruptured follicle fills with blood (corpus hemorrhagicum), and the luteinized theca and granulosa cells proliferate and replace the blood to form the corpus luteum. The cells of this structure produce **estrogens** and **progesterone** for the remainder of the cycle, or longer if pregnancy occurs.

If pregnancy does not occur, the corpus luteum begins to degenerate and ceases hormone production, eventually becoming a corpus albicans. The endometrium, which proliferated during the follicular phase and developed its glandular function during the luteal phase, is shed in the process of menstruation. These events are summarized in [Figure 40-1](#).

**FIGURE 40-1**

The ovary normally ceases its gametogenic and endocrine function with time. This change is accompanied by a cessation in uterine bleeding (menopause) and occurs at a mean age of 52 years in the United States. Although the ovary ceases to secrete estrogen, significant levels of estrogen persist in many women as a result of conversion of adrenal and ovarian steroids such as androstenedione to **estrone** and **estradiol** in adipose and possibly other nonendocrine tissues.

### Disturbances in Ovarian Function

Disturbances of cyclic function are common even during the peak years of reproduction. A minority of these result from inflammatory or neoplastic processes that influence the functions of the uterus, ovaries, or pituitary. Many of the minor disturbances leading to periods of amenorrhea or anovulatory cycles are self-limited. They are often associated with emotional or physical stress and reflect temporary alterations in the stress centers in the brain that control the secretion of GnRH. Anovulatory cycles are also associated with eating disorders (bulimia, anorexia nervosa) and with severe exercise such as distance running and swimming. Among the more common organic causes of persistent ovulatory disturbances are pituitary prolactinomas and syndromes and tumors characterized by excessive ovarian or adrenal androgen production. Normal ovarian function can be modified by androgens produced by the adrenal cortex or tumors arising from it. The ovary also gives rise to androgen-producing neoplasms such as andrenoblastomas, as well as to estrogen-producing granulosa cell tumors.

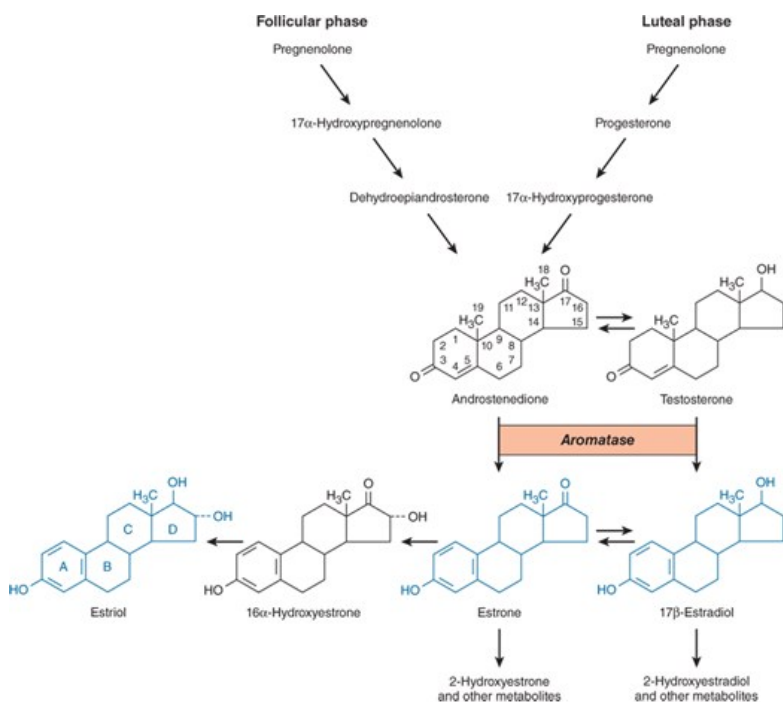

Estrogenic activity is shared by a large number of chemical substances. In addition to the variety of steroidal **estrogens** derived from animal sources, numerous nonsteroidal **estrogens** have been synthesized. Many phenols are estrogenic, and estrogenic activity has been identified in diverse forms of life including those found in ocean sediments. Estrogen-mimetic compounds (flavonoids) are found in many plants, including saw palmetto, and soybeans and other foods. A diet rich in these plant products may cause slight estrogenic effects. Additionally, some compounds used in the manufacture of plastics (bisphenols, alkylphenols, phthalate phenols) have been found to be estrogenic. It has been proposed that these agents are associated with an increased breast cancer incidence in both women and men in the industrialized world.

### Natural Estrogens

The major **estrogens** produced by women are **estradiol** (17 $\beta$ -estradiol, E<sub>2</sub>), **estrone** (E<sub>1</sub>), and **estriol** (E<sub>3</sub>) (Figure 40-2). **Estradiol** is the major secretory product of the ovary. Although some **estrone** is produced in the ovary, most **estrone** and **estriol** are formed in the liver from **estradiol** or in peripheral tissues from androstenedione and other androgens (see Figure 39-1). As noted above, during the first part of the menstrual cycle **estrogens** are produced in the ovarian follicle by the theca and granulosa cells. After ovulation, the **estrogens** as well as **progesterone** are synthesized by the luteinized granulosa and theca cells of the corpus luteum, and the pathways of biosynthesis are slightly different.

FIGURE 40-2

Biosynthesis and metabolism of **estrogens** and **testosterone**.

During pregnancy, a large amount of estrogen is synthesized by the fetoplacental unit—consisting of the fetal adrenal zone, secreting androgen precursor, and the placenta, which aromatizes it into estrogen. The estriol synthesized by the fetoplacental unit is released into the maternal circulation and excreted into the urine. Repeated assay of maternal urinary estriol excretion has been used in the assessment of fetal well-being.

One of the most prolific natural sources of estrogenic substances is the stallion, which liberates more of these hormones than the pregnant mare or pregnant woman. The equine estrogens—equilenin and equilin—and their congeners are unsaturated in the B as well as the A ring and are excreted in large quantities in urine, from which they can be recovered and used for medicinal purposes.

## Synthetic Estrogens

A variety of chemical alterations have been applied to the natural estrogens. The most important effect of these alterations has been to increase their oral effectiveness. Some structures are shown in Figure 40–3. Those with therapeutic use are listed in Table 40–1.

FIGURE 40–3

Compounds with estrogenic activity.

## Commonly used estrogens.

Preparation	Average Replacement Dosage
Ethinyl estradiol	0.005–0.02 mg/d
Micronized estradiol	1–2 mg/d
Estradiol cypionate	2–5 mg every 3–4 weeks
Estradiol valerate	2–20 mg every other week
Estropipate	1.25–2.5 mg/d
Conjugated, esterified, or mixed estrogenic substances:	
Oral	0.3–1.25 mg/d
Injectable	0.2–2 mg/d
Transdermal	Patch
Quinestrol	0.1–0.2 mg/week
Chlorotrianisene	12–25 mg/d
Methallenestril	3–9 mg/d

In addition to the steroidal estrogens, a variety of nonsteroidal compounds with estrogenic activity have been synthesized and used clinically. These include dienestrol, diethylstilbestrol, benzestrol, hexestrol, methestrol, methallenestril, and chlorotrianisene.

### Pharmacokinetics

When released into the circulation, estradiol binds strongly to an  $\alpha_2$  globulin (sex hormone-binding globulin [SHBG]) and with lower affinity to albumin. Bound estrogen is relatively unavailable for diffusion into cells, and it is the free fraction that is physiologically active. Estradiol is converted by the liver and other tissues to estrone and estriol (see Figure 40-2) and their 2-hydroxylated derivatives and conjugated metabolites (which are too insoluble in lipid to cross the cell membrane readily) and excreted in the bile. Estrone and estriol have low affinity for the estrogen receptor. However, the conjugates may be hydrolyzed in the intestine to active, reabsorbable compounds. Estrogens are also excreted in small amounts in the breast milk of nursing mothers.

Because significant amounts of estrogens and their active metabolites are excreted in the bile and reabsorbed from the intestine, the resulting enterohepatic circulation ensures that orally administered estrogens will have a high ratio of hepatic to peripheral effects. As noted below, the hepatic effects are thought to be responsible for some undesirable actions such as increased synthesis of clotting factors and plasma renin substrate. The hepatic effects of estrogen can be minimized by routes that avoid first-pass liver exposure, ie, vaginal, transdermal, or by injection.

### Physiologic Effects

#### A. Mechanism

**Estrogens** in the blood and interstitial fluid are bound to SHBG, from which they dissociate to cross the cell membrane, enter the nucleus, and bind to their receptor. Two genes code for two estrogen receptor isoforms,  $\alpha$  and  $\beta$ , which are members of the superfamily of steroid, steroid, retinoic acid, and thyroid receptors. Unlike glucocorticoid receptors, estrogen receptors are found predominantly in the nucleus, where they are bound to heat shock proteins that stabilize them (see [Figure 39-4](#)).

Binding of the hormone to its receptor alters the receptor's conformation and releases it from the stabilizing proteins (predominantly Hsp90). The receptor-hormone complex forms dimers (usually ER $\alpha$ -ER $\alpha$ , ER $\beta$ -ER $\beta$ , or ER $\alpha$ -ER $\beta$ ) that bind to a specific sequence of nucleotides, called **estrogen response elements (EREs)**, in the regulatory regions of various genes and regulate their transcription. The ERE is composed of two half-sites arranged as a palindrome separated by a small group of nucleotides called the spacer. The interaction of a receptor dimer with the ERE also involves a number of nuclear proteins, the coregulators, as well as components of the transcription machinery. Complex interactions with various coregulators appear to be responsible for some of the tissue-specific effects that govern the actions of **selective estrogen receptor modulators (SERMs)**, see below). The receptor may also bind to other transcription factors to influence the effects of these factors on their responsive genes. Interestingly, although ER $\beta$  has its own separate actions from ER $\alpha$ , it also acts as a dominant negative inhibitor of ER $\alpha$ . Thus, while ER $\alpha$  has many growth-promoting properties, ER $\beta$  has antigrowth effects. Many phytoestrogens act via the ER $\beta$  protecting cells from the pro-growth effects of ER $\alpha$ .

The relative concentrations and types of receptors, receptor coregulators, and transcription factors confer the cell specificity of the hormone's actions. The genomic effects of **estrogens** are mainly due to proteins synthesized by translation of RNA transcribed from a responsive gene. Some of the effects of **estrogens** are indirect, mediated by the autocrine and paracrine actions of autacoids such as growth factors, lipids, glycolipids, and cytokines produced by the target cells in response to estrogen.

Rapid estrogen-induced effects such as granulosa cell Ca<sup>2+</sup> uptake and increased uterine blood flow do not require gene activation. These appear to be mediated by nongenomic effects of the classic estrogen receptor-estrogen complex, influencing several intracellular signaling pathways.

Recently, all steroid receptors except the mineralocorticoid receptors were shown to have palmitoylation motifs that allow enzymatic addition of palmitate and increased localization of the receptors in the vicinity of plasma membranes. Such receptors are available for direct interactions with, and effects on, various membrane-associated or cytoplasmic proteins without the need for entry into the nucleus and induction of transcriptional actions.

#### B. Female Maturation

**Estrogens** are required for the normal sexual maturation and growth of the female. They stimulate the development of the vagina, uterus, and uterine tubes as well as the secondary sex characteristics. They stimulate stromal development and ductal growth in the breast and are responsible for the accelerated growth phase and the closing of the epiphyses of the long bones that occur at puberty. They contribute to the growth of axillary and pubic hair and alter the distribution of body fat to produce typical female body contours. Larger quantities also stimulate development of pigmentation in the skin, most prominent in the region of the nipples and areolae and in the genital region.

#### C. Endometrial Effects

In addition to its growth effects on uterine muscle, estrogen plays an important role in the development of the endometrial lining. When estrogen production is properly coordinated with the production of **progesterone** during the normal human menstrual cycle, regular periodic bleeding and shedding of the endometrial lining occur. Continuous exposure to **estrogens** for prolonged periods leads to hyperplasia of the endometrium that is usually associated with abnormal bleeding patterns.

#### D. Metabolic and Cardiovascular Effects

**Estrogens** have a number of important metabolic and cardiovascular effects. They seem to be partially responsible for maintenance of the normal structure and function of the skin and blood vessels in women. **Estrogens** also decrease the rate of resorption of bone by promoting the apoptosis of osteoclasts and by antagonizing the osteoclastogenic and pro-osteoclastic effects of parathyroid hormone and interleukin 6. **Estrogens** also stimulate adipose tissue production of leptin and are in part responsible for the higher levels of this hormone in women than in men.

In addition to stimulating the synthesis of enzymes and growth factors leading to uterine and breast growth and differentiation, **estrogens** alter the production and activity of many other proteins in the body. Metabolic alterations in the liver are especially important, so that there is a higher circulating level of proteins such as transcortin (corticosteroid-binding globulin [CBG]), thyroxine-binding globulin (TBG), SHBG, transferrin, renin

substrate, and fibrinogen. This leads to increased circulating levels of thyroxine, estrogen, [testosterone](#), iron, [copper](#), and other substances.

Alterations in the composition of the plasma lipids caused by [estrogens](#) are characterized by an increase in the high-density lipoproteins (HDL), a slight reduction in the low-density lipoproteins (LDL), and a reduction in total plasma cholesterol levels. Plasma triglyceride levels are increased. [Estrogens](#) decrease hepatic oxidation of adipose tissue lipid to ketones and increase synthesis of triglycerides.

#### E. Effects on Blood Coagulation

[Estrogens](#) enhance the coagulability of blood. Many changes in factors influencing coagulation have been reported, including increased circulating levels of factors II, VII, IX, and X and decreased [antithrombin III](#), partially as a result of the hepatic effects mentioned above. Increased plasminogen levels and decreased platelet adhesiveness have also been found (see [Hormonal Contraception](#), below).

#### F. Other Effects

[Estrogens](#) induce the synthesis of [progesterone](#) receptors. They are responsible for estrous behavior in animals and may influence behavior and libido in humans. Administration of [estrogens](#) stimulates central components of the stress system, including the production of corticotropin-releasing hormone and the activity of the sympathetic system, and promotes a sense of well-being when given to women who are estrogen-deficient. They also facilitate the loss of intravascular fluid into the extracellular space, producing edema. The resulting decrease in plasma volume causes a compensatory retention of sodium and water by the kidney. [Estrogens](#) also modulate sympathetic nervous system control of smooth muscle function.

### Clinical Uses

#### A. Primary Hypogonadism

[Estrogens](#) have been used extensively for replacement therapy in estrogen-deficient patients.\* The estrogen deficiency may be due to primary failure of development of the ovaries, premature menopause, castration, or menopause.

Treatment of primary hypogonadism is usually begun at 11–13 years of age in order to stimulate the development of secondary sex characteristics and menses, to stimulate optimal growth, to prevent osteoporosis, and to avoid the psychological consequences of delayed puberty and estrogen deficiency. Treatment attempts to mimic the physiology of puberty. It is initiated with small doses of estrogen (0.3 mg conjugated [estrogens](#) or 5–10 mcg ethinyl [estradiol](#)) on days 1–21 each month and is slowly increased to adult doses and then maintained until the age of menopause (approximately 51 years of age). A progestin is added after the first uterine bleeding. When growth is completed, chronic therapy consists mainly of the administration of adult doses of both [estrogens](#) and progestins, as described below.

#### B. Postmenopausal Hormonal Therapy

In addition to the signs and symptoms that follow closely upon the cessation of normal ovarian function—such as loss of menstrual periods, vasomotor symptoms, sleep disturbances, and genital atrophy—there are longer-lasting changes that influence the health and well-being of postmenopausal women. These include an acceleration of bone loss, which in susceptible women may lead to vertebral, hip, and wrist fractures; and lipid changes, which may contribute to the acceleration of atherosclerotic cardiovascular disease noted in postmenopausal women. The effects of [estrogens](#) on bone have been extensively studied, and the effects of hormone withdrawal have been well characterized. However, the role of [estrogens](#) and progestins in the cause and prevention of cardiovascular disease, which is responsible for 350,000 deaths per year, and breast cancer, which causes 35,000 deaths per year, is less well understood.

When normal ovulatory function ceases and the estrogen levels fall after menopause, oophorectomy, or premature ovarian failure, there is an accelerated rise in plasma cholesterol and LDL concentrations, while LDL receptors decline. HDL is not much affected, and levels remain higher than in men. Very-low-density lipoprotein and triglyceride levels are also relatively unaffected. Since cardiovascular disorders account for most deaths in this age group, the risk for these disorders constitutes a major consideration in deciding whether hormonal “replacement” therapy (HRT, also correctly called HT) is indicated and influences the selection of hormones to be administered. Estrogen replacement therapy has a beneficial effect on circulating lipids and lipoproteins, and this was earlier thought to be accompanied by a reduction in myocardial infarction by about 50% and of fatal strokes by as much as 40%. These findings, however, have been disputed by the results of a large study from the Women’s Health Initiative (WHI)

project showing no cardiovascular benefit from estrogen plus progestin replacement therapy in perimenopausal or older postmenopausal patients. In

www.konkur.in may be a small increase in cardiovascular problems as well as breast cancer in women who received the replacement therapy. Interestingly, a small protective effect against colon cancer was observed. Although current clinical guidelines do not recommend routine hormone therapy in postmenopausal women, the validity of the WHI report has been questioned. In any case, there is no increased risk for breast cancer if therapy is given immediately after menopause and for the first 7 years, while the cardiovascular risk depends on the degree of atherosclerosis at the onset of therapy. Transdermal or vaginal administration of estrogen may be associated with decreased cardiovascular risk because it bypasses the liver circulation. Women with premature menopause should definitely receive hormone replacement therapy.

In some studies, a protective effect of estrogen replacement therapy against Alzheimer disease was observed. However, several other studies have not supported these results.

Progestins antagonize estrogen's effects on LDL and HDL to a variable extent. However, one large study has shown that the addition of a progestin to estrogen replacement therapy does not influence the cardiovascular risk.

Optimal management of the postmenopausal patient requires careful assessment of her symptoms as well as consideration of her age and the presence of (or risks for) cardiovascular disease, osteoporosis, breast cancer, and endometrial cancer. Bearing in mind the effects of the gonadal hormones on each of these disorders, the goals of therapy can then be defined and the risks of therapy assessed and discussed with the patient.

If the main indication for therapy is hot flushes and sleep disturbances, therapy with the lowest dose of estrogen required for symptomatic relief is recommended. Treatment may be required for only a limited period of time and the possible increased risk for breast cancer is avoided. In women who have undergone hysterectomy, **estrogens** alone can be given 5 days per week or continuously, since progestins are not required to reduce the risk for endometrial hyperplasia and cancer. Hot flushes, sweating, insomnia, and atrophic vaginitis are generally relieved by **estrogens**; many patients experience some increased sense of well-being; and climacteric depression and other psychopathologic states are improved. Recently, neurokinin 3 receptor antagonists have completed phase 3 studies for prevention of menopausal or estrogen deficiency-related hot flushes.

The role of **estrogens** in the prevention and treatment of osteoporosis has been carefully studied (see [Chapter 42](#)). The amount of bone present in the body is maximal in the young active adult in the third decade of life and begins to decline more rapidly in middle age in both men and women. The development of osteoporosis also depends on the amount of bone present at the start of this process, on vitamin D and calcium intake, and on the degree of physical activity. The risk of osteoporosis is highest in smokers who are thin, Caucasian, and inactive and have a low calcium intake and a strong family history of osteoporosis. Depression also is a major risk factor for development of osteoporosis in women.

