Chapter 41 Peri-Mucositis and Peri-Implantitis Diagnosis, Classification, Etiologies, and Therapies

Foreword

After 50 years of involvement in dental implant evaluation and research and 47 years of clinical implant practice, I feel greatly honored as well as having a substantial professional responsibility to provide the Foreword to *Misch's Contemporary Implant Dentistry* authored by Dr. Randolph R. Resnik. Why? This book should, simply put, have an incalculable influence on dentistry for years to come.

Since 1972 I have also served continuously on the Executive Committee of the International Congress of Oral Implantologists (ICOI). Today, the ICOI is one of the largest implant societies in the world. For many years, Dr. Carl E. Misch and I were Co-Chairman of the ICOI. Since his death, I have acted as CEO. ICOI's mission has always been to promote worldwide dental implant education, research and international fraternity.

Having known Dr. Randy Resnik for many years, I can assure you that he is a shining example of a multi-talented individual who has pursued these goals and has dedicated his life to oral implantology/implant dentistry and expanding the impact of the Contemporary Implant Dentistry texts.

Because of his extensive teaching and mentoring background, he appreciates like few others the "gestalt" of oral implantology/implant dentistry. With the exponential growth of this field, fueled by exceptional professional acceptance and growing consumer awareness, Dr. Resnik has been able to thoughtfully identify the numerous sources of complications that can occur and propose many solutions. Further, he makes a strong case that dental implants are for the many, not just the privileged few. In this view several clinicians around the world are attempting to influence manufacturers to lower the price of implants or the required number of implants used in specific cases to increase their availability to patients and yet obtain satisfactory results.

Having spent many hours discussing the question with Dr. Resnik, I can assure you that he feels, as I do, that implants are the purview of generalists as well as specialists worldwide. What determines the elements of treatment that individual practitioners do should be determined by how well they train, by how much they are committed to lifelong education, and by how well they are influenced by mentors who are open, honest and caring, such as Dr. Resnik.

Several aspects of *Misch's Contemporary Implant Dentistry* have to be emphasized so that casual reading is not encouraged. There are eight sections with 42 chapters, all of which have been updated. Further, approximately 20 chapters are brand new and present in-depth multiple new topics. Dr. Resnik is very aware of how much and how fast the field of oral implantology/implant dentistry is changing. To this end, Dr. Resnik has asked multiple colleagues, researchers and specialists to contribute their knowledge.

Misch's Contemporary Implant Dentistry, authored by Dr. Randolph R. Resnik, is a classic guide for the student and the young practitioner and a valuable reference for well-experienced clinicians.

With great personal and professional respect,
Kenneth W. M. Judy, DDS, FAGD, FACD, MICD
CEO & Co-Chairman, ICOI
Clinical Professor, *New York University College of Dentistry*, New York, New York
Clinical Professor Department of Oral Implantology, Dental Medicine Section of Oral, Diagnostic and Rehabilitation Sciences, Division of Prosthodontics, *Columbia University College of Dental Medicine*, New York, New York

*To my wife Diane, and children Christopher and
Allison, for their patience and understanding
along with enriching my life.*

Carl E. Misch Dedication

The sign of a true genius is someone who has the innate ability to foresee what the future beholds. This is reflective of Dr. Carl E. Misch's life. Over 30 years ago, he was responsible for pioneering the foundation and protocols that are universally utilized today in the mainstream field of dental implantology. He had the unbelievable foresight to develop these concepts, usually against much resistance, to unprecedented perfection. When Carl, like other gifted geniuses, leave this life, the accomplishments they achieved reveal the true impact they have made on our daily lives.

Carl will always be known as one of the true "fathers" in implant dentistry, as most techniques and procedures today are based on his original principles and classifications. He had more to do with the inception, evolution and current theories of today's implant dentistry than any other practitioner in the field. He dedicated his life's work to the field of implant dentistry and worked painlessly every day to achieve these accomplishments.

Carl had a singular focus toward the understanding that if properly utilized, dental implants would have significant positive impacts on the health of the population at large. His passion was centered on perfecting the clinical outcomes of implant patients and his vision allowed implant dentistry to become a reality. He was a true innovator that has led to dental implants becoming the standard of care in dentistry even though he went against the odds and encountered much resistance.

Carl will be remembered as the consummate clinician, researcher, educator and father. He lived and taught what he believed, teaching right up to the end of his life. He was relentless and determined to further implant dentistry in the medical community. Not only did he continue teaching every one of us about dental implantology, he was also imparting further wisdom with his love for life. Carl was able to stimulate a renaissance in oral implantology that will continue to impact the field forever.

That is the beauty of life. Certain geniuses come along with great gifts. The best of these decide to dedicate their lives to sharing those gifts with others. That is a great description of Dr. Carl E. Misch, and I, as well as the rest of our profession, will never forget him. His legacy will live on in the clinicians he has educated, the teachers he has influenced, and the patients who will benefit from his tireless and profound work.

Carl, thank you for allowing me to continue your legacy. You are truly missed and you are in our thoughts every day. Rest in peace, my friend!

Preface

The use of dental implants in the field of dentistry has become a widely acceptable treatment modality to rehabilitate patients with edentulous sites. Dental implant clinicians and researchers continue to dedicate a significant amount of time and resources to the future development of the field. The global dental implant market continues to grow at an unprecedented rate, expected to exceed 7.0 billion by 2024. With an ever-increasing public awareness of the benefits of dental implantology, the popularity of dental implant rehabilitation will continue to increase for the future. A growing number of the population experience partial or complete edentulism, and the dental implant is now the preferred method of choice to replace a single, multiple, or completely edentulous sites. Therefore, it is imperative the dental implant clinician have a strong foundation of the accepted principles for treatment planning, radiographic evaluation, surgical procedures, prosthetic rehabilitation and postoperative care.

In the fourth edition of Contemporary Implant Dentistry, the underlying theme of past editions is clearly maintained with respect to the science-based concept of implant dentistry. This new edition is a comprehensive overview of all surgical aspects of implant dentistry, which include eight sections and 42 chapters. Each chapter in this book is specifically written to be related to all other chapters in the text with the concept of consistent and predictable care as the priority. The fourth edition has nearly tripled in size from the first edition written in the early 1990s. New chapters on treatment planning, implant surgery, pharmacology, medical evaluation, immediate placement and immediate loading, bone grafting techniques, Botox and dermal fillers, and the treatment of peri-implant disease have been added to this fourth edition.

The first part of the fourth edition Contemporary Implant Dentistry is related to the scientific basis for dental implants. It presents the rationale for the use of dental implants as inert replacements for missing teeth and why biomechanics play such a significant role in the treatment planning process. A comprehensive outline of the terminology is explained with clear and concise examples. Science based research is used as the basis for discussing implant design and biomaterials, along with the physiologic bone response to these materials.

The second part of this book discusses the biomechanical properties which relate to the dental implant process. The pioneering stress theorem concepts postulated by Dr. Carl Misch are the basis for these chapters as the various force factors which dental implants are exposed to are presented. The effects of these forces along with how different implant surfaces relate to the stresses are discussed in detail.

The third part of Contemporary Implant Dentistry provides information concerning the related basic sciences of oral implantology. The medical evaluation chapter details medical conditions and medications which have direct and indirect effects on the short

and long-term success of dental implants. The radiographic evaluation chapter allows the reader to have a comprehensive understanding of normal anatomy as well as anatomic and pathologic variants related to dental implantology. An updated pharmacology chapter encompasses all prophylactic and therapeutic medications related to pre- and postoperative care of dental implants. And lastly, applied anatomy of the head and neck is discussed with an overview on possible infectious episodes that may result from dental implant treatment.

The fourth part of Contemporary Implant Dentistry is based upon all aspects of the treatment planning process. The pioneering classifications from Dr. Carl Misch including available bone, prosthetic options, key implant positions and bone density are updated. A new chapter added to this section details the use of interactive cone beam computerized tomography (CBCT) in the treatment planning process. Valuable treatment planning concepts are discussed with a generic protocol for the use of CBCT.

The fifth part of Contemporary Implant Dentistry discusses generalized treatment planning concepts related to anatomical regions within the oral cavity. Single , multiple, and fully edentulous treatment planning principles are presented according to anatomic areas in the anterior and posterior maxilla and mandible. The edentulous treatment planning process for fixed versus removable prostheses are compared with respect to anatomic areas in the maxilla and mandible.

The sixth part of Contemporary Implant Dentistry is dedicated to the implant surgery process. A new chapter related to surgical techniques entails basic surgical principles and protocols, as well as the armamentarium required in the field of oral implantology. Various surgical protocols are discussed related to the specific anatomy in the maxilla and mandible. In addition, a full array of possible complications of implant surgery with respect to etiology, management, and prevention is presented. And lastly, new classifications and protocols related to immediate implant placement surgery along with immediate loading techniques are explained in science- and research-based techniques.

The seventh part of Contemporary Implant Dentistry discusses all aspects of soft and hard tissue rehabilitation. A detailed chapter explains guidelines and techniques for atraumatic extraction and socket grafting. A new chapter specifically discussing the available bone substitutes and membranes, with advantages and disadvantages based on science and the latest research is presented. In addition, updated and comprehensive bone grafting chapters on guided tissue regeneration, maxillary sinus augmentation, intraoral bone grafts, and extraoral techniques are included in this part. And lastly, a new chapter related to the use of Botox and dermal fillers is added to this section which includes the use for esthetic and functional aspects of oral implantology.

The last section of Contemporary Implant Dentistry is related to the postoperative care, specifically the treatment of

peri-implant disease with an emphasis on treatment protocols. The last chapter includes a detailed protocol and treatment techniques on the maintenance of dental implants.

In summary, Contemporary Implant Dentistry has been used over the years as a textbook for dental schools, dental residents, postgraduate programs, lab technicians, general dentists, and dental specialists. The translations into many languages has shown the popularity and acceptance of this textbook in the field of oral implantology worldwide. The fourth edition of this textbook comprehensively updates the reader on all aspects of dental implantology with the goal of elevating the educational standards through a science-based approach.

Randolph R. Resnik, DMD, MDS

Acknowledgments

I would like to express my sincere gratitude for the many individuals who helped shape my career and provided the foundation for the writing of this book. First and foremost, I would never have had the ambition, aspiration, and discipline to write this book if not for the two mentors in my life, my late father, Dr. Rudolph Resnik, and the true pioneer in oral implantology, Dr. Carl E. Misch. My father was the perfect role model, educator, clinician, and a true pioneer in the field of fixed prosthetics. He was my hero and best friend, and the number one reason I am where I am today. His endless support and encouragement motivated me to give 100% to every endeavor that I ever pursued.

Secondly, Dr. Carl Misch was not only my mentor, but also a very close friend. His endless energy and ability to foresee the future of oral implantology and its impact on dentistry allowed me to be at the forefront of this challenging profession. His dedication and contributions to the field of oral implantology are unprecedented and will never be forgotten. The scientific basis for his classifications and principles will be an integral component in the field forever.

I would also like to acknowledge the thousands of doctors, whom over the past 30 years, have attended my various lectures, symposiums and especially the past graduates of the Misch International Implant Institute. It is through their inquisitiveness and ambition to learn that has empowered me to write the Fourth Edition of Contemporary Implant Dentistry. They have given me the determination and desire to raise the standard of care in our profession and elevate implant dentistry to the next level.

I am sincerely thankful to all the additional chapter authors for sharing their expertise with the writing of this book. Their dedication to implant dentistry, and especially their friendship and personal support to me, is greatly appreciated: Dean Jon Suzuki, Steven Caldwell, Robert Resnik, Christopher Resnik, David Datillo, Joseph Cillo, Neil Park, Grant Bullis, Mauri Kerr, Amanda Sheehan, Kevin Suzuki, Diana Bronstein, Ralph Powers, Francine Misch- Dietsh, and Mohamed Sharowry.

A special note of thanks to the staff at Elsevier Publishing for their, encouragement, enthusiasm and guidance with the content of this book. In particular, Content Strategist, Alexandra Mortimer and Senior Content Development Specialist, Anne E. Snyder, for their dedication and endless hours of work in the development and creativity of this book. Without their help, this book would never have come to fruition.

At last but not least, I would like to thank my family, for their support and encouragement they gave me during this project, despite the sacrifice and burden it often imposed on them. My wife, Diane, who's unwavering support always gives me the strength to succeed. So proud of both of my children, Christopher, currently in a residency program at the University of Pittsburgh and soon to be third generation Prosthodontist and my beautiful daughter, Allison, who is currently in medical school at Georgetown University.

Contents

PART I

Scientific Basis

1

Rationale for Dental Implants

RANDOLPH R. RESNIK AND CARL E. MISCH

The goal of modern dentistry is to restore the patient to normal contour, function, comfort, esthetics, speech, and health by removing a disease process from a tooth or replacing teeth with a prosthesis. What makes implant dentistry unique is the ability to achieve this goal, regardless of the atrophy, disease, or injury of the stomatognathic system.[1] However, the more teeth a patient is missing, the more challenging this task becomes. As a result of continued research, diagnostic tools, treatment planning, implant designs, advanced materials, and techniques, predictable success is now a reality for the rehabilitation of many challenging clinical situations.

The impact of dental implants has surely affected the field of dentistry in the United States. The number of dental implants placed in the United States has increased more than 10-fold from 1983 to 2002, and another fivefold from 2000 to 2005. More than 1 million dental implants are inserted each year and the industry is expected to be a $10 billion industry in 2020.[2,3] More than 90% of interfacing surgical specialty dentists currently provide dental implant treatment on a routine basis in their practices, 90% of prosthodontists restore implants routinely, and more than 80% of general dentists have used implants to support fixed and removable prostheses, compared with only 65% 15 years ago.[4-7]

Despite these figures demonstrating implants are incorporated into dentistry more than ever before, there is still a great deal of room for continued growth. Utilization of dental implants varies widely in different countries. For example, it is estimated that the number placed each year per 10,000 people is 230 for Israel (the greatest number); 180 for South Korea and Italy; 140 for Spain and Switzerland; 100 for Germany; 60 each for Brazil, the Netherlands, and the United States; 50 for Japan and France; 40 for Canada and Australia; and Taiwan and the United Kingdom, at 20 per year, use implants less often. The six countries with the greatest use of implants (five in Europe and South Korea) accounted for more than half the total market growth from 2002 to 2007. A long-term growth of 12% to 15% is expected in the future in most countries using implants at this time (Fig. 1.1).

The percentage of teeth replaced with an implant, rather than traditional fixed or removable prostheses, also dramatically varies by country. In countries such as Israel, Italy, and South Korea, 30% to 40% of teeth replaced incorporate a dental implant. In Spain, Switzerland, Germany, and Sweden, 20% to 26% of restorations to replace teeth are supported by an implant, whereas in Brazil and Belgium approximately 13% to 16% of restorations use an implant. Surprisingly, the United States, Japan, France, and Canada use implants in 10% or fewer of the teeth replaced, however this number is increasing (Fig. 1.2).[8]

Increasing Demand for Dental Implants

The increased need and use of implant-related treatments result from the combined effect of several factors, including (1) patients living longer, (2) age-related tooth loss, (3) patients are more socially active and esthetic conscious, (4) a higher incidence of partial and complete edentulism, (5) conventional prosthesis complications, and (6) the inherent advantages of implant-supported restorations.

Patients Living Longer

According to the literature, age is directly related to every indicator of tooth loss[9,10]; therefore the aging population is an important factor to consider in implant dentistry. When Alexander the Great conquered the ancient world, he was only 17 years old. However, life expectancy at that time was only 22 years of age. From 1000 BCE to CE 1800, life span remained less than 30 years (Fig. 1.3). The latest statistics from the National Center for Health Statistics show that the average American life expectancy is approximately 78.6 years, with women (81.1 years) living approximately 5 years longer than men (76.1 years). The group older than age 65 is projected to increase from 12% in 2000 to more than 20% of the population before 2025 (Fig. 1.4).[11]

In addition, not only is the percentage of the population over 65 years increasing, but the overall population as a whole is increasing. The population in 2000 was 282 million and is projected to increase 49% to 420 million by 2050. Considering the effect of both a population increase and a greater percentage of that population being older than age 65, a dramatic overall increase in patient numbers can be expected. In 2003, 35 million people were older than age 65. This number is expected to increase 87% by 2025, resulting in almost 70 million people being older than age 65[9] (Fig. 1.5). Because older people are more likely to be missing teeth, the need for implant dentistry will dramatically increase over the next several decades.
• **Fig. 1.1** Implant used to replace teeth varies by country. Estimated implant use per 10,000 people per year is greatest in Israel, South Korea, and Italy. (From Misch CE. Rationale for dental implants. In: Misch CE, ed. *Dental Implant Prosthetics*. 2nd ed. St Louis: Mosby; 2015.)
• **Fig. 1.2** Implant versus nonimplant tooth replacement (percentage) varies greatly by country. In the United States only 1 of every 10 teeth replaced incorporates an implant. (From Misch CE. Rationale for dental implants. In: Misch CE, ed. *Dental Implant Prosthetics*. 2nd ed. St Louis: Mosby; 2015.)
• **Fig. 1.3** Average life expectancy remained approximately 20 to 30 years for several hundred years of human civilization. Since the late 18th century, there has been a gradual increase in life span. (Redrawn from *Le Figaro Magazine*, Paris, 2004.)
• **Fig. 1.4** By 2050, 20.7% of the population will be older than age 65. In addition to the increasing percentage of 65 year olds, the population is also increasing. As a result, 34.9 million people were older than 65 in 2000, and 86.6 million people will reach this milestone by 2050.

Life expectancy has increased significantly past the age of retirement. A 65 year old person can now expect to live more than 20 additional years, and an 80-year-old person can expect to live 9.5 more years[10] (Fig. 1.6). Women represent two-thirds of the population older than age 65. It is not unusual for a 70-year-old patient to ask, "Is it worth it for me to spend a lot of money to repair my mouth at my age?" The response should be very positive because the patient's life expectancy will extend for two more decades on average, and his or her current oral situation will normally become worse if not corrected.

Over 69% of Americans between 35 and 44 years have at least one missing tooth. According to the National Center for Health Statistics, 91% of the people in the United States aged 20 to 64 had dental caries in their permanent teeth. The National Health and Nutrition Examination survey estimated that approximately 42% of the children aged 2 to 11 years have tooth caries, and over 23% are left untreated. The National Institute of Dental and Craniofacial Research has determined that tooth loss in American adults begins between the ages of 35 and 45, and more than 24% of adults older than 74 years are completely edentulous.[12]

Age-Related Tooth Loss

The aging process directly affects the oral cavity with negative consequences. As the tooth enamel wears away, teeth become more vulnerable to disease processes and eventual tooth loss. Many medications directly affect the teeth, especially causing xerostomia. Xerostomia not only weakens the teeth, but also results in hard and soft tissue loss. Therefore, a direct correlation between the aging process and tooth loss exists.

The posterior regions of the oral cavity are the most common areas for single-tooth loss[13] (Fig. 1.7). The first molars are the first permanent teeth to erupt in the mouth and, unfortunately, are often the first teeth lost as a result of decay, failed endodontic therapy, or fracture (usually after endodontics).

The molar teeth are vitally important for maintenance of the arch form and proper occlusal schemes. In addition, the adult patient often has one or more crowns as a consequence of previous larger restorations required to repair the integrity of the tooth. Longevity reports of crowns have yielded very disparate results. The mean life span at failure has been reported as approximately 10.3 years. Other reports range from a 3% failure rate at 23 years to a 20% failure rate at 3 years. The primary cause of failure of the crown is caries followed by periodontal disease and endodontic therapy.[14] The tooth is at risk for extraction as a result of these complications, which are the leading causes of single posterior tooth loss in the adult (Fig. 1.8, Fig. 1.9).[15]

Researchers have found a direct correlation of tooth loss in the elderly population exhibiting physical and mental decline. The data showed that subjects who had lost all their natural teeth performed approximately 10% worse in both memory and mobility (walking) than counterparts with natural teeth. Usually, tooth loss is less with patients of higher socioeconomic status. However, in this study, the link between total tooth loss and mobility (slower walking speed) remained significant when all variables were taken into consideration.

Patients More Socially Active and Esthetic Conscious

With patients living longer, their social pleasures, including dining and dating, are continuing into their elderly years. In the past, treatment of elderly patients emphasized nonsurgical approaches and palliative treatment. Today, the full scope of dental services for elderly patients is increasing in importance to both the public and the profession because of the increasing age of our society. Studies have shown that
• **Fig. 1.5** Adult population older than the age of 60 years will increase by 87% from the year 2000 to the year 2025. (From Misch CE. Rationale for dental implants. In: Misch CE, ed. *Dental Implant Prosthetics*. 2nd ed. St Louis: Mosby; 2015.)
• **Fig. 1.6** When a person reaches age 65 years, he or she may often feels an investment in health is less appropriate. A 65-year-old healthy woman will live 23 more years 50% of the time and 29 more years 25% of the time. Her present oral condition will become worse during this extended time frame if treatment is not rendered.

elderly patients that are more socially active will have a slower progression of health declines than elderly people who become less socially active. Engaging older people have been shown to be more motivated to maintain their health than their less-engaged peers. Therefore with patients living longer, patient education is vitally important as the demand for more comprehensive dental implant treatment will be most definitely increasing in the future to maintain social activity.

Higher Prevalence of Partial and Complete Edentulism

Partial Edentulism

Currently, the prevalence of partial edentulism in the general population has resulted in an increased need for dental implants.
● **Fig. 1.7** (A and B) The most common tooth to be lost is the first molar. Approximately 80% of the time, the adjacent teeth are unrestored or have minimal restorations.
● **Fig. 1.8** Posterior molar tooth exhibiting caries and endodontic fracture, which are two of the most common complications leading to an unrestorable tooth.
● **Fig. 1.9** Posterior missing tooth is a frequent occurrence in a general practice. The most common single tooth missing is the first molar. which results in many dental arch complications. (From Misch CE. Rationale for dental implants. In: Misch CE, ed. *Dental Implant Prosthetics*. 2nd ed. St Louis: Mosby; 2015.)
● **Fig. 1.10** There are more than 44 million people in the United States missing at least one quadrant of posterior teeth (most often in the mandible). (From Misch CE. Rationale for dental implants. In: Misch CE, ed. *Dental Implant Prosthetics*. 2nd ed. St Louis: Mosby; 2015.)

Various studies have shown this pattern to be as high as 48% of the population. Many variables which have been associated this increase include gender, ethnicity, and chronic disease. In addition, adults exhibiting partial edentulism were 22.6% more likely to be from rural areas and 31.5% from depressed locations.[16]

As stated previously, the most common missing teeth are have been shown to be molars.[17] Partial free-end edentulism is of particular concern because in these patients, teeth are often replaced with removable partial prostheses. Implant placement in the posterior regions is often challenging because of the location of the maxillary sinus and the mandibular canal. Mandibular free-end edentulism frequency is greater than its maxillary counterpart in all age groups. Unilateral free-end edentulism is more common than bilateral edentulism in both maxillary and mandibular arches in the younger age groups (ages 25–44). About 13.5 million persons in these younger age groups have free-end edentulism in either arch (Fig. 1.10).

In 45- to 54-year-old patients, 31.3% have mandibular free-end edentulism, and 13.6% have free-end edentulism in the maxillary arch. Approximately 9.9 million persons in the 45- to 54-year-old group have at least one free-end edentulous quadrant, and almost half of these have bilateral partial edentulism. The pattern of posterior edentulism evolves in the 55- to 64-year-old group, in which 35% of mandibular arches show free-end

edentulism compared with 18% of maxillary arches. As a result, approximately 11 million individuals in this age group are potential candidates for implants. An additional 10 million show partial free-end edentulism at age 65 or older. Additional US survey studies have documented approximately 44 million people to have at least one quadrant of posterior missing teeth. For example, if each of these arches requires three implants to support a fixed prosthesis, 132 million implants, added to the 192 million for edentulous patients, would be required.[18-20]

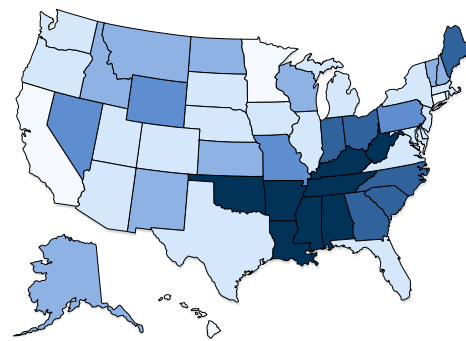
Total Edentulism

Although the percentage of patients with total edentulism is decreasing because of the baby-boomer population, the total number of patients exhibiting edentulism that will require treatment will increase in the future. In the past, full arch extractions were mainly indicated because of the combined pathologic processes of dental caries, periodontal disease, or as a method to reduce the costs associated with dental treatment. However, because of the high success rate of dental implants today, it is not uncommon for full-mouth extractions to be completed when teeth are questionable, especially in anticipation of future implant placement. Similar to other pathologic outcomes of disease, the occurrence of total loss of teeth is directly related to the age of the patient. The rate of edentulism increases approximately 4% per 10 years in early adult years and increases to more than 10% per decade after age 70.[21]

The average total edentulous rate worldwide is approximately 20% at age 60, although there is wide disparity between the countries with the highest and lowest rates. For example, in the 65- to 74-year age group, the total edentulous rate in Kenya and Nigeria was 0%, whereas the Netherlands and Iceland have a 65.4% and 71.5% rate, respectively. The edentulous Canadian rate was 47% at ages 65 to 69 and 58% from ages 70 to 98 (with Quebec at 67% for those older than age 65 compared with Ontario with a 41% rate).[22]

In the United States the comparison of edentulism from 1957 to 2012 decreased from 19% to 5%. Income is often related to education and may also play a role in the rate of edentulism in the United States from 1988 to 1994, studies reported an edentulous rate of 22% for those with less than 8 years of education, 12% for those with 9 to 11 years of school, 8% for those with 12 years of school, and 5% for individuals with more than 12 years of education.

Studies show that edentulism in the United States is rarely seen in high-income individuals. The level of education is inversely proportional to edentulism. Geographically, edentulism was found to be highest in states that are bordered by the Appalachian Mountains and the Mississippi Delta. The lowest prevalence was found in California, Connecticut, Hawaii, and Minnesota. The prevalence in southern states is nearly twice that in western states (Fig. 1.11).[23]

In the National Institute of Dental Research national surveys, the occurrence of total edentulism (absence of teeth) of a single arch (35 times more frequent in the maxilla) was slight in the 30- to 34-year-old age group, but it increased at around age 45 to 11% and then remained constant after 55 years at approximately 15% of the adult population. A total of approximately 12 million individuals in the United States have edentulism in one arch, representing 7% of the adult population overall. With the passing of generations born in the mid-20th century, the rate of decline in edentulism is projected to slow, reaching approximately 2.6% by the year 2050. This continuing decline, however will be offset by population aging. The projected number of edentulous people in


Prevalence ☐<4% ☐4-<5% ☐5-<6% ☐6-<7% ☐7-<8% ■>=8%

● **Fig. 1.11** Age-standardized edentulism prevalence among adults aged ≥25 years in the United States in 2010. (From Slade GD, Akinkugbe AA, Sanders, AE. Projections of U.S. edentulism prevalence following 5 decades of decline. *J Dent Res.* 2014;93(10):959–965.)
● **Fig. 1.12** The US population completely edentulous rate ranges from 5% for 40 year olds to 44% for those older than age 75. As a result, 20 million people (10.5% of the population) in the United States have no teeth. An additional 12 million people (7% of the adult population) have no maxillary teeth opposing at least some mandibular teeth.

2050 will be approximately 8.6 million. This will be 30% lower than the 12.2 million edentulous people in 2010.[23]

The present younger population is benefiting from today's advanced knowledge and restorative techniques. Edentulism has been noted in 5% of employed adults aged 40 to 44, gradually increasing to 26% at age 65, and almost 44% in seniors older than age 75 (Fig. 1.12).[24] As expected, older persons are more likely to be missing all their teeth. Gender was not found to be associated with tooth retention or tooth loss once adjustments were made for age. The percentages of one- or two-arch edentulism translate into more than 30 million people, or about 17% of the entire US adult population. To put these numbers in perspective, 30 million people represent approximately the entire US African American population, or the entire population of Canada. Although the edentulism rate is decreasing every decade, the elderly population is rising so rapidly that the adult population in need of one or two complete dentures will actually increase from 33.6 million adults in 1991 to 37.9 million adults in 2020. The total number of edentulous arches is estimated at 56.5 million in 2000, 59.3 million in 2010, and 61 million in 2020. Complete edentulism, therefore, remains a significant concern, and affected patients often

• BOX 1.1   Consequences of Complete Edentulism

• Continued bone loss of the maxilla and mandible
• Negative soft tissue changes of the face and jaws
• Negative facial esthetic changes
• Decreased masticatory function
• Increased Health Issues
• Negative dietary effects
• Psychological Issues
• Patients Less Socially Active

• **Fig. 1.13** The alveolar bone forms as a result of the tooth root formation. When no tooth root is present, the alveolar process does not form (i.e., ectodermal dysplasia when partial or complete anodontia of both primary and secondary teeth occurs).

Continuous loss for 25 years

• **Fig. 1.14** After the initial extraction of teeth, studies have shown the average first-year bone loss is more than 4 mm in height and 30% in crestal bone width. Although the rate of bone loss is slower after the first year, the bone loss is continuous throughout life.

require dental implant treatment to solve several related problems. For example, to show the need for implant treatment with the edentulous group, if four implants were used to help support each complete edentulous arch in 2000, a total of 226 million implants would have been required. However, only approximately 1 million implants were inserted for all patient treatment (partially or completely edentulous) that year. Almost 70% of dentists spend less than 1% to 5% of their treatment time on edentulous patients, leaving a great unfulfilled need for implant dentistry.[25]

When the partially edentulous figures are added to the complete edentulous percentages, almost 30% of the adult US population are candidates for a complete or partial removable prosthesis. The need for additional retention, support and stability, and the desire to eliminate a removable prosthesis are common indications for dental implants. As a result, 74 million adults (90 million arches) are potential candidates for dental implants. Because a minimum of five appointments is required to implant and restore a patient, every US dentist would need approximately 20 appointments every month for 20 years to treat the present posterior partial and complete edentulous population with implant-supported prostheses. The population's evolution to an increased average age, combined with the existing population of partially and completely edentulous patients, guarantees implant dentistry's future for several generations of dentists.

In the elderly population, tooth loss is more common. The baby-boomer population in the United States is the major purchaser of elective plastic surgery and antiaging procedures and medications. This generation is destined to be the most affluent older generation ever in the United States, and they will inherit the largest inflation-adjusted transfer of wealth in history at approximately $10 trillion.[26] This propensity for discretionary spending has fueled unprecedented growth in implant dentistry during the last decade, and it is expected to continue. The 65-year-plus population in the United States is expected to increase at annual rates of 1.5% to 3% from 2010 through 2035. The population of 65+ age group will increase from 12.4% of the population in 2000 to 20.6% in 2050.[27,28]

Anatomic Consequences Of Edentulism

Hard Tissue Loss. Basal bone forms the dental skeletal structure, contains most of the muscle attachments, and begins to form in the fetus before teeth develop (Box 1.1). Alveolar bone first appears when the Hertwig root sheath of the tooth bud evolves (Fig. 1.13). The alveolar bone does not form in the absence of primary or secondary tooth development. The close relationship between the tooth and the alveolar process continues throughout life. Wolff's law (1892) stated that bone remodels in relationship to the forces applied. Every time the function of bone is modified, a definite change occurs in the internal architecture and external configuration.[29,30] In dentistry, the consequences of complete edentulous and remaining bone volume was noted by Misch in 1922, in which he described the skeletal structure of a 90-year-old woman without teeth for several decades.[31]
Bone requires stimulation to maintain its form and density. Roberts and colleagues[32] reported that a 4% strain to the skeletal system maintains bone and helps balance the resorption and formation phenomena. Teeth transmit compressive and tensile forces to the surrounding bone. These forces have been measured as a piezoelectric effect in the imperfect crystals of durapatite that compose the inorganic portion of bone. When a tooth is lost, the lack of stimulation to the residual bone causes a decrease in trabeculae and bone density in the area, with loss in external width, then height, of the bone volume.[32] There is a 25% decrease in the width of bone during the first year after tooth loss and an overall 4-mm decrease in height during the first year after extractions for an immediate denture. In a pioneering longitudinal 25-year study, demonstrated continued bone loss during this time span; in comparing the bone loss of the maxilla to the mandible, a fourfold greater loss was observed in the mandible (Fig. 1.14).[33] Although, initially the mandibular bone height is twice that of the maxilla, maxillary bone loss is very significant in the long-term edentulous patient. In fact, maxillary implant placement and bone graft procedures may be more challenging in comparison to the mandible.

Prostheses also contribute to bone loss. In general, a tooth is necessary for the development of alveolar bone, and stimulation of this bone is required to maintain its density and volume. A removable denture (complete or partial) does not stimulate and maintain bone; rather, it accelerates bone loss. The load from

mastication is transferred to the bone surface only and not the entire bone. As a result, blood supply is reduced and total bone volume loss occurs. This issue, which is of utmost importance, has been observed but not addressed until recently in traditional dentistry. Most often dentists overlook the insidious bone loss that will occur after tooth extraction. Therefore, it is imperative patients be educated about the anatomic changes and the potential consequences of continued bone loss. The bone loss accelerates when the patient wears a poorly fitting soft tissue–borne prosthesis. Patients do not understand that bone is being lost over time and at a greater rate beneath poorly fitting dentures (Fig. 1.15). Patients infrequently return for follow-up visits for evaluation of their edentulous condition; instead, they will return for a repair of the prosthesis. Hence the traditional method of tooth replacement (e.g. removable prosthesis) often affects bone loss in a manner not sufficiently considered by the doctor and the patient. Bone loss has been shown to increase with the use of a poorly fitting soft tissue–borne prosthesis. Patients should be informed of periodic evaluations to reline or fabricate a new prosthesis (Fig. 1.16).

Preventive dentistry has traditionally emphasized methods to decrease tooth loss. No predictable therapy had been accepted by the profession to avoid the bone changes resulting from tooth loss. Today, the profession must consider the loss of both teeth and bone. The loss of teeth causes remodeling and resorption of the surrounding alveolar bone and eventually leads to atrophic edentulous ridges. The rate and amount of bone loss may be influenced by such things as gender, hormones, metabolism, parafunction, and ill-fitting dentures (Box 1.2). Yet almost 40% of denture wearers have been wearing an ill-fitting prosthesis for more than 10 years. Patients wearing dentures day and night place greater forces on the hard and soft tissues, which accelerates bone loss. Nonetheless, studies have shown that approximately 80% of dentures are worn both day and night.[34] Atrophic edentulous ridges are associated with anatomic problems that often impair the predictable results of traditional dental therapy (Fig. 1.17; Box 1.3).

Loss of bone in the maxilla or mandible is not limited to alveolar bone; portions of the basal bone also may be resorbed, especially in the posterior aspect of the mandible in which severe resorption may result in catastrophic bone loss.[35] The contents of the mandibular canal or mental foramen eventually become dehiscent and serve as part of the support area of the prosthesis. As a result, acute pain and transient to permanent nerve impairment of the areas supplied by the mandibular nerve are possible. The body of the mandible is also at increased risk of pathologic fracture, even under very low impact forces. The mandibular fracture causes the jaw to shift to one side and makes stabilization and an esthetic result most difficult to obtain during treatment of the fracture.

• **Fig. 1.15** Atwood described six different stages of resorption in the anterior mandible. Stage 1 represents the tooth and surrounding alveolar process and basal bone. Stages II and III illustrate the initial residual ridge after tooth loss. Stages IV to VI primarily describe a continuous loss in length of anterior residual bone.

• BOX **1.2**	**Factors Effecting Rate and Amount of Bone Loss**

- Gender
- Medications
- Hormones
- Age
- Metabolism
- Bone Quality
- Parafunction (Increased Biting Force)
- Ill-fitting prosthesis
- Facial type (brachiocephalic versus dolichocephalic)
- Time period dentures are worn
- Past History of Dental Disease

Modified from Misch CE. Rationale for dental implants. In: Misch CE, ed. Dental Implant Prosthetics. *2nd ed. St Louis: Mosby; 2015.*

• **Fig. 1.16** Loss of bone height in the mandible may be significant resulting in loss of function. This vertical bone loss has a large impact on restoring the patient back to dental health. The patient should understand that to restore the hard and soft tissue loss, more extensive treatment is usually indicated.

• **Fig. 1.17** Maxillary and Mandibular edentulous arches depicting irregular bone resorption with varying degrees of quality soft tissue (i.e. attached tissue).

In the maxilla, extensive bone loss can also be problematic. In some cases, the complete anterior ridge and even the anterior nasal spine may be resorbed in the maxilla, causing pain and an increase in maxillary denture movement during function. Masticatory forces generated by short facial types (brachiocephalics) can be three to four times that of long facial types (dolichocephalics). Short facial–type patients are at increased risk for developing severe atrophy.

Many of these similar conditions exist in the partially edentulous patient wearing a removable soft tissue–borne prosthesis (e.g. removable partial denture) (Fig. 1.18). In addition, the natural abutment teeth, on which direct and indirect retainers are designed, experience significant lateral forces. Because these teeth

are often compromised by deficient periodontal support or large restorations, the resultant forces may be damaging. These forces may result in an increase in mobility of the removable prosthesis and greater soft tissue support. These conditions often will lead to accelerated the bone loss in the edentulous regions (see Box 1.3).

Soft Tissue Consequences. As bone loses width, then height, then width and height again, the attached gingiva gradually decreases. A very thin attached tissue usually lies over the advanced atrophic mandible or maxilla. The increased zones of nonkeratinized gingiva are prone to abrasions caused by the overlaying prosthesis. In addition, unfavorable high muscle attachments and hypermobile tissue often complicate the situation (Fig. 1.19).

As the bone resorbs from Division A to Division B, the resultant narrow residual ridge will often cause discomfort when pressure (from a prosthesis) is applied to the ridge. This often occurs in the posterior mandible, as atrophy may cause a prominent mylohyoid and internal oblique ridges covered by thin, movable, unattached mucosa. In severe atrophy cases the anterior residual alveolar process will continue to resorb, and the superior genial tubercles (which are approximately 20 mm below the crest of bone when teeth are present) eventually become the most superior aspect of the anterior mandibular ridge. This results in excessive movement of the prosthesis during function or speech. This condition is further compromised by the vertical movement of the distal aspect of the prosthesis during contraction of the mylohyoid and buccinator muscles and the anterior incline of the atrophic mandible compared with that of the maxilla.[36]

The thickness of the mucosa on the atrophic ridge is also related to the presence of systemic disease and the physiologic changes that accompany aging. Conditions such as hypertension, diabetes, anemia, and nutritional disorders have a deleterious effect on the vascular supply and soft tissue quality under removable prostheses. These disorders result in a decreased oxygen tension to the basal cells of the epithelium. Surface cell loss occurs at the same rate, but the cell formation at the basal layer is slowed. As a result, the

• BOX 1.3   Edentulous Patient Complications

- Continued loss of supporting bone width
- Prominent mylohyoid and internal oblique ridges with increased sore spots
- Progressive decrease in keratinized mucosa surface
- Prominent superior genial tubercles with sore spots and increased denture movement
- Muscle attachment near crest of ridge
- Elevation of prosthesis with contraction of mylohyoid and buccinator muscles serving as posterior support
- Forward movement of prosthesis from anatomic inclination (angulation of mandible with moderate to advanced bone loss)
- Thinning of mucosa, with sensitivity to abrasion
- Loss of basal bone
- Possible Nerve Impairment from dehiscent mandibular neurovascular canal
- More active role of tongue in mastication
- Effect of bone loss on esthetic appearance of lower third of face
- Increased risk of mandibular body fracture from advanced bone loss
- Loss of anterior ridge and nasal spine, causing increased denture movement and sore spots during function

• **Fig. 1.18** (A) Lateral cephalogram of a patient demonstrates the restored vertical dimension of occlusion with a denture. However, because of the advanced basal bone loss in the mandible, the superior genial tubercles (red arrow) are positioned above the residual anterior ridge. The body of the mandible is only a few millimeters thick, and the mandibular canal is completely dehiscent. In the maxillary anterior ridge, only the nasal spine remains (not the original alveolar ridge), and the posterior maxillary bone is very thin because of basal bone loss at the crest and the pneumatization of the maxillary sinus. (B) A denture may restore the vertical dimension of the face, but the bone loss of the jaws can continue until the basal bone becoems pathologically thin.
● **Fig. 1.19** Resorption of an edentulous mandible may result in dehiscence of the mandibular canal and associated nerve impairment. In addition, a conventional removable prosthesis is often difficult to wear because of the associated discomfort from the exposed nerve. The soft tissue is often thin and is usually hypersensitive, especially if the patient is wearing a conventional removable prosthesis
● **Fig. 1.20** Panoramic radiograph exhibiting extensive mandibular posterior atrophy. Note that the anterior teeth have maintained the bone in the anterior mandible and has resulted in the degradation of the pre-maxilla (Combination Syndrome). Wearing of a mandibular class I removable partial denture has escalated the posterior bone loss.

thickness of the surface tissues gradually decreases. Therefore, soft tissue irritation usually results.

The tongue of the patient with edentulous ridges often enlarges to accommodate the increase in space formerly occupied by teeth. At the same time, the tongue is used to limit the movements of the removable prostheses and takes a more active role in the mastication process. As a result, the removable prosthesis decreases in stability. The decrease in neuromuscular control, often associated with aging, further compounds the problems of traditional removable prosthodontics. The ability to wear a denture successfully may be largely a learned, skilled task. The aged patient who recently became edentulous may lack the motor skills needed to adjust to the new conditions (Fig. 1.20; Box 1.4).

● **BOX 1.4** **Soft Tissue Consequences of Edentulism**

- Attached, keratinized gingiva is lost as bone is lost
- Unattached mucosa for denture support causes increased soft spots
- Thickness of tissue decreases with age, and systemic disease causes more sore spots for dentures
- Tongue increases in size, which decreases denture stability
- Tongue has more active role in mastication, which decreases denture stability
- Decreased neuromuscular control of jaw in the elderly
● **Fig. 1.21** Esthetics of the inferior third of the face are related to the position of the teeth and include the muscles that attach to the bone.

● **Fig. 1.23** Loss of bone height can lead to a closed bite with rotation of the chin anterior to the tip of the nose.

Collapse of edentulous bite
● **Fig. 1.22** Long term denture use leads to many soft tissue changes. The loss of vertical dimension results in many changes, including a closed bite, a mandible that rotates forward, a receding maxilla, reverse smile line, increased number and depth of lines in the face, more acute angle between the nose and the face, loss of vermilion border in the lips, jowls, and witch's chin from loss of muscle attachment.

Esthetic Consequences. The facial changes that naturally occur in relation to the aging process can be accelerated and potentiated by the loss of teeth. Several esthetic consequences result from the loss of alveolar bone (Figs. 1.21 and 1.22). A decrease in facial height from a collapsed vertical dimension results in several facial changes. The loss of the labiomental angle and deepening of vertical lines in the area create a harsh appearance. As the vertical dimension progressively decreases, the occlusion evolves toward a pseudo class III malocclusion. As a result, the chin rotates forward and creates a prognathic facial appearance (Fig. 1.23). These conditions result in a decrease in the horizontal labial angle at the corner of the lips, and the patient appears unhappy when the mouth is at rest. Short facial types suffer higher bite forces, greater bone loss, and more dramatic facial changes with edentulism compared with others.

A thinning of the vermilion border of the lips results from the poor lip support provided by the prosthesis and the loss of muscle tone; its retruded position is related to the loss of premaxilla ridge and the loss of tonicity of the muscles involved in facial expression. Sutton et. al. evaluated 179 white patients at different stages of jaw atrophy, the collapse of the lips and circumoral musculature.[37] The contraction of the orbicularis oris and buccinator muscles in the patient with moderate to advanced bone atrophy displaces the modiolus and muscles of facial expression medially and posteriorly. As a result, a narrowing of the commissure, inversion of the lips, and hollowing of the cheeks are very characteristic findings (Fig. 1.24).[37] Women often use one of two techniques to hide this cosmetically undesirable appearance: either no lipstick and minimal makeup, so that little attention is brought to this area of the face, or lipstick drawn on the skin over the vermilion border to give the appearance of fuller lips. A deepening of the nasolabial groove and an increase in the depth of other vertical lines in the upper lip are related to normal aging but are accelerated with bone loss. This usually is accompanied by an increase in the columella-philtrum angle and can make the nose appear larger than if the lip had more support (Fig. 1.25). The maxillary lip naturally becomes longer with age as a result of gravity and loss of muscle tone, resulting in less of the anterior teeth shown when the lip is at rest. This has a tendency to "age" the smile, because the younger the patient, the more the teeth show in relation to the upper lip at rest or when smiling. Loss of muscle tone is accelerated in the edentulous patient, and the lengthening of the lip occurs at a younger age.

The attachments of the mentalis and buccinator muscles to the body and symphysis of the mandible also are affected by bone atrophy. The tissue sags, producing "jowls" or a "witch's chin." This effect is cumulative because of the loss in muscle tone with the loss of teeth, the associated decrease in bite force, and the loss of bone in the regions in which the muscles used to attach.

Patients usually are unaware the hard and soft tissue changes are from the loss of teeth. Studies have shown that 39% of denture

patients have have been wearing the same prosthesis for more than 10 years.[35] Therefore the consequences of tooth loss is a slow process and must be explained to the partially or completely edentulous patient during the early phases of treatment (Box 1.5).

● **Fig. 1.24** This patient has severe bone loss in the maxilla and mandible. Although she is wearing her 15-year-old dentures, the facial changes are significant. The loss of muscle attachments lead to ptosis of the chin (witch's chin), loss of vermilion border (lipstick is applied to the skin), reverse lip line (decrease in horizontal angles), increased vertical lines in the face and lips, increased lip angle under the nose, and a lack of body in the masseter and buccinator muscles.

Conventional Prosthesis Complications

Fixed Partial Denture Morbidity

In the past, the most common treatment option to replace a posterior single tooth was a three-unit fixed partial denture (FPD). This type of restoration can be fabricated within a very short period of time and usually satisfies the criteria of normal contour, comfort, function, esthetics, speech, and health. Because of these benefits, a FPD has been the treatment of choice for the last 6 decades. This is a widely accepted procedure within the profession. Hard and soft tissue considerations in the missing site are minimal. Every dentist is familiar with the procedure, and it is widely accepted by the profession, patients, and dental insurance companies. In the United States, approximately 70% of the population is missing at least one tooth. Almost 30% of those aged 50 to 59 examined in a US National Survey exhibited either single or multiple edentulous

---

● BOX **1.5** **Esthetic Consequences of Bone Loss**

- Decreased facial height
- Loss of labiomental angle
- Deepening of vertical lines in lip and face
- Chin rotates forward giving a prognathic appearance
- Decreased horizontal labial angle of lip, which makes the patient look unhappy
- Loss of tone in muscles of facial expression
- Thinning of vermilion border of the lips from loss of muscle tone
- Deepening of nasolabial groove
- Increase in columella-philtrum angle
- Increased length of maxillary lip, so less teeth show at rest and smiling, which ages the smile
- Ptosis of buccinator muscle attachment, which leads to jowls at side of face
- Ptosis of mentalis muscle attachment, which leads to "witch's chin"

● **Fig. 1.25** (A) Panoramic radiograph of a 68-year-old female. The maxillary arch has severe atrophy and almost complete basal bone loss, including most of the nasal spine. The maxillary sinuses are completely pneumatized. The mandible exhibits severe atrophy with associated nerve dehiscence (B) Profile view. Note the maxillary bone loss effect: the lack of vermilion border of the lip, deep labial folds, and the columella-philtrum angle. The lower lip has a normal vermilion border and the muscles to the lower jaw are still attached, providing a normal contour.
● **Fig. 1.26** (A) Three-unit fixed partial denture is the most common method to replace missing teeth in the posterior regions of the jaws. (B) Three-unit fixed partial dentures have an increased possibility of recurrent decay or fracture with a poorer long-term success rate than an implant supported prosthesis.

spaces bordered by natural teeth.[38] However, there exist many inherent complications with FPDs. A three-unit FPD also presents survival limitations to the restoration and, more importantly, to the abutment teeth.[39] In an evaluation of 42 reports since 1970, Creugers and colleagues[15] calculated a 74% survival rate for FPDs for 15 years. The mean life spans of 9.6 to 10.3 years have been reported by Walton and colleagues[40] and Schwartz colleagues,[41] respectively. However, reports are very inconsistent, with as little as 3% loss over 23 years to 20% loss over 3 years. Caries and endodontic failure of the abutment teeth are the most common causes of prostheses failure. Up to 15% of abutment teeth for an FPD require endodontic therapy compared with 3% of nonabutment teeth that have crown preparations. The long-term periodontal health of the abutment teeth, including bone loss, may also be at greater risk.[39] Unfavorable outcomes of FPD failure include both the need to replace the failed prosthesis and the loss of an abutment and the need for additional pontics and abutment teeth in the replacement bridge. The abutment teeth of an FPD may be lost at rates as high as 30% within 14 years. Approximately 8% to 12% of the abutment teeth holding an FPD are lost within 10 years. The most common reason for single-tooth loss is endodontic failure or fracture of a tooth (usually after endodontic therapy).[42] Because 15% of abutment teeth require endodontics, and root canal therapy may be 90% successful at the 8-year mark, abutment teeth are at increased risk of loss. In addition, abutment teeth are more prone to caries when splinted together with an intermediary pontic. Individual crowns have decay rates below 2%; however, the risk of caries in abutment teeth is approximately 20%, mainly because the pontic region acts as a plaque reservoir. The carious lesion at the crown margin may cause structural failure, even if endodontic treatment is possible (Fig. 1.26). Almost 80% of abutments prepared for a three-unit FPD have no existing or only minimal restorations.[33] Rather than removing sound tooth structure and crowning two or more teeth, increasing the risk of decay and endodontic therapy (and splinting teeth together with pontics, which have the potential to cause additional tooth loss), a dental implant may replace the single tooth with a very high success rate (Box 1.6).

Therefore even though an FPD is an accepted treatment in dentistry, many inherent complications may develop. When evaluating partially edentulous spaces, a treatment option for replacement with a dental implant should always be included in the possible options presented to the patient.

Removable Partial Denture Morbidity

Removable soft tissue–borne partial dentures (RPD's) have one of the lowest patient acceptance rates in dentistry. Half the patients with a removable partial denture chew better without the prosthesis. A 44-year Scandinavian study revealed that only 80% of patients were wearing such prostheses after 1 year. The number further decreased to only 60% of the free-end partial dentures worn by the patients after 4 years.[43,44]

Wetherall et. al. reported a 60% tolerance and success in a 5-year distal extension RPD study. After 10 years, this was reduced to 35%[45] Wilding et. al. showed that very few partial dentures survived more than 6 years.[46] Although one of five US adults has had a removable prosthesis of some type, 60% reported at least one problem with it.[47] Reports of removable partial dentures indicate that the health of the remaining dentition and surrounding oral tissues often deteriorates. In a study that evaluated the need for repair of an abutment tooth as the indicator of failure, the survival rate of conventional removable partial dentures was 40% at 5 years and 20% at 10 years.[43,45] Those patients wearing the partial dentures often exhibit greater mobility of the abutment teeth, greater plaque retention, increased bleeding on probing, higher incidence of caries, speech inhibition, taste inhibition, and noncompliance of use. A report by Shugars and colleagues found abutment tooth loss for a removable partial denture may be as high as 23% within 5 years and 38% within 8 years.[39] Aquilino and colleagues reported a 44% abutment tooth loss within 10 years for a removable partial denture.[48] In addition, it should be noted that those patients wearing an RPD will accelerate bone loss

- Low survival rate: 60% at 4 years
- Low survival rate: 35% at 10 years
- Morbidity of abutment teeth: 60% at 5 years and 80% at 10 years
- Increased mobility, plaque, bleeding on probing, and caries of abutment teeth
- 44% abutment tooth loss within 10 years
- Accelerated bone loss in edentulous region if wearing removable partial denture

in the soft tissue support regions. Therefore alternative therapies that improve oral conditions and maintain bone are often warranted (Box 1.7).

Complete Denture Morbidity

Masticatory function is an important factor when discussing complete denture function. The difference in maximum occlusal forces recorded in a person with natural teeth and one who is completely edentulous is dramatic. In the first molar region of a dentate person, the average force has been measured at 150 to 250 pounds per square inch (psi).[49] A patient who grinds or clenches the teeth may exert a force that approaches 1000 psi. The maximum occlusal force in the edentulous patient has been shown to be reduced to less than 50 psi. The longer patients are edentulous, the less force they are able to generate. Patients wearing complete dentures for more than 15 years may have a maximum occlusal force of 5.6 psi.[50]

As a result of decreased occlusal force and the instability of the denture, masticatory efficiency also decreases with tooth loss. Within the same 15-year time frame, 90% of the food chewed with natural teeth fits through a No. 12 sieve; this is reduced to 58% in the patient wearing complete dentures.[51] The 10-fold decrease in force and the 40% decrease in efficiency affects the patient's ability to chew. In persons with dentures, 29% are able to eat only soft or mashed foods,[52] 50% avoid many foods, and 17% claim they eat more efficiently without the prosthesis. A study of 367 denture wearers (158 men and 209 women) found that 47% exhibited a low masticatory performance.[53] Lower intakes of fruits, vegetables, and vitamin A by women were noted in this group. These patients took significantly more medications (37%) compared with those with superior masticatory ability (20%), and 28% were taking medications for gastrointestinal disorders. The reduced consumption of high-fiber foods could induce gastrointestinal problems in edentulous patients with deficient masticatory performance. In addition, the coarser bolus may impair proper digestive and nutrient extraction functions.[54] There are systemic consequences from patients wearing conventional dentures. The literature includes several reports suggesting that a compromised dental function causes poor swallowing and masticatory performance, which in turn may influence systemic changes favoring illness, debilitation, and shortened life expectancy.[55-59] In a study evaluating the ability to eat fruit, vegetables, and other dietary fiber in edentulous subjects, 10% claimed difficulty, and blood tests demonstrated reduced levels of plasma ascorbate and plasma retinol compared with dentate subjects. These two blood tests are correlated with an increased risk of dermatologic and visual problems in aging adults.[60] In a study, the masticatory performance and efficiency in denture wearers were compared with dentate individuals. This report noted that when appropriate connections were made for different performance norms and levels, the chewing efficiency of

a denture wearer was less than one-sixth of a person with teeth. Several reports in the literature correlate a patient's health and life span to dental health.[61] Poor chewing ability may be a cause of involuntary weight loss in old age, with an increase in mortality. In contrast, persons with a substantial number of missing teeth were more likely to be obese.[62] After conventional risk factors for strokes and heart attacks were accounted for, there was a significant relationship between dental disease and cardiovascular disease, with the latter still remaining as the major cause of death. It is logical to assume that restoring the stomatognathic system of these patients to a more normal function may indeed enhance the quality and length of their lives.[63-65]

When patients wear a removable prosthesis, there exists a significant psychological component to the associated drawbacks of the prosthesis. The psychological effects of total edentulism are complex and varied and range from very minimal to a state of neuroticism. Although complete dentures are able to satisfy the esthetic needs of many patients, there are those who feel their social life is significantly affected.[66] They are concerned with kissing and romantic situations, especially if a new partner in a relationship is unaware of their oral handicap. Fiske and colleagues,[66] in a study of interviews with edentulous subjects, found tooth loss was comparable to the death of a friend or loss of other important parts of a body in causing a reduction of self-confidence ending in a feeling of shame or bereavement.

One dental survey of edentulous patients found 66% were dissatisfied with their mandibular complete dentures. Primary reasons were discomfort and lack of retention causing pain and discomfort.[67] Past dental health surveys indicated that only 80% of the edentulous population are able to wear both removable prostheses all the time.[68] Some patients wear only one prosthesis, usually the maxillary, whereas others are able to wear their dentures for short periods only. In addition, approximately 7% of patients are not able to wear their dentures at all and become "oral invalids." They rarely leave their home environment and when they feel forced to venture out, the thought of meeting and talking to people when not wearing their teeth is unsettling.

A report of 104 completely edentulous patients seeking treatment was performed by Misch.[53] Of the patients studied, 88% claimed difficulty with speech, with one-fourth having great difficulty. As a consequence, it is easy to correlate the reported increase with concern relative to social activities. Awareness of movement of the mandibular denture was cited by 62.5% of these patients, although the maxillary prosthesis stayed in place most of the time at almost the same percentage. Mandibular discomfort was listed with equal frequency as movement (63.5%), and surprisingly, 16.5% of the patients stated they never wear the mandibular denture.

In comparison, the maxillary denture was uncomfortable half as often (32.6%), and only 0.9% were seldom able to wear the prosthesis. Function was the fourth most common problem reported by these 104 denture wearers. Half the patients avoided many foods, and 17% claimed they were able to masticate more effectively without the prostheses. The psychological effects of the inability to eat in public can be correlated with these findings. Other reports agree that the major motivating factors for patients to undergo treatment were related to the difficulties with eating, denture fit, and discomfort. The psychological need of the edentulous patient is expressed in many forms. For example, in 1970, Britons used approximately 88 tons of denture adhesive.[69] In 1982, more than 5 million Americans used denture adhesives (Ruskin Denture Research Associates: AIM study, unpublished

---

• BOX 1.8   Negative Effects of Conventional Denture Prostheses

- Bite force is decreased from approximately 200 to 50 psi
- 15-year denture wearers have reduced bite force to 6 psi
- Masticatory efficiency is decreased
- Lack of proprioception
- Higher incidence of gastrointestinal disorders
- Patients life span may be decreased
- Food selection is limited
- Psychological factors

psi, *Pounds per square inch.*

• BOX 1.9   Advantages of Implant-Supported Prostheses

- Maintain bone
- Restore and maintain occlusal vertical dimension
- Maintain facial esthetics (muscle tone)
- Improve esthetics (teeth positioned for appearance versus decreasing denture movement)
- Improve phonetics
- Improve occlusion
- Improve/regain oral proprioception (occlusal awareness)
- Increase prosthesis success
- Improve masticatory performance/maintain muscles of mastication and facial expression
- Reduce size of prosthesis (eliminate palate, flanges)
- Provide fixed versus removable prostheses
- Improve stability and retention of removable prostheses
- Increase survival times of prostheses
- No need to alter adjacent teeth
- More permanent replacement
- Improve psychological health
- Overall health improved

● **Fig. 1.27** Note the long term bone maintenance around the multiple splinted implants.

increase in bone trabeculae and density when the dental implant is inserted and functioning. The overall volume of bone is also maintained with a dental implant. Even grafts of iliac crest bone to the jaws, which usually resorb without dental implant insertion within 5 years, are instead stimulated and maintain overall bone volume and implant integration. An endosteal implant can maintain bone width and height as long as the implant remains healthy and stimulates the bone within physiologic limits.[71]

The benefit of bone maintenance is especially noteworthy in the maxillary edentulous arch. Rather than using implants only in the edentulous mandibular arch, because the main mechanical denture problems are in this arch, the maxillary arch should also be addressed. Once implant prostheses are placed to support and retain the mandibular restoration, the bone in the maxillary region continues to be lost and eventually the patient may complain of loss of retention and inability of the maxillary denture to function. The loss of facial esthetics is most often first noted in the maxillary arch, with the loss of vermilion border of the lip, increased length of the maxilla lip, and lack of facial bone support. Implants should be used to treat the continued bone loss and prevent the later complications found in the maxillary arch.

A mandibular denture often moves when the mylohyoid and buccinator muscles contract during speech or mastication. The teeth are often positioned for denture stability rather than where natural teeth usually reside. With implants, the teeth may be positioned to enhance esthetics and phonetics rather than in the neutral zones dictated by traditional denture techniques to improve the stability of a prosthesis. The features of the inferior third of the face are closely related to the supporting skeleton. When vertical bone is lost, the dentures only act as "oral wigs" to improve the contours of the face. The dentures become bulkier as the bone resorbs, making it more difficult to control function, stability, and retention. With implant-supported prostheses, the vertical dimension may be restored, similar to natural teeth. In addition, the implant-supported prosthesis allows a cantilever of anterior teeth for ideal soft tissue and lip contour and improved appearance in all facial planes. This occurs without the instability that usually occurs when an anterior cantilever is incorporated in a traditional denture. The facial profile may be enhanced for the long term with implants, rather than deteriorating over the years, which can occur with traditional dentures.

data, 1982), and a report shows that in the United States, more than $200 million is spent each year on denture adhesives, representing 55 million units sold.[70] The patient is often willing to accept the unpleasant taste, need for recurring application, inconsistent denture fit, embarrassing circumstances, and continued expense for the sole benefit of increased retention of the prosthesis. Clearly the lack of retention and psychological risk of embarrassment in the denture wearer with removable prostheses is a concern the dental profession must address (Box 1.8).

Advantages of Implant-Supported Prostheses

The use of dental implants to provide support for prostheses offers many advantages compared with the use of FPDs or removable soft tissue–borne restorations (Box 1.9).

Maintenance of Bone

A primary reason to consider dental implants to replace missing teeth is the maintenance of alveolar bone (Fig. 1.27). The dental implant placed into the bone serves both as an anchor for the prosthesis and as one of the effective maintenance procedures in dentistry. Stress and strain may be applied to the bone surrounding the implant. As a result, the decrease in trabeculation and loss of bone that occurs after tooth extraction is reversed. There is an

Occlusion Stability

Occlusion is difficult to establish and stabilize with a completely soft tissue–supported prosthesis. Because the mandibular prosthesis may move as much as 10 mm or more during function, proper occlusal contacts occur by chance, not by design,[72,73] but an implant-supported restoration is stable. The patient can more consistently return to centric-relation occlusion rather than adopt variable positions dictated by the prosthesis' instability. Proprioception is awareness of a structure in time and place. The receptors in the periodontal membrane of the natural tooth help determine its occlusal position. Although endosteal implants do not have a periodontal membrane, they provide greater occlusal awareness than complete dentures. Patients with natural teeth can perceive a difference of 20 μm between the teeth, whereas implant patients can determine a 50-μm difference with rigid implant bridges compared with 100 μm in those with complete dentures (either uni- or bilateral).[74]

Occlusal Awareness

As a result of improved occlusal awareness, the patient functions in a more consistent range of occlusion. With an implant-supported prosthesis, the direction of the occlusal loads is controlled by the restoring dentist. Horizontal forces on removable prostheses accelerate bone loss, decrease prosthesis stability, and increase soft tissue abrasions. Therefore the decrease in horizontal forces that are applied to implant restorations improves the local parameters and helps preserve the underlying soft and hard tissues.

Masticatory Efficiency

In a randomized clinical trial by Kapur and colleagues, the implant group of patients demonstrated a higher level of eating enjoyment and improvement of speech, chewing ability, comfort, denture security, and overall satisfaction.[75] The ability to eat several different foods among complete denture versus mandibular overdenture patients was evaluated by Awad and Feine.[76] The implant overdenture was superior for eating not only harder foods, such as carrots and apples, but also softer foods, such as bread and cheese.[76] Geertman and colleagues evaluated complete denture wearers with severely resorbed mandibles before and after mandibular implant overdentures. The ability to eat hard or tough foods significantly improved.[77,78]

General Health

Researchers at McGill University in Montreal evaluated blood levels of complete denture patients and mandibular implant prostheses 6 months after treatment. Within this rather short period, implant patients had higher B_{12} hemoglobin (related to iron increase) and albumin levels (related to nutrition). These patients also had greater body fat in their shoulders and arms, with decreased body fat in their waists.[79]

Higher Success in Comparison To Other Treatments

The success rate of implant prostheses varies, depending on a host of factors that change for each patient. However, compared with traditional methods of tooth replacement, the implant prosthesis offers increased longevity, improved function, bone preservation, and better psychological results. According to 10-year survival surveys of fixed prostheses on natural teeth, decay is indicated as the most frequent reason for replacement; survival rates are approximately 75%.[42]

In the partially edentulous patient, independent tooth replacement with implants may preserve intact adjacent natural teeth as abutments, further limiting complications such as decay or endodontic therapy, which are the most common causes of fixed prosthesis failure. A major advantage of the implant-supported prosthesis is that the abutments cannot decay and never require endodontics. The implant and related prosthesis can attain a 10-year survival of more than 90%.

Increased Biting Force

The maximum occlusal force of a traditional denture wearer ranges from 5 to 50 psi. Patients with an implant-supported fixed prosthesis may increase their maximum bite force by 85% within 2 months after the completion of treatment. After 3 years, the mean force may reach more than 300%, compared with pretreatment values. As a result, an implant prosthesis wearer may demonstrate a force similar to that of a patient with a fixed restoration supported by natural teeth. Chewing efficiency with an implant prosthesis is greatly improved compared with that of a soft tissue–borne restoration. The masticatory performance of dentures, overdentures, and natural dentition was evaluated by Rissin and colleagues.[51] The traditional denture showed a 30% decrease in chewing efficiency; other reports indicated a denture wearer has less than 60% of the function of people with natural teeth. The supported overdenture loses only 10% of chewing efficiency compared with natural teeth. These findings are similar with implant-supported overdentures. In addition, rigid, implant-supported fixed bridges may function the same as natural teeth.

Nutrition

Beneficial effects such as a decrease in fat, cholesterol, and the carbohydrate food groups have been reported, as well as significant improvement in eating enjoyment and social life.[80,81] Stability and retention of an implant-supported prosthesis are great improvements over soft tissue–borne dentures. Mechanical means of implant retention are far superior to the soft tissue retention provided by dentures or adhesives and cause fewer associated problems. The implant support of the final prosthesis is variable, depending on the number and position of implants, yet all treatment options demonstrate significant improvement to the patients health.[82,83]

Phonetics

Phonetics may be impaired by the instability of a conventional denture. The buccinator and mylohyoid muscles may flex and propel the posterior portion of the denture upward, causing clicking, regardless of the vertical dimension.[73] As a result, a patient in whom the vertical dimension is collapsed may still produce clicking sounds during speech. Often the tongue of the denture wearer is flattened in the posterior areas to hold the denture in position. The anterior mandibular muscles of facial expression may be tightened to prevent the mandibular prosthesis from sliding forward. The implant prosthesis is stable and retentive and does not require these oral manipulations. The implant restoration allows reduced flanges or palates of the prostheses. This is of special benefit to the new denture wearer who often reports discomfort with the bulk of the restoration. The extended soft tissue coverage also affects the taste of food, and the soft tissue may be tender in the extended regions. The palate of a maxillary prosthesis may cause gagging in some patients, which can be eliminated in an implant-supported overdenture or fixed prosthesis.

Psychological Health

Patients treated with implant-supported prostheses judge their overall psychological health as improved by 80% compared with their previous state while wearing traditional, removable prosthodontic prostheses. This group perceived the implant-supported prosthesis

as an integral part of their body.[84] For example, Raghoebar and colleagues evaluated 90 edentulous patients in a randomized multi-center study.[85] Five years after treatment, a validated questionnaire targeted patient esthetic satisfaction, retention, comfort, and the ability to speak and eat with either a complete mandibular denture, complete mandibular denture with vestibuloplasty, or mandibular two-implant overdenture. Implant overdentures had significantly higher ratings, whereas no significant difference was found between the two complete-denture groups.[85] Geertman et al. reported similar results comparing chewing ability of conventional complete dentures with mandibular implant overdentures (Box 1.10).[78,86]

The Future of Implant Dentistry

The future of oral implantology is very positive and is expected to continue as one of the fastest and largest growth areas in medicine. The compound annual growth rate (CAGR) for dental implants is expected to grow at an annual rate of 9.7% through 2020, which is supported by improvement in techniques, technology, and materials.[87]

Techniques

Advancements in surgical procedures have had a significant impact on the field of oral implantology. Understanding bone density and modifications in surgical techniques has allowed an increase in success rates in poorer bone qualities. Modification of the bone using new techniques similar to osseodensification now can improve the quality of bone. With more biomechanically advantageous implant designs and the use of resonance frequency analysis (RFA), immediate implant placement and loading protocols have become more predictable. The RFA technology allows for the clinician to measure the bone-to-implant contact (Implant Stability Quotation), which is more accurate and predictable than subjective techniques. The use of better bone substitutes has allowed for predictable bone regeneration procedures to restore the hard and soft tissue loss from extractions. The ability to use bone growth factors (e.g., bone morphogenic proteins [BMPs]) increases the predictability of these procedures.

Technology

Technological advances have had a significant effect on the field of implant dentistry. The use of computerized tomography, mainly cone beam computerized tomography (CBCT), has changed the way clinicians plan and design implant cases. Faster, more efficient, low-radiation scanning machines allow the clinician to virtually plan the implant case with remarkable accuracy. New computer-aided design/computer-aided manufacturing (CAD/CAM) technology associated with CBCT scans allow clinicians to plan, design, and mill the entire case from provisionalization to the final prosthesis in the office setting.

The advent and accuracy of intraoral scanning technologies has risen to a level that has made conventional impression techniques almost obsolete. From a simple digital scan of the area of interest, the image data may be exported to a laboratory for fabrication and design of custom abutments, provisional restorations, and final restorations. Final casts or models may be fabricated via CAD/CAM milling or three-dimensional (3D) printing techniques. In-office 3D printers have given the clinician the luxury of printing models and prostheses in their offices, which is fast and simple.

Materials

One of the major advances in implant dentistry that will have a lasting effect on implant dentistry is the use of zirconia. This material allows the clinician to have a more predictable prosthetic option, which results in fewer and less maintenance and complication issues. The use of CAD/CAM to fabricate zirconia prostheses provides superior marginal integrity, fracture resistance, and flexural strength never seen in dentistry before. Zirconia is used for implant prosthetics and as a dental implant material. Major implant manufacturers are now creating zirconia implant options, showing a significant trend and a real presence of increased use of zirconia in the implant world.

Summary

The goal of modern dentistry is to return patients to oral health in a predictable fashion. The partial and complete edentulous patient may be unable to recover normal function, esthetics, comfort, or speech with a traditional prosthesis. The patient's function when wearing a denture may be reduced to one-sixth of that level formerly experienced with natural dentition; however, an implant prosthesis may return the function to near-normal limits. The esthetics of the edentulous patient are affected as a result of muscle and bone atrophy. Continued bone resorption leads to irreversible facial changes. An implant prosthesis allows normal muscle function, and the implant stimulates the bone and maintains its dimension in a manner similar to healthy natural teeth. As a result, the facial features are not compromised by lack of support, as is often required for removable prostheses. In addition, implant-supported restorations are positioned in relation to esthetics, function, and speech, not in neutral zones of soft tissue support. The soft tissues of the edentulous patients are tender from the effects of thinning mucosa, decreased salivary flow, and unstable or unretentive prostheses. The implant-retained restoration does not require soft tissue support and improves oral comfort. Speech is often compromised with soft tissue–borne prostheses because the tongue and perioral musculature may be compromised to limit the movement of the mandibular prosthesis. The implant prosthesis is stable and retentive without the efforts of the musculature. An implant-supported prostheses offers a more predictable treatment course than traditional prosthetic restorations. The profession and the public are becoming increasingly aware of this dental discipline. Manufacturers' sales are increasing and expected to increase in the future at an alarming rate. Almost all professional dental journals now publish refereed reports on dental implants. All US dental schools now teach implant dentistry, and this discipline has become an integral part of most specialty programs. The future of implant dentistry is very exciting with unlimited expansion via technology and development. Implant dentistry has become the ideal and primary option for tooth replacement.

Terminology in Implant Dentistry

NEIL I. PARK AND MAYURI KERR

The terminology used in implant dentistry is distinct, in many ways, from the terms and nomenclature used in other disciplines of clinical dentistry. Much of the instrumentation used in the placement and restoration of dental implants has been developed for those specific purposes and will be new to clinicians entering the field. There is also an extensive variation in types of implants and their designs, as well as surgical techniques used for site preparation, implant placement, and restoration. This chapter presents an overview to familiarize the reader with many of the terms used in implant dentistry.

Generic and Proprietary Terminology

As treatment with dental implants gained widespread acceptance in the 1980s and 1990s, several manufacturers developed instruments and components for commercial distribution. These companies also developed proprietary naming systems for their various components that were usually different, and sometimes conflicting, from one manufacturer to another. For example, Nobelpharma, the Swedish company formed to commercialize Professor Brånemark's treatment methods, discouraged the use of the term *implant,* preferring to call its anchoring devices *fixtures,* to differentiate them from the previous generation of dental implants.

Because these companies have been actively involved in sponsoring educational programs to bring new users to implant dentistry, these varying and conflicting terms have the potential to create confusion for clinicians and laboratory technicians attempting to treat patients with these products. Although it is appropriate for commercial manufacturers to develop proprietary names for product developments and refinements that are differentiated from the competition and protected by intellectual property laws, such situations of true product differentiation are increasingly rare. This chapter will present a generic nomenclature system for instruments and components that has developed over time and entered common usage in the literature. Every effort will be made to maintain consistency with published terms from sources such as the *Glossary of Implant Dentistry* from the International Congress of Oral Implantologists (ICOI) and the *Glossary of Prosthodontic Terms* from the American College of Prosthodontists (ACP). The ICOI document is a glossary developed specifically for terms used in implantology. ICOI released *Glossary III* to the public in 2017 as a digital document intended to allow changes and additions as clinicians and researchers provide suggestions in the years to come.[1] The *Glossary of Prosthodontic Terms,* now in its ninth edition, was first published by the Academy of Denture Prosthetics in 1956. The editors of the ninth edition sought to develop the glossary consistent with the spoken vernacular, and they have produced a highly useful document.[2]

Osseointegration

Although dental implants in varying forms have been used in the replacement of missing teeth for many years, current scientifically based concepts and treatment protocols owe their origins to the pioneering work of Per-Ingvar Brånemark, who was a Swedish physician and researcher (Fig. 2.1). Brånemark and colleagues first described **osseointegration** as direct contact between an implant and living bone at the light microscope level (Fig. 2.2).[3] He found this accidentally in 1952 while studying blood flow in the rabbit femur using titanium chambers inserted into the bony tissue; over time the chambers became firmly affixed to the bone and could not be removed. A bond was found between the bone and the titanium surface. In fact, when fractures occurred during the experiment, they were always found between bone and bone, never between the bone and the implant.[4] This definition of osseointegration was intended to distinguish the treatment method described by the Brånemark group from previously reported implant methods that frequently resulted in a soft tissue interface between the implant and supporting bone. The Swedish group presented clinical evidence resulting from a treatment protocol with specified instrumentation, drilling methods, cooling requirements, insertion techniques, and prosthetic loading protocols designed to minimize heating and denaturation of the bone. Together these protocols resulted in the regeneration of bone, rather than replacement with fibrous soft tissue, around the implant. The result was a treatment method that provided the patient with a bone-anchored prosthesis that restored function and could be maintained over a long period of time.

Other authors have proposed definitions of osseointegration that may be more useful in the clinical setting. The description of osseointegration as "a process whereby clinically asymptomatic rigid fixation of alloplastic materials is achieved, and maintained, in bone during functional loading"[5] provides specific parameters for the clinical assessment of implants in situ.

Osseointegration is also referred to as *secondary stability.* When implants are surgically placed, they rely on the *macrostructure,*

• **Fig. 2.1** Per-Ingvar Brånemark. (From Garg A. *Implant Dentistry: A Practical Approach*. 2nd ed. St Louis: Mosby; 2010.)
• **Fig. 2.2** Brånemark described osseointegration as a direct bone-implant interface viewed under the power of light microscopy. (From Misch CE. Generic root form component terminology. In: Misch CE, ed. *Dental implant prosthetics*. St Louis: Elsevier Mosby; 2015.)

or overall shape of the implant, combined with the surgical protocol to provide ***primary stability,*** which is an initial level of mechanical or frictional stability in the bone. As the bone heals, the process of osseointegration produces secondary stability, which is responsible for the long-term success of the implant. During the bone remodeling process after implant placement, primary stability decreases while secondary stability increases from new bone formation

Stability of implant over time
• **Fig. 2.3** Implant stability graph.