**Estrogens** should be used in the smallest dosage consistent with relief of symptoms. In women who have not undergone hysterectomy, it is most convenient to prescribe estrogen on the first 21–25 days of each month. The recommended dosages of estrogen are 0.3–1.25 mg/d of conjugated estrogen or 0.01–0.02 mg/d of ethinyl **estradiol**. Dosages in the middle of these ranges have been shown to be maximally effective in preventing the decrease in bone density occurring at menopause. From this point of view, it is important to begin therapy as soon as possible after the menopause for maximum effect. In these patients and others not taking estrogen, calcium supplements that bring the total daily calcium intake up to 1500 mg are useful.

Patients at low risk of developing osteoporosis who manifest only mild atrophic vaginitis can be treated with topical preparations. The vaginal route of application is also useful in the treatment of urinary tract symptoms in these patients. It is important to realize, however, that although locally administered **estrogens** escape the first-pass effect (so that some undesirable hepatic effects are reduced), they are almost completely absorbed into the circulation, and these preparations should be given cyclically.

As noted below, the administration of estrogen is associated with an increased risk of endometrial carcinoma. The administration of a progestational agent with the estrogen prevents endometrial hyperplasia and markedly reduces the risk of this cancer. When estrogen is given for the first 25 days of the month and the progestin **medroxyprogesterone** (10 mg/d) is added during the last 10–14 days, the risk is only half of that in women not receiving hormone replacement therapy. On this regimen, some women will experience a return of symptoms during the period off estrogen administration. In these patients, the estrogen can be given continuously. If the progestin produces sedation or other undesirable effects, its dose can be reduced to 2.5–5 mg/d for the last 10 days of the cycle with a slight increase in the risk for endometrial hyperplasia. These regimens are usually accompanied by bleeding at the end of each cycle. Some women experience migraine headaches during the last few days of the cycle. The use of a continuous estrogen regimen will often prevent their occurrence. Women who object to the cyclic bleeding associated with sequential therapy can also consider continuous therapy. Daily therapy with 0.625 mg of conjugated equine **estrogens** and 2.5–5 mg of **medroxyprogesterone** will eliminate cyclic bleeding, control vasomotor symptoms, prevent genital atrophy, maintain bone density, and show a favorable lipid profile with a small decrease in LDL and an increase

It is not known whether other **estrogens** have a similar effect or whether the observed phenomena are peculiar to diethylstilbestrol. This agent should be used only in the treatment of cancer (eg, of the prostate) or as a “morning after” contraceptive (see page 761).

### C. Other Effects

Nausea and breast tenderness are common and can be minimized by using the smallest effective dose of estrogen. Hyperpigmentation also occurs. Estrogen therapy is associated with an increase in frequency of migraine headaches as well as cholestasis, gallbladder disease, and hypertension.

### Contraindications

**Estrogens** should not be used in patients with estrogen-dependent neoplasms such as carcinoma of the endometrium or in those with—or at high risk for—carcinoma of the breast. They should be avoided in patients with undiagnosed genital bleeding, liver disease, or a history of thromboembolic disorder. In addition, the use of **estrogens** should be avoided by heavy smokers.

### Preparations & Dosages

The dosages of commonly used natural and synthetic preparations are listed in [Table 40–1](#). Although all of the **estrogens** produce almost the same hormonal effects, their potencies vary both between agents and depending on the route of administration. As noted above, **estradiol** is the most active endogenous estrogen, and it has the highest affinity for the estrogen receptor. However, its metabolites **estrone** and **estriol** have weak uterine effects.

For a given level of gonadotropin suppression, oral estrogen preparations have more effect on the circulating levels of CBG, SHBG, and a host of other liver proteins, including angiotensinogen, than do transdermal preparations. The oral route of administration allows greater concentrations of hormone to reach the liver, thus increasing the synthesis of these proteins. Transdermal preparations were developed to avoid this effect. When administered transdermally, 50–100 mcg of **estradiol** has effects similar to those of 0.625–1.25 mg of conjugated oral **estrogens** on gonadotropin concentrations, endometrium, and vaginal epithelium. Furthermore, the transdermal estrogen preparations do not significantly increase the concentrations of renin substrate, CBG, and TBG and do not produce the characteristic changes in serum lipids. Combined oral preparations containing 0.625 mg of conjugated **estrogens** and 2.5 mg of **medroxyprogesterone** acetate are available for menopausal replacement therapy. Tablets containing 0.625 mg of conjugated **estrogens** and 5 mg of **medroxyprogesterone** acetate are available to be used in conjunction with conjugated **estrogens** in a sequential fashion. **Estrogens** alone are taken on days 1–14 and the combination on days 15–28.

\*The use of **estrogens** in contraception is discussed later in this chapter.

## THE PROGESTINS

### Natural Progestins: Progesterone

**Progesterone** is the most important progestin in humans. In addition to having important hormonal effects, it serves as a precursor to the **estrogens**, androgens, and adrenocortical steroids. It is synthesized in the ovary, testis, and adrenal cortex from circulating cholesterol. Large amounts are also synthesized and released by the placenta during pregnancy.

In the ovary, **progesterone** is produced primarily by the corpus luteum. Normal males appear to secrete 1–5 mg of **progesterone** daily, resulting in plasma levels of about 0.03 mcg/dL. The level is only slightly higher in the female during the follicular phase of the cycle, when only a few milligrams per day of **progesterone** are secreted. During the luteal phase, plasma levels range from 0.5 mcg/dL to more than 2 mcg/dL (see [Figure 40–1](#)). Plasma levels of **progesterone** are further elevated and reach their peak levels in the third trimester of pregnancy.

### Synthetic Progestins

A variety of progestational compounds have been synthesized. Some are active when given by mouth. They are not a uniform group of compounds, and all of them differ from **progesterone** in one or more respects. [Table 40–2](#) lists some of these compounds and their effects. In general, the 21-carbon compounds (hydroxyprogesterone, **medroxyprogesterone**, **megestrol**, and dimethisterone) are the most closely related, pharmacologically as well as chemically, to **progesterone**. A new group of third-generation synthetic progestins has been introduced, principally as components of oral contraceptives. These “19-nor, 13-ethyl” steroid compounds include desogestrel (see [Figure 40–4](#)), gestodene, and norgestimate. They are claimed to

TABLE 40-2

**Properties of some progestational agents.**

	Route	Duration of Action	Activities <sup>1</sup>				
			Estrogenic	Androgenic	Antiestrogenic	Antiandrogenic	Anabolic
<b>Progesterone and derivatives</b>

## Pharmacokinetics

**Progesterone** is rapidly absorbed following administration by any route. Its half-life in the plasma is approximately 5 minutes, and small amounts are stored temporarily in body fat. It is almost completely metabolized in one passage through the liver, and for that reason it is quite ineffective when the usual formulation is administered orally. However, high-dose oral micronized **progesterone** preparations have been developed that provide adequate progestational effect.

In the liver, **progesterone** is metabolized to pregnanediol and conjugated with glucuronic acid. It is excreted into the urine as pregnanediol glucuronide. The amount of pregnanediol in the urine has been used as an index of **progesterone** secretion. This measure has been very useful despite the fact that the proportion of secreted **progesterone** converted to this compound varies from day to day and from individual to individual. In addition to **progesterone**, 20 $\alpha$ - and 20 $\beta$ -hydroxyprogesterone (20 $\alpha$ - and 20 $\beta$ -hydroxy-4-pregnene-3-one) also are found. These compounds have about one fifth the progestational activity of **progesterone** in humans and other species. Little is known of their physiologic role, but 20 $\alpha$ -hydroxyprogesterone is produced in large amounts in some species and may be of some importance biologically.

The usual routes of administration and durations of action of the synthetic progestins are listed in [Table 40–2](#). Most of these agents are extensively metabolized to inactive products that are excreted mainly in the urine.

## Physiologic Effects

### A. Mechanism

The mechanism of action of progesterone—described in more detail above—is similar to that of other steroid hormones. Progestins enter the cell and bind to **progesterone** receptors that are distributed in the nucleus and the cytoplasm. The ligand-receptor complex binds to a **progesterone** response element (PRE) to activate gene transcription. The response element for **progesterone** appears to be similar to the corticosteroid response element, and the specificity of the response depends upon which receptor is present in the cell as well as upon other cell-specific receptor coregulators and interacting transcription factors. The progesterone-receptor complex forms a dimer before binding to DNA. Like the estrogen receptor, it can form heterodimers as well as homodimers between two isoforms, A and B. These isoforms are produced by alternative splicing of the same gene.

### B. Effects of **Progesterone**

**Progesterone** has little effect on protein metabolism. It stimulates lipoprotein lipase activity and seems to favor fat deposition. The effects on carbohydrate metabolism are more marked. **Progesterone** increases basal **insulin** levels and the **insulin** response to glucose. There is usually no manifest change in carbohydrate tolerance. In the liver, **progesterone** promotes glycogen storage, possibly by facilitating the effect of **insulin**. **Progesterone** also promotes ketogenesis.

**Progesterone** can compete with aldosterone for the mineralocorticoid receptor of the renal tubule, causing a decrease in Na<sup>+</sup> reabsorption. This leads to an increased secretion of aldosterone by the adrenal cortex (eg, in pregnancy). **Progesterone** increases body temperature in humans. The

mechanism of this effect is not known, but an alteration of the temperature-regulating centers in the hypothalamus has been suggested. Progesterone also alters the function of the respiratory centers. The ventilatory response to CO<sub>2</sub> is increased by progesterone but synthetic progestins with an ethinyl group do not have respiratory effects. This leads to a measurable reduction in arterial and alveolar Pco<sub>2</sub> during pregnancy and in the luteal phase of the menstrual cycle. Progesterone and related steroids also have depressant and hypnotic effects on the brain.

Progesterone is responsible for the alveolobular development of the secretory apparatus in the breast. It also participates in the preovulatory LH surge and causes the maturation and secretory changes in the endometrium that are seen following ovulation (see Figure 40-1).

Progesterone decreases the plasma levels of many amino acids and leads to increased urinary nitrogen excretion. It induces changes in the structure and function of smooth endoplasmic reticulum in experimental animals.

Other effects of progesterone and its analogs are noted below in the section, Hormonal Contraception.

### C. Synthetic Progestins

The 21-carbon progesterone analogs antagonize aldosterone-induced sodium retention (see above). The remaining compounds (“19-nortestosterone” third-generation agents) produce a decidual change in the endometrial stroma, do not support pregnancy in test animals, are more effective gonadotropin inhibitors, and may have minimal estrogenic and androgenic or anabolic activity (Table 40-2; see Figure 40-4). They are sometimes referred to as “impeded androgens.” Progestins without androgenic activity include desogestrel, norgestimate, and gestodene. The first two of these compounds are dispensed in combination with ethinyl estradiol for oral contraception (Table 40-3) in the United States. Oral contraceptives containing the progestin cyproterone acetate (also an antiandrogen) in combination with ethinyl estradiol are investigational in the United States.

## Clinical Uses

### A. Therapeutic Applications

The major uses of progestational hormones are for hormone replacement therapy (see above) and hormonal contraception (see below). In addition, they are useful in producing long-term ovarian suppression for other purposes. When used alone in large doses parenterally (eg, medroxyprogesterone acetate, 150 mg intramuscularly every 90 days), prolonged anovulation and amenorrhea result. This therapy has been employed in the treatment of dysmenorrhea, endometriosis, and bleeding disorders when estrogens are contraindicated, and for contraception. The major problem with this regimen is the prolonged time required in some patients for ovulatory function to return after cessation of therapy. It should not be used for patients planning a pregnancy in the near future. Similar regimens will relieve hot flashes in some menopausal women and can be used if estrogen therapy is contraindicated.

Medroxyprogesterone acetate, 10–20 mg orally twice weekly—or intramuscularly in doses of 100 mg/m<sup>2</sup> every 1–2 weeks—will prevent menstruation, but it will not arrest accelerated bone maturation in children with precocious puberty.

Progestins do not appear to have any place in the therapy of threatened or habitual abortion. Early reports of the usefulness of these agents resulted from the unwarranted assumption that after several abortions the likelihood of repeated abortions was over 90%. When progestational agents were administered to patients with previous abortions, a salvage rate of 80% was achieved. It is now recognized that similar patients abort only 20% of the time even when untreated. On the other hand, progesterone was given experimentally to delay premature labor with encouraging results.

Progesterone and medroxyprogesterone have been used in the treatment of women who have difficulty in conceiving and who demonstrate a slow rise in basal body temperature. There is no convincing evidence that this treatment is effective.

Preparations of progesterone and medroxyprogesterone have been used to treat premenstrual syndrome. Controlled studies have not confirmed the effectiveness of such therapy except when doses sufficient to suppress ovulation have been used.

### B. Diagnostic Uses

Progesterone can be used as a test of estrogen secretion. The administration of progesterone, 150 mg/d, or medroxyprogesterone, 10 mg/d, for 5–7 days, is followed by withdrawal bleeding in amenorrheic patients only when the endometrium has been stimulated by estrogens. A combination of estrogen and progestin can be given to test the responsiveness of the endometrium in patients with amenorrhea.

Studies of progestational compounds alone and with combination oral contraceptives indicate that the progestin in these agents may increase blood pressure in some patients. The more androgenic progestins also reduce plasma HDL levels in women. (See section [Hormonal Contraception](#).) Two recent studies suggest that combined progestin plus estrogen replacement therapy in postmenopausal women may increase breast cancer risk significantly compared with the risk in women taking estrogen alone. These findings require careful examination and if confirmed will lead to important changes in postmenopausal hormone replacement practice.

## OTHER OVARIAN HORMONES

The normal ovary produces small amounts of **androgens**, including [testosterone](#), androstenedione, and dehydroepiandrosterone. Of these, only [testosterone](#) has a significant amount of biologic activity, although androstenedione can be converted to [testosterone](#) or [estrone](#) in peripheral tissues. The normal woman produces less than 200 mcg of [testosterone](#) in 24 hours, and about one-third of this is probably formed in the ovary directly. The physiologic significance of these small amounts of androgens is not established, but they may be partly responsible for normal hair growth at puberty, for stimulation of female libido, and, possibly, for metabolic effects. Androgen production by the ovary may be markedly increased in some abnormal states, usually in association with hirsutism and amenorrhea as noted above.

The ovary also produces **inhibin** and **activin**. These peptides consist of several combinations of  $\alpha$  and  $\beta$  subunits and are described in greater detail later. The  $\alpha\beta$  dimer (inhibin) inhibits FSH secretion while the  $\beta\beta$  dimer (activin) increases FSH secretion. Studies in primates indicate that inhibin has no direct effect on ovarian steroidogenesis but that activin modulates the response to LH and FSH. For example, simultaneous treatment with activin and human FSH enhances FSH stimulation of [progesterone](#) synthesis and aromatase activity in granulosa cells. When combined with LH, activin suppressed the LH-induced [progesterone](#) response by 50% but markedly enhanced basal and LH-stimulated aromatase activity. Activin may also act as a growth factor in other tissues. The physiologic roles of these modulators are not fully understood.

**Relaxin** is another peptide that can be extracted from the ovary. The three-dimensional structure of relaxin is related to that of growth-promoting peptides and is similar to that of [insulin](#). Although the amino acid sequence differs from that of [insulin](#), this hormone, like [insulin](#), consists of two chains linked by disulfide bonds, cleaved from a prohormone. It is found in the ovary, placenta, uterus, and blood. Relaxin synthesis has been demonstrated in luteinized granulosa cells of the corpus luteum. It has been shown to increase glycogen synthesis and water uptake by the myometrium and to decrease uterine contractility. In some species, it changes the mechanical properties of the cervix and pubic ligaments, facilitating delivery.

In women, relaxin has been measured by immunoassay. Levels were highest immediately after the LH surge and during menstruation. A physiologic role for this peptide has not been established.

Clinical trials with relaxin have been conducted in patients with dysmenorrhea. Relaxin has also been administered to patients in premature labor and during prolonged labor. When applied to the cervix of a woman at term, it facilitates dilation and shortens labor.

Several other nonsteroidal substances such as corticotropin-releasing hormone, follistatin, and prostaglandins are produced by the ovary. These probably have paracrine effects within the ovary.

## HORMONAL CONTRACEPTION (ORAL, PARENTERAL, & IMPLANTED CONTRACEPTIVES)

A large number of oral contraceptives containing [estrogens](#) or progestins (or both) are now available for clinical use (see [Table 40–3](#)). These preparations vary chemically and pharmacologically and have many properties in common as well as definite differences important for the correct selection of the optimum agent.

Two types of preparations are used for oral contraception: (1) combinations of [estrogens](#) and progestins and (2) continuous progestin therapy without concomitant administration of [estrogens](#). The combination agents are further divided into **monophasic** forms (constant dosage of both components during the cycle) and **multiphasic** forms (dosage of one or both components is changed once or more during the cycle). The preparations for oral use are all adequately absorbed, and in combination preparations the pharmacokinetics of neither drug is significantly altered by the other.

Only one implantable contraceptive preparation is available at present in the USA. [Etonogestrel](#), also used in some oral contraceptives, is available in the subcutaneous implant form listed in [Table 40–3](#). Several hormonal contraceptives are available as vaginal rings or intrauterine devices.

Telegrams@pharmajournal.com  
Injection of large doses of [medroxyprogesterone](#) also provides contraception of long duration.

### A. Mechanism of Action

The combinations of [estrogens](#) and progestins exert their contraceptive effect largely through selective inhibition of pituitary function that results in inhibition of ovulation. The combination agents also produce a change in the cervical mucus, in the uterine endometrium, and in motility and secretion in the uterine tubes, all of which decrease the likelihood of conception and implantation. The continuous use of progestins alone does not always inhibit ovulation. The other factors mentioned, therefore, play a major role in the prevention of pregnancy when these agents are used.

### B. Effects on the Ovary

Chronic use of combination agents depresses ovarian function. Follicular development is minimal, and corpora lutea, larger follicles, stromal edema, and other morphologic features normally seen in ovulating women are absent. The ovaries usually become smaller even if enlarged before therapy.

The great majority of patients return to normal menstrual patterns when these drugs are discontinued. About 75% will ovulate in the first posttreatment cycle and 97% by the third posttreatment cycle. About 2% of patients remain amenorrheic for periods of up to several years after administration is stopped.

The cytologic findings on vaginal smears vary depending on the preparation used. However, with almost all of the combined drugs, a low maturation index is found because of the presence of progestational agents.

### C. Effects on the Uterus

After prolonged use, the cervix may show some hypertrophy and polyp formation. There are also important effects on the cervical mucus, making it more like postovulation mucus, ie, thicker and less copious.

Agents containing both [estrogens](#) and progestins produce further morphologic and biochemical changes of the endometrial stroma under the influence of the progestin, which also stimulates glandular secretion throughout the luteal phase. The agents containing “19-nor” progestins—particularly those with the smaller amounts of estrogen—tend to produce more glandular atrophy and usually less bleeding.

### D. Effects on the Breast

Stimulation of the breasts occurs in most patients receiving estrogen-containing agents. Some enlargement is generally noted. The administration of [estrogens](#) and combinations of [estrogens](#) and progestins tends to suppress lactation, but when the doses are small, the effects on breast-feeding are not appreciable. Studies of the transport of the oral contraceptives into breast milk suggest that only small amounts of these compounds cross into the milk, and they have not been considered to be of importance.

### E. Other Effects of Oral Contraceptives

#### 1. Effects on the central nervous system

The central nervous system effects of the oral contraceptives have not been well studied in humans. A variety of effects of estrogen and [progesterone](#) have been noted in animals. [Estrogens](#) tend to increase excitability in the brain, whereas [progesterone](#) tends to decrease it. The thermogenic action of [progesterone](#) and some of the synthetic progestins is also thought to occur in the central nervous system.

It is very difficult to evaluate any behavioral or emotional effects of these compounds in humans. Although the incidence of pronounced changes in mood, affect, and behavior appears to be low, milder changes are commonly reported, and [estrogens](#) are being successfully employed in the therapy of premenstrual tension syndrome, postpartum depression, and climacteric depression.

#### 2. Effects on endocrine function

The inhibition of pituitary gonadotropin secretion has been mentioned. [Estrogens](#) also alter adrenal structure and function. [Estrogens](#) given orally or

at high doses increase the plasma concentration of the  $\alpha_2$  globulin that binds cortisol (corticosteroid-binding globulin). Plasma concentrations may be more than double the levels found in untreated individuals, and urinary excretion of free cortisol is elevated.

These preparations cause alterations in the renin-angiotensin-aldosterone system. Plasma renin activity has been found to increase, and there is an increase in aldosterone secretion.

Thyroxine-binding globulin is increased. As a result, total plasma thyroxine ( $T_4$ ) levels are increased to those commonly seen during pregnancy. Since more of the thyroxine is bound, the free thyroxine level in these patients is normal. **Estrogens** also increase the plasma level of SHBG and decrease plasma levels of free androgens by increasing their binding; large amounts of estrogen may decrease androgens by gonadotropin suppression.

### **3. Effects on blood**

Serious thromboembolic phenomena occurring in women taking oral contraceptives gave rise to a great many studies of the effects of these compounds on blood coagulation. A clear picture of such effects has not yet emerged. The oral contraceptives do not consistently alter bleeding or clotting times. The changes that have been observed are similar to those reported in pregnancy. There is an increase in factors VII, VIII, IX, and X and a decrease in **antithrombin** III. Increased amounts of coumarin anticoagulants may be required to prolong prothrombin time in patients taking oral contraceptives.

There is an increase in serum iron and total iron-binding capacity similar to that reported in patients with hepatitis.

Significant alterations in the cellular components of blood have not been reported with any consistency. A number of patients have been reported to develop folic acid deficiency anemias.

### **4. Effects on the liver**

These hormones also have profound effects on the function of the liver. Some of these effects are deleterious and will be considered below in the section on adverse effects. The effects on serum proteins result from the effects of the **estrogens** on the synthesis of the various  $\alpha_2$  globulins and fibrinogen. Serum haptoglobins produced in the liver are depressed rather than increased by estrogen. Some of the effects on carbohydrate and lipid metabolism are probably influenced by changes in liver metabolism (see below).

Important alterations in hepatic drug excretion and metabolism also occur. **Estrogens** in the amounts seen during pregnancy or used in oral contraceptive agents delay the clearance of sulfobromophthalein and reduce the flow of bile. The proportion of cholic acid in bile acids is increased while the proportion of chenodeoxycholic acid is decreased. These changes may be responsible for the observed increase in cholelithiasis associated with the use of these agents.

### **5. Effects on lipid metabolism**

As noted above, **estrogens** increase serum triglycerides and free and esterified cholesterol. Phospholipids are also increased, as are HDL; levels of LDL usually decrease. Although the effects are marked with doses of 100 mcg of mestranol or ethinyl **estradiol**, doses of 50 mcg or less have minimal effects. The progestins (particularly the "19-nortestosterone" derivatives) tend to antagonize these effects of estrogen. Preparations containing small amounts of estrogen and a progestin may slightly decrease triglycerides and HDL.

### **6. Effects on carbohydrate metabolism**

The administration of oral contraceptives produces alterations in carbohydrate metabolism similar to those observed in pregnancy. There is a reduction in the rate of absorption of carbohydrates from the gastrointestinal tract. **Progesterone** increases the basal **insulin** level and the rise in **insulin** induced by carbohydrate ingestion. Preparations with more potent progestins such as norgestrel may cause progressive decreases in carbohydrate tolerance over several years. However, the changes in glucose tolerance are reversible on discontinuing medication.

### **7. Effects on the cardiovascular system**

These agents cause small increases in cardiac output associated with higher systolic and diastolic blood pressure and heart rate. The pressure returns

to posttreatment levels when treatment is terminated. Although the magnitude of the pressure change is small in most patients, it is marked in a few. It is important that blood pressure be followed in each patient. An increase in blood pressure has been reported to occur in a few postmenopausal women treated with **estrogens** alone.

#### 8. Effects on the skin

The oral contraceptives have been noted to increase pigmentation of the skin (chloasma). This effect seems to be enhanced in women with dark complexions and by exposure to ultraviolet light. Some of the androgen-like progestins might increase the production of sebum, causing acne in some patients. However, since ovarian androgen is suppressed, many patients note decreased sebum production, acne, and terminal hair growth. The sequential oral contraceptive preparations as well as **estrogens** alone often decrease sebum production.

### Clinical Uses

The most important use of combined **estrogens** and progestins is for oral contraception. A large number of preparations are available for this specific purpose, some of which are listed in [Table 40-3](#). They are specially packaged for ease of administration. In general, they are very effective; when these agents are taken according to directions, the risk of conception is extremely small. The pregnancy rate with combination agents is estimated to be about 5–12 per 100 woman-years at risk. (Under conditions of perfect adherence, the pregnancy rate would be 0.5–1 per 100 woman-years.) Contraceptive failure has been observed in some patients when one or more doses are missed, if **phenytoin** is also being used (which may increase catabolism of the compounds), or if antibiotics are taken that alter enterohepatic cycling of metabolites.

Progestins and **estrogens** are also useful in the treatment of endometriosis. When severe dysmenorrhea is the major symptom, the suppression of ovulation with estrogen alone may be followed by painless periods. However, in most patients this approach is inadequate. The long-term administration of large doses of progestins or combinations of progestins and **estrogens** prevents the periodic breakdown of the endometrial tissue and in some cases will lead to endometrial fibrosis and prevent the reactivation of implants for prolonged periods.

As is true with most hormonal preparations, many of the undesired effects are physiologic or pharmacologic actions that are objectionable only because they are not pertinent to the situation for which they are being used. Therefore, the product containing the smallest effective amounts of hormones should be selected for use.

### Adverse Effects

The incidence of serious known toxicities associated with the use of these drugs is low—far lower than the risks associated with pregnancy. There are a number of reversible changes in intermediary metabolism. Minor adverse effects are frequent, but most are mild and many are transient. Continuing problems may respond to simple changes in pill formulation. Although it is not often necessary to discontinue medication for these reasons, as many as one-third of all patients started on oral contraception discontinue use for reasons other than a desire to become pregnant.

#### A. Mild Adverse Effects

1. Nausea, mastalgia, breakthrough bleeding, and edema are related to the amount of estrogen in the preparation. These effects can often be alleviated by a shift to a preparation containing smaller amounts of estrogen or to agents containing progestins with more androgenic effects.
2. Changes in serum proteins and other effects on endocrine function (see above) must be taken into account when thyroid, adrenal, or pituitary function is being evaluated. Increases in sedimentation rate are thought to be due to increased levels of fibrinogen.
3. Headache is mild and often transient. However, migraine is often made worse and has been reported to be associated with an increased frequency of cerebrovascular accidents. When this occurs or when migraine has its onset during therapy with these agents, treatment should be discontinued.
4. Withdrawal bleeding sometimes fails to occur—most often with combination preparations—and may cause confusion with regard to pregnancy. If this is disturbing to the patient, a different preparation may be tried or other methods of contraception used.

#### B. Moderate Adverse Effects

1. Breakthrough bleeding is the most common problem in using progestational agents alone for contraception. It occurs in as many as 25% of patients. It is more frequently encountered in patients taking low-dose preparations than in those taking combination pills with higher levels of progestin and estrogen. The biphasic and triphasic oral contraceptives (see [Table 40-3](#)) decrease breakthrough bleeding without increasing the total hormone content.
2. Weight gain is more common with the combination agents containing androgen-like progestins. It can usually be controlled by shifting to preparations with less progestin effect or by dieting.
3. Increased skin pigmentation may occur, especially in dark-skinned women. It tends to increase with time, the incidence being about 5% at the end of the first year and about 40% after 8 years. It is thought to be exacerbated by vitamin B deficiency. It is often reversible upon discontinuance of medication but may disappear very slowly.
4. Acne may be exacerbated by agents containing androgen-like progestins (see [Table 40-2](#)), whereas agents containing large amounts of estrogen usually cause marked improvement in acne.
5. Hirsutism may also be aggravated by the “19-nortestosterone” derivatives, and combinations containing nonandrogenic progestins are preferred in these patients.
6. Ureteral dilation similar to that observed in pregnancy has been reported, and bacteriuria is more frequent.
7. Vaginal infections are more common and more difficult to treat in patients who are using oral contraceptives.
8. Amenorrhea occurs in some patients. Following cessation of administration of oral contraceptives, 95% of patients with normal menstrual histories resume normal periods and all but a few resume normal cycles during the next few months. However, some patients remain amenorrheic for several years. Many of these patients also have galactorrhea. Patients who have had menstrual irregularities before taking oral contraceptives are particularly susceptible to prolonged amenorrhea when the agents are discontinued. Prolactin levels should be measured in these patients, since many have prolactinomas.

### C. Severe Adverse Effects

#### 1. Vascular disorders

Thromboembolism was one of the earliest of the serious unanticipated effects to be reported and has been the most thoroughly studied.

##### a. VENOUS THROMBOEMBOLIC DISEASE

Superficial or deep thromboembolic disease in women not taking oral contraceptives occurs in about 1 patient per 1000 woman years. The overall incidence of these disorders in patients taking low-dose oral contraceptives is about threefold higher. The risk for this disorder is increased during the first month of contraceptive use and remains constant for several years or more. The risk returns to normal within a month when use is discontinued. The risk of venous thrombosis or pulmonary embolism is increased among women with predisposing conditions such as stasis, altered clotting factors such as [antithrombin III](#), increased levels of homocysteine, or injury. Genetic disorders, including mutations in the genes governing the production of protein C (factor V Leiden), protein S, hepatic cofactor II, and others, markedly increase the risk of venous thromboembolism. The incidence of these disorders is too low for cost-effective screening by current methods, but prior episodes or a family history may be helpful in identifying patients with increased risk.

The incidence of venous thromboembolism appears to be related to the estrogen but not the progestin content of oral contraceptives and is not related to age, parity, mild obesity, or cigarette smoking. Decreased venous blood flow, endothelial proliferation in veins and arteries, and increased coagulability of blood resulting from changes in platelet functions and fibrinolytic systems contribute to the increased incidence of thrombosis. The major plasma inhibitor of [thrombin](#), [antithrombin III](#), is substantially decreased during oral contraceptive use. This change occurs in the first month of treatment and lasts as long as treatment persists, reversing within a month thereafter.

##### b. MYOCARDIAL INFARCTION

Use of oral contraceptives is associated with a slightly higher risk of myocardial infarction in women who are obese, have a history of preeclampsia

or hypertension, or have hyperlipoproteinemia or diabetes. There is a much higher risk in women who smoke. The risk attributable to oral contraceptives in women 30–40 years of age who do not smoke is about 4 cases per 100,000 users per year, as compared with 185 cases per 100,000 among women 40–44 who smoke heavily. The association with myocardial infarction is thought to involve acceleration of atherogenesis because of decreased glucose tolerance, decreased levels of HDL, increased levels of LDL, and increased platelet aggregation. In addition, facilitation of coronary arterial spasm may play a role in some of these patients. The progestational component of oral contraceptives decreases HDL cholesterol levels, in proportion to the androgenic activity of the progestin. The net effect, therefore, will depend on the specific composition of the pill used and the patient's susceptibility to the particular effects. Recent studies suggest that risk of infarction is not increased in past users who have discontinued oral contraceptives.

#### *C. CEREBROVASCULAR DISEASE*

The risk of stroke is concentrated in women over age 35. It is increased in current users of oral contraceptives but not in past users. However, subarachnoid hemorrhages have been found to be increased among both current and past users and may increase with time. The risk of thrombotic or hemorrhagic stroke attributable to oral contraceptives (based on older, higher-dose preparations) has been estimated at about 37 cases per 100,000 users per year.

In summary, available data indicate that oral contraceptives increase the risk of various cardiovascular disorders at all ages and among both smokers and nonsmokers. However, this risk appears to be concentrated in women 35 years of age or older who are heavy smokers. It is clear that these risk factors must be considered in each individual patient for whom oral contraceptives are being considered. Some experts have suggested that screening for coagulopathy should be performed before starting oral contraception.

#### **2. Gastrointestinal disorders**

Many cases of cholestatic jaundice have been reported in patients taking progestin-containing drugs. The differences in incidence of these disorders from one population to another suggest that genetic factors may be involved. The jaundice caused by these agents is similar to that produced by other 17-alkyl-substituted steroids. It is most often observed in the first three cycles and is particularly common in women with a history of cholestatic jaundice during pregnancy. Jaundice and pruritus disappear 1–8 weeks after the drug is discontinued.

These agents have also been found to increase the incidence of symptomatic gallbladder disease, including cholecystitis and cholangitis. This is probably the result of the alterations responsible for jaundice and bile acid changes described above.

It also appears that the incidence of hepatic adenomas is increased in women taking oral contraceptives. Ischemic bowel disease secondary to thrombosis of the celiac and superior and inferior mesenteric arteries and veins has also been reported in women using these drugs.

#### **3. Depression**

Depression of sufficient degree to require cessation of therapy occurs in about 6% of patients treated with some preparations.

#### **4. Cancer**

The occurrence of malignant tumors in patients taking oral contraceptives has been studied extensively. It is now clear that these compounds *reduce* the risk of endometrial and ovarian cancer. The lifetime risk of breast cancer in the population as a whole does not seem to be affected by oral contraceptive use. Some studies have shown an increased risk in younger women, and it is possible that tumors that develop in younger women become clinically apparent sooner. The relation of risk of cervical cancer to oral contraceptive use is still controversial. It should be noted that a number of recent studies associate the use of oral contraceptives by women who are infected with human papillomavirus with an increased risk of cervical cancer.

#### **5. Other**

In addition to the above effects, a number of other adverse reactions have been reported for which a causal relation has not been established. These include alopecia, erythema multiforme, erythema nodosum, and other skin disorders.

These drugs are contraindicated in patients with thrombophlebitis, thromboembolic phenomena, and cardiovascular and cerebrovascular disorders or a past history of these conditions. They should not be used to treat vaginal bleeding when the cause is unknown. They should be avoided in patients with known or suspected tumors of the breast or other estrogen-dependent neoplasms. Since these preparations have caused aggravation of preexisting disorders, they should be avoided or used with caution in patients with liver disease, asthma, eczema, migraine, diabetes, hypertension, optic neuritis, retrobulbar neuritis, or convulsive disorders.

The oral contraceptives may produce edema, and for that reason they should be used with great caution in patients in heart failure or in whom edema is otherwise undesirable or dangerous.

**Estrogens** may increase the rate of growth of fibroids. Therefore, for women with these tumors, agents with the smallest amounts of estrogen and the most androgenic progestins should be selected. The use of progestational agents alone for contraception might be especially useful in such patients (see below).

These agents are contraindicated in adolescents in whom epiphyseal closure has not yet been completed.

Women using oral contraceptives must be made aware of an important interaction that occurs with antimicrobial drugs. Because the normal gastrointestinal flora increase the enterohepatic cycling (and bioavailability) of **estrogens**, antimicrobial drugs that interfere with these organisms may reduce the efficacy of oral contraceptives. Additionally, coadministration with potent inducers of the hepatic microsomal metabolizing enzymes, such as **rifampin**, may increase liver catabolism of **estrogens** or progestins and diminish the efficacy of oral contraceptives.

### Contraception with Progestins Alone

Small doses of progestins administered orally or by implantation under the skin can be used for contraception. They are particularly suited for use in patients for whom estrogen administration is undesirable. They are about as effective as intrauterine devices or combination pills containing 20–30 mcg of ethinyl **estradiol**. There is a high incidence of abnormal bleeding.

Effective contraception can also be achieved by injecting 150 mg of depot **medroxyprogesterone** acetate (DMPA) every 3 months. After a 150-mg dose, ovulation is inhibited for at least 14 weeks. Almost all users experience episodes of unpredictable spotting and bleeding, particularly during the first year of use. Spotting and bleeding decrease with time, and amenorrhea is common. This preparation is not desirable for women planning a pregnancy soon after cessation of therapy because ovulation suppression can sometimes persist for as long as 18 months after the last injection. Long-term DMPA use reduces menstrual blood loss and is associated with a decreased risk of endometrial cancer. Suppression of endogenous estrogen secretion may be associated with a reversible reduction in bone density, and changes in plasma lipids are associated with an increased risk of atherosclerosis.

The progestin implant method utilizes the subcutaneous implantation of capsules containing **etonogestrel**. These capsules release one fifth to one-third as much steroid as oral agents, are extremely effective, and last for 2–4 years. The low levels of hormone have little effect on lipoprotein and carbohydrate metabolism or blood pressure. The disadvantages include the need for surgical insertion and removal of capsules and some irregular bleeding rather than predictable menses. An association of intracranial hypertension with an earlier type of implant utilizing norgestrel was observed in a small number of women. Patients experiencing headache or visual disturbances should be checked for papilledema.

Contraception with progestins is useful in patients with hepatic disease, hypertension, psychosis or mental retardation, or prior thromboembolism. The side effects include headache, dizziness, bloating and weight gain of 1–2 kg, and a reversible reduction of glucose tolerance.

#### A. Postcoital Contraceptives

Pregnancy can be prevented following coitus by the administration of **estrogens** alone, progestin alone, or in combination (**morning after** contraception). When treatment is begun within 72 hours, it is effective 99% of the time. Some effective schedules are shown in **Table 40–4**. The hormones are often administered with antiemetics, since 40% of patients have nausea or vomiting. Other adverse effects include headache, dizziness, breast tenderness, and abdominal and leg cramps. Considerable controversy has accompanied the proposal to make these agents available without a prescription in the United States.

### Schedules for use of postcoital contraceptives.

Conjugated <b>estrogens</b> : 10 mg three times daily for 5 days
Ethinyl <b>estradiol</b> : 2.5 mg twice daily for 5 days
Diethylstilbestrol: 50 mg daily for 5 days
<b>Mifepristone</b> : 600 mg once with <b>misoprostol</b> , 400 mcg once <sup>1</sup>
L-Norgestrel: 1.5 mg once (Plan B One-Step <sup>2</sup> )
L-Norgestrel: 0.75 mg twice daily for 1 day (eg, Plan B <sup>2</sup> )
Norgestrel, 0.5 mg, with ethinyl <b>estradiol</b> , 0.05 mg (eg, Ovral, Preven <sup>2</sup> ): Two tablets and then two in 12 hours

<sup>1</sup>Mifepristone given on day 1, **misoprostol** on day 3.

<sup>2</sup>Sold as emergency contraceptive kits.

**Mifepristone**, an antagonist at **progesterone** and glucocorticoid receptors, has a luteolytic effect and is effective as a postcoital contraceptive. When combined with a prostaglandin it is also an effective abortifacient.

### Beneficial Effects of Oral Contraceptives

It has become apparent that reduction in the dose of the constituents of oral contraceptives has markedly reduced mild and severe adverse effects, providing a relatively safe and convenient method of contraception for many young women. Treatment with oral contraceptives has also been shown to be associated with many benefits unrelated to contraception. These include a reduced risk of ovarian cysts, ovarian and endometrial cancer, and benign breast disease. There is a lower incidence of ectopic pregnancy. Iron deficiency and rheumatoid arthritis are less common, and premenstrual symptoms, dysmenorrhea, endometriosis, acne, and hirsutism may be ameliorated with their use.