(Fig. 2.3). The period between primary and secondary stability in which inadequate total stability exists is referred to as the ***stability dip.*** Implant manufacturers attempted to reduce the duration and magnitude of this stability dip by improving the mechanical and surface characteristics of the implant, and by altering the drilling protocol.[6]

The biomechanical concept of secondary stability, or osseointegration, of dental implants has been characterized as a structural and functional connection between newly formed bone and the implant surface.[7] Osseointegration is comprised of a cascade of complex physiologic mechanisms similar to direct fracture healing.[8] The secondary stability of a dental implant largely depends on the degree of new bone formation at the bone-to-implant interface. At the end of the remodeling phase, about 60% to 70% of the implant surface is in contact with bone.[9] This is termed ***bone-to-implant contact (BIC)*** and is widely used in research to measure the degree of osseointegration.[6,10]

In 1986, Albrektsson and colleagues proposed the following criteria for an implant to be regarded as clinically successful[11]:
1. The unattached implant exhibits no clinical mobility.
2. Radiography demonstrates no evidence of radiolucency between implant and bone.
3. Marginal bone loss is less than 0.2 mm annually after the first year of service.
4. Absence of persistent pain, discomfort, or infection.

Albrektsson and colleagues proposed that these criteria (with a success rate of 85% at the end of a 5-year observation period and 80% at the end of a 10-year period) should be the minimum acceptable levels for a treatment method to be considered successful.[11]

Determination of Stability

Primary stability is an important factor in implant survival. Without primary stability, the implant may experience micromotion during the healing process, which may compromise the osseointegration process. Two methods are commonly used to determine primary stability. ***Insertion torque*** is the rotational force recorded during the surgical insertion of a dental implant into the prepared site, and it is expressed in Newton centimeters.[1] Although helpful in forming a clinical impression of initial stability, this measurement can be influenced by implant macrostructure and the comparative relationship between that design and the shape of the surgical osteotomy.

In an effort to more accurately report the primary stability of an implant, a technique using ***resonance frequency analysis***

• **Fig. 2.4** Resonance frequency analysis using the Penguin RFA. (Integration Diagnostics Sweden AB, Göteborg, Sweden.)

(RFA) was introduced in the late 1990s.[12] RFA stability measurements essentially apply a bending load, which mimics the clinical load and direction and provides information about the stiffness of the implant–bone junction.[13] Implant Stability Quotient (ISQ) is a measurement (based on a scale from 1–100) of the lateral stability of the dental implant, which serves as a surrogate for the degree of stability achieved. Fig. 2.4 shows the Penguin RFA (Integration Diagnostics Sweden AB, Göteborg, Sweden) device and its use clinically.

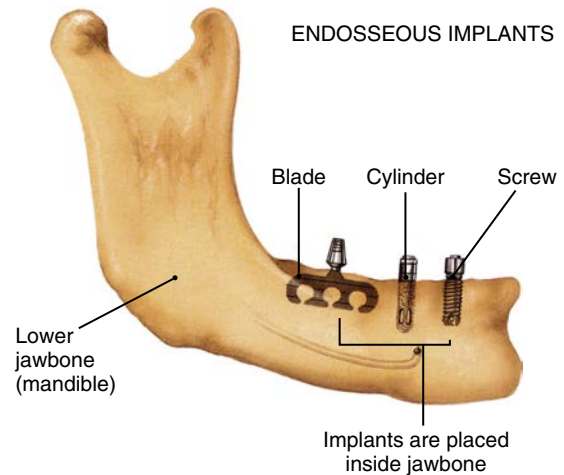
Devices such as the Osstell (Osstell AB, Göteborg, Sweden) and the Penguin RFA that measure ISQ can be used in the clinical setting to assess the stability of an implant and, most significantly, to determine the changes in stability over time.

Other methods to determine implant stability have been proposed, such as *percussion testing* and *reverse torque testing.* The percussion test involves the tapping of a mirror handle or other instrument against the implant carrier and judging stability by the sound. *Reverse torque testing* is the application of a reverse or unscrewing torque to the implant at the time of abutment connection. The latter two methods have not been shown to produce reliable results and are no longer commonly recommended.[13]

Types of Dental Implants

Endosseous Implants

An *endosteal* or *endosseous* dental implant is designed for placement into the alveolar or basal bone of the mandible or maxilla while maintaining the body of the implant within the bone. There are two basic types of endosseous implants, *blade* and *root form* (Fig. 2.5).

In contrast to earlier designs, such as the *periosteal* or *transosteal* (which are discussed in later sections of this chapter), in which one implant is usually fabricated to treat the entire arch, endosseous implants are individual units. This design provides the opportunity for the clinician to vary the number and size of the implants placed in the patient to maximize use of the supporting anatomy and to properly support the prosthetic reconstruction. This allows significantly greater flexibility in treatment planning and in the design of the prosthesis and provides better options for long-term maintenance, as well as for dealing with any future complications. Endosseous implants are currently the most widely used implant types.


• **Fig. 2.5** Endosteal implant design. Shown here are three different endosseous implant designs. Notice that all of the designs are implanted directly within the bone. Although the blade design has fallen out of use, the cylinder and screw-shaped versions continue to be the most widely placed implant designs in use today. (From Sakaguchi RL, Powers JM, eds. *Craig's Restorative Dental Materials*. 14th ed. St Louis: Mosby; 2019.)
• **Fig. 2.6** Radiograph of a blade implant supporting the distal aspect of a mandibular fixed partial denture. (From White SN, Sabeti MA. History of Single Implants. In: Torabinejad M, Sabeti MA, Goodacre CJ, eds. *Principles and Practice of Single Implant and Restorations*. Philadelphia: Saunders; 2014.)

Modern endosseous implants are designed with a macrostructure that optimizes initial stability and a *microstructure,* or surface texture, which promotes osseointegration. Similarly, the recommended surgical and restorative protocols are designed to promote and maintain primary stability and osseointegration of the implant.

Blade Implants

Blade implants are endosseous implants with a flat shape and are available in one-piece and two-piece designs (Fig. 2.6). Popularized by Linkow, the original blade was constructed from a CrNiVa alloy, but titanium alloy, aluminum oxides, and vitreous carbon materials have also been used. Cranin, Rabkin, and Garfinkel reported the outcome of 952 blades placed in 458 patients. The 5-year success rate was 55%. Smithloff and Fritz reported the outcome of 33 Linkow blades inserted in 22 patients (5 maxillae and 28 mandibles), with a 5-year success rate estimated at 42% to

66%. Ten-year results did not exceed a 50% success rate. Armitage found a 49% 5-year survival in a clinical study of 77 blade-vent implants[11] (Fig. 2.7).

With the widespread utilization and high success rates of root-form implants, overall usage of blade implants has decreased,[14] but they remain available from several manufacturers and find usage in the narrow bony ridge as an option for horizontal bone grafting.

Cylinder Implants

A *cylinder or press-fit implant* is an endosseous design consisting of a straight cylinder that is pushed or tapped into the surgical osteotomy (Fig. 2.8). Cylinder implants gained widespread popularity in the late 1980s to early 1990s because of their simple surgical placement protocol. Primary stability of these designs

• **Fig. 2.7** Radiograph of blade implant with significant bone loss.[14]

relies on a highly roughened surface texture to increase frictional resistance to dislodgement from the bone. Surfaces used for these implants included hydroxyapatite (HA), titanium plasma spray (TPS), and small metal balls sintered to the surface of the implant. These implants are used infrequently today because the highly roughened surfaces are associated with increased risk of peri-implant complications and because of improvements in other implant designs and surgical protocols.

Screw-Shaped Implants

Screw-shaped implants, in which the implant body exhibits screw threads throughout most or all its length, have become the most commonly used implant design. Current designs feature improved primary stability and simplified surgical placement protocols that have enabled thousands of practitioners globally, after receiving the required training and experience, to successfully treat millions of patients worldwide.

The original Brånemark implant was a *parallel-walled* design, featuring an implant body that maintained the same diameter throughout its length. Current designs feature a *tapered screw* design, in which the diameter of the implant body decreases toward the apex (Fig. 2.9).

One-Piece versus Two-Piece

The *two-piece* implant design consists of an *implant body,* which provides anchorage within the bone, and a *platform,* which provides a connection. This connection is used to join the implant to various instruments and components and, finally, to an abutment or prosthesis. A one-piece implant, as seen in Fig. 2.10, has an abutment as part of the implant.

Small Diameter Implants

Small diameter implants (SDIs), often called *mini-implants* (Fig. 2.11), are screw-shaped implants with diameters from 1.8 to 2.9 mm and lengths ranging from 10 to 18 mm. The primary indication for SDIs is for treating patients with thin residual ridges that do not allow the placement of standard implants of 3.0 mm and greater and as a treatment alternative to lateral ridge augmentation.
• **Fig. 2.8** Diagram showing a wide range of implant macro designs. (A) Brånemark solid screw implant. (B) straight flange intramobile cylinder press-fit implant. (C) flared flange in International Team of Implantology press-fit implant. (D) straight flange in a solid screw Astra implant. (From Huang YS, McGowan T, Lee R, Ivanovski S. Dental implants: biomaterial properties influencing osseointegration. *Comp Biomater.* 2017;7:[II]:444–466.)

Micro-threads zone

Internal hex connection

Buttress threads

Self-tapping groove

• **Fig. 2.11** One-piece mini-implants.
• **Fig. 2.12** Bone-level versus tissue-level implant.

• **Fig. 2.10** One-piece versus two-piece implants.

SDIs are usually a one-piece design and, in addition to thin ridge cases, have been used for retention of provisional restorations during implant healing and as orthodontic anchorage devices.

Bone-Level versus Tissue-Level Implants

Most root-form implants can be described as ***bone-level implants,*** because they are designed to be placed with the collar at or near the bone crest. This design provides additional flexibility for creation of the soft tissue emergence profile of the implant restoration. Implants that are designed for placement with the collar at or near the soft tissue margin are referred to as ***tissue-level*** implants (Fig. 2.12).

In 1961, Gargiulo and colleagues theorized that the vertical dimension of the dentogingival junction, comprised of sulcus depth (SD), junctional epithelium (JE), and connective tissue attachment (CTA), is a physiologically formed and stable dimension, subsequently called ***biologic width,*** and that this unit forms at a level dependent on the location of the crest of the alveolar bone.[15] Tissue-level implants were developed to increase the distance of the implant–abutment interface

from the bone surface to provide the required biologic width. Bone-level designs were later developed with conical connections and platform shifts, which serve similar goals.[16]

Implant Macrostructure

Implant macrostructure, or overall shape, is designed to optimize precise placement, initial stability within the bone, and distribution of forces within the bone. The predominating macrostructure for root-form endosseous implants is the screw shape, which includes the parallel-sided screw and the tapered screw (Fig. 2.13).

- The parallel-sided screw was documented extensively by Brånemark and colleagues and was considered to be the standard design

- **Fig. 2.13** Parallel-sided screw-shaped implant (left) and the tapered screw design (right). Comparison of the two designs illustrated design refinements made from approximately 1988 to 2015.

for many years. The surgical protocol for placing this implant shape included graduated drills of increasing diameter and usually ended with a tapping or thread-forming instrument that created threads that complemented the threads of the implant. Later, self-tapping implants were developed with a more aggressive apical shape that did not require this thread-forming step. For self-tapping designs, the surgical protocol normally dictated an osteotomy that conformed to the inner diameter of the screw, allowing the threads to cut their way in the bone during insertion.

- The tapered screw design was developed to provide two advantages over the parallel-sided implant: increased initial stability and anatomic conformity. A tapered screw implant design can provide improved primary stability because it condenses bone in areas of reduced bone quality.[17] Tapered screw implants also distribute occlusal forces to adjacent bone to a greater degree than parallel walled types.[18] Additionally, the anatomic shape of this design makes perforation of the buccal and lingual bony walls less likely to occur[19] and creates a more favorable opportunity to safely position the implant between adjacent tooth roots. Schiegnitz and colleagues found that the tapered design demonstrated greater primary implant stability than cylindrical implants.[20] In experimental groups, tapered implants were found to have better primary stability than parallel-sided implants.[21,22]

Implant Threads

Dental implants on the market today come in several different thread configurations; they can be understood using screw design terminology from engineering. The **crest** is the outer surface of the thread, and it joins the two sides of the thread. The diameter measured around the crest is the **outer diameter (OD)** of the implant. The **root** is the inner surface of the thread, and it joins the two sides of the thread. The diameter measured around the root is the **inner diameter (ID)** of the implant. The **helix angle** describes the angulation between the wall of the thread and the perpendicular axis. The **pitch** is the distance between two adjacent threads. Greater pitch is considered to be more aggressive in cutting through bone. The lead is the axial distance that the implant is inserted with one complete turn (Fig. 2.14).

One-Start Thread — Helix Angle, Pitch, Crest, Root

Four-Start Thread — Helix Angle, Pitch, Lead
- **Fig. 2.14** Demonstrating the difference in lead depending on the threads. (From Bullis G, Abai S. Form and function of implant threads in cancellous bone. *Inclusive Mag.* 2013;4[1].)

—— V-Thread ——   —— Square Thread ——   —— Buttress Thread ——   —— Reverse Buttress Thread ——
• **Fig. 2.15** Types of implant macrothreads. (From Bullis G, Abai S. Form and function of implant threads in cancellous bone. *Inclusive Mag.* 2013;4[1].)

The geometry of the threads themselves influences stress distribution around the implant. Deeper threads seem to improve primary stability, particularly in bone of poor quality.[23]

V-threads, square threads, and buttress threads are dental implant thread forms with a long history of successful use. These threads serve to dissipate occlusal loads into the bone surrounding the implant; however, they differ in form, inherent strength, and in how they transmit forces. V-threads are strong, but they transmit more shear forces to the surrounding bone. Square-thread forms transmit occlusal forces with less shear force than V-threads. Buttress threads minimize shear forces in a manner similar to square threads, and they combine excellent primary stability with the best features of both V- and square-thread forms (Fig. 2.15).[23]

The original Brånemark parallel-sided threaded implant was designed for placement into an osteotomy in which negative threads had been created during the surgical protocol using a *screw tap instrument* as a *threadformer*. Later, *self-tapping implants* were introduced, primarily for use in bone of lower density to improve the primary stability of the implant. With a non–self-tapping implant, the osteotomy is prepared to a size approaching the OD of the implant, whereas with a self-tapping implant the osteotomy is prepared to the approximate size of the inner diameter of the implant.

Most implants in use today feature the tapered screw design that has a self-tapping feature, which eliminates the need for tapping in all but the most dense bone.

Microthreads

Microthreads are a series of threads of small pitch placed in the crestal or collar portion of the implant. Microthreads help spread forces from the collar of the implant and can assist with the maintenance of crestal bone height.[21,24]

Implant Surfaces

Implant microstructure refers to the surface structure, or degree of surface roughness, of the dental implant. The surface structure of dental implants is critical for adhesion and differentiation of cells during the bone remodeling process.[6]

After the machining of a titanium or titanium alloy implant, contact with air causes the immediate development of a titanium oxide surface on the implant. Until the late 1980s, further surface treatments were rarely performed. Since that time, several surface
• **Fig. 2.16** Resorbable blast media blasted surface of the Hahn tapered implant.

modifications have been developed in an effort to modify the surface roughness of the implant to promote the process of osseointegration, particularly with poor bone quality.[6]

These modifications can be divided into *subtractive* and *additive* processes, depending on whether material is removed or deposited on the implant surface in the development of the surface. Commonly used scientific parameters to describe the surface roughness are the two-dimensional (2D) *Ra* (profile roughness average) and the three-dimensional (3D) *Sa* (area roughness average).[25] Although the ideal surface roughness is undetermined, according to Albrektsson and Wennerberg,[26] *Ra* in the range of 1 to 2 µm seems to provide the optimal degree of roughness to promote osseointegration. Pits, grooves, and protrusions characterize the microtopography and set the stage for biologic responses at the bone-to-implant interface. The modifications of microtopography contribute to an increase in surface area. Studies have shown increased levels of BIC for microrough surfaces.[25,27]

Subtractive processes include the following:
1. Etching with acid
2. Blasting with an abrasive material, such as silicon or HA; blasting with HA, known as *resorbable blast media (RBM),* is particularly advantageous because, unlike with grit or sandblasting, any particles remaining on the surface are resorbable (Fig. 2.16)
3. Treatment with lasers

• **Fig. 2.17** External versus internal implant–abutment connections.

• **Fig. 2.18** Various connection types.

Additive processes share the same goal of modifying the implant surface to a moderately rough degree, and they include:
1. HA coating
2. TPS
3. Anodization to thicken the titanium oxide surface

Implant Platforms and Connections

Connection Type

Implant connections are defined by the geometry of the connecting elements. The Brånemark implant design features an ***external hex*** on the implant, which mates with an ***internal hex*** on the abutment. In contrast, ***internal connection*** implants feature a chamber within the implant body to which an external projection of the abutment can engage (Fig. 2.17). Commonly used internal connections include hexagon, octagon, and trichannel, and many of these include a conical interface as part of their internal geometry (Fig. 2.18).

External hex designs are less commonly used today because of the mechanical and restorative advantages of internal connections. Screw loosening is a risk for external hex connections because greater lateral forces are transferred to the connection screw and because preload of the screw is the only force that resists occlusal forces.[28-30]

The IMZ implant, which is no longer manufactured, was distinguished by an intramobile element (IME) that included a Delrin spacer designed for placement between the implant and abutment. The design was thought to reduce the mechanical stress on the implant, but clinical experience over time resulted in the discontinuation of the design.

Platform Switched versus Platform Matching

Traditional implant designs, such as the Brånemark external hex, maintained the same diameter from the implant collar to the portion of the abutment that connects to the implant in a design known as a ***butt-joint*** or ***platform matched.*** With the advent of the internal

• **Fig. 2.19** Platform-matching versus platform-switched implants.

conical connection, it became possible to create a stable implant–abutment connection while reducing the diameter of the abutment. The situation in which the abutment is narrower than the implant at the connection is termed ***platform switching*** (Fig. 2.19). Platform switching has been shown to be beneficial in reducing bone loss around the implant, and it allows a greater volume of soft tissue at the implant–abutment interface to help achieve soft tissue esthetics.[31,32]

Surgical Protocols

Three different surgical protocols have been used for two-piece implant systems: ***one stage, two stage,*** and ***immediate restoration.***

- Biocompatibility
- Bioactive to promote cell differentiation and proliferation
- Low incidence of infection
- Nontoxic and nonimmunogenic
- Ability to maintain space and volume over time
- Ability to be replaced entirely with new bone growth
- Resorption rate to coincide with bone formation

From Resnik RR. Bone substitutes in oral implantology. Chairside Mag. 2017;12(3).

Using the standard, or two-stage protocol, the implant body, with a **cover screw,** is submerged below the soft tissue until the initial bone healing has occurred. During a **second-stage surgery,** the soft tissues are reflected to attach a component that passes from the implant connection, through the soft tissue, and enters the oral cavity. With the one-stage surgical approach, the surgeon places the implant body and a **temporary healing abutment,** which emerges through the soft tissue. During the restorative process, the healing abutment is replaced so that the prosthetic abutment or restoration can be connected, eliminating the need for a second surgery.

With the immediate restoration approach, the implant body and a prosthetic abutment are both placed at the initial surgery. A provisional restoration is then attached to the abutment.

Immediate Placement after Extraction versus Placement in Healed Sites

The standard protocol promulgated by Brånemark and colleagues dictated that after tooth extraction the site should be allowed to heal before implant placement. Pioneering work by Hahn and others showed high success rates for implants placed into the alveolus immediately after tooth extraction. A procedure known as the **emergency implant** was developed and popularized as a method used to provide an immediate implant replacement for a nonrestorable tooth.[33]

Bone Grafting

Insufficient bone volume may result from atrophy after tooth extraction, trauma, congenital deficiency, or surgical resection. Because an adequate volume of bone in the surgical site is an inviolable prerequisite for successful implant placement, **bone augmentation** techniques have been developed to facilitate implant treatment that would otherwise not be an option for some patients. **Site preparation** refers to bone grafting procedures performed before implant placement, whereas simultaneous grafting refers to procedures performed at the same time as implant placement. There are numerous alternative techniques and various agents and biomaterials currently used to augment bone for various indications.

Materials for Grafting

Materials used to augment bone volume include (Box 2.1):

Autogenous bone grafts are harvested from an adjacent or remote site in the same patient and used to build up the deficient area. Because of their osteogenic potential and low patient risk,

autogenous grafts are considered the ideal bone grafting material.

Allografts are bone grafts harvested from cadavers of the same species and processed to remove contamination and antigenic potential. The grafts are supplied by specially licensed tissue banks in particulate or block form.

Xenografts are bone grafts derived from nonhuman sources. Grafts from bovine, porcine, or equine sources are highly processed to completely remove the organic content.

Alloplastic graft material are synthetic bone substitutes, including calcium phosphates and bioactive glasses.

Table 2.1 lists considerations in selecting a bone grafting material.

Bone Augmentation Techniques

Guided bone regeneration (GBR) uses **barrier membranes** to protect bony defects from the rapid ingrowth of soft tissue cells so that bone progenitor cells may develop bone uninhibited. Ingrowth of soft tissue may disturb or totally prevent osteogenesis in a defect or wound. Examples of membranes used in this technique include **collagen** and **expanded polytetrafluoroethylene (PTFE).** Membranes are referred to as **resorbable** or **nonresorbable,** depending on whether they require a subsequent surgery for removal (Figs. 2.20 and 2.21).

• **Fig. 2.20** Bone graft material placement.

• **Fig. 2.21** Membrane placement for guided bone regeneration.

TABLE 2.1   **Bone Graft Material Considerations**

Graft type	Advantages	Disadvantages	Healing			Space Maintenance	Resorption Time	Indications
			Osteogenesis	Osteoinductive	Osteoconductive			
Autograft	• Gold standard • Nonimmunogenic • Predictable	• Requires second surgical site • Limited availability • Additional skill set required • Resorbs quickly	+	+	+	+	Medium to fast	All deficient areas
Demineralized allograft	• Osteoinductive qualities • No second surgical site • Readily available • Predictable	• Immunogenicity • Slight potential for disease transmission • Cultural concerns • Not for large graft sites	–	+	+	–	Fast	GBR, socket, sinus grafts
Mineralized allograft	• No second surgical site • Readily available • Predictable	• Potential immunogenicity • Slight potential for disease transmission • Cultural concerns • Not for large graft sites	–	–	+	+	Medium to slow	GBR, socket, sinus grafts
Xenograft	• No second surgical site • Readily available	• Increased inflammatory response • Slow resorption • Only osteoconductive • Immunogenicity • Potential for disease transmission • Cultural concerns • Not for large graft sites	–	–	+	+	Medium to slow	GBR, socket, sinus grafts
Alloplast	• No disease transmission • No immunogenicity • Greater acceptance • No second surgical site • Readily available	• Resorption • Unpredictability • Not for large graft sites	–	–	+	+	Fast to slow	Larger defects, sinus grafts

GBR, Guided bone regeneration.

From Resnik RR. Bone substitutes in oral implantology. *Chairside Mag.* 2017;12(3).

Some surgical techniques used to augment bone volume include only grafting, inlay grafting, ridge expansion, and socket-shield technique.

Onlay grafting describes a technique of applying the graft material over the defective area to increase width or height of the implant site.

With *inlay grafting,* a section of the jaw is surgically separated and graft material is sandwiched between two sections.

In *ridge expansion* techniques, the alveolar ridge is split longitudinally and parted to allow placement of an implant or graft material in the void.[35]

The *socket-shield* technique (Fig. 2.22) is designed to maintain the volume and contours of hard and soft tissue to optimize implant placement after tooth extraction. The technique involves preserving the buccal part of the root and placing an implant lingual to it. The gap between the implant and bone is filled with graft material and the area is allowed to heal[36] (Fig. 2.23).

Sinus Augmentation

The posterior maxilla is an area that frequently lacks adequate bone volume for implant placement. Several predictable techniques have been developed to graft bone to augment the sinus floor to accommodate dental implant insertion.

Maxillary sinus floor augmentation (MSFA), using the *lateral window technique,* was originally developed by Tatum in the mid-1970s and was later described by Boyne and James in 1980. This surgical intervention is still the most frequently used method to enhance the alveolar bone height of the posterior part of the maxilla before or in conjunction with implant placement.[37] The *crestal sinus lift* or *sinus bump* consists of raising the sinus floor and inserting graft material through the osteotomy.[38]

Bone Graft Properties

Bone grafts can be described as *osteogenic, osteoinductive,* and *osteoconductive* based on their contribution to bone healing. These properties of bone grafts directly affect the success or failure of graft incorporation, and the selection of the proper grafting protocol.[34]

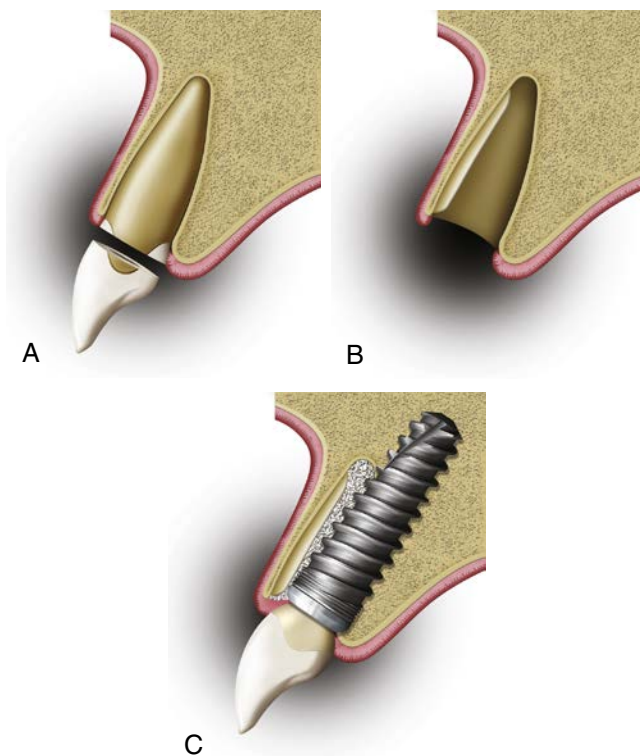
Osteogenesis is the ability of the graft to produce new bone, and it is a property found only in fresh autogenous bone and in bone marrow cells.[39]

Osteoconduction is the property of the graft to serve as a scaffold for viable bone healing. Osteoconduction allows for the ingrowth of neovasculature and the infiltration of osteogenic precursor cells into the graft site. Osteoconductive properties are found in cancellous autografts and allografts, demineralized bone matrix, HA, collagen, and calcium phosphate.[39]

Osteoinduction is the ability of graft material to induce stem cells to differentiate into mature bone cells. This process is typically associated with the presence of bone growth factors within the graft material or as a supplement to the bone graft. Bone morphogenic proteins and demineralized bone matrix are the principal osteoinductive materials. Autograft and allograft bone also have some osteoinductive properties.[39]

The ideal bone-graft substitute is biocompatible, bioresorbable, osteoconductive, osteoinductive, structurally similar to bone, easy to use, and cost-effective.

Surgical Instrumentation

Dental implants are designed and sold as *implant systems* that include a *surgical instrumentation kit* with drills designed for the surgical protocol for that specific implant system. Depending on the


• **Fig. 2.22** Stages of the socket-shield technique. (A) Crown sectioned. (B) Removal of the root, keeping the buccal "shield" intact. (C) Socket is grafted and the implant is placed.

manufacturer, surgical instrumentation kits include an assortment of ***drills, drivers, wrenches, screw taps,*** and ***implant mounts*** (Fig. 2.24).

Implant Drills

Implant drills are rotary cutting instruments that are used to create an osteotomy in bone. They are made of various materials, including surgical stainless steel, titanium alloy, and ceramics. When used in the proper sequence with the recommended rotary speed, torque, and irrigation, the drills are designed to create the correct size and shape of the osteotomy, providing initial stability without causing mechanical or thermal damage to the bone.[40]

Drivers

Various drivers are included in the surgical kit, depending on the manufacturer. Screws used in the course of implant treatment are engaged with hexed, slotted, or unigrip drivers.

Implant Mounts

Some systems require an implant mount to be attached to the implant to enable placement with the correct instrumentation. An implant mount serves to facilitate the delivery of a dental implant to the surgical site, and it can be used to rotate the implant to the correct depth. The implant mount is then removed from the implant to obtain visual confirmation of the position.

Other implant systems incorporate a direct-drive feature, in which an instrument engages directly into the implant, allowing for a simpler procedure and better vision during implant placement (Fig. 2.25).

Wrenches

Surgical kits include a ratchet wrench or ***torque wrench*** to place the implant. A torque wrench or torque driver is a manual instrument used to apply a specific amount of torque when placing an implant or prosthetic screw. A ***torque controller*** refers to an electronic machine designed for the same purpose. A torque wrench is recommended to ensure the application of a force that conforms to the manufacturer's recommendation.

Implant Components

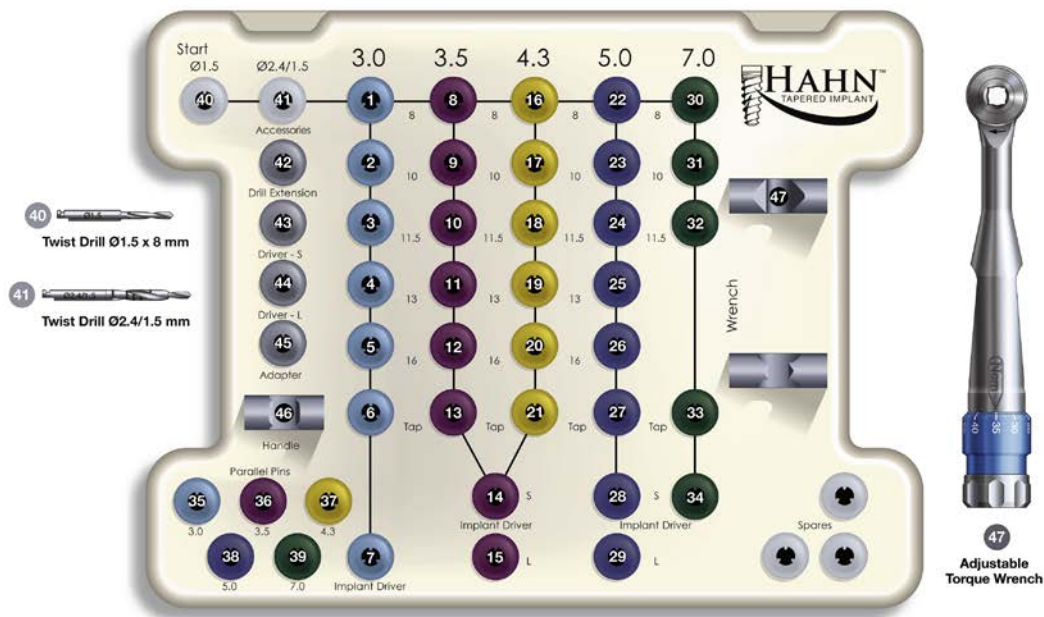
The ***cover screw,*** sometimes called a ***healing screw,*** is a component used to occlude the connection of the implant while submerged during a two-stage procedure (Fig. 2.26).
• **Fig. 2.23** Clinical case using the socket-shield technique. (A) Unrestorable tooth #7 with crown missing. (B) Removal of bulk of the root while retaining the buccal shield in the socket. (G and H) Intraoral views of Hahn implant with BruxZir crown on #7. Note maintenance of ideal gingival margin.


Fig. 2.24 Hahn implant surgery kit with various components. (Prismatik Dentalcraft, Irvine, California.)

A *healing abutment* is a component that connects to the dental implant and protrudes through the soft tissue. It can be connected to the implant at the second-stage surgical procedure, or it can be inserted at the time of implant placement to eliminate the need for a second surgery. This component has also been referred to as a *healing collar, permucosal extension, permucosal abutment,* or *healing cuff* (Fig. 2.27). Healing abutments are typically provided as stock components with a cylindrical shape, but they also can be customized for the specific case (Fig. 2.28). Healing abutments are typically left in place temporarily until the soft tissue has healed sufficiently to allow restoration of the implant. At that time, the healing abutment is removed, providing access to the restorative platform of the implant (Fig. 2.29).

Guided Surgery

A *surgical guide,* or *surgical template* (Figs. 2.30–2.32), is a device created for a specific case to assist the surgeon in placing the implants in the intended location. Guided surgery involves the use of a guide that directs placement of the implant. Fig. 2.30 illustrates the components of the Hahn guided surgery kit. Before the availability of 3D imaging digital data, guides were created based on a diagnostic wax-up of the final restoration and an approximate transfer of data from radiographs and intraoral examination. Currently, surgical guides are most commonly created from cone beam computerized tomography (CBCT) data, using dedicated software to digitally plan the case and design the surgical guide (Fig. 2.33).

Implant Restorations

Loading Protocols

The restoration of dental implants consists of the procedures needed for the connection of a prosthesis to one or more implants.

Restoration is accomplished using one of these basic loading protocols:

1. *Conventional loading:* Restoration occurs after the initial bone and soft tissue healing process, usually in 3 to 6 months, depending on bone density.
2. *Immediate loading:* A prosthesis is connected at the time of implant placement. This is usually a provisional restoration that is replaced with a definitive restoration after implant and soft tissue healing.
3. *Early loading:* The prosthesis connection occurs from 2 to 3 weeks after implant placement. This is considered to be a less predictable loading protocol because the restoration is sometimes placed during the stability dip, which is the period of lowest implant stability.
4. *Delayed loading:* The prosthesis is connected 6 to 12 months after implant placement. This method is often chosen in poor-quality bone and in situations in which primary stability cannot be achieved during surgical placement.

A summary of loading protocols is provided in Table 2.2.[41]

Standardized and Custom Components

Implant restorative components are said to be *standardized* when they are stock parts produced by the implant manufacturer.

• **Fig. 2.25** Hand driver (left) and rotary driver (right).

• **Fig. 2.27** Stock/standardized healing abutments.

• **Fig. 2.26** Hahn implant with holder and cover screw.

• **Fig. 2.28** (A) Custom healing abutment with ideal contours. (B) Healing abutment connected after implant placement.

• **Fig. 2.29** Removing the custom healing abutment reveals an ideal soft tissue cuff around the implant.

Custom components are designed and fabricated for a specific site in the same way that restorations are customized for a specific patient.

Impression Procedures

Impressions for implant restorations can be accomplished at the implant level or at the abutment level. *Implant-level impressions* are made by attaching a standardized *implant-level impression coping* directly to the implant and capturing that position in an impression. Implant-level impression copings are specific to the implant brand, platform diameter, and connection design. A cast is produced by attaching an *implant analog* to the impression coping and pouring the impression with dental stone. The implant analog is a standardized component that reproduces the implant platform and connection. From this, a cast is produced on which the doctor or technician may (1) select the appropriate standardized abutment to attach to the implant analog; (2) design and fabricate a custom abutment using the cast; or (3) fabricate an *implant-level prosthesis,* which attaches directly to the implant.

Abutment-level impressions are made intraorally after a standardized or custom abutment has been attached directly to the implant. If a custom abutment is used, then the abutment-level impression is very similar to an impression made for a typical fixed prosthesis, capturing the shape, position, and marginal detail of the custom abutment. In the case of a standardized abutment, an *abutment-level impression coping,* which is also a standardized component, is sometimes used.

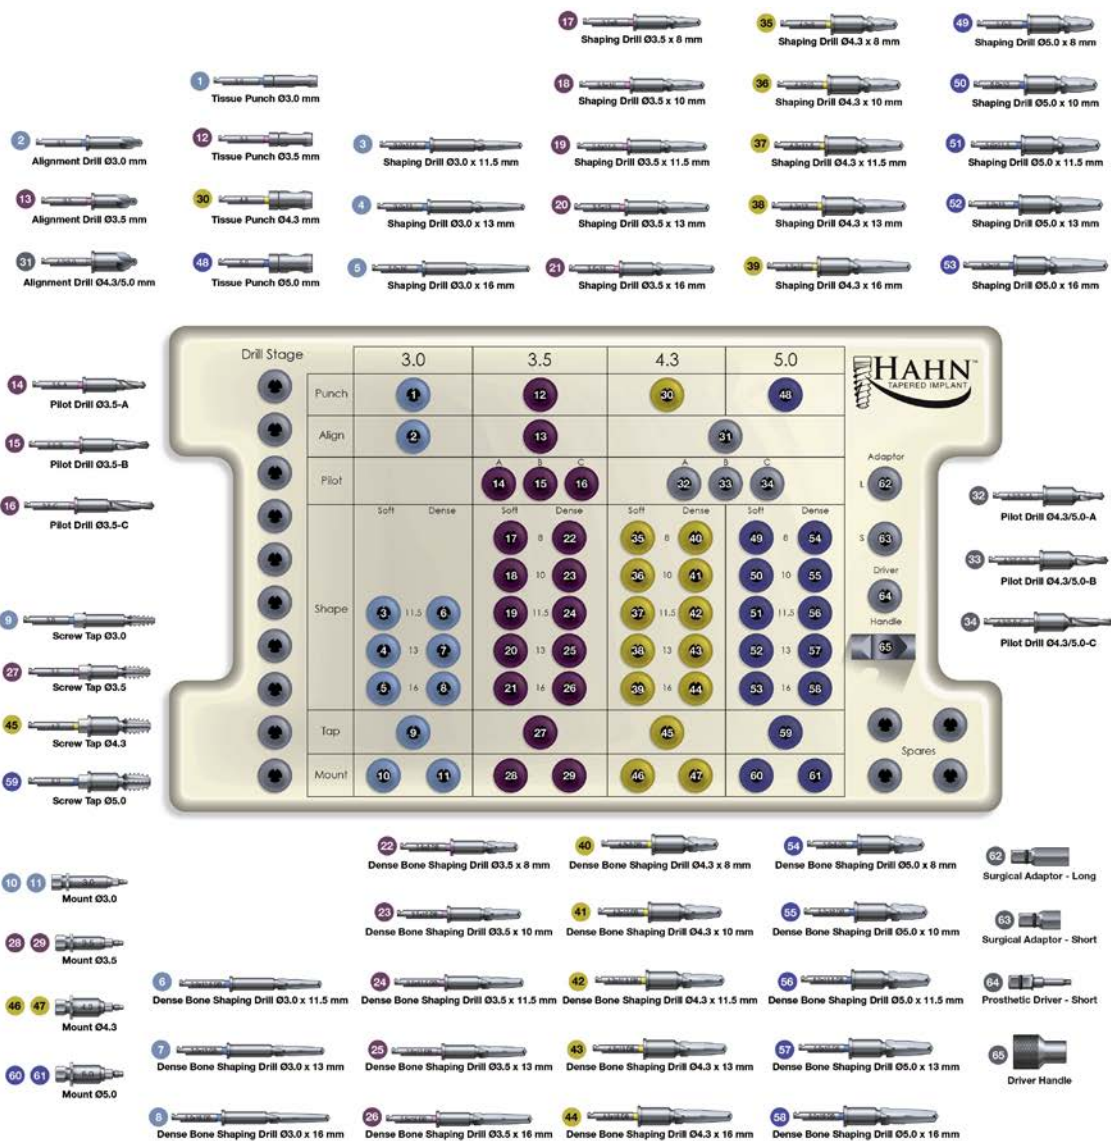
Implant components are said to be *engaging or nonengaging* depending on how they connect with the implant connection. Engaging components fit into the hex, octagon, or cams of the implant, preventing rotation after screw clamping. Nonengaging components bypass the antirotation feature of the implant to reduce the difficulty of engagement for multi-implant prostheses.

Impression Techniques

There are two major techniques used for making impressions using impression copings. Each method is facilitated by a specific coping design. In the *transfer* or *closed-tray* technique, the impression coping has a tapered shape and is attached to the implant or abutment, and it remains attached when the impression is removed from the mouth. The copings are then removed from the mouth and inserted into the impression. Analogs are attached to the impression copings before or after insertion, and the cast is poured[42] (Fig. 2.34).

With the *pick-up* or *open-tray* technique, the impression coping features squares or other retentive elements and is attached to the implant or abutment before the impression is made. The screws, which retain the impression copings, project through the impression tray and are loosened before impression removal. The impression copings are removed with the impression, analogs are connected, and the cast is poured[42] (Fig. 2.35).

Scanning abutments, or *scan bodies,* are used when making digital impressions of implants using an intraoral scanner (Fig. 2.36). The scanning abutment is attached to the implant before the digital scan, and it is recognized by the scanning or design software to indicate the correct implant position.

An *implant verification jig (IVJ)* is a device used to verify the accuracy of the master cast for an implant restoration. It consists of pick-up impression copings embedded in an acrylic framework and sectioned between the implants. The clinician then attaches each section to the implant, fuses the sections together intraorally, and provides the device to the laboratory for model verification (Fig. 2.37).


• **Fig. 2.30** Hahn guided surgery kit. (Prismatik Dentalcraft, Irvine, California.)

Screw-Retained versus Cement-Retained Restorations

Fixed implant restorations may be *screw retained* or *cement retained.* For a screw-retained restoration, the prosthesis can be attached to the implant directly, or indirectly, through the use of a standardized abutment. Cement-retained restorations may use a standardized abutment that has been modified for the specific case or, more commonly, a custom abutment that has been designed for the specific case. Custom abutments can be fabricated using a
- **Fig. 2.31** Guide created for the Hahn guided surgery kit. Note the hex sleeve placed in a three-dimensional position to direct the surgical drills and implant and the windows to ensure a tooth-supported guide has seated completely.
castable abutment, or through a computer-aided design (CAD)/computer-aided manufacturing (CAM) process, and can be produced from titanium, gold alloy, or milled zirconia with a titanium base (Figs. 2.38–2.43). Implant components are machined to close tolerances to ensure a precise fit, as seen in Fig. 2.44, which shows a computed tomographic (CT) scan of a Hahn implant with a stock abutment (Fig. 2.45).

Implant Overdenture

An *implant overdenture* is a full-arch prosthesis retained or supported by implants that is removable by the patient for daily maintenance. The implants may be unattached, or *free-standing,* or *splinted* together to increase the capacity for the prosthesis to resist biomechanical forces. *Overdenture attachments* are mechanical devices used to provide retention between the removable prosthesis and the implants. For splinted overdenture cases, the attachments are normally incorporated into the design of the splinting bar. For free-standing implants, the attachments are often in the form of an abutment that attaches directly to the implant, such as a ball or Locator attachment (Fig. 2.46).

*Temporary abutments* are standardized components embedded in the provisional prosthesis that are screw retained to the implant (Fig. 2.47).

Peri-implant Disease

Peri-implant disease refers to inflammatory reactions found in the soft and hard tissues surrounding an implant, and it is a well-reported complication of implant treatment. *Peri-implant mucositis* refers to the presence of inflammation in the soft tissue surrounding an implant with no signs of lost supporting bone. *Peri-implantitis* describes an inflammatory process

Shaping Drills

- **Fig. 2.32** Hahn guided surgery drills are designed with a cuff that fits precisely into the guide sleeve and eliminates the need for a spoon to hold the drill in place. Each drill is matched with the corresponding implant height.

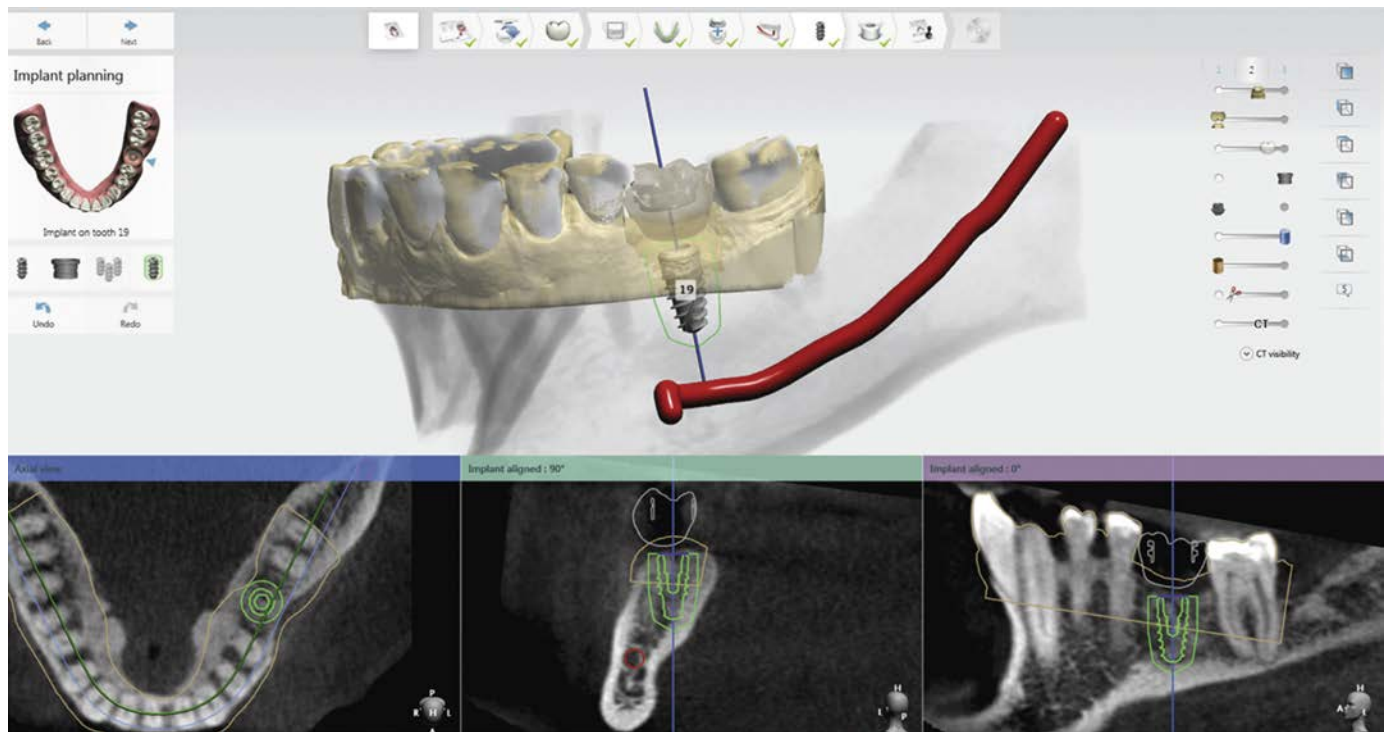
around an implant, characterized by soft tissue inflammation and loss of supporting bone[43-45] (Fig. 2.48). Tissue loss from peri-implantitis can result in the failure of implants and the associated prosthesis.

Other Types of Implants

Based on the site of implantation, there are three main types of dental implants: eposteal, transosteal, and endosseous. A fourth type of implant depends on extraoral anchorage, such as the zygomatic arch and the pterygoid process.

Eposteal Implants

Eposteal implants receive their primary support from contact against the remaining bone of the jaw.

The *subperiosteal implant* is the eposteal implant system that has received the greatest amount of usage and study in this


• **Fig. 2.33** Three-dimensional imaging data is used to plan the surgical guide.

TABLE 2.2 **Loading Strategies for Dental Implants**

Immediate loading	Enhanced primary stability	Loading is temporally irrelevant with respect to osseointegration	Implant placement with primary stability and prosthetic loading occurs at the same clinical visit
Early loading	Primary stability	Loading after onset of osteogenesis, before attaining osseointegration	Implant loading occurs 2–3 weeks[a] after implant placement
Conventional loading	Primary stability	Loading after osteogenesis and woven bone remodeling to load-bearing lamellar bone	Implants are loaded 3–6 months after healing in a submerged or nonsubmerged mucosal orientation
Delayed loading	Stability limited	Loading after protracted period and process of bone formation involving low-density or augmented bone	Loading 6–12 months after implants are placed without primary stability, when implants are placed into bone of low density, and when implants are placed into extraction sockets or concomitant with bone grafting without significant primary stability

[a]Rapid loading should not perturb initial healing (blood clot formation, cellular infiltration, and onset of epithelialization; approximately 2–3 weeks of healing). Provisionalization infers no occlusal contact for restoration of unsplinted implants.

category. Introduced by Dahl in 1943, with additional contributions from Goldberg and Gershkoff[46] and Linkow and Ghalili,[47] the subperiosteal implant is used principally for treatment of the edentulous mandible. The predominant treatment method involves two surgical interventions. During the first surgery, the operator reflects the oral mucosa and periosteum to uncover the bony edentulous alveolar process and the surrounding basal mandibular bone. While this tissue is reflected, an impression is made of the denture-bearing area. The surgical incision is then sutured, and a custom frame is fabricated, usually from a cobalt-chromium alloy. In a second surgical procedure, this frame is placed subperiosteally with several projections through the mucosa for attachment of the prosthesis. Fixed or removable prostheses can then be connected to these transmucosal posts.

Subperiosteal implants have been used for treatment of the edentulous mandible and maxilla. However, the best results have been reported for treatment of the edentulous mandible because of the greater bone density and resulting capacity to support the load of the prosthesis. Subperiosteally anchored implants are not considered to be osseointegrated implants, but they are intended to gain support by resting on the residual bony ridge (Fig. 2.49).

The *ramus frame,* another eposteal implant design, has also received significant clinical documentation. This is a one-piece implant, used in the mandible only, with right and left posterior extensions that are surgically placed into the corresponding right and left ascending rami, and an anterior foot, which is surgically placed in the bone of the symphysis (Fig. 2.50). Because long-term results for ramus frame and subperiosteal implants are less favorable than those from root-form implants, these designs are not currently considered as the first option for treatment of the edentulous arch.[4,11,37,47-49]

Transosteal Implants

Transosteal implants are a group of implant designs that pass completely through the bone. The *transmandibular implant (TMI)* refers to a design in which posts are inserted through the mandible in an inferior-superior direction to fixate a metal framework on which the prosthesis is attached. Implants included in this category include the *Smooth Staple* implant and the *Bosker.* These systems were developed specifically for the extremely atrophied mandible. In published studies, the majority of the patients treated had an anterior mandibular bone height of less than 12 mm.[50-53] The TMI is inserted through an extraoral approach, with the baseplate fixed to the inferior border of the mandible with the cortical screws. The transosseous posts, connected to the baseplate, perforate the mandible and the oral mucosa and are connected to each other with a bar equipped with two distal cantilevers. Three months after placement, an implant-supported overdenture is usually constructed. The completed prosthesis is retained by clips held in the mandibular denture. The clips engage bar segments, which are a part of the implant superstructure, and provide the necessary retention for the overdenture[54] (Fig. 2.51).

The TMI has been shown to be a successful clinical solution to prosthetic rehabilitation of patients with severe mandibular atrophy. In a study of 1356 patients over a period of 13 years, the implants show a consistent success rate of 96.8%.[50]

Studies comparing the TMI with endosseous implants[55,56] showed no significant differences between the two systems after 1 year,[55] but thereafter significantly more complications were reported with the TMI system. After 6 years, a survival rate of 97% was reported for the endosseous implants versus a survival rate of 72% for the TMI group.[57] In the highly resorbed mandible, short endosseous implants perform significantly better than the TMI.[56]

The staple bone implant system was developed as an alternative to subperiosteal frames because of the major complications that were encountered in the clinical application of subperiosteal frames.[58] The staple bone implant consists of a baseplate with two or four (parallel) transosseous pins and from two to five retentive pins (or screws) to stabilize the baseplate to the inferior border. The implant is made of a titanium alloy to allow for osseointegration. To prevent overloading of this implant system, a tissue-supported overdenture is fabricated with stress-breaking attachments to the implant. The mandibular staple bone implant has been evaluated in several retrospective studies that have reported survival rates of between 86% and 100%.[56,59-61]

Zygomatic and Pterygoid (Tubero-Pterygo-Maxillary) Implants

Although prosthetic treatment with osseointegrated implants is a predictably successful treatment method, in many cases severe maxillary atrophy remains a clinical challenge.[62] The success rate for root-form implants placed in the nongrafted severely resorbed

Dental implantation. In: Ratner BD, Hoffman A, Schoen F, Lemons J, eds. *Biomaterials Science*. 3rd ed. Waltham, MA: Academic Press; 2013.)

posterior maxilla is approximately 85%.[62] In these cases, implants placed in the zygomatic and pterygoid processes may offer patients an opportunity to have full arch prostheses by finding anchorage outside the maxilla.

The *zygomatic implant* enables the clinician to provide support for a maxillary prosthesis by anchoring implants in facial bone of sufficient volume and density. The technique involves the placement of implants of 50 mm or longer, extending from the maxilla to the zygomatic process. Several techniques have been proposed, with some involving a transosseous drilling path, and others remaining lateral to the sinus. Because of the challenges of limited direct vision and risks of associated anatomic structures, specialized training and careful technique are required for placement of this implant design. Because of the greater length of these implants, a significant error can result from even a small deviation from the intended drilling path.[62] The zygomatic implant has been established as a valuable treatment option for the patient with a highly resorbed maxilla. Angled abutments, as well as angled implant collars and prosthetic connections, have been developed to facilitate the fabrication of screw-retained prostheses supported by this type of implant (Fig. 2.52).

Clinical studies of the zygomatic implant show high rates of clinical success. Chrcanovic and colleagues published a review of studies on zygomatic implants. The 68 studies described 4556 zygomatic implants in 2161 patients, with only 103 failures (12-year Cumulative Survival Rate CSR, 95.21%). The survival rates reported suggest that zygomatic implants can successfully support immediate loading when patient selection and loading protocols are carefully controlled. The protocol dictated the prosthetic connection of all maxillary implants with a rigid connector, which results in a favorable load distribution, particularly important for immediate or early loading.[63]

Pterygoid implants were introduced as another method of maximizing the usable bone for placement of implants in the posterior maxilla. First described by Tulasne in 1989, the pterygoid implant is intended to pass through the maxillary tuberosity and pyramidal process of palatine bone and then engage the pterygoid process of the sphenoid bone. Implants used in this technique usually range from 15 to 20 mm. The implant enters in the maxillary first or second molar region and follows an oblique mesiocranial direction proceeding posteriorly toward the pyramidal process. It subsequently proceeds upward between both wings of the pterygoid processes and finds anchorage in the pterygoid or scaphoid fossa of the sphenoid bone (Fig. 2.53).

The advantages of using pterygoid implants are the availability of dense cortical bone for engagement of the implant and the potential to avoid the need for augmentation of the maxillary sinus and other grafting procedures. This may shorten the treatment time and allow immediate loading of the pterygoid implant. Increasing implant anchorage in the posterior maxilla also allows for a prosthesis with greater posterior extensions, eliminating the need for distal cantilevers. The disadvantages of the pterygoid
• **Fig. 2.51** Panoramic radiograph of a one-piece transosseous implant consisting of a metal plate located on the inferior border of the mandible, five posts that are placed into the mandible, and four posts that pass through the mandible. A bar has been attached to the four posts to provide retention and stability for a mandibular implant overdenture. (From White SN, Sabeti MA. History of single implants. • **Fig. 2.53** Virtual implant placement following the pterygoid bone corridor. The mesiodistal inclination (panoramic view) is shown. (From Rodriguez X, Lucas-Taulé E, Elnayef B, et al. Anatomical and radiological approach to pterygoid implants: a cross-sectional study of 202 cone beam computed tomography examinations. *Int J Oral Maxillofac Surg.* 2016;45[5]:636–640.)
• **Fig. 2.54** (A) Zygoma implant plus pterygoid implant with contralateral conventional implants. (B) Zygoma implant and pterygoid implants penetrating the radial forearm flap for reconstruction after left maxillectomy. (From Dierks EJ, Higuchi KW. Zygoma implants in a compromised maxilla. In: Baheri SC, Bell RB, Ali H, eds. *Current Therapy in Oral Maxillofacial Surgery.* Amsterdam: Elsevier; 2012. Courtesy David Hirsch, New York.)

implant are technique sensitivity associated with the procedure, proximity to vital anatomic structures, and access difficulty for clinicians and patients.[64] The success rate for pterygoid implants has been reported from 71% to nearly 100%.[65] Fig. 2.54 shows conventional, pterygoid and zygomatic implants in the patient's upper jaw.

Tuberosity implants originate at the most distal aspect of the maxillary alveolar process and may engage the pyramidal process.[66] There is some lack of consistency in the literature regarding the terminology associated with implants placed in this region. The terms "pterygoid implants," "pterygomaxillary

implants," and "tuberosity implants" are sometimes used interchangeably. The pterygoid implant has been defined as "implant placement through the maxillary tuberosity and into the pterygoid plate," and authors using the term pterygomaxillary implant are likely referring to implants placed in this complex, which involves the maxillary tuberosity, pyramidal process of palatine bone, and pterygoid plates. In contrast, the maxillary tuberosity is defined as "the most distal aspect of the maxillary alveolar process," and significant differences exist between pterygoid and tuberosity implants (Fig. 2.55). Pterygoid implants originate at the tuberosity, and a major portion

• **Fig. 2.55** Two implants were placed in the left maxilla, one in the tuberosity region and the other in the first molar region, and splinted with a ceramometal fixed bridge. (From Park YJ, Cho SA. Retrospective chart analysis on survival rate of fixtures installed at the tuberosity bone for cases with missing unilateral upper molars: a study of 7 cases. *J Oral Maxilllofac Surg.* 2010;68[6]:1338–1344.)

of the tuberosity body and apex is embedded in dense cortical bone of the pterygoid plates and pyramidal process of palatine bone, whereas tuberosity implants originate at the most distal aspect of the maxillary alveolar process and may engage the pyramidal process. Because the tuberosity region is predominantly composed of dense bone, the difference in bony support for a pterygoid implant and a tuberosity implant can be significant.[64]

Conclusion

A specific set of terms has been developed within the field of dental implantology to describe the instruments, components, and techniques used in clinical and laboratory practice. The basic terms have been described in this chapter, and, for further information, the reader is advised to consult the *Glossary of Implant Dentistry* (ICOI) and the *Glossary of Prosthodontic Terms* (ACP).

Functional Basis for Dental Implant Design

GRANT BULLIS

Dental implant therapy is a widely accepted treatment method for restoring chewing function in partially or fully edentulous patients. Treatment planning for dental implants requires consideration of the type of prosthesis, bone density, occlusion, function, bone volume, and any medically compromising factors.[1,2] Compromised bone density, large occlusal loads, and/or parafunction require greater implant support for the desired treatment outcome.[3-5] When compromising factors exist, the implant treatment plan must be adjusted to mitigate them to the maximum extent possible. Mitigation options include bone grafting,[6,7] lateral compression with osteotomes to improve bone density at the time of surgery,[8] implant site localization in conjunction with prosthesis design to minimize unfavorable occlusal loads,[9,10] and use of dental implants with attributes that address these compromising factors.[11]

Implant designs have progressed over time from the early press-fit blade designs, to press-fit cylinders, and finally to the straight and tapered threaded implants that comprise the majority of implant designs today. Press-fit cylinders are relatively easy to place because they do not have external threads that have to be advanced into the implant site. This ease of placement, however, comes with some compromise in primary stability and lower bone-implant contact relative to a threaded implant of comparable length and diameter. The surgical placement of press-fit blade implants in thin alveolar crests is also often easier than threaded implants because bone grafting can be avoided, and the surgical technique is relatively simple and can be performed with standard instuments.[12]

The aforementioned implant designs have high osseointegration success rates before loading; however, reported long-term success rates in function can be significantly lower (Table 3.1).[13-15] With this in mind, implant design should be predicated around addressing potential complications that may arise during function. Marginal bone loss after uncovering or loading of the implant is the most frequently reported complication in the dental literature. In a study conducted at the Brånemark Clinic in Gothenburg, Sweden, 28% of the 662 patients with implant-supported prostheses in function at least 5 years exhibited progressive bone loss to the level of three or more threads on at least one implant.[16] Bone quality, implant diameter, and implant length also contribute to implant failure rates after loading with softer bone, smaller diameter, and shorter implants exhibiting higher failure rates related to inadequate support relative to the load placed on these implants in function.[17,18] Because some percentage of restorative situations will present with soft bone and/or compromised bone volume, the design of the implant should compensate for these loading conditions.

Implant survival and marginal bone maintenance can vary greatly between implant designs. In a clinical report on the success of 43 consecutively placed Core-Vent Implants examined and followed from 3 months to 4 years, Malmqvist et al.[19] reported a success rate of 37.2%. A total of 11 implants were removed, 9 because of progressive vertical bone loss and 2 because of fractures. The vertical bone loss was calculated for the 32 remaining implants. Twenty-eight implants demonstrated a bone loss of more than 2 mm, and 16 showed a loss of more than one-third of the implant height.[19]

A study of 550 one-piece Nobel Direct implants by Albrektsson et al.[20] found a 10.7% average failure rate after 1 year from placement, with significant crestal bone loss on many of the remaining implants. Implant design contributed to the high failure rates of these implants relative to their peers (Table 3.2). Another study by Ormianer et al.[21] evaluated marginal bone loss using three dental implant thread designs with differences in thread pitch, lead, and helix angle. These implants had the same material and surfaces. The mean bone loss observed was between 1.90 and 2.02 mm for the single lead V-thread and double-lead progressive thread implants, respectively (Table 3.3). The overall implant survival rate was 96.3%. The remainder of this chapter applies biomechanical principles to dental implant design to improve short- and long-term outcomes and minimize complications. The function, form, and materials considered in the design of modern, threaded implants are examined in detail.

Function and Implant Design

Dental implants provide support for the prosthesis and transfer the occlusal forces to the supporting bone. The transfer of the forces to the supporting bone is determined by the resultant force transferred from the prosthesis to the implant and the amount of implant area available to transfer the force to the supporting bone. Implants have features designed to provide transfer occlusal forces to the bone and provide a secure, stable prosthetic connection (Fig. 3.1).

Besides the transfer of occlusal forces into the supporting bone, dental implants have features that facilitate the correct position of prefabricated and customized prosthetics, provide a mechanism

TABLE 3.1	Implant Long-Term Success Rates in Function			
Study Author(s)	Implant Type	Time Period		Success Rate
Bodine and Yanase	Subperiosteal	15 years		54%
Cranin, Rabkin, Garfinkel	Blade	5 years		55%
Smithloff and Fritz	Blade	10 years		~50%
Armitage	Blade	5 years		50%
McCoy	Cylinder	5 years		31%

TABLE 3.2	Reported Failure Rates of Nobel Direct One-Piece Implants		
Implant Diameter	Number of Implants	Number Lost	Failure Rate
3 mm	55	11	20%
3.5 mm	68	8	12%
4.3 mm	287	8	3%
5.0 mm	60	8	13%
Not specified	80	24	30%
All diameters	550	59	11%

From Albrektsson T, Gottlow J, Meirelles L, Östman PO, Rocci A, Sennerby L. Survival of Nobel Direct implants: an analysis of 550 consecutively placed implants at 18 different clinical centers. *Clin Implant Dent Relat Res.* 2007;9:65-70.

for insertion into the implant site, contribute to the seal stability and strength of the prosthetic connection, and aid in the correct identification of restorative components for the specific prosthetic connection. Combining features that are robust for their intended use helps to minimize complications during the surgical placement of implants and long after they are in function.[22,23]

Occlusal Forces and Implant Design

Force Type

Bone response to occlusal forces varies with the magnitude and the direction of the forces applied. Occlusal forces along the axis of the implant result in primarily compressive loading of the supporting bone. Nonaxial occlusal forces that are transverse to the implant axis result in significant tensile and shear forces (Fig. 3.2). Prosthesis design plays an important role in the transmission of occlusal forces to the implant and then to the supporting bone. Prostheses with cantilevered designs will transmit more tensile forces to the bone adjacent to the implant.[24,25] Bone is best able to resist loads that place it in compression, less resistant to tensile forces, and significantly less resistant to shear forces.[26] Because bone is strongest when resisting compression forces, implant design should facilitate compressive transfer of occlusal forces to

bone.[27] Load transfer to the supporting bone is most efficiently accomplished by the implant surfaces perpendicular to the axis of the implant. These surfaces transfer compressive and tensile forces to the bone. Implant surfaces that are not perpendicular or parallel to the implant axis will transfer shear forces, along with compressive and tensile forces, to the supporting bone (Fig. 3.3).

Force Magnitude

Bite force varies with the region of the mouth, muscularity, and the type of dentition. Observed mean bite forces in the molar region where forces are highest approach 200 psi for men and 135 psi for women with significant variation.[28] For some individuals, average bite forces can approach 1000 psi in the posterior regions.[29] Using a larger number of implants also helps distribute the bite forces.[30] These large bite forces require implant designs and materials robust enough to withstand peak and sustained forces of these magnitudes. Currently, titanium and titanium alloys provide the best strength properties without unacceptable compromises in other areas, such as biocompatibility.

Force Direction

As forces that diverge from the axis of the implant, the load-bearing capabilities of the supporting bone are compromised. The greater the divergence of the direction of the load from the implant axis, the greater the stresses at the implant-bone interface. Vertical loading of angled implants significantly increases the compressive stress values in the cervical region of the angled implants relative to those in axially loaded vertical implants.[31] The nonisotropic behavior of bone under different loading conditions further exacerbates the adverse effect of angled loads of bone. The tensile, compressive, shear, and ultimate strength of bone vary with the direction of the occlusal load applied to the bone.[32] Ideally, the implant should be placed with the implant axis loaded as near to vertical as possible to minimize shear and tensile force transmission to the interface between the bone and the implant. Prosthesis design, such as the avoidance of excessive distal cantilevers, that minimizes nonaxial load transfer to the implant and supporting bone also helps to minimize the stress to the components in the restoration. This also decreases the risk for force-related complications.

Force Duration

The duration of bite forces is widely distributed. Under ideal conditions the teeth come together during swallowing and eating, but only briefly. A study by Sheppard et al.[33] indicated that there is no tooth contact during most of the time spent in mastication. Approximately 19.5% of the time required for mastication was involved in possible tooth contacts for three foods.[33] The total time varies with the amount of mastication; however, it is estimated to be less than 30 minutes per day.[34] Bruxism increases force duration and is considered to be a contributing factor of dental implant and prosthetic complications and dental implant failure.[35]

Implant Geometry

Implant Shape

As mentioned previously, forces applied to the implant can be evaluated in magnitude, duration, type, and direction. The area over which the forces are applied serves to transmit the forces to the supporting bone. The larger the implant surface available for force transmission, the lower the stress experienced by the implant system and vice versa.

Implant	Thread Type	Thread Pitch	Thread Lead	Implant Qty	Implant Survival	Bone loss (mm)
SPI	Progressive	1.05 mm	2.1 mm	388	96.6%	2.02 (±1.70)

The surface area of the implant that participates in the transmission of occlusal forces to the supporting bone can be characterized as the area beneath the alveolar crest. Of that surface area, the surface area that participates in compressive load dissipation is most beneficial. Compressive load dissipation best serves to dissipate occlusal forces because bone is best able to resist compressive loads.[26] The bone-implant contact area available for occlusal force distribution in compression is therefore the most effective area for force transfer to the supporting bone.

Force transfer is not uniform across crestal and trabecular bone. Crestal bone stresses are highest when crestal bone thickness is less than 2 mm.[36] This distribution of occlusal stresses to the cortical bone dictates that the implant design in the cortical bone region suitably distributes occlusal forces to the surrounding bone without detrimental overload.[37-42]

Below the cortical region of the dental implant, implant geometry has a direct effect on the implant surface area and occlusal load distribution. In this region, trabecular bone is responsible for dissipating the remaining occlusal forces. The implant shape in the trabecular region reflects the need to transmit occlusal forces to the supporting bone in compression to the greatest extent possible. The shape of the implant, along with the implant length and diameter, all contribute to the area available to transmit forces in a compressive manner to bone in contact with the implant. This is particularly important with poor-quality bone because the area of the bone in direct contact with the implant is compromised by the lower bone density. As bone density decreases, more implant surface area is required to dissipate occlusal forces.[11]

Different implant survival rates and amounts of marginal bone loss may be directly related to different implant shapes. The shape of the implant relates to the surface area involved in the transfer of forces to the supporting bone. Any geometric features that extend outward from the axis of the implant may transfer stresses to the bone under load (Fig. 3.4).

Vandamme et al.[43] installed a repeated sampling bone chamber with a central implant in the tibia of 10 rabbits and performed highly controlled loading experiments with cylindrical and screw-shaped implants. They concluded that well-controlled immediate implant loading accelerates tissue mineralization at the bone-implant interface. Adequate bone stimulation via mechanical coupling may account for the larger bone response around the screw-type implant compared with the cylindrical implant. Implant shape was a contributing factor.

Ormianer and Palti[44] studied long-term performance of tapered screw implants placed in patients with a variety of potentially compromising clinical variables. They found that tapered implants maintained crestal bone levels even in clinically compromised conditions. Concerns that tapered implant designs may be more prone to crestal bone loss than cylinder designs were unsupported by the results of their study.[44]

Atieh et al.[45] reviewed the implant stability of tapered and parallel-walled dental implants. Their analysis showed greater implant stability at insertion and after 8 weeks, but the difference was not statistically significant. Failure rates were not significantly different between the two implant shapes. Marginal bone loss, however, was significantly less for the tapered implants compared with the parallel-walled implants.

Implant Diameter

For a given implant length, increasing the implant diameter will increase the implant surface area that is available for force transfer to the bone. Provided there is sufficient bone volume, a larger diameter implant is better able to resist occlusal forces, particularly in the molar region. Nevertheless, implant diameter alone is not a predictor of better clinical success in all situations. In a 5-year retrospective study of clinical results, Krennmair et al.[46] studied the survival and success rates of 541 CAMLOG tapered implants of 3.8, 4.3, and 5/6 mm placed and restored. The failure rates were 3.7%, 1.4%, and 1.0% for the respective implant diameters. There was no difference in the observed peri-implant marginal bone resorption among the implant diameters.[46]

Javed and Romanos[47] reviewed literature regarding the influence of implant diameter on long-term survival of dental implants placed in the posterior maxilla. Their study examined threaded, rough-surfaced dental implants with diameters ranging between 3.0 and 5.5 mm, and follow-up periods and cumulative survival rates ranging between 5 and 15 years and 80.5% and 100%, respectively. They concluded that "the role of implant diameter on long-term survival of dental implants placed in posterior maxilla is secondary. A well-designed surgical protocol, achievement of sufficient primary stability at the time of implant placement, and pre- and postsurgical oral hygiene maintenance visits are critical factors that influence the long-term survival of dental implants placed in posterior atrophic maxilla."

Olate et al.[48] studied the influence of implant diameter and length on early implant failure. They examined 1649 implants in 650 patients from three different manufacturers. All of the implants were of cylindrical shape and similar surface (acid-etched). The implants were placed in all regions of the mouth. The early survival rate was 96.2% for all implants, with wide implants (2.7%) experiencing lower losses than regular (3.8%) and narrow (5.5%) implants. Short implants (6–9 mm) related to the largest (9.9%) incidence rate of early implant loss.

Wider implants decrease stress at the bone-implant interface. Conversely, smaller-diameter implants show increased stress at this interface. Stress is force divided by the cross-sectional area the force is acting on. For implants of a given length and geometry, wider implants have more surface area to occlusal forces to act on and thus lower stress. This is most pronounced with implants smaller than 4 mm in diameter (Fig. 3.5). Smaller-diameter implants with shorter implants lengths have significantly less surface area to distribute forces to the supporting bone (Fig. 3.6). This unfavorable combination should be avoided to the extent possible, particularly in the posterior region, where bite forces are greater.

Besides decreased stress at the bone-implant interface, wider implants are generally more resistant to fracture from occlusal overload and fatigue conditions. Prosthetics are fastened to the implant by means of an abutment screw, which extends internally
● **Fig. 3.5** Stresses around 10-mm length implants of 3.5-, 4.3-, and 5.0-mm diameters. Note the signifi-cant decline in stress as diameter increases to more than 3.5 mm. *(Image courtesy of Glidewell Dental, Newport Beach, California)*

	3.5 x 10 mm	3.5 x 16 mm	5.0 x 10 mm	5.0 x 16 mm
Surface Area	137.84 mm^2	208.93 mm^2	271.93 mm^2	320.89 mm^2

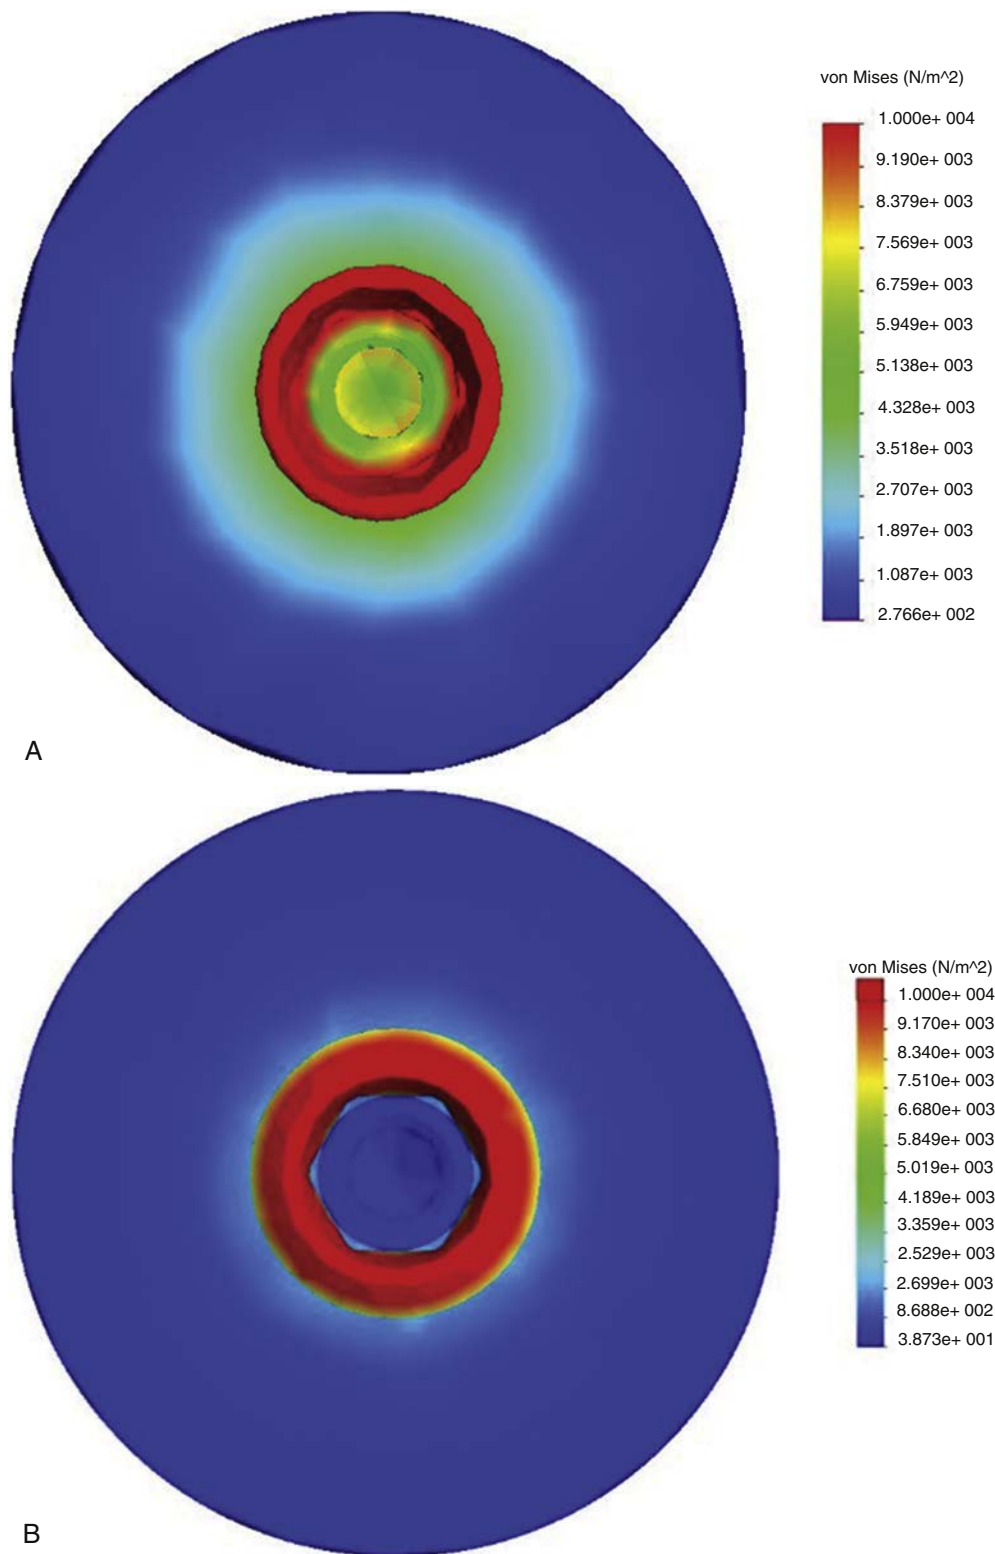
● **Fig. 3.6** There is a large variation in surface area among implant lengths and diameters. *(Image courtesy of Glidewell Dental, Newport Beach, California)*

into the implant and engages the internal threads of the implant. The screw receiving bore inside the implant removes material and increases stress on the implant because the cross-sectional area acted on by occlusal forces is reduced. After accounting for the loss of area for the abutment screw bore, wider implants will still have more cross-sectional area (wall thickness) than narrower implants, lower stress, and more fracture resistance (Fig. 3.7).

Most modern implant designs also use the prosthetic connec-tion geometry to insert the implant into the implant site. The insertion tool or fixture transmits stress to the connection geom-etry, which can deform the connection or lead to fracture of the implant in the connection region (Fig. 3.8). Wider-diameter implants with greater wall thickness are most resistant to implant fractures of this nature.

In a retrospective study of 2670 patients consecutively treated with implant-supported prostheses, Chrcanovic et al.[49] analyzed anatomic, patient, and implant-related factors as explanatory vari-ables to implant fracture. They analyzed 44 fractured implants from a total population of 10,099 and found implant diameter to be a strong explanatory variable related to the probability of implant fracture. For every 1-mm increase in implant diameter, there was a 96.9% decrease in the probability of implant frac-ture (Table 3.4). Other factors such as direct adjacency to canti-levers and bruxism increased the probability of implant fracture by 247.6% and 1819.5%, respectively. Wider implants offer increased resistance to the stresses encountered in these clinical situations when prosthesis design and parafunctional habits are not optimal.

Implant Length

Implant length is another parameter to consider in implant design. Along with implant diameter, implant length affects the


• **Fig. 3.7** With more surface area, the wider implant (B) transfers less stress to the surrounding bone (shown as blue circular perimeter) than the narrower implant (A). *(Image courtesy of Glidewell Dental, Newport Beach, California)*

stability and the transfer of forces to the surrounding bone. In a study of 2907 implants from placement to 36 months, Winkler et al.[50] studied the implant survival and stability for implants with lengths varying from 7 to 16 mm. Survival rates varied from 66.7% for 7-mm length implants to 96.4% for 16-mm length implants. Shorter implants had statistically lower survival rates compared with longer implants.

Conversely, a prospective clinical study with 1 to 10 years of follow-up by Mangano et al.[51] of 215 locking taper implants (8 mm) supporting single-tooth crowns in the posterior region

TABLE 3.4	Factors Influencing Probability of Implant Fracture

Factor	Change in Probability of Implant Fracture
Use of stronger grades of titanium	−72.9%
Bruxism	+1819.5%
Directly adjacent to cantilever	+247.6%
1 mm increase in implant length	+22.3%
1 mm increase in implant diameter	−96.9%

From Chrcanovic BR, Kisch J, Albrektsson T, Wennerberg A. Factors influencing the fracture of dental implants. *Clin Implant Dent Relat Res.* 2018;20:58-67. https://doi.org/10.1111/cid.12572

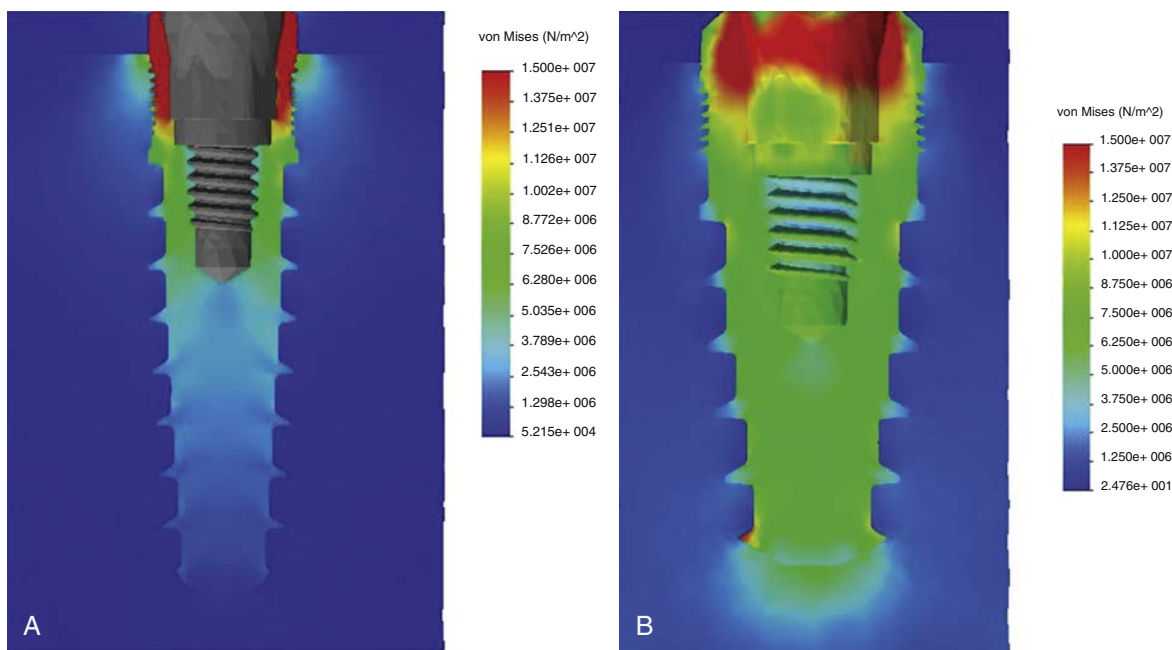
showed an implant survival rate greater than 98%. Marginal bone loss was 0.31 (±0.24), 0.43 (±0.29), and 0.62 (±0.31) mm at the 1-, 5-, and 10-year follow-up session.

Another study by Ding et al.[52] used a finite element mandibular model to evaluate the effects of diameter and length on stress distribution of the alveolar crest around immediate loading of Straumann implants with diameters ranging from 3.3 to 4.8 mm and length ranging from 6 to 14 mm. The implants were loaded vertically and obliquely, and the stresses and strains in the surrounding cortical bone were evaluated. Under both vertical and oblique loading conditions, maximal values were recorded in the 3.3 × 10 mm implant configuration, the second-highest values in the 4.1 × 6 mm implant configuration, and the lowest values in the 4.8 × 10 mm implant configuration. Increasing the diameter and length of the implant decreased the stress and strain on the alveolar crest; however, diameter had a more significant effect than length to relieve the crestal stress and strain concentration. The 10-mm length of the 3.3-mm implant was not sufficient to compensate for the larger diameter of the 4.1-mm implant despite the 4.1-mm implant having 4 mm less length.

Greater implant length is beneficial in decreasing stress and strain in the supporting bone; however, a larger implant diameter is more effective (Fig. 3.9). Implant length alone may be insufficient to compensate for diameter, particularly if bone quality is poor. For example, a 7.0 × 8.0 mm Hahn implant has approximately 20% more surface area than a 5.0 × 10.0 mm implant.

Implant Features

Implant Collar

The implant collar serves as the transition area between the prosthesis and the body of the implant. Its design dictates the placement of the prosthetic interface relative to the bone and gingival tissue surrounding the implant site, as well as stress distribution into the surrounding cortical bone. These characteristics make the implant collar a critical implant feature with important implications for the long-term success of the implant restoration.


Implant collars designed for a supragingival prosthetic connection are characterized by an extended region above the implant threads that protrudes above the gingival tissue (Fig. 3.10). The surface of the collar is typically smoother than the threaded region of the implant body, and the diameter of the collar region is larger than the body of the implant below it. Because the collar is designed to position the prosthetic platform above tissue height, there is little to no need for healing abutments and tissue-forming components.

Collars for bone-level implants have subgingival design considerations. Because of the curvature of the osseous crest, the crestal bone interface for bone level implants can vary at the time of placement (Fig. 3.11). Unless the implant placement is significantly subcrestal, some portion of the implant collar will be supracrestal and in contact with the gingival tissue immediately after surgical placement. In an animal study of tissue reactions to plaque formation after ligature removal of commercially available implants exposed to experimental peri-implantitis, Albouy et al.[54] found that spontaneous progression of experimentally induced peri-implantitis occurred at implants with different geometry and surface characteristics. The progression was most pronounced at implants with an anodized (TiUnite) surface. In another animal study of the progression of peri-implantitis around implants with different surface roughness, Berglund et al.[55] found that the progression of peri-implantitis, if left untreated, is more pronounced at implants with a moderately rough surface than at implants with a polished surface. The upper region of the implant collar may be transosteal after placement, and roughened surfaces in this region can leave the implant more vulnerable to the progression of peri-implantitis. A machined rather than roughened surface at the upper region of the implant collar is more beneficial during the epithelial wound-healing process[56] (Fig. 3.12).

Although animal studies have shown bone formation in the crestal region despite the presence of significant circumferential defects at the time of implantation,[57,58] at the crestal bone level, and below, the implant collar helps to seal the implant site against fibrous tissue encapsulation and bacterial contamination. Initial bone-implant contact is improved with an implant collar at least the same diameter or slightly larger than the body of the implant. Petrie and Williams[59] studied the influence of diameter, length, and taper on strains in the alveolar crest, and found a strong correlation between increased implant diameter leading to reduced stresses in the crestal region. Taper in the implant collar region was found to increase crestal bone stress because it reduced the diameter and surface area in contact with the cortical bone. The distribution of stress at the crestal area is dictated by the surface area of the implant collar (Fig. 3.13).

An implant with a slightly larger collar surface area reduces stress in the crestal region compared with the implant with the smaller collar.

Besides the diameter and surface texture of the implant collar, features in the collar region of the implant that have been

• **Fig. 3.9** The 3.5-mm diameter implant (A) is 3 mm longer, but it has more crestal stress and strain than the 4.3-mm implant (B). *(Images courtesy of Glidewell Dental, Newport Beach, California)*

attributed with preserving crestal bone levels include microthreads and platform switching. These features were created to improve the dissipation of occlusal loads in the crestal bone region and to mitigate complications related to biologic width development during and subsequent to the implant wound healing process.

Microthreads in the implant collar region have been shown to help maintain marginal bone levels.[60,61] In an animal study of implants with and without microthreads in the marginal region connected to fixed partial dentures in the mandibles of beagle dogs, Abrahamsson and Berglundh[62] observed that the degree of bone-implant contact within the marginal portion of the implants was

significantly higher at the test (microthread) implants (81.8%) than at the control implants (72.8%). Using axisymmetric finite element analysis, Hansson and Werke[63] analyzed the effect of variations of the size and the profile of the thread of an axially loaded, screw-shaped bone implant on the magnitude of the stress peaks in cortical bone. They found that very small threads of a favorable profile can be quite effective at distributing stress in the cortical bone region and that the shape of the thread profile has a profound effect on the magnitude of the stresses in the bone. Hudieb et al.[64] conducted a finite element analysis of the magnitude and

direction of mechanical stress of a microthreaded implant relative to the same implant design without microthreads. The analysis showed that regardless of the loading angle, principal stresses at the bone-implant interface of the microthread model were always perpendicular to the lower flank of each microthread. Whereas in the implant without microthreads, stresses were affected by the loading angle and directed obliquely to the bone-implant interface, resulting in higher shear stress. The lower shear-stress component of the microthreaded implant in this simulation was an explanatory biomechanical variable for crestal bone preservation in implants with microthreads (Fig. 3.14).

Platform shifting, or the use of abutments with a diameter less than the implant collar, is thought to be beneficial to the preservation of marginal bone levels[65] and to provide a biomechanical advantage in osseointegrated implants by shifting the stress concentration area away from the cervical bone-implant interface with

an inverse relationship between the amount of implant-abutment diameter mismatch and cortical bone stress concentration.[66,67] There has not been a conclusive correlation between platform switching and implant placement relative to the crestal bone level. With delayed loading, differences in crestal and subcrestal placement of platform-switched implants have not been significant after up to 36 months of follow-up for soft tissue parameters and crestal bone levels[68] (Fig. 3.15).

Canullo et al.[69] evaluated the microbiota associated with implants restored with and without platform switching. They found no statistically significant differences between groups for any of the species of peri-implant microbiota. The results of their study suggest that the difference in preservation of marginal bone levels between implants restored with platform switching and traditionally restored implants is not associated with differences in the peri-implant microbiota. Rocha et al.[70] evaluated differences in

the clinical performance and crestal bone levels between identical implants restored with single crowns with either platform-matched or platform-switched abutments after 3 years. This study found that platform-switching restorations showed a significant effect in the preservation of marginal bone levels compared with platform-matching restorations. Platform switching has a beneficial effect when it comes to the preservation of marginal bone levels; however, the biological and/or biomechanical processes underlying platform switching are not fully understood at this time.

Implant Prosthetic Connection

There are many different designs for implant-abutment prosthetic connections. They can be characterized as external and internal connection types by the position of the connection geometry relative to the body of the implant. External prosthetic connections, mostly hexagonal, place the connection external to the implant body. Internal implant connections have the connection geometry inside the implant body. Both types of connections have a history of safe and effective use, and are well documented in the clinical literature.[71,72]

The prosthetic connection has multiple functions. It serves as the junction between the implant and the prosthesis, as the feature used to transmit the insertion forces required to place the implant into the osteotomy, and to orient the corresponding mating feature geometry of prosthetic components. In most contemporary implant designs, the prosthesis is fastened to the implant by an abutment screw. Because loads pass from the prosthesis to the implant at the prosthetic connection, the connection design must be strong enough to withstand any clinically relevant forces.[73] Implant diameter and cross section and the abutment screw also have a significant effect on the overall strength of the prosthetic connection[74,75] (Fig. 3.16).

External prosthetic connections were the first prosthetic connections in wide use on screw-type implants. The Brånemark external hex implant, with its 0.7-mm-tall external hex, was designed to connect to a fixture mount for placement of the implant and then connect to a transmucosal element of a restoration for an edentulous arch. The external hex connection worked well for this treatment modality; however, it was not ideal when used for single-crown and partially edentulous restorations because the abutment screw was subjected to more lateral loading than in splinted restorations, and increasing the height of the external hex to provide more resistance to lateral loads interfered with angled abutments.[76-78]

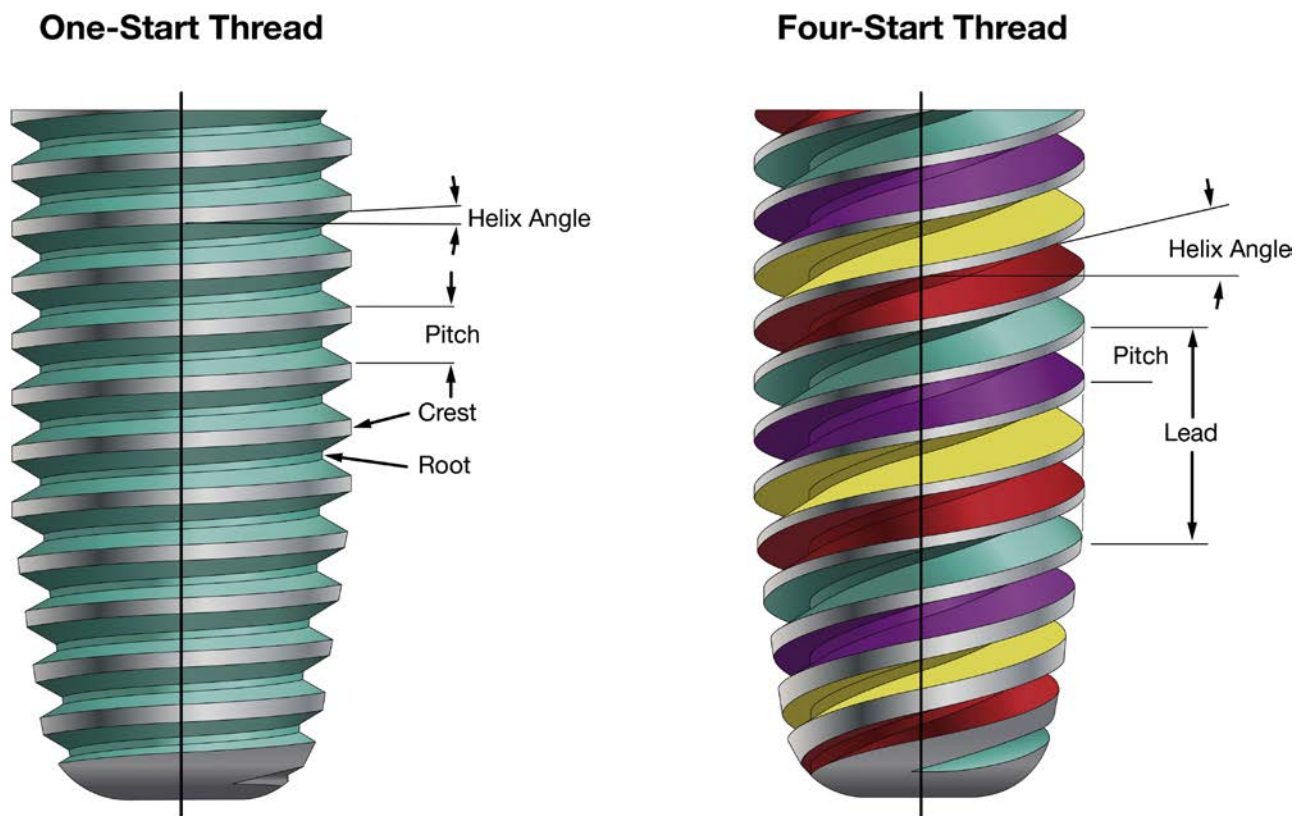
Internal prosthetic connection implants were developed to overcome some of the complications arising from the use of external hex implants in partially edentulous cases. The desire for a stronger, more stable implant connection led to the development of the internal connection implants in wide use today. One of the first internal connection designs to be widely adopted was an internal hex connection below a 45-degree lead-in bevel. The internal hex design is still in wide use more than 30 years after it was first developed.[79] The design of the internal hex connection mitigated some of the inherent challenges of the external hex connection, such as angled abutments, and the lead-in bevel stabilized the connection better against tipping forces, reducing the incidence of screw loosening.[80]

Another internal prosthetic connection that is widely used is the conical implant connection. The conical connection is deeper within the implant body, and the angle of the abutment interface is smaller. The conical connection interface area improves abutment stability, fit, and seal performance.[81] Caricasulo et al.[82] reviewed the influence of implant-abutment connection to peri-implant bone loss and found that conical connections exhibited lower peri-implant bone loss in the short to medium term compared with external connections. Quaresma et al.[83] conducted a finite element analysis of an internal hexed connection implant and a conical connection implant. They found that the conical connection implant connected to a solid, internal, conical abutment put lower stresses on the alveolar bone and prosthesis, and greater stresses on the abutment relative to the internal hexed connection implant. Hansson[84] used finite element analysis to study the distribution of stresses in supporting bone for conical connection implants placed at the level of the marginal bone. He found that the peak bone stresses resulting from an axial load arose farther down in the bone, with the conical implant-abutment interface at the level of the marginal bone. Conical prosthetic connections provide a stable abutment connection, lower peak bone stresses when placed at the level of the marginal bone, and a high resistance to axial loads.[85]

Implant Threads

Most dental implants are of the threaded cylinder and tapered threaded cylinder types. Study of threaded implant bodies retrieved from patients shows a greater bone-implant contact from the coronal region of the implant to the first bone-implant contact and a greater percentage of bone-implant contact compared with non-threaded cylinder implants.[86] The threads of the implant increase the surface area available to distribute occlusal forces into the supporting bone, and they transmit more of the forces in compression and less in shear than nonthreaded cylindrical implants. Because the bone is strongest in compression, this lessens the potential for occlusal overload at the bone-implant interface, potentially leading to microfractures and subsequent osteoclastogenesis.[63] The threads of the implant are important for achieving primary stability, particularly in sites with poor bone density, as well as dissipating forces during the healing period and throughout the life of the

• **Fig. 3.16** (A and B) Implant connections. (*Images courtesy of Glidewell Dental, Newport Beach, California*)

restoration. The geometric characteristics of the thread influence how stresses are transferred from the implant to the bone. Sufficient initial contact with surrounding bone is important to facilitate primary stability of the implant. Macroenhancements to the surface area of the implant from the thread geometry itself increase potential bone apposition and both the primary and secondary stability of the implant. Implant threads can be described by their thread shape, thread pitch, and thread depth. These thread parameters vary significantly between implants, and there are many possible combinations of these parameters (Fig. 3.17).


Thread Pitch

Thread pitch can be defined as the distance from a point on one thread to a corresponding point on the adjacent thread, measured parallel to the axis. Thread lead is the axial distance that the implant advances in one complete turn. For a single-start thread, thread pitch and thread lead are the same. For multiple-start threads the lead is a multiple of the pitch. For a two-start thread the lead is twice the pitch. A three-start thread has a lead that is three times the pitch (Fig. 3.18). Although the implant advances farther into the bone axially for each revolution on implants with multiple start threads, the surface area is not increased because the pitch remains the same.

Smaller thread pitch increases surface area and is thought to improve stress distribution in the surrounding bone. Orsini et al.[87] tested implants with a 0.5-mm pitch and 1.7-mm pitch for osseointegration after 0 days and 4 and 8 weeks in a sheep iliac crest model. Their findings showed that initial mechanical anchorage and subsequent early endosseous integration in low-density bone could be improved by a reduction of thread pitch. The smaller thread pitch increased bone-implant contact and primary stability from the time of implant placement, and exhibited a higher quantity of newly deposited bone and a more regular and mature geometric distribution of bone tissue at the interface. Their research suggests that, all other factors being equal, a thread pitch less than 1.7 mm is more optimal for primary stability and osseointegration.

However, because of the interaction between thread pitch, thread form, and thread depth, the optimum thread pitch for stress distribution in cortical and cancellous bone may vary. Hassan et al.[88] used three-dimensional (3D) finite element analysis to investigate the influence of the number of threads in the neck of the implant on implant-cortical bone interface stresses. Overall, their analysis showed that stress was highest in the cortical bone at the neck of implant and lowest in the cancellous bone regardless of the number of threads in contact with cortical bone. On the other hand, reducing the number of threads in the neck resulted in a decrease in the developed stresses in both types of bones. The developed stresses around the bone decreased gradually in cortical bones and dramatically in cancellous bones when the number of threads decreased in the neck of the implant.[88]

Kong et al.[89] evaluated the effects of the implant thread pitch on the maximum von Mises stresses in jaw bones and the implant-abutment complex using a finite element method. The thread pitches used in the analysis ranged from 0.5 to 1.6 mm. Their results suggested that under axial load, the maximum equivalent stresses in cortical bone, cancellous bone, and implant-abutment complex decreased by 6.7%, 55.2%, and 22.3%, respectively, with the variation of thread pitch, and 2.7%, 22.4%, and 13.0%, respectively, under buccolingual load. When thread pitch

One-Start   **Two-Start**   **Three-Start**   **Four-Start**
• **Fig. 3.18** Depiction of the difference between single-thread and multiple-thread dental implants. (*Image courtesy of Glidewell Dental, Newport Beach, California*)

exceeded 0.8 mm, minimum stresses were obtained. Their data indicated that cancellous bone was more sensitive to thread pitch than cortical bone, thread pitch played a greater role in protecting dental implant under axial load than under buccolingual load, and thread pitch exceeding 0.8 mm was the optimal selection for a threaded implant by biomechanical consideration.[89]

In another finite element analysis conducted for 3D optimization and sensitivity analysis of dental implant thread parameters, Geramizadeh et al.[90] found that a thread pitch of 0.808 mm in the implant body area was optimal for stress distribution. This thread pitch parameter was for a V-shaped thread and agrees closely with the analysis by Kong et al.[89] Optimal thread pitch parameters may vary according to the thread shape. Lan et al.[91] conducted an analysis of alveolar bone stress around implants with different thread designs and pitches in the mandibular molar area. Their analysis showed that an optimal thread pitch was 1.2 mm for a triangular-thread implant, and a trapezoidal-threaded implant with thread pitch of 1.6 mm had the lowest stress value among trapezoidal-threaded implants. Each thread shape had a unique optimal thread pitch concerning lower concentration of bone stress.[91]

Thread pitch also relates to the placement torque and time required to place the implant. Implants with more threads also require more revolutions to place the implant. It will therefore take more time to insert implants with more threads, and placement will require more force in dense bone. Thread pitch is a factor that affects both primary stability and initial healing of the implant site. It is part of the overall implant thread parameters in combination with thread shape and thread depth. Varying the thread pitch affects stress distribution, primary stability, and the quantity and quality of osseointegration.
Thread Shape

Thread shape is another geometric characteristic that has bearing on the distribution of forces into the supporting bone. Thread forms in dental implant designs include square, V-form, buttress, and reverse buttress (Fig. 3.19). These thread shapes are not exclusive to dental implants. They were adapted from existing thread shapes developed for other purposes. V-form threads were developed for general-purpose fastener applications. Square and buttress threads were developed to repeatedly move machine parts against heavy loads.[92] Square and buttress threads have the flank of the thread, which transfers force to the bone, nearly perpendicular to the thread axis, whereas reverse-buttress threads have the nearly perpendicular flank oriented in reverse relative to square and buttress threads. Dental implant applications dictate the need for a thread form optimized for long-term function (load transmission) under occlusal, intrusive (the opposite of pullout) load directions. The buttress or square thread provides an optimized surface area for intrusive, compressive load transmission. Many contemporary implant designs use a buttress thread for compressive load transmission (Hahn Tapered, Inclusive Tapered, Implant Direct), and a few implant designs have incorporated a square thread design (Ankylos, Biohorizons).

As with thread pitch, thread shape does not act in isolation at the bone-implant interface. Other factors such as the implant shape, thread pitch, thread depth, and load type also influence the stress transfer to the bone surrounding the implant.[91] Much of the published literature concerning the direct and indirect effects of thread shape on implant performance takes the form of literature searches and finite element analysis. Eraslan and İnan[93] conducted a 3D finite element analysis on the effect of thread design on stress distribution in a solid screw implant. They analyzed the maximum stress concentrations of V-thread, buttress, reverse buttress, and square thread designs in cortical and cancellous bone regions under a 100-N static load applied to the occlusal surface of the abutment. The results of their analysis showed that stress concentration at cortical bone (18.3 MPa) was higher than cancellous bone (13.3 MPa), and stress concentration at the first thread (18 MPa) was higher than other threads (13.3 MPa). The study showed that the use of different thread form designs did not affect the von Mises stress concentration at the supporting bone structure. However, thread shape did affect compressive stress.

Geng et al.[94] performed a finite element analysis of four thread-form configurations in a stepped screw implant. They analyzed V-thread, thin-thread, and two square-thread forms of different width under oblique loading. Their results indicated that a

V-thread and large square thread were the optimal thread shapes for their experimental stepped screw implant.[94] Force direction affected the stress distribution of the thread shapes evaluated in this study. McAllister et al.[95] conducted a multicenter clinical trial for a 2-year evaluation of a variable-thread tapered implant in extraction sites with immediate temporization. Their results indicated that variable-thread shape tapered implants are a safe and effective immediate postextraction tooth replacement treatment option under immediate load conditions.[95] Arnhart et al.[96] conducted a randomized, controlled, multicenter trial aimed at comparing two versions of a variable-thread dental implant design with a standard tapered dental implant design in cases of immediate functional loading for 36 months after loading. Their results showed stable or improving bone levels for all treatment groups after the initial bone remodeling seen during the first 3 months after placement. The variable-thread implants showed results comparable with those of standard tapered implants with reverse buttress threads in cases of immediate function.[96] Finite element analysis simulations have shown similar stress concentrations in the supporting bone among different thread shapes under occlusal loading and favorable stress distribution for V-shape and square threads under oblique loads. Actual human clinical trials of immediately loaded implants showed very good performance of variable and reverse buttress thread shapes after 3 years in function. Because of their thread flanks transfer forces to the bone nearly perpendicular to the implant axis, buttress and square thread shapes have an optimal implant thread shape under axial load conditions.

Thread Depth

The thread depth is measured as the distance between the root and the crest of the thread. Thread depth directly affects the compressive load-bearing surface of the inferior flank of the implant thread. The deeper the thread, the larger the surface area available for compressive force transfer to the supporting bone (Fig. 3.20). Implant wall thickness relative to thread depth is a consideration, particularly for smaller-diameter implants, because increasing the distance between the root and crest of the thread comes at the expense of cross-sectional thickness and will affect the strength of the implant body. Increasing thread depth also increases the insertion torque and primary stability in low-density bone because it increases initial bone-implant contact. In denser bone the increased insertion torque of implants with greater thread depth may require the use of a bone tap to fully seat the implant.

In a study of the effect of thread depth on the mechanical properties of dental implants, Lee et al.[97] tested implants with four different thread depths and found that implants with deeper thread depth had higher mean insertion torque values but not lower compressive strength. The thread depth in the implants of this study was increased by increasing the major diameter of the implant body and not by reducing the minor diameter at the root of the threads. This maintained a similar cross section and resultant compressive strength between implants. For the implant with the deepest thread depth (1.1 mm), doubling the density of the bone also nearly doubled the required insertion torque.

In a finite element analysis study of the effects of thread depth and width on an immediately loaded cylinder implant, Ao et al.[98] found that thread depths greater than 0.44 mm and widths between 0.19 and 0.23 mm caused the lowest stresses in moderately dense bone. Thread depth had a greater effect than thread width on bone stress and implant primary stability than thread width. Insertion force was not a component of this study. Table 3.5 shows the relative gain in surface area attributable to increasing the implant major diameter rather than decreasing the thread minor diameter to increase the depth of thread. Either method will increase the thread depth; however, increasing the major diameter of the implant creates more surface area in contact with bone and available to dissipate forces. Decreasing the minor diameter of the

5.0 mm	10 mm	271.93 mm²	97%

implant thread also reduces the wall thickness and strength of the implant, and should be avoided.

Implant Apical Region

The apical region of the implant has features to facilitate insertion into the osteotomy and initiate engagement of the implant threads with the surrounding bone. The tip of the implant is tapered to allow some of the axial length of the implant to enter the implant site before the threads come into contact with the walls of the osteotomy (Fig. 3.21). This makes it easier to keep the implant axis aligned with the axis of the osteotomy and is more comfortable for the patient because it does not require the patient to open his or
● **Fig. 3.21** Tapered apical ends of implants. (*Image courtesy of Glidewell Dental, Newport Beach, California*)

her mouth as much. The implant taper typically matches the apical portion of the implant drill used to prepare the hole, with the exception of some small-diameter implants that are designed to be placed deeper than the implant site is drilled to improve primary stability. The apical end of conventional implants should be flat to rounded in shape to minimize the probability of perforating sinus membranes during placement. The apical end on small-diameter implants typically tapers to a sharp point to advance into the bone below the implant hole without further site preparation (Fig. 3.22).

The apical region may include a hole or slot feature through the implant body for bone to grow into and increase anchorage against torsional forces, such as healing abutment and healing screw removal and tightening of screws used to fasten the prosthesis to the implant. These features are still found on some implant designs in use today, such as the Zimmer Screw-Vent implant; however, their use has declined in favor of other features that serve the same purpose. More often the apical region of the implant incorporates flat regions or grooves circumferentially arranged on the implant body and originating in the apical region to stabilize the implant against rotation and aid in insertion. During the healing phase, bone will grow against these regions, forming an interlocking matrix that resists rotation. These features also help with the tapping of the implant threads into the wall of the osteotomy. As the threads advance, they create small bone chips that accumulate in these features instead of building up on the bottom of the implant site or being forced into the wall of the osteotomy, resulting in difficulty in seating the implant to depth or increased insertion forces. Incorporating an angled or helical tapping feature in the apical region of the implant further improves the tapping performance because the cutting forces are distributed over a larger region (Figs. 3.23 and 3.24).
Implant Materials

Materials suitable for dental implants and their prosthetic components must meet several specific criteria. The material must be

• **Fig. 3.22** Implant apical regions on small-diameter implants. (*Image courtesy of Glidewell Dental, Newport Beach, California*)

• **Fig. 3.23** Radiograph showing hole features in the apical end of Steri-Oss implants. (*Image courtesy of Glidewell Dental, Newport Beach, California*)

biocompatible and capable of functioning indefinitely without causing damage or degradation of the surrounding bone and tissues. It must also have sufficient tensile and compressive strength to resist forces encountered during function and parafunction over long periods. Further, implant materials require excellent fracture toughness and fatigue resistance to cyclic loading. Finally, materials used in dental implants must have adequate resistance to corrosion and wear, and should have a modulus of elasticity as close as practical to that of the surrounding bone (Fig. 3.25).

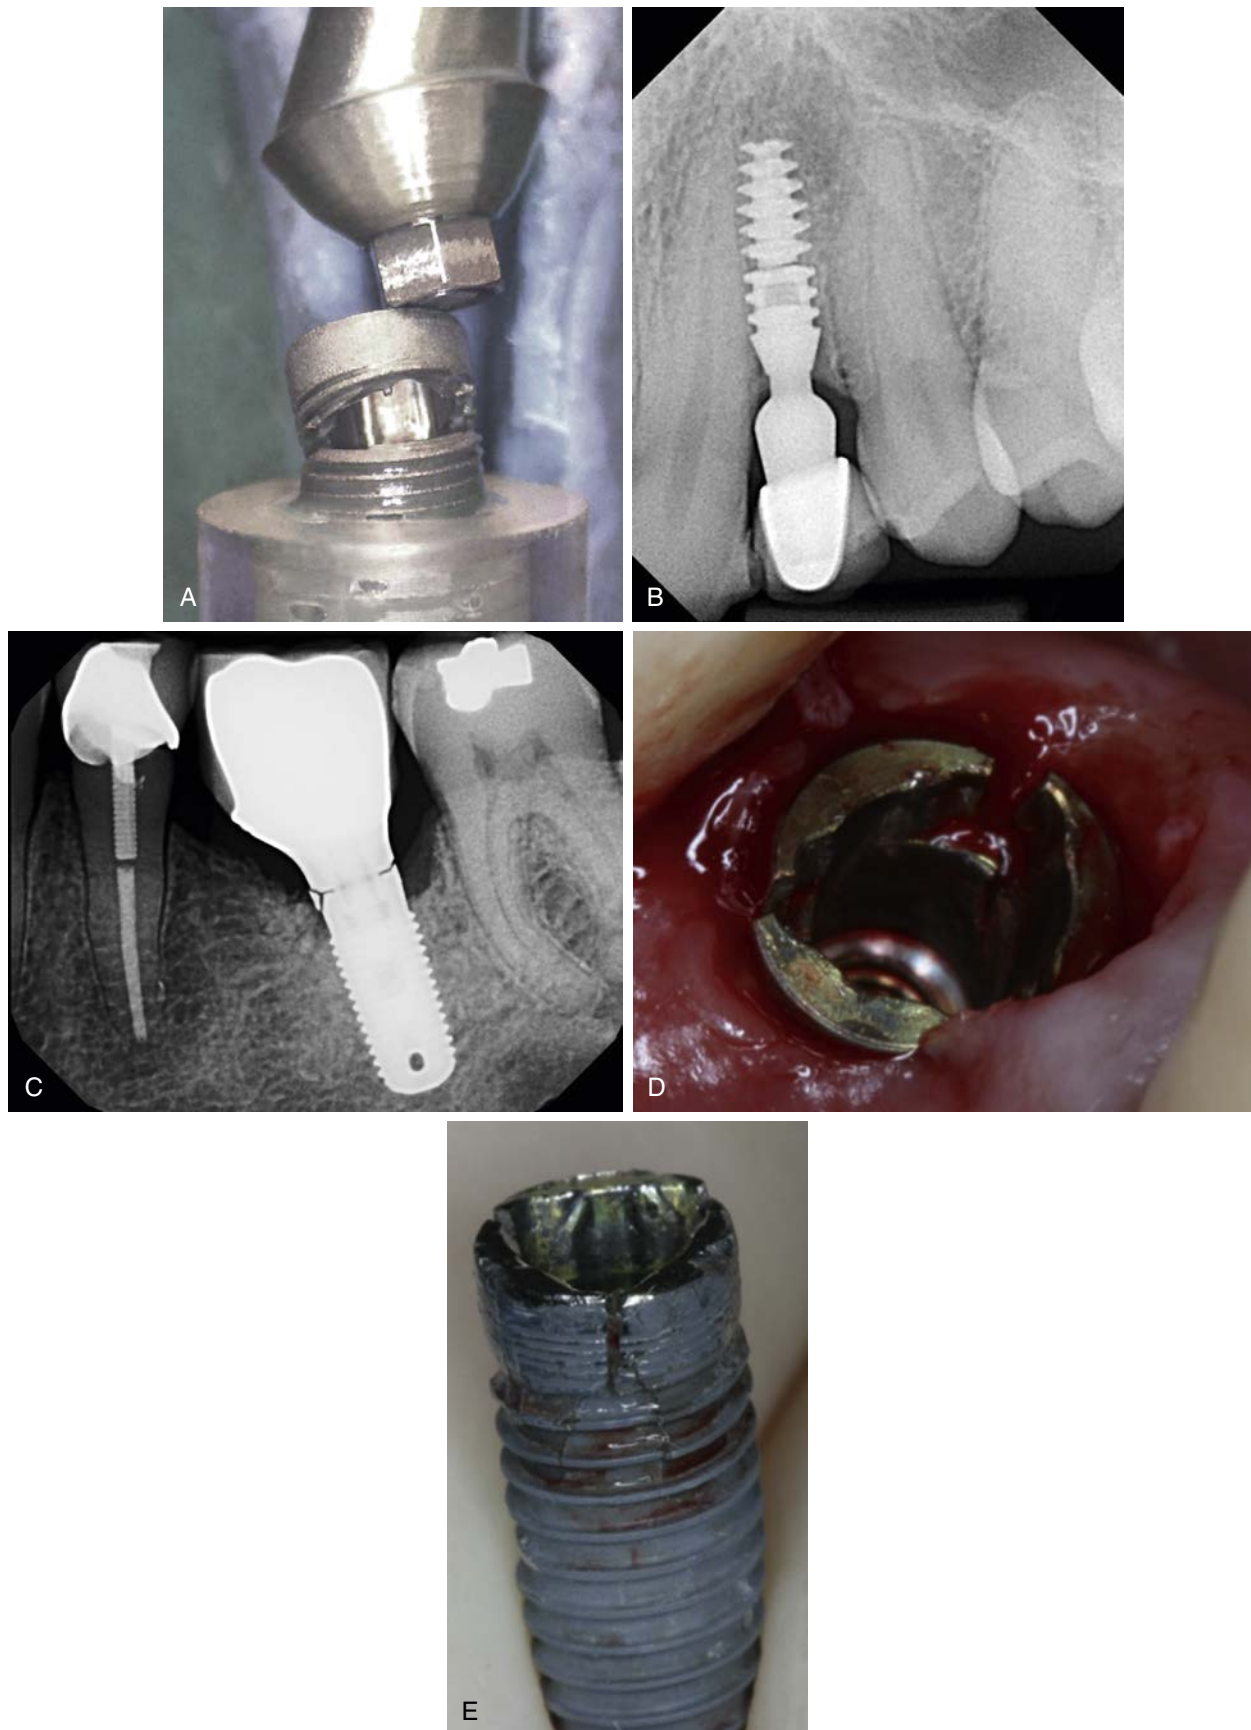
Biocompatibility

A number of materials are suitable for dental implants from a biocompatibility standpoint. Currently, commercially pure titanium, titanium alloys, and zirconia (zirconium dioxide, ZrO_2) ceramic implants are the representative biomaterials in wide use for dental

• **Fig. 3.24** Implant with helical self-tapping feature designed to reduce tapping force and collect bone chips. (*Image courtesy of Glidewell Dental, Newport Beach, California*)

implant applications. Commercially pure titanium has the longest history of use for dental implant applications, and its biocompatibility with bone and soft tissues is well established.[100] Titanium alloys, mostly titanium alloyed with varying amounts of aluminum, vanadium, niobium, and zirconium, also exhibit excellent biocompatibility for dental implant applications.[101,102] The most often used titanium alloy is grade 5 titanium, which contains 6% aluminum and 4% vanadium as alloying elements.[103] Although it is not used as frequently as titanium and titanium alloys, zirconia has been proven to be biocompatible in vitro and in vivo; it has interesting microstructural properties; and it is osseoconductive.[104]

Strength

Tensile, compressive, and fatigue strength properties vary between commercially pure titanium, titanium alloy, and zirconia ceramic materials. Titanium and titanium alloy specifications are defined in ASTM International specification B348.[103] The specifications for commercially pure titanium are described by grades 1 through 4, and alloy titanium specifications are described by grades 5 and above. Grade 4 titanium is more than twice as strong as grade 1 titanium, and grade 5 titanium is more than 60% stronger than grade 4 titanium. Grade 23 is a higher-purity form of grade 5 titanium with better fatigue properties. The mechanical properties of titanium grades 1, 4, 5, and 23 are summarized in Table 3.6. Zirconia has much larger compressive strength than titanium; however, it has relatively poor tensile strength, and it is vulnerable to bending loads.[104,105] The ultimate strength of a material determines the amount of load it can withstand before yielding or breaking. Titanium and zirconia implant materials have sufficient ultimate strength to resist clinically relevant loads provided the implant cross section is sufficient. However, more implants fail because of fatigue fractures than from loads that exceed the ultimate strength of the material. Fatigue strength, the maximum cyclical load that the implant and restoration can withstand


• **Fig. 3.25** (A) Implant fracture caused by fatigue (sustained loading). (B and C) Implant neck fracture. (D and E) Tri-lobe design implant fracture. (*A: Image courtesy of Glidewell Dental, Newport Beach, California*)

repeatedly without failure or loss of function, is the more relevant property. Fatigue strength relates to material strength; however, it is affected to a large degree by loading conditions such as cantilever length, force direction, among others. It is important to determine the fatigue limit of the implant in combination with its premanufactured prosthetic components to ensure that it will have sufficient strength to function reliably for the patient. Fatigue limits are established by in vitro dynamic testing usually in accordance with the ISO 14801 standard for dynamic loading test for endosseous dental implants.[106]

Corrosion Resistance

Titanium and its alloys have outstanding corrosion resistance under physiologic environmental conditions. They spontaneously form a passive titanium oxide passive film at the surface that resists corrosion very well in the oral environment and immediately reforms if it is damaged or removed by mechanical means.[107] Zirconia ceramic is essentially inert in the oral environment and not susceptible to metallic corrosion. However, zirconia is susceptible to low-temperature degradation. Zirconium dioxide has three crystalline states: monoclinic at room temperature, tetragonal above 1170°C, and cubic above 2100°C.[108] Dental zirconia is stabilized in the tetragonal state by addition of yttrium oxide. The tetragonal crystalline state is responsible for the high strength and fracture toughness of Y-TZP (yttrium oxide stabilized tetragonal zirconium dioxide polycrystals) materials. Contact with water can transform zirconia from the stronger tetragonal phase to the weaker monoclinic phase, resulting in a reduction in strength of the affected area. The degradation-related failure of the Prozyrs femoral heads in 2001 to 2002 is one well-known example.[109] Careful attention to technique is suggested when handling and adjusting zirconia implants and prosthetics.[110]

Modulus of Elasticity

When the modulus of elasticity of the implant and the surrounding bone are not matched, the stress transfer between the implant and the bone is compromised. The mean modulus of elasticity (a measure of stiffness) of dense cortical bone is approximately 16 GPa,[111] compared with the mean modulus of grade 4 commercially pure titanium (105 GPa), grade 5 (Ti-6Al-4V) (109 GPa), and grade 23 (Ti-6Al-4V ELI) (114 GPa). In comparison, zirconia ceramic is very stiff (200 GPa) and may have a higher potential for relative motion or disuse atrophy related to stress shielding at the bone-implant interface. Loading zirconia implants after

osseointegration is complete[112] has been suggested as a mitigating measure to reduce the possibility of crestal bone loss.

At this time, titanium alloys remain the best biomaterial for dental implants. They possess the best combination of biocompatibility, strength, corrosion resistance, and fatigue performance under repetitive loading. They have a long history of safe and effective use that is well documented in the dental literature, and they are suitable for use in all regions of the mouth and all treatment modalities.

Functional Basis for Dental Implant Design

Dental implants transfer forces from the prosthesis to the supporting bone, and the form of dental implants follows this basic function. Dental implant designs have progressed from early subperiosteal, blade type, and press-fit cylinder implants to the straight and tapered threaded implants of today. Their design remains an area of intense activity even now, decades after success rates in the upper 90th percentile are considered the norm. The form and design features of these implants relate to the knowledge base of what was known and believed to be effective and clinically sound at the time. Because force transfer is central to the function of dental implants, their form has evolved to make this ever more efficient and predictable. A functional basis for dental implant design blends current advances in dental technology with proven principles. The form of an implant designed on this basis has features that are briefly described in this section.

For the implant shape a tapered implant body is more advantageous because it is beneficial for implant stability at the time of insertion (primary stability) and marginal bone-level maintenance. As for implant diameter, wider is better, provided the bone volume exists. All other factors (such as length) being equal, wider implants have more surface area to dissipate stress at the bone-implant interface, and they are more resistant to fracture than narrower implants with the same connection geometry due to their increased cross section. Implant length is another parameter where more is generally better when it comes to stress distribution into the supporting bone. However, increasing implant diameter is more effective at decreasing stress and strain in the supporting bone.

The implant collar is important because it dictates the placement of the prosthetic interface relative to the bone and the gingival tissue surrounding the implant, as well as stress distribution into the cortical bone. Because the upper region of the implant collar may be transosteal after placement, and rougher surfaces in this region can leave the implant more vulnerable to peri-implantitis, a machined rather than roughened surface at the upper region of the implant collar is more beneficial during the epithelial wound-healing process. The implant collar should be at least the same diameter or slightly larger than the implant to improve initial bone-implant contact and to help seal the implant site against fibrous tissue encapsulation and bacterial contamination. The collar region should also have microthreads to help distribute stress in the cortical bone region and maintain marginal bone levels. When the cross section of the implant permits, platform shifting should be used in order to shift the stress area away from the bone-implant interface. Current knowledge of prosthetic connections suggests that an internal prosthetic connection provides the best functionality. Of the internal prosthetic connection types in use today, the conical prosthetic connection possesses the best feature set. Conical prosthetic connections provide a stable abutment connection, lower peak bone stresses when placed at the level of the marginal bone, and a high resistance to axial loads.

Implant threads are important for achieving primary stability, particularly in sites with poor bone quality and for dissipating stresses at the bone-implant interface during the healing period and throughout the life of the restoration. Study of the effect of thread pitch on the primary stability, osseointegration, and stress distribution into the surrounding bone suggests that a thread pitch between 0.8 and 1.6 mm is optimal, depending on the thread shape and depth. Buttress and square thread shapes transfer forces to the bone nearly perpendicular to the implant axis and are the optimal thread shapes under axial load conditions. Increasing thread depth also increases the functional surface area available for compressive force transfer into the supporting bone and improves primary stability at the expense of some increase in insertion force. Thread depths greater than 0.4 mm appear to be the most beneficial for reducing stress in moderately dense bone.

The implant apical region should be tapered to facilitate insertion into the osteotomy and initial engagement of the implant threads. The apical end should be rounded or flat to minimize the probability of perforating membranes during placement. It will have flat regions or grooves circumferentially arranged on the implant body to stabilize the implant against rotation after healing and to aid in insertion. Titanium alloys still have the best mechanical and biocompatibility properties for dental implants, and their use is recommended.

Summary

Dental implants provide support for the prosthesis and transfer the occlusal forces to the supporting bone. The design of the dental implant has to take into account primary stability, insertion forces, stress transfer to the surrounding bone, strength, fatigue resistance, and biocompatibility. The dental implants of today address all of these factors in some capacity, and advances in dental technology suggest there are more improvements yet to come.

Bone Physiology, Metabolism, and Biomechanics

W. EUGENE ROBERTS

Consistent success with implant-supported prostheses requires a thorough knowledge of the physiology, metabolism, and biomechanics of bone as a tissue, and bones as musculoskeletal organs. Bone is a vital mineralized tissue, and bones are unique morphologic organs composed of calcified and soft tissues that provide structural and metabolic support for a wide variety of interactive functions (Fig. 4.1).

Understanding the clinical manipulation of bone begins with an appreciation of the fundamental genetic and environmental mechanisms of osseous development and adaptation. The genome codes for growth factors, ischemic agents, vascular induction/invasion mechanisms, and mechanically induced inflammation. These biological mechanisms interact with the physical factors of diffusion limitation and mechanical loading to produce bone morphology (Fig. 4.2). Fundamental principles control the quality and quantity of bone that directly and indirectly supports stomatognathic function. A firm grasp of the modern concepts of bone physiology, metabolism, and biomechanics is an essential prerequisite for innovative clinical practice. These principles are an objective basis for designing a realistic treatment plan that has a high probability of meeting the esthetic and functional expectations of the patient.

Bone is a dynamic structure that is adapting constantly to its environment. Because the skeleton is the principal reservoir of calcium, bone remodeling (physiologic turnover) performs a critical life support role in mineral metabolism (Fig. 4.3). Collectively, bones are essential elements for locomotion, antigravity support, and life-sustaining functions such as mastication. Mechanical adaptation of bone is the physiologic basis of stomatognathic reconstruction with implant-supported prostheses. A detailed knowledge of the dynamic nature of bone physiology and biomechanics is essential to enlightened clinical practice.
Osteology

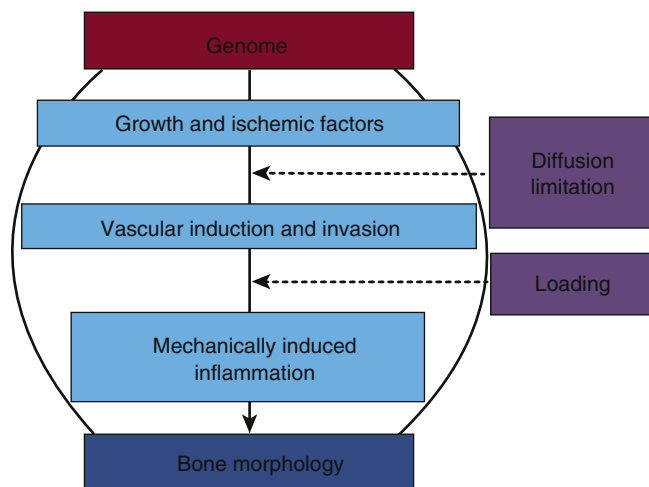
In defining the physiologic basis of orthodontics, the initial consideration is bone morphology (osteology) of the craniofacial complex. Via the systematic study of a personal collection of more than 1000 human skulls, Spencer Atkinson[1] provided the modern basis of craniofacial osseous morphology as it relates to the biomechanics of stomatognathic function. A frontal section of an adult skull shows the bilateral symmetry of bone morphology and functional loading (Figs. 4.4 and 4.5). Because the human genome contains genes to pattern the structure of only half of the body, the contralateral side is a mirror image. Consequently, normal development of the head is symmetric. Thus unilateral structures are on the midline, and bilateral structures are equidistant from it. As shown in Fig. 4.5, the vertical components of the cranium tend to be loaded in compression (negative stress), and the horizontal components are loaded in tension (positive stress). From an engineering perspective, the internal skeletal structure of the midface is similar to that of a ladder: vertical rails loaded in compression connected by rungs loaded in tension. This is one of the most efficient structures for achieving maximal compressive strength with minimal mass in a composite material.

Differential Osteology of the Maxilla and Mandible

Although equal and opposite functional loads are delivered to the maxilla and mandible, the maxilla transfers stress to the entire cranium, whereas the mandible must absorb the entire load. Consequently, the mandible is much stronger and stiffer than the maxilla. A midsagittal section through the incisors (Fig. 4.6) and a frontal section through the molar region (Fig. 4.7) show the distinct differences in the osseous morphology of the maxilla and mandible. The maxilla has relatively thin cortices that are interconnected by a network of trabeculae (see Figs. 4.4, 4.6, and 4.7). Because it is loaded primarily in compression, the maxilla is structurally similar to the body of a vertebra.

The mandible, however, has thick cortices and more radially oriented trabeculae (see Figs. 4.6 and 4.7). The structural array is similar to the shaft of a long bone and indicates that the mandible is loaded predominantly in bending and torsion. This biomechanical impression based on osteology is confirmed by in vivo strain gauge studies in monkeys. Hylander[2,3] demonstrated substantial bending and torsion in the body of the mandible associated with normal masticatory function (Fig. 4.8). A clinical correlation consistent with this pattern of surface strain is the tendency of some humans to form tori in the areas of maximal bending and torsion (Fig. 4.9). The largest tori are on the side on which the individual habitually chews (preferential working side).

● **Fig. 4.1** Schematic drawing of a wedge of a cortical bone that is growing to the left demonstrates the morphology of circumferential lamellae *(CL)* and secondary osteons *(SO)*. Depending on the mechanical loading at the time the matrix is formed, bone lamellae may have a collagen orientation that is an alternating bias *(1)* or alternating horizontal *(2)* and vertical *(3)* orientations. (From Roberts WE, Hartsfield Jr JK. Bone development and function: genetic and environmental mechanisms. *Semin Orthod.* 2004;10:100–122.)



● **Fig. 4.2** Genome dictates bone morphology by a sequence of three genetic mechanisms: (1) growth and ischemic factors, (2) vascular induction and invasion, and (3) mechanically induced inflammation. The latter two are influenced by two major physical influences: (1) diffusion limitation for maintaining viable osteocytes and (2) mechanical loading history. (From Roberts WE, Hartsfield Jr JK. Bone development and function: genetic and environmental mechanisms. *Semin Orthod.* 2004;10:100–122.)

Temporomandibular Articulation

The temporomandibular joint (TMJ) is the principal adaptive center for determining the intermaxillary relationship in all three planes of space. Fig. 4.10 shows optimal skeletal development consistent with normal morphology of the TMJ. Fig. 4.11 shows aberrant skeletal and dental relationships consistent with degeneration of the fossa and mandibular condyle (i.e., the enlarged
● **Fig. 4.3** Artist's rendition of the dynamic principles of cortical bone remodeling produced by the renowned dental illustrator Rolando De Castro. Remodeling is a vascularly mediated process of bone turnover that maintains the integrity of structural support and is a source of metabolic calcium. Osteoblasts are derived from preosteoblasts circulating in the blood, and perivascular mesenchymal cells give rise to osteoblasts. Note the three colored chevrons (yellow, green, and orange) progressively marking the mineralization front of the evolving second osteon that is moving superiorly on the left. (From Roberts WE, Arbuckle GR, Simmons KE. What are the risk factors of osteoporosis? Assessing bone health. *J Am Dent Assoc.* 1991;122:59–61.)
● **Fig. 4.4** Frontal section of a human skull in the plane of the first molars. (From Atkinson SR. Balance: the magic word. *Am J Orthod.* 1964;50:189.)

KEY
− = Compression
+ = Tension
P = Assumed load
applied to upper
jaw, bilaterally
Approximate stress
Diagram of skull section D265

• **Fig. 4.5** Two-dimensional vector analysis of stress in the frontal section of the human skull depicted in Fig. 4.4. Relative to a bilateral biting force of 100 arbitrary units, the load is distributed to the vertical components of the midface as compressive (negative) stress. The horizontal structural components are loaded in tension. In a nongrowing individual the stress across the midpalatal suture is 0. When masticating, loads increase and the midpalatal suture is subjected to a tensile load, resulting in an increase in maxillary width. (From Atkinson SR. Balance: the magic word. *Am J Orthod.* 1964;50:189.)

• **Fig. 4.6** Midsagittal section of a human skull shows that the maxilla primarily is composed of trabecular (spongy) bone. The opposing mandible has thick cortices connected by relatively coarse trabeculae. (From Atkinson SR. Balance: the magic word. *Am J Orthod.* 1964;50:189.)

• **Fig. 4.7** Frontal section of the maxilla and mandible in the plane of the first molars. Because it transmits masticatory loads to the entire cranium, the maxilla has thin cortices connected by relatively fine trabeculae. The mandible, however, is loaded in bending and torsion; therefore it is composed of thick cortical bone connected by coarse, oriented trabeculae. (From Atkinson SR. Balance: the magic word. *Am J Orthod.* 1964;50:189.)

intermaxillary discrepancies in the sagittal, vertical, and frontal dimensions. Adaptation of the TMJ allows for substantial growth change to occur without disturbing the intermaxillary relationship of the dentition (e.g., class I occlusion remains class I). In the adult years the intermaxillary relationship continues to change but at a slower rate. The face lengthens and may rotate anteriorly as much as 10 mm over the adult lifetime.[4] The mandible adapts to this change by lengthening and maintaining the intermaxillary dental relationship (Fig. 4.12). However, if the TMJs of an adult undergo bilateral degenerative change, whether symptomatic or not, the mandible can decrease in length, resulting in a shorter, more convex face (Fig. 4.13).

Within physiologic limits, the TMJ has remarkable regenerative and adaptive capabilities, allowing for spontaneous recovery from degenerative episodes (Fig. 4.14). Unlike other joints in the body, the TMJ has the ability to adapt to altered jaw structure and function. After a subcondylar fracture, the condylar head is pulled medially by the superior pterygoid muscle and resorbs. If the interocclusal relationship is maintained, a new condyle forms from the medial aspect of the ramus and assumes normal function. Unilateral subcondylar fractures usually result in regeneration of a new functional condyle with no significant deviation of the mandible.[5] However, about one-fourth of subcondylar fractures result in a mandibular deviation toward the injured side, resulting in an asymmetric class II malocclusion with a midline deviation. Another sequela of mandibular trauma is internal derangement such as a unilateral closed lock (a condyle distally displaced relative to the disk). If the range of motion is reduced in a growing patient, the compromised function may inhibit mandibular growth, resulting in a cant of the occlusal plane. Progressive dysfunction and pain may ensue, particularly when associated with occlusal trauma. Reestablishing normal bilateral function allows the compromised condyle or condyles to adapt favorably.
mushroom shape of the condylar process, the roughened topography of the articulating surfaces, the loss of articular cartilage and subchondral plate). Progressive degeneration or hyperplasia of one or both mandibular condyles may result in substantial

• **Fig. 4.8** Stress patterns in the primate mandible during unilateral mastication. F_c and F_m are the condylar reaction and the resultant muscle forces on the balancing side, respectively. F_{bal} is the force transmitted through the symphysis from the balancing to the working side. T and C indicate the location of tensile stress and compressive stress, respectively. (A) During the power stroke, the mandibular corpus on the balancing side is bent primarily in the sagittal plane, resulting in tensile stress along the alveolar process and compressive stress along the lower border of the mandible. (B) On the working side, the corpus is twisted primarily about its long axis (it also experiences direct shear and is slightly bent). The muscle force on this side tends to evert the lower border of the mandible and invert the alveolar process *(curved arrow M)*. The twisting movement associated with the bite force has the opposite effect *(curved arrow B)*. The portion of the corpus between these two twisting movements experiences maximal twisting stress. (From Hylander WL. Patterns of stress and strain in the macaque mandible. In: Carlson DS, ed. *Craniofacial Biology.* Ann Arbor, MI: Center for Human Growth and Development;1981.)

Bone Physiology

The morphology of bone has been well described, but its physiology is elusive because of the technical limitations inherent in the study of mineralized tissues. Accurate assessment of the orthodontic or orthopedic response to applied loads requires time markers (bone labels) and physiologic indexes (DNA labels, histochemistry, and in situ hybridization) of bone cell function. Systematic investigation with these advanced methods has defined new concepts of clinically relevant bone physiology.

Specific Assessment Methodology

Physiologic interpretation of the response to applied loads requires the use of specially adapted methods, as follows:

• **Fig. 4.9** Occlusal view of the mandibular dentition of a male patient with extensive buccal and lingual tori. Note that the exostoses are most extensive in the area of the second premolar and first molar, which is the area of maximal torsion in the posterior segment of the mandible.
• **Fig. 4.10** Adult human skull with ideal occlusion and osseous form of the maxilla and mandible. Note the ideal anatomic form of the condyle and articular fossa of the temporomandibular joint. (From Atkinson SR. Balance: the magic word. *Am J Orthod.* 1964;50:189.)

- Mineralized sections are an effective means of accurately preserving structure and function relationships.[6]
- Polarized light birefringence detects the preferential orientation of collagen fibers in the bone matrix.[7]
- Fluorescent labels (e.g., tetracycline) permanently mark all sites of bone mineralization at a specific point in time (anabolic markers).[7]
- Microradiography assesses mineral density patterns in the same sections.[8]
- Autoradiography detects radioactively tagged precursors (e.g., nucleotides, amino acids) used to mark physiologic activity.[9-11]
- Nuclear volume morphometry differentially assesses osteoblast precursors in a variety of osteogenic tissues.[12]
- Cell kinetics is a quantitative analysis of cell physiology based on morphologically distinguishable events in the cell cycle (i.e., DNA synthesis [S] phase, mitosis, and differentiation-specific change in nuclear volume).[12,13]
- Finite-element modeling is an engineering method of calculating stresses and strains in all materials, including living tissue.[14-17]
● **Fig. 4.11** Adult human skull with a severe class II malocclusion. Note the degeneration of the temporomandibular joint (i.e., the large, mushroom-shaped condyle and the enlarged, roughened articular fossa). (From Atkinson SR. Balance: the magic word. *Am J Orthod.* 1964;50:189.)

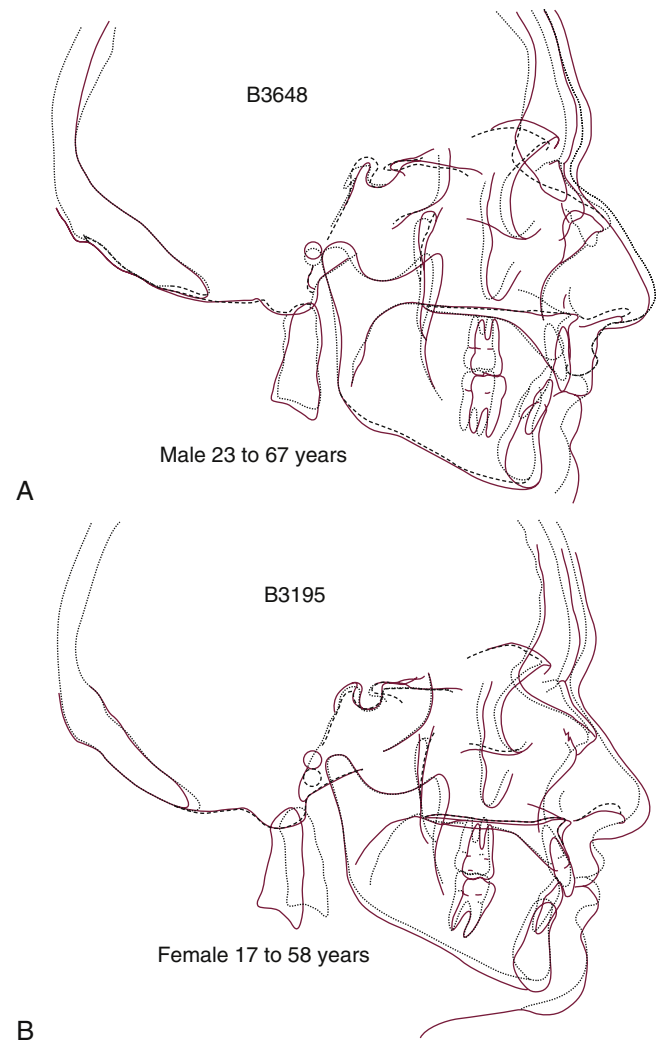
- Microelectrodes inserted in living tissue such as the periodontal ligament (PDL) can detect electrical potential changes associated with mechanical loading.[13,18]
- Backscatter emission is a variation of electron microscopy that assesses relative mineral density at the microscopic level in a block specimen.[19]
- Microcomputed tomography is an in vitro imaging method for determining the relative mineral density of osseous tissue down to a resolution of approximately 5 μm (about the size of an osteoblast nucleus).[20]
- Microindentation testing is a method for determining the mechanical properties of bone at the microscopic level.[21]

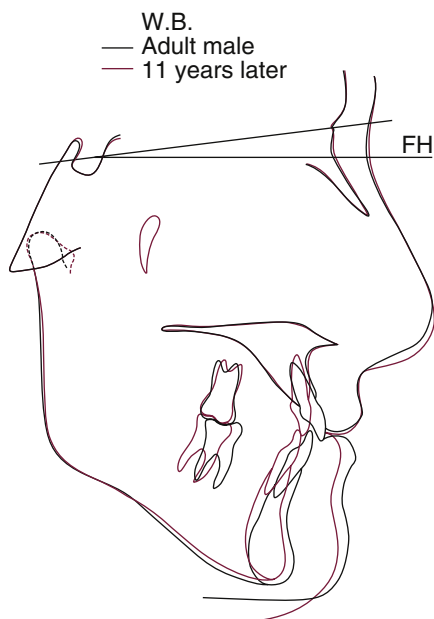
Mineralized Sections

Fully mineralized specimens are superior to routine demineralized histologic sections for most critical analyses of teeth, periodontium, and supporting bone because fully mineralized specimens experience less processing distortion. Furthermore, the inorganic mineral and organic matrix can be studied simultaneously.[6-8,22] For tissue-level studies, Sections 100 mm thick are appropriate because they can be studied by means of several analytic methods. Even without bone labels, microradiographic images of polished mineralized sections provide substantial information about the strength, maturation, and turnover rate of cortical bone (Fig. 4.15A). Reducing the thickness of the section to less than 25 mm considerably enhances cellular detail and resolution of bone labels. Specific stains are useful for enhancing the contrast of cellular and extracellular structures. The disadvantages of thin mineralized sections are (1) bone labels quench more rapidly, and (2) tissue density is inadequate for microradiographic analysis.

Polarized Light

Birefringence of polarized light (see Fig. 4.15B) has particular biomechanical significance. The lamellar fringe patterns revealed with polarized light indicate the preferential collagen orientation within the matrix.[23] Most lamellar bone has alternating layers of collagen fibers at right angles. However, two specialized collagen configurations can be seen in the same or adjacent osteons: (1)





● **Fig. 4.12** (A) Superimposed cephalometric tracings of a male patient at ages 23 and 67 years (black and red tracings, respectively). Note the downward and forward growth of the mandible and the substantial increase in the length of the face. The nasal form was altered by a rhinoplasty in the intervening years. (B) Superimposed cephalometric tracings of an adult female at ages 17 and 58 years (black and red tracings, respectively). Note the downward growth of the mandible and the substantial increase in the length of the face. (From Behrents RG. Adult facial growth. In: Enlow DH, ed. *Facial growth.* 3rd ed. Philadelphia: WB Saunders; 1990.)

longitudinally aligned collagen fibers efficiently resist tension, and (2) transverse or circumferential collagen fibers are preferential supports for compression.[24] Loading conditions at the time of bone formation appear to dictate the orientation of the collagen fibers to best resist the loads to which the bone is exposed. The important point is that bone formation can adapt to different loading conditions by changing the internal lamellar organization of mineralized tissue.

Fluorescent Labels

Administered in vivo, calcium-binding labels are anabolic time markers of bone formation. Histomorphometric analysis of label incidence and interlabel distance is an effective method of determining the mechanisms of bone growth and functional adaptation (see Fig. 4.15C). Because they fluoresce at different wavelengths (colors), six bone labels can be used: (1) tetracycline (10 mg/kg,

W.B.
— Adult male

FH

● **Fig. 4.13** Superimposed cephalometric tracings of a middle-aged man over an 11-year period. Although the soft tissue changes are similar to those seen in other adult males (see Fig. 4.12A), the less prominent mandible and more convex skeletal profile are consistent with a shortened mandible. This man had a history of bilateral temporomandibular internal derangement that progressed to crepitus. However, despite the substantial change in facial form and occlusal compensation, no appreciable pain was reported.

— 13.5 years — Before orthodontic treatment
— 18.0 years — After orthodontic treatment
— 25.5 years — Follow-up
● **Fig. 4.14** Superimposed tracings of a series of panoramic radiographs documenting the degeneration of a mandibular condyle between 13.5 and 18 years of age. Between the ages of 18 and 25.5 years, the degenerative condyle "grew," restoring the original length of the mandible. (From Peltola JS, Kononen M, Nystrom M. A follow-up study of radiographic findings in the mandibular condyles of orthodontically treated patients and associations with TMD. *J Dent Res.* 1995;74:1571.)

bright yellow), (2) calcein green (5 mg/kg, bright green), (3) xylenol orange (60 mg/kg, orange), (4) alizarin complexone (20 mg/kg, red), (5) demeclocycline (10 mg/kg, gold), and (6) oxytetracycline (10 mg/kg, dull or greenish yellow). The multiple-fluorochrome method (sequential use of a variety of different colored labels) is a powerful method of assessing bone growth, healing, functional adaptation, and response to applied loads.[7,25]
Microradiography

High-resolution images require polished sections approximately 100 mm thick. Differential radiographic attenuation shows that new bone is less mineralized than mature bone. Newly formed bone matrix is osteoid and requires about 1 week of maturation to become mineralized bone matrix. Depending on the collagen configuration of the bone matrix, osteoblasts deposit 70% to 85% of the eventual mineral complement by a process called *primary mineralization.*[7,24] Secondary mineralization (mineral maturation) completes the maturation process in about 8 months by a crystal growth process (see Fig. 4.15D). Because the strength of bone tissue is related directly to mineral content, the stiffness and strength of an entire bone depends on the distribution and relative degree of mineralization of its osseous tissue.[26] The initial strength of new bone is the result of the cell-mediated process of primary mineralization, but its ultimate strength is dictated by secondary mineralization, which is the physiochemical process of crystal growth. This concept has important clinical value in orthodontics. Fully mineralized lamellar bone (i.e., bone in steady state with respect to modeling and remodeling) is expected to be less susceptible to relapse tendencies than its woven and composite bone predecessors.[6,27] After active orthodontic therapy, retaining dental corrections for at least 6 to 8 months is important to allow for mineral maturation of the newly formed bone (Fig. 4.16).

Endosseous implants can be placed in the nasal bones of rabbits to serve as anchorage units to load the nasal suture. Slow sutural expansion (Fig. 4.17) produces high-quality lamellar bone along the osseous margins of the suture and the periosteal (superior) surface of the nasal bones (Fig. 4.18). Compression of the nasal bones (see Fig. 4.17A) is manifested by resorption along the margins of the suture (Fig. 4.19). Compressive and tensile loading of the suture are associated with extensive bone modeling and remodeling of the adjacent bones. Sutural adaptation to physiologic and therapeutic loads is associated with a regional acceleration of modeling and remodeling in the adjacent bones.

The PDL is the adaptive connective tissue interface between a tooth and its supporting bone. The overall quality and relative maturation of alveolar bone supporting a rat maxillary molar is shown by a microradiographic image of a histologic section (Fig. 4.20A). If the same section is viewed with fluorescent light, the pattern of osteogenic activity in the bone directly supporting the PDL is visible. Sharp labels mark lamellar bone, and diffuse labels indicate woven bone. Extensive turnover (remodeling) of the alveolar process is shown by uptake of internal labels (Fig. 4.20B). These data reveal that the entire alveolar process responds to tooth movement. Uncoupled anabolic and catabolic modeling occurs along bone surfaces that border the periosteum and PDL. Remodeling (coupled foci of bone resorption and formation) is the process of internal turnover and adaptation.

To a limited extent the temporal fossa can adapt to growth and functional loading, primarily in an anteroposterior direction, but the principal site of skeletal growth and adaptation is the mandibular condyle. In one study, multifluorochrome labeling and microradiography were used to compare bone in growing adolescent rabbits (Fig. 4.21) with that in adult female rabbits who had completed growth (Fig. 4.22). The adolescent primary spongiosa, the layer of endochondral bone immediately beneath the articular cartilage, is predominantly woven bone (marked by the diffuse labels in Fig. 4.22). More inferiorly, the primary spongiosa is remodeled to secondary spongiosa (broad, distinct labels). Progressing deeper into the secondary spongiosa (trabecular bone),

• **Fig. 4.15** (A) Microradiography provides a physiologic index of bone turnover and relative stiffness. The more radiolucent (dark) osteons are the youngest, the least mineralized, and the most compliant. Radiodense (white) areas are the oldest, most mineralized, and rigid portions of the bone. (B) Polarized light microscopy shows the collagen fiber orientation in bone matrix. Lamellae with a longitudinally oriented matrix *(C)* are particularly strong in tension, whereas a horizontally oriented matrix (dark) has preferential strength in compression (*arrows,* resorption arrest lines; *asterisks,* vascular channels). (C) Multiple fluorochrome labels administered at 2-week intervals demonstrate the incidence and rates of bone formation. (D) This microradiograph shows an array of concentric secondary osteons (haversian systems) characteristic of rapidly remodeling cortical bone. Primary *(p)* and beginning secondary *(s)* mineralization are more radiolucent and radiodense, respectively. (From Roberts WE, Garetto LP, Katona TR. Principles of orthodontic biomechanics; metabolic and mechanical control mechanisms. In: Carlson DS, Goldstein S, eds. *Bone Biodynamics in Orthodontic and Orthopedic Treatment*. Ann Arbor, MI: Center for Human Growth and Development; 1992. Craniofacial Growth Series; vol. 27.)

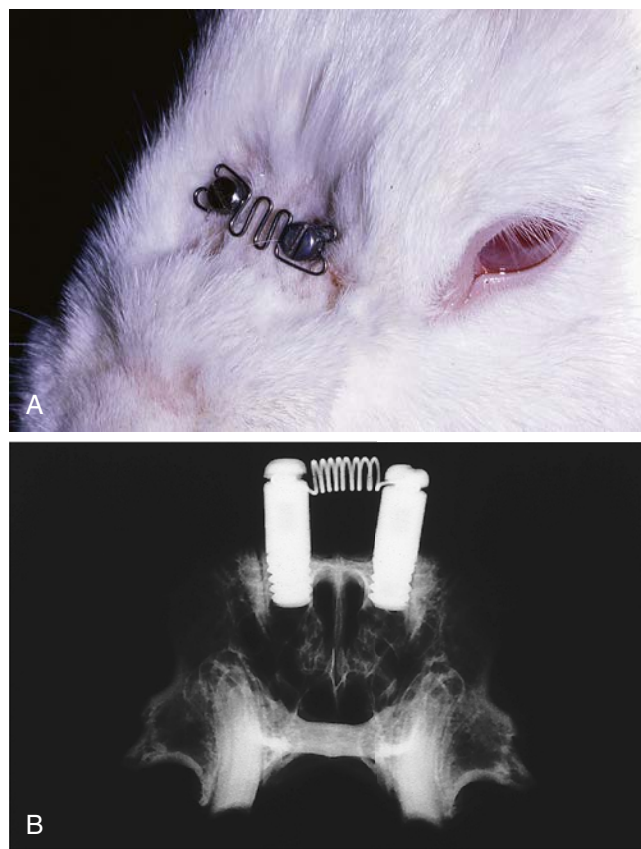
continuing remodeling of lamellar bone is shown by the sharp labels (see Fig. 4.21). This progressive pattern of bone modeling and remodeling is characteristic of the skeletal mechanism of long bone growth.

In contrast, the nongrowing condyles of adult animals have a much thinner subchondral plate composed primarily of woven bone (see Fig. 4.22). The supporting metaphysis is composed entirely of secondary spongiosa. Bone-label uptake documents a high rate of remodeling of lamellar bone.

These data suggest that the mandibular condyle has a high rate of remodeling consistent with heavy functional loading. All things considered, the substantial histologic variance of functioning condyles in adolescent and adult animals indicates that the TMJ is highly adaptable. However, the presence of woven bone and diffuse labels in the thin subchondral plate of adults suggests that the mandibular condyle may be fragile and susceptible to degenerative changes if overloaded. Nevertheless the high rate of physiologic activity in the mandibular condyle of young and old animals may

explain the remarkable ability of this joint to heal and even regenerate after injury (see Fig. 4.14).