## ESTROGEN & PROGESTERONE INHIBITORS & ANTAGONISTS

### TAMOXIFEN & RELATED PARTIAL AGONIST ESTROGENS

**Tamoxifen**, a competitive partial agonist inhibitor of **estradiol** at the estrogen receptor (Figure 40–5), was the first **selective estrogen receptor modulator (SERM)** to be introduced. The mechanism of its mixed agonist/antagonist relations to the estrogen receptor has been intensively studied but is still not completely understood. Proposals include recruitment of different coregulators to the estrogen receptor when it binds **tamoxifen** rather than estrogen, differential activation of heterodimers (ER $\alpha$ -ER $\beta$ ) versus homodimers, competition of ER $\alpha$  by ER $\beta$  and others. **Tamoxifen** is extensively used in the palliative treatment of breast cancer in postmenopausal women and is approved for chemoprevention of breast cancer in high-risk women (see Chapter 54). It is a nonsteroidal agent (see structure below) that is given orally. Peak plasma levels are reached in a few hours. **Tamoxifen** has an initial half-life of 7–14 hours in the circulation and is predominantly excreted by the liver. One of its metabolites via CYP2D6 is 4-hydroxytamoxifen (endoxifen), a more potent SERM. Therefore, strong inhibitors of 2D6 should be avoided in patients receiving **tamoxifen**. It is used in doses of 10–20 mg twice daily. Hot flushes and nausea and vomiting occur in 25% of patients, and many other minor adverse effects are observed. Studies of patients treated with **tamoxifen** as adjuvant therapy for early breast cancer have shown a 35% decrease in contralateral breast cancer. However, adjuvant therapy extended beyond 5 years in patients with breast cancer has shown no further improvement in outcome. In fact, resistant lines of tumor cells may recognize **tamoxifen** as an agonist rather than an antagonist, perhaps due to changes in the coregulators that interact with the estrogen receptor.

Telegram: @pharm\_uk

Control of ovarian secretion and the actions of its hormones. In the follicular phase the ovary produces mainly **estrogens**; in the luteal phase it produces **estrogens** and **progesterone**. SERMs, selective estrogen receptor modulators. See text.

Prevention of the expected loss of lumbar spine bone density and plasma lipid changes consistent with a reduction in the risk for atherosclerosis have also been reported in tamoxifen-treated patients following spontaneous or surgical menopause. However, this agonist activity also affects the uterus and may increase the risk of endometrial cancer.

**Raloxifene** is another partial estrogen agonist-antagonist at some but not all target tissues. It has estrogenic effects on lipids and bone but appears not to stimulate the endometrium or breast. Although subject to a high first-pass effect, **raloxifene** has a very large volume of distribution and a long half-life (>24 hours), so it can be taken once a day. **Raloxifene** has been approved in the United States for the prevention of postmenopausal osteoporosis and prophylaxis of breast cancer in women with risk factors. Newer SERMs have been developed and one, **bazedoxifene**, in combination with conjugated **estrogens**, is approved for treatment of menopausal symptoms and prophylaxis of postmenopausal osteoporosis.

**Clomiphene** is an older partial agonist, a weak estrogen that also acts as a competitive inhibitor of endogenous **estrogens** (see Figure 40-5). It has found use as an ovulation-inducing agent (see below).

### MIFEPRISTONE (RU-486)

**Mifepristone** is a "19-norsteroid" that binds strongly to the **progesterone** and glucocorticoid receptors and inhibits the activity of **progesterone** and that of glucocorticoids (see Chapter 39). The drug has luteolytic properties in 80% of women when given in the midluteal period. The mechanism of this effect is unknown, but it may provide the basis for using **mifepristone** as a contraceptive (as opposed to an abortifacient). However, because the compound has a long half-life of 20-40 hours, large doses may prolong the follicular phase of the subsequent cycle and so make it difficult to use continuously for this purpose. A single dose of 600 mg is an effective emergency postcoital contraceptive, though it may result in delayed ovulation in the following cycle. As noted in Chapter 39, the drug also binds to and acts as an antagonist at the glucocorticoid receptor. Limited clinical studies suggest that **mifepristone** or other analogs with similar properties may be useful in the treatment of endometriosis, Cushing syndrome, breast cancer, and possibly other neoplasms such as meningiomas that contain glucocorticoid or **progesterone** receptors.

**Mifepristone's** major use thus far has been to terminate early pregnancies. Doses of 400–600 mg/d for 4 days or 800 mg/d for 2 days successfully terminated pregnancy in >85% of the women studied. The major adverse effect was prolonged bleeding that on most occasions did not require treatment. The combination of a single oral dose of 600 mg of **mifepristone** and a vaginal pessary containing 1 mg of prostaglandin E<sub>1</sub> or oral **misoprostol** has been found to effectively terminate pregnancy in over 95% of patients treated during the first 7 weeks after conception. The adverse effects of the medications included vomiting, diarrhea, and abdominal or pelvic pain. As many as 5% of patients have vaginal bleeding requiring intervention. Because of these adverse effects, **mifepristone** is administered only by physicians at family planning centers. *Note:* In a very small number of cases, use of a vaginal tablet for the prostaglandin dose has been associated with sepsis, so it is recommended that *both* drugs be given by mouth in all patients.

**ZK 98734 (lilopristone)** is a potent experimental **progesterone** inhibitor and abortifacient in doses of 25 mg twice daily. Like **mifepristone**, it also appears to have antiglucocorticoid activity.

## DANAZOL

**Danazol**, an isoxazole derivative of ethisterone (17 $\alpha$ -ethinyl-testosterone) with weak progestational, androgenic, and glucocorticoid activities, is used to suppress ovarian function. **Danazol** inhibits the midcycle surge of LH and FSH and can prevent the compensatory increase in LH and FSH following castration in animals, but it does not significantly lower or suppress basal LH or FSH levels in normal women (see [Figure 40-5](#)). **Danazol** binds to androgen, **progesterone**, and glucocorticoid receptors and can translocate the androgen receptor into the nucleus to initiate androgen-specific RNA synthesis. It does not bind to intracellular estrogen receptors, but it does bind to sex hormone-binding and corticosteroid-binding globulins. It inhibits P450scc (the cholesterol side chain-cleaving enzyme), 3 $\beta$ -hydroxysteroid dehydrogenase, 17 $\alpha$ -hydroxysteroid dehydrogenase, P450c17 (17 $\alpha$ -hydroxylase), P450c11 (11 $\beta$ -hydroxylase), and P450c21 (21 $\beta$ -hydroxylase). However, it does not inhibit aromatase, the enzyme required for estrogen synthesis. It increases the mean clearance of **progesterone**, probably by competing with the hormone for binding proteins, and may have similar effects on other active steroid hormones. Ethisterone, a major metabolite of **danazol**, has both progestational and mild androgenic effects.

**Danazol** is slowly metabolized in humans, having a half-life of >15 hours. This results in stable circulating levels when the drug is administered twice daily. It is highly concentrated in the liver, adrenals, and kidneys and is excreted in both feces and urine.

**Danazol** has been employed as an inhibitor of gonadal function and has found its major use in the treatment of endometriosis. For this purpose, it can be given in a dosage of 600 mg/d. The dosage is reduced to 400 mg/d after 1 month and to 200 mg/d in 2 months. About 85% of patients show marked improvement in 3–12 months.

**Danazol** has also been used in the treatment of fibrocystic disease of the breast and hematologic or allergic disorders, including hemophilia, Christmas disease, idiopathic thrombocytopenic purpura, and angioneurotic edema.

The major adverse effects are weight gain, edema, decreased breast size, acne and oily skin, increased hair growth, deepening of the voice, headache, hot flushes, changes in libido, and muscle cramps. Although mild adverse effects are very common, it is seldom necessary to discontinue the drug because of them. Occasionally, because of its inherent glucocorticoid activity, **danazol** may cause adrenal suppression.

**Danazol** should be used with great caution in patients with hepatic dysfunction, since it has been reported to produce mild to moderate hepatocellular damage in some patients, as evidenced by enzyme changes. It is also contraindicated during pregnancy and breast-feeding, as it may produce urogenital abnormalities in the offspring.

## OTHER INHIBITORS

**Anastrozole**, a selective nonsteroidal inhibitor of aromatase (the enzyme required for estrogen synthesis; see [Figures 40-2](#) and [40-5](#)), is effective in some women whose breast tumors have become resistant to **tamoxifen** (see [Chapter 54](#)). **Letrozole** is similar. **Exemestane**, a steroid molecule, is an irreversible inhibitor of aromatase. Like **anastrozole** and **letrozole**, it is approved for use in women with advanced breast cancer (see [Chapter 54](#)).

Several other aromatase inhibitors are undergoing clinical trials in patients with breast cancer. **Fadrozole** is an oral nonsteroidal (triazole) inhibitor of aromatase activity. These compounds appear to be as effective as **tamoxifen**. In addition to their use in breast cancer, aromatase inhibitors have been successfully employed as adjuncts to androgen antagonists in the treatment of precocious puberty and as primary treatment in the excessive

**Fulvestrant** is a pure estrogen receptor antagonist that has been somewhat more effective than those with partial agonist effects in some patients who have become resistant to **tamoxifen**. **Fulvestrant** is approved for use in breast cancer patients who have become resistant to **tamoxifen**. ICI 164,384 is a newer antagonist; it inhibits dimerization of the occupied estrogen receptor and interferes with its binding to DNA.

**GnRH** and its analogs (**nafarelin**, **buserelin**, etc) have become important in both stimulating and inhibiting ovarian function. They are discussed in [Chapter 37](#).

## OVULATION-INDUCING AGENTS

### CLOMIPHENE

**Clomiphene** citrate, a partial estrogen agonist, is closely related to the estrogen chlorotrianisene (see [Figure 40-3](#)). This compound is well absorbed when taken orally. It has a half-life of 5–7 days and is excreted primarily in the urine. It exhibits significant protein binding and enterohepatic circulation and is distributed to adipose tissues.

#### Pharmacologic Effects

##### A. Mechanisms of Action

**Clomiphene** is a partial agonist at estrogen receptors. The estrogenic agonist effects are best demonstrated in animals with marked gonadal deficiency. **Clomiphene** has also been shown to effectively inhibit the action of stronger **estrogens**. In humans it leads to an increase in the secretion of gonadotropins and **estrogens** by inhibiting **estradiol**'s negative feedback effect on the release of gonadotropins (see [Figure 40-5](#)).

##### B. Effects

The pharmacologic importance of **clomiphene** rests on its ability to stimulate ovulation in women with oligomenorrhea or amenorrhea and ovulatory dysfunction. The majority of patients suffer from polycystic ovary syndrome, a common disorder affecting about 7% of women of reproductive age. The syndrome is characterized by gonadotropin-dependent ovarian hyperandrogenism associated with anovulation and infertility. The disorder is frequently accompanied by adrenal hyperandrogenism. **Clomiphene** probably blocks the feedback inhibitory influence of **estrogens** on the hypothalamus, causing a surge of gonadotropins, which leads to ovulation.

#### Clinical Use

**Clomiphene** is used in the treatment of disorders of ovulation in patients who wish to become pregnant. Usually, a single ovulation is induced by a single course of therapy, and the patient must be treated repeatedly until pregnancy is achieved, since normal cyclic ovulatory function does not usually resume. The compound is of no value in patients with ovarian or pituitary failure.

When **clomiphene** is administered in a dosage of 100 mg/d for 5 days, a rise in plasma LH and FSH is observed after several days. In patients who ovulate, the initial rise is followed by a second rise of gonadotropin levels just prior to ovulation.

#### Adverse Effects

The most common adverse effects in patients treated with this drug are hot flushes, which resemble those experienced by menopausal patients. They tend to be mild, and disappear when the drug is discontinued. There have been occasional reports of eye symptoms due to intensification and prolongation of afterimages. These are generally of short duration. Headache, constipation, allergic skin reactions, and reversible hair loss have been reported occasionally.

The effective use of **clomiphene** is associated with some stimulation of the ovaries and usually with ovarian enlargement. The degree of enlargement tends to be greater and its incidence higher in patients who have enlarged ovaries at the beginning of therapy.

A variety of other symptoms such as nausea and vomiting, increased nervous tension, depression, fatigue, breast soreness, weight gain, urinary frequency, and heavy menses have also been reported. However, these appear to result from the hormonal changes associated with an ovulatory

menstrual cycle rather than from the medication. The incidence of multiple pregnancy is approximately 10%. **Clomiphene** has not been shown to have an adverse effect when inadvertently given to women who are already pregnant.

### Contraindications & Cautions

Special precautions should be observed in patients with enlarged ovaries. These women are thought to be more sensitive to this drug and should receive small doses. Any patient who complains of abdominal symptoms should be examined carefully. Maximum ovarian enlargement occurs after the 5-day course has been completed, and many patients can be shown to have a palpable increase in ovarian size by the seventh to tenth days. Treatment with **clomiphene** for more than a year may be associated with an increased risk of low-grade ovarian cancer; however, the evidence for this effect is not conclusive.

Special precautions must also be taken in patients who have visual symptoms associated with **clomiphene** therapy, since these symptoms may make activities such as driving more hazardous.

### OTHER DRUGS USED IN OVULATORY DISORDERS

In addition to **clomiphene**, a variety of other hormonal and nonhormonal agents are used in treating anovulatory disorders. They are discussed in [Chapter 37](#).

## THE TESTIS (ANDROGENS & ANABOLIC STEROIDS, ANTIANDROGENS, & MALE CONTRACEPTION)

The testis, like the ovary, has both gametogenic and endocrine functions. The onset of gametogenic function of the testes is controlled largely by the secretion of FSH by the pituitary. High concentrations of **testosterone** locally are also required for continuing sperm production in the seminiferous tubules. The Sertoli cells in the seminiferous tubules may be the source of the **estradiol** produced in the testes via aromatization of locally produced **testosterone**. With LH stimulation, **testosterone** is produced by the interstitial or Leydig cells found in the spaces between the seminiferous tubules.

The Sertoli cells in the testis synthesize and secrete a variety of active proteins, including müllerian duct inhibitory factor, inhibin, and activin. As in the ovary, inhibin and activin appear to be the product of three genes that produce a common  $\alpha$  subunit and two  $\beta$  subunits, A and B. Activin is composed of the two  $\beta$  subunits ( $\beta_A\beta_B$ ). There are two inhibins (A and B), which contain the  $\alpha$  subunit and one of the  $\beta$  subunits. Activin stimulates pituitary FSH release and is structurally similar to transforming growth factor- $\beta$ , which also increases FSH. The inhibins in conjunction with **testosterone** and dihydrotestosterone are responsible for the feedback inhibition of pituitary FSH secretion.

### ANDROGENS & ANABOLIC STEROIDS

In humans, the most important androgen secreted by the testis is **testosterone**. The pathways of synthesis of **testosterone** in the testes are similar to those previously described for the adrenal gland and ovary (see [Figures 39–1](#) and [40–2](#)).

In men, approximately 8 mg of **testosterone** is produced daily. About 95% is produced by the Leydig cells and only 5% by the adrenals. The testis also secretes small amounts of another potent androgen, dihydrotestosterone, as well as androstenedione and dehydroepiandrosterone, which are weak androgens. Pregnenolone and **progesterone** and their 17-hydroxylated derivatives are also released in small amounts. Plasma levels of **testosterone** in males are about 0.6 mcg/dL after puberty and appear to decline after age 50. **Testosterone** is also present in the plasma of women in concentrations of approximately 0.03 mcg/dL and is derived in approximately equal parts from the ovaries and adrenals and by the peripheral conversion of other hormones.

About 65% of circulating **testosterone** is bound to sex hormone-binding globulin. SHBG is increased in plasma by estrogen, by thyroid hormone, and in patients with cirrhosis of the liver. It is decreased by androgen and growth hormone and is lower in obese individuals. Most of the remaining **testosterone** is bound to **albumin**. Approximately 2% remains free and available to enter cells and bind to intracellular receptors.

### Metabolism

In many target tissues, **testosterone** is converted to dihydrotestosterone by 5 $\alpha$ -reductase. In these tissues, dihydrotestosterone is the major active

androgen. The conversion of **testosterone** to **estradiol** by P450 aromatase also occurs in some tissues, including adipose tissue, liver, and the hypothalamus, where it may be of importance in regulating gonadal function.

The major pathway for the degradation of **testosterone** in humans occurs in the liver, with the reduction of the double bond and ketone in the A ring, as is seen in other steroids with a  $\Delta^4$ -ketone configuration in the A ring. This leads to the production of inactive substances such as androsterone and etiocholanolone that are then conjugated and excreted in the urine.

Androstenedione, dehydroepiandrosterone (DHEA), and dehydroepiandrosterone sulfate (DHEAS) are also produced in significant amounts in humans, although largely in the adrenal gland rather than in the testes. They contribute slightly to the normal maturation process supporting other androgen-dependent pubertal changes in the human, primarily development of pubic and axillary hair and bone maturation. As noted in [Chapter 39](#), some studies suggest that DHEA and DHEAS may have other central nervous system and metabolic effects and may prolong life in rabbits. In men they may improve the sense of well-being and inhibit atherosclerosis. In a placebo-controlled clinical trial in patients with systemic lupus erythematosus, DHEA demonstrated some beneficial effects (see Adrenal Androgens, [Chapter 39](#)). Adrenal androgens are to a large extent metabolized in the same fashion as **testosterone**. Both steroids—but particularly androstenedione—can be converted by peripheral tissues to **estrone** in very small amounts (1–5%). The P450 aromatase enzyme responsible for this conversion is also found in the brain and is thought to play an important role in development.

### Physiologic Effects

In the normal male, **testosterone** or its active metabolite 5 $\alpha$ -dihydrotestosterone is responsible for the many changes that occur in puberty. In addition to the general growth-promoting properties of androgens on body tissues, these hormones are responsible for penile and scrotal growth. Changes in the skin include the appearance of pubic, axillary, and beard hair. The sebaceous glands become more active, and the skin tends to become thicker and oilier. The larynx grows and the vocal cords become thicker, leading to a lower-pitched voice. Skeletal growth is stimulated and epiphyseal closure accelerated. Other effects include growth of the prostate and seminal vesicles, darkening of the skin, and increased skin circulation. Androgens play an important role in stimulating and maintaining sexual function in men. Androgens increase lean body mass and stimulate body hair growth and sebum secretion. Metabolic effects include the reduction of hormone binding and other carrier proteins and increased liver synthesis of clotting factors, triglyceride lipase,  $\alpha_1$ -antitrypsin, haptoglobin, and sialic acid. They also stimulate renal erythropoietin secretion and decrease HDL levels.

### Synthetic Steroids with Androgenic & Anabolic Action

**Testosterone**, when administered by mouth, is rapidly absorbed. However, it is largely converted to inactive metabolites, and only about one sixth of the dose administered is available in active form. **Testosterone** can be administered parenterally, but it has a more prolonged absorption time and greater activity in the propionate, enanthate, undecanoate, or cypionate ester forms. These derivatives are hydrolyzed to release free **testosterone** at the site of injection. **Testosterone** derivatives alkylated at the 17 position, eg, **methyltestosterone** and fluoxymesterone, are active when given by mouth.

**Testosterone** and its derivatives have been used for their anabolic effects as well as in the treatment of **testosterone** deficiency. Although **testosterone** and other known active steroids can be isolated in pure form and measured by weight, biologic assays are still used in the investigation of new compounds. In some of these studies in animals, the anabolic effects of the compound as measured by trophic effects on muscles or the reduction of nitrogen excretion may be dissociated from the other androgenic effects. This has led to the marketing of compounds claimed to have anabolic activity associated with only weak androgenic effects. Unfortunately, this dissociation is less marked in humans than in the animals used for testing ([Table 40–5](#)), and all are potent androgens.