Microindentation, Backscatter Imaging, and Microcomputed Tomography

Huja and colleagues[21] developed a microindentation method for determining the material properties of bone in a block specimen and demonstrated that the lamellar bone within 1 mm of the surface of an implant is more compliant than the supporting bone of the jaw. Polarized microscopy demonstrates the more irregular collagen pattern of the compliant lamellar bone near the interface (Fig. 4.23). Backscatter emission imaging[19] recently has been refined as a high-resolution method for assessing the bone mineral density and surface topography patterns of the osseous interface of dental implants (Fig. 4.24). In another important technologic advancement, Yip and colleagues[20] developed a special tuning sequence for the microcomputed tomography that allows three-dimensional detection of bone mineral density patterns to a


• **Fig. 4.16** Periapical radiographs comparing bone maturation at the end of active orthodontic treatment and 2 years later. (A) At the end of treatment, large amorphous areas of relatively immature bone can be seen. (B) After retention and restorative treatment, including endodontics, distinct definition of cortices and trabeculae is evident. (From Roberts WE, Garetto LP, Katona TR. Principles of orthodontic biomechanics; metabolic and mechanical control mechanisms. In: Carlson DS, Goldstein S, eds. *Bone Biodynamics in Orthodontic and Orthopedic Treatment*. Ann Arbor, MI: Center for Human Growth and Development; 1992. Craniofacial Growth Series; vol. 27.)

• **Fig. 4.17** (A) Endosseous implants in rabbit nasal bones are loaded in tension to expand the suture between the nasal bones. (B) Radiograph of a postmortem specimen of rabbit maxilla and nasal bones shows two bilateral endosseous implants used as abutments for a coil spring that delivers a compressive load across the internasal suture. (From Don MT. *Orthopedic Anchorage with Endosseous Implants in Rabbit Nasal Bones.* [master's thesis]. San Francisco: University of the Pacific; 1988.)

resolution of 5 mm (Fig. 4.25). Furthermore, this exciting new method can detect bone-remodeling foci within intact specimens (Fig. 4.26) and can differentiate between primary and secondary lamellar bone along the metallic surfaces of endosseous implants. Collectively, these new methods have been valuable for assessing the material properties and mineral density of bone integrating endosseous implants that are used for orthodontic and dentofacial orthopedic anchorage. However, these advanced technologies offer the promise of considerably exceeding the capability of previous histologic methods for defining the adaptive response of the oral and craniofacial structures to therapeutic loads.

Autoradiography

Radioactive precursors for structural and metabolic materials can be detected in tissue by coating histologic sections with a nuclear track emulsion. By localizing radioactive disintegrations, one can determine the location of the radioactive precursors (Fig. 4.27). Specific radioactive labels for proteins, carbohydrates, and nucleic acids are injected at a known interval before tissue sampling is done. Qualitative and quantitative assessment of label uptake is a physiologic index of cell activity. The autoradiographic labeling procedures most often used in bone research are ^{3}H-thymidine labeling of cells synthesizing DNA (S-phase cells) and ^{3}H-proline

labeling of newly formed bone matrix. Bromodeoxyuridine immunocytochemistry, a nonradioactive method of labeling S-phase cells in vivo (Fig. 4.28), shows promise of becoming an important bone cell kinetic method of the future.[14]

Nuclear Volume Morphometry

Measuring the size of the nucleus is a cytomorphometric procedure for assessing the stage of differentiation of osteoblast precursor cells. This method has been particularly useful for assessing the mechanism of osteogenesis in orthodontically activated PDLs (Fig. 4.29). Preosteoblasts (C and D cells) have significantly larger nuclei than committed osteoprogenitor (A′) cells or their less differentiated precursors (A cells). The B-cell compartment is a group of fibroblast-like cells that appear to have little or no osteogenic potential.[28] Careful cytomorphometric assessment of the size of the nucleus (Fig. 4.30) has proved to be an effective means of determining the relative differentiation of PDL and other bone-lining cells.

Classification of Bone Tissue

Orthodontic tooth movement involves a cytokine-mediated bone adaptation response similar to wound healing; therefore tooth movement is a good experimental model for understanding the types of bone formed during the postoperative bone
• **Fig. 4.18** (A) Microradiograph of the superficial portion of an internasal suture loaded in tension shows smooth bone surfaces consistent with bone apposition. (B) Fluorescent light photomicrograph of rabbit nasal bones loaded in tension shows bone-modeling and remodeling patterns associated with mechanical expansion of the suture. Bone-forming surfaces were labeled with fluorescent dyes at weekly intervals. The superior portion of the labeled suture corresponds to the microradiograph in (A). Bone-forming surfaces were labeled with fluorescent dyes at weekly intervals. (From Don MT. *Orthopedic Anchorage with Endosseous Implants in Rabbit Nasal Bones.* [master's thesis]. San Francisco: University of the Pacific; 1988.)
• **Fig. 4.20** (A) Microradiograph of a midsagittal section through the mesial root of a rat maxillary first molar shows the varying degrees of mineralization of the alveolar bone and the tooth root. (B) Fluorescent light photomicrograph of the corresponding section shows the bone modeling and remodeling patterns associated with extrusion and distal (left) tipping of the root. (From Shimizu KA. The *Effects of Hypofunction and Hyperfunction on the Supporting Structures of Rat Molar Teeth*. [master's thesis]. San Francisco: University of the Pacific; 1987.)
● **Fig. 4.21** (A) Microradiograph of a frontal section through the mandibular condyle of a young, growing rabbit reveals that the superior cortical plate (primary spongiosa) is composed of relatively porous, primary cortical bone that is supported by a secondary spongiosa of lamellar trabeculae. (B) Fluorescent light photomicrograph of the corresponding section shows that the superior cortical plate is composed primarily of woven bone (indistinct labels). The supporting trabeculae are composed of remodeling trabecular bone (sharp labels). (From Larsen SJ. *The Influence of Age on Bone Modeling and Remodeling.* [master's thesis]. San Francisco: University of the Pacific; 1986.)
● **Fig. 4.22** (A) Microradiograph of a frontal section through the mandibular condyle of a mature adult rabbit shows that the superior cortical plate (primary spongiosa) is composed of a thin layer of porous primary bone supported by a secondary spongiosa of lamellar trabeculae. (B) Fluorescent light photomicrograph of the corresponding section shows that the superior cortical plate is composed primarily of woven bone (indistinct labels). The supporting trabeculae are composed of remodeling trabecular bone (sharp labels). (From Larsen SJ. *The Influence of Age on Bone Modeling and Remodeling.* [master's thesis]. San Francisco: University of the Pacific; 1986.)

modeling and long-term remodeling response to bone manipulative therapy. The first bone formed is relatively immature woven bone (Fig. 4.31). Woven bone is compacted to form composite bone (primary ostons) and subsequently is remodeled to lamellar bone. To appreciate the biologic mechanism of bone healing and adaptation, the practitioner must have knowledge of bone types.

Woven Bone

Woven bone varies considerably in structure; it is relatively weak, disorganized, and poorly mineralized. However, it serves a crucial role in wound healing by (1) rapidly filling osseous defects; (2) providing initial continuity for fractures, osteotomy segments, and endosseous implants; and (3) strengthening a bone weakened by surgery or trauma. The first bone formed in response to wound healing is the woven type. Woven bone is not found in the adult skeleton under normal, steady-state conditions; rather, it is compacted to form composite bone, remodeled to lamellar bone, or rapidly resorbed if prematurely loaded.[8,29] The functional limitations of woven bone are an important aspect of orthodontic retention (see Fig. 4.16), as well as postoperative healing of implants and orthognathic surgery segments.[30]

Lamellar Bone

Lamellar bone, a strong, highly organized, well-mineralized tissue, makes up more than 99% of the adult human skeleton. When new lamellar bone is formed, a portion of the mineral component (hydroxyapatite) is deposited by osteoblasts during primary mineralization (see Fig. 4.15D). Secondary mineralization, which completes the mineral component, is a physical process (crystal growth) that requires many months. Within physiologic limits, the strength of bone is related directly to its mineral content.[24,26] The relative strengths of different histologic types of osseous tissue are such that woven bone is weaker than new lamellar bone, which is weaker than mature lamellar bone.[30] Adult human bone is almost entirely comprised of the remodeled variety: secondary osteons and spongiosa.[7,8,24] The full strength of lamellar bone that supports an endosseous implant is not achieved until about 1 year postoperatively. This is an important consideration in planning the functional loading of an implant-supported prosthesis.

Composite Bone

Composite bone is an osseous tissue formed by the deposition of lamellar bone within a woven bone lattice, which is a process called *cancellous compaction.*[6,31] This process is a rapid means of
• **Fig. 4.23** Polarized illumination photomicrograph shows the healed interface of a titanium implant in rabbit cortical bone. Note the layer of newly formed lamellar bone *(A)* formed by multidirectional remodeling within about 1 mm of the implant surface. Compare the more compliant layer of primarily mineralized lamellar bone *(A)* with the fully mineralized lamellar bone *(B)* supporting the interfacial layer.
• **Fig. 4.24** Backscatter emission imaging of the bone surface immediately adjacent to an implant (removed) reveals the mineral density of surface topography of the rapidly remodeling interfacial layer. (From Huja SS, Roberts WE. Mechanism of osseointegration: characterization of supporting bone with indentation testing and backscattered imaging. *Semin Orthod.* 2004;10:162–173.)

producing relatively strong bone in a short period.[26] Composite bone is an important intermediary type of bone in the physiologic response to functional loading (see Fig. 4.31), and it usually is
• **Fig. 4.25** Microcomputed tomography of a section through an implant placed in canine cortical bone reveals a broad array of mineralized tissues. The original gray-level distribution has been color coded gold, blue, red, and yellow to demonstrate decreasing levels of mineral density. The method can resolve structures as small as an osteoblast. (From Yip G, Schneider P, Roberts WE. Micro-computed tomography: high resolution imaging of bone and implants in three dimensions. *Semin Orthod.* 2004;10:174–187.)

the predominant osseous tissue for stabilization during the early process of postoperative healing. When the bone is formed in the fine compaction configuration, the resulting composite of woven and lamellar bone forms structures known as *primary osteons.* Although composite bone may be high-quality, load-bearing osseous tissue, it is eventually remodeled into secondary osteons.[7,30]

Bundle Bone

Bundle bone is a functional adaptation of lamellar structure to allow attachment of tendons and ligaments. Perpendicular striations, called *Sharpey's fibers,* are the major distinguishing characteristics of bundle bone. Distinct layers of bundle bone usually are seen adjacent to the PDL (see Fig. 4.31) along physiologic bone-forming surfaces.[32] Bundle bone is the mechanism of ligament and tendon attachment throughout the body. First-generation blade implants were thought to form a ligamentous attachment to bone, which was deemed a *pseudoperiodontium.* However, histologic studies could not demonstrate any bundle bone attaching fibrous connective tissue to bone at the interface. Because the fibrous tissue encapsulation had no physiologic role, it was actually scar tissue, which was equivalent to a nonunion in a failed facture repair.

Skeletal Adaptation: Modeling and Remodeling

Skeletal adaptation to the mechanical environment is achieved through changes in (1) bone mass, (2) geometric distribution, (3) matrix organization, and (4) collagen orientation of the lamellae. In addition to these adaptive mechanisms that influence bone formation, the mechanical properties of osseous structures change as a result of maturation, function, aging, and pathologic processes.
• **Fig. 4.26** Three-dimensional microcomputed tomography view of the peri-implant radiolucent areas reveals an uneven distribution of vascular areas and remodeling foci. This image of the cervical half of a cylindric implant is consistent with the intense bone-remodeling pattern focused within the center of the endosseous portion. This image was tuned to demonstrate less-mineralized structures: internal vascularity including remodeling foci (cutting/filling cones). (From Yip G, Schneider P, Roberts WE. Microcomputed tomography: high resolution imaging of bone and implants in three dimensions. *Semin Orthod.* 2004;10:174–187.)

• **Fig. 4.27** At 56 hours after initiation of orthodontic force, new bone *(N)* is forming on the original *(O)* alveolar bone surface. The ^{3}H-thymidine–labeled osteoblasts *(arrows)* are derived from preosteoblasts in the periodontal ligament *(P)* (×450).

A few physiologic and pathologic examples are (1) secondary mineralization, (2) mean bone age, (3) fatigue damage, and (4) loss of vitality (pathologic hypermineralization).[33]

Trabecular and cortical bone grow, adapt, and turn over by means of two fundamentally distinct mechanisms: modeling and remodeling. In bone modeling, independent sites of resorption and formation change the form (shape, size, or both) of a bone. In bone remodeling, a specific, coupled sequence of resorption and formation occurs to replace previously existing bone (Fig. 4.32). The mechanism for internal remodeling (turnover) of dense compact bone involves axially oriented cutting and filling cones (Fig. 4.33).[6] From an orthodontic perspective the biomechanical response to tooth movement involves an integrated array of bone-modeling and remodeling events (Fig. 4.34A). Bone modeling is the dominant process of facial growth and adaptation to applied loads such as headgear, rapid palatal expansion, and functional appliances. Modeling changes can be seen on cephalometric tracings (see Fig. 4.34B), but remodeling events, which usually occur at the same time, are apparent only at the microscopic level.
• **Fig. 4.28** (A) Histogenesis sequence of osteoblasts *(Ob).* Precursor cells, located around blood vessels in the periodontal ligament (PDL), migrate toward bone as they differentiate through several stages (A→A′→C→D→Ob) to become alveolar bone-forming cells (Ob). The A′→C step is believed to be mediated by stress and strain. (B) The area between the lines is the PDL; *R,* root, *B,* bone. The 5-bromo-2′-deoxyuridine (BDU) is a thymidine analog taken up by cells in the PDL (dark dots) in which the nuclei are synthesizing DNA. BDU-labeled regions in the PDL are adjacent to areas of eventual bone formation (thick line segments). The BDU immunohistochemically labeled pattern of cells in the PDL of a young control rat is consistent with proliferation supporting tooth eruption. (Adapted from Katona TR, Paydar NH, Akay HU, Roberts WE. Stress analysis of bone modeling response to rat molar orthodontics. *J Biomech.* 1995;28:27–38.)
• **Fig. 4.29** (A) Bone *(B),* periodontal ligament *(P),* and cementum *(C)* in the control periodontium of a young adult rat (6–8 weeks of age) (×100). (B) At 56 hours after application of force, new bone is noted; a ³H-thymidine–labeled preosteoblast is selected from the periodontal ligament *(circle)* and magnified to 1000 times in the upper right corner (×100) *(large arrow* indicates the zoom in magnification to show cellular detail).
• **Fig. 4.30** Frequency distribution of nuclear volume for fibroblast-like cells in unstimulated rat periodontal ligament. A, A′, C, and D cells are a morphologic classification based on peaks in the distribution curve. The osteoblast histogenesis sequence is a progression of five morphologically and kinetically distinguishable cells. The process involves two DNA S phases *(S)* and two mitotic *(M)* events. (Redrawn from Roberts WE, Morey ER. Proliferation and differentiation sequence of osteoblast histogenesis under physiologic conditions in rat periodontal ligament. *Am J Anat.* 1985;174:105.)

True remodeling usually is not imaged on clinical radiographs,[34] but it can be detected with clinical scintillation scans. Constant remodeling (internal turnover) mobilizes and redeposits calcium by means of coupled resorption and formation: bone is resorbed and redeposited at the same site. Osteoblasts, osteoclasts, and possibly their precursors are thought to communicate by chemical messages known as *coupling factors.* Transforming growth factor β is thought to be a coupling factor.[35]

Cortical Bone Growth and Maturation

Enlow[31] sectioned human skulls and histologically identified areas of surface apposition and resorption. The overall patterns of bone modeling ("external remodeling") helped define the mechanisms of facial growth. Although the method could not distinguish between active and inactive modeling sites, it was adequate for determining the overall direction of regional activity in the maxilla and mandible. This method of osseous topography was a considerable advance in the understanding of surface modeling of facial bones.

Melsen[36] used microradiographic images of mineralized sections to extend the capability of the osseous topography method. Patterns of primary and secondary mineralization (as described in Fig. 4.15) identified active appositional sites and provided a crude index of bone formation rates. Through the systematic study of autopsy specimens of 126 normal males and females from birth to 20 years of age, the most stable osseous structures in the anterior cranial base of growing children and adolescents were defined anatomically (Fig. 4.35A). This research established that the three most stable osseous landmarks for superimposition of cephalometric radiographs are (1) the anterior curvature of the sella turcica, (2) the cribriform plate, and (3) the internal curvature of the frontal bone (see Fig. 4.35B). In effect, this research established the gold standard for reliable superimposition on the anterior cranial base. This information is valuable for implantologists because a superimposed tracing of serial cephalometric radiographs is the most reliable means for determining when postadolescent growth is complete. The latter is essential for treatment planning implant placement during the late adolescent and early adult periods.

Roberts and colleagues[6,7,25] introduced simultaneous use of multiple fluorochrome labels and microradiography to assess modeling and remodeling patterns over extended periods of time. Noorda[37] applied these methods for a three-dimensional assessment of subcondylar growth of the mandible of adolescent rabbits. Twenty-week-old rabbits (early adolescents) were labeled every 2 weeks with a rotating series of six different multifluorochrome labels for 18 weeks. Cross sections of the subcondylar region (Fig. 4.36A) were superimposed on original, oldest-labeled, and newest-labeled bone according to fluorescent time markers (see Fig. 4.36B). Because all three sections were at the same relative level at a point in time, superimposition on original (unlabeled) bone and the oldest-labeled bone (see Fig. 4.36C) provided an index of the relative amounts of bone resorbed and formed as the mandible grew superiorly (see Fig. 4.36D). This method provides the most accurate assessment to date of cortical bone drift over time. The major mechanism of the increase in interramal width during adolescent growth in rabbits is lateral drift of the entire subchondral region.

The Noorda study also produced important quantitative data on the rates of surface modeling (apposition and resorption) of primary bone (Fig. 4.37). During the last 18 weeks of growth to adult stature, the surface apposition rate decreased from more than 25 μm/day to less than 5 μm/day (Fig. 4.38A). The secondary osteon census peaked at about 8 to 10 weeks (see Fig. 4.38B). Therefore under conditions of relatively rapid growth, primary cortical bone is remodeled to secondary osteons in about
● **Fig. 4.31** Section of human periodontium from the lower first molar region shows a typical histologic response to orthodontic tooth movement. With respect to the mature lamellar bone *(L)* on the left, the tooth *(T)* is being moved to the right. The first bone formed adjacent to the periodontal ligament *(P)* is of the woven type *(W).* Subsequent lamellar compaction forms primary osteons of composite bone *(arrows).* Bundle bone *(B)* is formed where ligaments, such as the periodontal ligament, are attached. (From Roberts WE, Turkey PK, Breznia KN, Fielder PJ. Implants: bone physiology and metabolism. *CDA J.* 1987;15:54–61.)
● **Fig. 4.32** Schematic cross section of cortical bone shows surface modeling *(M),* which is the process of uncoupled resorption and formation. Remodeling *(R)* is the turnover of existing bone. (From Roberts WE, Garetto LP, DeCastro RA. Remodeling of devitalized bone threatens periosteal margin integrity of endosseous titanium implants. *J Indiana Dent Assoc.* 1989; 68:19–24.)

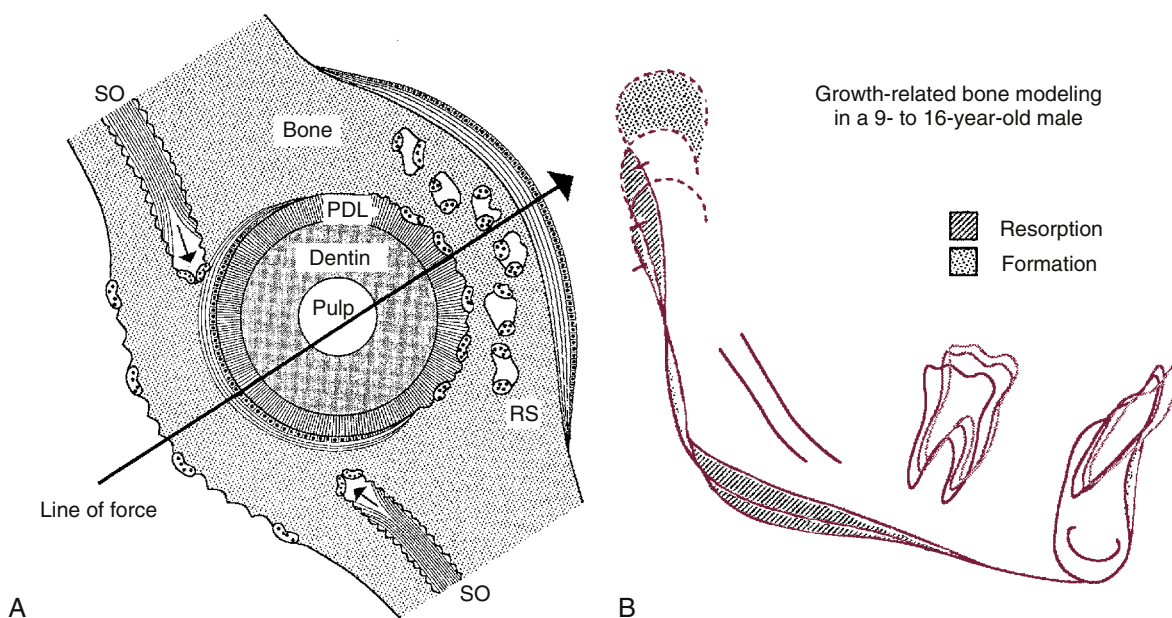
2 months. Remodeling therefore is a time-dependent maturation of primary cortical bone.[6,7]

There is little long-term documentation of the bone remodeling response to functional loading of implant-supported restorations. The same methods used for defining the growth and development of the rabbit mandible would provide valuable new information for the field of implantology.

Cutting and Filling Cones

The rate at which cutting and filling cones progress through compact bone is an important determinant of turnover. The progression is calculated by measuring the distance between initiation of labeled bone-formation sites along the resorption arrest line in longitudinal sections.[6] Using two fluorescent labels administered 2 weeks apart in adult dogs, the velocity was 27.7 ± 1.9 mm/day (mean ± SEM [standard error of the mean], *n* = 4 dogs, 10 cutting and filling cones sampled from each). At this speed, evolving secondary osteons travel about 1 mm in 36 days. Newly remodeled secondary osteons (formed within the experimental period of the dog study) contained an average of 4.5 labels (administered 2 weeks apart); the incidence of resorption cavities is about one-third the incidence of labeled osteons.[25] These data are consistent with a remodeling cycle of about 12 weeks in dogs,[25] compared with 6 weeks in rabbits[6] and 17 weeks in humans.[7,8] This relationship is useful for extrapolating animal data to human applications. More recent experimental studies have shown that new secondary osteons may continue to fix bone labels for up to 6 months, indicating that terminal filling of the lumen is slow.[38]

Traumatic or surgical wounding usually results in intense but localized modeling and remodeling responses. After an osteotomy or placement of an endosseous implant, callus formation and resorption of necrotic osseous margins are modeling processes; however, internal replacement of the devitalized cortical bone surrounding these sites is a remodeling activity. In addition, a gradient of localized remodeling disseminates through the bone adjacent to any invasive bone procedure. This process, called *regional acceleratory phenomenon,* is an important aspect of postoperative healing.[8,39]
● **Fig. 4.33** The cutting/filling cone has a head of osteoclasts that cut through the bone and a tail of osteoblasts that form a new secondary osteon. The velocity through bone is determined by measuring between two tetracycline labels *(1 and 2)* administered 1 week apart. (Adapted from Roberts WE, Garetto LP, Arbuckle GR, Simmons KE, DeCastro, RA. What are the risk factors of osteoporosis? Assessing bone health. *J Am Dent Assoc.* 1991;122:59–61.)

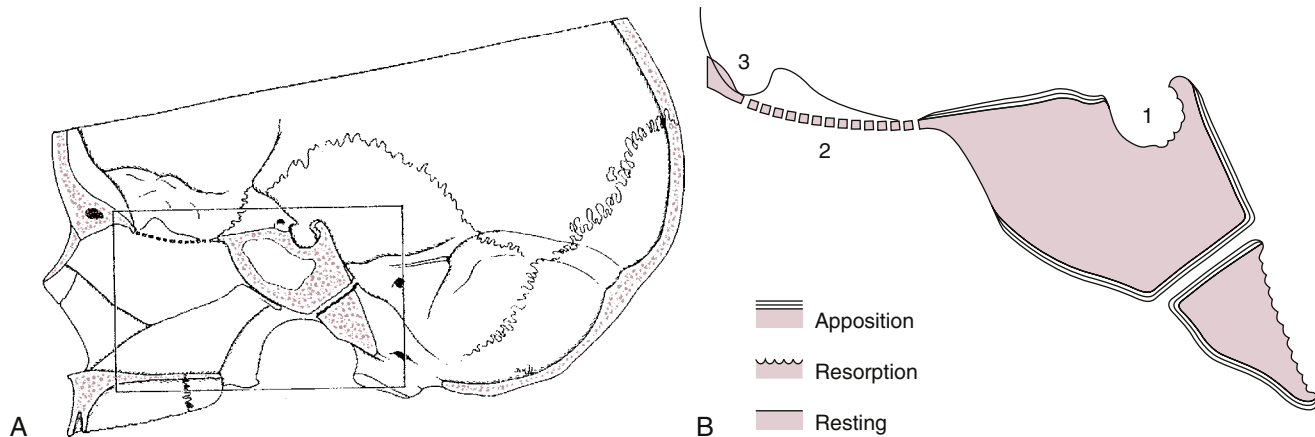


● **Fig. 4.34** (A) Orthodontic bone modeling, or site-specific formation and resorption, occurs along the periodontal ligament (PDL) and periosteal surfaces. Remodeling, or turnover, occurs within alveolar bone along the line of force on both sides of the tooth. (B) Orthopedic bone modeling related to growth in an adolescent male involves several site-specific areas of bone formation and resorption. Although extensive bone remodeling (i.e., internal turnover) also is underway, it is not evident in cephalometric radiographs superimposed on stable mandibular structures. (SO = Secondary Osteon, BM = Bone Remodeling)

Modeling and remodeling are controlled by an interaction of metabolic and mechanical signals. Bone modeling is largely under the integrated biomechanical control of functional applied loads (Table 4.1). However, hormones and other metabolic agents have a strong secondary influence, particularly during periods of growth and advanced aging. Paracrine and autocrine mechanisms, such as local growth factors and prostaglandins, can override the mechanical control mechanism temporarily during wound healing.[40] Remodeling responds to metabolic mediators such as parathyroid hormone (PTH) and estrogen, primarily varying the rate of bone turnover (Box 4.1). Bone scans with ^{99}Te-bisphosphate, a marker of bone activity, indicate that the alveolar processes, but not the basilar mandible, have a high remodeling rate.[41,42] Uptake of the marker in alveolar bone is similar to uptake in trabecular

bone of the vertebral column. The latter is known to remodel at a rate of about 20% to 30% per year compared with most cortical bone, which turns over at a rate of 2% to 10% per year.[43] Metabolic mediation of continual bone turnover provides a controllable flow of calcium to and from the skeleton.

Structural and Metabolic Fractions

The structural fraction of cortical bone is the relatively stable outer portion of the cortex; the metabolic fraction is the highly reactive inner aspect (Fig. 4.39A). The primary metabolic calcium reserves of the body are found in trabecular bone and the endosteal half of the cortices. Analogous to orthodontic wires, the stiffness and strength of a bone are related directly to its cross-sectional area. Diaphyseal rigidity quickly is enhanced by adding a


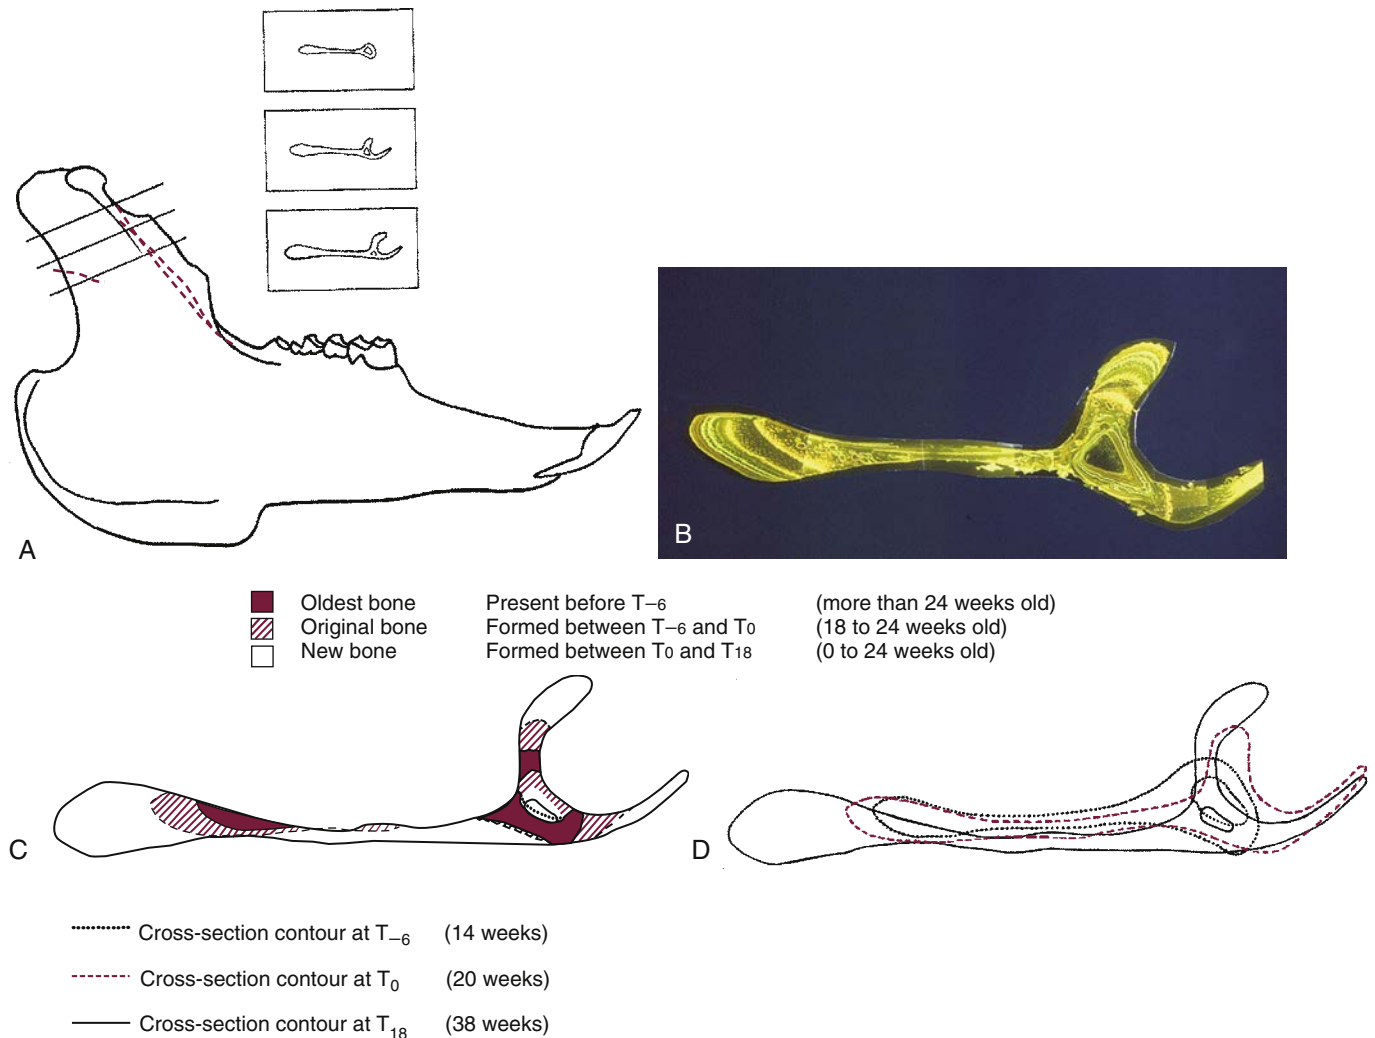
• **Fig. 4.35** (A) Schematic drawing of a skull showing the tissue block removed at autopsy from a series of growing children and adolescents from birth to 20 years of age. (B) Diagrammatic representation of the bone-modeling patterns of the cranial base in growing children. Histologic and microradiographic analysis established that the three most stable anatomic landmarks are *(1)* the anterior curvature of the sella turcica, *(2)* the cribriform plate, and *(3)* the internal curvature of the frontal bone. (From Melsen B. The cranial base. *Acta Odontol Scand.* 1974;32[suppl 62]:S103.)

circumferential lamella at the periosteal surface. Even a thin layer of new osseous tissue at the periosteal surface greatly enhances bone stiffness because it increases the diameter of the bone. In engineering terms, cross-sectional rigidity is related to the second moment of the area. The same general relationship of round wire diameter and stiffness (strength) is well known to orthodontists. The rigidity of a wire increases as the fourth power of diameter.[44] Therefore when a relatively rigid material (bone or wire) is doubled in diameter, the stiffness increases 16 times.

The addition of new osseous tissue at the endosteal (inner) surface has little effect on overall bone strength. Structurally, the long bones and mandible are modified tubes, which is an optimal design for achieving maximal strength with minimal mass.[26] Within limits, loss of bone at the endosteal surface or within the inner third of the compacta has little effect on bone rigidity. The inner cortex can be mobilized to meet metabolic needs without severely compromising bone strength (see Fig. 4.39B); this is the reason patients with osteoporosis have bones with a normal diameter but thin cortices. Even under severe metabolic stress, the body follows a cardinal principle of bone physiology: *maximal strength with minimal mass.*[45]

Bone Metabolism

Restoration of esthetics and function with implant-supported prostheses requires substantial bone manipulation. The biomechanical response to altered function and applied loads depends on the metabolic status of the patient. Bone metabolism is an important aspect of clinical medicine that is directly applicable to implant dentistry. This section discusses the fundamentals of bone metabolism with respect to clinical practice.

The skeletal system is composed of highly specialized mineralized tissues that have structural and metabolic functions. Structurally, lamellar, woven, composite, and bundle bone are unique types of osseous tissue adapted to specific functions. Bone modeling and remodeling are distinct physiologic responses to integrated mechanical and metabolic demands. Biomechanical manipulation of bone is the physiologic basis of stomatognathic reconstruction.


However, before addressing dentofacial considerations, the clinician must assess the patient's overall health status. Implantology is bone-manipulative therapy, and favorable calcium metabolism is an important consideration. Because of the interaction of structure and metabolism, a thorough understanding of osseous structure and function is fundamental to patient selection, risk assessment, treatment planning, and retention of desired dentofacial relationships.[45,46]

Bone is the primary calcium reservoir in the body (Fig. 4.40). Approximately 99% of the calcium in the body is stored in the skeleton. The continual flux of bone mineral responds to a complex interaction of endocrine, biomechanical, and cell-level control factors that maintain the serum calcium level at about 10 mg/dL (10 mg%).

Calcium homeostasis is the process by which mineral equilibrium is maintained. Maintenance of serum calcium levels at about 10 mg/dL is an essential life-support function. Life is thought to have evolved in the sea; calcium homeostasis is the mechanism of the body for maintaining the primordial mineral environment in which cellular processes evolved.[45]

Calcium metabolism is one of the fundamental physiologic processes of life support. When substantial calcium is needed to maintain the critical serum calcium level, bone structure is sacrificed (see Fig. 4.40). The alveolar processes and basilar bone of the jaws also are subject to metabolic bone loss.[47] Even in cases of severe skeletal atrophy, the outer cortex of the alveolar process and the lamina dura around the teeth are preserved. This preservation is analogous to the thin cortices characteristic of osteoporosis.

Calcium homeostasis is supported by three temporally related mechanisms: (1) rapid (instantaneous) flux of calcium from bone fluid (which occurs in seconds), (2) short-term response by osteoclasts and osteoblasts (which extends from minutes to days), and (3) long-term control of bone turnover (over weeks to months) (Fig. 4.41). Precise regulation of serum calcium levels at about 10 mg/dL is essential for nerve conductivity and muscle function. A low serum calcium level can result in tetany and death. A sustained high serum calcium level often is a manifestation of hyperthyroidism and some malignancies. Hypercalcemia may lead to kidney stones and dystrophic calcification of soft tissue.

Oldest bone — Present before T_{-6} — (more than 24 weeks old)
Original bone — Formed between T_{-6} and T_0 — (18 to 24 weeks old)

• **Fig. 4.36** (A) Schematic drawing of a rabbit mandible showing the plane of sectioning in the subcondylar region of the ramus. (B) Fluorescent light photomicrographs of the most inferior section are arranged in a composite. The weekly deposition of bone labels over 4 months shows the patterns of bone modeling and remodeling associated with the growth and development of the subcondylar region. (C) Based on the uptake of bone labels, the age of specific areas in a given cross section can be determined accurately. (D) Because the subcondylar region of the ramus is growing superiorly, superimposition of the three sections on the oldest bone gives an estimation of the patterns of bone resorption (catabolic modeling) associated with growth of the mandibular ramus. (From Noorda CB. *Modeling and Remodeling in the Cortical Bone of Both Growing and Mature Rabbits.* [master's thesis]. San Francisco: University of the Pacific; 1986.)

Normal physiology demands precise control of the serum calcium level.[45,46,48]

Instantaneous regulation of calcium homeostasis is accomplished in seconds by selective transfer of calcium ions into and out of bone fluid (see Fig. 4.41B). Bone fluid is separated from extracellular fluid by osteoblasts or relatively thin bone-lining cells (the latter are thought to be atrophied remnants of osteoblasts). A decrease in the serum calcium level stimulates secretion of PTH, which enhances transport of calcium ions from bone fluid into osteocytes and bone-lining cells. The active metabolite of vitamin D (1,25-dihydroxy-cholecalciferol [1,25-DHCC]) enhances pumping of calcium ions from bone-lining cells into the extracellular fluid. By means of this sequence of events, calcium is transported across the bone-lining cells, resulting in a net flux of calcium ions from bone fluid to extracellular fluid. Within physiologic limits, support of calcium homeostasis is possible without resorption of bone. Radioisotope studies have confirmed that bone contains a diffuse mineral component that can be mobilized or redeposited without osteoblastic and osteoclastic activity.[24] However, a sustained negative calcium balance can be compensated for only by removing calcium from bone surfaces.[45,46]
• **Fig. 4.37** (A) Fluorescent microscopy of weekly bone labels shows the patterns of anabolic modeling (bone apposition) in a rabbit. Note the diminishing space between the labels as growth slows and the animal achieves an adult skeletal form. (B) A similar section from another rabbit in the same study shows the consistency of the growth pattern. (C) In the first rabbit, the adjacent microscopic field shows several sites of bone remodeling in primary cortical bone formed about 6 to 12 weeks earlier. (D) In the second rabbit, the adjacent microscopic field shows a consistent pattern of remodeling of new cortical bone at about 6 to 12 weeks after formation. (From Noorda CB. *Modeling and Remodeling in the Cortical Bone of Both Growing and Mature Rabbits.* [master's thesis]. San Francisco: University of the Pacific; 1986.)

• **Fig. 4.38** (A) Age-related changes in the rate of periosteal apposition that occur in the posterior border of the mandibular ramus of the rabbit. Note the progressive decrease in the rate of periosteal bone apposition as the adolescent animals mature. (B) Remodeling of new cortical bone. The highest incidence of remodeling to secondary osteons occurs when new cortical bone is 6 to 12 weeks old. (From Noorda CB. *Modeling and Remodeling in the Cortical Bone of Both Growing and Mature Rabbits.* [master's thesis]. San Francisco: University of the Pacific; 1986.) (SE = Standard Error)

• BOX 4.1   Control Factors for Bone Remodeling

Metabolic
Parathyroid hormone: ↑ activation frequency
Estrogen: ↓ activation frequency

Mechanical
<1000 $\mu\epsilon$: more remodeling
>2000 $\mu\epsilon$: less remodeling

Short-term control of serum calcium levels affects rates of bone resorption and formation within minutes through the action of the three calcific hormones: PTH, 1,25-DHCC, and calcitonin. Calcitonin, a hormone produced by interstitial cells in the thyroid gland, is believed to help control hypercalcemia by transiently suppressing bone resorption. PTH, acting in concert with 1,25-DHCC, accomplishes three important tasks: (1) it enhances osteoclast recruitment from promonocyte precursors,[49] (2) it increases the resorption rate of existing osteoclasts, and (3) it may suppress the rate at which osteoblasts form bone.[45,46]

Long-term regulation of metabolism has profound effects on the skeleton. Biomechanical factors (e.g., normal function, exercise, posture, habits), noncalcific hormones (e.g., sex steroids, growth hormone), and the metabolic mechanisms previously discussed (see Figs. 4.40 and 4.41) dictate mass, geometric distribution, and the mean age of bone (Fig. 4.42). Mass and geometric distribution of bone are influenced strongly by load history (biomechanics) and sex hormone status. PTH is the primary regulator of the frequency of remodeling (Box 4.2). Because the adult skeleton is composed almost entirely of secondary (remodeled) bone, the PTH-mediated activation frequency determines mean bone age. Bone age is an important determinant of fragility because old bone presumably has been weakened by fatigue damage.[45,46]

Calcium Conservation

Calcium conservation is the aspect of bone metabolism that involves preservation of skeletal mass. A failure in calcium conservation because of one problem or a combination of metabolic and biomechanical problems may leave a patient with inadequate bone mass for reconstructive dentistry.

The kidney is the primary calcium conservation organ in the body. Through a complex series of excretion and endocrine functions, the kidney excretes excess phosphate while minimizing the loss of calcium (see Figs. 4.40 and 4.41A). A patient with impaired renal function often is a high risk for osseous manipulative procedures such as endosseous implants or orthognathic surgery. Because of its components of secondary hyperparathyroidism and impaired vitamin D metabolism, kidney disease may result in poor bone quality, which is a condition often referred to as *renal osteodystrophy.*[45,46,50]

Absorption from the small intestine is the primary source of exogenous calcium and phosphate. Phosphate is absorbed passively and rarely is deficient. Optimal calcium uptake, however, requires an active absorption mechanism. A unique factor involved in the gut absorption process is calcium-binding protein, which is formed in response to the active metabolite of vitamin D.[51] Common clinical profiles associated with poor calcium absorption include a diet deficient in dairy products, vitamin D deficiency, liver disease, and kidney problems.[16,45,46]

Under normal physiologic conditions, the body expends about 300 mg of calcium per day, primarily as a result of secretory processes in the intestines and kidneys. To maintain the serum calcium level, this 300-mg deficit must be recovered by absorption from the gut. However, absorption of calcium from the gut depends on vitamin D and is only about 30% efficient. If less than about 300 mg/day of calcium is absorbed from the intestine, the serum calcium level drops, PTH secretion ensues, and the necessary calcium is removed from the bones (see Fig. 4.40).

Positive calcium balance normally occurs during the growing period and for about 10 years thereafter. The skeletal mass of prepubertal children can be enhanced with regular calcium supplements.[52] Peak skeletal mass is attained between 25 and 30 years. After the early adult years, natural aging is associated with a slightly negative calcium balance that progressively erodes bone volume throughout life. Zero calcium balance (see Fig. 4.40) is the ideal metabolic state for maintaining skeletal mass. Preservation of bone requires a favorable diet, endocrine balance, and adequate exercise.[45,46]

Diet

Animal studies have documented endosteal bone loss of the alveolar processes of dogs maintained on a low-calcium diet.[47] These
• **Fig. 4.39** (A) Structural *(S)* and metabolic *(M)* fractions of cortical bone are revealed by multiple fluoro-chrome labeling of a rabbit femur during the late growth and early adult periods. Continuing periosteal bone formation (right) contributes to structural strength, and high remodeling of the endosteal half of the compacta provides a continual supply of metabolic calcium. (B) Structural and metabolic fractions of bone in the mandible. (From Roberts WE, Garetto LP, Katona TR. Principles of orthodontic biomechanics; metabolic and mechanical control mechanisms. In: Carlson DS, Goldstein S, eds. *Bone Biodynamics in Orthodontic and Orthopedic Treatment*. Ann Arbor, MI: Center for Human Growth and Development; 1992. Craniofacial Growth Series; vol. 27.)
• **Fig. 4.40** Calcium metabolism is a complex physiologic process. Maintaining zero calcium balance requires optimal function of the gut, parathyroid glands, bone, liver, and kidneys. Parathyroid hormone (PTH) and the active metabolite of vitamin D, 1,25 dihydroxycholecalciferol, are the major hormones involved. (From Roberts WE, Garetto LP, Katona TR. Principles of orthodontic biomechanics; metabolic and mechanical control mechanisms. In: Carlson DS, Goldstein S, eds. *Bone Biodynamics in Orthodontic and Orthopedic Treatment*. Ann Arbor, MI: Center for Human Growth and Development; 1992. Craniofacial Growth Series; vol. 27.) (ECF = Extracellular Fluid)

• **Fig. 4.41** (A) Flowchart of calcium homeostasis shows the roles of parathyroid hormone (PTH); vitamin D; and the kidneys, gut, and bone in maintaining serum calcium levels. Note that bone has immediate, short-term, and long-term responses. (B) PTH, the active metabolite of vitamin D (1,25 DHCC), and calcitonin (CT) play active roles in transporting ionic calcium (Ca^{++}) between the bone fluid and extracellular fluid compartments. This is the mechanism of immediate homeostatic control of the serum calcium level. (Redrawn from Roberts WE, Simmons KE, Garetto LP, DeCastro RA. Bone physiology and metabolism in dental implantology: risk factors for osteoporosis and other metabolic bone diseases. *Implant Dent.* 1992;1:11–21.)

● **Fig. 4.42** Structural integrity (fracture resistance) of osseous tissue is affected by bone mass, connectivity (geometric distribution), mean bone age, and fatigue damage. Fragile bone may be fractured by normal functional loads or minor injuries.

data indicate that a low-calcium diet may have severe effects on the bones of the oral cavity. In adult humans the current recommended daily allowance of calcium is 1000 to 1500 mg/day (Table 4.2). Growing adolescents, pregnant or lactating women, and particularly pregnant teenagers, need as much as 1500 mg/day. Postmenopausal women who are not receiving estrogen replacement therapy should get 1500 mg of calcium per day. In the United States dairy products supply about 70% of dietary calcium. As previously mentioned, dietary phosphate deficiency is a rare problem.[16,27,45,46]

Obesity has few health benefits; however, it is a protective factor against osteoporosis. This most probably is a result of the high rates of mechanical loading needed to support an overweight body. Slight stature, however, is a risk factor for osteoporosis. Because weight control is a concern for the population at risk, the calcium-to-calorie ratio is an important consideration in dietary counseling (Table 4.3). The most favorable dairy products with respect to the calcium-to-calorie ratio are nonfat milk; part-skim mozzarella cheese; Swiss cheese; and plain, low-fat yogurt. Typical servings of these products have about 300 mg of calcium and 100 to 200 calories. Some adults avoid milk because of intolerance to lactose. These patients often assume that they have a milk allergy, which should be determined according to symptoms. Lactose intolerance usually is manifested by an upset stomach rather than a classic anaphylaxis. Even patients who are intolerant of milk usually can tolerate cultured products such as buttermilk, cheese, and yogurt. Calcium supplements are indicated if a patient is allergic to milk or fails to achieve a calcium-sufficient diet for any other reason. Other foods, particularly green, leafy vegetables (e.g., turnip greens, spinach), contain substantial amounts of calcium, but the calcium is tightly bound and little ionic calcium is absorbed. In effect, to consume adequate calcium in a diet that excludes dairy products is difficult.[45,46] Calcium supplements of many varieties are available in pharmacies and health food stores, and most supplements provide adequate calcium when used as directed. However, consumers should beware of toxic contaminants in some natural supplements, such as bone meal and dolomite, which may contain significant amounts of lead, arsenic, or other heavy metals.

Among the least expensive, readily tolerated supplements are calcium carbonate (e.g., Tums, calcium-rich Rolaids). To determine the amount of elemental calcium in a supplement, consumers must remember to use the molecular weight. For instance, calcium carbonate is only 40% calcium, which means that a 500-mg tablet provides only 200 mg of calcium.[45,46]

Endocrinology

Peptide hormones (e.g., PTH, growth hormone, insulin, calcitonin) bind receptors at the cell surface and may be internalized with the receptor complex. Steroid hormones (e.g., vitamin D, androgens, estrogens) are lipid soluble and pass through the plasma membrane to bind receptors in the nucleus.[45,46] PTH increases serum calcium by direct and indirect vitamin D–mediated effects. Vitamin D (cholecalciferol) originally was thought to be an essential dietary factor. However, vitamin D is not a vitamin at all; it is a hormone. Cholecalciferol is synthesized in skin irradiated by ultraviolet light, hydroxylated in the liver at the No. 25 position, and then hydroxylated in the kidney at the No. 1 position to produce the active metabolite 1,25-DHCC. The last step is feedback controlled; hydroxylation at the No. 1 position is induced by a low serum calcium level, probably through PTH (see Fig. 4.40). Clinically a major effect of 1,25-DHCC is induction of active absorption of calcium from the gut. Because of the complexity of vitamin D synthesis and the metabolic pathway, calcium absorption may be inhibited at many levels. Some of these inhibitors are (1) lack of skin exposure to adequate sunlight of the proper wavelength; (2) failure to consume vitamin D through the diet, thereby not compensating for the lack of vitamin D synthesis; (3) a genetic defect in the skin; (4) liver disease; and (5) kidney failure.[45,46]

Sex hormones have profound effects on bone. Androgens (testosterone and other anabolic steroids) build and maintain musculoskeletal mass. The primary hypertrophic effect of androgens is to increase muscle mass. The anabolic effect on bone is a secondary biomechanical response to increase loads generated by the enhanced muscle mass. Estrogen, however, has a direct effect on bone; it conserves skeletal calcium by suppressing

• BOX 4.2   Temporomandibular Discrepancies: A Case Study

A 52-year-old man sought treatment for a long history of facial pain, occlusal dysfunction, and an internal derangement of the right mandibular condyle (see figures). Intracapsular surgery was performed on the right temporomandibular joint (TMJ) accelerated, the pain increased, and a progressive anterior open bite malocclusion developed. Masticatory function deteriorated, and an internal derangement of the left TMJ was noted. Bilateral intracapsular surgery was performed to restore "normal jaw function." After the second surgical

procedure, the patient suffered for 10 years with chronic pain and progressive bilateral degeneration of both TMJs. Orthodontic and orthotic (splint) therapy failed to relieve the pain and functional debilitation. The patient declined further treatment was managed with pain medication. From a physiologic perspective, intracapsular surgery usually is contraindicated because it inhibits the natural ability of the joint to adapt to changing biomechanical demands. The TMJ is a remarkably regenerative and adaptive joint if its physiologic limits are respected.
(A) Frontal view, (B) lateral view, (C) maxillary occlusal view, and (D) mandibular occlusal view of the dentition of a 52-year-old man with a partly edentulous open bite malocclusion. Note the atrophic extraction sites and gingival recession. (From Roberts WE. Adjunctive orthodontic therapy in adults over 50 years of age: clinical management of compensated, partially edentulous malocclusion. *J Indiana Dent Assoc.* 1997;76:33–41.)
(A) Cephalometric radiograph of the previously described patient shows a skeletal open bite with a steep mandibular plane and a relatively short ramus. The thin symphyseal cortex is consistent with a systemic osteopenia. (B) A full-mouth radiographic survey shows a generalized lack of cortical bone at the alveolar crest and a pattern of indistinct lamina dura and trabeculae. This generalized ground-glass approach of the alveolar bone is consistent with high-turnover metabolic bone disease. (From Roberts WE. Adjunctive orthodontic therapy in adults over 50 years of age: clinical management of compensated, partially edentulous malocclusion. *J Indiana Dent Assoc.* 1997;76:33–41.)

Dietary Calcium Recommendations

Group	Age	Dosage (mg/day)
Infants	Birth–6 months	400
	6–12 months	600
Children	1–5 years	800
	6–10 years	800–1200
Adolescents and young adults	11–24 years	1200–1500
Men	25–65 years	1000
Women	25–50 years	1000
Pregnant or lactating	—	1200–1500
Postmenopausal		
Receiving estrogen replacement therapy	—	1000
Not receiving estrogen replacement therapy	—	1500
Men and women	>65 years	1500

From National Institutes of Health. *Consensus statement: optimal calcium intake;* 1994.

Calcium and Calorie Content of Common Dairy Products

Product	Calcium (mg)	Calories	Ratio (calcium:calories)
Milk			
Whole, 3.3% fat, 1 cup	291	150	1.9:1
Low-fat, 2% fat, 1 cup	297	120	2.5:1

the activation frequency of bone remodeling.[53] At menopause, enhanced remodeling activation increases turnover.[54] Because a slight negative calcium balance is associated with each remodeling event, a substantial increase in the turnover rate can result in rapid bone loss, leading to symptomatic osteoporosis. Even young women are susceptible to significant bone loss if the menstrual cycle (menses) stops.[55] Bone loss is a common problem in women who have low body fat and who exercise intensely (e.g., running, gymnastics) and in women who are anorexic.[56] Clearly, estrogen protects the female skeleton from bone loss during the childbearing years. Lack of menses in women of any age is a high-risk factor for the development of osteoporosis later in life.[45,46]

Estrogen replacement therapy is widely recommended for calcium conservation and the prevention of osteoporosis in postmenopausal women.[57,58] A major concern of many patients and of some physicians is the relationship of estrogen therapy to the incidence and progression of breast cancer.[59] It generally is accepted that estrogen replacement therapy increases the risk of breast cancer by about 2% but decreases the risk of osteoporosis, heart disease, colon cancer, and Alzheimer's disease by as much as 50%. For many women, estrogen replacement therapy remains a wise health measure.

The antiestrogen tamoxifen is used to treat some forms of breast cancer. Fortunately, in postmenopausal women, tamoxifen has a beneficial effect on bone similar to that of estrogen.[60] Recently raloxifene (Evista) has been shown to reduce the risk of osteoporosis and heart disease without increasing the risk of breast cancer. Some studies have even shown a substantial anticancer protective effect.[61]

Skeletal Compromise

Skeletal health is related to diet, exercise, lifestyle, and proper functioning of numerous organ systems. To provide optimal support over a broad spectrum of conditions, the skeletal system has evolved complex mechanical, endocrine, and cell-level regulatory mechanisms. A failure of one or more of these homeostatic mechanisms can result in metabolic bone disease. Low skeletal mass and/or poor osteogenic capability may make some patients poor candidates for orthodontic or orthognathic procedures. Skeletally compromised patients who seek unrelated dental treatment provide dentists with unique diagnostic opportunities. Timely medical referral of individuals with high-risk profiles can result in substantial health benefits. If osteopenia is confirmed, corrective medical therapy can be started before the onset of the debilitating symptoms associated with osteoporosis.[45,46]

The concept of structural and metabolic fractions (see Fig. 4.39) has considerable clinical significance. The dietary requirement for calcium increases during the growing years. A high dietary calcium intake (1200 mg/day) is essential during the adolescent period (see Table 4.2) to provide structural strength without compromising the metabolic reserve. Pregnancy and lactation before the age of 19 may be precipitating factors for osteopenia later in life. Multiple births during the teenage years are of particular concern. Under these circumstances, young women may fail to deposit sufficient skeletal reserves to withstand the sustained negative calcium balance that follows menopause.[45,46,61]

Although the metabolic fraction of cortical bone can make a substantial contribution, the major source of serum calcium under steady-state conditions is trabecular bone. The primary reason for this is the differential remodeling rates. Cortical bone turns over about 2% to 10% per year, whereas trabecular bone, which is much more active, remodels at 20% to 30% per year.[62] Because it is more labile, trabecular bone is more susceptible to loss under conditions of negative calcium balance. For this reason, patients with osteoporosis have a tendency to suffer structural failure at sites primarily dependent on trabecular bone: the spine (compression fracture), the wrist (Colles' fracture), and the hip (femoral neck fracture). Degenerative changes in the TMJ have not been related directly to skeletal atrophy. However, some relationship is likely because these problems tend to affect the same high-risk group (postmenopausal women).[45,46,63]

Women depend on estrogen to maintain skeletal mass. Lack of normal menses, even in young women, usually indicates an estrogen deficiency and probable negative calcium balance. Numerous national and international consensus conferences[64,57] have recommended that most postmenopausal white and Asian women should be treated with estrogen to prevent osteoporosis. Surveys indicate that some physicians fail to prescribe estrogen for their postmenopausal patients[65]; however, the most common problem is the failure of many women to comply despite the recommendations of their physicians. For this reason many women in Western society are estrogen deficient. About 20% will develop frank osteoporosis, and as many as 50% will have some signs or symptoms.[46] All health care providers should be concerned particularly about the skeletal status of postmenopausal white and Asian women. However, even low-risk groups, such as men and black women, have an incidence of osteoporosis that approaches 5%. Osteopenia and osteoporosis therefore are significant health risks for almost everyone. Bone metabolic evaluation is an important diagnostic concern for all patients being considered for dental implants or any other bone-manipulative therapy.[16,45,66]

Metabolic Bone Disease

Osteoporosis is a generic term for low bone mass (osteopenia). The most important risk factor for the development of osteoporosis is age: after the third decade, osteopenia is related directly to longevity. Other high-risk factors are (1) a history of long-term glucocorticoid treatment, (2) slight stature, (3) smoking, (4) menopause or dysmenorrhea, (5) lack of or little physical activity, (6) low-calcium diet, (7) excessive consumption of alcohol, (8) vitamin D deficiency, (9) kidney failure, (10) liver disease (cirrhosis), and (11) a history of fractures. These risk factors are effective in identifying 78% of those with the potential for osteopenia.[61,67] This is a particularly good screening method for skeletally asymptomatic dental patients. However, one must realize that more than 20% of individuals who eventually develop osteoporosis have a negative history for known risk factors. Any clinical signs or symptoms of low bone mass (e.g., low radiographic density of the jaws, thin cortices, excessive bone resorption) are grounds for referral. A thorough medical workup, including bone mineral density measurement, usually is necessary to establish the diagnosis of osteopenia. The term *osteoporosis* usually is reserved for patients with evidence of fracture or other osteoporotic symptoms. The treatment of metabolic bone diseases such as osteoporosis depends on the causative factors. Physicians specifically trained in bone metabolism best handle medical management of these often complex disorders.[45,46]

Because the loss of teeth is an important risk factor for osteoporosis, dental patients, especially adult women, are at high risk for developing osteoporosis. A sampling of all adult female dental patients at a midwestern dental school showed that about 65% were at high risk for developing osteoporosis (estrogen deficient or had at least two other risk factors).[68]

See Box 4.1 for a relevant case study.

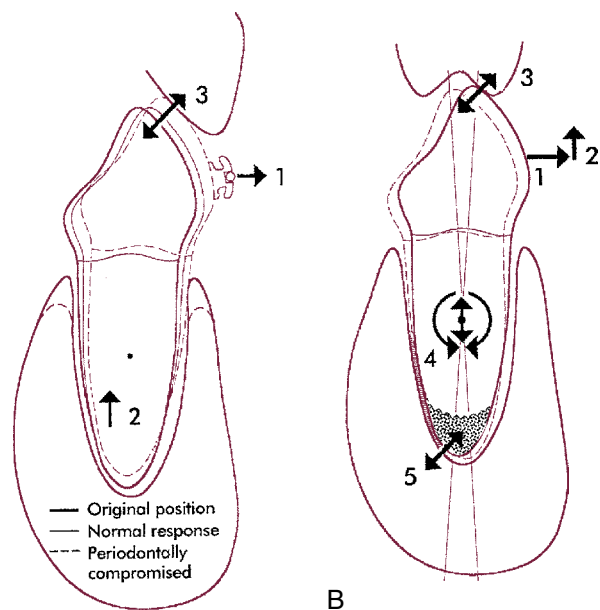
Biomechanics

Gravitational loads have a substantial influence on normal skeletal physiology. Osteoblast differentiation that leads to new bone formation is stimulated by mechanical loading[12] but inhibited by weightlessness.[28,69] Space flight studies have established that gravity helps maintain skeletal mass.[70,71] A substantial part of the physiologic loading of the mandible is related to antigravity posturing. In erect posture, gravity tends to open the mouth; muscular force is used to hold the mouth closed. Apparently, growth of the rat mandibular condyle may be inhibited during space flight because of weightlessness and the decrease in functional loading.[72] Gravity may prove to be an important factor in the secondary growth mechanism of the mandible.

Mechanical loading is essential to skeletal health. Control of most bone modeling (see Table 4.1) and some remodeling processes are related to strain history, which usually is defined in microstrain ($\mu\varepsilon$).[73] Repetitive loading generates a specific response, which is determined by the peak strain.[74-78] In an attempt to simplify the often conflicting data, Frost[79] proposed the mechanostat theory. Reviewing the theoretical basis of this theory, Martin and Burr[24] proposed that (1) subthreshold loading of less than 200 $\mu\varepsilon$ results in disuse atrophy, manifested as a decrease in modeling and an increase in remodeling; (2) physiologic loading of about 200 to 2500 $\mu\varepsilon$ is associated with normal, steady-state activities; (3) loads exceeding the minimal effective strain (about 2500 $\mu\varepsilon$) result in a hypertrophic increase in modeling and a concomitant decrease in remodeling; and (4) after peak strains exceed about 4000 $\mu\varepsilon$, the structural integrity of bone is threatened, resulting in pathologic overload. Fig. 4.43 is a representation of the mechanostat. Many of the concepts and microstrain levels are based on experimental data.[24] The strain range for each given response probably varies between species and may be site specific in the same individual.[16,24,74,76,78] However, the mechanostat provides a useful clinical reference for the hierarchy of biomechanical responses to applied loads.

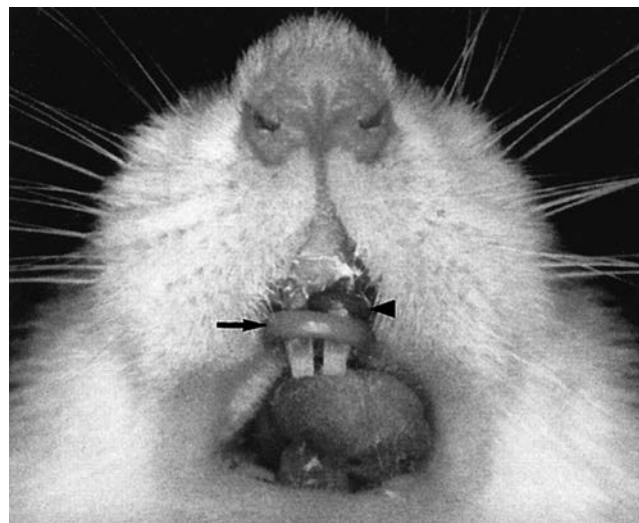
Normal function helps build and maintain bone mass. Suboptimally loaded bones atrophy as a result of increased remodeling frequency and inhibition of osteoblast formation.[80] Under these conditions, trabecular connections are lost and cortices are thinned from the endosteal surface. Eventually the skeleton is weakened until it cannot sustain normal function. Assuming that the negative calcium balance is corrected and adequate bone structure remains, patients with a history of osteoporosis or other metabolic bone disease are viable candidates for reconstructive dental procedures. The crucial factor is the residual bone mass in the area of interest after the disease process has been arrested (Fig. 4.44).

When flexure (strain) exceeds the normal physiologic range, bones compensate by adding new mineralized tissue at the periosteal surface. Adding bone is an essential compensating mechanism because of the inverse relationship between load (strain magnitude) and the fatigue resistance of bone.[81] When loads are less
• **Fig. 4.43** Mechanostat concept of Frost as defined by Martin and Burr. Bone formation *(F)* and resorption *(R)* are the modeling phenomena that change the shape and/or form of a bone. The peak strain history determines whether atrophy, maintenance, hypertrophy, or fatigue failure occurs. Note that the normal physiologic range of loading (maintenance *R = F*) is only at less than 10% of maximal bone strength (spontaneous fracture). Fatigue damage can accumulate rapidly at greater than 4000 $\mu\varepsilon$.



• **Fig. 4.44** Two postmenopausal females with systemic osteopenia present widely varying patterns of lower posterior bone loss. (A) Alveolar bone in the buccal segments is well preserved by functional loading of natural teeth. (B) Severe resorption of the alveolar process and basilar mandible has occurred in the absence of adequate functional loading. (From Roberts WE. Fundamental principles of bone physiology, metabolism and loading. In: Naert I, van Steenberghe D, Worthington P, eds. *Osseointegration in Oral Rehabilitation: an Introductory Textbook.* London: Quintessence; 1993.)

than 2000 με, lamellar bone can withstand millions of loading cycles, more than a lifetime of normal function. However, increasing the cyclic load to 5000 με (about 20% of the ultimate strength of cortical bone) can produce fatigue failure in 1000 cycles, which is achieved easily in only a few weeks of normal activity. Repetitive overload at less than one-fifth of the ultimate strength of lamellar bone (25,000 με, or 2.5% deformation) can lead to skeletal failure, stress fractures, and shin splints.

From a dental perspective, occlusal prematurities or parafunction may lead to compromise of periodontal bone support. Localized fatigue failure may be a factor in periodontal clefting, alveolar recession, tooth oblation (cervical ditching), or TMJ arthrosis. Guarding against occlusal prematurities and excessive tooth mobility, while achieving an optimal distribution of occlusal loads, are important objectives for orthodontic treatment. The human masticatory apparatus can achieve a biting strength of more than 2200 N, or more than 500 pounds of force.[82,83] Because of the high magnitude and frequency of oral loads, functional prematurities during reconstructive treatment could contribute to isolated incidences of alveolar clefting (Fig. 4.45A) and root resorption (see Fig. 4.45B). Excessive tooth mobility should be monitored carefully. Prevention of occlusal prematurities is a particular concern in treating periodontally compromised teeth.


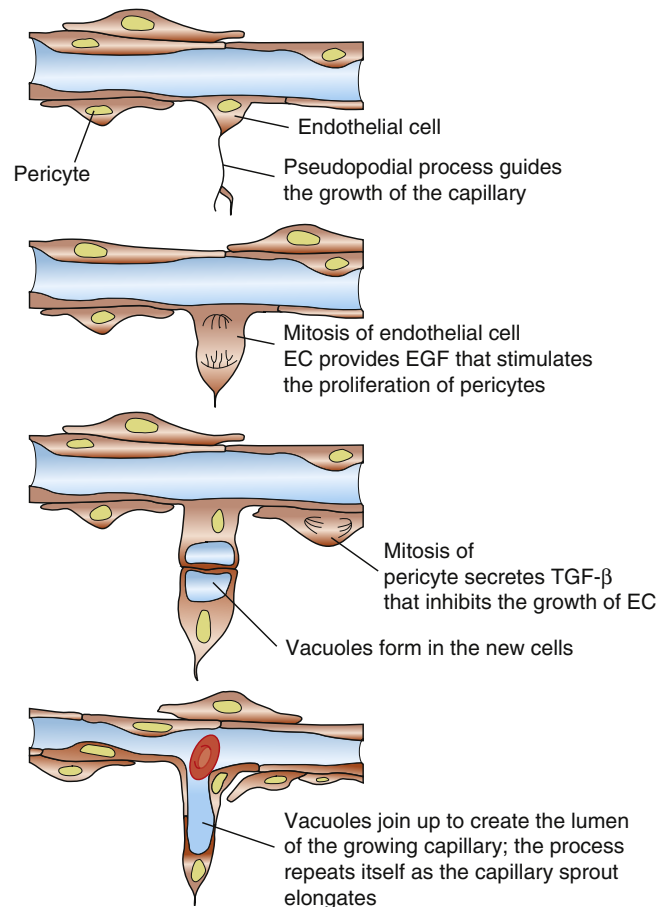
Sutures

The facial sutures are important mediators of skeletal adaptation to craniofacial growth and biomechanical therapy. Expansion of the midpalatal suture often is a key objective in dentofacial orthopedic treatment. Although the potential for sutural expansion has been appreciated since the middle of the 19th century, Haas[84] introduced the modern clinical concepts of rapid palatal expansion in the last half of the 20th century. Despite the long history of this important clinical procedure, little was known of the cell kinetics of osteogenesis and the bone remodeling response associated with it. Sutures and the PDL were widely assumed to have similar mechanisms of osseous adaptation.
Chang and colleagues[85,86] compared the osteogenic reaction in the expanded midpalatal suture with orthodontically induced osteogenesis in the PDL of adjacent incisors (Figs. 4.46–4.49). The widened PDL resulted in direct osteogenic induction of new bone, whereas the adjacent expanded suture experienced hemorrhage, necrosis, and a wound-healing response. Vascular invasion of the blood clot in the expanded suture was a prerequisite for new bone formation. Chang and colleagues[85] also defined the angiogenic capillary budding process associated with the propagation of perivascular osteogenic cells (Fig. 4.50). After its vascularity had been reestablished, the expanded midpalatal suture and adjacent widened PDL produced new osteoblasts by the same mechanism. Pericytes, the osteogenic cells that are perivascular to the venules (Fig. 4.51), are the cells of origin for preosteoblasts.[85,86] The role of perivascular cells in the origin of PDL osteoblasts first was reported in 1987.[87] Over the last decade a number of investigators have reported the same mechanism for the production of osteoblasts throughout the body. Doherty and colleagues[88] recently reviewed the literature and provided evidence that vascular pericytes express osteogenic potential in vivo and in vitro. What is now clear is that perivascular osteogenesis is not a mechanism unique to the PDL and sutures; rather, it is the source of osteoblasts all over the body under a variety of osteogenic conditions. Parr and colleagues[89] used an innovative endosseous implant mechanism (see Fig. 4.17) to expand the nasal bones in young adult rabbits with forces from 1 to 3 N. Injection of multiple fluorochrome bone labels documented the bone-modeling and remodeling

• **Fig. 4.45** (A) A moderate load in the buccal direction *(1)* results in tipping displacement of the crown. In the absence of vertical constraint, a normal healthy tooth would be expected to extrude slightly because of the inclined plane effect of the root engaging the tapered alveolus *(2)*. As a result of diminished bone support and destruction of restraining collagen fibers at the alveolar crest, a periodontally compromised tooth may tip and extrude considerably more. Depending on the occlusion, this displacement may cause an occlusal prematurity *(3)*. (B) Orthodontic tipping *(1)* with an extrusive component *(2)* may produce an occlusal prematurity *(3)* and mobility *(4)*. An individual tooth in chronic occlusal trauma is expected to fatigue the root apex continuously. This combination of physical failure in a catabolic environment may lead to progressive root resorption *(5)*.

• **Fig. 4.46** Expansion appliance placed on the maxillary incisors of a rat. A 1-mm-diameter elastomeric ring *(arrowhead)* was fitted into the left incisor; a 2-mm-diameter elastomeric ring *(arrow)* encircled both incisors, 2 mm from cutting edges. The 2-mm ring constricts the incisors, whereas the interproximal elastic elicits a parallel separation of the interpremaxillary suture. (From Chang HN, Garetto LP, et al. Angiogenesis and osteogenesis in an orthopedically expanded suture. *Am J Orthod Dentofacial Orthop.* 1997;3:382–390.)
• **Fig. 4.47** Forces (F) and moments (M) on a tooth. F1 and F2 were produced by inner and outer elastomeric rings, respectively. This illustration of the device demonstrates the formation of a couple that resulted in parallel separation of the interpremaxillary suture. As measured in a pilot study using a Dontrix tension gauge, the outer elastomeric ring exerted about 200 g of initial separation force (F2), of which 90 g remained at the end of day 3. This force level (90 g) is suitable for premaxillary expansion in rats. (From Chang HN, Garetto LP, Potter RH, et al. Angiogenesis and osteogenesis in an orthopedically expanded suture. *Am J Orthod Dentofacial Orthop.* 1997;3:382–390.)

• **Fig. 4.48** Dry skull, expanded as illustrated in Fig. 4.55, shows parallel separation of the interpremaxillary suture (arrow). (From Chang HN, Garetto LP, Potter RH, et al. Angiogenesis and osteogenesis in an orthopedically expanded suture. *Am J Orthod Dentofacial Orthop.* 1997;3:382–390.)



• **Fig. 4.49** Photomicrograph of a sagittal section of the interpremaxillary suture, showing the relationship of expanded suture (s), alveolar bone (b), and periodontal ligament (p). (Stained with hematoxylin and eosin; original magnification ×40.) (From Chang HN, Garetto LP, Potter RH, et al. Angiogenesis and osteogenesis in an orthopedically expanded suture. *Am J Orthod Dentofacial Orthop.* 1997;3:382–390.)

reactions that occurred not only adjacent to the suture but also throughout the nasal bones. Expansion of a suture results in a regional adaptation of adjacent bones similar to the postoperative regional acceleratory phenomenon that is characteristic of bone wound healing.[24] Parr and colleagues[89] described the bone formation rate and mineral apposition rate for new bone formed in the suture (Figs. 4.52–4.54). Sutural expansion, relative to load decay, is shown for repeatedly reactivated 1- to 3-N loads (Fig. 4.55). Osseointegrated implants were excellent abutments for sutural expansion mediated by loads as large as 3 N.

• **Fig. 4.51** Photomicrograph of autoradiography of an expanded interpremaxillary suture, showing blood vessel *(bv)* and paravascular cells. Note the relationship of pericyte *(solid arrow),* fibroblast-like cells *(arrowhead),* and mature osteoblast *(open arrow)* lining the suture-bone interface. (Stained with hematoxylin and eosin; original magnification ×400.) (From Chang HN, Garetto LP, Potter RH, et al. Angiogenesis and osteogenesis in an orthopedically expanded suture. *Am J Orthod Dentofacial Orthop.* 1997;3:382–390.)

• **Fig. 4.52** Expansion of the suture between the nasal bones of a rabbit (see Fig. 4.17A) is expressed as the mean difference of initial and final measurements between implants for the three loading groups (mean ± SEM, all groups significant at $p < 0.05$). (From Parr JA, Garetto LP, Wohlford ME, Arbuckle GR, Roberts WE. Sutural expansion using rigidly integrated endosseous implants: an experimental study in rabbits. *Angle Orthod.* 1978;67:283–290.)

Overall, expanded sutures are less efficient at initiating osteogenesis because of postactivation necrosis. However, after a wound-healing response has occurred to reestablish sutural vitality, the vascularly mediated origin of osteoblasts is the same as for the PDL and other skeletal sites. Expansion of a suture results in a regional acceleration of bone adaptive activity, which allows for extensive adaptation of the affected bones to new biomechanical conditions. These results indicate that sutural expansion within physiologic limits is a clinically viable means of repositioning the bones of the craniofacial complex to improve esthetics and function. With respect to fundamental bone physiology, sutural expansion is similar to surgically mediated distraction osteogenesis.

Using sequential labels of ^{3}H-thymidine and bromodeoxyuridine in rabbits, Sim[90] demonstrated that the osteoblast histogenesis sequence for evolving secondary osteons was a perivascular
• **Fig. 4.53** Volume percent of suture and bone for three loading groups (mean ± SEM); an asterisk *(*)* indicates significant difference in the percentage of sutural expansion from the control at $p < 0.05$; a dagger *(†)* indicates significant difference in the percentage of bone from the control at $p < 0.05$. process (Fig. 4.56) similar to that previously demonstrated for the PDL[91] and the intermaxillary suture.[85,86] The Sim data confirmed the hypothesis that the perivascular connective tissue cells proliferate and migrate along the surface of the invading capillaries or venules. Fig. 4.57 is a three-dimensional perspective of a remodeling foci (cutting/filling cone) in cortical bone, which

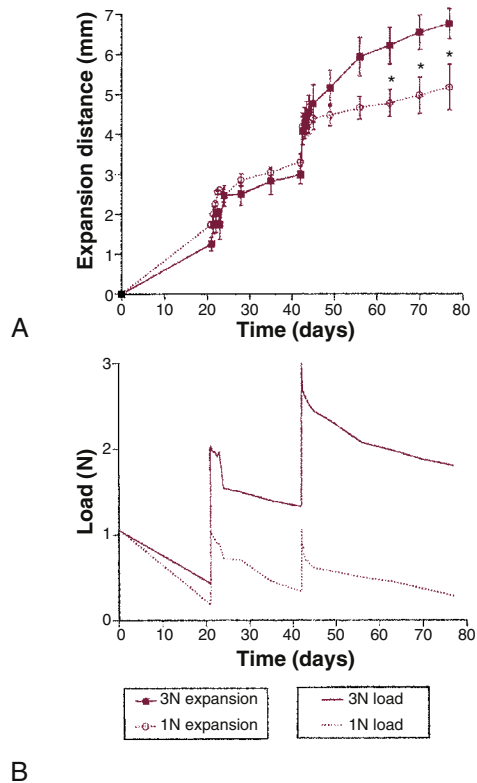
A

B


• **Fig. 4.55** (A) Sutural expansion measured as an increase in the distance between implants. The slope of this curve is the rate of sutural expansion; 3 N is significantly greater than 1 N at these time points $p < 0.05$. (B) Load on the suture as a function of time. Load was calculated using the formula $F = kx$, where k is the spring constant and x is the distance between implants. As sutural expansion occurs, force decays. Loads were placed at day 0 and adjusted at days 21 and 42. (From Parr JA, Garetto LP, Wohlford ME, Arbuckle GR, Roberts WE. Sutural expansion using rigidly integrated endosseous implants: an experimental study in rabbits. *Angle Orthod.* 1978;67:283–290.)

• **Fig. 4.56** Cutting/filling cone in rabbit cortical bone shows the intravascular origin of osteoclasts *(A).* The perivascular proliferation and migration away for the perivascular surface *(B)* is demonstrated by bromodeoxyuridine (BrdU) labeling and nuclear volume morphometry. A sequence of ^{3}H-thymidine labels from 2 to 72 hours before sacrifice and nuclear morphometric analysis revealed migration of proliferating perivascular cells in the direction of vascular invasion *(C).* These data demonstrate the perivascular origin of osteoblasts in evolving secondary osteons. (From Sim Y. *Cell Kinetics of Osteoblast Histogenesis in Evolving Rabbit Secondary Haversian Systems Using a Double Labeling Technique with ^{3}H-thymidine and Bromodeoxyuridine.* [doctoral thesis]. Indianapolis: Indiana University School of Dentistry; 1995.)

demonstrates that perivascular cells, near the head of the proliferating blood vessel, are the source of osteoblasts for the filling cone. Confirmation of a perivascular origin of osteoblasts in PDL,
• **Fig. 4.57** Evolving secondary osteon, moving to the right, shows a head of multinucleated osteoclasts (right), followed by a layer of mononuclear cells secreting cement substance *(blue)* to cover the scalloped resorption arrest line. The perivascular osteogenic cells proliferate and differentiate to osteoblasts, which form the new secondary osteon. Three sequential colored bone labels (*yellow, green,* and *orange*) allow the calculation of the velocity of the cutting/filling cone through cortical bone.

sutures, and cortical bone remodeling foci strongly suggests that all osteoblasts, at least in the peripheral skeleton, are derived from perivascular precursors. These data suggest that less differentiated osteogenic cells grow along the surface of bone-related blood vessels (capillaries and venules) as they invade blood clots or other connective tissue spaces in preparation for osteogenesis. From a clinical perspective, the perivascular origin of osteoblasts confirms an important surgical principle: preservation of the blood supply is essential for optimal healing of bone.

Implant-Anchored Orthodontics

A major problem in orthodontics and facial orthopedics is anchorage control.[30] Undesirable movement of the anchorage units is a common problem that limits the therapeutic range of biomechanics.[92] An important application of the basic principles of bone physiology is the use of rigid endosseous implants for orthodontic and orthopedic anchorage. Animal studies[25] and clinical trials of custom orthodontic devices[34] have established that rigidly integrated implants do not move in response to conventional orthodontic and orthopedic forces. These devices are opening new horizons in the management of asymmetry, mutilated dentition, severe malocclusion, and craniofacial deformity.[93]

A preclinical study in dogs tested the anchorage potential of two prosthetic-type titanium implants: (1) a prototype of an endosseous device with a cervical post, asymmetric threads, and an acid-etched surface and (2) a commercially available implant with symmetric threads (Fig. 4.58). Based on label incidence (Fig. 4.59A) and the relative number of new osteons in microradiographs (see Fig. 4.59B), the rate of bone remodeling near the implant was higher compared with the basilar mandible only a few millimeters away.[94] Compared with titanium implants with a smooth surface, the degree of remodeling at the interface is greater for threaded implants placed in a tapped bone preparation.[30] This may be related to the increased resistance of threaded implants to torsional loads over time.[95]

Direct bone apposition at the endosseous interface results in rigid fixation (osseointegration).[96] From an anchorage perspective, a rigid endosseous implant is the functional equivalent of an ankylosed tooth. Complete bony encapsulation is not necessary for an implant to serve as a rigid anchorage unit. The crucial feature is indefinite maintenance of rigidity despite continuous orthodontic loads. Over time, orthodontically loaded implants achieve
• **Fig. 4.58** (A) Two titanium implants of different design were placed in the partly edentulous mandible of young adult dogs. (B) After 2 months of unloaded healing, a 3-N compressive load was applied between the implants for 4 months. Increased periosteal apposition *(*)* was noted between the implants of some dogs. None of the rigidly integrated fixtures was loosened by the continuous load superimposed on function. (From Roberts WE, Helm FR, Marshall KJ, Gongloff RK. Rigid endosseous implants for orthodontic and orthopedic anchorage. *Angle Orthod.* 1989;59:247–256.)
• **Fig. 4.59** (A) Multiple fluorochrome labels in bone adjacent to an implant *(I)* show a high rate of remodeling at the bone-implant surface. (B) Microradiographic image of the same section shows direct bone contact on the surface of the implant. (From Roberts WE, Garotto LP, Katona TR. Principle of orthodontic biomechanics: metabolic and mechanical control mechanisms. In: Carlson DS, Goldstein SA, eds. *Bone Biodynamics in Orthodontic and Orthopedic Treatment.* Ann Arbor, MI: University of Michigan Press; 1992.)

a greater fraction of direct osseous interface.[34,95] From an orthodontic and orthopedic perspective, titanium implants can resist substantial continuous loads (1–3 N superimposed on function) indefinitely. Histologic analysis with multiple fluorochrome labels and microradiography confirm that rigidly integrated implants do not move relative to adjacent bone (see Fig. 4.59).[25] By definition, maintaining a fixed relationship with supporting bone is true osseous anchorage. Endosseous (osseointegrated) implants are well suited to many demanding orthodontic applications.[30,34]

Routine use of rigid implants for prosthetic or orthodontic applications requires that fixtures are placed between or near the roots of teeth. Inadvertent impingement on the PDL and the root of an adjacent tooth still may provide an acceptable result (Fig. 4.60). Cementum repair occurs where the root is cut, the PDL

● **Fig. 4.60** Endosseous implant inadvertently impinged on the root of a canine. The implant successfully integrated with bone and served as a rigid anchor for orthopedic loading. (From Roberts WE, Helm FR, Marshall KJ, Gongloff RK. Rigid endosseous implants for orthodontic and orthopedic anchorage. *Angle Orthod.* 1989;59:247–256.)
reorganizes, and the implant surface is integrated rigidly with osseous tissue. No evidence exists of ankylosis of the tooth.[25]

Retromolar Implant Anchorage

The isolated loss of a lower first molar with a retained third molar is a common problem. Rather than extract the third molar and replace the first molar with a three-unit bridge, mesial translation of second and third molars to close the edentulous spaces often is preferable (Fig. 4.61). The first case with long-term follow-up has been published.[34] Because of the increasing incidence of progressive bone loss and fatigue fracture associated with single-tooth implants in lower first and second molar areas, the orthodontic option for mesially translating the molars to close the space is increasing in popularity.

External Abutment Mechanism

An anchorage wire that is secured to a retromolar implant can be used to intrude and protract mandibular second and third molars to close an atrophic first molar extraction site (see Fig. 4.61B).[16] The tipping and extrusion of residual lower molars limits potential orthodontic repositioning. Rigid retromolar implants offer a unique capability for intrusion and alignment. Fig. 4.62 demonstrates the mechanics for achieving three-dimensional control to intrude the third molar to the plane of occlusion and translate

● **Fig. 4.61** (A) Mechanics of using a retromolar implant with an external abutment as anchorage to stabilize the premolar anterior to an extraction site. (B) Using buccal and lingual mechanics to balance the load and shield the periosteum in the extraction site, the atrophic extraction site is closed without periodontal compromise of any of the adjacent teeth. (From Roberts WE, Garotto LP, Katona TR. Principle of orthodontic biomechanics: metabolic and mechanical control mechanisms. In: Carlson DS, Goldstein SA, eds. *Bone Biodynamics in Orthodontic and Orthopedic Treatment.* Ann Arbor, MI: University of Michigan Press; 1992.)

● **Fig. 4.62** (A) The mechanics of intruding a third molar with implant anchorage before space closure. (B) Removable lingual arch prevents extrusion of the second molar. (C) Because the intrusive force on the third molar is buccal to the center of resistance, the tooth tends to tip buccally. This problem is controlled by placing lingual crown torque in the rectangular wire inserted in the tube. (From Roberts WE, Garotto LP, Katona TR. Principle of orthodontic biomechanics: metabolic and mechanical control mechanisms. In: Carlson DS, Goldstein SA, eds. *Bone Biodynamics in Orthodontic and Orthopedic Treatment.* Ann Arbor, MI: University of Michigan Press; 1992.)
• **Fig. 4.63** (A) Pretreatment, finish, and 3-year postretention cephalometric tracings document 10 to 12 mm of molar translation to close an atrophic first molar extraction site. (B) Mandibular superimposition shows the mesial movement of the second and third molars, as well as lingual root torque of the lower incisors. (From Roberts WE, Marshall KJ, Mozsary PG. Rigid endosseous implant utilized as anchorage to protract molars and close an atrophic extraction site. *Angle Orthod.* 1990;60:135–152.)

both teeth mesially. Cephalometric tracings (Fig. 4.63) document the more than 10 mm of mesial translation and its stability. Panoramic radiographs show the initial alignment (Fig. 4.64A) and the final space closure (see Fig. 4.64B). Clinical details are published.[34]

Histologic analysis of implants recovered after completion of treatment has revealed important information about the continuous remodeling process that maintains the rigid integration and anchorage value of the endosseous device. Two intravital bone labels, administered within 2 weeks of implant recovery, have shown a continuing high rate of bone remodeling (more than 500% per year) within 1 mm of the implant surface (see Fig. 4.64C–D). This biological mechanism apparently is the means by which rigid osseous integration is maintained indefinitely.[8,34] If no fracture is present at the implant interface or in its supporting bone, rigid implants are not moved by orthodontic loads.[6,25,34] Well-integrated endosseous implants remain rigid despite continued remodeling of the bone supporting them because only a portion of the osseous resorbed interface is turned over at any given time.[34] Fig. 4.65 shows the mechanics for mesial translation of molars to close an edentulous space when a premolar is congenitally missing. Rigid endosseous implants show great promise for considerably extending the therapeutic possibilities of orthodontics and dentofacial orthopedics.

Internal Abutment Mechanism

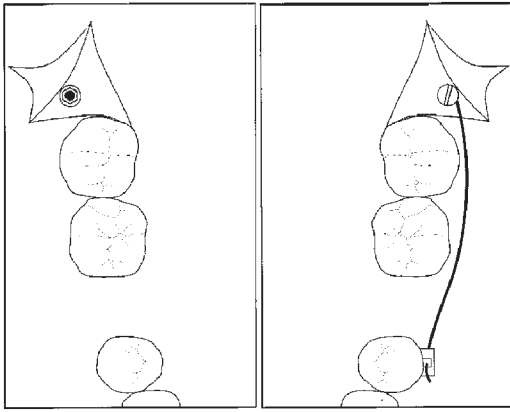
The 0.019 × 0.025-inch titanium-molybdenum alloy anchorage wire (Ormco Corporation, Orange, California) is secured to the endosseous implant when the implant is placed (Fig. 4.66). A 7 to 10 × 3.75-mm Brånemark implant (Nobel Biocare, Gothenburg, Sweden) is placed in the retromolar area 3 to 5 mm buccal and distal to the terminal molar. The end of the anchorage wire is bent into a circle and firmly attached to the implant with a standard healing cap (Figs. 4.67 and 4.68). This "internal abutment" approach offers a number of advantages over the original external abutment method as follows:

- Minimal surgery: no postoperative uncovering is required.
- Less expense: only one surgical procedure is needed, and no transmucosal abutment is required.
- Better hygiene: wire exiting in the depth of the buccal fold requires little or no periodontal maintenance.
- Immediate loading: no healing period is necessary.
- More versatile intrusive force: control of the intrusive load on the mandibular molars is easier.

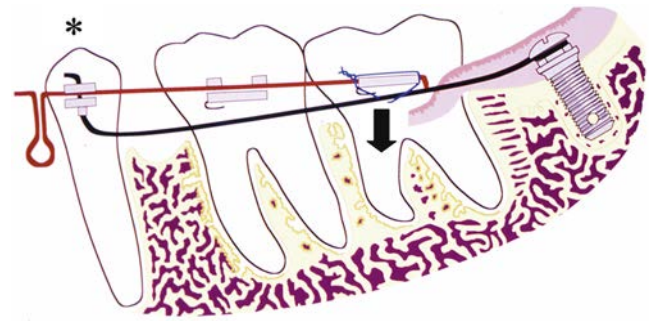
Nineteen years of experience with the internal abutment mechanism (Fig. 4.69) has established its utility as an implant anchorage mechanism for managing edentulous spaces in the mandibular buccal segments.[97-100]

Indirect anchorage with a retromolar implant is proving to be useful for closing missing second premolar spaces in growing children. However, an increased tendency for soft tissue irritation exists if the anchorage wire is positioned in the depth of the mucobuccal fold (Fig. 4.70A). When the wire is repositioned to just under the brackets of the molars (see Fig. 4.70B), soft tissue irritation ceased to be a problem and the second molar space was closed in about 10 months.

Mini-Implants for Orthodontic Anchorage

Kanomi[101] introduced a series of miniscrews as miniature implants for orthodontic anchorage. Although some of the
● **Fig. 4.64** (A) Panoramic radiograph of the initial buccal alignment before an implant is uncovered. (B) Panoramic radiograph of the closed extraction site. (C) Polarized light microscopy of lamellar bone *(L)* around the implant *(I)* recovered after completion of treatment. (D) Two demeclocycline labels *(*)* in bone adjacent to the implant *(I)* document the high rate of bone remodeling that apparently is the mechanism for long-term maintenance of rigid osseous fixation (osseointegration). (From Roberts WE, Marshall KJ, Mozsary PG. Rigid endosseous implant utilized as anchorage to protract molars and close an atrophic extraction site. *Angle Orthod.* 1990;60:135–152.)
● **Fig. 4.65** This 44-year-old female has a partly edentulous mandibular arch and a long history of temporomandibular dysfunction and pain. (A) A progress radiograph shows restoration of occlusion in the left mandibular buccal segment with implants. (B) The molars on the right side are being intruded and rotated mesially with the retromolar implant anchorage mechanism. (C) By the end of active treatment, the mandibular curve of Spee has flattened and ideal alignment of the residual dentition has been achieved. (From Epker BN, Stella JP, Fish LC: *Dentofacial Deformities: Integrated Orthodontic and Surgical Correction.* Vol. 4. 2nd ed. St Louis: Mosby; 1999.)


● **Fig. 4.66** Drawing on the left shows the soft tissue flap design for placing a retromolar anchorage implant distal to a mandibular right third molar. The drawing on the right illustrates the attachment of the 0.019 × 0.025-inch titanium-molybdenum alloy wire to the implant with a standard cover screw. Note that the free end of the passive anchorage wire is inserted into the vertical slot of a bracket bonded to the buccal surface of a mandibular left second premolar. (From Epker BN, Stella JP, Fish LC: *Dentofacial Deformities: Integrated Orthodontic and Surgical Correction.* Vol. 4. 2nd ed. St Louis: Mosby; 1999.)
● **Fig. 4.67** (A) Cross section of the mandible distal to the third molar shows that the retromolar implant is inclined buccally *(B)*. Using the shelf of bone on the lingua *(L)*, the 7- to 10-mm implant is oriented toward the inferior alveolar nerve *(1)* and away from the lingual nerve *(2)*. (Redrawn from Epker BN, Stella JP, Fish LC: *Dentofacial Deformities: Integrated Orthodontic and Surgical Correction.* Vol. 4. 2nd ed. St Louis: Mosby; 1999.)

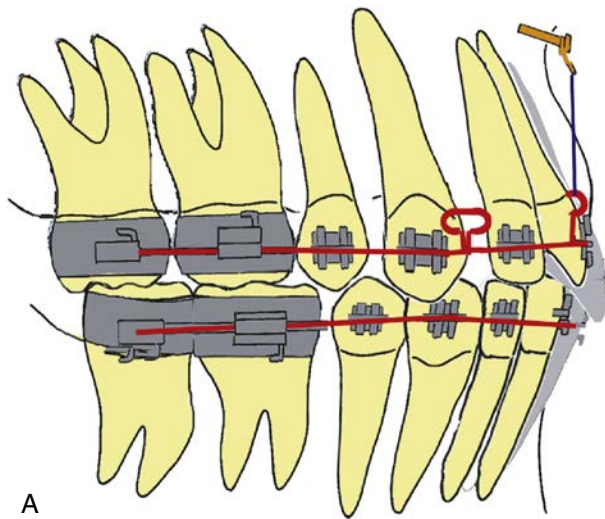
nonintegrated titanium screws served as adequate anchorage units, some loosened and failed during treatment. A new series of osseointegrated mini-implants was developed and tested in animals.[43] Deguchi and colleagues[102] found that 97% of 96 implants placed in eight dogs successfully integrated, and 100% of the implants that achieved osseointegration were successful as anchorage units. Clinical use of these simple devices has produced some impressive results. Fig. 4.71 documents the treatment of a 15-year-old girl with a gummy smile and bimaxillary protrusion. Four first premolars were extracted and the maxillary


● **Fig. 4.68** Schematic drawing of the implant anchorage mechanism shows an internal abutment (i.e., the titanium-molybdenum alloy anchorage wire) attached to the endosseous base with the cover screw (healing cap). The anchorage wire passes through the mucosa in the depth of the buccal fold on the buccal aspect of the terminal molar. Extrusion of the molars during axial alignment and space closure is controlled by the intrusive force *(arrow)* generated by ligating the molar bracket to the anchorage wire with a steel ligature. Sagittal anchorage for mesial movement of the molars is achieved by inserting the passive anchorage wire into the vertical tube of a bracket anterior to the extraction site *(*)*. To achieve unidirectional space closure, the "keyhole" vertical loop is activated by pulling the arch wire at the distal of the terminal molar and bending it down. (Redrawn from Epker BN, Stella JP, Fish LC: *Dentofacial Deformities: Integrated Orthodontic and Surgical Correction.* Vol. 4. 2nd ed. St Louis: Mosby; 1999.)

anterior segment was intruded with mini-implant anchorage (see Fig. 4.71A–B). Comparison of frontal smile photographs pretreatment (see Fig. 4.71C) and posttreatment (see Fig. 4.71D) demonstrate the effective anchorage of the mini-implants. Fig. 4.71E is a cephalometric superimposition that demonstrates intrusion of the maxillary anterior segment and a horizontal vector of mandibular growth. Clearly, miniscrews are effective osseous anchorage for some types of malocclusion.

Summary

Bone physiologic, metabolic, and cell kinetic concepts have important clinical applications in all phases of stomatognathic reconstruction: implant surgery, orthodontics, prosthodontics, and long-term functional loading. The application of fundamental concepts is limited only by the knowledge and imagination of the clinician. Modern clinical practice is characterized by a continual evolution of methods based on fundamental and applied research.

Acknowledgments
• **Fig. 4.69** (A) Mock-up demonstrates retromolar implant anchorage. Orthodontic mechanics are designed to align mandibular second and third molars and close the edentulous spaces by translating the molars mesially. The left retromolar implant shows the relationship of the fixture to supporting bone (surgical view). The right implant is covered with wax to simulate the closure of soft tissue over the implant with the titanium-molybdenum alloy anchorage wire attached. (B) Mechanics are shown for mesial root movement of the second molar into the first molar extraction site. Note that the mesial arm on the root spring is immediately adjacent to the first premolar bracket to prevent the second molar from moving distally as it is positioned upright. To prevent space from opening mesial to the first premolar, a steel ligature ("rope tie") connects the first premolar to the canine. A steel ligature connecting the bracket of the second molar to the titanium-molybdenum alloy anchorage wire controls molar extrusion. (C) Similar mechanics as shown in (B) are used for simultaneous alignment of both molars. A rectangular arch wire segment connects the two molars. Extrusion is controlled by tying the second molar to the anchorage wire with a steel ligature.
• **Fig. 4.70** (A) Postoperative panoramic radiograph reveals a retromolar implant to be used for indirect anchorage to close the space caused by a missing second premolar in an 11-year-old girl. Note that the anchorage wire is positioned too far apically. (B) A panoramic radiograph shows the rapid space closure associated with mesial movement of the molars. Note the anchorage wire has been repositioned just under the molar brackets to lessen soft tissue irritation.


• **Fig. 4.71** (A) Drawing of space closure mechanics demonstrates the use of a mini-implant apical to the central incisors to intrude the maxillary anterior segment. (B) An occlusal radiograph shows the two miniscrews apical to the maxillary incisors. (C) Pretreatment photograph of a 15-year-old girl reveals a gummy smile. (D) Posttreatment photograph shows a pleasant smile line with ideal gingival exposure. (E) Pretreatment *(black)* and posttreatment *(red)* tracings of cephalometric radiographs are superimposed on the anterior cranial base. Note the intrusion of the maxillary anterior incisors and the horizontal component to mandibular growth. (Courtesy Ryuzo Kanomi.)

Biomaterials for Dental Implants

**JACK E. LEMONS, FRANCINE MISCH-DIETSH, AND
RANDOLPH R. RESNIK**

Compatibility of Surgical Biomaterials and the Role of Synthetic Materials

The biocompatibility profiles of synthetic substances (biomaterials) used for the replacement or augmentation of biological tissues have always been a critical concern within the health care disciplines. Special circumstances are associated with dental implant prosthetic reconstruction of the oral-maxillofacial areas because the devices extend from the mouth, across the protective epithelial zones, and onto or into the underlying bone. The functional aspects of use also include the transfer of force from the occlusal surfaces of the teeth through the crown and bridge and neck-connector region of the implant into the implant for interfacial transfer to the supporting soft and hard tissues. This situation represents a complex series of chemical and mechanical environmental conditions.

This most critical aspect of biocompatibility is, of course, dependent on the basic bulk and surface properties of the biomaterial. All aspects of basic manufacturing, finishing, packaging and delivering, sterilizing, and placing (including surgical placement) must be adequately controlled to ensure clean and nontraumatizing conditions. The importance of these considerations has been reemphasized through the concept and practice of osteointegration of endosteal root form implant systems.

The disciplines of biomaterials and biomechanics are complementary to the understanding of device-based function. The physical, mechanical, chemical, and electrical properties of the basic material components must always be fully evaluated for any biomaterial application, because these properties provide key inputs into the interrelated biomechanical and biological analyses of function. It is important to separate the roles of macroscopic implant shape from the microscopic transfer of stress and strain along biomaterial–tissue interfaces. The macroscopic distribution of mechanical stress and strain is predominantly controlled by the shape and form of the implant device. One important material property related to design (shape and form) optimization is the elastic strain (one component of the elastic modulus) of the material.

The localized microscopic strain distribution is controlled more by the basic properties of the biomaterial (e.g., surface chemistry, microtopography, modulus of elasticity) and by whether the biomaterial surface is attached to the adjacent tissues. Engineering analyses of implant systems include optimization considerations related both to the design and to the biomaterial used for construction. Therefore the desire to positively influence tissue responses and to minimize biodegradation often places restrictions on which materials can be used safely within the oral and tissue environments. Designs are often evolved for specific biomaterials because of the imposed environmental or restorative conditions.

Bulk Properties

History of Materials and Designs

Over the past several decades, definitions of material biocompatibilities have evolved and reflect an ever-changing opinion related to philosophies of surgical implant treatment. In general the definition of biocompatibility has been given as an appropriate response to a material (biomaterial) within a device (design) for a specific clinical application.[1] Metallic and nonmetallic implantable materials have been studied in the field of orthopedics since the turn of the twentieth century.[2-7]

In the 1960s emphasis was placed on making the biomaterials more inert and chemically stable within biological environments. The high-purity ceramics of aluminum oxide (Al_2O_3), carbon, and carbon-silicon compounds and extra-low interstitial–grade alloys are classic examples of these trends. In the 1970s biocompatibility was defined in terms of minimal harm to the host or to the biomaterial. The importance of a stable interaction then moved into central focus for both the research and the clinical communities. In the 1980s the focus transferred to bioactive substrates intended to positively influence tissue responses, whereas most recently emphasis on chemically and mechanically anisotropic substrates combined with growth (mitogenic) and inductive (morphogenic) substances. Today many biomaterials are being constituted, fabricated, and surface modified to directly influence short- and long-term tissue responses. Bioactive coatings on most classes of biomaterials have continued to evolve from human clinical trials to acceptable modalities of surface preparation, and research focus has shifted to combinations of active synthetic and biological implants.

Of interest, dental implants have significantly influenced these trends. In the 1960s dental devices were recognized as being in a

research and development phase, and critical longitudinal reviews of clinical applications were strongly recommended.[8] During this time, longevity studies of various devices demonstrated that the longest duration of clinical applications were for orthopedic prostheses. In the 1980s controlled clinical trials showed that dental implants provided functional longevities that exceeded most other types of functional tissue replacement modalities.[9,10] Clearly, these clinical studies have strongly influenced both the research and development and the clinical application processes. Presently the exponential growth of implant use and related scientific reports support the views expressed by early visionaries several decades ago.

The evolution of any implant modality is a multipart story in which significant roles have been played by biomaterials; biomechanical analyses of designs, tissues, and function; wound healing along interfaces; surgical methods to minimize mechanical, chemical, and thermal trauma; prosthodontic and periodontal restorative and maintenance treatment modalities; and protocols for controlled multidisciplinary clinical trials. The interdependence of all phases of basic and applied research should be recognized. All interrelate and must evolve to provide a level of better understanding of the basic physical and biological phenomena associated with the implant systems before the longer clinical outcomes will be fully described.

Evaluations of endosteal and subperiosteal dental implants raise interesting questions with respect to the interrelationships between material and design selection. Opportunities exist to select a material from a number of systems, such as metals, ceramics, carbons, polymers, or composites. In addition, only the available anatomic dimensions and the requirement to attach some form of intraoral restorative device limit implant shape and form (design). Because of the wide range of biomaterial properties demonstrated by the classes of materials available, it is not advisable to fabricate any new implant design without a thorough biomechanical analysis. Another approach now often used is to determine a specific design based on clinical considerations and then to select the biomaterial of choice from computer-based analyses. The safety of these combinations can then be demonstrated through laboratory and animal investigations. Controlled clinical trials following prospective protocols, of course, provide the final evaluation for both safety and effectiveness. Long-term success is thus determined clinically in investigator follow-up studies and is clearly an area that should be emphasized for many available dental implant systems.

Research and Development

Basic studies within the physical and biological sciences have been supportive of the development of surgical implant systems. One example is the continued progress from materials that have been available for industrial applications to the new classes of composites that have evolved for biomedical applications. This same situation exists within a broad area; for example, surface science and technology, mechanics and biomechanics of three-dimensional structures, pathways and processes of wound healing along biomaterial interfaces, and the description of the first biofilms that evolve on contact with blood or tissue fluids.[11-14] The progressive move from materials to quantitatively characterized biomaterials has been extremely important to the biomedical applications of surgical implants. Dental implant investigations now play a leadership role within selected areas of this overall process, and all phases of medicine and dentistry should benefit.

Physical, Mechanical, and Chemical Requirements for Implant Materials

Physical and Mechanical Properties

Forces exerted on the implant material consist of tensile, compressive, and shear components. As for most materials, compressive strengths of implant materials are usually greater than their shear and tensile counterparts. A hypothesis that dental implants are less affected by alternating stresses than implants of the cardiovascular and locomotor systems because of the significantly lower number of loading cycles must be qualified because of the special concern that dental implants are considerably smaller in physical dimension. All fatigue failures obey mechanical laws correlating the dimensions of the material to the mechanical properties of said material.[11,15] In addition, when present, parafunction (nocturnal and/or diurnal) can be greatly detrimental to longevity because of the mechanical properties, such as maximum yield strength, fatigue strength, creep deformability, ductility, and fracture. Limitations of the relevance of these properties are mainly caused by the variable shape and surface features of implant designs. A recurring problem exists between the mechanical strength and deformability of the material and the recipient bone. A different approach to match more closely the implanted material and hard tissue properties led to the experimentation of polymeric, carbonitic, and metallic materials of low modulus of elasticity.[16,17]

Because bone can modify its structure in response to forces exerted on it, implant materials and designs must be designed to account for the increased performance of the musculature and bone in jaws restored with implants. The upper stress limit decreases, with an increasing number of loading cycles sometimes reaching the fatigue limit after 10^6 to 10^7 loading cycles.[11,15,18] In other words, the higher the applied load, the higher the mechanical stress—and therefore the greater the possibility for exceeding the fatigue endurance limit of the material.

In general the fatigue limit of metallic implant materials reaches approximately 50% of their ultimate tensile strength.[11,18] However, this relationship is applicable only to metallic systems, and polymeric systems have no lower limit in terms of endurance fatigue strength. Ceramic materials are weak under shear forces because of the combination of fracture strength and no ductility, which can lead to brittle fracture. Metals can be heated for varying periods to influence properties, modified by the addition of alloying elements or altered by mechanical processing such as drawing, swagging, or forging, followed by age or dispersion hardening, until the strength and ductility of the processed material are optimized for the intended application.

The modifying elements in metallic systems may be metals or nonmetals. A general rule is that constitution or mechanical process hardening procedures result in an increased strength but also invariably correspond to a loss of ductility. This is especially relevant for dental implants. Consensus standards for metals (ASTM International [formerly American Society for Testing and Materials], International Standardization Organization [ISO], American Dental Association) require a minimum of 8% ductility to minimize brittle fractures. Mixed microstructural-phase hardening of austenitic materials with nitrogen (e.g., stainless steels) and the increasing purity of the alloys seem most indicated to achieve maximum strength and maintain this high level of possible plastic deformation.[1,15,19-23]

Corrosion and Biodegradation

Corrosion is a special concern for metallic materials in dental implantology, because implants protrude into the oral cavity, where electrolyte and oxygen compositions differ from that of tissue fluids. In addition, the pH can vary significantly in areas below plaque and within the oral cavity. This increases the range of pH that implants are exposed to in the oral cavity compared with specific sites in tissue.[24-29]

Plenk and Zitter[15] state that galvanic corrosion (GC) could be greater for dental implants than for orthopedic implants. Galvanic processes depend on the passivity of oxide layers, which are characterized by a minimal dissolution rate and high regenerative power for metals such as titanium. The passive layer is only a few nanometers thick and is usually composed of oxides or hydroxides of the metallic elements that have greatest affinity for oxygen. In reactive group metals such as titanium, niobium, zirconium, tantalum, and related alloys, the base materials determine the properties of the passive layer. The stability zones of the oxides of passivable elements cover the redox potentials and pH values typical of the oral environment. However, titanium, tantalum, and niobium oxides cover a markedly larger zone of environmental stability compared with chromium oxides.

The risk for mechanical degradation, such as scratching or fretting of implanted materials, combined with corrosion and release into bone and remote organs has been previously considered. For example, investigators such as Laing,[30] Willert et al.,[31] and Lemons[32,33] have studied extensively the corrosion of metallic implants. Steinemann[34] and Fontana and Greene[35] have presented many of the basic relationships specific to implant corrosion. Mears[26] addressed concerns about GC and studied the local tissue response to stainless steel and cobalt-chromium-molybdenum (Co-Cr-Mo), and showed the release of metal ions in the tissues. Williams[36] suggested that three types of corrosion were most relevant to dental implants: (1) stress corrosion cracking (SCC), (2) GC, and (3) fretting corrosion (FC).

Stress Corrosion Cracking

The combination of high magnitudes of applied mechanical stress plus simultaneous exposure to a corrosive environment can result in the failure of metallic materials by cracking, where neither condition alone would cause the failure. Williams[36] presented this phenomenon of SCC in multicomponent orthopedic implants. Others hypothesized that it may be responsible for some implant failures in view of high concentrations of forces in the area of the abutment–implant body interface.[37-39] Most traditional implant body designs under three-dimensional finite-element stress analysis show a concentration of stresses at the crest of the bone support and cervical third of the implant. This tends to support potential SCC at the implant interface area (i.e., a transition zone for altered chemical and mechanical environmental conditions). This has also been described in terms of corrosion fatigue (i.e., cyclical load cycle failures accelerated by locally aggressive medium). In addition, nonpassive prosthetic superstructures may incorporate permanent stress, which strongly influences this phenomenon under loaded prostheses (Fig. 5.1A and 5.1B).[37,40,41]

GC occurs when two dissimilar metallic materials are in contact and are within an electrolyte, resulting in current flowing between the two. The metallic materials with the dissimilar potentials can have their corrosion currents altered, thereby resulting in a greater corrosion rate (Fig. 5.1C). FC occurs when a micromotion and rubbing contact occur within a corrosive environment (e.g., the perforation of the passive layers and shear-directed loading along adjacent contacting surfaces). The loss of any protective film can result in the acceleration of metallic ion loss. FC has been shown to occur along implant body–abutment–superstructure interfaces.

Normally the passive oxide layers on metallic substrates dissolve at such slower rates that the resultant loss of mass is of no mechanical consequence to the implant. A more critical problem is the irreversible local perforation of the passive layer that chloride ions often cause, which may result in localized pitting corrosion. Such perforations can often be observed for iron-chromium-nickel-molybdenum (Fe-Cr-Ni-Mo) steels that contain an insufficient amount of the alloying elements stabilizing the passive layer (i.e., Cr and Mo) or local regions of implants that are subjected to abnormal environments. Even ceramic oxide materials are not fully degradation resistant. Corrosion-like behavior of ceramic materials can then be compared with the chemical dissolution of the oxides into ions or complex ions of respective metallic oxide substrates. An example of this is the solubility of Al_2O_3 as alumina or titanium oxide as titanium. This statement is generally valid; however, most metallic oxides and nonmetallic substrates have amorphous hydroxide-inclusive structures, whereas bulk ceramics are mostly crystalline. The corrosion resistance of synthetic polymers, in contrast, depends not only on their composition and structural form but also on the degree of polymerization. Unlike metallic and ceramic materials, synthetic polymers are not only dissolved but also penetrated by water and substances from biological environments. The resulting degree of alteration depends on the material property conditions for the manufactured component.

Toxicity and Consideration

Toxicity is related to primary biodegradation products (simple and complex cations and anions), particularly those of higher atomic weight metals. Factors to be considered include: (1) the amount dissolved by biodegradation per time unit, (2) the amount of material removed by metabolic activity in the same time unit, and (3) the quantities of solid particles and ions deposited in the tissue and any associated transfers to the systemic system. For example, the quantity of elements released from metals during corrosion time (e.g., grams per day) can be calculated by using the following formula[15]:

$$\text{TE}\left(\frac{g}{\text{day}}\right) = \frac{\text{TEA}\,(\%) \times \text{CBR}\,(g/cm^2 \times \text{day}) \times \text{IS}\,(cm^2)}{100}$$

where TE = toxic element; TEA = toxic elements in alloy; CBR = corrosion biodegradation; and IS = implant surface.

It is of little importance for the formula whether the metallic substrate is exposed because the passive layer is dissolved. The critical issue is that the surface represents the "finished" form of the implant. The formula is also valid for ceramic materials and for substances transferred from synthetic polymers. Therefore it appears that the toxicity is related to the content of the materials' toxic elements and that they may have a modifying effect on corrosion rate.[15]

The transformation of harmful primary products is dependent on their level of solubility and transfer. It is known that chromium and titanium ions react locally at low concentrations, whereas cobalt, molybdenum, or nickle can remain dissolved at higher relative concentrations, and thus may be transported
Fig. 5.1 (A) Stainless-steel (316L) fracture fixation screw showing crevice corrosion after 1 year in vivo (approximately ×5). (C) As-polished microstructure of cobalt alloy subperiosteal showing porosity associated with galvanically assisted corrosion (approximately ×100).

and circulated in body fluids. Several studies have documented the relative toxicity of titanium and its various alloys. Lemons[32] reported on the formation of electrochemical couples as a result of oral implant and restorative procedures, and stressed the importance of selecting compatible metals to be placed in direct contact with one another in the oral cavity to avoid the formation of adverse electrochemical couples. The electrochemical behavior of implanted materials has been instrumental in assessing their biocompatibility.[42] Zitter and Plenk[43] have shown that anodic oxidation and cathodic reduction take place in different spaces but must always balance each other through charge transfer. This has been shown to impair both cell growth and transmission of stimuli from one cell to another. Therefore an anodic corrosion site can be influenced by ion transfer but also by other possibly detrimental oxidation phenomena. Charge transfer appears to be a significant factor specific to the biocompatibility of metallic biomaterials. Passive layers along the surfaces of titanium, niobium, zirconium, and tantalum increase resistance to change-transfer processes by isolating the substrate from the electrolyte, in addition to providing a higher resistance to ion transfers. In contrast, metals based on iron, nickel, or cobalt are not as resistant to transfers through the oxide-like passive surface zones.

Metals and Alloys

To date, most of the dental implant systems available within the United States are constructed from metals or alloys. These materials are reviewed in this chapter by separating the metals and alloys according to their elemental compositions, because a growing proportion have modified surface characteristics.

Several organizations have provided guidelines for the standardization of implant materials.[44] ASTM Committee F4 (ASTM F4) and ISO (ISOTC 106, ISOTR 10541) have provided the basis for such standards.[19,20] To date a multinational survey by ISO indicated that titanium and its alloy are mainly used. The most widely used nonmetallic implants are oxidic, carbonitic, or graphitic oxide-like materials.[45] The major groups of implantable materials for dentistry are titanium and alloys, cobalt chromium alloys, austenitic Fe-Cr-Ni-Mo steels, tantalum, niobium and zirconium alloys, precious metals, ceramics, and polymeric materials.

TABLE 5.1   Engineering Properties of Metals and Alloys Used for Surgical Implants

Material	Nominal Analysis (w/o)	Modulus of Elasticity GN/m^2 (psi × 10^6)	Ultimate Tensile Strength MN/m^2 (ksi)	Elongation to Fracture (%)	Surface
Titanium	99$^+$Ti	97 (14)	240–550 (25–70)	>15	Ti oxide
Titanium-aluminum-vanadium	90Ti-6Al-4V	117 (17)	869–896 (125–130)	>12	Ti oxide
Cobalt-chromium-molybdenum (casting)	66Co-27Cr-7Mo	235 (34)	655 (95)	>8	Cr oxide
Stainless steel (316L)	70Fe-18Cr-12Ni	193 (28)	480–1000 (70–145)	>30	Cr oxide
Zirconium	99$^+$Zr	97 (14)	552 (80)	20	Zr oxide
Tantalum	99$^+$Ta	—	690 (100)	11	Ta oxide
Gold	99$^+$Au	97 (14)	207–310 (30–45)	>30	Au
Platinum	99$^+$Pt	166 (24)	131 (19)	40	Pt

Minimum values from the American Society for Testing and Materials Committee F4 documents are provided. Selected products provide a range of properties.

Titanium and Titanium-6 Aluminum-4 Vanadium

This reactive group of metals and alloys (with primary elements from reactive group metallic substances) form tenacious oxides in air or oxygenated solutions. Titanium oxidizes (passivates) on contact with room-temperature air and normal tissue fluids. This reactivity is favorable for dental implant devices. In the absence of interfacial motion or adverse environmental conditions, this passivated (oxidized) surface condition minimizes biocorrosion phenomena. In situations in which the implant would be placed within a closely fitting receptor site in bone, areas scratched or abraded during placement would repassivate in vivo. This characteristic is one important property consideration related to the use of titanium for dental implants.[37,46-48] Some reports show that the oxide layer tends to increase in thickness under corrosion testing[48] and that breakdown of this layer is unlikely in aerated solutions.[49]

Bothe et al.[50] studied the reaction of rabbit bone to 54 different implanted metals and alloys, and showed that titanium allowed bone growth directly adjacent to the oxide surfaces. Leventhal[51] further studied the application of titanium for implantation. Beder and Eade,[52] Gross and Gold,[53] Clarke and Hickman,[54] and Brettle[55] were able to expand indications of these materials. In all cases, titanium was selected as the material of choice because of its inert and biocompatible nature paired with excellent resistance to corrosion.[1,56-60]

Specific studies in the literature have addressed the corrosion of titanium implants. Unfortunately most are for in vitro and unloaded conditions, and few identify precisely the type of titanium and titanium surface studied.

The general engineering properties of the metals and alloys used for dental implants are summarized in Table 5.1. Titanium shows a relatively low modulus of elasticity and tensile strength compared with most other alloys. The strength values for the wrought soft and ductile metallurgic condition (normal root forms and plate form implants) are approximately 1.5 times greater than the strength of compact bone. In most designs in which the bulk dimensions and shapes are simple, strength of this magnitude is adequate. Because fatigue strengths are normally 50% weaker or less than the corresponding tensile strengths, implant design criteria are decidedly important. The creation of sharp corners or thin sections must be avoided for regions loaded under tension or shear conditions. The modulus of elasticity of titanium is five times greater than that of compact bone, and this property places emphasis on the importance of design in the proper distribution of mechanical stress transfer. In this regard, surface areas that are loaded in compression have been maximized for some of the newer implant designs. Four grades of unalloyed titanium and titanium alloy are the most popular. Their ultimate strength and endurance limit vary as a function of their composition.

The alloy of titanium most often used is titanium-aluminum-vanadium. The wrought alloy condition is approximately six times stronger than compact bone and thereby affords more opportunities for designs with thinner sections (e.g., plateaus, thin interconnecting regions, implant-to-abutment connection screw housing, irregular scaffolds, porosities). The modulus of elasticity of the alloy is slightly greater than that of titanium, being about 5.6 times that of compact bone. The alloy and the primary element (i.e., titanium) both have titanium oxide (passivated) surfaces. Information has been developed on the oxide thickness, purity, and stability as related to implant biocompatibilities.[9,14,19] In general, titanium and alloys of titanium have demonstrated interfaces described as *osteointegrated* for implants in humans. In addition, surface conditions in which the oxide thickness has varied from hundreds of angstroms of amorphous oxide surface films to 100% titania (titanium dioxide [TiO_2] rutile form ceramic) have demonstrated osteointegration.

The possible influences of aluminum and vanadium biodegradation products on local and systemic tissue responses have been reviewed from the perspectives of basic science and clinical applications.[61] Extensive literature has been published on the corrosion rate of titanium within local tissue fluids[62-64] and the peri-implant accumulation of "black particles."[65] A few adverse effects have been reported.[66] Increased titanium concentrations were found in both peri-implant tissues and parenchymal organs,[67,68] mainly the lung, and much lesser concentrations in the liver, kidney, and

spleen.[25,66-70] However, alloy compositions were not well defined or controlled. Corrosion and mechanical wear have been suggested as possible causes.[48,67,68] Authors who still caution about the applicability of these results to the presently available titanium alloys have developed other alloys using iron, molybdenum, and other elements as primary alloying agents.[17] More recently, several new titanium alloys of higher strength have been introduced.[33,71]

Although many basic science questions remain, clinical applications of these alloys in dental and orthopedic surgical systems have been very positive, especially in light of improved strength, and the titanium alloys have not demonstrated significant numbers of identifiable negative sequelae.[19] Electrochemical studies support the selection of conditions in which elemental concentrations would be relatively low in magnitude.[11] Electrochemically, titanium and titanium alloy are slightly different in regard to electromotive and galvanic potentials compared with other electrically conductive dental materials. Results of these electrochemical potentials and how they relate to in vivo responses have been published previously.[9,42,63] In general, titanium- and cobalt-based systems are electrochemically similar; however, comparative elements imitating the conditions in an aeration cell revealed that the current flow in titanium and titanium alloys is several orders of magnitude lower than that in Fe-Cr-Ni-Mo steels or Co-Cr alloys.[15] Gold-, platinum-, and palladium-based systems have been shown to be noble, and nickel-, iron-, copper-, and silver-based systems are significantly different (subject to galvanic coupling and preferential in vivo corrosion).

Mechanically, titanium is much more ductile (bendable) than titanium alloy. This feature has been a favorable aspect related to the use of titanium for endosteal plate form devices. The need for adjustment or bending to provide parallel abutments for prosthetic treatments has caused manufacturers to optimize microstructures and residual strain conditions. Coining, stamping, or forging followed by controlled annealing heat treatments are routinely used during metallurgic processing. However, if an implant abutment is bent at the time of implantation, then the metal is strained locally at the neck region (bent), and the local strain is both cumulative and dependent on the total amount of deformation introduced during the procedure. This is one reason, other than prior loading fatigue cycling, why reuse of implants is not recommended. In addition, mechanical processes can sometimes significantly alter or contaminate implant surfaces. Any residues of surface changes must be removed before implantation to ensure mechanically and chemically clean conditions.

The emerging techniques to cast titanium and titanium alloys remain limited for dental implant application because of high melting points of the elements and propensity for absorption of oxygen, nitrogen, and hydrogen, which may cause metallic embrittlement. A high vacuum or ultrapure protective gas atmosphere allows the production of castings in titanium and its alloys at different purity levels,[72,73] although microstructures and porosity are relatively unfavorable related to fatigue and fracture strengths.[9,32] Typical strengths of cast commercially pure titanium grade 2 and titanium-6 aluminum-4 vanadium (Ti-6Al-4V) after heat treatment and annealing can be in the range of those of wrought titanium alloys used for dental implants.[74]

Cobalt-Chromium-Molybdenum–Based Alloy

The cobalt-based alloys are most often used in an as-cast or cast-and-annealed metallurgic condition. This permits the fabrication of implants as custom designs such as subperiosteal frames. The elemental composition of this alloy includes cobalt, chromium, and molybdenum as the major elements. Cobalt provides the continuous phase for basic properties; secondary phases based on cobalt, chromium, molybdenum, nickel, and carbon provide strength (four times that of compact bone) and surface abrasion resistance (see Table 5.1); chromium provides corrosion resistance through the oxide surface; and molybdenum provides strength and bulk corrosion resistance. All of these elements are critical, as is their concentration, which emphasizes the importance of controlled casting and fabrication technologies. Also included in this alloy are minor concentrations of nickel, manganese, and carbon. Nickel has been identified in biocorrosion products, and carbon must be precisely controlled to maintain mechanical properties such as ductility. Surgical alloys of cobalt are not the same as those used for partial dentures, and substitutions should be avoided.

In general the as-cast cobalt alloys are the least ductile of the alloy systems used for dental surgical implants, and bending of finished implants should be avoided. Because many of these alloy devices have been fabricated by dental laboratories, all aspects of quality control and analysis for surgical implants must be followed during alloy selection, casting, and finishing. Critical considerations include the chemical analysis, mechanical properties, and surface finish as specified by the ASTM F4 on surgical implants and the American Dental Association.[19,21] When properly fabricated, implants from this alloy group have shown to exhibit excellent biocompatibility profiles.

Iron-Chromium-Nickel–Based Alloys

The surgical stainless-steel alloys (e.g., 316 low carbon [316L]) have a long history of use for orthopedic and dental implant devices. This alloy, as with titanium systems, is used most often in a wrought and heat-treated metallurgic condition, which results in a high-strength and high-ductility alloy. The ramus blade, ramus frame, stabilizer pins (old), and some mucosal insert systems have been made from the iron-based alloy.

The ASTM F4 specification for surface passivation was first written and applied to the stainless-steel alloys.[19] In part, this was done to maximize corrosion-biocorrosion resistance. Of the implant alloys, this alloy is most subject to crevice and pitting biocorrosion, and care must be taken to use and retain the passivated (oxide) surface condition. Because this alloy contains nickel as a major element, use in patients allergic or hypersensitive to nickel should be avoided. In addition, if a stainless-steel implant is modified before surgery, then recommended procedures call for repassivation to obtain an oxidized (passivated) surface condition to minimize in vivo biodegradation.

The iron-based alloys have galvanic potentials and corrosion characteristics that could result in concerns about galvanic coupling and biocorrosion if interconnected with titanium, cobalt, zirconium, or carbon implant biomaterials.[75-77] In some clinical conditions, more than one alloy may be present within the same dental arch of a patient. For example, if a bridge of a noble or a base-metal alloy touches the abutment heads of a stainless-steel and titanium implant simultaneously, then an electrical circuit would be formed through the tissues. If used independently, where the alloys are not in contact or not electrically interconnected, then the galvanic couple would not exist, and each device could function independently. As with the other metal and alloy systems discussed, the iron-based alloys have a long history of clinical applications. Long-term device retrievals have demonstrated that, when used properly, the alloy can function without

significant in vivo breakdown. Clearly, the mechanical properties and cost characteristics of this alloy offer advantages with respect to clinical applications.

Other Metals and Alloys

Many other metals and alloys have been used for dental implant device fabrication. Early spirals and cages included tantalum, platinum, iridium, gold, palladium, and alloys of these metals. More recently, devices made from zirconium, hafnium, and tungsten have been evaluated.[15,78,79] Some significant advantages of these reactive group metals and their alloys have been reported, although large numbers of such devices have not been fabricated in the United States.

Gold, platinum, and palladium are metals of relatively low strength, which places limits on implant design. In addition, cost-per-unit weight and weight-per-unit volume (density) of the device along the upper arch have been suggested as possible limitations for gold and platinum. These metals, especially gold because of nobility and availability, continue to be used as surgical implant materials. For example, the Bosker endosteal staple design represents use of this alloy system.[80]

Ceramics and Carbon

Ceramics are inorganic, nonmetallic, nonpolymeric materials manufactured by compacting and sintering at elevated temperatures. They can be divided into metallic oxides or other compounds. Oxide ceramics were introduced for surgical implant devices because of their inertness to biodegradation, high strength, physical characteristics such as color and minimal thermal and electrical conductivity, and a wide range of material-specific elastic properties.[81,82] In many cases, however, the low ductility or inherent brittleness has resulted in limitations. Ceramics have been used in bulk forms and more recently as coatings on metals and alloys.

Aluminum, Titanium, and Zirconium Oxides

High-strength ceramics from aluminum, titanium, and zirconium oxides have been used for the root form, endosteal plate form, and pin type of dental implants.[83] The overall characteristics of these ceramics are summarized in Table 5.2. The compressive, tensile, and bending strengths exceed the strength of compact bone by three to five times. These properties, combined with high moduli of elasticity, and especially with fatigue and fracture strengths, have resulted in specialized design requirements for these classes of biomaterials.[19,84] For example, the fabrication of a subperiosteal

device from a high ceramic should not be done because of the custom nature of these devices, the lower fracture resistance, and the relative cost for manufacturing. The aluminum, titanium, and zirconium oxide ceramics have a clear, white, cream, or light-gray color, which is beneficial for applications such as anterior root form devices. Minimal thermal and electrical conductivity, minimal biodegradation, and minimal reactions with bone, soft tissue, and the oral environment are also recognized as beneficial compared with other types of synthetic biomaterials. In early studies of dental and orthopedic devices in laboratory animals and humans, ceramics have exhibited direct interfaces with bone, similar to an osteointegrated condition with titanium. In addition, characterization of gingival attachment zones along sapphire root form devices in laboratory animal models has demonstrated regions of localized bonding.[9,85-89]

Although the ceramics are chemically inert, care must be taken in the handling and placement of these biomaterials. Exposure to steam sterilization results in a measurable decrease in strength for some ceramics; scratches or notches may introduce fracture initiation sites; chemical solutions may leave residues; and the hard and sometimes rough surfaces may readily abrade other materials, thereby leaving a residue on contact. Dry-heat sterilization within a clean and dry atmosphere is recommended for most ceramics.

One series of root form and plate form devices used during the 1970s resulted in intraoral fractures after several years of function.[90] The fractures were initiated by fatigue cycling, where biomechanical stresses were along regions of localized bending and tensile loading. Although initial testing showed adequate mechanical strengths for these polycrystalline alumina materials,[91] the long-term clinical results clearly demonstrated a functional design-related and material-related limitation. This illustrates the need for controlled clinical investigation to relate basic properties to in vivo performance. The established chemical biocompatibilities, improved strength and toughness capabilities of sapphire and zirconia, and the basic property characteristics of high ceramics continue to make them excellent candidates for dental implants.

Bioactive and Biodegradable Ceramics Based on Calcium Phosphates

Bone Augmentation and Replacement

The calcium phosphate ($CaPO_4$) materials (i.e., calcium phosphate ceramics [CPCs]) used in dental reconstructive surgery include a wide range of implant types and thereby a wide range of clinical applications. Early investigations emphasized solid and porous particulates with nominal compositions that were

TABLE 5.2 Engineering Properties of Some Inert Ceramics Used as Biomaterials

Material	Modulus of Elasticity GN/m² (psi × 10⁶)	Ultimate Bending Strength MPa (ksi)	Surface
Aluminum oxide polycrystalline	372 (54)	300–550 (43–80)	Al_2O_3

relatively similar to the mineral phase of bone ($Ca_5[PO_4]_3OH$). Microstructural and chemical properties of these particulates were controlled to provide forms that would remain intact for structural purposes after implantation. The laboratory and clinical results for these particulates were most promising and led to expansions for implant applications, including larger implant shapes (e.g., rods, cones, blocks, H-bars) for structural support under relatively high-magnitude loading conditions.[92,93] In addition, the particulate size range for bone replacements was expanded to both smaller and larger sizes for combined applications with organic compounds. Mixtures of particulates with collagen, and subsequently with drugs and active organic compounds such as bone morphogenetic protein, increased the range of possible applications. These types of products and their uses have continued to expand significantly.[93-96]

Endosteal and Subperiosteal Implants

The first series of structural forms for dental implants included rods and cones for filling tooth-root extraction sites (ridge retainers)[97] and, in some cases, load-bearing endosteal implants.[98] Limitations in mechanical property characteristics soon resulted in internal reinforcement of the CPC implants through mechanical (central metallic rods) or physicochemical (coating over another substrate) techniques.[99,100] The numbers of coatings of metallic surfaces using flame or plasma spraying (or other techniques) increased rapidly for the CPCs.[93] The coatings have been applied to a wide range of endosteal and subperiosteal dental implant designs, with an overall intent of improving implant surface biocompatibility profiles and implant longevities (they are addressed later in this chapter).[101-103]

Advantages and Disadvantages

Box 5.1 summarizes the advantages and disadvantages of CPCs. The recognized advantages associated with the CPC biomaterials are as follows[104]:

1. chemical compositions of high purity and of substances that are similar to constituents of normal biological tissue (calcium, phosphorus, oxygen, and hydrogen);
2. excellent biocompatibility profiles within a variety of tissues, when used as intended;

3. opportunities to provide attachments between selected CPC and hard and soft tissues;
4. minimal thermal and electrical conductivity plus capabilities to provide a physical and chemical barrier to ion transport (e.g., metallic ions);
5. moduli of elasticity more similar to bone than many other implant materials used for load-bearing implants;
6. color similar to bone, dentin, and enamel; and
7. an evolving and extensive base of information related to science, technology, and application

Some of the possible disadvantages associated with these types of biomaterials are as follows:
1. variations in chemical and structural characteristics for some currently available implant products;
2. relatively low mechanical tensile and shear strengths under condition of fatigue loading;
3. relatively low attachment strengths for some coating-to-substrate interfaces;
4. variable solubilities depending on the product and the clinical application (The structural and mechanical stabilities of coatings under in vivo load-bearing conditions—especially tension and shear—may be variable as a function of the quality of the coating.);
5. alterations of substrate chemical and structural properties related to some available coating technologies; and
6. expansion of applications that sometimes exceed the evolving scientific information on properties.

Critical to applications are the basic properties of these substances. Table 5.3 provides a summary of some properties of bioactive and biodegradable ceramics. In general these classes of bioceramics have lower strengths, hardness, and moduli of elasticity than the more chemically inert forms previously discussed. Fatigue strengths, especially for porous materials, have imposed limitations with regard to some dental implant designs. In certain instances, these characteristics have been used to provide improved implant conditions (e.g., biodegradation of particulates). Calcium aluminates, sodium-lithium invert glasses with $CaPO_4$ additions (Bioglass or Ceravital), and glass ceramics (AW glass ceramic) also provide a wide range of properties and have found extended applications.[96,100]

Bioactive Ceramic Properties

Physical properties are specific to the surface area or form of the product (block, particle), porosity (dense, macroporous, microporous), and crystallinity (crystalline or amorphous). Chemical properties are related to the calcium-phosphate ratio, composition, elemental impurities (e.g., carbonate), ionic substitution in atomic structure, and the pH of the surrounding region. These properties, plus the biomechanical environment, all play a role in the rate of resorption and the clinical application limits of the materials.

The atomic relationships of the basic elements, stoichiometric ratios, and the normal chemical names for several characterized CPCs are provided in Table 5.4. The general family of apatites has the following formula:

$$M_{10}^{2+}\left(XO_4^{3}\right)_6 Z_2^{1}$$
Often apatite atomic ratios are nonstoichiometric; that is, 1 mol apatite may contain fewer than 10 mol metallic ions (M^{2+}) and fewer than 2 mol anions Z^{-1}.[105] The number of XO retains a number of 6. Multiple metals and anions can be substituted within

• BOX 5.1	Advantages and Disadvantages of Calcium Phosphate Ceramics

Advantages	Disadvantages
• Chemistry mimics normal biological tissue (C, P, O, H)	• Variable chemical and structural characteristics (technology and chemistry related)
• Excellent biocompatibility	• Low mechanical tensile and shear strengths under fatigue loading
• Attachment between calcium phosphate ceramics and hard and soft tissues	• Low attachment between coating and substrate
• Minimal thermal and electrical conductivity	• Variable solubility
• Moduli of elasticity closer to bone than many other implantable materials	• Variable mechanical stability of coatings under load-bearing conditions
• Color similar to hard tissues	• Overuse
• Extensive research	

this formulation. Most important, the relative physical, mechanical, and chemical properties of each final $CaPO_4$ material, including each of the apatites, are different from one another.[89,95] In addition, the microstructure of any final product (solid structural form or coating) is equally important to the basic properties of the substance alone. The crystalline monolithic hydroxyapatite (HA) (fired ceramic $Ca_{10}[PO_4]_6[OH]_2$) of high density and purity (50 maximum ppm impurities) has provided one standard for comparison related to implant applications. The ratio of calcium to phosphorus of $Ca_{10}(PO_4)_6(OH)_2$ is 1.67, and the ceramic can be fully crystalline. Considerable differences exist between the synthetic HA ceramics that are produced by elevated temperature processing and biological apatites (HAs).[105] Biological apatites contain trace amounts of CO_3^2, sodium, magnesium, fluorine, and chlorine ions. These exist in varying ratios and distributions, and of course are only one phase of calcified tissues.

The crystalline tricalcium phosphate ($bCa_3[PO_4]_2$) (TCP) ceramic has also provided a high-purity (<50 ppm maximum impurities) biomaterial for comparison with other products. National standard specifications related to the basic properties and characteristics of both HA and TCP have been published.[19] These

two compositions have been used most extensively as particulates for bone augmentation and replacement, carriers for organic products, and coatings for endosteal and subperiosteal implants.

One of the more important aspects of the CPCs relates to the possible reactions with water. For example, hydration can convert other compositions to HA; also, phase transitions among the various structural forms can exist with any exposure to water. This has caused some confusion in the literature, in that some CPCs have been steam autoclaved for sterilization purposes before surgical implantation. Steam or water autoclaving can significantly change the basic structure and properties of CPCs (or any bioactive surface), and thereby provide an unknown biomaterial condition at the time of implantation. This is to be avoided through the use of presterilized or clean, dry heat or gamma sterilized conditions.

Forms, Microstructures, and Mechanical Properties

Particulate HA, provided in a nonporous (<5% porosity) form as angular or spherically shaped particles, is an example of a crystalline, high-purity HA biomaterial[106] (Fig. 5.2A). These particles can have relatively high compressive strengths (up to 500 MPa), with tensile strengths in the range of 50 to 70 MPa. Usually, dense

TABLE 5.3 Properties of Bioactive and Biodegradable Ceramics

Material	Modulus of Elasticity GPa (psi × 10⁶)	Ultimate Bending Strength MPa (ksi)	Surface
Hydroxyapatite	40–120 (6–17)	40–300 (6–43)	$Ca_{10}(PO_4)_6(OH)_2$
Tricalcium phosphate	30–120 (4–17)	15–120 (2–17)	$Ca_3(PO_4)_2$
Bioglass or Ceravital	40–140 (6–20)	20–350 (3–51)	$CaPO_4$
AW ceramic	124 (18)	213 (31)	$CaPO_4 + F$
Carbon	25–40 (4–6)	150–250 (22–36)	C
Carbon-silicon (low-temperature isotropic)	25–40 (4–6)	200–700 (29–101)	CSi

These ceramics and carbons have 0% permanent elongation at fracture.

GPa, Gigapascal; *ksi*, thousand pounds per inch squared; *MPa*, megapascal.

**TABLE 5.4** Names, Formulae, and Atomic Ratios for Some Calcium Phosphate Materials

Mineral or General Name	Formula	Ca:P Ratio	Applications
Monetite (DVP)	$CaHPO_4$	1	Nonceramic bone substitute particulate
Brushite (DCPD)	$CaHPO_42H_2O$	1	Phase of some $CaPO_4$ biomaterials
Octacalcium phosphate (OCP)	$Ca_8(HPO_4)_2(PO_4)\ 5H_2O$	1.33	Phase of some $CaPO_4$ biomaterials
Whitlockite (WH)	$Ca_{10}(HPO_4)(PO_4)_6$	1.43	Phase of some $CaPO_4$ biomaterials
Beta-tricalcium phosphate (b-TCP)	$Ca_3(PO_4)_2$	1.48	Biodegradable $CaPO_4$ ceramic for bone substitute and coatings; also a phase of some $CaPO_4$ biomaterials
Defective hydroxyapatite (DOHA) biomaterials	$Ca_9(HPO_4)(PO_4)_5(OH)$	1.5	Component of some $CaPO_4$ biomaterials
Hydroxyapatite (HA)	$Ca_{10}(PO_4)_6(OH)_2$	1.67	Major mineral phase of bone; when fired as a ceramic, named HA
• **Fig. 5.2** (A) Particulate dense hydroxyapatite presents as a crystalline nonporous material with angular or spherical particles. (B and C) Macroporous (B) and microporous (C) particulate offer the advantage of increased surface area per unit volume, which facilitates solution and cell-mediated resorption. (*Courtesy Ceramed Corp, Denver, CO*)

polycrystalline ceramics consisting of small crystallites exhibit the highest mechanical strength, apart from monocrystalline ceramics free of defects (e.g., single-crystal sapphire implants). Ceramics are brittle materials and exhibit high compressive strengths compared with tensile strengths. However, less resistance to tensile and shear stresses limit their application as dental implants because of mechanical constraints of implant form and volume. Nonresorbable, "bioinert" ceramics exhibiting satisfactory load-bearing capability are limited to dense monocrystalline and polycrystalline aluminum, zirconium, and titanium oxide ceramics. These same mechanical characteristics exist for the solid portions of several porous HA particulates and blocks. The macroporous (>50 mm) or microporous (<50 mm) particulates have an increased surface area per unit volume. This provides more surface area for solution- and cell-mediated resorption under static conditions and a significant reduction in compressive and tensile strengths (Figs. 5.2B, 5.2C, and 5.3). The porous materials also provide additional regions for tissue ingrowth and integration (mechanical stabilization), and thereby a minimization of interfacial motion and dynamic (wear-associated) interfacial breakdown. The strength characteristics after tissue ingrowth would then become a combination of the ceramic and the investing tissues.[107]

A number of the CPCs are phase mixtures of HA and TCP, whereas some compounds are composites or mechanical mixtures with other materials[93] (see Table 5.4). These classes of bioactive ceramics, including glasses, glass ceramics, mixtures of ceramics,
• **Fig. 5.3** Scanning electron microscopy of cells, which actively endocytosed fragments of granules (×1500). (*Courtesy Ceramed Corp, Denver, CO*)

combinations of metals and ceramics, or polymers and ceramics, exhibit a wide range of properties. In general, these biomaterials have shown acceptable biocompatibility profiles from laboratory and clinical investigations. Bulk-form implant designs made

from CPCs, which were contraindicated for some implant designs because of poor mechanical performance, have found a wide range of indications as coatings of stronger implant materials.

The coatings of CPCs onto metallic (cobalt- and titanium-based) biomaterials have become a routine application for dental implants. For the most part these coatings are applied by plasma spraying, have average thickness between 50 and 70 mm, are mixtures of crystalline and amorphous phases, and have variable microstructures (phases and porosities) compared with the solid portions of the particulate forms of HA and TCP biomaterials.[93,108] At this time, coating characteristics are relatively consistent, and the quality-control and stricter quality-assurance programs from the manufacturers have greatly improved the consistency of coated implant systems. (A more detailed discussion of surface treatment options is presented in the next section.)

Concerns continue to exist about the fatigue strengths of the $CaPO_4$ coatings and coating–substrate interfaces under tensile and shear loading conditions. There have been some reports of coating loss as a result of mechanical fracture, although the numbers reported remain small.[89] This has caused some clinicians and manufacturers to introduce designs in which the coatings are applied to shapes (geometric designs) that minimize implant interface shear or tensile loading conditions (e.g., porosities, screws, spirals, plateaus, vents). From theoretic considerations, the coating of mechanically protected areas seems most desirable.

Density, Conductivity, and Solubility

Bioactive ceramics are especially interesting for implant dentistry because the inorganic portion of the recipient bone is more likely to grow next to a more chemically similar material. The bioactive (bioreactive) categorization includes $CaPO_4$ materials such as TCP, HA, calcium carbonate (corals), and calcium sulfate–type compounds and ceramics. A chemical-biochemical contact between the host bone and grafted material may be developed, as well as a possible stimulus of bone activity.[95] Their limitations have been associated with the material forms that have lower strengths (i.e., similar to or less than bone).[95]

The very technique-sensitive fabrication steps related to phase transition and thermal expansion during cooling might cause the final product of $CaPO_4$-type coatings to be more or less resorbable. In addition, the original categories of resorbable versus nonresorbable for these materials must be carefully weighed as a function of their particle size, porosity, chemical structure, and environmental exposure conditions.

Dissolution characteristics of bioactive ceramics have been determined for both particulates and coatings.[109,110] In general, solubility is greater for TCP than for HA. Each increase relative to increasing surface area per unit volume (porosity) and the CPC solubility profiles depend on the environment (e.g., pH, mechanical motion). If one considers a uniform material chemistry, then the larger the particle size is, the longer the material will remain at an augmentation site. Thus 75-mm particles will be resorbed more rapidly than 3000-mm particles.

In addition, the porosity of the product affects the resorption rate. Tofe et al.[111] reported on the porosity of dense, macroporous, and microporous $CaPO_4$. Some of the dense HA lacks any macroporosity or microporosity within the particles. The longest resorption rate occurred with the dense nonporous HA type because osteoclasts may attack only the surface and cannot penetrate the nonporous material. Macroporous $CaPO_4$ (e.g., corallin
● **Fig. 5.4** Diagram of solubility of hydroxyapatite in function of percent porosity.

HA) demonstrated 100-mm or 500-mm pores, which comprised 15% or more of the total material volume. Minimal porosity was found in the HA bulk material that surrounded the large pores. Microporous apatites often have their origin in bovine or human bone. The porosity observed in these materials is approximately 5 mm or less and comprises less than 28% of the total volume. The pores or holes are regions where blood components and organic materials can reside when placed within bone, and they represent the regions where living material existed before the processing of the implant material. The greater the porosity is, the more rapid is the resorption of the graft material. For example, clinical observation shows dense crystalline forms of HA may last longer than 15 years in the bone, the macroporous 5 years, and the microporous HA as short as 6 months (Fig. 5.4).

The crystallinity of HA also affects the resorption rate of the material. The highly crystalline structure is more resistant to alteration and resorption. An amorphous product has a chemical structure that is less organized with regard to atomic structure. The hard or soft tissues of the body are more able to degrade the components and resorb the amorphous forms of grafting materials. Thus crystalline forms of HA are found to be very stable over the long term under normal conditions, whereas the amorphous structures are more likely to exhibit resorption and susceptibility to enzyme- or cell-mediated breakdown.[112] Therefore, in general, the less crystalline the material, the faster its resorption rate.[92,93,95,112,113]

The purity of the HA bone substitutes may also affect the resorption rate. The resorption of the bone substitute may be cell or solution mediated. Cell-mediated resorption requires processes associated with living cells to resorb the material, similar to the modeling and remodeling process of living bone, which demonstrates the coupled resorption and formation process. A solution-mediated resorption permits the dissolution of the material by a chemical process. Impurities or other compounds in bioactive ceramics, such as calcium carbonate, permit more rapid solution-medicated resorption, which then increases the porosity of the bone substitute. Although the coralline HA does not demonstrate micropores along the larger holes, the HA may have carbonates incorporated within the material, which hastens the resorption process.

The pH in the region in which the bone substitutes are placed also affects the rate of resorption. As the pH decreases (e.g., because of chronic inflammation or infection), the components of living bone, primarily $CaPO_4$, resorb by a solution-mediated process (i.e., they become unstable chemically).

The $CaPO_4$ coatings are nonconductors of heat and electricity. This can provide a relative benefit for coated dental implants, where mixtures of conductive materials may be included in the overall prosthetic reconstruction. In combination with color (off-white), these properties are considered to be advantageous.

In most applications within bone, solubilities are higher during the first few weeks, then decrease with continued in vivo exposure and the apposition of mineralized structures.[109,110] However, some investigators have shown situations in which osteoclastic resorption has removed localized zones of $CaPO_4$ coatings.[114] This raises interesting questions about long-term in vivo stabilities. At this time, clinical results have been favorable, and expanded applications have continued.

Current Status and Developing Trends

The CPCs have proved to be one of the more successful high technology–based biomaterials that have evolved most recently. Their advantageous properties strongly support the expanding clinical applications and the enhancement of the biocompatibility profiles for surgical implant uses. Within the overall theme for new-generation biomaterials to be chemically (bonding to tissue) and mechanically (nonuniform, multidirectional properties) anisotropic, the CPCs could be the biomaterial surfaces of choice for many device applications.[115,116]

Carbon and Carbon Silicon Compounds

Carbon compounds are often classified as *ceramics* because of their chemical inertness and absence of ductility; however, they are conductors of heat and electricity. Extensive applications for cardiovascular devices, excellent biocompatibility profiles, and moduli of elasticity close to that of bone have resulted in clinical trials of these compounds in dental and orthopedic prostheses. One two-stage root replacement system (Vitredent) was quite popular in the early 1970s.[10] However, a combination of design, material, and application limitations resulted in a significant number of clinical failures and the subsequent withdrawal of this device from clinical use.

Ceramic and carbonitic substances continue to be used as coatings on metallic and ceramic materials. Advantages of coatings as mentioned in an earlier section include tissue attachment; components that are normal to physiologic environments; regions that serve as barriers to elemental transfer, heat, or electrical current flow; control of color; and opportunities for the attachment of active biomolecules or synthetic compounds. Possible limitations relate to mechanical strength properties along the substrate–coating interface; biodegradation that could adversely influence tissue stabilities; time-dependent changes in physical characteristics; minimal resistance to scratching or scraping procedures associated with oral hygiene; and susceptibility to standard handling, sterilizing, or placing methodologies. Greater uses of surface-coated dental implants have been developed by the research and development communities.

Zirconia

The use of ceramic implants has been available in implant dentistry. since the 1970's. These types of implants never gained acceptance because they were at a biomechanical disadvantage and clinically had a poor success rate. However, today a new type of implant made out of zirconia has recently been introduced into dental implantology as an alternative to titanium implants.

Initially zirconia was used in medicine with orthopedic procedures for total hip replacements, artificial hips, and finger and acoustic implants. In the 1990s, zirconia was introduced to dentistry for fabrication of endodontic posts, crown and bridge prostheses, esthetic orthodontic brackets, and custom implant abutments.[117] Zirconia possesses many advantages over titanium in its biologic, esthetic, mechanical, and optical properties, as well as its inherent biocompatibility and low plaque affinity. This zirconia-based material has been shown to have improved flexural strength and fracture resistance over early versions of ceramic implants.[118] Even though zirconia implants are becoming more popular, they have become extremely controversial. Zirconia implants have been plagued by high fracture rates. Since receiving U.S. Food and Drug Administration approval in 2011, zirconia dental implants have been touted as the next generation of dental implants. Zirconia implants initially were used in cases of metal-free dentistry, mainly for patients with known metal allergies or hypersensitivities. The prevalence rate of titanium allergy has been estimated to be approximately 0.6%.[119] Originally, zirconia implants were available only as a one-piece implant, but the introduction of two-piece zirconia implants now allows for abutments to be fully customized, creating the best outcomes.

Zirconia Chemical Composition

Zirconia implants are fabricated from a shiny, gray-white metal named zirconium, which has an atomic number of 40 and is symbolized in the periodic table as Zr. Zirconia is the oxide form of zirconium, which was first isolated in an impure form by Jöns Jacob Berzelius in 1824. The pure form of zirconia occurs in two basic forms: (1) crystalline zirconia, which is soft, white, and ductile; and the (2) amorphous form, which is bluish-black and powdery in nature. The powder form of zirconia is refined and treated at high temperatures to produce an optically translucent form of crystalline zirconia. There exist three crystalline phases with zirconia implants: monoclinic (m), tetragonal (t), and cubic (c). The monoclinic phase of zirconia exists at room temperature and is stable for up to approximately 1170°C. At greater than 1170°C, the monoclinic phase changes to tetragonal phase with approximately 5% decrease in volume. At 2370°C, the cubic phase starts to appear. Upon cooling, a tetragonal-to-monoclinic transformation with a 3% to 4% increase in volume takes place for about 100°C until 1070°C. Unfortunately, the increase in volume and resultant expansion without a mass transfer on cooling generates stress and causes it to become unstable at room temperature[120] (Fig. 5.5).

Therefore to minimize this phenomenon and to generate a partially stabilized zirconia (PSZ) with stable tetragonal and/or cubic phases, various stabilizing oxides [16 mol% magnesia (MgO), 16 mol% of limestone (CaO), or 8 mol% yttria (Y_2O_3)] are added in the fabrication of zirconia implants.[121] This martensitic-like phase transformation significantly increases the crack and fracture toughness, and the longevity of zirconia endosseous implants.[122] Today the most common type of ceramic implants is produced from yttria-stabilized tetragonal zirconia polycrystal.

In addition, other variants of zirconia implants being studied include 12Ce-TZP (ceria-stabilized zirconia) and alumina-toughened zirconia. Alumina has also been added to yttria-stabilized tetragonal zirconia polycrystal in small quantities (0.25 wt%) that results in a tetragonal zirconia polycrystal with alumina. This new zirconia form significantly improves the durability and stability of zirconia crystals along with minimizing degradation of
● **Fig. 5.5** Zirconia: (a) is the oxide form of the metal zirconium, (b) Zirconia is available in different size and shapes for use in implant dentistry. (*From Telford M. The case for bulk metallic glass.* Materials Today. *2004;7:36–43.*)

the zirconia.[123,124] Most significantly, research has shown that implants without alumina, when exposed to the oral cavity, have a survival rate of 50%, whereas implants with alumina have a much greater survival rate of approximately 87% to 100%.[125]

Physical Properties. The physical properties of zirconia implants are dependent on many factors, including the composition, crystalline structure, polymorphic structure, percentage of stabilizing metal oxide, aging process, and the macrodesign and microdesign of the implant.[126,127] An ideal grain size (0.2–0.6 μm) should be used to retain the tetragonal phase of the material, to minimize the degradation or aging of zirconia. Watanabe et al.[128] reported that too small of a grain size results in a less stable material. However, a larger grain size (e.g., >1 μm) exhibits a decrease in strength with an increased amount of tetragonal-monoclinic transformation.[128]

Surface Roughness. Many studies have shown that zirconia with a moderately rough surface is advantageous in attracting osteoblasts and osseointegration.[129,130] By modifying the zirconia surface into a microrough surface, acceleration of the osseointegration process results. Currently, sandblasting followed by acid etching is the method of choice in adjusting the zirconia surface.[130] In addition, the zirconia surface may be chemically modified, which increases the hydrophilicity of the material.[131]

Types of Zirconia Implants

Zirconia implants are classified as either one piece or two piece. The one-piece implant consists of an implant and abutment as a single unit. The two-piece is similar to traditional implant, where the abutment may be screwed or cemented in place.[132] Currently, most available research has been completed for one-piece zirconia implants, which show superior mechanical properties relative to two-piece implants[133] (Fig. 5.6).