**Androgens: Preparations available and relative androgenic:anabolic activity in animals.**

Drug	Androgenic:Anabolic Activity
Testosterone	1:1
Testosterone cypionate	1:1
Testosterone enanthate	1:1
Methyltestosterone	1:1
Fluoxymesterone	1:2
Oxymetholone	1:3
Oxandrolone	1:3–1:13
Nandrolone decanoate	1:2.5–1:4

**Pharmacologic Effects**

**A. Mechanism of Action**

Like other steroids, **testosterone** acts intracellularly in target cells. In skin, prostate, seminal vesicles, and epididymis, it is converted to 5 $\alpha$ -dihydrotestosterone by 5 $\alpha$ -reductase. In these tissues, dihydrotestosterone is the dominant androgen. The distribution of this enzyme in the fetus is different and has important developmental implications.

**Testosterone** and dihydrotestosterone bind to the intracellular androgen receptor, initiating a series of events similar to those described above for **estradiol** and **progesterone**, leading to growth, differentiation, and synthesis of a variety of enzymes and other functional proteins.

**B. Effects**

In the male at puberty, androgens cause development of the secondary sex characteristics (see above). In the adult male, large doses of testosterone—when given alone—or its derivatives suppress the secretion of gonadotropins and result in some atrophy of the interstitial tissue and the tubules of the testes. Since fairly large doses of androgens are required to suppress gonadotropin secretion, it has been postulated that inhibin, in combination with androgens, is responsible for the feedback control of secretion. In women, androgens are capable of producing changes similar to those observed in the prepubertal male. These include growth of facial and body hair, deepening of the voice, enlargement of the clitoris, frontal baldness, and prominent musculature. The natural androgens stimulate erythrocyte production.

The administration of androgens reduces the excretion of nitrogen into the urine, indicating an increase in protein synthesis or a decrease in protein breakdown within the body. This effect is much more pronounced in women and children than in normal men.

**Clinical Uses**

**A. Androgen Replacement Therapy in Men**

Androgens are used to replace or augment endogenous androgen secretion in hypogonadal men (**Table 40-6**). Even in the presence of pituitary deficiency, androgens are used rather than gonadotropins except when normal spermatogenesis is to be achieved. In patients with hypopituitarism,

androgens are not added to the treatment regimen until puberty, at which time they are instituted in gradually increasing doses to achieve the growth spurt and the development of secondary sex characteristics. In these patients, therapy should be started with long-acting agents such as **testosterone** enanthate or cypionate in doses of 50 mg intramuscularly, initially every 4, then every 3, and finally every 2 weeks, with each change taking place at 3-month intervals. The dose is then doubled to 100 mg every 2 weeks until maturation is complete. Finally, it is changed to the adult replacement dose of 200 mg at 2-week intervals.

TABLE 40-6

**Androgen preparations for replacement therapy.**

Drug	Route of Administration	Dosage
Methyltestosterone	Oral	25–50 mg/d
	Sublingual (buccal)	5–10 mg/d
Fluoxymesterone	Oral	2–10 mg/d
Testosterone enanthate	Intramuscular	See text
Testosterone cypionate	Intramuscular	See text
Testosterone	Transdermal	2.5–10 mg/d
	Topical gel (1%)	5–10 g/d

**Testosterone** propionate, though potent, has a short duration of action and is not practical for long-term use. **Testosterone** undecanoate can be given orally, administering large amounts of the steroid twice daily (eg, 40 mg/d); however, this is not recommended because oral **testosterone** administration has been associated with liver tumors. **Testosterone** can also be administered transdermally; skin patches or gels are available for scrotal or other skin area application. Two applications daily are usually required for replacement therapy. Implanted pellets and other longer-acting preparations are under study. The development of polycythemia or hypertension may require some reduction in dose.

**B. Gynecologic Disorders**

Androgens are used occasionally in the treatment of certain gynecologic disorders, but the undesirable effects in women are such that they must be used with great caution. Androgens have been used to reduce breast engorgement during the postpartum period, usually in conjunction with **estrogens**. The weak androgen **danazol** is used in the treatment of endometriosis (see above).

Androgens are sometimes given in combination with **estrogens** for replacement therapy in the postmenopausal period in an attempt to eliminate the endometrial bleeding that may occur when only **estrogens** are used and to enhance libido. They have been used for chemotherapy of breast tumors in premenopausal women.

**C. Use as Protein Anabolic Agents**

Androgens and anabolic steroids have been used in conjunction with dietary measures and exercises in an attempt to reverse protein loss after trauma, surgery, or prolonged immobilization and in patients with debilitating diseases. Evidence to support this use of androgens is poor except when hypogonadism is also present.

**D. Anemia**

In the past, large doses of androgens were employed in the treatment of refractory anemias such as aplastic anemia, Fanconi anemia, sickle cell

#### E. Osteoporosis

Androgens and anabolic agents have been used in the treatment of osteoporosis, either alone or in conjunction with **estrogens**. With the exception of substitution therapy in hypogonadism, bisphosphonates have largely replaced androgen use for this purpose.

#### F. Use as Growth Stimulators

These agents have been used to stimulate growth in boys with delayed puberty. If the drugs are used carefully, these children will probably achieve their expected adult height. If treatment is too vigorous, the patient may grow rapidly at first but will not achieve full predicted final stature because epiphyseal closure is accelerated. It is difficult to control this type of therapy adequately even with frequent x-ray examination of the epiphyses, since the action of the hormones on epiphyseal centers may continue for many months after therapy is discontinued.

#### G. Anabolic Steroid and Androgen Abuse in Sports

The use of anabolic steroids by athletes has received worldwide attention. Many athletes and their coaches believe that anabolic steroids—in doses 10–200 times larger than the daily normal physiologic production—increase strength and aggressiveness, thereby improving competitive performance. Such effects have been unequivocally demonstrated only in women. Furthermore, the adverse effects of these drugs clearly make their use inadvisable. As a result, most sports organizations have developed extremely sensitive assays, conduct random testing, and apply strong penalties if drugs are detected.

#### H. Aging Men

Androgen production falls with age in men and may contribute to a decline in muscle mass, strength, and libido. **Testosterone** levels decline gradually with advancing age after peaking in the second and third decades of life, and genetic factors, obesity and its comorbid conditions, and generally, the gradual age-dependent worsening of the so-called “chronic noncommunicable diseases,” influence the trajectory of age-related decline in **testosterone** levels. About 10% of middle-aged and older men have low morning fasting total **testosterone** (<250 ng/dL). Such men usually have low or inappropriately normal luteinizing hormone level, ie, secondary hypogonadism, while a smaller fraction has elevated luteinizing hormone, ie, primary hypogonadism. Age-related secondary hypogonadism is usually associated with presence of chronic noncommunicable diseases, while primary hypogonadism is mainly associated with age.

The majority of **testosterone** prescriptions today are written for middle aged and older men, even though **testosterone** is not approved by the US Food and Drug Administration (FDA) for age-related decline in **testosterone** levels. As experts have debated whether older men with **testosterone** deficiency might indeed benefit from **testosterone** treatment, several recent randomized controlled trials have provided important information on the efficacy and short-term safety of **testosterone** treatment in older men. Studies of androgen replacement in aging males with low **testosterone** levels show an increase in lean body mass and hematocrit and a decrease in bone turnover. Sense of well-being may improve, and increased energy and muscle strength are reported. To date, it does not seem that there is an association of this treatment with an increase in prostate cancer diagnosis. It is important to recommend, however, that the pros and the cons for an aging man’s decision to receive **testosterone** therapy should be discussed with an expert physician, the risk for prostate cancer should be taken into account, and careful monitoring of the patient should take place.

#### Adverse Effects

The adverse effects of these compounds are due largely to their masculinizing actions and are most noticeable in women and prepubertal children. In women, the administration of more than 200–300 mg of **testosterone** per month is usually associated with hirsutism, acne, amenorrhea, clitoral enlargement, and deepening of the voice. These effects may occur with even smaller doses in some women. Some of the androgenic steroids exert progestational activity, leading to endometrial bleeding upon discontinuation. These hormones also alter serum lipids and could conceivably increase susceptibility to atherosclerotic disease in women.

Except under the most unusual circumstances, androgens should not be used in infants. Recent studies in animals suggest that administration of androgens in early life may have profound effects on maturation of central nervous system centers governing sexual development, particularly in the female. Administration of these drugs to pregnant women may lead to masculinization or undermasculinization of the external genitalia in the female

www.drugs.com, respectively. Although the above-mentioned effects may be less marked with the anabolic agents, they do occur.

Sodium retention and edema are not common but must be carefully watched for in patients with heart and kidney disease.

Most of the synthetic androgens and anabolic agents are 17-alkyl-substituted steroids. Administration of drugs with this structure is often associated with evidence of hepatic dysfunction. Hepatic dysfunction usually occurs early in the course of treatment, and the degree is proportionate to the dose. Bilirubin levels may increase until clinical jaundice is apparent. The cholestatic jaundice is reversible upon cessation of therapy, and permanent changes do not occur. In older males, prostatic hyperplasia may develop, causing urinary retention.

Replacement therapy in men may cause acne, sleep apnea, erythrocytosis, gynecomastia, and azoospermia. Supraphysiologic doses of androgens produce azoospermia and decrease in testicular size, both of which may take months to recover after cessation of therapy. The alkylated androgens in high doses can produce peliosis hepatis, cholestasis, and hepatic failure. They lower plasma HDL and may increase LDL. Hepatic adenomas and carcinomas have also been reported. Behavioral effects include psychological dependence, increased aggressiveness, and psychotic symptoms.

### Contraindications & Cautions

The use of androgenic steroids is contraindicated in pregnant women or women who may become pregnant during the course of therapy.

Androgens should not be administered to male patients with carcinoma of the prostate or breast. Until more is known about the effects of these hormones on the central nervous system in developing children, they should be avoided in infants and young children.

Special caution is required in giving these drugs to children to produce a growth spurt. In most patients, the use of somatotropin is more appropriate (see [Chapter 37](#)).

Care should be exercised in the administration of these drugs to patients with renal or cardiac disease predisposed to edema. If sodium and water retention occurs, it will respond to diuretic therapy.

[Methyltestosterone](#) therapy is associated with creatinuria, but the significance of this finding is not known.

**Caution:** Several cases of hepatocellular carcinoma have been reported in patients with aplastic anemia treated with androgen anabolic therapy. Erythropoietin and colony-stimulating factors (see [Chapter 33](#)) should be used instead.

## ANDROGEN SUPPRESSION & ANTIANDROGENS

### ANDROGEN SUPPRESSION

In contrast to the lack of strong indications for the use of androgen supplementation (except in the case of hypogonadism), the use of inhibitors of androgen synthesis and of androgen antagonists has several well-documented applications. The treatment of advanced prostatic carcinoma often requires orchiectomy or large doses of [estrogens](#) to reduce available endogenous androgen. The psychological effects of the former and gynecomastia produced by the latter make these approaches undesirable. As noted in [Chapter 37](#), the GnRH analogs, such as [goserelin](#), [nafarelin](#), [buserelin](#), and [leuprolide](#) acetate, produce effective gonadal suppression when blood levels are continuous rather than pulsatile (see [Chapter 37](#) and [Figure 40–6](#)).

#### FIGURE 40–6

Control of androgen secretion and activity and some sites of action of antiandrogens: (1) competitive inhibition of GnRH receptors; (2) stimulation (+, pulsatile administration) or inhibition via desensitization of GnRH receptors (–, continuous administration); (3) decreased synthesis of [testosterone](#) in the testis; (4) decreased synthesis of dihydrotestosterone by inhibition of 5 $\alpha$ -reductase; (5) competition for binding to cytosol androgen receptors.

**ANTIANDROGENS**

The potential usefulness of antiandrogens in the treatment of patients producing excessive amounts of testosterone has led to the search for effective drugs that can be used for this purpose. Several approaches to the problem, especially inhibition of synthesis and receptor antagonism, have met with some success.

**Ketoconazole**, used primarily in the treatment of fungal disease, is an inhibitor of adrenal and gonadal steroid synthesis, as described in [Chapter 39](#). It does not affect ovarian aromatase, but it reduces human placental aromatase activity. It displaces **estradiol** and dihydrotestosterone from sex hormone-binding protein in vitro and increases the **estradiol:testosterone** ratio in plasma in vivo by a different mechanism. However, it does not appear to be clinically useful in women with increased androgen levels because of the toxicity associated with prolonged use of the 400–800 mg/d required. The drug has also been used experimentally to treat prostatic carcinoma, but the results have not been encouraging. Men treated with **ketoconazole** often develop reversible gynecomastia during therapy; this may be due to the demonstrated increase in the **estradiol:testosterone** ratio.

#### Inhibition of Conversion of Steroid Precursors to Androgens

Several compounds have been developed that inhibit the 17-hydroxylation of **progesterone** or pregnenolone, thereby preventing the action of the side chain-splitting enzyme and the further transformation of these steroid precursors to active androgens. A few of these compounds have been tested clinically but have been too toxic for prolonged use. As noted in [Chapter 39](#), **abiraterone**, a newer 17 $\alpha$ -hydroxylase inhibitor, has been approved for use in metastatic prostate cancer.

Since dihydrotestosterone—not testosterone—appears to be the essential androgen in the prostate, androgen effects in this and similar dihydrotestosterone-dependent tissues can be reduced by an inhibitor of 5 $\alpha$ -reductase (see [Figure 40–6](#)). **Finasteride**, a steroid-like inhibitor of this enzyme, is orally active and causes a reduction in dihydrotestosterone levels that begins within 8 hours after administration and lasts for about 24 hours. The half-life is about 8 hours (longer in elderly individuals). About 40–50% of the dose is metabolized; more than half is excreted in the feces. **Finasteride** has been reported to be moderately effective in reducing prostate size in men with benign prostatic hyperplasia and is approved for this use in the United States. The dosage is 5 mg/d. **Dutasteride** is a similar orally active steroid derivative with a slow onset of action and a much longer half-life than **finasteride**. It is approved for treatment of benign prostatic hyperplasia at a dosage of 0.5 mg daily. These drugs are not approved for use in women or children, although **finasteride** has been used successfully in the treatment of hirsutism in women and is approved for treatment of early male pattern baldness in men (1 mg/d). Toxicity includes decreased libido and possible erectile and ejaculatory dysfunction. A recent study suggested that, compared to antimuscarinic agents (**tamsulosin**), use of 5 $\alpha$ -reductase inhibitors may increase the risk of type 2 diabetes.

#### Receptor Inhibitors

**Flutamide**, a substituted anilide, is a potent antiandrogen that has been used in the treatment of prostatic carcinoma. Although not a steroid, it behaves like a competitive antagonist at the androgen receptor. It is rapidly metabolized in humans. It frequently causes mild gynecomastia (probably by increasing testicular estrogen production) and occasionally causes mild reversible hepatic toxicity. Administration of this compound causes some improvement in most patients with prostatic carcinoma who have not had prior endocrine therapy. Preliminary studies indicate that **flutamide** is also useful in the management of excess androgen effect in women.

Flutamide

**Bicalutamide**, **nilutamide**, and **enzalutamide** are potent orally active antiandrogens that can be administered as a single daily dose and are used in patients with metastatic carcinoma of the prostate. Studies in patients with carcinoma of the prostate indicate that these agents are well tolerated. **Bicalutamide** is recommended (to reduce tumor flare) for use in combination with a GnRH analog and may have fewer gastrointestinal side effects than **flutamide**. A dosage of 150–200 mg/d (when used alone) is required to reduce prostate-specific antigen levels to those achieved by castration, but, in combination with a GnRH analog, 50 mg/d may be adequate. **Nilutamide** is administered in a dosage of 300 mg/d for 30 days followed by 150 mg/d. The dosage of **enzalutamide** is 160 mg/d orally.

**Cyproterone** and **cyproterone acetate** are effective antiandrogens that inhibit the action of androgens at the target organ. The acetate form has a marked progestational effect that suppresses the feedback enhancement of LH and FSH, leading to a more effective antiandrogen effect. These compounds have been used in women to treat hirsutism and in men to decrease excessive sexual drive and are being studied in other conditions in which the reduction of androgenic effects would be useful. **Cyproterone** acetate in a dosage of 2 mg/d administered concurrently with an estrogen is used in the treatment of hirsutism in women, doubling as a contraceptive pill; it has orphan drug status in the United States.

**Spirolactone**, a competitive inhibitor of aldosterone (see Chapter 15), also competes with dihydrotestosterone for the androgen receptors in target tissues. It also reduces 17 $\alpha$ -hydroxylase activity, lowering plasma levels of **testosterone** and androstenedione. It is used in dosages of 50–200 mg/d in the treatment of hirsutism in women and appears to be as effective as **finasteride**, **flutamide**, or **cyproterone** in this condition.

## CHEMICAL CONTRACEPTION IN MEN

Although many studies have been conducted, an effective and nontoxic oral contraceptive for men has not yet been found. For example, various androgens, including **testosterone** and **testosterone** enanthate, in a dosage of 400 mg per month, produced azoospermia in less than half the men treated. Minor adverse reactions, including gynecomastia and acne, were encountered. **Testosterone** in combination with **danazol** was well tolerated but no more effective than **testosterone** alone. Androgens in combination with a progestin such as **medroxyprogesterone** acetate were no more effective. However, preliminary studies indicate that the intramuscular administration of 100 mg of **testosterone** enanthate weekly together with 500 mg of **levonorgestrel** daily orally can produce azoospermia in 94% of men. Retinoic acid is important in the maturation of sperm and the testis contains a unique isoform of the **alcohol** dehydrogenase enzyme that converts retinol to retinoic acid but no nontoxic inhibitor of this enzyme has been found to date.

**Cyproterone** acetate, a very potent progestin and antiandrogen, also produces oligospermia; however, it does not cause reliable contraception.

At present, pituitary hormones—and potent antagonist analogs of GnRH—are receiving increased attention. A GnRH antagonist in combination with **testosterone** has been shown to produce reversible azoospermia in nonhuman primates.

## GOSSYPOL

Extensive trials of this cottonseed derivative have been conducted in China. This compound destroys elements of the seminiferous epithelium but does not significantly alter the endocrine function of the testis.

In Chinese studies, large numbers of men were treated with 20 mg/d of gossypol or gossypol acetic acid for 2 months, followed by a maintenance dosage of 60 mg/week. On this regimen, 99% of men developed sperm counts below 4 million/mL. Preliminary data indicate that recovery (return of normal sperm count) following discontinuance of gossypol administration is more apt to occur in men whose counts do not fall to extremely low levels and when administration is not continued for more than 2 years. Hypokalemia is the major adverse effect and may lead to transient paralysis. Because of low efficacy and significant toxicity, gossypol has been abandoned as a candidate male contraceptive.

## PREPARATIONS AVAILABLE\*

GENERIC NAME	AVAILABLE AS
<b>ESTROGENS</b>	
Conjugated <b>estrogens</b> (equine)	Premarin
Diethylstilbestrol†	Generic, DES, Stilphostrol
Esterified <b>estrogens</b>	Cenestin, Enjuvia, Menest
<b>Estradiol</b>	Generic, Estrace, others
<b>Estradiol</b> cypionate in oil	Depo-Estradiol, others
<b>Estradiol</b> transdermal	Generic, Estraderm, Estrasorb, Estrogel, others
<b>Estradiol</b> valerate in oil	Generic, Delestrogen
Estropipate	Generic, Ogen
<b>PROGESTINS</b>	
<b>Levonorgestrel</b>	Generic, Plan B, others
<b>Medroxyprogesterone</b> acetate	Generic, Provera
<b>Megestrol</b> acetate	Generic, Megace
<b>Norethindrone</b> acetate	Generic, Aygestin
<b>Progesterone</b>	Generic, Prometrium, others
<b>ANDROGENS &amp; ANABOLIC STEROIDS</b>	
Fluoxymesterone	Androxy
<b>Methyltestosterone</b>	Android, others
Nandrolone decanoate	Generic, Deca Durabolin, others
<b>Oxandrolone</b>	Generic, Oxandrin
<b>Oxymetholone</b>	Androl-50
<b>Testosterone</b>	Generic

Testosterone enanthate in oil

Generic, Delatestryl

Testosterone transdermal system

Androderm, AndroGel

Testosterone pellets

Testopel

**ANTAGONISTS & INHIBITORS**(See also [Chapter 37](#))

Abiraterone

Zytiga

Anastrozole

Generic, Arimidex

Bazedoxifene (in combination with conjugated equine [estrogens](#))

Duavee

Bicalutamide

Generic, Casodex

Clomiphene

Generic, Clomid, Serophene, Milophene

Danazol

Generic, Danocrine

Dutasteride

Avodart

Enzalutamide

Xtandi

Exemestane

Generic, Aromasin

Finasteride

Generic, Propecia, Proscar

Flutamide

Generic, Eulexin

Fulvestrant

Faslodex

Letrozole

Generic, Femara

Mifepristone

Mifeprex, Korlym

Nilutamide

Nilandron

Raloxifene

Evista

Tamoxifen

Generic, Nolvadex

Toremifene

Fareston

\*Oral contraceptives are listed in [Table 40-3](#).