Fracture Resistance. In early studies, zirconia implants exhibited high rates of fractures in preclinical animal studies using canine mandibles. In two different studies, Thoma et al.[134,135] reported a higher incidence of zirconia implant fractures before and after loading in comparison with titanium implants. The fracture resistance of zirconia implants is dependent on many variables, but most importantly on the occlusal load and physical characteristics of the abutment. Numerous studies have shown the flexural strength (900–1200 MPa), fracture toughness (8–10 MPa-m$^{1/2}$), and static fracture strength (725–850 N).[136]

● **Fig. 5.6** Two different types of zirconia implants: one piece and two piece.

When comparing the fracture resistance, the type (i.e., one or two piece) of zirconia implant must be determined. Kohal et al.[137] compared the mechanical properties and effect of occlusal loading on one- and two-piece zirconia implants. They concluded that the fracture strength was less for two-piece zirconia, both under loaded and unloaded conditions. Therefore two-piece zirconia implants are becoming more popular; however, they have an increased morbidity.[137]

The type and extent of modification of the zirconia implant influences the fracture resistance. Kohal et al.[137] evaluated the effects of cyclic loading and finish line design on the fracture strength of one-piece zirconia implants. They concluded that a chamfer finish line along with cyclic loading decrease the fracture strength of zirconia implants.[137] When circumferential preparation was completed, a depth of 0.5 mm on the zirconia abutments was better than 0.6 and 0.7 mm. Each increase in preparation depth of 0.2 mm decreases the fracture load by 68 N, and aging and chewing simulations decrease the fracture load to 102 N.[138,139]

Spies et al.[140] reported on the fracture resistance of different types of two-piece zirconia implant systems (e.g., bonded and screwed) and single-piece zirconia implants after the process of thermomechanical cycling under an aqueous environment. The results showed that both screwed and bonded two-piece zirconia implants had a significant decreased fracture resistance and were weak and susceptible to fracture[140] (Fig. 5.7).

Osseointegration. Zirconia-based implants are advantageous because they exhibit excellent osseointegration qualities. Zirconia is chemically inert, with minimal local or systemic adverse reactions. They possess enhanced cell adhesion, favorable tissue responses, and excellent biocompatibility with the surrounding hard and soft tissues. There exists numerous animal and human studies that have verified that new mature bone forms around zirconia implants with minimal inflammation and abundance of active osteoblasts.[141-143] Several in vitro and in vivo studies have shown zirconia possesses osteoconductive features with no cytotoxic or mutagenic effects on the bone and fibroblasts after implantation.[144-146] When evaluating osseointegration differences of titanium and zirconia implants, most studies show little difference between the two implant materials. Scarano et al.[147] showed an excellent bone response to zirconia implants at 4 weeks with bone–implant contact of 68.4%. Dubruille et al.[148] compared the bone implant contact in titanium, alumina, and zirconia implants. They concluded no statistically significant difference between the three types of implants (i.e., 68% for alumina, 64.6% for zirconia, and 54% for titanium). Hoffman et al.[149] showed at 2 weeks postinsertion, zirconia implants had a higher degree of bone apposition (54%–55%) compared with titanium implants (42%–52%). However, at 4 weeks, titanium had a higher bone–implant contact (68%–91%) in comparison with zirconia (62%–80%).

Zirconia Implant Success Studies

Unfortunately few clinical studies exist on the long-term success of zirconia implants. Oliva et al.[150] reported on the first zirconia implant study involving 100 implants with different surface roughness. There overall success rate approached 98%. Osman et al.[151] evaluated the 1-year success of one-piece zirconia implants compared with titanium implants with conventional loading protocols. No difference in success rates in the mandible was seen; however, in the maxilla a significant difference was seen (i.e., titanium, 72%; zirconia, 55% success rate).

Devji et al.[152] conducted a metaanalysis of patients treated with only zirconia implants and found an average implant survival rate of 95.6% after 12 months, with an expected decrease of 0.05% per year for 5 years (0.25% after 5 years). After 1 year the marginal bone loss around zirconia implants was favorable at 0.79 mm.

Narrow-diameter zirconia implants have not proven to be predictable in clinical studies because success rates have been unfavorable. Various studies have shown up to a 30% incidence rate of fracture with zirconia implants.[153]

In summary, zirconia dental implants are a new and exciting development in implant dentistry. The limited preliminary studies are positive, showing less inflammation in the peri-implant tissues, less biofilm accumulation, and a favorable bone–implant contact. In addition, they exhibit excellent esthetics and are ideal for patients who exhibit metal sensitivities or who prefer a metal-free option. However, there is room for further technical progress of currently available zirconia implant systems. Two-piece zirconia implant systems are ideal; however, they are still technically challenging because of limitations in the material. Zirconia dental implants have the potential to become the future ideal alternative to titanium alloy dental implants (Boxes 5.2 and 5.3).

Polymers and Composites

The use of synthetic polymers and composites continues to expand for biomaterial applications. Fiber-reinforced polymers offer advantages in that they can be designed to match tissue properties, can be anisotropic with respect to mechanical characteristics, can be coated for attachment to tissues, and can be fabricated at relatively low cost. Expanded future applications for dental implant systems, beyond inserts for damping force transfers such as those
• **Fig. 5.7** Zirconia Implant Fracture. One of the most significant disadvantages of zirconia implants to date is the high fracture rate. (A) Immediate postinsertion radiograph depicting #8 and #9 zirconia implants. (B) Radiograph showing the fracture of both zirconia implants within 1 year of insertion.

used in the IMZ (Interpore, Inc.) and Flexiroot (Interdent Corp.) systems, are anticipated as interest continues in combination synthetic and biological composites.

Structural Biomedical Polymers

The more inert polymeric biomaterials include polytetrafluoroethylene (PTFE), polyethylene terephthalate, polymethylmethacrylate (PMMA), ultra-high-molecular-weight polyethylene, polypropylene, polysulfone, and polydimethylsiloxane (or silicone rubber). These are summarized in Table 5.5. In general the polymers have lower strengths and elastic moduli, and higher elongations to fracture compared with other classes of biomaterials. They are thermal and electrical insulators, and when constituted as a high-molecular-weight system without plasticizers, they are relatively resistant to biodegradation. Compared with bone, most polymers have lower elastic moduli with magnitudes closer to soft tissues.

Polymers have been fabricated in porous and solid forms for tissue attachment, replacement, and augmentation, and as coatings

---

• BOX 5.2　Advantages of Zirconia Implants

- More esthetically pleasing
- Retains less plaque and calculus in comparison with titanium (less biofilm)
- Excellent flexural strength and fracture toughness
- Favorable and possibly better bone–implant contact in comparison with titanium
- Does not undergo corrosion
- No piezoelectric current with dissimilar metals
- Thermally nonconductive

• BOX 5.3　Disadvantages of Zirconia Implants

- Clinical studies into long-term success are limited
- One-piece implants require a load-free healing period
- One-piece implants may require modification depending on positioning
- Modification leads to reduction of physical properties of material
- Lack of research on two-piece zirconia abutments
- Slightly higher fracture rates than titanium

---

for force transfer to soft tissue and hard tissue regions. Cold-flow characteristics and creep and fatigue strengths are relatively low for some classes of polymers (e.g., silicone rubber and PMMA) and have resulted in some limitations. In contrast, some are extremely tough and fatigue-cycle resistant (e.g., polypropylene, ultra-high-molecular-weight polyethylene, PTFE) and afford opportunities for mechanical force transfer within selected implant designs. Most uses have been for internal force distribution connectors for osteointegrated implants, where the connector is intended to better simulate biomechanical conditions for normal tooth functions. The indications for PTFE have grown exponentially recently because of the development of membranes for guided tissue regeneration techniques. However, PTFE has a low resistance to contact abrasion and wear phenomena.

Composites

Combinations of polymers and other categories of synthetic biomaterials continue to be introduced. Several of the more inert polymers have been combined with particulate or fibers of carbon, Al_2O_3, HA, and glass ceramics. Some are porous, whereas others are constituted as solid-composite structural forms.[154,155]

In some cases, biodegradable polymers, such as poly vinyl alcohol, polylactides or glycolides, cyanoacrylates, or other hydratable forms have been combined with biodegradable $CaPO_4$ particulate or fibers.[156] These are intended as structural scaffolds, plates, screws, or other such applications. Biodegradation of the entire system, after tissues have adequately reformed and remodeled, has allowed the development of significantly advantageous procedures such as bone augmentation and peri-implant defect repairs.

In general, polymers and composites of polymers are especially sensitive to sterilization and handling techniques. If intended for implant use, then most cannot be sterilized by steam or ethylene oxide. Most polymeric biomaterials have electrostatic surface properties and tend to gather dust or other particulate if exposed to semiclean air environments. Because many can be shaped by cutting or autopolymerizing in vivo (PMMA), extreme care must be taken to maintain quality surface conditions of the implant. Porous polymers can be deformed by elastic deformation, which can close open regions intended for tissue ingrowth. In addition, cleaning of contaminated porous polymers is not possible without a laboratory environment. In this regard, talc or starch on surgical

TABLE 5.5　Engineering Properties of Polymers (Some Medical Grades)

Material	Modulus of Elasticity GPa (Psi × 10⁵)	Ultimate Tensile Strength MPa (ksi)	Elongation to Fracture (%)
PTFE	0.5–3 (0.07–4.3)	17–28 (2.5–4)	200–600
PET	3 (4.3)	55 (8)	50–300
PMMA	3 (4.3)	69 (10)	2–15
PE	8 (1.2)	48 (7)	400–500
PP	9 (1.3)	35 (5)	500–700
PSF	3.5 (5)	69 (10)	20–100
SR	0.1 (0.014)	5 (1.1)	300–900
POM	3 (4.3)	70 (10.1)	10–75

Polymer properties exhibit a wide range depending on processing and structure. These values have been taken from general tables.

GPa, Gigapascal; *ksi*, thousand pounds per inch squared; *MPa*, megapascal; *PE*, polyethylene; *PET*, polyethylene terephthalate; *PMMA*, polymethylmethacrylate; *POM*, polyoxymethylene (IME insert); *PP*, polypropylene; *PSF*, polysulfone; *PTFE*, polytetrafluoroethylene; *SR*, silicone rubber.

gloves, contact with a towel or gauze pad, or the touching of any contaminated area must be prevented for all biomaterials.

Long-term experience, excellent biocompatibility profiles, ability to control properties through composite structures, and properties that can be altered to suit the clinical application make polymers and composites excellent candidates for biomaterial applications, as the constant expansion of the applications of this class of biomaterials can verify.

Inserts and Intramobile Elements

Relatively low moduli of elasticity (compared with metals and ceramics), high elongations to fracture, and inherent toughness have resulted in use of selected polymers for connectors or interpositional spacers for dental implants. One popular polymer insert system was included in Table 5.5 for general reference purposes. The most significant limitation has been the polymeric materials' resistance to cyclical-load creep and fatigue phenomena. Retrieved transfer systems, in some clinical retrievals, have shown significant plastic deformation and fracture.[157] Although the desire to achieve such a stress-damping effect seems well founded, the inadequate long-term performance of the materials and high time and cost associated with maintenance of these devices have limited their field of application, and they are used less today than during the previous decade.

Future Areas of Application

Synthetic substances for tissue replacement have evolved from selected industrial-grade materials such as metals, ceramics, polymers, and composites. This situation offers opportunities for improved control of basic properties. The simultaneous evolution of the biomechanical sciences also provides optimization of design and material concepts for surgical implants. Knowledge of tissue properties and computer-assisted modeling and analyses also supports the present developments. The introduction of anisotropy with respect to mechanical properties; chemical gradients from device surface to center, with bonding along the tissue interfaces; and control of all aspects of manufacturing, packaging, delivering, placing, and restoring enhance the opportunities for optimal application and, it is hoped, device treatment longevities. Health care delivery would benefit from better availability and decreased per-unit costs.

Combinations to provide compositions with bioactive surfaces, the addition of active biomolecules of tissue-inductive substances, and a stable transgingival attachment mechanism could improve device systems. An integrated chemical and physical barrier at the soft tissue transition region would, at least theoretically, enhance clinical longevities. Devices that function through bone or soft tissue interfaces along the force-transfer regions could be systems of choice, depending on the clinical situation.[9]

Unquestionably, the trend for conservative treatment of oral diseases will continue. Thus it can be anticipated that dental implants will frequently be a first-treatment option. Therefore increased use of root-form systems is to be expected. Clearly the true efficacy of the various systems will be determined by controlled clinical studies with 10- to 20-year follow-up periods, which include statistically significant quantitative analyses.

Surface Characteristics

Many aspects of biocompatibility profiles established for dental surgical implants have been shown to depend on interrelated biomaterial, tissue, and host factors. For discussion purposes, the biomaterial characteristics can be separated into categories associated with either: (1) surface or (2) bulk properties. In general, the biomaterial surface chemistry (purity and critical surface tension for wetting), topography (roughness), and type of tissue integration (osseous, fibrous, or mixed) can be correlated with shorter- and longer-term in vivo host responses. In addition, the host environment has been shown to directly influence the biomaterial-to-tissue interfacial zone specific to the local biochemical and biomechanical circumstances of healing and longer-term clinical aspects of load-bearing function. The interfacial interaction between recipient tissues and implanted material are limited to the surface layer of the implant and a few nanometers into the living tissues. The details of the integration (hard or soft tissue) and force transfer that results in static (stability) or dynamic (instability or motion) conditions have also been shown to significantly alter the clinical longevities of intraoral device constructs.

Many of the conference proceedings cited have focused on biomaterial-to-tissue interfacial interactions, which strongly supports the value of scrutinizing the surface characteristics of dental implants. This was one consistent recommendation from the 1978 and 1988 consensus conferences on the benefit and risk aspects of dental implant-based clinical treatments.[9,10,158]

The synthetic biomaterials used for the construction of dental implants and the associated abutments that contact subepithelial zones of oral tissues can be classified into *metallic*, *ceramic*, and *surface-modified* (coated, reacted, or ion-implanted) groups. It has long been recognized that synthetic biomaterials should be mechanically and chemically clean at the time of surgical placement. Surface properties are chemical in nature and have been described in terms of atomic structural characteristics with extensions to the subatomic scale. These characteristics are critical to the surface composition, corrosion resistance, cleanliness, surface energy, flexure, and tendency to interact, such as the ability to denature proteins. Surface characteristics are the theme of this section, with emphasis on metallic, ceramic, and surface-modified dental implant biomaterials.

Surface Characterization and Tissue Interaction

Metal and Alloy Surfaces

Standard grades of alpha (unalloyed) titanium and alpha-beta and beta-base alloys of titanium exist with an oxide surface at normal temperatures, with ambient air or normal physiologic environments that act as oxidizing media. A formation of a thin oxide exists via dissociation of and reactions with oxygen or other mechanisms such as oxygen or metal ion diffusion from and to the metallic surface, especially for titanium. Independent from the fabrication process, the oxide is primarily TiO_2, with small quantities of Ti_2O_3 and TiO, with some minor variable stoichiometry.[159-163] This thin layer of amorphous oxide will rapidly re-form if removed mechanically. Surface properties are the result of this oxide layer and differ fundamentally from the metallic substrate.[63,160] Therefore the oxidation parameters such as temperature, type and concentration of the oxidizing elements, and eventual contaminants all influence the physical and chemical properties of the final implant product. The type of oxide on surgical implants is primarily amorphous in atomic structure (brookite) if formed in normal-temperature air or tissue fluid environments, and is usually very adherent and thin in thickness dimensions (<20 nm). In contrast, if unalloyed titanium (alpha) substrates (titanium grades 1–4) are processed at elevated temperatures (above approximately 350° C [660° F]) or anodized in organic acids at higher voltages (above 200 mV), then the oxide

forms a crystalline atomic structure (rutile or anatase) and can be 10 to 100 times thicker. The grain structure of the metal and the oxidation process also condition the microstructure and morphology of the surface oxides. Porosity, density, and general homogeneity of the substrate are all related to this process. Low-temperature thermal oxides are relatively homogeneous and dense[164]; with increasing temperatures they become more heterogeneous and more likely to exhibit porosity as scale formations, and some have glass-like surface oxide conditions (semicrystalline).[162,164]

Depending on the mechanical aspects of polishing and the chemical and electrochemical aspects of cleaning and passivating, these amorphous or crystalline oxides can exhibit microscopically smooth or rough topographies at the micrometer level. However, surface macroscopic roughness is normally introduced into the substrate beneath the oxide zone by mechanical (grinding), particulate blasting (resorbable blast media or other), or chemical (acid-etching) procedures. The surface topography and roughness obtained by such techniques is characteristic of each fabrication process.[11,165] The oxide dimension (thickness) along these rougher surfaces remains relatively constant and within nanometer dimensional thicknesses under normal temperature and environmental exposure conditions.

The titanium alloys used for dental implant components include microstructural phases of alpha and beta or room temperature–stabilized beta (only). The alpha-phase surface regions of the alloy are similar to unalloyed titanium in atomic arrangement (close-packed hexagonal), whereas the beta phases demonstrate a different atomic structure (body-centered cubic) and elemental chemistry. However, the beta-phase oxide formation kinetics, chemistry, dimensions, and environmental stabilities are relatively similar to the alpha-phase regions. Electrochemical investigations have shown that the alpha- and beta-phase oxides provide substrate coverage and a high degree of chemical and biochemical inertness (resistance to corrosion and ion transfer) for titanium and alloys of titanium. Both titanium and Ti-6Al-4V have been reported to contain small amounts of titanium nitride along their surface oxide.[161,166,167] Ions, carbon, and substances other than alloying elements may be picked up in the oxide through the preparation process, similar to that found at the surface of commercially pure titanium.[163,168-171] Nevertheless, in the cases of titanium and titanium alloy, the oxide layer grows homogeneously, and a well-controlled inert coating of very stable insoluble oxide normally contacts the living tissues.

Considerable research has been conducted on the roles of alloying elements in titanium alloys and how these elemental compositions may influence oxide properties and host tissue compatibility. This is dependent on the amount of the ions available to the tissues and relative rates of ion transfers, which could result in host tissue toxicity. In general, adequately processed and finished titanium alloys have shown integration with bone and soft tissue environments for a wide range of dental and medical implant devices. Surface analysis studies have shown that the titanium alloy exhibits a similar oxide layer and as such is able to interact with surrounding bone in ways that are similar to unalloyed titanium.[172] Predictable results can be achieved with titanium alloy implant with a similar degree of bone integration.[173] In addition, electrochemical measurements of corrosion and ion release rates strongly support the chemical-biochemical stability properties of titanium alloys.

Some reports have expressed concerns because titanium alloy surface oxides contain significant amounts of alloying elements and exhibit different morphology and crystallization.[166,174-177] Aluminum in particular has been reported in both the outermost and the innermost layers. At the innermost layer, it was found especially overmixed phases (alpha and beta) grains of the alloy.[166] The different surface oxides are then argued to be responsible for a "lesser" quality of osseointegration in particular because of the potential of corrosion products that contain aluminum and vanadium.[178-180] The orthopedic and dental literature specific to in vivo animal and human studies have also documented long-term success with titanium alloys that demonstrated close physical adaption of the bone to the surface of the alloy.[181-188]

Tissue Interactions

Oxide modification during in vivo exposure has been shown to result in increased titanium oxide layer thickness of up to 200 nm.[189-191] The highest oxide growth area corresponded to a bone marrow site, whereas the lowest growth was associated with titanium in contact with cortical regions of bone. Increased levels of calcium and phosphorus were found in the oxide surface layers and seemed to indicate an active exchange of ions at the interface. Hydrogen peroxide environmental conditions have been shown to interact with Ti and form a complex gel.[192-194] "Titanium gel conditions" are credited with attractive in vitro properties such as low apparent toxicity, inflammation, bone modeling, and bactericidal characteristics. The authors restricted their studies to commercially pure titanium exclusively and not titanium alloys.

Other elements interacting with the surface layer of several implanted materials are calcium and phosphorus,[195,196] exhibiting a $CaPO_4$ structure somewhat similar to apatite on the titanium surface. However, the low percentage of these elements along the material surface indicates this was the result of transfer and adsorption of these elements from tissue fluids, not an osteointegration process per se. The surface biointeraction processes may be slow or activated by local reactions, and may cause ion release and oxide alteration of the substrate. Local and systemic increases of the ion concentration have been reported.[197,198] In vitro studies showed that both titanium and titanium alloy were released in measurable quantities of the substrate elements at the surface.[23,199] Especially high rates of ion release were observed in ethylenediamine tetraacetic acid and sodium citrate solutions, and varied as a function of the corroding medium.[199] Ion release corresponds to an oxide layer thickness growth with inclusions of calcium, phosphorus, and sulfur in particular. This is especially a concern for larger orthopedic or porous implants, where such ion release may be a part of the origin of implant failure and allergic reactions, and has even proposed to be a local or systemic reason for the formation of tumors. In addition, free-titanium ions have been shown to inhibit the growth of HA crystals (i.e., the mineralization of calcified tissues at the interface).[200-202]

Integration With Titanium and Alloys

Although titanium is known to exhibit better corrosion resistance, independent of the surface preparation, in vivo and in vitro studies have shown that titanium may interact with the recipient living tissues over several years. This interaction results in the release of small quantities of corrosion products even though a thermodynamically stable oxide film exists.

Several studies have concentrated on the behavior of titanium and titanium alloys in simulated biological environments. Williams[36] cautioned that although titanium can demonstrate excellent properties of its tenacious oxide film, it is usually not sufficiently stable to prevent wear and galling in bearing systems under load. Some situations have resulted in metal-to-metal contact and local welding.

Solar et al.[203] stated that under static conditions, titanium and titanium alloy should withstand exposure to physiologic chlorine solutions at body temperature indefinitely but would be susceptible to oxide changes caused by mechanical micromotion.

Bundy et al.[204] exposed implant alloys simultaneously to tensile stress and corrosive environments (stress-applied conditions). In vivo, stainless-steel and titanium alloy demonstrated crack-like features when loaded to yield stress and then reimplanted under laboratory conditions for 8 weeks. Crack-like features also were seen in stainless-steel and titanium alloy loaded to or beyond the yield stress and subsequently electrochemically polarized for 38 weeks in the in vitro part of the study. None of the samples actually failed by completely cracking, but the authors presumed that it would have occurred with a longer exposure time, as previously suggested.[36,205]

Geis Gerstorfer and Weber[39] used linear polarization methods to show that titanium showed minimal breakdown in simulated tissue fluids, whereas Ni-Ti showed rapid breakdown of passivity with increased chlorine product–related concentrations in unbuffered solutions. Therefore body fluids could be responsible for the dissolution of some metallic passive oxide films.[206]

Lemons[75] studied single-stage solid implants modified by bending or cutting, and showed that damage could increase corrosion.

Rostoker and Pretzel[207] studied couple corrosion in vitro for alloys and found that dissimilar metals in a combined prosthesis did not create a regional breakdown of the titanium passive layer. A second in vivo study evaluated couple and crevice corrosion of prosthetic alloys in vertebral muscles of dogs for 30 weeks (non-load-bearing, nonosseointegrated).[208] It was concluded that metals of superior corrosion resistance, such as titanium alloy, and wrought cobalt alloys can be combined with titanium alloy in one prosthesis to provide superior mechanical performance without creating additional corrosion. However, repeated oxide breakdown such as sustained abrasion was likely to damage the corrosion resistance of an alloy for any type of coupling.

Results from Thompson et al.[209] did not predict accelerated corrosion for titanium alloy coupled to carbon for galvanic couples under static conditions.

Marshak and colleagues[210,211] studied the potential for existence of SCC, GC, and FC in an in vitro study of titanium alloy and gold alloy abutment implants and abutment complexes simultaneously submitted to a laterally oriented 10-kg loading and a simulated tissue fluid solution at 37°C. SCC was studied in the most likely area, that is, the screw-to-abutment connection, which was under constant and simultaneous tension and compression stresses. These studies showed possibilities for interactions at contact regions between the cast gold and titanium alloy and components under selected environmental conditions.

Cohen and Burdairon[212] showed that odontologic fluoride gels, which create an acidic environment, could lead to the degradation of the titanium oxide layer and possibly inhibit the osseointegration process. Deposits consistent with the presence of GC by-products were detected on various surfaces of the experimental metal.[213,214] Liles et al.[215] investigated the GC between titanium and seven crown and bridge alloys in 1% sodium chloride (NaCl) solution. The nonprecious Ni-Co complex was likely to trigger GC. Clinically this means that in the short term, the presence of the surface impurities such as iron found on some implant parts, as well as other contaminants related to the machining process, could result in loss of bone and integration in crestal areas exposed to corrosion products. The long-term presence of corrosion reaction products and ongoing corrosion could also lead to fracture of the affected alloy–abutment interface, the abutment, or possibly the implant body itself. This combination of stress and corrosion, possibly together with factors associated with bacteria, could be one of the reasons why implants fail at the local or individual levels rather than in a generalized fashion.[216] Protocols for manufacturing and cleaning prosthetic titanium parts (specifically abutments that contact the implant body) appear less stringent than those for implant bodies. This should not be the case, and the same standards should be applied to both implant body and prosthetic components. In addition, the short and longer clinical implications of the potential GC effect could be ideally nullified by the use of electrochemically compatible alloys for the superstructure.

Cobalt and Iron Alloys

The alloys of cobalt (Vitallium) and iron (surgical stainless steel—316L) exhibit oxides of chromium (primarily Cr_2O_3 with some suboxides) under normal implant surface–finishing conditions after acid or electrochemical passivation. These chromium oxides, as with titanium and alloys, result in a significant reduction in chemical activity and environmental ion transfers. Under normal conditions of acid passivation, these chromium oxides are relatively thin (nanometer dimensions) and have an amorphous atomic structure. The oxide atomic spatial arrangement can be converted to a crystalline order by elevated temperature or electrochemical exposures.

The chromium oxides on cobalt and iron alloys are microscopically smooth, and again, roughness is usually introduced by substrate processing (grinding, blasting, or etching). Because these oxides, similar to titanium oxides, are very thin (nanometer dimensions), the reflected light color of the alloys depends on the metallic substrate under the oxide.[33] However, as mentioned earlier, the titanium, cobalt, and iron metallic systems depend on the surface reaction zones with oxygen (oxides) for chemical and biochemical inertness.

The cobalt and iron alloy bulk microstructures are normally mixtures of the primary alloy phases with regions of metallic carbides distributed throughout the material.[33,56,76,77] Along the surfaces the chromium oxide covers the matrix phase (metallic regions), whereas the carbides stand as secondary components (usually as mounds above the surface) at the microscopic level. In contrast with homogenization-annealed alloys, the as-cast cobalt alloys exhibit multiphasic characteristics within their microstructure, with relatively extensive regions of the alloy surfaces occupied by complex metallic carbides. Thus tissue-to-oxide and tissue-to-metallic carbide zones could be used to describe tissue integration of cobalt alloy. This is uniquely different compared with titanium implant biomaterials, where tissue-to-oxide regions predominate at the interface.[76,77]

The iron-based alloy chromium oxide and substrate are more susceptible to environmental breakdown, in comparison with cobalt- and titanium-based biomaterials. This has been discussed in the literature related to crevice and pitting corrosion biodegradation phenomena for stainless-steel implant systems.[59,76,77] In general, if stainless steel implant surfaces are mechanically altered during implantation, or if the construct introduces an interface that is subjected to biomechanical fretting, then the iron alloy will biodegrade in vivo, and the fatigue strength of surgical stainless steel can be significantly decreased in a corrosive environment.[217] In some cases this has resulted in implant loss. However, in the absence of surface damage, the chromium oxides on stainless steel biomaterials have shown excellent resistance to breakdown, and

multiple examples of tissue and host biocompatibility have been shown for implants removed after long-term (beyond 30 years in vivo) implantations.

Dental implants and implant abutments have also been fabricated from gold alloy, with many abutments fabricated from palladium or Co-Cr-Ni-Mo alloys.[37] The minimally alloyed gold and palladium systems are noble electrochemically and do not depend on surface oxides for chemical and biochemical inertness. This would be the case for the high noble alloys (major compositions of gold, platinum, palladium, iridium, and ruthenium). However, some palladium alloys and other lower noble element content alloys gain chemical and biochemical inertness from complex metallic surface oxides.[37] As mentioned earlier, the multicomponent (wrought) cobalt-based alloys, as with other base-metal systems, depend on chromium oxide surface conditions for inertness. In general the noble-metal alloys do not demonstrate the same characteristics of tissue interaction compared with the base-metal (Ti and Co alloy) systems. The ultrastructural aspects of tissue integration have not been extensively investigated for noble-alloy systems, although some have presented results describing osteointegration of gold alloys. The noble alloys, when used in a polished condition, are resistant to debris accumulation on a relative basis compared with other alloys. This has been listed as an advantage for their use in intraoral abutment systems. In addition, mechanical finishing of the more noble alloys can result in a high degree of polish and a minimal concern about damaging or removing surface oxides.

Ceramics

Al_2O_3 ceramics have been extensively investigated related to surface properties and how these properties relate to bone and soft tissue integration.[92,93,104-116,154] Al_2O_3 ceramics are fully oxide materials (bulk and surface), thereby affording advantages related to tissue interface–related investigation. In addition, studies have included the polycrystalline (alumina) and single-crystalline (sapphire) forms of the oxide structure. These forms have introduced very different surface roughness values for the same material substrate plus bulk properties where ion transfer and electrochemical phenomena are minimal influences. Bone and soft tissue integration have been demonstrated for this oxide material over the long term in humans and laboratory animals. Direct relationships have been established between the interfacial events of tissue integration for metallic surface oxides of titanium and chromium and the Al_2O_3 systems. As mentioned previously, surface quality can be directly correlated with tissue integration and clinical longevity. Because the Al_2O_3 ceramics are crystalline and extend throughout the surface and bulk zones, biomechanical instabilities do not alter the chemical aspects of biomaterial properties. (No electrochemical change is introduced if the surface is removed.) Ceramic coatings (e.g., Al_2O_3) have been shown to enhance the corrosion resistance and biocompatibility of metal implants, in particular surgical stainless steel and Ni-Cr, Co-Cr alloys.[218] However, the Ni-Cr and steel alloys can be subject to crevice corrosion. Studies in orthopedics caution that the Al_2O_3 coating may cause a demineralization phenomenon caused by a high local concentration of substrate ions in the presence of metabolic bone disease.[219] This remains to be established within the use of Al_2O_3 implants for clinical applications.

Hydroxyapatite

In addition to the bulk Al_2O_3 biomaterials, $CaPO_4$-based ceramic or ceramic-like coatings have been added to titanium and cobalt alloy substrates to enhance tissue integration and biocompatibility. These coatings, for the most part, are applied by plasma spraying small-size particles of crystalline HA ceramic powders. The process of coating and the coating dimensions and property characteristics are addressed further in the next section.

The surface topography is characteristic of the preparation process. Variations in the roughness and porosity of the surface (<100 mm) can be categorized in function of the surfacing process. Machined implants exhibit an irregular surface with grooves, ridges, and pits, including a nanometer scale.[220,221] Proponents of such a surface argue that it is the most conducive to cell attachment[159-161] (Fig. 5.8).

Surface roughening by particulate blasting can be achieved by different media. Sandblasting provides irregular rough surfacing with <10-mm scales and a potential for impurity inclusions. Researchers used a titanium alloy Ti-6Al-4V to improve the mechanical properties and elected to electropolish the surface to reduce surface roughness to be only in the 0.1-mm scale by controlled removal of the surface layer by dissolution.[220,222,223] Titanium implants may be etched with a solution of nitric and hydrofluoric acids to chemically alter the surface and eliminate some types of contaminant products (Fig. 5.9). The acids rapidly attack metals other than titanium, and these processes are electrochemical in nature. Proponents of this technique argue that implants treated by sandblasting and acid etch provide superior radiographic bone densities along implant interfaces compared

with titanium plasma-sprayed surfaces.[224] Recently, concerns have been expressed regarding embedded media from glass beading (satin finish) and grit blasting (alumina Al_2O_3), and a possible risk for associated osteolysis caused by foreign debris.[225,226] Ricci et al.[226] reported on failed retrieved implants that exhibited extensive surface inclusions consisting of silicon and/or Al_2O_3-related product, which were also present in the surrounding tissues. A relatively new process (resorbable blast media) has been said to provide a comparable roughness to an alumina grit blast finish, which can be a rougher surface than the machined, glass-beaded, or acid-etched surfaces (Fig. 5.10).[227]

Porous and Featured Coatings

The implant surface may also be covered with a porous coating. These may be obtained with titanium or HA particulate–related fabrication processes. Examples of coatings and processes for producing surface-modified implants are summarized in the following sections.

Titanium Plasma Sprayed

Porous or rough titanium surfaces have been fabricated by plasma spraying a powder form of molten droplets at high temperatures. At temperatures in the order of 15,000°C, an argon plasma is associated with a nozzle to provide very high-velocity (600 m/sec) partially molten particles of titanium powder (0.05- to 0.1-mm diameter) projected onto a metal or alloy substrate.[63,228] The plasma-sprayed layer after solidification (fusion) is often provided with a 0.04- to 0.05-mm thickness. When examined microscopically, the coatings show round or irregular pores that can be connected to each other (Fig. 5.11). Hahn and Palich[229] first developed these types of surfaces and reported bone ingrowth in titanium hybrid powder plasma spray–coated implants inserted in animals. Karagianes and Westerman[230] assessed the suitability of porous titanium and titanium alloy to achieve bone–implant bonding characteristics in miniature swine and likened it to a three-dimensional surface. Kirsch[157] conducted histologic studies for plasma flame-sprayed particulate titanium coating root form specimen (IMZ) implanted and integrated to the bone in dogs, with complete integration reported at 6 weeks. In animal experiments and histologic studies, Schroeder et al.[231] concluded that the rough and porous surfaces showed a three-dimensional, interconnected

configuration likely to achieve bone–implant attachment for stable anchorage. Other animal studies concluded that a porous titanium surface from various fabrication methods may increase the total surface area (up to several times), produce attachment by osteoformation, enhance attachment by increasing ionic interactions, introduce a dual physical and chemical anchor system, and increase the load-bearing capability 25% to 30%.[100,157,232-237] In vitro studies of fibroblast attachment conducted by Lowenberg et al.[238] showed superior attachment to surface-ground titanium alloy disks compared with porous titanium but with a better cell orientation on porous forms of titanium.

In 1981 Clemow et al.[239] showed that the rate and percentage of bone ingrowth into the surface was inversely proportional to the square root of the pore size for sizes greater than 100 mm and that the shear properties of the interface were proportional to the extent of bone ingrowth. The optimum pore size for bone ingrowth was determined in a study of cobalt-base alloy porous implants inserted in canine femurs. The optimum pore size was deduced from the maximum fixation strength measurements. These surface porosities ranged from 150 to 400 mm and coincidentally correspond to surface feature dimensions obtained by some plasma-spraying processes.[240-243] In addition, porous surfaces can result in an increase in tensile strength through ingrowth of bony tissues into three-dimensional features. High shear forces determined by the torque-testing methods and improved force transfer into the peri-implant area have also been reported.[244,245]

In 1985 at the Brussels Osseointegration Conference, the basic science committee did not present results that showed any major differences between smooth, rough, or porous surfaces regarding their ability to achieve osseointegration. However, proponents of porous surface preparations reported that there have been results showing faster initial healing compared with noncoated porous titanium implants and that porosity allows bone formation within the porosities even in the presence of some micromovement during the healing phase.[246,247] Such surfaces were also reported to allow the successful placement of shorter-length implants compared with noncoated implants. The basic theory was based on increased area for bone contact. Reports in the literature caution about cracking and scaling of coatings because of stresses produced by elevated temperature processing[248,249] and risk for accumulation of abraded material in the interfacial zone during implanting of titanium plasma-sprayed implants. It may be indicated to

restrict the limit of coatings in lesser bone densities that cause less frictional torque transfer during the implant placement process. In addition, the present technology allows metallurgic bonding of coatings and a high resistance against mechanical separation of the coating, with many coating test values exceeding the published standard requirements.[250]
Hydroxyapatite Coating

HA coating by plasma spraying was brought to the dental profession by deGroot.[92] Kay et al.[251] used scanning electron microscopy and spectrographic analyses to show that the plasma-sprayed HA coating could be crystalline and could offer chemical and mechanical properties compatible with dental implant applications. Block et al.[252] and Thomas et al.[253] showed an accelerated bone formation and maturation around HA-coated implants in dogs compared with noncoated implants. HA coating can also reduce the corrosion rate of the same substrate alloys.[254] Researchers measured the HA coating thickness after retrieval from specimens inserted in animals for 32 weeks, and it showed a consistent thickness of 50 mm, which is in the range advocated for manufacturing.[19,89,255,256] The bone adjacent to the implant has been reported to be better organized than with other implant materials and with a higher degree of mineralization.[257] In addition, numerous histologic studies have documented the greater surface area of bone apposition to the implant in comparison with uncoated implants,[252,258,259] which may enhance the biomechanics and initial load-bearing capacity of the system. HA coating has been credited with enabling HA-coated titanium or titanium alloy implants to obtain improved bone–implant attachment compared with machined surfaces.

Studies also demonstrated that the HA–bone attachment is superior to the HA–implant interface.[253,255,256] However, proponents of such surfaces report excellent reliability of HA-coated implants.[260,261] The most significant result is the increase in bone penetrations, which enhances fixation in areas of limited initial bone contact.[37,40,41,262] However, controversies still exist, and some authors caution that HA coatings do not necessarily represent an advantage for the long-term prognosis of the system.

Implants of solid sintered HA have been shown to be susceptible to fatigue failure.[98,256,263] This situation can be altered by the use of a CPC coating along metallic substrates. Although several methods may be used to apply CPC coatings, the majority of commercially available implant systems are coated by a plasma spray technique. A powdered crystalline HA is introduced and melted by the hot, high-velocity region of a plasma gun and propelled onto the metal implant as a partially melted ceramic (Fig. 5.12).[108,228] One of the concerns regarding CPC coatings is the strength of the bond between the CPC and the metallic substrate. Investigative ion beam–sputtering coating techniques for CPC or CPC-like nonresorbable coatings to varied substrates appear to produce dense, more tenacious, and thinner coatings (a few micrometers), which would minimize the problem of poor shear strength and fatigue at the coating–substrate interface.[108] Recent reports have introduced a new type of treatment for coatings, which appear primarily amorphous in nature, and further in vivo studies are needed to determine tissue response.[264,265] Other investigations include developing new biocompatible coatings based on TCP or titanium nitride.[266]

It has been shown that the plasma-spraying technique can alter the nature of the crystalline ceramic powder and can result in the

● **Fig. 5.12** Hydroxyapatite (HA) coatings on implant surface provide several clinical properties because of the osteoconductive properties of HA (scanning electron microscopy of BioHorizons D4 implant; ×500).

deposition of a variable percentage of a resorbable amorphous phase.[267] A dense coating with a high crystallinity has been listed as desirable to minimize in vivo resorption. In addition, the deposited CPC may be partially resorbed through remodeling of the osseous interface.[28,268,269] It is therefore wise to provide a biomechanically sound substructure design[267,268] that is able to function under load-bearing conditions to compensate for the potential loss of the CPC coating over years. In addition, the CPC coatings may resorb in infected or chronic inflammation areas. Animal studies also show reductions in coating thickness after in vivo function.[270] One advantage of CPC coatings is that they can act as a protective shield to reduce potential slow ion release from the Ti-6Al-4V substrate.[271] In addition, the interdiffusion between titanium and calcium (and phosphorus and other elements) may enhance the coating substrate bond by adding a chemical component to the mechanical bond.[269,272-275]

When these coatings were introduced in the 1990's., many researchers expressed concerns about the biomechanical and gingival sulcus area biochemical stabilities. It was recommended that national and international standards for these coatings be developed, in part to provide detailed description of coating properties using consistent and uniform (standardized) test methods. Initial national standards were developed for *Beta Tricalcium Phosphate for Surgical Implantation by the ASTM Committee F4* (ASTM F4-1088). A standard specification for *Composition of Ceramic Hydroxyapatite for Surgical Implants* (ASTM F4-1185) was developed, and additional standards have been more recently approved, including *Glass and Glass-Ceramic Biomaterials for Implantation* (ASTM F4-1538), *Standard Test Method for Tension Testing of Calcium Phosphate Coatings* (ASTM F4-1501 F1147-05), *Standard Test Method for Calcium Phosphate Coatings for Implantable Materials* (ASTM F4-1609), *Test Method for Bending and Shear Fatigue Testing of Calcium Phosphate Coatings on Solid Metallic Substrates* (ASTM F4-1659 1160), and a *Standard Test Method for Shear Testing of Calcium Phosphate Coatings* (ASTM F4-1658 1044).[19] Additional standards being developed at the task-group level with ASTM F4 include *Calcium Phosphate Coating Crystalline Characteristics, Mechanical Requirements for Calcium Phosphate Coatings,* and *Environmental Stability of Calcium Phosphate Coatings F1926.* An additional standard on anorganic bone (ASTM F4-1581) has also been established within the ceramics subcommittee of ASTM F4.[19] These national and related international standards

(ISO) should provide basic property information for CaPO$_4$ materials and coatings. This information should prove most useful as longer-term investigations on biocompatibility are conducted for dental implant systems.

In addition, national and international standards have been established for the surgical implant alloys, bulk ceramics, and surface finishing of metallic biomaterials. The concerns related to CaPO$_4$ coatings have focused on: (1) the biomechanical stability of the coatings and coating–substrate interface under in vivo conditions of cyclic loading, and (2) the biochemical stability of these coatings and interfaces within the gingival sulcus (especially in the presence of inflammation or infection) and during enzymatic processes associated with osteoclasis remodeling of the bone–coating interfacial zones. Some of these questions were addressed at an ASTM symposium on CaPO$_4$ coatings, and some researchers related that the longer-term clinical studies (less than 10 years' experience) do not support reasons for concern. It will be interesting to reevaluate these questions and answers after 20 years of clinical experience.

Other Surface Modifications

Surface modification methods include controlled chemical reactions with nitrogen or other elements or surface ion implantation procedures. The reaction of nitrogen with titanium alloys at elevated temperatures results in titanium nitride compounds being formed along the surface. These nitride surface compounds are biochemically inert (like oxides) and alter the surface mechanical properties to increase hardness and abrasion resistance. Most titanium nitride surfaces are gold in color, and this process has been used extensively for enhancing the surface properties of industrial and surgical instruments.[19] Increased hardness, abrasion, and wear resistance can also be provided by ion implantation of metallic substrates. The element most commonly used for surface ion implantation is nitrogen. Electrochemically the titanium nitrides are similar to the oxides (TiO$_2$), and no adverse electrochemical behavior has been noted if the nitride is lost regionally. The titanium substrate reoxidizes when the surface layer of nitride is removed. Nitrogen implantation and carbon-doped layer deposition have been recommended to improve the physical properties of stainless steel without affecting its biocompatibility.[276] Again, questions could be raised about coating loss and crevice corrosion.

Surface Cleanliness

A clean surface is an atomically clean surface with no other elements than the biomaterial constituents. Contaminants can be particulates, continuous films (e.g., oil, fingerprints), and atomic impurities or molecular layers (inevitable) caused by the thermodynamic instability of surfaces. Even after reacting with the environment, surfaces have a tendency to lower their energy by binding elements and molecules. The typical composition of a contaminated layer depends on atmospheres and properties of surface. For example, high-energy surfaces (metals, oxides, ceramics) usually tend to bind more to this type of monolayer than polymers and carbon (amorphous).

In the earlier times of dental implantology, no specific protocol for surface preparation, cleaning, sterilization, and handling of the implants was established.[277] Researchers have respectively demonstrated adverse host responses caused by faulty preparation and sterilization, omission to eliminate adsorbed gases, and organic and inorganic debris.[159,160,174,278] According to Albrektsson,[177] implants that seem functional may fail even after years of function, and the cause may be attributed to improper ultrasonic cleaning, sterilization, or handling during the surgical placement.

A systematic study of contamination layers is not available. Lausmaa et al.[161] showed that titanium implants had large variations in carbon contamination loads (20%–60%) in the 0.3- to 1-nm thickness range, attributed to air exposure and residues from cleaning solvents and lubricants used during fabrication. Trace amounts of Ca, P, N, Si, S, Cl, and Na were noted from other studies.[169,170,278-280] Residues of fluorine could be attributed to passivation and etching treatments; Ca, Na, and Cl to autoclaving; and Si to sand and glass-beading processes.

Surface Energy

Measurements of surface property values of an implant's ability to integrate within bone include contact angle with fluids, local pH, and surface topography. These are often used for the determination of surface characteristics. Numerous studies were conducted to evaluate liquid, solid, and air contact angles, wetting properties, and surface tensions as criteria to assess surface cleanliness, because these parameters have been shown to have a direct consequence on osseointegration.[12,281,282] An intrinsically high surface energy is said to be most desirable. High surface energy implants showed a threefold increase in fibroblast adhesion, and higher-energy surfaces such as metals, alloys, and ceramics are best suited to achieve cell adhesion.[12] Surface tension values of 40 dyne/cm and higher are characteristic of very clean surfaces and excellent biological integration conditions.[281] A shift in contact angle (increase) is related to the contamination of the surface by hydrophobic contaminants and decreases the surface tension parameters. Because a spontaneously deposited, host-dependent conditioning film is a prerequisite to the adhesion of any biological element, it is suggested that the wetting of the surface by blood at the time of placement can be a good indication of the high surface energy of the implant.[281]

Passivation and Chemical Cleaning

ASTM International (ASTM B600, ASTM F-86) specifications for final surface treatment of surgical titanium implants require pickling and descaling with molten alkaline base salts. This is often followed by treatment with a solution of nitric or hydrofluoric acid to decrease and eliminate contaminants such as iron. Iron or other elements may contaminate the implant surface as a result of the machining process. This type of debris can have an effect of demineralizing the bone matrix.[283,284] However, these finishing requirements remain very general. Studies of fibroblast attachment on implant surfaces showed great variations, depending on the different processes of surface preparation. Inoue et al.[181] showed that fibroblasts developed a capsule or oriented fibrous attachment following the grooves in titanium disks. Contact angles are also greatly modified by acid treatment or water rinsing.[285] Machining operations, polishing, texturing process, residual chemical deposits, and alloy microstructure all inadvertently affect the surface composition. In addition, many ways exist to intentionally modify the surface of the implant. They include conventional mechanical treatment (sandblasting), wet or gas chemical reaction treatment, electroplating or vapor plating, and ion beam processing, which leaves bulk properties intact and has been newly adapted to dentistry from thin film technology. Preliminary studies by Schmidt[286] and Grabowski et al.[287] showed modified fibroblast adhesion on nitrogen and carbon-ion implanted titanium. A general rule has been that cleaner is better.

Sterilization

Manipulation with bare fingers or powdered gloves, tap water, and residual vapor-carried debris from autoclaving can all contaminate implant surfaces. Baumhammers,[277] in a scanning electron microscopy study of dental implants, showed contamination of the surface with acrylic materials, powder from latex gloves, and bacteria. Today, in most cases, the manufacturer guarantees precleaned and presterilized implants with high-technology procedures, with the implants ready to be inserted. If an implant needs to be resterilized, then conventional sterilization techniques are not normally satisfactory. It appears at the present time that no sterilization medium is totally satisfactory for all biomaterials and designs. Metal or alloy constituents, inorganic and organic particles, corrosion products, polymers, and precipitates can be absorbed at the surface throughout the manufacturing, polishing, cleaning, sterilization, packaging, and storage processes. Baier et al.[12] correlated the usual type of contaminant found in relation to the sterilization technique used. Baier and Meyer[281] showed that steam sterilization can cause deposits of organic substances resulting in poor tissue adhesion. Doundoulakis[169] submitted titanium samples to different sterilization techniques, concluded the adverse effect of steam sterilization and degradative effect of endodontic glass bead sterilizers, found that dry heat sterilization leaves organic deposits on the surface, and suggested that ultraviolet (UV) light sterilization may become a good alternative after further evaluation. In addition, accelerated oxide growth on titanium may occur with impurity contamination leading to surface discoloration.[32,159,288] In a study by Keller et al.,[289] corrosion products and films from autoclaving, chemicals, and cytotoxic residues from solutions were identified at the surface of implants submitted to sterilization. They suggested that alteration of the titanium surface by sterilization methods may in turn affect the host response and adhesive properties of the implant. In contrast, Schneider et al.[290] compared the surface of titanium plasma-sprayed and HA-coated titanium implants after steam or ethylene dioxide sterilization using energy-dispersive radiograph analysis and concluded that these techniques do not modify the elemental composition of the surface. Keller and colleagues[291] studied the growth of fibroblasts on disks of commercially pure titanium sterilized by autoclaving, ethylene oxide, ethyl alcohol, or solely passivated with 30% nitric acid, and concluded that sterilization seems to inhibit cell growth, whereas passivation does not.

Presently, proteinaceous deposits and their action as films can be best eliminated by the radiofrequency glow discharge technique (RFGDT), which seems to be a suitable final cleaning procedure. The implants are treated within a controlled noble-gas discharge at very low pressure. The gas ions bombard the surface and remove surface atoms and molecules, which are absorbed onto it or are constituents of it. However, the quality of the surface treated depends on the gas purity. Baier and Glantz[292] showed that RFGDT is good for cleaning and, at the same time, for granting a high-energy state to the implant, which is related to improved cell adhesion capabilities. Thinner, more stable oxide films and cleaner surfaces have been reported with RFGDT plus improved wettability and tissue adhesion.[292-294] The principal oxide at the surface is unchanged by the RFGDT process.[295] A decrease in bacteria contamination on HA-coated implant surfaces was reported after RFGDT,[296] and studies suggest that RFGDT may enhance calcium and/or phosphate affinity because of an increase in elemental zone at the surface resulting in the formation of amorphous $CaPO_4$ compounds.[294]

Recently a modified UV light sterilization protocol was shown to enhance bioreactivity, which was also effective for eliminating some biological contaminants. Singh and Schaaf[297] assessed the quality of UV light sterilization and its effects on irregularly shaped objects, and they established its effectiveness on spores and its ability to safely and rapidly clean the surface and to grant high surface energy. Hartman et al.[298] submitted implants to various pretreatment protocols (RFGDT, UV light, or steam sterilization) and inserted them in miniature swine. Although RFGDT- and UV-sterilized implants showed rapid bone ingrowth and maturation, steam-sterilized implants seemed to favor thick collagen fibers at the surface. In contrast, Carlsson et al.[299] inserted implants in rabbits and compared the performances of conventionally treated implants with implants treated with RFGDT, found similar healing responses, and further cautioned that the RFGDT process produces a much thinner oxide layer at the surface of the implant and may deposit silica oxide from the glass envelope.

Adequate sterilization of clean, prepackaged dental implants and related surgical components has resulted in an ever-expanding use of gamma radiation procedures. Because gamma radiation sterilization of surgical implants is a well-established methodology within the industry, facilities, procedures, and standards are well known. Most metallic systems are exposed to radiation doses exceeding 2.5 Mrad, where the packaging and all internal parts of the assembly are sterilized. This is an advantage in that components remain protected, clean, and sterile until the inner containers are opened within the sterile field of the surgical procedure. The healing screws, transfer elements, wrenches, and implants are all exposed to the gamma sterilization, which reduces opportunities for contamination.

Some ceramics can be discolored and some polymers degraded by gamma radiation exposures. The limits are known for classes of biomaterials, and all types of biomaterials can be adequately sterilized within the industry. Systems control, including prepackaging and sterilization, has been an important part of the success of dental implantology.

Summary

In the 1960s dental implantology as a clinical discipline was judged by some to be rather disorganized, and treatments provided were often said to be not as successful as hospital-based orthopedic and cardiovascular surgery procedures. One part of this opinion related to the use of standard intraoral dental materials for implants plus general dental operatories for surgical activities (e.g., no gloves, high-speed drills, tap water). The biomaterials discipline evolved rapidly in the 1970s. Successful uses of synthetic biomaterials have been based on experience within the field of dental implantology. The basis for many of the newer and more clinically successful surgical reconstructions evolved within dentistry, with some now recognized as the most successful types of musculoskeletal reconstructive surgery. The biomaterials discipline therefore has evolved significantly since the 1990's, and synthetic biomaterials are now constituted, fabricated, and provided to health care professionals as mechanically and chemically clean devices that have a high predictability of success when used appropriately within the surgical disciplines. This chapter on biomaterials has been separated into sections related to bulk and surface properties of biomaterials, and emphasis has been placed on the published literature on how these biomaterial properties relate to interactions at the tissue interface.

Surface characterization and working knowledge about how surface and bulk biomaterial properties interrelate to dental implant biocompatibility profiles represent an important area in implant-based reconstructive surgery. This chapter has provided summary information on surface and bulk properties for metallic, ceramic, and surface-modified biomaterials. The authors strongly recommend the reference material listed, in addition to a desire to have investigators always provide biomaterial surface and bulk property information as a component of any research studies on tissue response (biocompatibility) profiles.

PART II

Biomechanical Properties of Dental Implants

6

Clinical Biomechanics in Implant Dentistry

MARTHA WARREN BIDEZ AND CARL E. MISCH†

The discipline of biomedical engineering, which applies engineering principles to living systems, has unfolded a new era in diagnosis, treatment planning, and rehabilitation in patient care. One aspect of this field, biomechanics, concerns the response of biological tissues to applied loads. Biomechanics uses the tools and methods of applied engineering mechanics to search for structure–function relationships in living materials.[1] Advancements in prosthetic, implant, and instrumentation design have been realized because of mechanical design optimization theory and practice.[2] This chapter provides fundamental concepts and principles of dental biomechanics as they relate to long-term success of dental implants and restorative procedures.

Loads Applied to Dental Implants[i]

Dental implants are subjected to occlusal loads when placed in function. Such loads may vary dramatically in magnitude, frequency, and duration depending on the patient's parafunctional habits. Passive mechanical loads also may be applied to dental implants during the healing stage because of mandibular flexure, contact with the first-stage cover screw, and second-stage permucosal extension.

Perioral forces of the tongue and circumoral musculature may generate low but frequent horizontal loads on implant abutments. These loads may be of greater magnitude with parafunctional oral habits or tongue thrust. Finally, application of nonpassive prostheses to implant bodies may result in mechanical loads applied to the abutment, even in the absence of occlusal loads. So many variables exist in implant treatment that it becomes almost impossible to compare one treatment philosophy with another. However, basic units of mechanics may be used to provide the tools for the consistent description and understanding of such physiologic (and nonphysiologic) loads. Two different approaches may render a similar short-term result; however, a biomechanical approach can still determine which treatment renders more risk over the long term.

Mass, Force, and Weight

Mass, a property of matter, is the degree of gravitational attraction the body of matter experiences. As an example, consider two cubes composed of hydroxyapatite (HA) and commercially pure

†Deceased.

titanium, respectively. If the two cubes are restrained by identical springs, then each spring will deflect by a certain amount relative to the attraction of gravity for the two cubes. The two spring deflections in this example can be made equal by removing part of the material from the titanium cube. Even though the cubes are of completely different composition and size, they can be made equivalent with respect to their response to the pull of gravity. This innate property of each cube that is related to the amount of matter in physical objects is referred to as *mass.* The unit of mass in the metric (International System of Units) system is the kilogram (kg); in the English system, it is the pound mass (lbm).[3]

In 1687, Sir Isaac Newton described a force in what is now referred to as *Newton's laws of motion.*[3] In his second law, Newton stated that the acceleration of a body is inversely proportional to its mass and directly proportional to the force that caused the acceleration. The familiar relation expresses this law:

$$F = ma$$

where *F* is force (newtons [N]), *m* is mass (kg), and *a* is acceleration (meters per second squared [m/s^2]). In the dental implant literature, force commonly is expressed as kilograms of force. The gravitational constant ($a = 9.8$ m/s^2) is approximately the same at every location on Earth; therefore mass (kilograms) is the determining factor in establishing the magnitude of a static load.

Weight is simply a term for the gravitational force acting on an object at a specified location. Weight and force can be expressed by the same units, newtons or pound force (lbf). If a titanium cube is considered as though placed on the moon, then its weight (force caused by gravity) is different from its weight on the Earth. The mass in the cube has not changed, but the *acceleration caused by gravity* has changed. Recalling Sir Isaac Newton's work, an apple weighs approximately 1 N (0.225 lbf). The reader will find the conversion factors in Box 6.1 useful.[4]

Forces

Forces may be described by magnitude, duration, direction, type, and magnification factors. Forces acting on dental implants are referred to as *vector quantities;* that is, they possess magnitude and direction. Restated, to state simply that "a force of 75 lb exists on the distal abutment" is not sufficient. The more correct statement is "a force of 75 lb exists on the distal abutment directed axially along the long axis of the implant body." The dramatic influence of load direction on implant

longevity and bone maintenance is discussed later in this chapter and in other chapters. Typical maximum bite force magnitudes exhibited by adults are affected by age, sex, degree of edentulism, bite location, and especially parafunction[5-9] (Table 6.1).

A force applied to a dental implant rarely is directed absolutely longitudinally along a single axis. In fact, three dominant clinical loading axes exist in implant dentistry: (1) mesiodistal, (2) faciolingual, and (3) occlusoapical (Fig. 6.1). A single occlusal contact most commonly results in a three-dimensional occlusal force. Importantly, this three-dimensional force may be described in terms of its component parts (fractions) of the total force that are directed along the other axes. For example, if an occlusal scheme on an implant restoration is used that results in a large magnitude of force component

directed along the faciolingual axis (lateral loading), then the implant is at extreme risk for fatigue failure (described later in this chapter). The process by which three-dimensional forces are broken down into their component parts is referred to as *vector resolution* and may be used routinely in clinical practice for enhanced implant longevity.

Components of Forces (Vector Resolution)

Occlusion serves as the primary determinant in establishing load direction. The position of occlusal contacts on the prosthesis directly influences the type of force components distributed throughout the implant system.

The dentist should visualize each occlusal contact on an implant restoration in its component parts. Consider the example of a restored dental implant subjected to a premature contact during occlusion. When the contact is broken down into its component parts directed along the three clinical loading axes, a large, potentially dangerous lateral component is observed. Occlusal adjustments consistent with implant protective occlusion to eliminate the premature contact minimize the development of such dangerous load components.

Angled abutments also result in development of dangerous transverse force components under occlusal loads in the direction of the angled abutment. Implants should be placed surgically to provide for mechanical loading down the long axis of the implant body to the maximum extent possible. Angled abutments are used to improve esthetics or the path of insertion of a restoration, not to determine the direction of load.

Three Types of Forces

Forces may be described as compressive, tensile, or shear. Compressive forces attempt to push masses toward each other. Tensile

---

• BOX **6.1**   **Useful Conversion Factors**

Mass
   1 kg = 2.205 lbm
   1 lbm = 0.45 kg
Force
   1 N = 1 kg(m/s^2) = 0.225 lbf
   1 lbf = 4.448 N
Area
   1 m^2 = 10.764 sq ft
   1 sq ft = 0.093 m^2
   1 sq in = 6.452 × 10^{-4} m^2
Pressure[a]
   1 lbf/sq in (psi) = 144 lbf/sq ft = 6894.8 Pa = 6.89 kPa = 0.0069 MPa
   1 Pa = 1 N/m^2 = 1.450 × 10^{-4} psi = 0.021 lbf/sq ft

[a]Stress uses these same units of measurement.
lbf, Pounds force; lbm, pound mass; psi, pounds per square inch.

TABLE 6.2	Cortical Bone Strengths in Human Femur Specimens	
Type of Force Applied	**Strength (MPa)[a]**	**Load Direction/ Comments**
Compressive	193.0 (13.9)	Longitudinal
	173.0 (13.8)	30° off axis
	133.0 (15.0)	60° off axis
	133.0 (10.0)	Transverse
Tensile	133.0 (11.7)	Longitudinal
	100.0 (8.6)	30° off axis
	60.5 (4.8)	60° off axis
	51.0 (4.4)	Transverse
Shear	68.0 (3.7)	Torsion

[a]Standard deviations are listed in parentheses.

From Reilly DT, Burstein AH. The elastic and ultimate properties of compact bone tissue. *J Biomech.* 1975;8:393.

F = resultant force

F_N = normal component

F_S = shear or tangential component
• **Fig. 6.2** Force can be resolved into a combination of normal and shear force components in a given plane. Depending on the direction of load application, the same magnitude of force has different effects.

forces pull objects apart. Shear forces on implants cause sliding. Compressive forces tend to maintain the integrity of a bone–implant interface, whereas tensile and shear forces tend to distract or disrupt such an interface. Shear forces are most destructive to implants and bone compared with other load modalities. In general, compressive forces are accommodated best by the complete implant-prosthesis system. Cortical bone is strongest in compression and weakest in shear (Table 6.2).[10] Additionally, cements and retention screws, implant components, and bone–implant interfaces all accommodate greater compressive forces than tensile or shear. For example, whereas the compressive strength of an average zinc-phosphate dental cement is 83 to 103 MPa (12,000–15,000 pounds per square inch [psi]), the resistance to tension and shear is significantly less (500 psi) (Fig. 6.2).

The implant body design transmits the occlusal load to the bone. Threaded or finned dental implants impart a combination of all three force types at the interface under the action of a single occlusal load. This "conversion" of a single force into three different types of forces is controlled completely by the implant geometry. The prevalence of potentially dangerous tensile and shear forces in threaded or finned implants may be controlled optimally through careful engineering design. Cylinder implants in particular are at highest risk for harmful shear loads at the implant–tissue interface under an occlusal load directed along the long axis of the implant body. As a consequence, cylinder implants require a coating to manage the shear stress at the interface through a more uniform bone attachment along the implant length. Bone loss adjacent to cylindrical implants and coating degradation result in a mechanically compromised implant.

Offset loading on single-tooth or multiple-abutment restorations results in moment (bending) loads (described later under the section "Force Delivery and Failure Mechanisms"). As a result,

an increase in tensile and shear force components is often found. Compressive forces typically should be dominant in implant prosthetic occlusion.

Multiple abutment restorations, particularly with distal cantilevers, produce a remarkably complex load profile in the prosthesis and in the bone–implant interface. These clinical realities underscore the need for optimizing dental implant design to provide the maximum functional surface area to dissipate such forces.

Stress

The manner in which a force is distributed over a surface is referred to as *mechanical stress.* Thus the familiar relation defines stress:

$$\sigma = F/A$$

where σ is stress (pounds per square inch; pascals), *F* is force (newtons; pound force), and *A* is area (square inches; square meters). The internal stresses that develop in an implant system and surrounding biological tissues under an imposed load may have a significant influence on the long-term longevity of the implants in vivo. As a general rule, a goal of treatment planning should be to minimize and evenly distribute mechanical stress in the implant system and the contiguous bone.

The magnitude of stress depends on two variables: (1) force magnitude and (2) cross-sectional area over which the force is dissipated. It is rare that a dentist can control the force magnitude completely. The magnitude of the force may be decreased by reducing these significant magnifiers of force: cantilever length, offset loads, and crown height. Night guards to decrease nocturnal parafunction; occlusal materials that decrease impact force; and overdentures, rather than fixed prostheses, that can be removed at night are further examples of force reduction strategies. The functional surface area over which the force is distributed, however, is controlled completely through careful treatment planning.

A *functional cross-sectional* area is defined as that surface that participates significantly in load bearing and stress dissipation. This area may be optimized by (1) increasing the number of implants for a given edentulous site and (2) selecting an implant geometry that has been designed carefully to maximize functional cross-sectional area. An increase in functional surface area serves to decrease the magnitude of mechanical stress imposed on the prosthesis, implant, and biological tissues.

Stress components are described as normal (perpendicular to the surface and given the symbol σ) and shear (parallel to the surface and given the symbol τ). One normal stress and two shear stresses act on each plane (x, y, z); therefore $\tau_{xy} = \tau_{yx}$, $\tau_{yz} = \tau_{zy}$, and $\tau_{xz} = \tau_{zx}$. Thus any three-dimensional element may have its stress state completely described by three normal stress components and three shear components.

The question arises as to what are the peak stresses or maximum stresses that an implant and the surrounding interfacial tissues experience. Peak stresses occur when the stress element is positioned in a particular orientation (or geometric configuration) in which all shear-stress components are zero. When an element is in this configuration, the normal stresses are given a particular name, *principal stresses,* and are indicated as σ_1, σ_2, and σ_3. By convention, maximum principal (σ_1) stresses represent the most positive stresses (typically peak tensile stresses) in an implant or tissue region and minimum principal (σ_3) stresses, which are the most negative stresses (typically peak compressive stresses). Sigma 2 (σ_2) represents a value intermediate between σ_1 and σ_3. Determination of these peak normal stresses in a dental implant system

and tissues may give valuable insight regarding sites of potential implant fracture and bone atrophy.

Deformation and Strain

A load applied to a dental implant may induce deformation of the implant and surrounding tissues. Biological tissues may be able to interpret deformation or a manifestation thereof and respond with the initiation of remodeling activity.

The deformation and stiffness characteristics of the materials used in implant dentistry, particularly the implant materials, may influence interfacial tissues, ease of implant manufacture, and clinical longevities. Elongation (deformation) of biomaterials used for surgical dental implants ranges from 0 for aluminum oxide ceramics to up to 55 for annealed 316 L stainless steel[11] (Table 6.3). Related to deformation is the concept of strain, which is a parameter believed to be a key mediator of bone activity.

Under the action of a tensile force (*F*), the straight bar (of original gauge length, l_0) undergoes elongation to a final length ($l_0 + \Delta 1$) (Fig. 6.3). Engineering strain, which is unitless, is defined as elongation per unit length and is described as:

$$\varepsilon = \frac{1 - 1_0}{1_0} = \frac{\Delta 1}{1_0}$$

where Δl is elongation, l_0 is original gauge length, and l is final length after elongation, Δl. Shear strain, γ, describes the change in a right angle of a body or stress element under the action of a pure shearing load. All materials (biological and nonbiological) are characterized by a maximum elongation possible before permanent deformation or fracture results. Furthermore, biological materials exhibit strain-rate dependence in that their material properties (e.g., modulus of elasticity, ultimate tensile strength) are altered as a function of the rate of loading (and subsequent deformation rate).

Experimental observation also has demonstrated that lateral strain also accompanies axial strain under the action of an axial load. Within an elastic range (defined later in this section), these two strains are proportional to one another as described by Poisson's ratio, *μ*. For tensile loading:

$$\mu = \frac{\text{Lateral Strain}}{\text{Axial Strain}}$$

The material and mechanical properties described provide for the determination of implant-tissue stress-strain behavior according to established relationships in solid-mechanics theory.[12]

Stress-Strain Relationship

A relationship is needed between the applied force (and stress) that is imposed on the implant and surrounding tissues and the subsequent deformation (and strain) experienced throughout the system. If any elastic body is subjected experimentally to an applied load, then a load versus deformation curve can be generated (Fig. 6.4A). Dividing the load (force) values by the surface area over which they act and the change in the length by the original length produces a classic engineering stress-strain curve (see Fig. 6.4B). Such a curve provides for the prediction of how much strain will be experienced in a given material under the action of an applied load. The slope of the linear (elastic) portion of this curve is referred to as the *modulus of elasticity (E),* and its value indicates the stiffness of the material under study.

• **Fig. 6.3** Under action of tensile force (F_N), the straight bar originally l_0 is elongated by an amount Δl. Engineering strain ε is the deformation per unit length. Shear strain γ is the change in a right angle of a body or stress element under action of a pure shearing load (F_S).

• **Fig. 6.4** (A) Load versus deformation curve may be generated for any elastic body experimentally subjected to a load. (B) Dividing load values by the surface area and the deformation of the original gauge length of the specimen produces a stress-strain curve.

The closer the modulus of elasticity of the implant resembles that of the contiguous biological tissues, the less the likelihood of relative motion at the tissue–implant interface. The cortical bone is at least five times more flexible than titanium. As the stress magnitude increases, the relative stiffness difference between bone and titanium increases. As the stress magnitude decreases, the stiffness difference becomes much less. Restated, the viscoelastic bone can stay in contact with more-rigid titanium more predictably when the stress is low. In terms of full-arch kinematics, the practitioner should consider that the mandible flexes toward the midline on opening. A prosthesis and implant support system that is splinted

from molar to molar must provide similar movement if the interface is to remain intact.

Once a particular implant system (i.e., a specific biomaterial) is selected, the only way for an operator to control the strain experienced by the tissues is to control the applied stress or change the density of bone around the implant (Fig. 6.5). Such stress (force/area) may be influenced by the implant design, size, implant number, implant angulation, and restoration. The macrogeometry of the implant (i.e., the amount and orientation of functional surface area available to dissipate loads) has a strong influence on the nature of the force transfer at the tissue–implant interface. Surgical grafting procedures may increase the quantity and quality of bone and allow placement of a larger implant with more bone contiguous to the interface implant. The applied stress is also influenced by the restoration, including the size of

• **Fig. 6.5** Once a particular implant system is selected, the only way to control strain (ε) on tissues is to control applied stress (σ). The greater the magnitude of stress applied to the system, the greater the difference in strain between implant material and bone. *E,* Modulus of elasticity.

occlusal tables, stress breakers, use of overdenture versus fixed prosthesis, and occlusal contact design. Generally, the greater the magnitude of stress applied to a dental implant system, the greater the difference in strain between the implant material and bone. In such cases, the implant is less likely to stay attached to the bone, and the probability of fibrous tissue ingrowth into the interfacial region to accommodate the range of difference becomes greater. The density of bone is related not only to the

bone strength but also to the modulus of elasticity (stiffness). The stiffer the bone, the more rigid it is; the softer the bone, the more flexible the bone. Therefore the difference in stiffness is less for commercially pure titanium (or its alloy) and division 1 dense bone compared with titanium and division 4 soft bone. Decreasing stress in softer bone is more important for two primary reasons: (1) to reduce the resultant tissue strains resulting from the elasticity difference and (2) because softer bone exhibits a lower ultimate strength.

Hooke's law is the name given to the relationship between stress and stain; in its simplest form, the law is described mathematically as the following:

$$\sigma = E\varepsilon$$

where σ is normal stress (pascal or pounds per square inch), *E* is the modulus of elasticity (pascal or pounds per square inch), and ε is normal strain (unitless). A similar relationship exists for shear stress and shear strain, where the constant of proportionality is the modulus of rigidity *(G)* expressed by the following:

$$\tau = G\gamma$$

where τ is shear stress (pascal or pounds per square inch), *G* is the modulus of rigidity (pascal or pounds per square inch), and γ is shear strain (unitless).

Impact Loads

When two bodies collide in a small interval of time (fractions of a second), large reaction forces develop. Such a collision is described as *impact.* In dental implant systems subjected to occlusal implant loads, deformation may occur in the prosthodontic restoration, in the implant itself, and in the contiguous interfacial tissues. The nature of the relative stiffness of these components in the overall implant system largely controls the response of the system to impact load. The higher the impact load, the greater the risk of implant and bridge failure and bone fracture.

Rigidly fixed implants generate a higher interfacial impact force with occlusion compared with natural teeth, which possess a
• **Fig. 6.6** Moment of a force is defined as a vector *(M),* the magnitude of which equals the product of the force magnitude multiplied by the perpendicular distance (moment arm) from the point of interest to the line of action of the force.
• **Fig. 6.7** Moment loads tend to induce rotations in three planes. Clockwise and counterclockwise rotations in these three planes result in six moments: lingual-transverse, facial-transverse, occlusal, apical, facial, and lingual.

periodontal ligament. Soft tissue–borne prostheses have the least impact force because the gingival tissues are resilient. Occlusal material fracture is a significant complication of fixed prostheses on natural teeth. The incidence of occlusal material fracture is greater on implants and may approach rates as high as 30%.

Various methods have been proposed to address the issue of reducing implant loads. Skalak[13] has suggested the need for using acrylic teeth along with osteointegrated fixtures partially to mitigate high-impact loads that might damage bony tissues adjacent to the implant. Weiss[14] has proposed that a fibrous tissue–implant interface provides for physiologic shock absorption in a fashion similar to that exhibited by a functioning periodontal ligament. At least one implant design has attempted to incorporate shock absorption capability in the design itself by the use of an "intra-mobile element" of lower stiffness compared with the rest of the implant.[15] Misch[16] has advocated an acrylic provisional restoration with a progressive occlusal loading to improve the bone–implant interface before the final restoration, occlusal design, and masticatory loads are distributed to the system. Only limited data exist concerning impact forces on natural dentition and tooth-supported bridgework.[17,18]

Force Delivery and Failure Mechanisms

The manner in which forces are applied to implant restorations within the oral environment dictates the likelihood of system failure. The duration of a force may affect the ultimate outcome of an implant system. Relatively low-magnitude forces, applied repetitively over a long time, may result in fatigue failure of an implant or prosthesis. Stress concentrations and, ultimately, failure, may develop if insufficient cross-sectional area is present to dissipate high-magnitude forces adequately. If a force is applied some distance away from a weak link in an implant or prosthesis, then bending or torsional failure may result from moment loads. An understanding of force delivery and failure mechanisms is critically important to the implant practitioner to avoid costly and painful complications.

Moment Loads

The moment of a force about a point tends to produce rotation or bending about that point. In Fig. 6.6, the moment is defined as a vector *(M)* (vectors are described in terms of magnitude and direction), the magnitude of which equals the product of the force magnitude

multiplied by the perpendicular distance (also called the *moment arm*) from the point of interest to the line of action of the force. This imposed moment load is also referred to as a *torque* or *torsional load* and may be destructive to implant systems. Torques or bending moments imposed on implants because of, for example, excessively long cantilever bridge or bar sections may result in interface breakdown, bone resorption, prosthetic screw loosening, or bar or bridge fracture. The negative effect of cantilevers has been reported for more than 30 years.[19,20] Proper restorative design must include consideration of forces and the moment loads caused by those forces.

Clinical Moment Arms

A total of six moments (rotations) may develop about the three clinical coordinate axes previously described (occlusoapical, faciolingual, and mesiodistal) (Fig. 6.7). Such moment loads induce microrotations and stress concentrations at the crest of the alveolar ridge at the implant–tissue interface, which lead inevitably to crestal bone loss.

Three clinical moment arms exist in implant dentistry: (1) occlusal height, (2) cantilever length, and (3) occlusal width.

Minimization of each of these moment arms is necessary to prevent unretained restorations, fracture of components, crestal bone loss, or complete implant system failure.

Occlusal Height

Fig. 6.8 shows that the occlusal height serves as the moment arm for force components directed along the faciolingual axis such as working or balancing occlusal contacts, tongue thrusts, or in passive loading by cheek and oral musculature (see Fig. 6.8B), as well as force components directed along the mesiodistal axis (see Fig. 6.8C).