†Withdrawn in the United States.

## CASE STUDY ANSWER

The patient should be advised to start daily transdermal [estradiol](#) therapy (100 mcg/d) along with oral natural [progesterone](#) (200 mg/d) for the last 12 days of each 28-day cycle. On this regimen, her symptoms should disappear and normal monthly uterine bleeding resume. She should also be advised to get adequate exercise and increase her calcium and vitamin D intake as treatment for her osteoporosis.

## Chapter 41: Pancreatic Hormones & Glucose-Lowering Drugs

Umesh Masharani; Lisa Kroon

### CASE STUDY

#### CASE STUDY

A 66-year-old obese Caucasian man presented to an academic Diabetes Center for advice regarding his diabetes treatment. His diabetes was diagnosed 10 years previously on routine testing. He was initially given **metformin** but when he was no longer achieving his glycemic targets, the **metformin** was stopped and **insulin** treatment initiated. The patient was taking 50 units of **insulin** glargine and an average of 25 units of **insulin** aspart pre-meals. He had never seen a diabetes educator or a dietitian. He was checking his glucose levels four times a day and smoking half a pack of cigarettes a day. On examination, his weight was 132 kg (BMI 39.5) and blood pressure 145/71, and signs of mild peripheral neuropathy were present. Laboratory tests noted an HbA<sub>1c</sub> value of 8.1% (normal <5.7%), urine **albumin** 3007 mg/g creatinine (normal <30), serum creatinine 0.86 mg/dL, estimated GFR >69 mL/min/1.73 m<sup>2</sup>, total cholesterol 128 mg/dL, triglycerides 86 mg/dL, HDL cholesterol 38 mg/dL, and LDL cholesterol 73 mg/dL (on **atorvastatin** 40 mg daily). How would you treat this patient?

### THE ENDOCRINE PANCREAS

The endocrine pancreas in the adult human consists of approximately 1 million islets of Langerhans interspersed throughout the pancreatic gland. Within the islets, at least four hormone-producing cells are present (Table 41-1). Their hormone products include **insulin**, the storage and anabolic hormone of the body; **islet amyloid polypeptide (IAPP, or amylin)**, which modulates appetite, gastric emptying, and **glucagon** and **insulin** secretion; **glucagon**, the hyperglycemic factor that mobilizes glycogen stores; **somatostatin**, a universal inhibitor of secretory cells; **pancreatic peptide**, a small protein that facilitates digestive processes by a mechanism not yet clarified; and **ghrelin**, a peptide known to increase pituitary growth hormone release.

TABLE 41-1

**Pancreatic islet cells and their secretory products.**

Cell Types <sup>1</sup>	Approximate Percent of Islet Mass	Secretory Products
Alpha (A) cell	20	<b>Glucagon</b> , proglucagon
Beta (B) cell	75	<b>Insulin</b> , C-peptide, proinsulin, amylin
Delta (D) cell	3-5	Somatostatin
Epsilon cell	<1	Ghrelin

<sup>1</sup>Within pancreatic polypeptide-rich lobules of adult islets, located only in the posterior portion of the head of the human pancreas, **glucagon** cells are scarce (<0.5%) and F cells make up as much as 80% of the cells.

## Chemistry

Human **insulin** is a small protein with a molecular weight of 5808 that contains 51 amino acids arranged in two chains (A and B) linked by disulfide bridges. There are species differences in the amino acids of both chains. Proinsulin, a long single-chain protein molecule, is processed within the Golgi apparatus of beta cells and packaged into granules, where it is hydrolyzed into **insulin** and a residual connecting segment called C-peptide by removal of four amino acids (Figure 41-1).

FIGURE 41-1

Structure of human proinsulin (C-peptide plus A and B chains of **insulin**). **Insulin** is shown as the shaded (orange color) peptide chains, A and B. Differences in the A and B chains and amino acid modifications for the rapid-acting **insulin** analogs (aspart, lispro, and glulisine) and long-acting **insulin** analogs (degludec, detemir, and glargine) are discussed in the text.  Basic & Clinical Pharmacology, Sixteenth Edition  
 Copyright © McGraw Hill. All rights reserved.

**Insulin** and C-peptide are secreted in equimolar amounts in response to all **insulin** secretagogues; a small quantity of unprocessed or partially hydrolyzed proinsulin is released as well. Although proinsulin may have some mild hypoglycemic action, C-peptide has no known physiologic function. Granules within the beta cells store the **insulin** in the form of hexameric crystals consisting of two atoms of zinc and six molecules of **insulin**. The entire human pancreas contains up to 8 mg of **insulin**, representing approximately 200 biologic units. Originally, the unit was defined on the basis of the hypoglycemic activity of **insulin** in rabbits. With improved purification techniques, the unit is presently defined on the basis of weight, and present **insulin** standards used for assay purposes contain 28 units per milligram.

## Insulin Secretion

**Insulin** is released from pancreatic beta cells at a low basal rate and at a much higher stimulated rate in response to a variety of stimuli, especially glucose. Other stimulants such as other sugars (eg, mannose), amino acids (especially gluconeogenic amino acids, eg, leucine, **arginine**), hormones such as glucagon-like polypeptide 1 (GLP-1), glucose-dependent insulinotropic polypeptide (GIP), **glucagon**, cholecystokinin, high concentrations of fatty acids, and  $\beta$ -adrenergic sympathetic activity are recognized. Stimulatory drugs include sulfonylureas, meglitinides, D-phenylalanine derivatives, **isoproterenol**, and **acetylcholine**. Inhibitory signals are hormones including **insulin** itself, islet amyloid polypeptide, somatostatin, and leptin;  $\alpha$ -adrenergic sympathetic activity; chronically elevated glucose; and low concentrations of fatty acids. Inhibitory drugs include **diazoxide**, **phenytoin**, **vinblastine**, **clonidine**, **verapamil**, and **colchicine**.

One mechanism of stimulated **insulin** release is diagrammed in Figure 41-2. As shown in the figure, glucose is taken up by the beta cell through the transporter, GLUT2. Hyperglycemia results in increased intracellular ATP levels, which close ATP-dependent potassium channels. Decreased outward potassium efflux results in depolarization of the beta cell and opening of voltage-gated calcium channels. The resulting increased intracellular calcium triggers secretion of the hormone. The **insulin** secretagogue drug group (sulfonylureas, meglitinides, and D-phenylalanine derivatives) exhibit their glucose lowering effects through parts of this mechanism.

FIGURE 41-2

One model of control of **insulin** release from the pancreatic beta cell by glucose and by sulfonylurea drugs. In the resting cell with normal (low) ATP levels, potassium diffuses down its concentration gradient through ATP-gated potassium channels, maintaining the intracellular potential at a fully polarized, negative level. **Insulin** release is minimal. If glucose concentration rises, ATP production increases, potassium channels close, and depolarization of the cell results. As in muscle and nerve, voltage-gated calcium channels open in response to depolarization, allowing more calcium to enter the cell. Increased intracellular calcium results in increased **insulin** secretion. **Insulin** secretagogues close the ATP-dependent potassium channel, thereby depolarizing the membrane and causing increased **insulin** release by the same mechanism.

## Insulin Degradation

The liver and kidney are the two main organs that remove **insulin** from the circulation. The liver normally clears the blood of approximately 60% of the **insulin** released from the pancreas by virtue of its location as the terminal site of portal vein blood flow, with the kidney removing 35–40% of the endogenous hormone. However, in insulin-treated diabetics receiving subcutaneous **insulin** injections, this ratio is reversed, with as much as 60% of exogenous **insulin** being cleared by the kidney and the liver removing no more than 30–40%. The half-life of circulating **insulin** is 3–5 minutes.

## Circulating Insulin

Basal serum **insulin** values of 5–15  $\mu\text{U}/\text{mL}$  (30–90  $\text{pmol}/\text{L}$ ) are found in normal humans, with a peak rise to 60–90  $\mu\text{U}/\text{mL}$  (360–540  $\text{pmol}/\text{L}$ ) during meals.

## The Insulin Receptor

After **insulin** has entered the circulation, it diffuses into tissues, where it is bound by specialized receptors that are found on the membranes of most tissues. The biologic responses promoted by these insulin-receptor complexes have been identified in the primary target tissues regulating energy metabolism, ie, liver, muscle, and adipose tissue. The receptors bind **insulin** with high specificity and affinity in the picomolar range. The full **insulin** receptor consists of two covalently linked heterodimers, each containing an  $\alpha$  subunit, which is entirely extracellular and constitutes the recognition site, and a  $\beta$  subunit that spans the membrane (Figure 41–3). The  $\beta$  subunit contains a tyrosine kinase. The binding of an **insulin** molecule to the  $\alpha$  subunits at the outside surface of the cell activates the receptor and through a conformational change brings the catalytic loops of the opposing cytoplasmic  $\beta$  subunits into closer proximity. This facilitates mutual phosphorylation of tyrosine residues on the  $\beta$  subunits and tyrosine kinase activity directed at cytoplasmic proteins.

FIGURE 41–3

The first proteins to be phosphorylated by the activated receptor tyrosine kinases are the docking proteins: **insulin** receptor substrates (IRS). After tyrosine phosphorylation at several critical sites, the IRS molecules bind to and activate other kinases subserving energy metabolism—most significantly phosphatidylinositol-3-kinase—which produce further phosphorylations. Alternatively, they may stimulate a mitogenic pathway and bind to an adaptor protein such as growth factor receptor-binding protein 2, which translates the **insulin** signal to a guanine nucleotide-releasing factor that ultimately activates the GTP binding protein, Ras, and the mitogen-activated protein kinase (MAPK) system. The particular IRS-phosphorylated tyrosine kinases have binding specificity with downstream molecules based on their surrounding 4–5 amino acid sequences or motifs that recognize specific Src homology 2 (SH2) domains on the other protein. This network of phosphorylations within the cell represents **insulin**'s second message and results in multiple effects, including translocation of glucose transporters (especially GLUT 4, [Table 41-2](#)) to the cell membrane with a resultant increase in glucose uptake; increased glycogen synthase activity and increased glycogen formation; multiple effects on protein synthesis, lipolysis, and lipogenesis; and activation of transcription factors that enhance DNA synthesis and cell growth and division.

## Glucose transporters.

Transporter	Tissues	Glucose $K_m$ (mmol/L)	Function
GLUT 1	All tissues, especially red cells, brain	1–2	Basal uptake of glucose; transport across the blood-brain barrier
GLUT 2	Beta cells of pancreas; liver, kidney; gut	15–20	Regulation of <b>insulin</b> release, other aspects of glucose homeostasis
GLUT 3	Brain, placenta	<1	Uptake into neurons, other tissues
GLUT 4	Muscle, adipose	~5	Insulin-mediated uptake of glucose
GLUT 5	Gut, kidney	1–2	Absorption of fructose

Various hormonal agents (eg, glucocorticoids) lower the affinity of **insulin** receptors for **insulin**; growth hormone in excess increases this affinity slightly. Aberrant serine and threonine phosphorylation of the **insulin** receptor  $\beta$  subunits or IRS molecules may result in **insulin** resistance and functional receptor down-regulation.

### Effects of **Insulin** on Its Targets

**Insulin** promotes the storage of fat as well as glucose (both sources of energy) within specialized target cells (Figure 41-4) and influences cell growth and the metabolic functions of a wide variety of tissues (Table 41-3).

#### FIGURE 41-4

**Insulin** promotes synthesis (from circulating nutrients) and storage of glycogen, triglycerides, and protein in its major target tissues: liver, fat, and muscle. The release of **insulin** from the pancreas is stimulated by increased blood glucose, incretins, vagal nerve stimulation, and other factors (see text).

**Endocrine effects of insulin.**

<b>Effect on liver:</b>
Reversal of catabolic features of <b>insulin</b> deficiency
Inhibits glycogenolysis
Inhibits conversion of fatty acids and amino acids to keto acids
Inhibits conversion of amino acids to glucose
Anabolic action
Promotes glucose storage as glycogen (induces glucokinase and glycogen synthase, inhibits phosphorylase)
Increases triglyceride synthesis and very-low-density lipoprotein formation
<b>Effect on muscle:</b>
Increased protein synthesis
Increases amino acid transport
Increases ribosomal protein synthesis
Increased glycogen synthesis
Increases glucose transport
Induces glycogen synthase and inhibits phosphorylase
<b>Effect on adipose tissue:</b>
Increased triglyceride storage
Lipoprotein lipase is induced and activated by <b>insulin</b> to hydrolyze triglycerides from lipoproteins
Glucose transport into cell provides glycerol phosphate to permit esterification of fatty acids supplied by lipoprotein transport
Intracellular lipase is inhibited by <b>insulin</b>

## GLUCAGON

### Chemistry & Metabolism

**Glucagon** is synthesized in the alpha cells of the pancreatic islets of Langerhans (see Table 41-1). **Glucagon** is a peptide—identical in all mammals—consisting of a single chain of 29 amino acids, with a molecular weight of 3485. Selective proteolytic cleavage converts a large precursor molecule of

approximately 18,000 MW to **glucagon**. One of the precursor intermediates consists of a 69-amino-acid peptide called **glicentin**, which contains the **glucagon** sequence interposed between peptide extensions.

**Glucagon** is extensively degraded in the liver and kidney as well as in plasma and at its tissue receptor sites. Its half-life in plasma is between 3 and 6 minutes, which is similar to that of **insulin**.

### Pharmacologic Effects of **Glucagon**

The first six amino acids at the amino terminal of the **glucagon** molecule bind to specific  $G_s$  protein-coupled receptors on liver cells. This leads to an increase in cAMP, which facilitates catabolism of stored glycogen and increases gluconeogenesis and ketogenesis. The immediate pharmacological result of **glucagon** infusion is to raise blood glucose by using stored hepatic glycogen. There is no effect on skeletal muscle glycogen, presumably because of the lack of **glucagon** receptors on skeletal muscle. Pharmacological amounts of **glucagon** cause release of **insulin** from normal pancreatic beta cells, catecholamines from pheochromocytoma, and **calcitonin** from medullary carcinoma cells.

**Glucagon** has a potent inotropic and chronotropic effect on the heart, mediated by the cAMP mechanism described above. Thus, it produces an effect very similar to that of  $\beta$ -adrenoceptor agonists without requiring functioning  $\beta$  receptors.

Large doses of **glucagon** produce profound relaxation of the intestine. In contrast to the above effects of the peptide, this action on the intestine may be due to mechanisms other than adenylyl cyclase activation.

### Clinical Uses

The major clinical use of **glucagon** is for emergency treatment of severe hypoglycemic reactions due to **insulin** therapy when a person is unable to self-treat with oral glucose (eg, unconsciousness) and intravenous glucose treatment is not possible. Recombinant **glucagon** is currently available in a 1-mg vial for parenteral (IV, IM, or SC) use; a single-dose 0.5-mg (for pediatric patients) or 1-mg (for adults) pen or prefilled syringe for subcutaneous injection; and a 3-mg dose of a nasal powder for inhalation. The main adverse effect is transient nausea and occasional vomiting. It is therefore important to place unconscious patients on their side after administering the drug.

Intravenous **glucagon** is commonly used in the endoscopic retrograde cholangiopancreatography procedure to facilitate the relaxation of the sphincter of Oddi. **Glucagon** is sometimes used in the treatment of beta blocker overdose because of the drug's ability to increase cAMP production in the heart independent of  $\beta$ -receptor function.

**Glucagon** should not be given to patients with pheochromocytoma in whom it can cause release of catecholamines and increase blood pressure; it also should not be given to patients with insulinoma where it can cause rebound hypoglycemia.

## DIABETES MELLITUS

**Diabetes mellitus** is defined as an elevated blood glucose associated with absent or inadequate pancreatic **insulin** secretion, with or without concurrent impairment of **insulin** action. The disease states underlying the diagnosis of diabetes mellitus are now classified into four categories: **type 1**, **type 2**, **other specific types**, and **gestational diabetes mellitus**.

### Type 1 Diabetes Mellitus

The hallmark of type 1 diabetes is selective beta cell destruction and *severe* or *absolute* **insulin** deficiency. Type 1 diabetes is further subdivided into immune-mediated (type 1a) and idiopathic causes (type 1b). The immune form is the most common form of type 1 diabetes. Although most patients are younger than 30 years of age at the time of diagnosis, the onset can occur at any age. Type 1 diabetes is found in all ethnic groups, but the highest incidence is in people from northern Europe and from Sardinia. Susceptibility appears to involve a multifactorial genetic linkage, but only 10–15% of patients have a positive family history. Most patients with type 1 diabetes have one or more circulating antibodies, including antibodies to glutamic acid decarboxylase 65 (GAD 65), **insulin** autoantibody, tyrosine phosphatase IA2 (ICA 512), and zinc transporter 8 (ZnT8) at the time of diagnosis. These antibodies facilitate the diagnosis of type 1a diabetes and can also be used to screen family members at risk for developing the disease. Most type 1 diabetes patients with acute symptomatic presentation have significant beta cell loss and **insulin** therapy is essential to control glucose levels and to

Some patients have a more indolent autoimmune process and initially retain enough beta cell function to avoid ketosis. They can be treated at first with oral glucose-lowering agents but then need [insulin](#) as their beta cell function declines. Antibody studies in northern Europeans indicate that up to 10–15% of “type 2” patients may actually have this milder form of type 1 diabetes (latent autoimmune diabetes of adulthood; LADA).

The CD3 complex is the major signal-transducing element of the T-cell receptor, and anti-CD3 antibodies have been shown to modulate the autoimmune response in persons with type 1 diabetes. **Teplizumab-mzwv**, a humanized monoclonal antibody against CD3, has been approved for use in individuals at high risk for type 1 diabetes (two positive antibodies and impaired glucose tolerance [stage 2 type 1 diabetes]) age 8 and older. The drug is infused daily for 14 days. The treatment delays the time to onset of overt type 1 diabetes (ie, stage 3 type 1 diabetes) by 25 months. Common adverse reactions include transient decreases in white cell and lymphocyte counts, rash, and headache.

## Type 2 Diabetes Mellitus

Type 2 diabetes is a heterogenous group of conditions characterized by tissue resistance to the action of [insulin](#) combined with a *relative* deficiency in [insulin](#) secretion. A given individual may have more [insulin](#) resistance or more beta cell deficiency, and the glucose abnormalities may be mild or severe. Although the circulating endogenous [insulin](#) is sufficient to prevent ketoacidosis, it is inadequate to prevent hyperglycemia. Patients with type 2 diabetes can initially be controlled with diet, exercise, and non-insulin glucose-lowering drugs (oral and injectable). Some patients have progressive beta cell failure and eventually may also need [insulin](#) therapy.