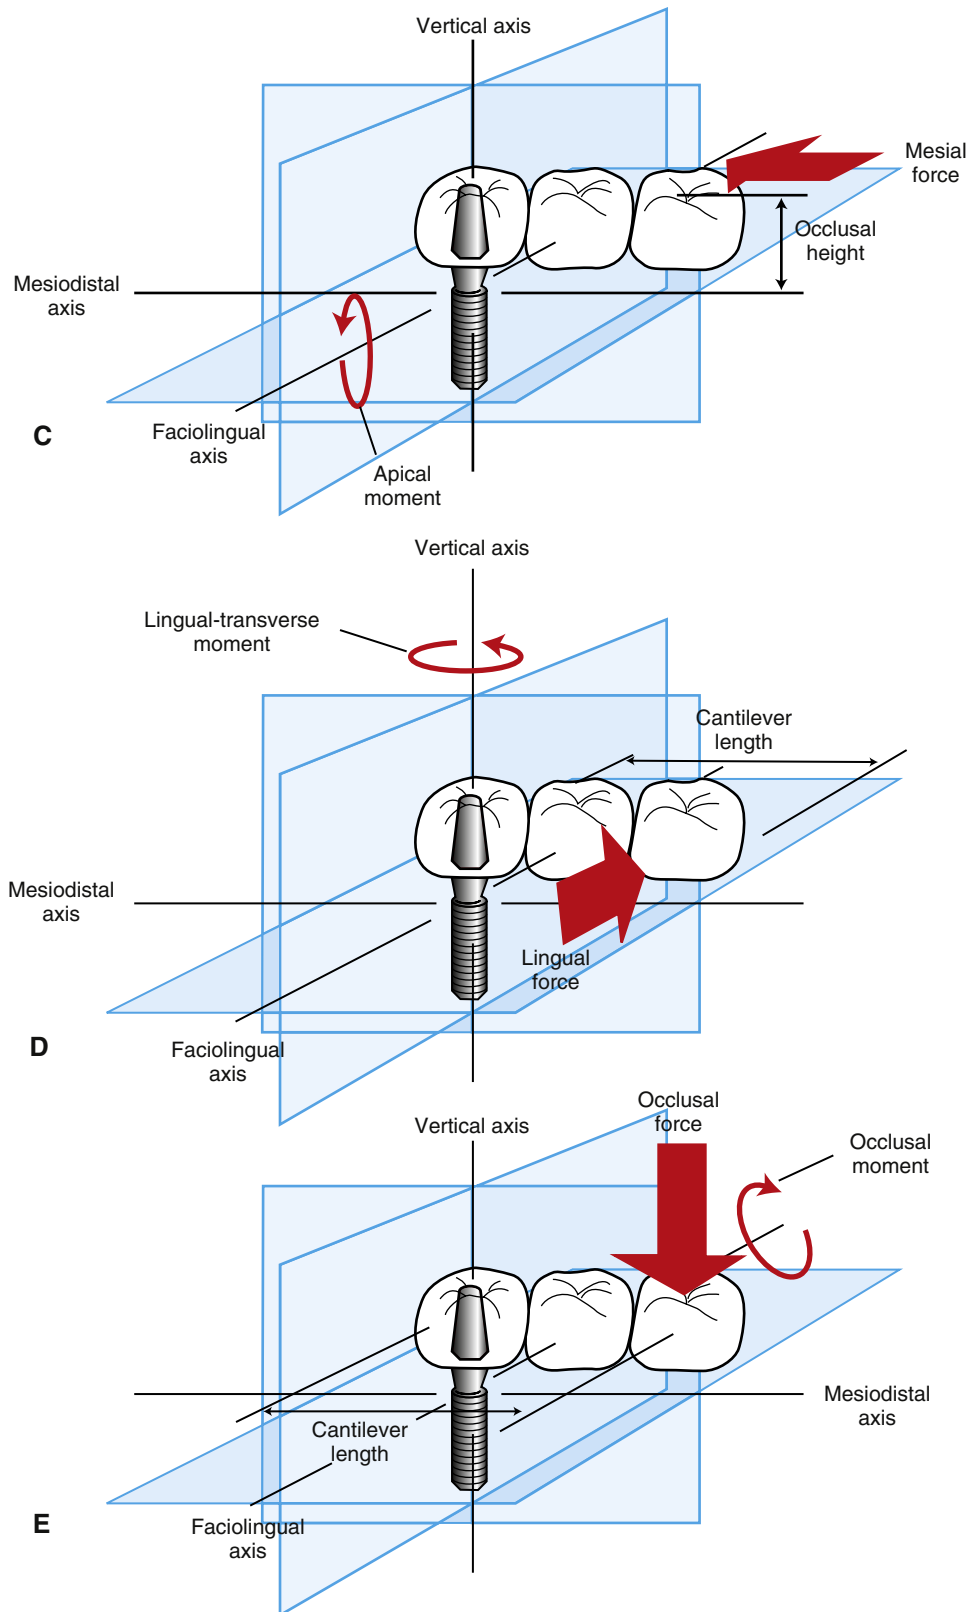
In division A bone, initial moment load at the crest is less than in division C or division D bone because the crown height is greater in division C and division D bone. Treatment planning must take into account this initially compromised biomechanical environment (Table 6.4). The moment contribution of a force component directed along the vertical axis is not affected by the occlusal height because no effective moment arm exists. Offset occlusal contacts or lateral loads, however, introduce significant moment arms (see Fig. 6.8E).
• **Fig. 6.8** (A) Three clinical moment arms contribute to torsional (moment) loads on dental implants: occlusal height, occlusal width, and cantilever length. (B) Occlusal height serves as moment arm for force components directed along faciolingual axis and


Fig. 6.8, cont'd (C) force components directed along mesiodistal axis. (D) Lingual force component also may induce twisting moment about the implant neck if applied through the cantilever length. (E) Moment of force along the vertical axis is not affected by occlusal height because its effective moment arm is zero if positioned centrically.

TABLE 6.4	Moment Load at Crest, Division A Bone When Subjected to Forces Shown in Fig. 6.3						
INFLUENCES ON MOMENT		IMPOSED MOMENTS (N/MM) AT IMPLANT CROWN–CREST INTERFACE					
Occlusal Height (mm)	Cantilever Length (mm)	Lingual	Facial	Apical	Occlusal	Facial-transverse	Lingual-transverse

20	20	200	0	100	400	0	200
20	30	200	0	100	600	0	300

Cantilever Length

Large moments may develop from vertical axis force components in prosthetic environments designed with cantilever extensions or offset loads from rigidly fixed implants. A lingual force component also may induce a twisting moment about the implant neck axis if applied through a cantilever length (see Fig. 6.8D).

An implant with a cantilevered mesobar extending 1 to 3 cm has significant ranges of moment loads. A 100-N force applied directly over the implant does not induce a moment load or torque because no rotational forces are applied through an offset distance. This same 100-N force applied 1 cm from the implant results in a 100 N-cm moment load. Similarly, if the load is applied 2 cm from the implant, then a 200 N-cm torque is applied to the implant-bone region, and at 3 cm a 300 N-cm moment load results. For comparison, recall that implant abutments typically are tightened with 30 N-cm of torque.

Cantilever prostheses attached to splinted implants result in a complex load reaction. In its simplest form, a class 1 lever action may be expressed. If two implants 10 mm apart are splinted together, and a 20-mm distal cantilever is designed with a 100-N load, then the following forces result. The 100-N load is resisted with a 200-N tensile force by the mesial implant, and the distal implant acts as a fulcrum with a 300-N compressive load (Fig. 6.9A). If the position and amount of distal load remain the same, but the distal implant is positioned 5 mm anterior, then the resultant loads on the implants change (see Fig. 6.9B). The anterior implant must resist a 500-N tensile force, and the distal, fulcrum implant receives a 600-N compressive force. Therefore the tensile force is increased 2.5 times on the anterior implant, whereas the compressive force is increased twofold. Because bone and screws are weaker under the action of tensile forces, both implants become more at risk for complications.

Similar principles regarding class 1 lever forces apply to cantilever loads with anterior splinted implants placed on a curve with distal extended prostheses. The Nobel Biocare (Zurich, Switzerland) prosthetic protocol uses four to six anterior implants placed in front of the mental foramen or maxillary sinuses and uses a full-arch fixed prosthesis with cantilevered segments.[21-23] Specific cantilever lengths are not stated, although two to three premolars are recommended. The cantilever length is suggested to be reduced when four rather than six implants are used to support the restoration[24] or when implants are in the softer bone of the maxilla.[25] A line is drawn from the distal of each posterior implant. The distance

to the center of the most anterior implant is called the *anteroposterior distance* (A-P spread).[26] The greater the A-P spread is between the center of the most anterior implant or implants and the most distal aspect of the posterior implants, the smaller the resultant loads on the implant system from cantilevered forces because of the stabilizing effect of the A-P distance. According to Misch,[25] the amount of stress applied to the system determines the length of this distal cantilever. Because stress equals force divided by area, both aspects must be considered. The magnitude and direction of force are determined by parafunction, crown height, masticatory dynamics, gender, age, and arch location. The functional surface area is determined by the number of implants, width, length, design, and bone density, which determines the area of contact and bone strength. Clinical experiences suggest that the distal cantilever should not extend 2.5 times the A-P spread under ideal conditions (e.g., parafunction absent or five division A implants). One of the greatest determinants for the length of the cantilever is the magnitude of the force. Patients with severe bruxism should not be restored with any cantilevers, regardless of other factors.

A square arch form involves smaller A-P spreads between splinted implants and should have shorter length cantilevers. A tapered arch form has the largest distance between anterior and posterior implants and may have the longest cantilever design. The maxilla has less dense bone than the mandible and more often has an anterior cantilever with the prosthesis. As a result, more distal implants may be required in the maxilla to increase the A-P spread for the anterior or posterior cantilever than in the mandible, and sinus augmentation may be required to permit posterior placement of the implant.

Occlusal Width

Wide occlusal tables increase the moment arm for any offset occlusal loads. Faciolingual tipping (rotation) can be reduced significantly by narrowing the occlusal tables or adjusting the occlusion to provide more centric contacts.

In summary, a vicious, destructive cycle can develop with moment loads and result in crestal bone loss. As crestal bone loss develops, occlusal height automatically increases. With an increased occlusal height moment arm, the faciolingual microrotation and rocking increases and causes even more crestal bone loss. Unless the bone increases in density and strength, the cycle continues to spiral toward implant failure if the biomechanical environment is not corrected.

Fatigue Failure

Fatigue failure is characterized by dynamic, cyclic loading conditions. Four fatigue factors significantly influence the likelihood of fatigue failure in implant dentistry: (1) biomaterial, (2) macrogeometry, (3) force magnitude, and (4) number of cycles.

Fatigue behavior of biomaterials is characterized graphically in what is referred to as an *S-N curve* (a plot of applied stress versus number of loading cycles) (Fig. 6.10A). If an implant is
• **Fig. 6.9** (A) If two implants are designed 10 mm apart and splinted together with a 20-mm distal cantilever, then a 100-N load is resisted by a 200-N force by the mesial implant, and the distal implant acts as a fulcrum with a 300-N load. (B) If implants are 5 mm apart, then the anterior implant must resist a 500-N force and the distal fulcrum implant receives a 600-N force.

subjected to an extremely high stress, then only a few cycles of loading can be tolerated before fracture occurs. Alternatively, an infinite number of loading cycles can be maintained at low stress levels. The stress level below which an implant biomaterial can be loaded indefinitely is referred to as its *endurance limit.* Titanium alloy exhibits a higher endurance limit compared with commercially pure titanium (see Fig. 6.10B).

The geometry of an implant influences the degree to which it can resist bending and torsional loads and ultimately fatigue fracture. Implants rarely, if ever, display fatigue fracture under axial compressive loads. Morgan and colleagues[27] reported fatigue fractures of Brånemark dental implants (Nobel Biocare, Zurich, Switzerland) caused by cyclical buccolingual loads (lateral loading) in an area of weak bending strength within the fixture (i.e., reduced moment of inertia [defined later]). The fracture of the implant body occurred in three of the patients studied, and fracture of the abutment screws for the Brånemark implant occurred in less than three patients. Fifteen acrylic or composite tooth fractures occurred on 10 to 20 of the fixed prostheses supported by implants over a 1- to 5-year period.[28-31]

The geometry also includes the thickness of the metal or implant. The fatigue fracture is related to the fourth power of the thickness difference. A material two times thicker in wall thickness is approximately 16 times stronger. Even small changes in thickness can result in significant differences. Often the weak link in an implant body design is affected by the difference in the inner and outer diameter of the screw and the abutment screw space in the implant.[32]

To the extent that an applied load (stress) can be reduced, the likelihood of fatigue failure is reduced. As described previously, the magnitude of loads on dental implants can be reduced by careful consideration of arch position (i.e., higher loads in the posterior compared with anterior mandible and maxilla), elimination of moment loads, and increase in surface area available to resist an applied load (i.e., optimize geometry for functional area or increase the number of implants used).

Finally, fatigue failure is reduced to the extent that the number of loading cycles is reduced. Thus aggressive strategies to eliminate parafunctional habits and reduce occlusal contacts serve to protect against fatigue failure.
• **Fig. 6.10** (A) Fatigue behavior of biomaterials is characterized by a plot of applied stress versus number of loading cycles (an S-N curve). (B) Endurance limit defines the stress level below which an implant biomaterial may be loaded indefinitely without failure. Titanium alloy is two to four times stronger in fatigue conditions compared with commercially pure titanium.

Moment of Inertia

Moment of inertia is an important property of cylindrical implant design because of its importance in the analysis of bending and torsion. The bending stress in a cylinder is given by the following equation:

$$\sigma = \frac{My}{I}$$

where M is moment (newton-centimeters), y is the distance from the neutral axis of bending (centimeters), and I is the moment of inertia (centimeters to the fourth power).

Root-form implants have varying cross-sectional geometries. The root-form implant may be modeled as a hollow circle because a channel exists in the implant body to allow for abutment screw engagement. In the distal (apical) region of a root-form implant, the cross-sectional geometry may more closely represent a solid circle. In some designs, vents that penetrate transversely through the cross-sectional geometry may interrupt the apical geometry.

The bending stress (and likelihood of bending fracture) decreases with an increasing moment of inertia. Consider the mathematical formulations for the solid versus hollow cylindrical cross-sectional geometry:

Solid circle (cylinder in the middle region) : $4\,I = \pi R^4$

Hollow circle (cylinder in apical region) : $4\,I = \pi R^4 - R_i^4$

where R is the outer radius (centimeters), and R_i is the inner wall radius.

Summary

The most common complications in implant-related reconstruction are related to biomechanical conditions. Implant healing failures may result from micromovement of the implant from too much stress. Early crestal bone loss may be related to occlusal overload conditions. Prostheses or abutment screws may become loose from bending or moment forces. Implant or component fracture may occur from fatigue conditions. Prosthesis failure may result from all of the foregoing or bending fracture resistance. In addition, the manifestation of biomechanical loads on dental implants (moments, stress, and strain) controls the long-term health of the bone–implant interface. Knowledge of basic biomechanical principles is thus required for the dentist.

Stress Treatment Theorem for Implant Dentistry

CARL E. MISCH AND RANDOLPH R. RESNIK

The field of dentistry is a unique aspect of medicine, blending science and art form. Some aspects of the dental field emphasize the art form, such as in dental esthetics, which deals with tooth color and shape to enhance a patient's smile and overall appearance. These may be separated into a biologic component and a biomechanic component. For general dentists, the biological aspects of oral health are well emphasized. Common complications related to the natural dentition are primarily of biological origins, with periodontal diseases, caries, and endodontic problems as examples.[1-4]

When evaluating failures of tooth-supported prostheses, a combination of biological and biomechanical factors exist. The four most common complications for a typical three-unit fixed prostheses are (1) caries, (2) endodontic involvement, (3) unretained prosthesis, and (4) material fracture.[5,6] The biological complications occur with greater frequency (11%–22%), compared with the biomechanical (7%–10%), but the clinician should have a strong foundation for both aspects. The field of implant dentistry most often involves the replacement of teeth. When implant complications are reported, the vast majority of problems are related to the implant sciences rather than esthetics.[7] But, unlike natural teeth, the biological aspects of implant dentistry have relatively few complications. For example, the development of a direct bone–implant interface is largely biological. Most recent reports indicated that the surgical phase of implants form a successful interface more than 95% of the time, regardless of the implant system used.[7] Hence the biological aspect of the field is very predictable. The most common implant-related complications are biomechanical in nature and occur after the implant is loaded. A literature review focusing on implant failure indicated these problems primarily occur within 18 months of initial implant loading. Most early implant loading failures occur in the softest bone types (16% failure). These failures are typically caused by biomechanical factors because poorer-quality bone is too weak for the occlusal forces applied to the implants (Fig. 7.1).[8-20]

The most common complications that do not lead to the failure of the implant are also biomechanical problems. Implant overdentures have been shown to have attachment fracture or complication (30%) and removable-prosthesis fracture (12%). With implant-supported fixed prostheses, abutment or prosthetic screw loosening has been shown to encompass 34% of prosthetic complications[21] and a complication rate of 40% after 5 years.[22] In addition, implant components (2%–4%) and even implant bodies may fracture (1%–2%) (Box 7.1). In summary, mechanical complications far outnumber biological implant problems.[7,20] Any complex engineering structure will fail at its "weakest link," and dental implant structures are no exception. A general concept in engineering is to determine the causes of complications and develop a system to reduce the conditions that cause the problems. The most common etiologic factors for implant-related complications are centered around stress. Thus the overall treatment plan should (1) assess the greatest force factors in the system and (2) establish mechanisms to protect the overall implant-bone-prosthetic system.

Biomechanical Overload

Surgical Failure

There are many reasons for the failure of an implant to integrate initially with the bone. The primary causes of early failure relate to excessive heat during the preparation of the osteotomy or excessive pressure at the implant–bone interface at the time of implant insertion (Fig. 7.2).[23] The excessive pressure (i.e., pressure necrosis) at implant insertion is observed most often in more dense bone (e.g., D1 or D2) with a greater thickness of cortical bone. An additional cause of surgical failure is micromovement of the implant while the developing interface is established (Fig. 7.3). A fractured arm is immobilized to prevent movement at the fracture site to decrease the risk of a fibrous nonunion. Movement as little as 20 microns has been reported to cause a fibrous interface to form at the fracture site. Brunski observed a fibrous tissue interface development when a dental implant moved more than 100 microns during initial healing.[24] The original Brånemark protocol used a two-stage surgical approach for the most part to avoid any undue pressure.[25,26] One of the main reasons for this concept was to place the implant at or below the crestal bone region to decrease the risk of implant movement during initial bone healing. Schroeder also suggested an unloaded healing period on implants, although the implant was placed at or slightly above the gingival tissues.[27] Occlusal forces applied to an interim removable prosthesis over a healing implant may also cause incision line opening of the soft tissue and delay soft tissue healing.[28] These occlusal forces may also affect the marginal bone around the developing implant site. Transferring these forces to an overlying soft tissue–borne prosthesis may cause micromovement of the implant–bone interface, whether the implant is healing below or
• **Fig. 7.1** Majority of early implant failures occur within 18 months after prosthetic loading and are related to poor-quality bone.

Framework fracture	Opposing prosthesis fracture

above the gingival tissues. Stresses applied to a healing implant increase the risk of complications. On the other hand, multicenter clinical reports indicate that an experienced surgeon may obtain rigid fixations after surgical placement 99% of the time.[29] The surgical component of implant failure is often the lowest risk associated with the overall implant treatment.

Early Loading Failure

On occasion, an implant may fail shortly after it has initially "integrated" to the bone. Before failure, the implant appears to have rigid fixation, and all clinical indicators are within normal limits. However, once the implant is loaded, the implant becomes mobile shortly thereafter. This has been termed *early loading failure* by Jividen and Misch.[9] The cause of early loading failure is usually excessive stress for the bone–implant interface, which has been

documented in many studies. Isidor and colleagues allowed eight implants to integrate in monkey jaws.[30] Crowns were attached to the healed implants with excessive premature occlusal contacts. Over a 20-month period, six of eight implants failed (Fig. 7.4). In these same animals, eight integrated implants with no occlusal loads had strings placed in the marginal gingiva to increase the amount of plaque retention. None of these implants failed over the next 20 months. The authors concluded that in this animal model, biomechanical occlusal stress was a greater risk factor for early implant failure than the biological component of bacterial plaque.[30,31]

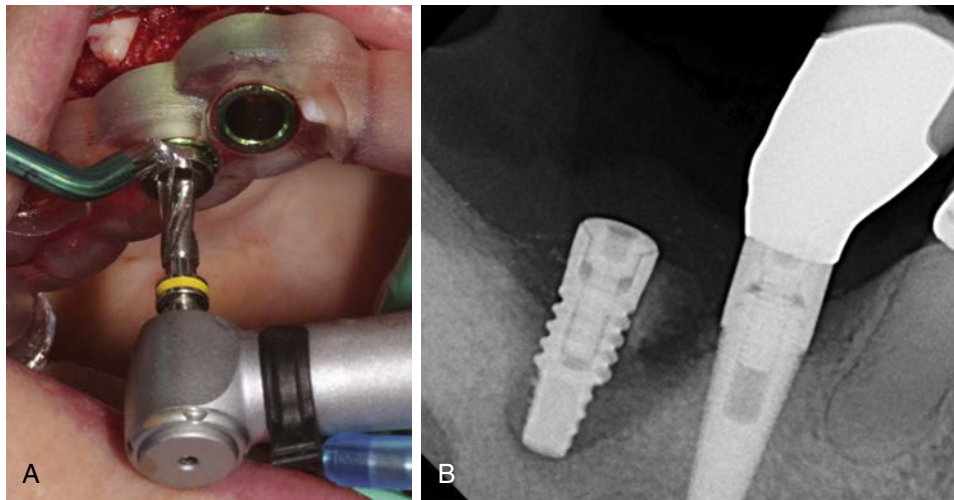
The morbidity of early loading failure is worse for the implant clinician than when a surgical failure occurs because the patient may lose confidence in the restoring dentist. In addition, there exists a significant financial and time commitment. Early loading failure is directly related to the amount of force applied to the prosthesis[8,24,32-35] and the density of the bone around the implants,[7,10-14,36] and it may affect up to 15% of implant restorations.[6-11] Early implant failure from biomechanical overload, as high as 40%, has been reported in the softest bone types.[13] No reports in the literature correlate such high incidence extreme with early implant failure rates related to the biological width-related complications observed in the field.

Impact of Occlusal Overload on Mechanical Components

Screw Loosening

Abutment-screw loosening has been shown to be the most common dental implant prosthetic complication, accounting for up to 33% of all postimplant prosthodontic issues.[37] The incidence of screw loosening with single implant crowns has been reported as high as 59.6% within 15 years of placement.[38] Unfortunately, screw loosening may cause many complications that contribute to crestal bone loss, screw fracture, implant fracture, or implant failure. Although screw loosening may occur in any area of the oral cavity, studies have shown the overwhelming majority of loosened screws occur in the maxillary and mandibular molar areas (~63%) and with single implant-crown restorations (~75%).[39]

Biomechanical forces are a significant etiologic factor with respect to screw loosening. When a screw is tightened (torque), it will elongate, which produces tension or preload within the screw joint. The preload exerts a force that leaves the screw joint in compression and promotes a springlike effect. The preload applied also has an associated elastic recovery that is transferred to the abutment and implant, pulling them together and creating a clamping force (i.e., equal in magnitude to the elongation and elastic recovery).[40]

For a screw to remain tight, the clamping force must be greater than the separating forces. Most often, these separating forces are in the form of external forces that act on a screw joint. Although these forces are termed joint-separating forces, they are the same forces that place the implant at risk for implant failure, crestal bone loss, and component fracture. When the external joint-separating forces are greater than the force holding the screws together (the clamping force), the screw will become loose. These external forces may result from many factors, including parafunction, excessive crown height, masticatory dynamics, prosthesis position in the dental arch, and opposing dentition. In addition, conditions that magnify or increase external forces include cantilevers, angled loads, and poor occlusal designs (Fig. 7.5).


• **Fig. 7.2** Early surgical failures. (A) Excessive heat is a common etiologic factor in the early failure of implants. A common problem is related to guided surgery, which results in compromised irrigation to the surgical site. This is especially common in more dense bone (e.g., D1 or D2). (B) Radiograph of early implant failure resulting from overheating the bone. A radiolucent area (necrotic bone) is usually present around the implant interface.
• **Fig. 7.3** Micromovement of a developing bone–implant interface may cause fibrous tissue to form around an implant rather than a bone–implant interface. Excessive stresses to an implant may cause overload and failure. This implant had occlusal overload, which resulted in fibrous tissue formation around the implant (From Isidor F. Loss of osseointegration caused by occlusal load of oral implants: a clinical and radiographic study in monkeys. *Clin Oral Implants Res.* 1996; 7:143–152.)

• **Fig. 7.4** Premature occlusal contacts caused six of eight integrated implants to fail within 18 months. Strings in the sulcus and excessive plaque accumulation caused no failure during this period. (From Isidor F. Loss of osseointegration caused by occlusal load of oral implants: a clinical and radiographic study in monkeys. *Clin Oral Implants Res.* 1996; 7:143–152.)

Implant Component Biomechanical Complications

Materials follow a fatigue curve, which is related to the number of cycles and the intensity of the force. There is a force so great that one cycle causes a fracture (e.g., karate blow to a piece of wood). However, if a lower force magnitude repeatedly hits an object, it will still fracture. The wire coat hanger that is bent does not break the first time, but repeated bends will fracture the material, not because the last bend was more forceful, but because of fatigue. Indeed, when the patient says he soaked his bread in coffee and then placed it in his mouth before the porcelain/abutment screw/cement seal/cantilevered prostheses fracture, it may have been "the straw that broke the camel's back."

Prosthesis screw fracture has been noted in both fixed-partial and complete-fixed prostheses, with a mean incidence of 4% and a range of 0% to 19%[7] (Fig. 7.6). Abutment screws are usually larger in diameter and therefore fracture less often, with a mean incidence of 2% and a range of 0.2% to 8% (Fig. 7.7). Metal framework fractures also have been reported in an average of 3% of fixed-complete and overdenture restorations, with a range of 0% to 27% (Fig. 7.8). Implant body fracture has the least incidence of this type

of complication, with an occurrence of 1% (Fig. 7.9). This condition is reported with more frequency in long-term fixed prostheses and may even account for the majority of long-term failures. Prosthetic material complications for fixed prostheses have been shown to have a 33% rate at 5 years and 67% after 10 years.[41] Prostheses-related fractures far outnumber implant component fractures.
• **Fig. 7.5** Risk of screw loosening is greatest for single-implant crowns most commonly from biomechanical force. A loose screw may lead to prosthesis failure and peri-implant disease if not corrected.

Uncemented restorations (or worse, partially uncemented prostheses) occur most often when chronic loads are applied to the cement interface or when shear forces are present (as found with cantilevers). Cement strengths are weakest in shear loads. For example, zinc phosphate cement may resist a compressive force of 12,000 pounds per square inch (psi) but can only resist a shear force of 500 psi. It is interesting to note that bone is also strongest to compression and 65% weaker to shear forces. A similar scenario relative to shear load is found with porcelain or other occlusal materials. As a consequence, the evaluation, diagnosis, and modification of treatment plans related to stress conditions are of considerable importance. Therefore once the implant dentist has identified the sources of additional force on the implant system, the treatment plan is altered in an attempt to minimize their negative effect on the longevity of the implant, bone, and final restoration.

Marginal Bone Loss

Crestal bone loss has been observed around the permucosal portion of dental implants for decades. It has been described in the crestal region of successfully osteointegrated implants regardless of surgical approaches. It can range from loss of marginal bone to complete failure of the implant[17,25,42,43] and dramatically decreases after the first year (Box 7.2). For the one-piece blade implants, this phenomenon was described as a "saucerization" and occurred after implant loading.[42]

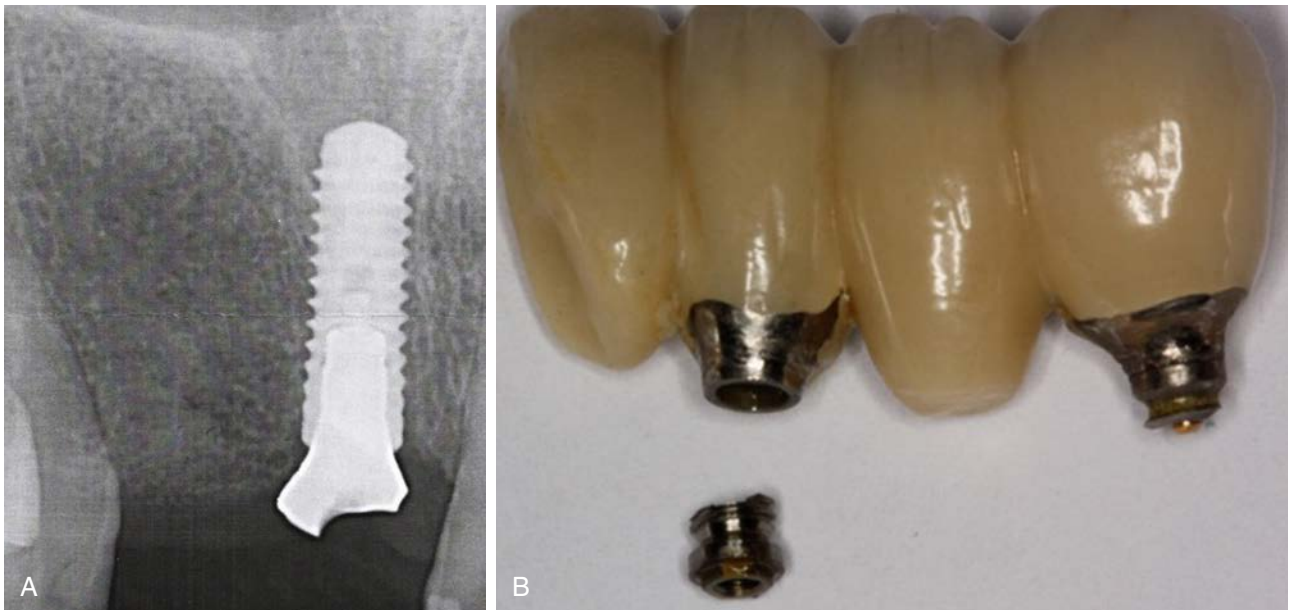
Occlusal Trauma: Bone Loss

Adell and colleagues[25] were the first to quantify and report marginal bone loss. The study also indicated greater magnitude and occurrence of bone loss during the first year of prosthesis loading, averaging 1.2 mm during this time frame, with a range of 0 to 3 mm. This report measured bone loss from the first thread as the 0-mm baseline, not from the original level of crestal bone
• **Fig. 7.6** Screw fracture. (A) prosthesis screw fractured, which leads to difficulty in removal. (B) Fractured retrieved screw.

at insertion, which was 1.8 mm above this baseline point. Thus the actual first-year crestal bone loss averaged 3.3 mm around the implants observed (Fig. 7.10). Years subsequent to the first showed an average of 0.05- to 0.13-mm bone loss per year. Other studies report an average first-year bone loss of 0.93 mm, with a range from 0.4 to 1.6 mm and a mean loss of 0.1 mm after the first year.[33,34] The early crestal bone loss has been observed so frequently that proposed criteria for successful implants often do not even include the first-year bone loss amount.[44]

The initial transosteal bone loss around an implant forms a V-shaped or a U-shaped pattern, which has been described as *ditching* or *saucerization* around the implant. The current hypotheses

for the cause of crestal bone loss have ranged from reflection of the periosteum during surgery, preparation of the implant osteotomy, the position of the "microgap" between the abutment and implant body, micromovement of the abutment components, bacterial invasion, the establishment of a biological width, and factors of stress.[17,25,43-48]

An understanding of the causes of marginal crestal bone loss around dental implants and early implant failure is critical in preventing such occurrences, fostering long-term peri-implant health, and improving long-term implant success rates and, foremost, implant prosthesis success. Marginal crestal bone loss may influence esthetics because the height of the soft tissue (e.g.,


• **Fig. 7.7** Abutment fracture. (A) most commonly fractured from overpreparation of the abutment and biomechanical force. (B) abutment fracture on a splinted implant prosthesis.

interdental papilla) is directly related to the marginal bone. If the tissue shrinks as a consequence of the bone loss, the emergence profile of the crown elongates and the papilla may disappear next to the adjacent tooth or implant. If the soft tissue does not shrink, then the increase in pocket depth may be related to the presence of anaerobic bacteria and peri-implantitis.

Over the years, the cause of marginal bone loss has kept the implant community busy with academic debates and clinical studies. However, clinical consequences are such that all phases of

implant dentistry, from diagnosis and treatment planning to the final stages of occlusion and prosthesis delivery, must focus on its reduction or elimination.

Periosteal Reflection Hypothesis

Periosteal reflection causes a transitional change in the blood supply to the crestal cortical bone. Ninety percent of the arterial blood supply and 100% of the venous return are associated with the periosteum in the long bones of the body.[49] When the periosteum is reflected off the crestal bone, the cortical bone blood supply is affected dramatically, causing osteoblast death on the surface from trauma and lack of nutrition. These events have fostered the periosteal reflection theory as a cause for early bone loss around an endosteal implant.

Although crestal bone cells may die of the initial trauma of periosteal reflection, the blood supply is reestablished once the periosteum regenerates. Cutting cones develop from monocytes in the blood and precede new blood vessels into the crestal regions of bone. Osteoblasts then are able to remodel the crestal bone anatomy.[50] Composite bone forms rapidly on periosteal surfaces to restore its original condition. In addition, the underlying trabecular bone is also a vascular source because its blood supply often is maintained in spite of crestal periosteal reflection. The greater the amount of trabecular bone under the crestal cortical bone, the less crestal bone loss is observed.[51] To place the implant in sufficient available bone, an implant ridge is usually 5 mm or wider at the crest. As a result, trabecular bone is readily available to assist in cortical blood supply and remodeling around the implants. The cortical bone is remodeled to its original contour, without significant loss of height.

The periosteal reflection theory would lead to a generalized horizontal bone loss of the entire residual ridge reflected and not the localized ditching pattern around the implant that typically is observed. In addition, generalized bone loss already would be directly noticeable at the second-stage uncovery of the implant body, 4 to 8 months after stage I implant placement surgery. Yet generalized bone loss rarely is observed at the second-stage uncovery surgery (Fig. 7.11). Therefore the periosteal reflection hypothesis does not appear as a primary causal agent of marginal crestal bone loss around an implant.

Implant Osteotomy Hypothesis

Preparation of the implant osteotomy has been reported as a causal agent of early implant bone loss. Bone is a labile organ and is sensitive to heat. The implant osteotomy causes trauma to the bone in immediate contact with the implant, and a devitalized bone zone of about 1 mm is created around the implant. A renewed blood supply and cutting cones are necessary to remodel the bone at the interface. The crestal region is more susceptible to bone loss during initial repair because of its limited blood supply and the greater heat generated in this denser bone, especially with the less efficient cutting of countersink drills used in this region.[51-53] This condition supports implant osteotomy preparation as a causal agent for marginal crestal bone loss around the implant.

However, if heat and trauma during implant osteotomy preparation were responsible for marginal crestal bone loss, the effect would be noticeable at the second-stage uncovery surgery 4 to 8 months later. The average bone loss of 1.5 mm from the first thread is not observed at stage II uncovery. In fact, bone often has grown over the first-stage cover screw, especially when level
• **Fig. 7.10** Marginal bone loss. (A and B) Marginal bone loss around the crestal portion of an implant often occurs during the first year of occlusal loading.
• **Fig. 7.11** Stage II uncovery. (A and B) Marginal bone level at stage II surgery is variable (i.e., minimal crestal bone loss, bone at the top of the implant, bone overgrowth of the cover screw). The bone loss has been attributed to the reflection of the periosteum or the osteotomy preparation.

or slightly countersunk below the bone. Reports in the literature indicated different surgical trauma causes and numbers for bone loss. For example, Manz[54] observed that bone loss at second-stage surgery ranged from 0.89 to 0.96 mm regardless of the bone density. Hoar and colleagues[55] reported only 0.2-mm bone loss at stage II uncovery. The surgical system or approach may influence these data, but usually this bone loss remains minimal. One should remember that these are averages of bone loss reported. Therefore if 2 mm of bone loss is found on one implant, and the next nine implants exhibit no bone loss, the average bone loss would be 0.2 mm. Most implants at stage II uncovery do not demonstrate any bone loss. Therefore the implant osteotomy hypothesis for marginal crestal bone loss cannot be primarily responsible for this routinely observed phenomenon.

Autoimmune Response of Host Hypothesis

The primary cause of bone loss around natural teeth is bacteria induced. Repeat studies demonstrated that bacteria are the causative element for vertical defects around teeth. Occlusal trauma may accelerate the process, but trauma alone is not deemed a determining factor.[56] The implant gingival sulcus in the partially edentulous implant patient exhibits a bacterial flora similar to that of natural teeth.[1] A logical assumption is that if implants are similar to teeth, then the marginal implant bone loss is caused primarily by bacteria, with occlusal factors playing a contributing or accelerating role.

In a prospective study of 125 implants, Adell and colleagues[43] reported 80% of implant sulcular regions were without inflammation. Lekholm and colleagues[57] found that deep gingival pockets around implants were not associated with crestal bone loss, yet the marginal crestal bone loss to the first thread of screw-type implants is a common radiologic finding. If bacteria were the causal agent for the initial bone loss, why does most bone loss occur the first year (1.5 mm) and less (0.1 mm) each successive year? The implant

sulcus depth (SD) progressively increases from the early bone loss, impairing hygiene and making anaerobic bacteria more likely the cause of bacteria-related bone loss. If bacteria are responsible for 1.5-mm early crestal bone loss, what local environmental changes occur to reduce their effect by 15 times after the first year?[25] The bacteria autoimmune theory cannot explain the marginal bone loss condition when it follows the pattern most often reported.

Although the bacteria theory does not explain adequately the marginal crestal bone loss phenomenon, this does not mean that bacteria are not a major contributor to bone loss around an implant. Threads and porous implant surfaces exposed to bacteria are reported to cause a more rapid loss of bone around an implant.[57] Poor hygiene also is reported to accelerate the bone loss observed around endosteal implants[58,59] (Fig. 7.12). To state that bacteria are never involved in marginal bone loss around an implant would be incorrect. Bone loss often is associated with bacteria as a causal agent. However, when most bone loss occurs in the first year and less bone loss is observed afterward, the hypothesis of bacteria as the primary causal agent for the early crestal bone loss cannot be substantiated.

Biological Width Hypothesis

The sulcular regions around an implant and around a tooth are similar in many respects. The rete peg formation within the attached gingiva and the histologic lining of the gingiva within the sulcus are similar in implants and teeth. A free gingival margin forms around an implant with nonkeratinized sulcular epithelium, and the epithelial cells at its base are similar to the functional epithelial cells described with natural teeth.[60] However, a fundamental difference characterizes the base of the gingival sulcus.

For a natural tooth, an average biological width of 2.04 mm exists between the depth of the sulcus and the crest of the alveolar bone (Fig. 7.13). It should be noted the biological "width" is actually a height dimension with a greater range in the posterior region compared with the anterior region and may be greater than 4 mm in height. In teeth, it is composed of a connective tissue (CT) attachment (1.07-mm average) above the bone and a junctional epithelial attachment (0.97-mm average) at the sulcus base, and the most consistent value between individuals is the CT attachment.[61-63]

The biological width allows gingival fibers and hemidesmosomes to establish direct contact with the natural tooth and acts as a barrier to the bacteria in the sulcus to the underlining periodontal tissues. When a crown margin invades the biological width, the crestal bone recedes to reestablish a favorable environment for the gingival fibers.[64,65]

Many surgical protocols recommend the placement of endosteal implants at or below the crest of the ridge during the first-stage surgery. The abutment-to-implant body connection may be compared with a crown margin. Berglundh and colleagues[66] observed 0.5 mm of bone loss below the implant-abutment connection within 2 weeks after stage II uncovery and abutment connection in dogs (Fig. 7.14). Lindhe and colleagues[67] reported an inflammatory CT extending 0.5 mm above and below this implant-abutment connection. Wallace and Tarnow[68,69] stated that the biological width also occurs with implants and may contribute to some of the marginal bone loss observed. The biological width theory seems attractive to explain the lack of bone loss from the first stage of surgery and the early bone loss seen within the first year after the second-stage abutment placement. However, it should be noted that the biological width in implants, as reported,

• **Fig. 7.12** Exudate around an implant is more likely to be present when the probing depth is greater than 5 mm because the biofilm is difficult to remove.
• **Fig. 7.13** Biological width of a natural tooth has a connective tissue (CT) zone that inserts into the cementum of the tooth. A periodontal probe will penetrate the sulcus and the junctional epithelial attachment. *FGM,* Free gingival margin; *JE,* junctional epithelium.

often includes the SD, whereas the natural tooth biological width does not include the SD.

Eleven different gingival fiber groups are observed around a natural tooth: dentogingival (coronal, horizontal, and apical), alveologingival, intercapillary, transgingival, circular, semicircular, dentoperiosteal, transseptal, periosteogingival, intercircular, and intergingival. At least six of these gingival fiber groups insert into the cementum of the natural tooth: the dentogingival (coronal, horizontal, and apical), dentoperiosteal, transseptal, circular, semicircular, and transgingival fibers. In addition, some crestal fibers from the periodontal fiber bundles also insert into the cementum above the alveolar bone.[63] However, in a typical implant gingival region, only two of these gingival fiber groups and no periodontal fibers are present (Fig. 7.15). These fibers do not insert into the implant body below the abutment margin as they do into the
• **Fig. 7.14** Bone levels recede to at least 0.5 mm around an abutment to implant connection after the implant extends through the soft tissue, regardless of whether the implant is loaded. (Courtesy Steve Wallace.)
• **Fig. 7.15** There are primarily two soft tissue fiber groups around an implant: circular fibers and crestal bone fibers. Neither of these fiber types insert into the implant or the abutment. The peri-implant probe penetrates the sulcus, junctional epithelial attachment, and most of the connective tissue (CT) zone. *FGM,* Free gingival margin; *JE,* junctional epithelium.

cementum of natural teeth.[62,70] Instead, the collagen fibers in the CT attachment around an implant run parallel to the implant surface, not perpendicular, such as with natural teeth.[71,72] The gingival and periosteal fiber groups are responsible for the CT attachment component of the biological width around teeth, and these are not present around the transosteal region of an implant. Therefore the CT attachment around the abutment-implant connection cannot be compared with the CT attachment of a tooth.

James and Keller[70] were first to begin a systematic scientific study to investigate the biological seal phenomenon of the soft tissue around dental implants. Hemidesmosomes help form a basal

lamina–like structure on the implant, which can act as a biological seal. However, collagenous components of the linear body cannot physiologically adhere to or become embedded into the implant body as they do in the cementum of the tooth.[73] The hemidesmosomal seal only has a circumferential band of gingival tissue to provide mechanical protection against tearing.[74] Therefore the biological seal around dental implants can prevent the migration of bacteria and endotoxins into the underlying bone. It is unable, however, to constitute a junctional epithelial attachment component of the biological width similar to the one found with natural teeth. The amount of early crestal bone loss therefore seems unlikely to be solely the result of the remodeling of the hard and soft tissues to establish a biological width below an abutment connection. No CT attachment zone or components of the linear body are embedded into an implant. The importance, amount, and mechanism for these anatomic structures require further investigation.

The crevice between the cover screw and the implant body during initial healing is similar to the crevice of the abutment-implant connection. Yet bone can grow over the cover screw, and therefore the crevice, in and of itself, may not be the cause of bone loss. The crevice between the implant and the abutment connection has been called a microgap. The actual dimension of this connection is usually 0 mm and has a direct metal-to-metal connection. However, when the crevice is exposed to the oral environment, bone loss is usually observed for at least 0.5 mm below the connection.[74-76]

The biological width hypothesis cannot fully explain the several millimeters of marginal crestal bone loss, which also has been observed readily with one-stage implants that extend through the tissue at the initial implant placement surgery and have no abutment-implant connections. For example, plate form (blade) implants, transosteal implants, pins, one-piece screw implants, and even subperiosteal implants, demonstrate the marginal crestal bone loss phenomenon. It is true that bone loss does occur around an exposed abutment-implant connection placed below the bone and is observed within 2 to 4 weeks once the connection is exposed to the oral environment. The bone loss often occurs before the implant is loaded with the prosthesis. It is logical to call this marginal bone loss the *biological width.*

The primary question remains, when the surgeon places the implant-abutment connection below the bone: How much bone loss is from the implant biological width, and therefore out of the influence of the dental practitioner? Several reports in the literature note implant macro- and microgeometry may affect the biological width dimensions or the amount of early crestal bone loss.[33,34,55,77-80]

The bone loss to the first thread observation implies that the amount of bone loss is similar for different implant designs. However, the first thread is a different distance from the abutment margin for several implant designs. A smooth, polished 4-mm collar below the bone has been associated with greater bone loss than a smooth 2-mm collar below the bone. The implant biological width concept does not explain completely the total amount of vertical bone loss observed. In addition, the amount of bone loss from the biological width occurs within 1 month, whether the implant is loaded or not, and is related to the crest module implant design and the position of the abutment-implant connection in relation to the bone but is unrelated to the density of the bone. The concept does not explain why greater crestal bone loss often is observed in soft bone compared with denser bone after loading, nor does it explain the higher implant failure rates in lesser-quality bone after loading.
• **Fig. 7.16** Mechanical stress applied to bone cells causes a change in shape or strain. The microstrains may trigger the release of cytokines and bone resorption.

Occlusal Trauma

Marginal bone loss on an implant may be from occlusal trauma.[45] *Occlusal trauma* may be defined as an injury to the attachment apparatus as a result of excessive occlusal force.[1] There is controversy as to the role of occlusion in the bone loss observed after an implant prosthesis delivery.[8] Some articles stated that peri-implant bone loss without implant failure is primarily associated with biological formations or complications.[16-18] Other authors suggested a correlation of crestal bone loss to occlusal overload.[8,45,47,81,82] The determination of the etiology of bone loss around dental implants is needed to minimize its occurrence and foster long-term peri-implant health that may ultimately determine implant prosthesis survival.

The association of occlusal trauma and bone loss around natural teeth has been debated since Karolyi claimed a relationship in 1901.[82] A number of authors concluded trauma from occlusion is a related factor in bone loss, although bacteria is a necessary agent.[83-88] On the other hand, Waerhaug and many others stated there is no relationship between occlusal trauma and the degree of periodontal tissue breakdown.[89-91] According to Lindhe and colleagues, "trauma" from occlusion cannot induce periodontal tissue breakdown.[92] However, occlusal trauma may lead to tooth mobility that can be transient or permanent. By extrapolation of this rationale, several authors have also concluded that occlusal trauma is not related to marginal bone loss around a dental implant.[16-18] To establish a further correlation between marginal bone loss and occlusal overload, related articles from cellular biomechanics, engineering principles, mechanical properties of bone, physiology of bone, implant design biomechanics, animal studies, and clinical reports were procured.[45]

Cellular Biomechanics

Bone remodeling at the cellular level is controlled by the mechanical environment of strain.[93] *Strain* is defined as the change in length divided by the original length, and the units of strain are given in percentages. The amount of strain in a material is directly related to the amount of stress applied.[94] Occlusal stress applied through the implant prosthesis and components can transmit stress to the bone–implant interface.[93] The amount of bone strain at the bone–implant interface is directly related to the amount of stress applied through the implant prosthesis. Mechanosensors in bone respond to minimal amounts of strain, and microstrain levels 100 times less than the ultimate strength of bone may trigger bone remodeling[95] (Fig. 7.16).

One of the earliest remodeling theories for a direct relationship between stress and the magnitude of bone remodeling was proposed by Kummer in 1972.[96] More recently, Frost reported on the cellular reaction of bone to different microstrain levels.[97,98] He observed that bone fractures at 10,000 to 20,000 microstrain units (1%–2% deformation). However, at levels 20% to 40% of this value (4000 units), bone cells may trigger cytokines to begin a resorption response. In other words, excessive bone strain may result in physical fracture, and it may cause bone cellular resorption. Therefore the hypothesis that occlusal stresses beyond the physiologic limits of bone may result in strain in the bone significant enough to cause bone resorption is plausible from a cellular biomechanics standpoint. To date, bone-cellular studies have not replicated this bone condition next to a dental implant. However, cytokines in the bone–implant interface tissue obtained from failed hip replacement devices leading to bone loss have been reported in humans.[99]

Engineering Principles

The relationship between stress and strain determines the modulus of elasticity (stiffness) of a material.[94] The modulus conveys the amount of dimensional change in a material for a given stress level. The modulus of elasticity of a tooth is similar to cortical bone. Dental implants are typically fabricated from titanium or its alloy. The modulus of elasticity of titanium is 5 to 10 times greater than that of cortical bone (Fig. 7.17). An engineering principle called the *composite beam analysis* states that when two materials of different elastic moduli are placed together
• **Fig. 7.17** Modulus of elasticity is greater for titanium (Ti) compared with bone. When stress is plotted on the Y-axis and strain on the X-axis, the modulus of elasticity can be obtained. Titanium is 5 to 10 times more rigid than cortical bone.

• **Fig. 7.18** Three-dimensional finite-element analysis of a titanium implant in a bone model after axial loading. The V-shape pattern of strain is greatest at the crestal region and decreases in intensity as the stress is dissipated throughout the implant length.

with no intervening material and one is loaded, a stress contour increase will be observed in which the two materials first come into contact.[100] In an implant–bone interface, these stress contours are of greater magnitude at the crestal bone region. This phenomenon was observed in both photoelastic and three-dimensional finite-element analysis studies when implants were loaded within a bone simulant.[101-104] These authors noted that the marginal bone loss observed clinically and radiographically around implants follows a pattern similar to the stress contours in these reports.

Bone Mechanical Properties

Bone density is directly related to the strength and elastic modulus of bone.[105] In denser bone, there is less strain under a given load compared with softer bone. As a result, there is less bone remodeling in denser bone compared with softer bone under similar load conditions.[97] A decrease in bone remodeling can result in a reduction of bone loss (Fig. 7.18). In a prospective human study, Manz observed that the amount of marginal bone loss next to an implant was related to the density of bone.[54] The initial peri-implant bone loss from implant insertion to uncovery was similar for all bone qualities. However, 6 months after prosthesis delivery, the additional radiographic-observed peri-implant bone loss ranged from 0.68 mm for quality 1 to 1.1 mm for quality 2-type bone, 1.24 mm for quality 3-type bone, and 1.44 mm for quality 4-type bone (Fig. 7.19). In other words, the more dense the bone, the less peri-implant bone loss was observed after prosthesis delivery. A clinical report by Appleton and colleagues[106,107] demonstrated that progressively loaded single-tooth implants in the first premolar region of human beings exhibited greater bone density increase in the crestal half of the implant interface and less marginal bone loss compared with nonprogressively loaded implants in the same jaw
region and even the same patient on the contralateral side without progressive loading. Because an increase in bone density is related to bone strength, elastic modulus, bone remodeling, and a decrease in marginal bone loss, these entities may be related to each other.

Animal Studies

Several animal studies in the literature demonstrated the ability of bone tissue to respond to a dental implant. For example, Hoshaw and colleagues inserted dental implants into a dog femur perpendicular to the axis of the long bone and perpendicular to the direction of the osteons.[108,109] After applying a tensile load to the implants for only 5 days, the bone cells reorganized to follow the implant-thread pattern and resist the load. This unique bone pattern was only observed for 3 to 4 mm around the implants. Crestal bone loss was also noted around these implants and explained as stress overload. To rearrange its osteal structure, bone must remodel.

Miyata placed crowns on integrated dental implants with no occlusal contacts (control group), and premature interceptive occlusal contacts of 100, 180, and 250 mm in a monkey animal model.[110-112] After 4 weeks of premature occlusal loads, the implants were removed in a block section and evaluated. The crestal bone levels for 100-mm and control implants with no loading were similar. However, statistically significant crestal bone loss was observed in the 180-mm group (Fig. 7.20). The 250-mm group experienced two to three times the bone loss of the crowns with moderate prematurities (Fig. 7.21).

Duyck used a dog model to evaluate the crestal bone loss around screw-type dental implants with no loads (controls), static loads, and dynamic loads.[113] The dynamic-loaded implants were the only group to demonstrate crestal bone loss. Because the only variable in these two studies was the intensity or type of occlusal load applied to the implants, these animal reports implied that dynamic occlusal loading may be a factor in crestal bone loss around rigid fixated dental implants.
• **Fig. 7.19** Mean peri-implant vertical bone change for study intervals by bone quality score. Many observed that the amount of bone loss from stage I to stage II was similar, regardless of bone quality. However, after 6 months of loading, the amount of marginal bone loss was directly related to the quality of the bone, with type 4 bone (the softest bone) exhibiting the greatest bone loss. (From Manz MC. Radiographic assessment of peri-implant vertical bone loss: DICRG Interim Report No 9. *J Oral Maxillofac Surg.* 1997;55(12 Suppl):62–71.)

• **Fig. 7.20** Miyata and colleagues loaded integrated implants for 4 weeks with premature contacts on crowns of 100, 180, and 250 mm. The implants with 180-mm premature contacts demonstrate a V-shaped crestal bone loss. (From Miyata T, Kobayashi Y, Araki H, et al. The influence of controlled occlusal overload on peri-implant tissue. Part 3: a histologic study in monkeys. *Int J Oral Maxillofac Implants.* 2000;15:425–431.)

• **Fig. 7.21** Implants with 250-mm premature contacts demonstrated greater bone loss than the 180-mm group. The 250-mm premature contact for 4 weeks lost the most bone. The higher stresses resulted in more crestal bone loss. (From Miyata T, Kobayashi Y, Araki H, et al. The influence of controlled occlusal overload on peri-implant tissue. Part 3: a histologic study in monkeys. *Int J Oral Maxillofac Implants.* 2000;15:425–431.)

Clinical Reports

Clinical reports have shown an increase in marginal bone loss around implants closest to a cantilever used to restore the lost dentition[114-116] (Fig. 7.22). Cantilever length and an increase in occlusal stress to the nearest abutment are directly related[117] and point to the fact that the increase in marginal bone loss may be related to occlusal stress. Quirynen and colleagues evaluated 93 implant patients with various implant restorations and concluded that the amount of crestal bone loss was definitely associated with occlusal loading.[33] These authors also reported increased crestal bone loss around implants in patients with no anterior occlusal contacts and parafunctional habits in full-arch fixed prostheses in both jaws.[33,34] These clinical reports did not provide statistical analyses to demonstrate a clear link between occlusal stress and bone loss. However, they indicated a consensus by some authors that occlusal overload may be related to the incidence of peri-implant bone loss around the cervical aspect of an implant. In fact, in a study of 589 consecutive implants, Naert and colleagues suggested that overload from parafunctional habits may be the most probable cause of implant loss and marginal bone loss after loading.[118]
• **Fig. 7.22** Cantilevers on fixed partial dentures have been shown to increase the marginal bone loss on the implant next to the cantilever.

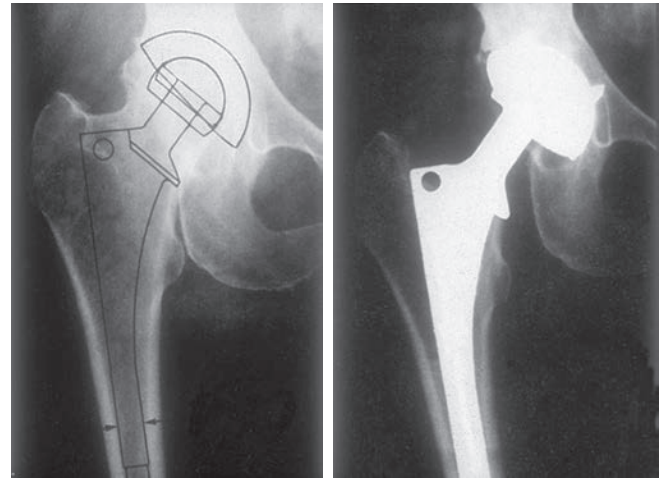
• **Fig. 7.23** Bone loss around orthopedic implants (osteolysis) is primarily caused by mechanical stress to the bone–implant interface.

Rangert and colleagues have noted that occlusal loads on an implant may act as a bending moment, which increases stress at the marginal bone level and can cause implant body fracture.[35] Before the fracture of the implant body, marginal bone loss was noted in this retrospective clinical evaluation. The same stress that caused implant fracture is the logical cause of the peri-implant bone loss before the event.

Rosenberg and colleagues found microbial differences in implant failures from both overload and biological complications.[81] Uribe and colleagues presented the case of a mandibular implant crown with a marginal peri-implantitis and osseous defect.[119] Histologic analysis revealed an infiltrate and a central zone of dense fibroconnective tissue with scanty inflammatory cells. According to the authors, this finding differed from chronic inflammatory tissue associated with infectious peri-implantitis and can be directly related to occlusal overload.

A clinical report by Leung and colleagues observed radiographic angular crestal bone loss to the seventh thread around one of two implants supporting a fixed prosthesis in hyperocclusion 2 weeks after prosthesis delivery.[120] The prosthesis was removed, and over the next few months radiographic observation showed that the crestal defect was repaired to almost the initial level, without any surgical or drug intervention. The prosthesis was then seated with proper occlusal adjustment. The bone levels stabilized at the second thread of the implant and remained stable over the next 36 months. This report indicated bone loss from occlusal overload is not only possible but may even be reversible when found early in the process. Therefore although no prospective clinical study to date has clearly demonstrated a direct relationship between stress and bone loss without implant failure, several practitioners agreed that a causal relationship may exist.

Discussion

Limited marginal bone loss during the first year of function after stage II surgery has been observed around the permucosal portion of dental implants for decades.[25,43] Hypotheses for the causes of crestal bone loss have included the reflection of the periosteum during surgery, preparation of the implant osteotomy, level of the microgap between the abutment and implant body, bacterial invasion, the establishment of a biological width, the implant crest module design, and occlusal overload (Fig. 7.23).[8,45,47,121]


The fact that occlusal overload may be an etiology for crestal bone loss does not mean other factors are not present. For example, the microgap position of the implant platform and abutment and the biological width often affect the marginal bone during the first month after the implant becomes permucosal.[54] However, the clinician has certain variables under their control that may influence the amount of peri-implant bone loss. The position of the microgap in relation to the bony crest and the implant crest module design are primarily under the control of the implant surgeon. On the other hand, the autoimmune or bacterial response of the patient, the biological width, and the patient response to the surgical trauma of implant placement are variables often escaping the control of the dentist. Once the final prosthesis is delivered to the patient, many events responsible for marginal bone loss have already occurred, whereas others such as occlusal overload and its relationship to the quality of bone persist. Occlusal overload is one factor most in control of the restoring dentist. If a relationship between occlusal overload and crestal bone loss exists, approaches to decrease stress to an implant interface appear appropriate.

A puzzling element in the relationship between occlusal force and peri-implant bone loss is the lack of continued bone loss until the implant fails. Implant crown height may be measured from the occlusal plane to the crest of the bone. The crown height is a vertical cantilever, which may magnify the stresses applied to the prosthesis. As a result of the greater crown height from the vertical bone loss, occlusal overload will be increased after crestal bone loss occurs. Therefore if occlusal loading forces can cause crestal bone loss, the resulting increased moment forces should further promote the loss of bone until the implant fails, yet most clinical studies indicate the rate of bone loss decreases after the first year of loading and is minimal thereafter. There are two reasons the bone levels may become stable after initial marginal bone loss, even when the cause is from occlusal overload: bone physiology and implant design mechanics.

Bone Physiology

The bone is less dense and weaker at stage II implant surgery than it is 1 year later after prosthetic loading.[122] Bone is 60% mineralized at 4 months and takes 52 weeks to complete its mineralization.[123]

Partially mineralized bone is weaker than fully mineralized bone. In addition, the microscopic organization of bone progresses during the first year. Woven bone is unorganized and weaker than lamellar bone, which is organized and more mineralized. Lamellar bone develops several months after the woven bone repair has replaced the devitalized bone caused by the surgical insertion trauma around the implant.[122] The occlusal stress levels may be high enough to cause woven bone microfracture or overload during the first year, but the increase in bone strength achieved after complete mineralization and organization may be able to resist the same stress levels during the subsequent years.

Because functional forces are placed on an implant, the surrounding bone can adapt to the stresses and increase its density, especially in the crestal half of the implant body during the first 6 months to 1 year of loading.[123] In a histologic and histomorphometric study of bone, Piatelli and colleagues reported reactions to unloaded and loaded nonsubmerged implants in monkeys (Figs. 7.24 and 7.25). The bone changed from a fine trabecular pattern after initial healing to a more dense and coarse trabecular pattern after loading, especially in the crestal half of the implant interface.[124] Hoshaw loaded threaded implants in dogs with a tensile load and noted that the fine trabecular bone pattern became coarse trabecular bone around the implant.[108,109] In addition, the bone reorganized to a more favorable condition to assist the direction and type of occlusal load (Fig. 7.26).

Fine trabecular bone is less dense than coarse trabecular bone.[122] Because the density of bone is directly related to its strength and elastic modulus, the crestal bone strength and biomechanical mismatch between titanium and bone may diminish gradually during the functional loading phase. In other words, the stresses applied to the peri-implant bone may be great enough to cause bone resorption during the first year because bone strains are greatest at the crest. However, the stresses applied below the crest of bone are of less magnitude and may correspond to the physiologic strain that allows the bone to gain density and strength. As a result, the occlusal load that causes bone loss initially (overload) is not great enough to cause continued bone loss once the bone matures and becomes more dense.

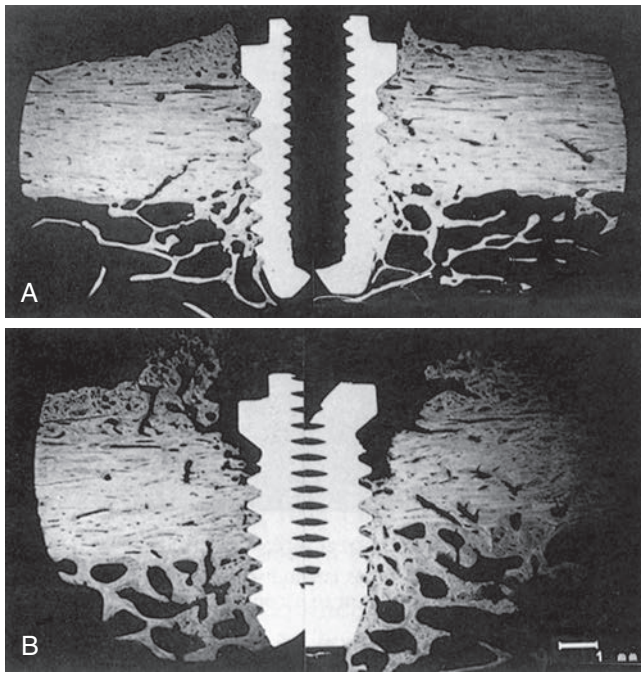
A clinical report by Appleton and colleagues demonstrated that progressively loaded single-tooth implants in the first premolar region of humans exhibited less bone loss and greater bone density increase in the crestal half of the implant interface compared with nonprogressively loaded implants in the same jaw region, and even in the same patient on the contralateral side (Fig. 7.27).[106,107] Marginal bone loss is less in the mandible compared with the maxilla in several clinical reports. The bone is denser in the mandible than the maxilla. The reduced crestal bone loss that has been reported in the mandible, in greater bone densities, and in progressively loaded implants points to the fact that stress/strain is a primary etiology of crestal bone loss after the implant is loaded. Therefore the stresses at the crest of the ridge may cause microfracture or overload during the first year, and the change in bone strength after loading and mineralization is complete alters the stress/strain relationship and reduces the risk of microfracture during the following years.[125]

Implant Design Biomechanics

Implant design may affect the magnitude or type of forces applied to the bone–implant interface. A smooth collar at the crest module may transmit shear forces to the bone. Bone is strongest under compressive forces, 30% weaker under tensile loads, and 65%

• **Fig. 7.24** In evaluating the bone around an implant after healing in a monkey model, a fine trabecular pattern is noted. (From Piatelli A, Ruggeri A, Franchi M, et al. An histologic and histomorphometric study of bone reactions to unloaded and loaded nonsubmerged single implants in monkeys: a pilot study. *J Oral Implantol.* 1993;19(4):314–320.)

• **Fig. 7.25** Once the implant is loaded, the fine trabecular bone became coarse trabecular bone, especially at the crestal region. When the stresses are too great, bone loss occurs. When the stresses are within the physiologic range, the bone density increases. (From Piatelli A, Ruggeri A, Franchi M, et al. An histologic and histomorphometric study of bone reactions to unloaded and loaded nonsubmerged single implants in monkeys: a pilot study. *J Oral Implantol.* 1993;19(4):314–320.)

weaker to shear forces.[126] Bone may heal to the smooth metal collar of the implant crest module from the time of implant insertion to implant uncovery; but placed under loading conditions,


• **Fig. 7.26** Researchers loaded threaded implants in dog tibiae and noted that the (A) fine trabecular bone in the apical region became (B) coarse trabecular after loading. In addition, crestal bone loss was observed on the loaded implant. (From Hoshaw SJ, Brunski JB, Cochran GVB: Mechanical loading of Brånemark fixtures affects interfacial bone modeling and remodeling, *Int J Oral Maxillofac Implants* 9:345–360, 1994.)
• **Fig. 7.27** Researchers observed in humans that less crestal bone loss and an increase in bone density were present around implants progressively loaded in the maxillary first premolar region. (From Appleton RS, Nummikoski PV, Pigno MA, et al. A radiographic assessment of progressive loading on bone around single osseointegrated implants in the posterior maxilla. *Clin Oral Implants Res.* 2005;16(2):161–167.)

the weaker shear interface is more likely to overload the bone. The first thread or a roughened surface condition of the implant is where the type of force changes from primarily shear to compressive or tensile loads. Therefore in many situations the 35% to 65% increase in bone strength, through changes from shear to compressive and/or tensile loads, is sufficient to halt the bone-loss process. This may be one of the reasons why implant designs with a 2-mm smooth collar above the first thread and a 4-mm smooth collar above the first thread lose bone to this "first thread" landmark.[127] (A previous review addressed the range of bone loss with different implant designs.[128-130]) Because implant crest module designs may affect the amount of bone loss, and the implant design contributes to the force transfer of the bone–implant interface, the stress-related theory for one of the etiologies of crestal bone loss is further enhanced.

Literature from cellular biomechanics, engineering principles, differences in bone loss related to bone density, animal studies, and clinical reports all substantiate that occlusal overload may be an etiology of peri-implant bone loss. Literature related to orthopedic joint replacement devices clearly indicate biomechanical stress and overload contribute to bone loss at the implant interface. The increase in bone mineralization and organization during the first year, the increase in bone density at the implant interface, and the type of force changes at the first thread of the implant body all are factors that may halt the bone loss phenomenon after the initial marginal loss. Although this occlusal overload concept does not negate other factors related to marginal bone loss, it is more clinician dependent than most other parameters. Treatment plans that emphasize occlusal stress reduction to the prosthesis are therefore mandated.

Biomechanical Stress Effects on Treatment Planning

Understanding the relationships of stress and related complications provides a basis for a consistent treatment system. The clinical success and longevity of endosteal dental implants as load-bearing abutments are controlled largely by the biomechanical milieu in which they function.[127,131] The stress treatment theorem, developed by the Dr. Carl E. Misch, states that most all treatment related to the science of implant dentistry should be centered around the biomechanical aspects of stress.[131]

Stress-related conditions that affect the treatment planning in implant dentistry include the bone volume lost after tooth loss, bone quality decrease after tooth loss, complications of surgery, implant positioning, initial implant interface healing, initial loading of an implant, implant design, occlusal concepts, prosthesis fixation, marginal bone loss, implant failure, component fracture, prosthesis fracture, and implant fracture. Biomechanical parameters are excellent predictors of increased risks because they are objective and can be measured. One can not only predict which condition presents greater stress, and therefore greater risk, but also how much the risk is increased. A risk factor is not an absolute contraindication, but it significantly increases the complication rate. With so many variables, success or failure in implant dentistry is often a complex subject and not necessarily an exact science, but this does not mean a method cannot be established to decrease the risk. Greater forces in one aspect of treatment do not always equal implant failure or complications, especially because so many factors are involved, including the density of bone around the implant. Yet the risks may be considerably reduced

by decreasing the overall stress to the overall system. To assess the increase in risk factors, each factor is considered separately. The goal is to decrease the overall risk. Understanding the relationships of stress and related complications provides a basis for a consistent treatment system. The stress-treatment theorem has evolved into a particular sequence of treatment planning (Box 7.3).

Prosthesis Design

When partially and completely edentulous patients seek implant treatment, their goal is to obtain teeth; therefore it is imperative the clinician visualize the prosthesis before the selecting the foundation (the implants). This is often termed "top-down" treatment planning. The design of the prosthesis is related to a number of factors with the number and position being of utmost importance. For example, if an inadequate number of implants are placed, then the final prosthesis is at risk from biomechanical stress. If the positions of the implants are not ideal, then the final prosthesis is compromised because of potential biomechanical stress issues.

Patient Force Factors

It is crucial the implant clinician take into consideration specific force factors related to the patient. There are numerous force factors to consider: (1) bruxism, (2) clenching, (3) tongue thrust, (4) crown height space, (5) masticatory dynamics, and (6) the opposing arch. The forces applied to the prosthesis also differ by their (1) magnitude, (2) duration, (3) type, and (4) predisposing factors (e.g., cantilevers).

Some patient force factors are more important than others. For example, severe bruxism is the most significant factor and, on a risk scale from 1 to 10, is a 10.[132] Forces from bruxism are often the most difficult forces to contend with on a long-term basis.[132,133] As a result of this condition, marginal implant bone loss, unretained abutments, and fatigue fractures of implants or prostheses are more likely. The increase in force magnitude and duration is a significant problem. A bruxing patient is at higher risk in two ways. The magnitude of the force increases because the muscles become stronger and the number of cycles on the prosthetic components is greater as a result of the parafunction. Eventually some component of the system will break if the occlusal disease cannot be reduced in intensity or duration.

The second-highest risk factor is severe clenching, which is a 9 on the risk scale. Cantilevers, including crown height, are next on the list, followed by masticatory muscle dynamics. The position of the implant in the arch is followed by the direction of load, with a risk of 5. These numbers are arbitrary because they are influenced by the other force factors. For example, angled forces greater than 30 degrees to the implant body are more damaging than a crown height of 20 mm with a long axis load.[134-136] The clinician should

---

evaluate the number of force conditions and their influencing severity factors. As the overall number increases, the risks increase, and the overall treatment plan should be modified to decrease the increased force or by increasing the area of support.

Bone Density

The density of bone is directly related to the strength of the bone.[105,137] Misch and colleagues have reported on the biomechanical properties of four different densities of bone in the jaws.[105] Dense cortical bone is 10 times stronger than the soft, fine trabecular bone. D2 bone is approximately 50% stronger than D3 bone. In addition, the stiffness of the bone is affected by the bone density. Young's modulus for compact bone is 10 times larger than that for cancellous bone. The denser the bone, the stiffer the bone, and there is less biomechanical mismatch to titanium during loading.

Therefore in poorer bone qualities that are susceptible to biomechanical stress, the concept of progressive bone loading may be implemented. Progressive bone loading changes the amount and density of the implant–bone contact. The bone is given time to respond to a gradual increase in occlusal load. This increases the quantity of bone at the implant interface, improves the bone density, and improves the overall support system mechanism.

Key Implant Positions and Implant/Abutment Number

Key Implant Positions

In any prostheses, there are implant positions that are more important from a stress management perspective. In one- or two-unit prostheses, an implant should be placed in each prospective tooth position, without a cantilever crown contour in any direction (e.g., facial, lingual, mesial, distal). In a three- to four-unit restoration, the most important abutments are the terminal abutments. If a terminal abutment is not present, a cantilever is created, which magnifies the stress to the rest of the support system. Cantilevers are a force magnifier and represent a considerable risk factor in implant support, screw loosening, crestal bone loss, fracture, and any other item negatively affected by force.[134,136,138] Therefore the goal of implant position should be to eliminate cantilevers whenever possible, especially when other force factors are increased.

In a 5- to 14-unit prosthesis, intermediary abutments are also important to limit the edentulous spans to less than three pontics. A three-pontic prosthesis flexes 18 times more than a two-pontic prosthesis, whereas a two-pontic restoration flexes eight times more than a one-pontic prosthesis.

The canine is an important implant position whenever the canine and two adjacent teeth are missing. Therefore when the two premolars, a first premolar and lateral, or a lateral and a central, are missing next to a canine, a canine implant is warranted. In addition, the ideal occlusion for an implant prosthesis is implant-protected occlusion. This entails disoccluding off the canine; therefore an implant in this position has significant occlusion benefits.

For fixed full-arch prostheses, the arches may be divided into sections. An edentulous mandible may be divided into three sections from a biomechanical perspective: the anterior (canine to canine) and the bilateral posterior regions (premolar and molars). A key implant position is one implant in each region, or at least three key implants.

The edentulous maxilla is divided in five regions: the anterior (laterals and centrals), bilateral canines, and the bilateral posterior (premolar and molars). A key implant position is one implant in each region, or at least five key implants.

Treatment plans should incorporate methods to reduce stress and minimize its initial and long-term complications. The definition of *stress* is force divided by the functional area over which it is applied. One biomechanical approach to decrease stress is to increase the surface area of the implant support system.[134] The overall stress to the implant system may be reduced by increasing the area over which the force is applied. The most effective method to increase the surface area of implant support is by increasing the number of implants used to support a prosthesis (Fig. 7.28).

Splinting

The concept of splinting is controversial in implant dentistry. Studies by Bidez and Misch demonstrated that force distributed over three abutments results in less localized stress to crestal bone than two abutments.[139] This study applied only to implants that are splinted together. Therefore the number of pontics should be reduced and the number of implant abutments should be increased whenever forces are increased compared with a treatment plan for an ideal patient with minimal force factors.[136,138,140-142] The retention of the prosthesis is also improved with a greater number of splinted abutments. This approach also decreases the incidence of unretained restorations and restorative material fracture. The overall amount of stress to the system is reduced, and the marginal ridges on the implant crowns are supported by the connectors of the splinted crowns, with resulting compressive forces rather than shear loads on the restorative material.

Common clinical sense indicates that it is better to err with one extra implant than to err with too few. One implant too few, and the entire treatment, along with the prosthesis, may fail. One implant too many rarely will be problematic. Because of the associated morbidity of too few implants (i.e., loss of the prosthesis, financial costs, loss of patient confidence), top-down treatment planning should always be adhered to (Fig. 7.29).

Implant Size

An excessive implant length is not critical at the crestal bone interface but it is critical for initial stability and the overall amount of bone–implant interface. The increased length also provides resistance to torque or shear forces when abutments are screwed into place. However, the additional length does little to decrease the stress that occurs at the transosteal region around the implant at the crest of the ridge during occlusal loading.[143-145] Therefore excessive implant length is not as effective in decreasing stress from force factors.

• **Fig. 7.28** Increasing the implant number is an effective method to decrease the stress to each component in the system. (A) Two implants supporting a three-unit prosthesis have more stress to the implant interface than (B) three implants supporting a similar restoration. The additional implant also decreases the pontic number and increases the retention of the prosthesis.

• **Fig. 7.29** Implant prosthesis splinting. Radiograph showing implant fracture in a patient with parafunction. Most likely if the implants were splinted, then the implant body fracture would not have occurred.

On the other hand, with improper biomechanical management, shorter implants may have higher failure rates after loading.[146,147] Therefore the initial treatment plan should use implants with lengths that are related to the amount of force expected, bone density, and patient-related force factors. Ideally, softer bone types require longer implants than denser bone. The surface area of each implant is directly related to the width of the implant. Wider root form implants have a greater area of bone contact than narrow implants (of similar design), which is a result of their increased circumferential bone contact areas. Each 0.25-mm increase in implant diameter may increase the overall surface area approximately 5% to 10% in a cylinder implant body. Bone augmentation in width may be indicated to increase implant diameter by 1 mm when force factors are greater than ideal. In addition, it has been suggested that an increase in implant diameter may be more effective than implant staggering to reduce stress.[148,149]

It is interesting to note that the natural teeth are narrower in the anterior regions of the mouth, in which the amount of force generated is less. The natural teeth increase in diameter in the premolar region and again in the molar region as the amount of force increases, with a total 300% surface area increase from the lower anterior teeth to the maxillary molars. The length of natural teeth roots does not increase from anterior to posterior regions of the arch, but their cross section does. The supplemental implant support gained from the greater diameter decreases stress and the likelihood of implant fracture and it reduces the force to the abutment screw, which results in less screw loosening.