## Other Specific Types of Diabetes Mellitus

The “other” designation refers to multiple *other* specific causes of an elevated blood glucose: pancreatectomy, pancreatitis, non-pancreatic diseases, drug therapy, etc. For a detailed list the reader is referred to the American Diabetes Association report, 2014.

## Gestational Diabetes Mellitus

Gestational diabetes (GDM) is defined as any abnormality in glucose levels noted for the first time during pregnancy. Gestational diabetes is diagnosed in approximately 7% of all pregnancies in the United States. During pregnancy, the placenta and placental hormones create an [insulin](#) resistance that is most pronounced in the last trimester. Risk assessment for diabetes is suggested starting at the first prenatal visit. High-risk women should be screened immediately. Screening may be deferred in lower-risk women until the 24th to 28th week of gestation.

## Laboratory Findings

### A. Plasma or Serum Glucose

A plasma glucose level of 126 mg/dL (7 mmol/L) or higher on more than one occasion after at least 8 hours of fasting is diagnostic of diabetes mellitus (see [Table 41–4](#)). Fasting plasma glucose levels of 100–125 mg/dL (5.6–6.9 mmol/L) are associated with increased risk of diabetes (impaired fasting glucose tolerance).

**Diagnostic criteria for diabetes.**

	<b>Normal Glucose Tolerance, mg/dL (mMol/L)</b>	<b>Prediabetes</b>	<b>Diabetes Mellitus<sup>2</sup></b>
Fasting plasma glucose mg/dL (mmol/L)	<100 (5.6)	100–125 (5.6–6.9) (impaired fasting glucose)	≥126 (7.0)
Two hours after glucose load <sup>1</sup> mg/dL (mmol/L)	<140 (7.8)	≥140.199 (7.8–11.0) (impaired glucose tolerance)	≥200 (11.1)
HbA <sub>1c</sub> (%) (ADA criteria)	<5.7	5.7–6.4	≥6.5

<sup>1</sup>Give 75 g of glucose dissolved in 300 mL of water after an overnight fast in persons who have been receiving at least 150–200 g of carbohydrate daily for 3 days before the test.

<sup>2</sup>A fasting plasma glucose ≥126 mg/dL (7.0 mmol) or HbA<sub>1c</sub> ≥6.5% is diagnostic of diabetes if confirmed by repeat testing.

Symptoms and random glucose level >200 mg/dL (11.1 mmol/L) are diagnostic, and there is no need to do additional testing.

**B. Hemoglobin A<sub>1c</sub> Measurements**

When plasma glucose levels are in the normal range, about 4–6% of hemoglobin A has one or both of the N terminal valines of their beta chains irreversibly glycosylated by glucose—referred to as hemoglobin<sub>1c</sub> (HbA<sub>1c</sub>). The HbA<sub>1c</sub> fraction is abnormally elevated in people with diabetes with chronic hyperglycemia. Since red blood cells have a lifespan of up to 120 days, the HbA<sub>1c</sub> value reflects plasma glucose levels over the preceding 8–12 weeks.

In patients who monitor their glucose levels, the HbA<sub>1c</sub> value provides a valuable check on the accuracy of their monitoring. In patients who do not monitor their glucose levels, HbA<sub>1c</sub> measurements are essential for adjusting treatment. The American Diabetes Association has endorsed the use of HbA<sub>1c</sub> as a diagnostic test for diabetes. A cutoff value of 6.5% was chosen because the risk of retinopathy increases substantially above this value. Less than 5.7% is normal, and patients with levels of 5.7–6.4% are considered at high risk for developing diabetes (see Table 41-4).

**C. Oral Glucose Tolerance Test**

If either the HbA<sub>1c</sub> level is less than 6.5% or the fasting plasma glucose level is less than 126 mg/dL (7 mMol/L) but diabetes is nonetheless suspected, then a standardized oral glucose tolerance test may be done (see Table 41-4). The patient should eat nothing after midnight prior to the test day. On the morning of the test, adults are then given 75 g of glucose in 300 mL of water; children are given 1.75 g of glucose per kilogram of ideal body weight. The glucose load is consumed within 5 minutes. Patients should not smoke or be active during the test. Blood samples for plasma glucose are obtained at 0 and 120 minutes after ingestion of glucose. An oral glucose tolerance test is normal if the fasting venous plasma glucose value is less than 100 mg/dL (5.6 mmol/L) and the 2-hour value falls below 140 mg/dL (7.8 mmol/L). A fasting value of 126 mg/dL (7 mmol/L) or higher or a 2-hour value of greater than 200 mg/dL (11.1 mmol/L) is diagnostic of diabetes mellitus. Patients with 2-hour value of 140–199 mg/dL (7.8–11.1 mmol/L) have impaired glucose tolerance.

**D. Urine or Blood Ketones**

Qualitative detection of ketone bodies can be accomplished by **nitroprusside** tests (Acetest or Ketostix). Although these tests do not detect beta-hydroxybutyric acid, which lacks a ketone group, the semiquantitative estimation of ketonuria thus obtained is nonetheless usually adequate for clinical purposes. Many laboratories now measure beta-hydroxybutyric acid, and meters are available (FORA meters; Nova Max Plus) for patient use that measure beta-hydroxybutyric acid levels in capillary blood glucose samples. Beta-hydroxybutyrate levels >0.6 mmol/L require evaluation. A level >3.0 mmol/L, which is equivalent to very high urinary ketones, will require hospitalization.

#### E. Self-Monitoring of Capillary Blood Glucose

Many blood glucose meters are available for measuring glucose from capillary blood samples. All are accurate, but they vary with regard to speed, convenience, size of blood samples required, reporting capability, and cost. Some meters are designed to communicate with an **insulin** pump. Providers and patients should be aware of the limitations of the blood glucose monitoring (BGM) systems. BGM strips have expiration dates; expired strips should not be used. Improper storage of strips (high temperature; open bottle) can affect their function. Conditions that impair the circulation to the fingers can artificially lower blood glucose measurements. When capillary glucose levels are measured at alternate sites such as the forearm, there can be a 5- to 20-minute lag in glucose response on the arm with respect to the glucose response on the finger. For this reason, alternate-site testing should not be used when the glucose is rapidly changing (eg, postprandial or if hypoglycemia is suspected).

#### F. Continuous Glucose Monitors

These systems utilize a subcutaneous sensor that measures glucose concentrations in the interstitial fluid for 10–14 days. Studies show that pediatric and adult patients with type 1 diabetes who use continuous glucose monitoring (CGM) devices have improved glucose control without an increased incidence of hypoglycemia. The glucose data are transmitted wirelessly to smart phones and the screens of **insulin** pumps. There are directional arrows that indicate rate and direction of change of glucose levels, and alerts can be set for high and low glucose levels. The data from these CGM devices can be used to automatically deliver **insulin** by continuous subcutaneous **insulin** infusion pump (closed loop systems).

## MEDICATIONS FOR HYPERGLYCEMIA

### Insulin Preparations

Human **insulin** is dispensed as regular (R) and neutral **protamine** hagedorn (NPH) formulations. There are also six analogs of human **insulin**. Three of the analogs are rapidly acting: **insulin** lispro, **insulin** aspart, and **insulin** glulisine; and three are long acting: **insulin** glargine, **insulin** detemir, and **insulin** degludec. Animal insulins are not available in the United States. Pork and beef preparations (isophane, neutral, 70/30, and lente) are still available in other parts of the world. Most insulins in the United States are available in a concentration of 100 units/mL (U100) and dispensed as 10-mL vials or 0.3-mL cartridges or prefilled disposable pens. Several insulins are also available at higher concentrations in the prefilled disposable pen form: **insulin** glargine 300 units/mL (U300); **insulin** degludec 200 units/mL (U200); **insulin** lispro 200 units/mL (U200); and regular **insulin** 500 units/mL (U500) (Tables 41–5, 41–6).

Summary of bioavailability characteristics of the insulins.

Insulin Preparations	Onset of Action	Peak Action	Effective Duration
Insulins lispro, aspart, glulisine	5–15 min	1–1.5 h	3–4 h
Human regular	30–60 min	2 h	6–8 h
Technosphere inhaled insulin	5–15 min	1 h	3 h
Human NPH	2–4 h	6–7 h	10–20 h
Insulin glargine	0.5–1 h	Flat	~24 h
Insulin detemir	0.5–1 h	Flat	17 h
Insulin degludec	0.5–1.5 h	Flat	>42 h

Some **insulin** preparations available in the United States.

Preparation	Species Source	Concentration
Short-acting insulins		
<b>Insulin</b> lispro (Humalog, Lyumjev, Lilly; Admelog, sanofi-aventis)	Human analog	U100 U200 (Humalog and Lyumjev only)
<b>Insulin</b> aspart, <b>insulin</b> aspart <b>niacinamide</b> (Novolog, Fiasp, Novo Nordisk)	Human analog	U100
<b>Insulin</b> glulisine (Apidra, sanofi-aventis)	Human analog	U100
Regular <b>insulin</b> (Humulin R, Lilly; Novolin R, Novo Nordisk)	Human	U100 U500 (Humulin R only)
Regular <b>insulin</b> inhaled (MannKind)	Human	—
Long-acting insulins		
NPH <b>insulin</b> (Humulin N, Lilly; Novolin N, Novo Nordisk)	Human	U100
<b>Insulin</b> glargine (Lantus, Toujeo, sanofi-aventis; Basaglar, Rezvoglar, Lilly; Semglee, <sup>1</sup> Mylan)	Human analog	U100 U300 (Toujeo only)
<b>Insulin</b> detemir (Levemir, Novo Nordisk)	Human analog	U100
<b>Insulin</b> degludec (Tresiba, Novo Nordisk)	Human analog	U100, U200
Premixed insulins		
70 NPH/30 regular (Novolin, Novo Nordisk; Humulin, Lilly)	Human	U100
75/25 NPL, Lispro (Humalog mix 75/25, Lilly)	Human analog	U100
50/50 NPL, Lispro (Humalog mix 50/50, Lilly)	Human analog	U100
70/30 NPA, Aspart (Novolog mix 70/30, Novo Nordisk)	Human analog	U100
70/30 Degludec/Aspart (Ryzodeg, Novo Nordisk)	Human analog	U100

All insulins are now made by recombinant technology; they should be refrigerated and brought to room temperature just before injection.

NPA, neutral **protamine** aspart; NPL, neutral **protamine** lispro.

<sup>1</sup>Semglee and Rezvoglar are interchangeable (biosimilar) insulins with Lantus.

#### A. Short-Acting **Insulin** Preparations

The short-acting preparations include regular human **insulin** and the three rapid-acting **insulin** analogs (Tables 41-5, 41-6). All are clear solutions at neutral pH. The **insulin** molecules exist as dimers that assemble into hexamers in the presence of two zinc ions. The hexamers are further stabilized by phenolic compounds such as **phenol** and meta-Cresol. The mutations engineered into the rapidly acting **insulin** analogs are designed to disrupt the stabilizing intermolecular interactions of the dimers and hexamers, leading to more rapid absorption into the circulation after subcutaneous injection.

### 1. Regular **insulin**

Regular **insulin** is a short-acting, soluble crystalline zinc **insulin** whose hypoglycemic effect appears within 30 minutes after subcutaneous injection, peaks at about 2 hours, and lasts for 5-7 hours when usual quantities (ie, 5-15 U) are administered. For very insulin-resistant subjects who would otherwise require large volumes of **insulin** solution, a U500 preparation of human regular **insulin** is available both in a vial and a disposable pen. A U500 **insulin** syringe should be used to measure the dose when using the vial. If a U100 **insulin** syringe or tuberculin syringe is used, then the clinician should carefully note the dose in both units and volume to avoid overdosage. The disposable pen avoids this conversion issue and dispenses the regular U500 **insulin** in 5-unit increments. U-500 regular **insulin**, a concentrated **insulin**, has a different time action profile than U-100 regular **insulin**; it is similar to NPH **insulin**.

When intravenous **insulin** is needed (eg, inpatient setting), regular **insulin** is used; it is particularly useful in the treatment of diabetic ketoacidosis and during perioperative glucose management.

### 2. Rapidly acting **insulin** analogs

**Insulin** lispro (Humalog) is an **insulin** analog in which the proline at position B28 is reversed with the lysine at B29. **Insulin** aspart (Novolog, Admelog, FiAsp) is a single substitution of proline by aspartic acid at position B28. **Insulin** glulisine (Apidra) differs from human **insulin** in that the amino acid asparagine at position B3 is replaced by lysine and the lysine in position B29 by glutamic acid. When injected subcutaneously, these three analogs quickly dissociate into monomers and are absorbed very rapidly, reaching peak serum values in as little as 1 hour. The amino acid changes in these analogs do not interfere with their binding to the **insulin** receptor, with the circulating half-life, or with their immunogenicity, which are all identical to those of human regular **insulin**. An **insulin** aspart formulation (FiAsp) that contains **niacinamide** (Vitamin B<sub>3</sub>) has a more rapid absorption and its onset of action is about 10 minutes faster than the standard **insulin** aspart formulation. Similarly, there is an **insulin** lispro formulation (Lyumjev) whose onset of action is 11 minutes faster than the **insulin** lispro formulation. This formulation contains citrate and **treprostinil**. The former increases vascular permeability and the latter induces vasodilatation, thus increasing the subcutaneous absorption speed.

Clinical trials have demonstrated that the optimal times of preprandial rapidly acting **insulin** analogs and regular human **insulin** are 15 minutes and 45 minutes before the meal, respectively. The rapidly acting insulins are more convenient as patients can inject immediately before eating and do not have to wait as with regular **insulin**. It is important that patients ingest adequate carbohydrate early in the meal to avoid hypoglycemia during the meal. These analogs also have lowest variability of absorption: approximately 5% variation, compared to 25% for regular **insulin**. Another desirable feature of rapidly acting **insulin** analogs is that their duration of action is consistently about 4 hours for most commonly used dosages. This contrasts with regular **insulin**, whose duration of action is significantly prolonged when larger doses are used.

The rapidly acting analogs are the **insulin** of choice for **insulin** pumps. In a double-blind crossover study comparing **insulin** lispro with regular **insulin** in **insulin** pumps, patients using **insulin** lispro had lower HbA<sub>1c</sub> values and improved postprandial glucose control with the same frequency of hypoglycemia.

## B. Long-Acting **Insulin** Preparations

### 1. NPH (neutral **protamine** Hagedorn, or isophane) **insulin**

NPH **insulin** is an intermediate-acting **insulin** whose absorption and onset of action are delayed by combining appropriate amounts of **insulin** and **protamine** so that neither is present in an uncomplexed form ("isophane") (Tables 41-5, 41-6). After subcutaneous injection, proteolytic tissue enzymes degrade the **protamine** to permit absorption of **insulin**. NPH **insulin** has an onset of approximately 2-4 hours, peak action 6-7 hours and duration of 10-20 hours (Figure 41-5); it is usually mixed with regular, lispro, aspart, or glulisine **insulin** and given two to four times daily for **insulin** replacement. The dose regulates the action profile; specifically, small doses have lower, earlier peaks and a short duration of action with the converse

Extent and duration of action of various types of **insulin** as indicated by the glucose infusion rates (mg/kg/min) required to maintain a constant glucose concentration. The durations of action shown are typical of an average dose of 0.2–0.3 U/kg. The durations of regular and NPH **insulin** increase considerably when dosage is increased.

## 2. **Insulin glargine**

**Insulin glargine** is a soluble, “peakless” (ie, having a broad plasma concentration plateau), long-acting **insulin** analog. The attachment of two **arginine** molecules to the B-chain carboxyl terminal and substitution of a glycine for asparagine at the A21 position created an analog that is soluble in an acidic solution but precipitates in the more neutral body pH after subcutaneous injection. Individual **insulin** molecules slowly dissolve away from the crystalline depot and provide a low, continuous level of circulating **insulin**. **Insulin glargine** has a slow onset of action (0.5–1 hours) and the effective duration of action is approximately 24 hours. Glargine is usually given once daily, although some very insulin-sensitive individuals (requiring small doses, less than about 20 units daily) or insulin-resistant individuals (requiring very large doses) benefit from split (twice a day) dosing. To maintain solubility, the formulation is unusually acidic (pH 4.0), and **insulin glargine** should not be mixed with other insulins. If administered via a syringe, a separate syringe must be used to minimize the risk of contamination and subsequent loss of efficacy. The absorption pattern of **insulin glargine** appears to be independent of the anatomic site of injection, and this drug is associated with less immunogenicity than human **insulin** in animal studies. Glargine’s interaction with the **insulin** receptor is similar to that of native **insulin** and shows no increase in mitogenic activity in vitro. It has sixfold to sevenfold greater binding than native **insulin** to the insulin-like growth factor 1 (IGF-1) receptor, but the clinical significance of this is unclear.

## 3. **Insulin detemir**

In this **insulin**, the terminal threonine is dropped from the B30 position and myristic acid (a C-14 fatty acid chain) is attached to the B29 lysine. These modifications prolong the availability of the injected analog by increasing both self-aggregation in subcutaneous tissue and reversible **albumin** binding. The affinity of **insulin detemir** is four- to five-fold lower than that of human soluble **insulin** and, therefore, the U100 formulation of **insulin detemir** has a concentration of 2400 nmol/mL compared with 600 nmol/mL for NPH. The duration of action for **insulin detemir** is about 17 hours at therapeutically relevant doses. It is recommended that the **insulin** be injected once or twice a day to achieve a stable basal coverage. This **insulin** has been reported to have lower within-subject pharmacodynamic variability compared with NPH **insulin** and **insulin glargine**.

## 4. **Insulin degludec**

In this **insulin** analog, the threonine at position B30 has been removed and the lysine at position B29 is conjugated to hexadecanoic acid via a gamma-L-glutamyl spacer. In solution and in the presence of **phenol** and zinc, the **insulin** is in the form of dihexamers; however, when injected subcutaneously, it self-associates into large multihexameric chains consisting of thousands of dihexamers. The chains slowly dissolve in the subcutaneous tissue, and **insulin** monomers are steadily released into the systemic circulation. The half-life of the **insulin** is 25 hours. Its onset of action is in 30–90 minutes, and its duration of action is more than 42 hours. Degludec is generally injected once a day to achieve a stable basal coverage. **Insulin degludec** is available

This is a basal **insulin** analog that is given once a week. The lysine at B29 of the **insulin** is conjugated to 1,20-icosanedioic acid (C20). There are three amino acid substitutions (A14E, B16H and B25H). The C20 diacid group results in strong, reversible binding to **albumin** thus delaying SC absorption, and the amino acid substitutions attenuate **insulin** receptor affinity and increase resistance to degradation.

#### 6. *Mixtures of insulins*

Because intermediate-acting NPH insulins require several hours to reach adequate therapeutic levels, their use in patients with diabetes usually requires supplements of rapid- or short-acting **insulin** before meals. For convenience, these can be mixed together in the same syringe before injection. The regular **insulin** or rapidly acting **insulin** analog is withdrawn first, then the NPH **insulin**, and then the mixture is injected immediately.

Stable premixed insulins (70% NPH and 30% regular) are available as a convenience to patients who have difficulty mixing **insulin** because of visual problems or insufficient manual dexterity. Premixed preparations of rapidly acting **insulin** analogs (lispro, aspart) and NPH are not stable because of exchange of the rapidly acting **insulin** analog for the human regular **insulin** in the **protamine** complex. Consequently, over time, the soluble component becomes a mixture of regular and rapidly acting **insulin** analog at varying ratios. To remedy this problem, intermediate insulins composed of isophane complexes of **protamine** with the rapidly acting **insulin** analogs were developed (neutral **protamine** lispro [NPL]; aspart **protamine**). Premixed combinations of NPL and **insulin** lispro are now available for clinical use (Humalog Mix 75/25 and Humalog Mix 50/50). These mixtures have a more rapid onset of glucose-lowering activity compared with 70% NPH/30% regular human **insulin** mixture and can be given within 15 minutes before or after starting a meal. A similar 70% **insulin** aspart **protamine**/30% **insulin** aspart (NovoLog Mix 70/30) is now available. The main advantages of these new mixtures are that (1) they can be given within 15 minutes of starting a meal and (2) they are more effective in achieving glucose targets with the postprandial glucose rise after a carbohydrate-rich meal. **Insulin** glargine and **insulin** detemir cannot be mixed in the same syringe with other insulins.

### Insulin Delivery Systems

#### A. **Insulin** Syringes and Needles

Disposable plastic syringes with needles attached are available in 1-mL (100 units), 0.5-mL (50 units), and 0.3-mL (30 units) sizes. The “low-dose” 0.3-mL syringes are popular because many patients with diabetes do not take more than 30 units of **insulin** in a single injection and the markings are easier to read. They are also available in half-unit markings. Three lengths of needles are available; longer needles are preferable in overweight/obese patients to ensure **insulin** absorption. If the skin is clean, it is not necessary to use **alcohol**. Rotation of sites is recommended to avoid problems with absorption due to lipohypertrophy from overuse of injection sites.

#### B. **Insulin** Pens

The pens eliminate the need for carrying **insulin** vials and syringes. Cartridges of **insulin** aspart and lispro are available for reusable pens (Novo Nordisk, Medtronic, and Owen Mumford). Smart pens are available that pair with the patient’s smart phone and help the patient calculate doses and keep track of the injections. Disposable prefilled pens are also available for regular **insulin** (U100, U500), **insulin** lispro, **insulin** aspart, **insulin** glulisine, **insulin** detemir, **insulin** glargine, **insulin** degludec, NPH, 70% NPH/30% regular, 75% NPL/25% **insulin** lispro, 50% NPL/50% **insulin** lispro, 70% **insulin** aspart **protamine**/30% **insulin** aspart, and 70% **insulin** degludec/30% **insulin** aspart (Table 41–6).

#### C. Continuous Subcutaneous **Insulin** Infusion Devices (CSII, **Insulin** Pumps)

In the United States, Medtronic MiniMed, Insulet, and Tandem make battery-operated pumps for continuous subcutaneous **insulin** infusion (CSII). The externally worn pumps are about the size of a pager and they deliver short-acting **insulin** throughout the day and night. The catheter connecting the **insulin** reservoir to the subcutaneous cannula can be disconnected, allowing the patient to remove the pump temporarily (eg, for bathing). Omnipod (Insulet Corporation) is a disposable waterproof electronic patch pump in which the **insulin** reservoir and infusion set are integrated into one unit (pod), so there is no catheter. The pod, placed on the skin, delivers subcutaneous basal and bolus **insulin** based on wirelessly transmitted instructions from a personal digital assistant.

Another advantage of an **insulin** pump is that it allows for establishment of a basal profile tailored to the patient allowing for better overnight, between-

meals glucose control, and management of glycemic excursions that occur with exercise. Software assists the patient in calculating boluses based on glucose reading and carbohydrates to be consumed. The **insulin** pumps keep track of the time elapsed since the last **insulin** bolus and reduce the risk of overcorrecting and subsequent hypoglycemia.

CSII therapy is appropriate for patients with type 1 diabetes who are motivated, mechanically inclined, educated about diabetes (diet, **insulin** action, treatment of hypoglycemia and hyperglycemia), and willing to monitor their blood glucose four to six times a day. Known complications of CSII include ketoacidosis, which can occur when **insulin** delivery is interrupted, and skin infections. Another disadvantage is its cost and the additional time needed by the clinician and staff to initiate therapy. Almost all patients use rapidly acting **insulin** analogs in their pumps.

V-Go (MannKind) is a wearable patch pump designed specifically for people with type 2 diabetes who use a basal/bolus **insulin** regimen. The device uses rapid-acting **insulin** and is preset to deliver one of three fixed and flat basal rates (0.83 units/h [20 units], 1.25 units/h [30 units], or 1.67 units/h [40 units]) for 24 hours (at which point the device must be replaced). It can also deliver 2-unit increments (up to 36 units) by pressing a button, for meal coverage and high sugar correction. CeQur Simplicity (CeQur) is a 3-day wearable patch device that holds 200 units of rapid-acting **insulin** and delivers 2-unit increments of rapid-acting **insulin** by squeezing two buttons for meal coverage and high sugar correction.

#### D. Closed-Loop Systems

Algorithms have been devised to use glucose data from the CGM systems to automatically deliver **insulin** by CSII pump. These closed-loop systems (“artificial pancreas”) have been shown to reduce nighttime hypoglycemia and lower HbA1c levels. The MiniMed 770 G closed loop uses glucose data from a sensor to automatically adjust basal **insulin** doses every 5 minutes, targeting a sensor glucose level of 120 mg/dL (6.7 mmol/L). **Insulin** delivery is suspended when the sensor glucose level falls below or is predicted to fall below target level. The Tandem Control-IQ targets a sensor glucose level of 112.5 mg/dL (6.25 mmol/L). The Omnipod 5 targets a user-programmed glucose value between 100 and 150 mg/dL. The patient is still responsible for bolusing **insulin** for meals and snacks. Communities of patients with type 1 diabetes have also developed open source algorithms for smart phone that use glucose data from CGM systems to automatically adjust **insulin** delivery by their pumps (open artificial pancreas, open APS). One such system, called the “Loop,” uses the Dexcom G6 sensor, the iPhone, and the Omnipod **insulin** pump. The “Loop” controller is downloaded on to the iPhone and it uses the Dexcom G6 sensor glucose measurements (also on the iPhone) to automatically adjust basal **insulin** delivery on the Omnipod pump. These open APS systems have not been approved for use by the FDA.

#### E. Inhaled **Insulin**

A dry powder formulation of regular human **insulin** (technosphere **insulin**, Afrezza) is approved for use in adults with diabetes. It consists of 2- to 2.5- $\mu\text{m}$  crystals of the excipient, fumaryl diketopiperazine, that provide a large surface area for adsorption of proteins like **insulin**. After inhalation from the small, single-use device, pharmacokinetic studies show that peak levels are reached in 12–15 minutes and decline to baseline in 3 hours, significantly faster in onset and shorter in duration than subcutaneous **insulin**. Pharmacodynamic studies show that median time to maximum effect with inhaled **insulin** is approximately 1 hour and declines to baseline by about 3 hours. In contrast, the median time to maximum effect with subcutaneous **insulin** lispro is about 2 hours and declines to baseline by 4 hours. In trials, inhaled **insulin** combined with injected basal **insulin** was as effective in lowering glucose as injected rapid-acting **insulin** combined with basal **insulin**. It is formulated as a single-use color coded cartridge delivering 4, 8, or 12 units immediately before the meal. The manufacturer provides a dose conversion table; patients injecting up to 4 units of rapid-acting **insulin** analog should use the 4-unit cartridge. Those injecting 5–8 units should use the 8-unit cartridge. For a dose of 9–12 units of rapid-acting **insulin** pre-meal, one 4-unit cartridge and one 8-unit cartridge or one 12-unit cartridge should be used. The most common adverse effect of inhaled **insulin** was cough, affecting 27% of trial patients. A small decrease in pulmonary function (forced expiratory volume in 1 second [FEV<sub>1</sub>]) was seen in the first 3 months of use, which persisted over 2 years of follow-up. Inhaled **insulin** is contraindicated in persons who smoke or those with chronic lung disease, such as asthma and chronic obstructive pulmonary disease. Spirometry should be performed to identify potential lung disease prior to initiating therapy. During the clinical trials, there were two cases of lung cancer in patients who were taking inhaled **insulin** and none in the comparator-treated patients.

#### Immunopathology of **Insulin** Therapy

At least five molecular classes of **insulin** antibodies may be produced in patients during the course of **insulin** therapy: IgA, IgD, IgE, IgG, and IgM. There are two major types of immune disorders in these patients:

**Insulin** allergy, an immediate type hypersensitivity, is a rare condition in which local or systemic urticaria results from histamine release from tissue mast cells sensitized by anti-insulin IgE antibodies. In severe cases, anaphylaxis results. Because sensitivity is often to non-insulin protein contaminants, the human and analog insulins have markedly reduced the incidence of **insulin** allergy, especially local reactions.

## 2. Immune **insulin** resistance

A low titer of circulating IgG anti-insulin antibodies that neutralize the action of **insulin** to a negligible extent develops in most insulin-treated patients. Rarely, the titer of **insulin** antibodies leads to **insulin** resistance and may be associated with other systemic autoimmune processes such as lupus erythematosus.

### Lipodystrophy at Injection Sites

Injection of animal **insulin** preparations sometimes led to atrophy of subcutaneous fatty tissue at the site of injection. Since the development of human and analog **insulin** preparations of neutral pH, this type of immune complication is almost never seen. Injection of these newer preparations directly into the atrophic area often results in restoration of normal contours.

Hypertrophy of subcutaneous fatty tissue remains a problem if **insulin** is injected repeatedly at the same site. However, this may be corrected by avoiding the specific injection site.

## MEDICATIONS FOR TREATMENT OF TYPE 2 DIABETES

Several categories of glucose-lowering agents are available for patients with type 2 diabetes: (1) agents that bind to the sulfonylurea receptor and stimulate **insulin** secretion (sulfonylureas, meglitinides, D-phenylalanine derivatives); (2) agents that lower glucose levels by their actions on liver, muscle, and adipose tissue (biguanides, thiazolidinediones); (3) agents that principally slow the intestinal absorption of glucose ( $\alpha$ -glucosidase inhibitors); (4) agents that mimic incretin effect or prolong incretin action (GLP-1 receptor agonists, glucose-dependent insulinotropic polypeptide [GIP]/GLP-1 receptor agonists, dipeptidyl peptidase 4 [DPP-4] inhibitors); (5) agents that inhibit the reabsorption of glucose in the kidney (sodium-glucose co-transporter inhibitors [SGLTs]); and (6) agents that act by other or ill-defined mechanisms (**pramlintide**, **bromocriptine**, **colesevelam**).

### DRUGS THAT PRIMARILY STIMULATE **INSULIN** RELEASE BY BINDING TO THE SULFONYLUREA RECEPTOR

#### SULFONYLUREAS

##### Mechanism of Action

The major action of sulfonylureas is to increase **insulin** release from the pancreas (Table 41-7). They bind to a 140-kDa high-affinity sulfonylurea receptor that is associated with a beta-cell inward rectifier ATP-sensitive potassium channel (see Figure 41-2). Binding of a sulfonylurea inhibits the efflux of potassium ions through the channel and results in depolarization. Depolarization opens a voltage-gated calcium channel and results in calcium influx and the release of preformed **insulin**.

## Regulation of insulin release in humans.

Stimulants of insulin release
Humoral: Glucose, mannose, leucine, arginine, other amino acids, fatty acids (high concentrations)
Hormonal: Glucagon, glucagon-like peptide 1 (7–37), glucose-dependent insulinotropic polypeptide, cholecystokinin, gastrin
Neural: $\beta$ -Adrenergic stimulation, vagal stimulation
Drugs: Sulfonylureas, meglitinide, nateglinide, isoproterenol, acetylcholine
Inhibitors of insulin release
Hormonal: Somatostatin, insulin, leptin
Neural: $\alpha$ -Sympathomimetic effect of catecholamines
Drugs: Diazoxide, phenytoin, vinblastine, colchicine

### Efficacy & Safety of the Sulfonylureas

Sulfonylureas are metabolized by the liver and, with the exception of acetohexamide, the metabolites are either weakly active or inactive. The metabolites are excreted by the kidney and, in the case of the second-generation sulfonylureas, partly excreted in the bile. Idiosyncratic reactions are rare, with skin rashes or hematologic toxicity (leukopenia, thrombocytopenia) occurring in less than 0.1% of cases. The second-generation sulfonylureas have greater affinity for their receptor compared with the first-generation agents. The correspondingly lower effective doses and plasma levels of the second-generation drugs therefore lower the risk of drug-drug interactions based on competition for plasma binding sites or hepatic enzyme action.

In 1970, the University Group Diabetes Program (UGDP) in the United States reported that the number of deaths due to cardiovascular disease in patients with type 2 diabetes treated with tolbutamide was excessive compared with either insulin-treated patients or those receiving placebos. Owing to design flaws, this study and its conclusions were not generally accepted. In the United Kingdom, the United Kingdom Prospective Diabetes Study (UKPDS) did not find an untoward cardiovascular effect of sulfonylurea usage in their large, long-term study. The sulfonylureas continue to be widely prescribed, and three are available in the United States.

### FIRST-GENERATION SULFONYLUREAS

**Tolbutamide** is well absorbed but rapidly metabolized in the liver. Its duration of effect is relatively short (6–10 hours), with an elimination half-life of 4–5 hours, and it is best administered in divided doses (eg, 500 mg before each meal). Some patients only need one or two tablets daily. The maximum dosage is 3000 mg daily. Because of its short half-life and inactivation by the liver, it is relatively safe in the elderly and in patients with renal impairment.

Chlorpropamide, tolazamide, and acetohexamide (no longer available in the US) are now rarely used in clinical practice and are not further discussed. Drug label information for tolazamide can be found at <https://dailymed.nlm.nih.gov/dailymed/>.

### SECOND-GENERATION SULFONYLUREAS

[www.konkur.in](http://www.konkur.in) Glyburide, glipizide, gliclazide, and glimepiride are 100–200 times more potent than tolbutamide. They should be used with caution in patients with cardiovascular disease or in elderly patients, in whom hypoglycemia would be especially dangerous.

**Glyburide** (also named glibenclamide outside the USA) is metabolized in the liver into products with low hypoglycemic activity. The usual starting dosage is 2.5 mg/d or less, and the average maintenance dosage is 5–10 mg/d given as a single morning dose; maintenance dosages higher than 20 mg/d are not recommended. A formulation of “micronized” **glyburide** (Glynase PresTab) is available in a variety of tablet sizes. However, there is some question as to its bioequivalence with non-micronized formulations, and the FDA recommends careful monitoring to re-titrate dosage when switching from standard **glyburide** doses or from other sulfonylurea drugs.

**Glyburide** is metabolized in the liver and the metabolic products of **glyburide** have hypoglycemic activity. This explains why assays specific for the unmetabolized compound suggest a plasma half-life of only 1–2 hours, yet the biologic effects of **glyburide** are clearly persistent 24 hours after a single morning dose in patients with diabetes. **Glyburide** is unique among sulfonylureas in that it not only binds to the pancreatic B cell membrane sulfonylurea receptor but also becomes sequestered within the B cell. This may also contribute to its prolonged biologic effect despite its relatively short circulating half-life.

**Glyburide** should not be used in patients with liver failure and chronic kidney disease because of an increased risk of hypoglycemia. Elderly patients are at particular risk for hypoglycemia.

**Glipizide** has the shortest half-life (2–4 hours) of the more potent sulfonylureas. Food can delay the absorption of this drug and if possible, the patient should wait 30 minutes before eating. With chronic use, the clinical significance of this recommendation is less clear and the drug is effective even if it is taken immediately before the meal. The recommended starting dosage is 5 mg/d, with up to 15 mg/d given as a single dose. When higher daily dosages are required, they should be divided and given before meals. The maximum total daily dosage recommended by the manufacturer is 40 mg/d, although some studies indicate that the maximum therapeutic effect is achieved by 15–20 mg of the drug. An extended-release preparation (Glucotrol XL) provides 24-hour action after a once-daily morning dose (maximum of 20 mg/d). However, this formulation appears to have sacrificed its lower propensity for severe hypoglycemia compared with longer-acting **glyburide** without showing any demonstrable therapeutic advantages over the latter (which can be obtained as a generic drug). At least 90% of **glipizide** is metabolized in the liver to inactive products, and the remainder is excreted unchanged in the urine. **Glipizide** therapy is therefore contraindicated in patients with significant hepatic impairment. Because of its shorter duration of action and completely inactive metabolites, it is preferable to **glyburide** in the elderly and for those patients with renal impairment.

**Glimepiride** is used as monotherapy or as combination therapy and taken once daily. **Glimepiride** achieves blood glucose lowering with the lowest dosage of any sulfonylurea compound. A single daily dose of 1 mg has been shown to be effective, and the recommended maximal daily dosage is 8 mg. **Glimepiride**'s half-life under multidose conditions is 5–9 hours. It is completely metabolized by the liver to metabolites with weak or no activity.

**Gliclazide** (not available in the United States) has a half-life of 10 hours. The recommended starting dosage is 40–80 mg daily with a maximum dosage of 320 mg daily. Higher dosages are usually divided and given twice a day. It is completely metabolized by the liver to inactive metabolites.

Hypoglycemia and weight gain are the most common adverse effects of the sulfonylureas. Some sulfonamides (sulfisoxazole) and oral azole antifungal medications can inhibit metabolism of **tolbutamide** and result in prolonged hypoglycemia. **Glyburide** can occasionally cause flushing after ethanol ingestion, and this compound slightly enhances free water clearance.

## MEGLITINIDE ANALOGS

**Repaglinide** is the first member of the meglitinide group of **insulin** secretagogues. These drugs modulate beta cell **insulin** release by regulating potassium efflux through the potassium channels previously discussed. There is overlap with the sulfonylureas in their molecular sites of action because the meglitinides have two binding sites in common with the sulfonylureas and one unique binding site.

**Repaglinide** has a fast onset of action, with a peak concentration and peak effect within approximately 1 hour after ingestion, but the duration of action is 4–7 hours. It is cleared by hepatic CYP3A4 with a plasma half-life of 1 hour. Because of its rapid onset, **repaglinide** is indicated for use in controlling postprandial glucose excursions. The drug should be taken just before each meal in doses of 0.25–4 mg (maximum 16 mg/d); hypoglycemia is a risk if the meal is delayed or skipped or contains inadequate carbohydrate. It can be used in patients with renal impairment and in the elderly. **Repaglinide** is used as monotherapy or as combination therapy. There is no sulfur in its structure, so **repaglinide** may be used in patients with type 2 diabetes with a severe sulfur or sulfonylurea allergy.

[Nateglinide](#) (not available in the United States) is a benzylsuccinic acid derivative that binds to the sulfonylurea receptor and is similar to [repaglinide](#) in its clinical effects. It is available for use in Japan.

## D-PHENYLALANINE DERIVATIVE

[Nateglinide](#) is a D-phenylalanine derivative and stimulates rapid and transient release of [insulin](#) from beta cells through closure of the ATP-sensitive  $K^+$  channel. It is absorbed within 20 minutes after oral administration with a time to peak concentration of less than 1 hour and is metabolized in the liver by CYP2C9 and CYP3A4 with a half-life of about 1 hour. The overall duration of action is about 4 hours. It is taken before the meal and reduces the postprandial rise in blood glucose levels. It is available as 60- and 120-mg tablets. The lower dose is used in patients with mild elevations in  $HbA_{1c}$ .

[Nateglinide](#) is efficacious when given alone or in combination with non-secretagogue oral agents (such as [metformin](#)). Hypoglycemia is the main adverse effect. It can be used in patients with renal impairment and in the elderly.

## DRUGS THAT PRIMARILY LOWER GLUCOSE LEVELS BY THEIR ACTIONS ON THE LIVER, MUSCLE, & ADIPOSE TISSUE

### BIGUANIDES

The structure of [metformin](#) is shown below.

**Metformin**

[Metformin](#)'s therapeutic effects primarily derive from increasing hepatic [adenosine](#) monophosphate-activated protein kinase activity, which reduces hepatic gluconeogenesis and lipogenesis. [Metformin](#) is a substrate for organic cation transporter 1, which is abundantly expressed in hepatocytes and in the gut.