Available Bone

Once the previous steps to the treatment plan sequence have been determined, the available bone in the potential implant sites is evaluated. If adequate bone is present to position the preselected implant number, size, and design, the treatment sequence proceeds to the next factor. If available bone is not present, then bone augmentation or modification is required. If these options are not possible, then the sequence of treatment is begun again, starting from the prosthesis design.

In the past, the available bone was the first condition evaluated and the treatment would proceed based on the number and position of implants, with little regard to size or design. This approach often led to the high complication rates related to increased stress conditions.

Implant Design

Implant macrodesign may affect surface area even more than an increase in width. A cylinder (bullet-shaped) implant provides 30% less surface area than a conventional threaded implant of the same size. Strong and colleagues have identified 11 different variables that affect the overall functional surface area of an implant.[150] A threaded implant with 10 threads for 10 mm has more surface area than one with five threads. A thread depth of 0.2 mm has less surface area than an implant with 0.4 mm. Therefore implant design be one of the easiest methods to increase surface area significantly and decrease overall risk to the implant interface.

In addition to the stress theorem and relative sequence of treatment plan, corollaries have been developed to facilitate the selection of the most appropriate therapy (Box 7.4).

• BOX 7.4   Stress Treatment Theorem Corollaries

A. Patients want teeth, not implants. The advantages and disadvantages of fixed versus removable should be discussed in detail with the patient.
B. If you had (1) ideal bone conditions, (2) optimal patient economic conditions, (3) optimal training, and (4) no time limitation, what would the treatment plan be?
C. Do not compromise a long-term prosthesis for a 3- to 6-month delay in treatment or the addition of an extra implant.
D. Understand the difference between *can* versus *should*.
E. When in doubt, overengineer the foundation (e.g., increase implant number increase surface area).
F. When two or more approaches may obtain a similar result, use the least invasive and least complicated to achieve a predictable result.
G. When two or more methods may obtain a similar result, use the least expensive yet predictable method when developing the treatment plan.
H. When two or more approaches may obtain a similar result, use the most predictable rather than the fastest method.
I. Time is a factor in treatment only when all other factors are equal.
J. The patient with economic limitations cannot afford complications.
K. Apply primarily compressive loads when possible at the following levels:
  1. Restorative material
  2. Cement
  3. Abutment
  4. Screw
  5. Implant body
  6. Implant–bone interface
L. If you do not understand biomechanical stress, it will lead to psychological stress.
M. It is often necessary to modify the mouth or modify the mind of the patient.
N. It is better to see the back of the patient's head once than it is to see their face over and over again

---

Summary

An understanding of the etiology of the most common implant complications has led to the development of a stress-based treatment plan theorem. Once the implant clinician has identified the sources of forces on the implant system, the treatment plan may be designed to minimize their potential effect on the implant, bone, and final prosthesis. Under these conditions, a consistent solution is an increase in implant–bone surface area. Additional implants are the solution of choice to decrease stress, along with an increase in implant width or height (i.e., poor bone density). In addition, the reduced pontic area helps to dissipate stresses more effectively to the bone structure, especially at the crest. The retention of the final prosthesis or superstructure is further improved with additional implant abutments. Therefore a number of variables and factors should be considered to reduce the morbidity of the implant process with respect to biomechanical stress.

Treatment Planning: Force Factors Related to Patient Conditions

RANDOLPH R. RESNIK AND CARL E. MISCH[†]

Biomechanic stress is a significant risk factor in implant dentistry. Its magnitude is directly related to force. As a result an increase in any dental force factor magnifies the risk for stress-related complications. Various patient conditions place different amounts of force in magnitude, duration, type, and direction. In addition, several factors may multiply or increase the effect of these other conditions. Once the prosthesis option and key implant positions are determined, the potential force levels that will be exerted on the prosthesis should be evaluated and accounted for to modify the overall treatment plan. Several factors observed during the dental evaluation predict additional forces on future implant abutments. The initial implant survival, loading survival, marginal crestal bone loss, incidence of abutment or prosthetic screw loosening, unretained restorations, porcelain fracture, and component fracture are all influenced by the force factors.

Box 8.1 includes primary patient factors that affect the stress environment of the implant and prosthesis.

Bite Force

The greatest natural forces exerted against teeth, and thus against implants, occur during mastication.[1,2] These forces are primarily perpendicular to the occlusal plane in the posterior regions, are of short duration, occur only during brief periods of the day, and range from 5 to 44 pounds for natural teeth. The actual force on each tooth during function has been recorded on strain gauges in inlays.[3] A force of 28 psi was needed to chew a raw carrot, and 21 psi was needed to chew meat. The actual time during which chewing forces are applied on the teeth was about 9 minutes each day.[4] The perioral musculature and tongue exert a more constant, yet lighter horizontal force on the teeth or on implants. These forces reach 3 to 5 psi during swallowing.[5] A person swallows 25 times per hour while awake and 10 times per hour while sleeping, for a total of 480 times each day.[4] Therefore natural forces against teeth are primarily in their long axis, less than 30 psi, and for less than 30 minutes for all normal forces of deglutition and mastication (Box 8.2). Forces of mastication placed on implant-supported bridges have been measured in a similar range as natural teeth.

[†]Deceased.

The maximum bite force differs from mastication force, varies widely among individuals, and depends on the state of the dentition and masticatory musculature. There have been many attempts to quantify the normal maximum bite force. In 1681 Borelli suspended weights on a thread over the molars while the mandible was open. The maximum load recorded for which the person was still able to close ranged from 132 to 440 lb. A force of 165 lb was recorded on a gnathodynamometer, the first instrument to record occlusal force; the gnathodynamometer was developed by Patrick and Dennis in 1892. Black[6] improved this early design and recorded average forces of approximately 170 lb. More recent studies indicate normal maximum vertical biting forces on teeth or implants can range from 45 to 550 psi.[7-22] The forces on the chewing side and the opposite side appear very similar in amplitude (Table 8.1).[8]

Awawdeh et al.[23] evaluated maximum bite force in endodontically treated teeth versus natural, vital teeth. They showed the maximum biting force was significantly higher in root-canaled teeth in comparison with vital natural teeth. The loss of the mechanoreceptor-mediated protective mechanism allows for the increased biting force. Therefore caution should be exercised when an implant prosthesis opposes an endodontically treated tooth because protective modifications need to be addressed in the occlusion and prosthesis design.[23]

In summary, maximum biting forces are not expressed quantitatively or qualitatively by patients. The implant clinician must take into consideration various factors that may dictate a higher biting force and therefore could increase risks for occlusal overload to the implant and implant prosthesis.

Parafunction

Parafunctional forces on teeth or implants are characterized by repeated or sustained occlusion and have long been recognized as harmful to the stomatognathic system.[24-26] These forces are also most damaging when applied to implant prostheses.[18] For example, the lack of rigid fixation during healing is often a result of parafunction from soft tissue–borne prostheses overlying the submerged implant. The most common cause of both early and late implant

- Opposing arch composition

• BOX **8.2**   **Normal Forces Exerted on Teeth**

Bite Forces
- Perpendicular to occlusal plane
- Short duration
- Brief total period (9 min/day)
- Force on each tooth: 20 to 30 psi
- Maximum bite force: 50 to 500 psi

Perioral Forces
- More constant
- Lighter
- Horizontal
- Maximum when swallowing (3–5 psi)
- Brief total swallow time (20 min/day)

---

failure after successful surgical fixation is the result of parafunction. Such complications occur with greater frequency in the maxilla because of a decrease in bone density and an increase in the resulting moment of force.[27] The presence of these conditions must be carefully noted during the early phases of treatment planning.

Nadler[25] has classified the causes of parafunction or nonfunctional tooth contact into the following six categories:

1. Local
2. Systemic
3. Psychological
4. Occupational
5. Involuntary
6. Voluntary

Local factors include tooth form or occlusion, as well as soft tissue changes such as ulcerations or pericoronitis. Systemic factors include cerebral palsy, epilepsy, and drug-related dyskinesia. Psychological causes occur with the greatest frequency and include the release of emotional tension or anxiety.[28] Occupational factors concern professionals such as dentists, athletes, and precision workers, as well as the seamstress or musician who develops altered oral habits. The fifth cause of parafunctional force is involuntary movement that provokes bracing of the jaws, such as during lifting of heavy objects or sudden stops while driving. Voluntary causes include chewing gum or pencils, bracing the telephone between the head and shoulder, and pipe smoking.

The parafunctional groups presented in this chapter are divided into bruxism, clenching, and tongue thrust or size. The dental literature usually does not identify bruxism and clenching as separate entities. Although several aspects of treatment are similar, their diagnosis and treatment are in some ways different. As such, they will be presented as different entities in this discussion. The magnitude of parafunction may be categorized as absent, mild, moderate, or severe. Bruxism and clenching are the most critical factors to evaluate in any implant reconstruction. No long-term

success will be obtained with severe parafunction of bruxism or clenching. Therefore the clinician should always try to diagnose the presence of these conditions.

This does not mean that patients with moderate and severe parafunction cannot be treated with implants. For example, a physician treats a patient with uncontrolled diabetes. However, the patient may lose his or her vision or require an amputation treatment. Unsuccessful treatment of the patient with diabetes may not be the fault of the physician. Not recognizing diabetes in the presence of obvious signs and symptoms, of course, is another issue. Because the patient with moderate-to-severe parafunction represents so many additional risks in implant dentistry, one must be aware of these conditions and the methods to reduce their noxious effects on the entire implant-related system.

Bruxism

Bruxism primarily includes the horizontal, nonfunctional grinding of teeth. The forces involved are in significant excess of normal physiologic masticatory loads. Bruxism may affect the teeth, muscles, joints, bone, implants, and prostheses. These forces may occur while the patient is awake or asleep, and may generate increased force on the system several hours per day. Bruxism is the most common oral habit.[25] Sleep clinic studies have evaluated nocturnal bruxism and found approximately 10% of those observed had obvious movement of the mandible with occlusal contacts.[29,30] More than half of these patients had tooth wear affecting esthetics. Only 8% of these patients were aware of their nocturnal bruxism, and only one quarter of the patients' spouses were aware of the nocturnal habit. Muscle tenderness in the morning was observed less than 10% of the time.[31] A study on bruxing patients with implants showed 80% of sleep bruxism occurred during light sleep stages but did not cause arousal.[32] Therefore patients with bruxism may or may not have obvious tooth wear affecting esthetics; may brux nocturnally, but their bed partners do not know most of the time; rarely have muscle tenderness when they are awake; and are usually unaware of their oral habit. In other words, nocturnal bruxism is sometimes difficult to diagnose.[33] Multiple studies have also shown a direct correlation between stress and bruxism.[34,35]

The maximum biting force of bruxing patients is greater than average. Just as an experienced weight lifter can lift more weight, the patient constantly exercising the muscles of mastication develops a greater bite force. For example, a man who chews paraffin wax for an hour each day for a month can increase the bite force from 118 to 140 psi within 1 week. Chewing gum, bruxism, and clenching may accomplish the same feat. Eskimos, with a very tenacious diet and who chew their leather to soften it before fabrication of clothing, have maximum bite forces of more than 300 psi. A 37-year-old patient with a long history of bruxism recorded a maximum bite force of more than 990 psi (four to seven times normal).[36] Fortunately the bite force does not continue to increase in most bruxing patients. When muscles do not vary their exercise regimen, their size and function adjust to the dynamics of the situation. As a result the higher bite forces and muscle size usually do not continue in an unending spiral.

Diagnosis

Bruxism does not necessarily represent a contraindication for implants, but it does dramatically influence treatment planning. The first step is to recognize the condition before the treatment is rendered. The symptoms of this disorder, which may be ascertained by a dental history, may include repeated headaches, a history of fractured teeth or restorations, repeated uncemented restorations, and jaw discomfort upon awakening.[24,37] Therefore

TABLE 8.1   Mean Maximum Biting Force Recorded on Natural Teeth or Implants

Authors	Natural Teeth Dental Implants	Mean Maximum Masticatory Force
Carr and Laney, 1987[a]	Conventional denture	59 N

when the patient is aware of muscle tenderness or the spouse is conscious of the nocturnal condition, the diagnosis is readily obtained. However, many patients do not attribute these problems to excessive forces on the teeth and report a negative history. A lack of these symptoms does not negate bruxism as a possibility.

Fortunately, many clinical signs warn of excessive grinding. The signs of bruxism include an increase in size of the temporal and masseter muscles (these muscles along with the external pterygoid may be tender), deviation of the lower jaw on opening, limited occlusal opening, increased mobility of teeth, cervical abraction of teeth, fracture of teeth or restorations, and uncemented crowns or fixed prostheses. However, the most accurate and easiest way to diagnose bruxism is to evaluate the wearing of teeth. Not only is this the simplest method to determine bruxism in an individual patient, it also allows the disorder to be classified as absent, mild, moderate, or severe (Figs. 8.1 through 8.3). No anterior wear patterns in the teeth signify an absence of bruxism. Mild bruxism has slight wearing of anterior teeth but is not a cosmetic compromise. Moderate bruxism has obvious anterior incisal wear facets but no posterior occlusal wear pattern. Severe bruxism has minimal to absent incisal guidance from excessive wear, and posterior wearing of the teeth is obvious.

Nonfunctional wear facets on the incisal edges may occur on both natural or replacement teeth, especially in the mandible and

• **Fig. 8.1** A patient has mild bruxism exhibiting a wear facet (incisal edge) on the mandibular canine and the slight notch in the maxillary lateral incisor.

maxillary canines, and there may be notching of the cingulum in the maxillary anterior teeth. Isolated anterior wear is usually of little significance if all posterior teeth contacts can be eliminated in excursions.

• **Fig. 8.2** Patients usually will grind their teeth in a specific, repeated movement of the mandible. When the opposing wear facets of the teeth are in contact, one should note the occlusal position of the teeth. The patient shown in Fig. 8.1 has a working contact on the mandibular premolar with the maxillary canine in this engram position (green arrow). The slight cervical abfraction of the mandibular first premolar is a consequence of the parafunction. The patient's posterior teeth should not occlude in this excursive position to decrease the amount of force on the anterior teeth.

• **Fig. 8.3** This patient has severe bruxism because occlusal wear is anterior and posterior. Because of the excessive wear, the incisal guidance should be reestablished before a maxillary arch fixed reconstruction.

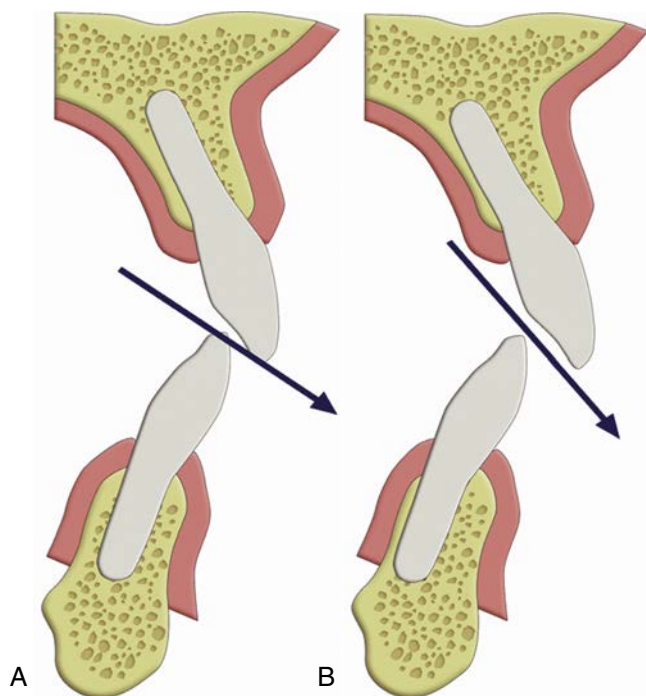
Tooth wear is most significant when found in the posterior regions, and it may changes the intensity of bruxism from the moderate to the severe category. Posterior wear patterns are more difficult to manage, because this usually is related to a loss of anterior guidance in excursions; once the posterior teeth contact in excursive jaw positions, greater forces are generated.[38] The masseter and temporalis muscles contract when posterior teeth contact. With incisal guidance and an absence of posterior contact, two-thirds of these muscles do not contract, and as a consequence the bite force is dramatically reduced. However, when the posterior teeth maintain contact, the bite forces are similar in excursions, as during posterior biting. Therefore in the patient with severe bruxism, the occlusal plane, the anterior incisal guidance, or both may need modification to eliminate all posterior contacts during mandibular excursions before the implant restoration.

Bruxing patients often repeat mandibular movements, which are different from border movements of the mandible and are in one particular direction. As a result the occlusal wear is very specific and primarily on one side of the arch, or even on only a few teeth

• **Fig. 8.4** This patient exhibits an engram pattern of bruxism primarily toward the left canine to central incisors. The right canine and lateral incisor have far fewer wear facets. This "pathway of destruction" is specific.

(Fig. 8.4). This engram pattern usually remains after treatment. If the restoring dentist reestablishes incisive guidance on teeth severely affected by an engram bruxing pattern, the incidence of complications on these teeth will be increased. The most common complications on teeth restored in this "pathway of destruction" are porcelain fracture, uncemented prostheses, and root fracture.[37] When implants support the crowns in the pathway of destruction, the implant may fail, fracture, or have crestal bone loss, abutment screw loosening, material fracture, or unretained restorations.[39,42] If the patient continues the severe bruxism pattern, the question is not whether but when and which complications will occur. The dentist should inform the patient that these habits will cause these problems. Treatment may be rendered to repair these problems, but there will be complications if the bruxism is not reduced.

Bruxism changes normal masticatory forces by the magnitude (higher bite forces), duration (hours rather than minutes), direction (lateral rather than vertical), type (shear rather than compression), and magnification (four to seven times normal).[36,43-45] The method to restore severe bruxism may be problematic, even when the desire is primarily cosmetic. As the anterior teeth wear, they often erupt, and the overall occlusal vertical dimension (OVD) remains unchanged. In addition, the alveolar process may follow the eruption of the tooth. As such, when the anterior teeth are restored for esthetics (or to obtain an incisal guidance), the reduced crown height cannot be increased merely by increasing the height of the crown to an average dimension. Instead, the following guidelines are suggested:

1. Determine the position of the maxillary incisor edge of the anterior teeth. They may be acceptable (if eruption occurred as they wore) or need greater coronal length to correct related incisal wear.
2. Determine the desired occlusal vertical dimension (OVD). This is not an exact dimension and may exist at several different positions without consequence. However, like most factors, there is a range that is patient specific and does follow guidelines. The most common methods to determine this dimension relate to facial measurements, closest speaking space, physiologic rest position, speech, and esthetics. This is one of the most important steps. If the vertical dimension is collapsed because of anterior and posterior occlusal wear, much more rehabilitation is required. This condition is observed more often when bruxism is severe, the anterior incisal guidance was lost, and as a consequence, the severe bruxism wear is increased due to an increase in force factors. The accelerated occlusal wear may cause a loss of OVD. The OVD is rarely decreased when incisal


● **Fig. 8.5** The incisal guidance for a patient with moderate-to-severe bruxism should be shallow (A), not deep (B) to reduce the force on the anterior teeth during excursive movement of the mandible.

guidance is still present, because the posterior teeth maintain the dimension and the anterior teeth have sufficient time to erupt because the forces are less and the wear rate is slower.

3. Evaluate and restore the position of the lower anterior teeth where necessary. In the past, several authors have stated that a reconstruction begins with the lower anterior teeth. The mandibular arch cannot be restored until the maxillary anterior teeth and OVD are established. Many esthetic and speech guidelines are available to help the restoring dentist with the position of the maxillary anterior teeth. For example, when a dentist begins the restoration of a completely edentulous patient, the maxillary anterior wax rim position is often first determined for similar reasons.

The position of the lower anterior teeth should contact the lingual surfaces of the maxillary anterior teeth at the established OVD, and the amount of vertical overlap of the maxillary incisal edge and the angle of the incisal contacts in protrusive movements of the mandible determines the angle and height of the anterior guidance. This dimension must be greater than the condylar disc assembly (the angle of the eminentia) so the posterior teeth will separate during mandibular excursions.

In patients with moderate-to-severe bruxism, the height of the vertical overjet and the angle of incisal guidance should not be extreme, because the amount of the force on the anterior abutments, cement seals, and restortaive material is directly related to these conditions (Fig. 8.5). In other words, the greater the incisal overjet, the greater the distance between the posterior teeth in excursions, and the greater the force generated on the anterior teeth during this movement. In patients with severe bruxism the intensity of the force should be reduced because the duration of the force is increased.

When anterior tooth wear is accompanied by tooth eruption and maintenance of the OVD, and alveolar bone in the region has extruded toward the incisal plane (dentoalveolar extrusion), the incisal edges of the teeth should not be elevated. Instead, the

- Overeruption of teeth
- Gingiva and bone move with teeth
- Curved or concave gingival line in relation to horizon
- Can occur in any teeth in the mouth
- Etiology
  - Uncoupled anterior teeth (i.e., Class II malocclusion)
  - Supereruption secondary to incisal wear
  - Supereruption secondary to lack of opposing teeth
  - Developmental cant
● **Fig. 8.6** On a fatigue curve for a material, stress corresponds to the vertical axis and cycles to failure to the horizontal axis. A point exists at which the stress is so great that the material breaks with only one cycle. When the stress is low enough, the material will not break, regardless of the number of cycles. The stress amount at the highest point of this safe zone is called the *endurance limit*. Patients with parafunction increase the amount of stress to the implant-prosthetic system and increase the number of the cycles for the higher levels. Fatigue failures are therefore common.

alveolar bone and cervical regions should be reduced, and crown lengthening should be performed on the teeth before their restoration. This is most often necessary in the mandibular anterior region but may be observed in any region of the mouth after long-term severe bruxism. Usually there exist anterior wear and extrusion with no posterior wear (i.e., posterior teeth maintain the vertical dimension). In addition, endodontic therapy may be required to allow proper anterior tooth preparation (Box 8.3). Crown lengthening and associated procedures are not necessary when the vertical dimension has been reduced in relation to the incisal wear. Instead, the teeth may be prepared in their present state. The restoration restores the OVD and reestablishes anterior incisal guidance.

4. The posterior plane of occlusion is then determined. This may be accomplished by using first the maxillary arch or the posterior mandibular arch. However, it is best if the same bilateral posterior quadrants are addressed at the same time, so that the posterior plane may be parallel to the horizontal plane. The maxillary posterior region is most often determined first in the completely edentulous patient.

Fatigue Fractures

The increase in duration of the force is a significant problem. Materials follow a fatigue curve, which is affected by the number of cycles and the intensity of the force (Fig. 8.6).[46-48] A force can be so great that one cycle causes a fracture (e.g., a karate blow to a piece of wood). However, if a lower force magnitude repeatedly hits an object, the object will still fracture. For example, the

● **Fig. 8.7** (A and B) FP-3 hybrid (acrylic + metal) prostheses exhibiting significant wear from parafunctional habits. (C) Porcelain fused to metal FP-3 showing metal framework fracture and porcelain fracture. (D) Zirconia framework fracture resulting from parafunctional habits.

wire coat hanger that is bent does not break the first time, but repeated bends will fracture the material, not because the last bend was more forceful but because of fatigue. A bruxing patient is at greater risk for fatigue fractures for two reasons: The magnitude of the forces increases over time as the muscles become stronger, and the number of cycles increases on the prosthetic components. Eventually, one of the components (i.e., implant, screw, abutment, prosthesis) will break if the parafunction cannot be reduced in intensity or duration (Fig. 8.7). No long-term prosthetic result is expected in patients with severe bruxism. Therefore once the implant dentist has identified the sources of additional force on the implant system, the treatment plan is altered in an attempt to minimize the negative effect on the longevity of the implant, bone, and final restoration. All elements able to reduce stress should be considered.

Occlusal Guards to Determine Direction of Force

The cause of bruxism is multifactorial and may include occlusal disharmony.[49] When an implant reconstruction is considered in a bruxing patient, occlusal analysis is warranted. Premature and posterior contacts during mandibular excursions increase stress conditions. An elimination of eccentric contacts may allow recovery of periodontal ligament health and muscle activity within 1 to 4 weeks. Occlusal harmony does not necessarily eliminate

bruxism, but this is no reason not to perform an occlusal analysis and eliminate the premature contacts. No study demonstrates an increase in parafunction after occlusal adjustment. Therefore the ability to decrease the risk for occlusal overload on particular teeth and the added benefit of perhaps reducing parafunction is warranted in almost every patient diagnosed with a parafunctional habit of bruxism or clenching.

The term *night guard* is often used to describe this type of prosthesis. However, this prosthesis should be termed an *occlusal guard*, as a night guard may be misconstrued to be used only at night. The occlusal guard can be a useful diagnostic tool to evaluate the influence of occlusal disharmony on nocturnal bruxism. The Michigan occlusal guard exhibits even occlusal contacts around the arch in centric relation occlusion and provides posterior disocclusion with anterior guidance in all excursions of the mandible.[50] This device may be fabricated with 0.5 to 1 mm colored acrylic resin on the occlusal surface. After 4 weeks of nocturnal wear, if the patient wears this device for an additional month or more, the influence of occlusion on the bruxism may be directly observed. There are no premature contacts while the device is worn; however, if the colored acrylic is still intact, the nocturnal parafunction has been reduced or eliminated.[51] Therefore occlusal reconstruction or modification may proceed. If the colored acrylic on the occlusal guard is ground through, an occlusal adjustment will have little influence

● **Fig. 8.8** A night guard for a partially edentulous patient restored with implants may be designed to transfer the force to the implant prosthesis. When the implant prosthesis is in the opposing arch to the guard, there are no occlusal contacts in centric or during excursion with the guard in place.

● **Fig. 8.9** Full-arch implant prostheses opposing each other may have only anterior occlusal contact in centric and during mandibular excursions with the guard in place.

on decreasing this parafunctional habit. The occlusal guard is still indicated to relieve stresses during nocturnal parafunction, but the treatment plan should account for the greater forces.

Forces from bruxism are the most difficult to address on a long-term basis. Education and informed consent of the patient are helpful to gain cooperation in eliminating or reducing the noxious effects. If the opposing arch is a soft tissue–supported removable prosthesis, the effects of the nocturnal habit may be minimized if the patient removes the prosthesis at night. The use of a occlusal guard is helpful for a patient with a fixed prosthesis, to transfer the weakest link of the system to the removable acrylic device.[52] Centric contacts in centric relation occlusion and anterior-guided disocclusion of the posterior teeth in excursions are strongly suggested on the occlusal guard, which may be designed to fit the maxilla or mandible.

Unlike teeth, implants do not extrude in the absence of occlusal contacts. As a result, in partially edentulous patients, the maxillary occlusal guard can be relieved around the implant crowns so the remaining natural teeth bear the entire load. For example, for a maxillary implant restoration, the night guard is hollow so no occlusal force is transmitted to the implant crown. When the restoration is in the mandible, the occluding surfaces of the maxillary occlusal guard are relieved over the implant crowns so no occlusal force is transmitted to the implants (Fig. 8.8).

A mandibular posterior cantilever on a full-arch implant prosthesis may also be taken out of occlusion with a maxillary night guard. When a posterior quadrant of implants supports a fixed prosthesis in the maxilla opposing mandibular teeth, a soft reline material is placed around the implant crowns to act as a stress relief element and decrease the impact force on the restoration (Fig. 8.9). When full-arch implant restorations are opposing each other, the night guard provides solely anterior contacts during centric occlusion and mandibular excursions. Thus the parafunctional force is reduced on the anterior teeth/implants and eliminated in the posterior regions.

Clenching

Clenching is a habit that generates a constant force exerted from one occlusal surface to the other without any lateral movement. The habitual clenching position does not necessarily correspond to centric occlusion. The jaw may be positioned in any direction before the static load; therefore a bruxing and clenching combination may exist. The clench position most often is in the same repeated position and rarely changes from one period to another. The direction of load may be vertical or horizontal. The forces involved are in significant excess of normal physiologic loads and are similar to bruxism in amount and duration; however, several clinical conditions differ in clenching.

Diagnosis

Many clinical symptoms and signs warn of excessive grinding. However, the signs for clenching are often less obvious. The forces generated during clenching are directed more vertically to the plane of occlusion, at least in the posterior regions of the mouth. Wearing of the teeth is usually not evident; therefore clenching often escapes notice during the intraoral examination. As a result the dentist must be more observant to the diagnosis of this disorder.[26,49,52]

Many of the clinical signs of clenching often resemble bruxism. When a patient has a dental history of muscle tenderness on awakening or tooth sensitivity to cold, parafunction is strongly suspected. In the absence of tooth wear, clenching is the prime suspect. Tooth mobility, muscle tenderness or hypertrophy, deviation during occlusal opening, limited opening, stress lines in enamel, cervical abfraction, and material fatigue (enamel, enamel pits, porcelain, and implant components) are all associated clinical signs of clenching. All of these conditions may also be found in the bruxing patient. However, enamel wear has such a strong correlation to bruxism that it is the primary and often the only factor needed to evaluate for bruxism. The clenching patient has the "sneaky disease of force." Therefore particular attention is paid to diagnose this disorder from less obvious clinical conditions.

A physical examination for the implant candidate should include palpation of the muscles of mastication. The masseter and temporalis muscles are easily examined at the initial appointment. Hyperactive muscles are not always tender, but tender muscles in the absence of trauma or disease is a sign of excess use or incoordination among muscle groups. The lateral pterygoid muscle is more often overused by the bruxing or clenching patient but is difficult to palpate. The ipsilateral medial pterygoid muscle provides more reliable information in this region. It acts as the antagonist to the lateral pterygoid in hyperfunction and, when tender, provides a good indicator of overuse of the lateral pterygoid.[49]

• **Fig. 8.10** Clenching habits are more difficult to diagnose because occlusal wear is often absent. This clenching patient has cervical abfraction of the mandibular anterior teeth. Cervical abfraction (green arrows) is often misdiagnosed as toothbrush abrasion.

• **Fig. 8.11** This patient has horizontal abfraction lines (red arrow) in the enamel from clenching.

Muscle evaluation for clenching also includes deviation during opening the jaw, limited opening, and tenderness of the temporomandibular joint. Deviation to one side during opening indicates a muscle imbalance on the same side.[49] Limited opening is easily evaluated and may indicate muscular imbalance or degenerative joint disease. The normal opening should be at least 40 mm from the maxillary incisal edge to the mandibular incisal edge in an Angle's Class I patient, taking into consideration an overjet or overlap. If any horizontal overjet or overlap exists, its value in millimeters is subtracted from the 40-mm minimum opening measurement.[53] The range of opening without regard for overlap or overjet has been measured in the range of 38 to 65 mm for men and 36 to 60 mm for women, from incisal edge to edge.[54]

Increased mobility of teeth may be an indication of a force beyond physiologic limits, bone loss, or their combination. This requires further investigation in regard to parafunction and is important if an implant may be placed in the region of the mobile teeth. The rigid implant may receive more than its share of occlusal force when surrounded by mobile teeth. Fremitus, a vibration type of mobility of a tooth, is often present in the clenching patient. To evaluate this condition, the dentist's finger barely contacts the facial surface of one tooth at a time and feels for vibrations while the patient taps the teeth together. Fremitus is symptomatic of local excess occlusal loads.

Cervical erosion is primarily a sign of parafunctional clenching or bruxism (Fig. 8.10). In the past, Black analyzed the eight most popular theories for gingival ditching of the teeth, finding all inconclusive. This observation has frequently been called *toothbrush abrasion*. McCoy[55] has reported this condition on every other tooth, only one tooth, and even on the teeth of some animals. Parafunction was the common link among patients presenting with this condition.[55] The notched appearance of the cervical portion of the tooth directly correlates with the concentration of forces shown in three-dimensional finite analysis[56] and photoelasticity studies.[57] Abfraction of teeth was also observed in cats, rats, and marmosets and was described in the literature as early as 1930.[58] A study of a noninstitutionalized older human population revealed that cervical abrasion was present in 56% of the participants.[59]

Other signs of enamel or occlusal material fatigue encountered in bruxing or clenching patients include occlusal invaginations or pits, stress lines in enamel, stress lines in alloy restorations or acrylic (lines of Luder), and material fracture (Fig. 8.11). Fremitus can be noticed clinically on many cervically eroded, nonmobile teeth. Not all gingival erosions are caused by parafunction. However,
when present, the occlusion should be carefully evaluated along with other signs of excess force. If excessive forces appear to be the cause, the condition is referred to as cervical abfraction.[60]

Clenching patients may also suffer from masseter hypertrophy. This may be easily diagnosed via radiographic identification of an antegonial notch. Because of the excessive parafunctional habits, the angle of the mandible "notches" or resorbs because of excess force applied from the masseter muscle. The insertion of the masseter muscle is in the lateral aspect of the ramus (angle of the mandible) (Fig. 8.12).

A common clinical finding of clenching is a scalloped border of the tongue (Fig. 8.13). The tongue is often braced against the lingual surfaces of the maxillary teeth during clenching, exerting lateral pressures and resulting in the scalloped border. This braced tongue position may also be accompanied by an intraoral vacuum, which permits a clench to extend for a considerable time, often during sleep.

Fatigue Fractures

An increase in force magnitude and duration is a significant problem, whether by bruxism or clenching. The fatigue curve previously presented for bruxism also applies to clenching. In addition, the clenching patient may suffer from a phenomenon called *creep*, which also results in fracture of components. Creep occurs in a material when an increasing deformation is expressed as a function of time, when subjected to a constant load (Fig. 8.14). Although the cycles of load may not be present to affect the deformation of a material, the constant force is still able to cause fracture. In other words, something will break if the continued force is not abated or at least reduced in intensity or duration (Fig. 8.15). This condition may also occur in bone, which may result with implant mobility and failure. All elements to reduce the excessive force of clenching and its consequence should be considered.

Clenching affects the treatment plan in a fashion similar to bruxism. However, the vertical forces are less detrimental than horizontal forces, and alteration of the anterior occlusal scheme is not as critical as with the bruxing patient. Occlusal guards are also less effective. However, a hard acrylic shell and softer, resilient liner night guard, which is slightly relieved over the implants, is often beneficial to a clenching patient. Unlike teeth, implants do not extrude. As a result the occlusal guard can be relieved around an intermediate implant, and the teeth bear the entire load. In a full-arch or quadrant implant restoration, the night guard provides a biomechanical advantage to reduce the impact of the force during clenching (Fig. 8.16).[61]

A common cause of implant failure during healing is parafunction in a patient wearing a soft tissue–supported prosthesis over a
• **Fig. 8.12** Panoramic radiographic depicting extensive antegonial notching (red arrows) resulting from masseter hypertrophy from parafunctional habits.

• **Fig. 8.13** A scalloped border of the tongue (green arrow) most often is found in a clenching patient. To maintain the force between the teeth, a vacuum is created in the mouth, and the impression of the lingual contours of the upper teeth is seen on the tongue.

• **Fig. 8.15** The patient exhibits clenching, diagnosed from the enlarged size of the masseter and temporalis muscles. The mandibular second molar has fractured from mesial to distal. Note the slight abfraction on the distal buccal root of the first mandibular molar (green arrow).
• **Fig. 8.14** A creep curve for materials is created, placing strain on the vertical axis and time on the horizontal axis when a constant load is applied. This is a creep curve for bone at a load of 60 MPa. The bone changes shape (i.e., strain) at the initial stress condition and then at an increasing amount over time until the material breaks.

• **Fig. 8.16** A night guard with a rigid acrylic shell and a soft resilient liner can decrease stress during clenching episodes.
● **Fig. 8.17** Interim prosthesis requires surface alteration when placed immediately after implant surgery. (A) Existing prosthesis. (B) Area over implant sites modified with a barrel bur. (C) Final altered prosthesis; note the stress-bearing areas are not adjusted (green arrows).

submerged implant. The tissue overlying the implant is compressed during the parafunction. The premature loading may cause micromovement of the implant body in the bone and may compromise osteointegration. When an overlying soft tissue–borne restoration exerts pressure as a result of parafunction, pressure necrosis causes soft tissue dehiscence over the implant. This condition is not corrected by surgically covering the implant with soft tissue, but the soft tissue support region of the prosthesis over the implant should be generously relieved during the healing period whenever parafunction is noted. A removable partial denture over a healing implant is especially of concern. The acrylic between the soft tissue–borne region and metal substructure is usually less than 1 mm thick. Removing the thin acrylic region over the implant is often insufficient. Instead, a 6-mm-diameter hole through the metal substructure should be prepared. With a full complete interim prosthesis, the implants should be hollowed out followed by removing the flanges in the area. Any pressure on the implant or bone graft leads to an increased morbidity (Figs. 8.17 and 8.18).

Treatment Planning for Bruxism and Clenching (Table 8.2)

To combat the detrimental effects of bruxism or clenching, numerous modifications to the standard treatment protocols may be implemented.

Progressive Bone Loading

The time intervals between prosthodontic restoration appointments may be increased to provide additional time to produce

● **Fig. 8.18** This patient fractured the porcelain on her fixed mandibular implant–supported restoration. The cervical regions were the primary sites of fracture because the patient had a clenching habit.

load-bearing bone around the implants through progressive bone-loading techniques.[62] By using the progressive bone-loading technique, poorer bone density may be transformed into better quality bone, which is more ideal for adapting to excessive occlusal loads.

Greater Surface Area

Anterior implants that are subjected to parafunctional forces are problematic because they are usually have nonaxial or shear forces

TABLE 8.2 Bruxism Versus Clenching	Bruxism	Clenching
Force direction	Horizontal, nonfunctional grinding	Mainly vertical
Type of force	Shear	Compression
Force magnification	4–7 times normal	_____
Tooth wear	Yes	Less common
Wear facets	Yes, on incisal edges Notching on the cingulum of maxillary anterior teeth	Less common
Headaches	Common	Less common
Fractured teeth/restorations	Common	Less common
Uncemented restorations	Common	Less common
Abfraction of teeth	Less common	Common
Fremitus	Common	Common
Incisal guidance	Absent in severe cases	Present
Muscle weakness upon awakening	Yes	Yes
Muscle hypertrophy	Significant	Moderate
Masseter, temporalis tenderness	Yes	Sometimes
Scalloped tongue	Not common	Very common
Deviation upon opening	Yes	Yes

applied to them. The use of wider-diameter implants or an additional number of implants (i.e., greater surface area) should be treatment planned to counteract this excessive force.

Occlusion

With parafunctional habits, the occlusion must be strictly designed and monitored. Ideally the patient should be maintained in a canine-guided occlusion, as long as the canines are healthy. Mutually protected occlusion, with additional anterior implants or teeth-distributing forces, is developed if the implants are in the canine position or if this tooth is restored as a pontic. The elimination of posterior lateral occlusal contacts (i.e., nonaxial loading) during excursive movements is recommended when opposing natural teeth or an implant or tooth-supported fixed prosthesis. The anterior teeth may be modified to re-create the proper incisal guidance and avoid posterior interferences during excursions. This is beneficial in two aspects. First, lateral forces dramatically increase stress at the implant–bone interface, and the elimination of posterior contacts diminishes the negative effect of angled forces during bruxism. Second, with the presence of posterior contacts during excursions, almost all fibers of the masseter, temporalis, and the external pterygoid muscles contract and place higher forces on the anterior teeth/implants. Kinsel et al.[63] showed patients exhibiting bruxism and with no night guard had approximately seven times the rate of porcelain fracture. Alderman et al.[26] related that during occlusal excursions in the absence of posterior contacts, fewer fibers of the temporalis and masseter muscles are stimulated, and the forces applied on the anterior implant/teeth system are reduced by as much as two-thirds.

Prosthesis Design

The prosthesis may be designed to improve the distribution of stress throughout the implant system with centric vertical contacts aligned with the long axis of the implant whenever possible. Narrow posterior occlusal tables to prevent inadvertent lateral forces and to decrease the occlusal forces are beneficial.[64] Enameloplasty of the cusp tips of the opposing natural teeth is indicated to help improve the direction of vertical forces within the guidelines of the intended occlusion (i.e., improve plane of occlusion). Newer occlusal materials (e.g., zirconia), wider implant bodies, harder cement types (e.g., resin versus zinc oxide), titanium alloy implant bodies, and more implants splinted together are all beneficial.

Occlusal Guard

The most important treatment for a patient with parafunctional habits is the use of an occlusal guard. Ideally patients should wear a hard, processed acrylic occlusal guard during times of parafunctional activity. The guard will absorb the majority of the parafunctional forces, reducing the damaging forces to the implant system. Patients should also be instructed to wear the guard during any time they might exhibit parafunction, such as stressful time periods, driving, and working at a computer.

Tongue Thrust and Size

Parafunctional tongue thrust is the unnatural force of the tongue against the teeth during swallowing.[65] A force of approximately 41 to 709 g/cm² on the anterior and lateral areas of the palate has been recorded during swallowing.[66] In orthodontic movement, a few grams of constant force is sufficient to displace teeth. Six different types of tongue thrust have been identified: anterior, intermediate, posterior, and either unilateral or bilateral may be found, and in most any combination (Figs. 8.19 and 8.20). A common question is which came first, the aberrant tongue position or the misalignment

• **Fig. 8.19** Six different types of tongue-thrust habits have been classified. This patient has an anterior tongue thrust and as a result does not have anterior guidance.

• **Fig. 8.21** This patient has a maxillary complete denture and no posterior mandibular teeth. The patient has developed a posterior tongue position to support the denture and prevent it from dropping posteriorly when the patient occludes (green arrow). This tongue will adapt easily to a mandibular posterior implant prosthesis.

• **Fig. 8.20** This patient has a unilateral posterior tongue thrust. When the patient swallows, the tongue is forced between the maxillary canine and first premolar (green arrow), the mandibular lateral incisor and canine, and the posterior edentulous regions in both arches. Posterior one-stage implants would receive an immediate horizontal load. The patient will feel that the implant prosthesis is constricting the tongue.

of teeth? Regardless, this condition can contribute to implant healing and prosthetic complications. Although the force of tongue thrust is of lesser intensity than in other parafunctional forces, it is horizontal in nature and can increase stress at the permucosal site of the implant. This is most critical for one-stage surgical approaches in which the implants are in an elevated position at initial placement and the implant interface is in an early healing phase. The tongue thrust may also contribute to incision line opening, which may compromise both the hard and soft tissues.

A tongue thrust habit may lead to tooth movement or mobility, which is of consequence when implants are present in the same quadrant. If the natural teeth in the region of the tongue thrust were lost as a result of an aberrant tongue position or movement, the implants are at increased risk during initial healing and early prosthetic loading. If the remaining teeth exhibit increased mobility, the implant prosthesis may be subject to increased occlusal loads. To evaluate anterior tongue thrust, the doctor holds the lower lip down, irrigates water into the mouth with the water syringe, and asks the patient to swallow. A normal patient forms a vacuum in the mouth, positions the tongue on the anterior aspect of the palate, and is able to swallow without difficulty. A patient with an anterior tongue thrust is not able to create the vacuum needed to swallow when the lower lip is retracted, because the seal and vacuum for the patient are achieved between the tongue and the lower lip. As a consequence the patient is unable to swallow while the lower lip is withdrawn.

A posterior tongue thrust is evaluated by retracting one cheek at a time away from the posterior teeth/edentulous region with a mirror, injecting water into the mouth with a water syringe, and asking the patient to swallow. Visual evidence of the tongue during deglutition may also be accompanied by pressure against the instrument and confirms a lateral force. The posterior tongue thrust may occur in patients wearing a maxillary denture opposing a Kennedy Class I mandibular arch, without a mandibular prosthesis replacing the posterior teeth. Under these conditions the maxillary denture often loses valve seal and drops posteriorly, as only anterior teeth contact. To limit this problem, the patient extends the lateral aspect of the tongue into the edentulous region to prevent the maxillary denture from dislodgement (Fig. 8.21).

A potential prosthetic complication for a patient with a lateral tongue thrust is the complaint of inadequate room for the tongue once the mandibular implants are restored. A prosthetic mistake is to reduce the width of the lingual contour of the mandibular teeth. The lingual cusp of the restored mandibular posterior teeth should follow the curve of Wilson and include proper horizontal overjet to protect the tongue during function. A reduction in the width of the posterior teeth often increases the occurrence of tongue biting and may not dissipate with time. Rather than being a short-term inconvenience, the prosthesis may need to be refabricated. The restoring dentist should identify the tongue position before treatment and inform the patient about the early learning curve for the tongue once the teeth are delivered on the implants.

Even in the absence of tongue thrust, the tongue often accommodates to the available space, and its size may increase with the loss of teeth. As a result, a patient not wearing a mandibular denture often has a larger-than-normal tongue. The placement of implants and prosthetic teeth in such a patient results in an increase in lateral force, which may be continuous. This patient complains of inadequate room for the tongue and may bite it during function.

● **Fig. 8.22** When a patient has missing teeth and no prosthetic replacement, such as a complete or partial denture, the tongue often increases in size (green arrow). Although the tongue does not transfer an active lateral force during swallowing, prosthetic complications of tongue biting are at a greater risk.

However, this condition is usually short-lived, and the patient eventually adapts to the new intraoral condition (Fig. 8.22).

A common complication occurs when patients are missing teeth and no interim prosthesis is worn. This can be especially problematic on the mandibular arch because the tongue will gradually increase in size. After implant restoration, whether a removable or fixed prosthesis, the patient will often report a "crowded" tongue with insufficient space. This usually will take weeks to months for the patient to adapt. If the patient refuses to wear the interim prosthesis socially, he or she can be instructed to wear it during the day to allow for better adaptation.

Treatment Planning for Tongue Thrust and Size

Even in the absence of tongue thrust, the tongue often accommodates to the available space, and its size may increase with the loss of teeth. As a result a patient who is not wearing a mandibu-lar denture often has a larger-than-normal sized tongue. The placement of implants and prosthetic teeth in such a patient results in an increase in lateral force, which may be continuous. The patient then complains of inadequate room for the tongue and may bite it during function. However, this condition is usually short-lived, and the patient eventually adapts to the new intraoral condition.

However, it has been observed that a fixed restoration is more advantageous for this type of patient. If the patient has an RP-5 prosthesis, it should be turned into an RP-4. An RP-5 restoration is much less stable in patients with tongue thrust or size issues, and patient complaints are more common with removable restorations in general.

Crown Height Space

The interarch distance is defined as the vertical distance between the maxillary and mandibular dentate or dentate arches under specific conditions (e.g., the mandible is at rest or in occlusion).[67] A dimension of only one arch does not have a defined term in prosthetics; therefore Misch proposed the term *crown height space* (CHS).[68]

The CHS for implant dentistry is measured from the crest of the bone to the plane of occlusion in the posterior region and the incisal edge of the arch in question in the anterior region (Fig.
● **Fig. 8.23** The crown height space is measured from the occlusal plane to the crest of the bone.

• **BOX 8.4** **Biomechanical Principles Related to Crown Height Space**

1. The CHS is measured from the occlusal plane to the crest of the bone.
2. Mechanical complications are the primary cause of complications after prosthesis delivery.
3. Mechanical complications are often caused by excessive stresses.
4. Excessive stress can cause implant failure, crestal bone loss, implant fracture, screw loosening, occlusal material fracture, prosthesis fracture, or attachment wear and fracture.
5. The crown height is a vertical cantilever.
6. The biomechanics are more unfavorable as the CHS increases.
7. An increase in CHS increases the forces on cantilevered or angled loads.
8. Crestal bone loss around the implant increases the CHS and therefore increases the moment forces to the implant and prosthesis components.
9. CHS does not have a specific ideal dimension. With fixed restorations, the acceptable range for CHS is between 8 and 12 mm.
10. Removable implant restorations (Overdentures RP-4 and RP-5) often require a CHS of 12 mm or more, especially when a bar connects the individual implants.
11. Stresses applied to implants are mainly concentrated in the crestal region, so increasing implant length is less effective to reduce the effects of crown height than a natural tooth root.
12. Methods to decrease stress should be considered when the CHS is increased (i.e., increase implant number, size, and surface area of design; splint implants together; shorten cantilevers; consider removable restorations; add soft tissue support in overdentures).
13. An increase in prosthetic complications occurs with either limited or excessive CHS.

CHS, *Crown height space.*

8.23; Box 8.4). In the anterior regions of the mouth the presence of a vertical overbite means the CHS is larger in the maxilla than the space from the crest of the ridge to the opposing teeth's incisal edge. In general, when the anterior teeth are in contact in centric occlusion, there is a vertical overbite. The anterior mandibular CHS is therefore usually measured from the crest of the ridge to the mandibular incisal edge. However, the anterior maxillary CHS

is measured from the maxillary crestal bone to the maxillary incisal edge, not the occlusal contact position.

The ideal CHS needed for a fixed implant prosthesis should range between 8 and 12 mm. Monolithic zirconia has been shown to be successful with as little as 8-mm interocclusal space. For most other types of restorative materials, space greater than 10 mm is usually indicated. This measurement accounts for the biological width, abutment height for cement retention or prosthesis screw fixation, occlusal material strength, esthetics, and hygiene considerations around the abutment crowns. Removable prostheses often require a CHS greater than 12 mm for denture teeth and acrylic resin base strength, attachments, bars, and oral hygiene considerations.[69,70] For a bar overdenture, approximately 15 mm is usually necessary, especially if being restored with acrylic/denture teeth prosthesis.

Biomechanic Consequences of Excessive Crown Height Space

Mechanical complication rates for implant prostheses are often the highest of all complications reported in the literature.[42,71] Mechanical complications are often caused by excessive stress applied to the implant–prosthetic system. Implant failure may occur from overload and result in prosthesis failure and bone loss around the failed implants. Implant body fracture may result from fatigue loading of the implant at a higher force, but occurs at less incidence than most complications. The higher the force, the fewer the number of cycles before fracture, so the incidence increases. Crestal bone loss may also be related to excessive forces and often occurs before implant body fracture. Occlusal material fracture rates may increase as the force to the restoration is increased. The risk for fracture to the opposing prosthesis increases with an average of 12% in implant overdentures opposing a denture.[71] With resin veneer implant fixed partial dentures, 22% of the veneers fractured. Clips or attachment fractures in overdentures may average 17%. Fracture of the framework or substructure may also occur as a result of an increase in biomechanical forces.

Force magnifiers are situations or devices that increase the amount of force applied and include a screw, pulley, incline plane, and lever.[46] The biomechanics of CHS are related to lever mechanics. The properties of a lever have been appreciated since the time of Archimedes, 2000 years ago. The issues of cantilevers and implants were demonstrated in the edentulous mandible, where the length of the posterior cantilever directly related to complications or failure of the prosthesis.[42] Rather than a posterior cantilever, the CHS is a vertical cantilever when any lateral or cantilevered load is applied, and therefore is also a force magnifier.[47,48] As a result, because CHS excess increases the amount of force, any of the mechanical-related complications related to implant prostheses may also increase (Fig. 8.24).

When the direction of a force is in the long axis of the implant, the stresses to the bone are not magnified in relation to the CHS. However, when the forces to the implant are placed on a cantilever, or a lateral force is applied to the crown, the forces are magnified in direct relationship to the crown height. Bidez and Misch[47,48] evaluated the effect of a cantilever on an implant and its relation to crown height. When a cantilever is placed on an implant, there are six different potential rotation points (i.e., moments) on the implant body (Fig. 8.25 and Table 8.3). When the crown height is increased from 10 to 20 mm, two of these six moments are increased 200%. A cantilevered force may be in any direction: facial, lingual, mesial, or distal. Forces cantilevered to the facial and lingual direction are often called *offset loads*. The bone width
• **Fig. 8.24** The Crown Height Space Is a Vertical Cantilever. The FP-3 prosthesis on the right will deliver greater stresses to the implant compared with the implant on the left. Therefore a wider-diameter implant is of benefit to support the implant restoration on the right.

decrease is primarily from the facial aspect of the edentulous ridge. As a result, implants are often placed more lingual than the center of the natural tooth root. This condition often results in a restoration cantilevered to the facial. When the available bone height is also decreased, the CHS is increased. Therefore the potential length of the implant reduced in excessive CHS conditions, and the implant position results in offset loads.

An angled load to a crown will also magnify the force applied to the implant. A 12-degree force to the implant will be increased by 20%. This increase in force is further magnified by the crown height. For example, a 12-degree angle with a force of 100 N will result in a force of 315 N/mm on a crown height of 15 mm.[47] Maxillary anterior teeth are usually at an angle of 12 degrees or more to the occlusal planes. Even implants placed in an ideal position are usually loaded at an angle. Maxillary anterior crowns are often longer than any other teeth in the arch, so the effects of crown height cause greater risk.

The angled force to the implant also may occur during protrusive or lateral excursions, as the incisal guide angle may be 20 degrees or more. Anterior implant crowns will therefore be loaded at a considerable angle during excursions, compared with the long axis position of the implant. As a result, an increase in the force to maxillary anterior implants should be compensated for in the treatment plan.

Most forces applied to the osteointegrated implant body are concentrated in the crestal 7 to 9 mm of bone, regardless of implant design and bone density.[72] Therefore implant body height is not an effective method to counter the effects of compromised crown height. In other words, crown/root ratio is a prosthetic concept that may guide the restoring dentist when evaluating a natural tooth abutment. The longer the natural tooth root, the shorter the crown height, which acts as a lever to rotate the tooth around an axis located two-thirds down the root. However, the crown height/implant ratio is not a direct comparison. Crown height is a vertical cantilever that magnifies any lateral or cantilever force in either a tooth- or an implant-supported restoration. However, this condition is not improved by increasing implant length to dissipate stresses, unless in very poor bone quality. The implant
● **Fig. 8.25** Moment Loads Tend to Induce Rotations in Three Planes. Clockwise and counterclockwise rotations in these three planes result in six moments: lingual-transverse, facial-transverse, occlusal, apical, facial, and lingual.

TABLE 8.3	**Moment Load at Crest, Division A Bone When Subjected to Forces Shown in Fig. 8.25**						
INFLUENCES ON MOMENT		**IMPOSED MOMENTS (N/MM) AT IMPLANT CROWN–CREST INTERFACE**					
Occlusal Height (mm)	Cantilever Length (mm)	Lingual	Facial	Apical	Occlusal	Facial Transverse	Lingual Transverse
10	10	100	0	0	200	0	100
10	20	100	0	0	400	0	200
10	30	100	0	0	600	0	300
20	10	200	0	100	200	0	100
20	20	200	0	100	400	0	200
20	30	200	0	100	600	0	300

does not rotate away from the force in relation to implant length. Instead, it captures the force at the crest of the ridge. The greater the CHS, the greater number of implants usually required for the prosthesis, especially in the presence of other force factors. This is a complete paradigm shift to the concepts advocated originally, with many implants in greater available bone and small crown heights and fewer implants with greater crown heights in atrophied bone (Figs. 8.26 and 8.27).

The CHS increases when crestal bone loss occurs around the implants. An increased CHS may increase the forces to the crestal bone around the implants and increase the risk for crestal bone loss. This in turn may further increase both the CHS and the moment forces to the entire support system, resulting in screw loosening, crestal bone loss, implant fracture, and implant failure.

The vertical distance from the occlusal plane to the opposing landmark for implant insertion is typically a constant in an individual. Therefore as the bone resorbs, the crown height becomes larger, but the available bone height decreases (Fig. 8.28). An indirect relationship is found between the crown and implant height. Moderate bone loss before implant placement may result in a crown height–bone height ratio greater than 1, with greater lateral forces applied to the crestal bone than in abundant bone (in which the crown height is less). A linear relationship exists between the applied load and internal stresses.[73,74] Therefore the greater the load applied, the greater the tensile and compressive stresses transmitted at the bone interface and to the prosthetic components. And yet many implant treatment plans are designed with more implants in abundant bone situations and fewer implants in atrophied bone volume. The opposite scenario should exist. The lesser the bone volume, the greater the crown height and the greater the number of implants indicated.

Excessive Crown Height Space

CHS greater than 15 mm is excessive; it is primarily the result of the vertical loss of alveolar bone from long-term edentulism. Other causes may include genetics, trauma, periodontal disease, and implant failure (Box 8.5). Treatment of excessive CHS before implant placement may include orthodontic and surgical methods. Orthodontics in partially edentulous patients is the method of choice, because other surgical or prosthetic methods are usually more costly and have greater risks for complications. Several

• **Fig. 8.26** In the past, treatment plans included more implants in abundant bone and fewer implants in less available bone. However, crown height increases as bone height decreases, and this approach creates unfavorable mechanics and is less ideal.
• **Fig. 8.27** Crown height is a force magnifier to any lateral load or horizontal cantilever. Therefore when available bone height decreases, more implants should be inserted and cantilever length reduced.

advanced surgical techniques may also be considered, including block onlay bone grafts, particulate bone grafts with titanium mesh or barrier membranes, interpositional bone grafts, and distraction osteo-genesis. A staged approach to reconstruction of the jaws is often preferred to simultaneous implant placement, especially when large-volume gains are required. Significant vertical bone augmentation may even require multiple surgical procedures.

In case of excessive CHS, bone augmentation may be preferred to prosthetic replacement. Surgical augmentation of the residual ridge height will reduce the CHS and improve implant biomechanics. Augmentation will often permit the placement of wider body implants with the associated benefit of increased surface area. Although prosthetics is the most commonly used option to

address excess CHS, it should be the last choice. Using gingival colored prosthetic materials (pink porcelain zirconia or acrylic resin) on fixed restorations or changing the prosthetic design to a removable restoration should often be considered when restoring excessive CHS (Fig. 8.29).

In the maxilla a vertical loss of bone results in a more palatal ridge position. As a consequence, implants are often inserted more palatal than the natural tooth position. Removable restorations have several advantages under these clinical circumstances. The removable prosthesis does not require embrasures for hygiene. The removable restoration may be removed during sleep to decrease the effects of an increase in CHS on nocturnal parafunction. The removable restoration may improve the lip and facial support, which is deficient because of the advanced bone loss. The overdenture may have sufficient bulk of acrylic resin to decrease the risk for prosthesis fracture. The increase in CHS permits denture tooth placement without infringement of the substructure.

Soft tissue support in addition to implant-supported removable implant restorations with an excessive CHS are recommended when it is not possible to overengineer the implant support system. A rigid overdenture has identical requirements to a fixed prosthesis because it is rigid during function. Misch[76] describes the "hidden cantilever" beyond the cantilevered bar with a rigid implant overdenture. When the overdenture has no movement during function, the cantilever does not stop at the end of the cantilevered substructure but ends at the last occlusal contact position on the prosthesis, often the distal of a second molar.

The position and type of overdenture attachments may render an overdenture rigid during function, even in the absence of distal cantilevers on the bar. For example, when three anterior implants are splinted together and a Hader clip is used to retain the prosthesis, if the Hader clips are placed at angles to the midline, the attachments have limited movement and result in a rigid overdenture during function. Misch[76] suggests the prosthesis movement, not the individual attachment movement, should be evaluated. Excessive CHS with overdentures are situations that benefit from a prosthesis designed to have more than one direction of movement.

The ideal CHS for a fixed prosthesis is between 8 and 12 mm, accounting for an ideal 3 mm of soft tissue, 2 mm of occlusal material thickness, and a 5 mm or greater abutment height. A CHS greater than 12 mm may be of concern in fixed restorations. The replacement teeth are elongated and often require the addition of gingival tone materials in esthetic regions (Fig. 8.30). The greater impact force on implants compared with teeth, combined with the increased crown height, creates increased moment forces on implants and risks for component and material fracture. These problems are especially noted when associated with less favorable biomechanics on cantilevered sections of fixed restorations.[42,71]

A CHS greater than 15 mm means a large amount of metal must be used in the substructure of a traditional fixed restoration to keep porcelain to its ideal 2-mm thickness (Fig. 8.31). Fine-tuning techniques for traditional fixed restorations allowed Dabrowsky[77] to manufacture and monitor multiple full-mouth, cement-retained prostheses with a large CHS, delivered in various centers across the United States. Controlling surface porosities of metal substructures after casting as their different parts cool at different rates becomes increasingly difficult. Furthermore, when the casting is reinserted into the oven to bake the porcelain, the heat is maintained within the casting at different rates, so the porcelain cools in different regions at different rates.[78] If not controlled properly, both these factors increase the risk for porcelain fracture after loading.[79] For excessive CHS, considerable weight of the
● **Fig. 8.28** As the crown height increases, the available bone height decreases. This is especially noteworthy in the maxillary arch, as the initial available bone height is less than in the mandible. As a consequence, shorter implants in the maxilla are a common occurrence.

• BOX 8.5 Excessive Crown Height Space

1. Excessive CHS increases mechanical complications in fixed prostheses.
2. The need for gingival replacement procedures should be evaluated before implant placement for fixed restorations.
3. Metal and porcelain shrinkage is a more significant problem in traditional fixed prosthetic cases.
4. Hybrid FP-3 fixed prostheses with denture teeth, metal substructure, and acrylic resin are indicated.
5. Overdentures are recommended in completely edentulous patients with RP-4 and RP-5.
6. The implant support for RP-4 should be as great as that for a fixed prosthesis.
7. When designing a RP-5, there should be adequate soft tissue support (i.e., maxilla: crest of ridge and horizontal palate; mandible: buccal shelf).
8. In overdentures, there may be two different components of the CHS: the distance from the crest of the bone to the height of the attachment and the distance from the attachment to the occlusal plane.

CHS, *crown height space.*

---

prosthesis (approaching 3 oz of alloy) may affect maxillary trial placement appointments, because the restoration does not remain in place without the use of adhesive. Noble metals must be used to control alloy's heat expansion or corrosion; therefore the costs of such implant restorations have dramatically increased. Proposed methods to produce hollow frames to alleviate these problems, including the use of special custom trays to achieve a passive fit, will double or triple the labor costs.[80]

An alternative method of fabricating fixed prostheses in situations of CHSs of 15 mm or greater is the fixed complete denture or hybrid prosthesis, with a smaller metal framework, denture teeth, and acrylic resin to join these elements together (Fig. 8.32). The reduced metal framework compared with a porcelain-to-metal fixed prosthesis exhibits fewer dimensional changes and may more accurately fit the abutments, which is important for a screw-retained restoration. It is less expensive to fabricate than a porcelain-to-metal fixed prosthesis, is highly esthetic (premade denture teeth), easily replaces teeth and soft tissue in appearance, and is easier to repair if fracture occurs. Because resin acts as an intermediary between the teeth and metal substructure, the impact force during dynamic occlusal loading may also be reduced. In addition, a hybrid prosthesis (acrylic/denture teeth) is far lighter than a metal-based prosthesis, which is advantageous in cases with excessive interocclusal space. Therefore this type of fixed prosthesis is often indicated for implant restorations with a large CHS. On occasion, undercontoured interproximal areas are designed by the laboratory in such restorations to assist oral hygiene and have been referred to as "high water" restorations. This is an excellent method in the mandible; however, it results in food entrapment, affects air flow patterns, and may contribute to speech problems in the anterior maxilla.

Because an increase in the biomechanical forces are in direct relationship to the increase in CHS, the treatment plan of the implant restoration should consider stress-reducing options whenever the CHS is increased. Methods to decrease stress include:[6,8,70]

1. Shorten cantilever length.
2. Minimize offset loads to the buccal or lingual.
3. Increase the number of implants.
4. Increase the diameters of implants.
5. Design implants to maximize the surface area of implants.
6. Fabricate removable restorations that are less retentive and incorporate soft tissue support.
• **Fig. 8.29** Excessive Crown Height Space (CHS). (A) Anterior implant placed too far apical leading to FP-3 prosthesis along with compromising the adjacent bone levels. (B) Edentulous maxillary arch displaying excessive hard and soft tissue loss. (C) Maxillary posterior is a common area for excessive CHS because of the vertical bone loss that is associated with this area. (D) Maxillary cuspid implant placed with an excessive CHS that perforated the nasal cavity.

7. Remove the removable restoration during sleeping hours to reduce the noxious effects of nocturnal parafunction.
8. Splint implants together, whether they support a fixed or removable prosthesis.
9. Narrow occlusal table (buccal-lingually).
10. Minimal cusp height on prosthesis.
11. Mutually protected if opposing fixed teeth.
12. Occlusal contacts centered over implants and eliminatd over cantilevers.

Because CHS is a considerable force magnifier, the greater the crown height, the shorter the prosthetic cantilever that should extend from the implant support system. In CHS greater than 15 mm, no cantilever should be considered, unless all other force factors

are minimal. The occlusal contact intensity should be reduced on any offset load from the implant support system. Occlusal contacts in centric relation occlusion may even be eliminated on the most posterior aspect of a cantilever. In this way a parafunction load may be reduced, because the most cantilevered portion of the prosthesis is loaded only during functional activity (such as chewing).

Masticatory Dynamics (Patient Size, Gender, Age, and Skeletal Position)

Masticatory muscle dynamics are responsible for the amount of force exerted on the implant system. Several criteria are included under this heading: patient size, gender, age, and skeletal position.[9,11,16,21,81-84]

The size of the patient can influence the amount of bite force. Large, athletic men can generate greater forces; patients of weak physical condition often develop less force than athletic patients (Fig. 8.33). In general the forces recorded in women are approximately 20 lb less than those in men. In a clinical report by van Steenberghe et al.,[85] partially edentulous men have a 13% implant failure rate compared with 77% for women. In a report by Wyatt and Zarb,[86] first-year radiograph bone loss was positively correlated with male sex, younger age, and implants supporting a distal extension prosthesis. Older patients record lower bite forces than young adults. In addition, the younger patient lives longer and requires the additional implant support for the prosthesis for a longer time. (An 80-year-old patient will need implant support for far fewer years than a 20-year-old, all other factors being equal.)

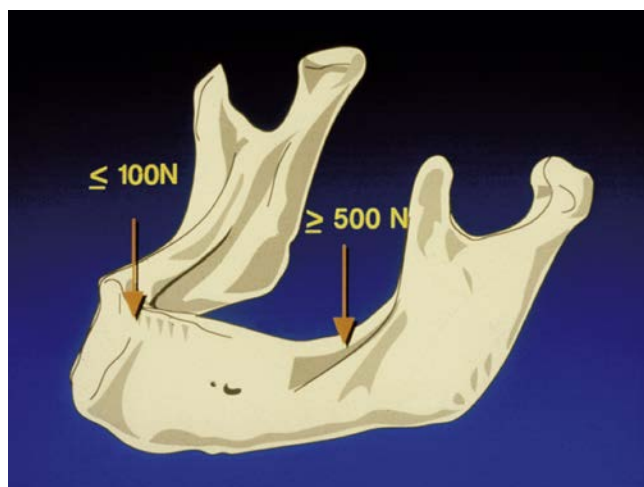
The skeletal arch position may influence the amount of maximum bite force. The brachiocephalic, with a stout head shape, may generate three times the bite force compared with a regular head shape. This is especially noteworthy when accompanied by moderate-to-severe bruxism or clenching. The maximum bite force decreases as muscle atrophy progresses throughout years of edentulism. A maximum occlusal force of 5 psi may be the result of 15 years without teeth.[82] This force may increase 300% in the 3 years after implant placement.[21,22,82-84] Therefore sex, muscle mass, exercise, diet, state of the dentition, physical status, and age all influence muscle strength, masticatory dynamics, and maximum bite force.

The skeletal Class III patient is primarily a vertical chewer and generates vertical forces with little excursive movement. However, some patients appear "pseudo-Class III" as a result of anterior bone resorption or loss of posterior support and collapse of the vertical dimension with an anterior rotation of the mandible. These patients do exhibit lateral excursive movements when the incisal edge position is restored to its initial position.

• **Fig. 8.30** When the crown height space is greater than 12 mm, pink (porcelain, acrylic, zirconia) is often used to replace the soft tissue drape in the prosthesis.

• **Fig. 8.31** Porcelain thickness for fixed prostheses should not be greater than 2 mm. When the crown height space is greater than 15 mm, the amount of metal in the substructure may be extensive.

• **Fig. 8.33** Masticatory dynamics are affected by the size of the patient (larger persons generally have greater bite forces).

• **Fig. 8.32** (A) A metal framework for a hybrid prosthesis composed of metal, acrylic, and denture teeth presents several advantages for fixed prostheses with a crown height space greater than 15 mm. (B) Denture teeth are then added to the metal substructure.


• **Fig. 8.34** The maximum bite forces are greater in the posterior regions of the jaws compared with the anterior regions (approximately 5:1).

• **Fig. 8.35** Mandibular anterior passive eruption leading to extrusion of the anterior segment (red arrow) and destruction of the premaxilla and hypertrophy of the maxillary posterior area (combination syndrome). A common incorrect treatment includes attempting bone grafting in the posterior mandible, which often leads to a neurosensory impairment. Ideally implants may be inserted after extraction of the mandibular teeth and associated osteoplasty.

As a general rule the implant treatment plan should reduce other force magnifiers when masticatory musculature dynamics increase. For example, a cantilever length should be reduced in cases of elevated masticatory dynamics. A crown height may be reduced by bone augmentation. The prosthesis may be made removable so nocturnal bruxism is reduced (if they do not wear their prosthesis). The implant number, size, and design may also be increased to increase the surface area of load.

Arch Position

The maximum biting force is greater in the molar region and decreases as measurements progress anteriorly. Maximum bite forces in the anterior incisor region correspond to approximately 35 to 50 psi, and those in the canine region range from 47 to 100 psi, whereas those in the molar area vary from 127 to 250 psi (Fig. 8.34).[8] Mansour et al.[87] evaluated occlusal forces and moments mathematically using a Class III lever arm, the condyles being the fulcrum and the masseter and temporalis muscles supplying the force. Similar figures were obtained by mathematical calculation and by direct measurement. In addition, the forces at the second molar were 10% higher than at the first molar, indicative of a range from 140 to 275 psi.

In a study by Chung et al.[88] with 339 implants in 69 patients in function for an average of 8.1 years (range of 3–24 years) the posterior implants (even with keratinized mucosa) showed a 3.5-fold greater average bone loss per year than anterior implants.

The anterior biting force is decreased in the absence of posterior tooth contact and greater in the presence of posterior occlusion or eccentric contacts.[38,89] Besides the mechanical properties of a Class III lever function, there also is a biological component to increased bite force in the posterior regions. When the posterior teeth are in contact, the large masticatory muscles contract. When the posterior teeth are not in contact, two-thirds of the temporalis and masseter muscles do not contract their fibers. As a consequence the bite force is reduced.

In the anterior regions with less force the anterior natural tooth roots are smaller in diameter and root surface area compared with posterior teeth. Yet in implant dentistry, we often alter the implant length primarily and place longer implants in the anterior region and shorter implants in the posterior regions (or cantilever off the anterior implants, which results in posterior bite forces magnified by the cantilever length). This approach should be corrected to conform to biomechanics similar to that observed with natural teeth. In other words, implants in the posterior regions should often be of greater diameter, especially in the presence of additional force factors. The greater increase in natural tooth surface area occurs in the molar region, with a 200% increase compared with the premolars. Hence the larger implant diameter is especially considered in the molar region.

The edentulous bone density varies in function of arch position. The natural teeth are surrounded by a thin cortical plate of bone and periodontal complex, which is similar for all teeth and arch positions. However, after the teeth are lost, the bone density in the edentulous site is different for each region of the mouth. The posterior regions, in general, form less bone density after tooth loss than the anterior regions. The mandibular anterior implant sites benefit from denser bone than the maxillary anterior implant sites. The denser the bone, the greater its resistance to stress applied at the implant–bone interface. In other words, the edentulous bone density is inversely related to the amount of force generally applied in that arch position. As a result the posterior maxilla is the most at-risk arch position, followed by the posterior mandible, and then the anterior maxilla. The most ideal region is the mandibular anterior.

Opposing Arch

Natural teeth transmit greater impact forces through occlusal contacts than soft tissue–borne complete dentures. In addition, the maximum occlusal force of patients with complete dentures is limited and may range from 5 to 26 psi.[82] The force is usually greater in recent denture wearers and decreases with time. Muscle atrophy, thinning of the oral tissues with age or disease, and bone atrophy often occur in the edentulous patient as a function of time.[90] Some denture wearers may clench on their prosthesis constantly, which may maintain muscle mass. However, this condition usually accelerates bone loss. Implant overdentures improve the masticatory performance and permit a more consistent return to centric relation occlusion during function. The maximum force generated in an implant prosthesis is related to the amount of tooth or implant supporting the opposing arch (Figs. 8.35 and 8.36).[12,82,83]
● **Fig. 8.36** Bilateral cantilever with a fixed prosthesis opposing natural teeth. (A and B) Note the associated bone loss (red arrows) because of the significant cantilever and large cusp heights (green arrows) leading to shear forces.
● **Fig. 8.37** When the opposing arch has a fixed implant prosthesis, the bite forces are greatest. The decrease in proprioception results in higher forces during function and parafunction. In this patient a posterior implant was placed on the mandible to counteract the excessive forces.
● **Fig. 8.38** Excessive maxillary crown height with mandibular subperiosteal implant leading to bone loss and failure of the subperiosteal implant.

Summary

Patient force factors are highly variable from one person to another. An implant foundation should be designed to support the load and resist the stresses of the prosthesis. An ideal treatment plan may be established relative to the number and position of missing teeth. The treatment plan is then modified dependent on the force factors of the individual patient.

It is far more advantageous to overengineer the amount of support necessary for a prosthesis. If just one too few or too small an implant is used, implant bone loss, fracture, and failure may occur. As a general rule, the best way to reduce the risk for biomechanical overload is to add additional implants.

The five most important force factors related to patient conditions were presented in this chapter. Of these, parafunction is the predominant element to account for in the treatment plan. On a scale of 1 to 10, severe bruxism is a 10; an excessive CHS can double a force, and therefore is a 7 on the importance scale. Severe masticatory dynamics can also double a force component and result in a 7 on this scale. Position of the abutment in the arch determines the magnitude of force and is a 1 or 2 when in the mandibular anterior region, a 3 or 4 in the maxillary anterior, a 5 in the posterior mandible, and a 6 or 7 in the posterior maxilla (because bone density is most ideal in the anterior mandible and least biomechanically favorable in the posterior maxilla). Direction of load under ideal implant placement conditions is a factor

A complete implant fixed prosthesis does not benefit from proprioception as do natural teeth, and patients bite with a force four times greater than with natural teeth. Thus the highest forces are created with implant prostheses (Fig. 8.37). In addition, premature contacts in occlusal patterns or during parafunction on the implant prostheses do not alter the pathway of closure, because occlusal awareness is decreased with implant prostheses compared with natural teeth.[17,18] Therefore continued stress increases can be expected to occur with the implant restoration.

Partial denture patients may record forces intermediate between that of natural teeth and complete dentures, depending on the location and condition of the remaining teeth, muscles, and joints. In the partially edentulous patient with implant-supported fixed prostheses, force ranges are more similar to those of natural dentition, but lack of proprioception may magnify the load amount during parafunctional activity.

As a consequence of the opposing arch affecting the intensity of forces applied to an implant prosthesis, the treatment plan may be modified to reduce the risk for overload. Rarely should the opposing arch be maintained in a traditional denture to decrease the stress to the implant arch. Instead, the implant arch should be designed to compensate for the higher stresses expected from an implant-supported opposing arch (Fig. 8.38).

of 3 or 4 in the maxillary anterior regions. The other arch positions may have a more ideal direction of load, unless cantilever loads are positioned on the implant restoration. The opposing arch under typical treatment conditions is the least important force component modifier. A complete implant restoration may be a factor of 3, natural teeth a factor of 2, and an opposing soft tissue–supported denture a factor of 1.

Dental Implant Surfaces

NEIL I. PARK AND MAYURI KERR

Introduction

Successful oral rehabilitation with dental implants is dependent on the interrelationship of the following key determinants of life-long osseointegration, presented by Albrektsson and colleagues:[1]

1. The status of the implant bed: The patient must exhibit a state of general health that will support the healing process. In addition, bone of sufficient quality and quantity is required.
2. The surgical technique: Successful treatment requires the use of proven surgical principles as well as the instruments, equipment, and techniques appropriate for the specific implant system.
3. Long-term loading: After successful implant placement, protocols for prosthesis design, selection of restorative materials, occlusal relationships, esthetics, and maintenance must be followed to support the long-term health of the implants.
4. Biocompatibility of the implant material: Dental implants must be constructed of materials that will be tolerated by the patient and not generate significant antigenic responses. Although commercially pure titanium (cpTi) and titanium alloys predominate, there are other materials, most notably zirconia, that are also used.
5. Implant macrostructure, or overall design of the implant: Although many different implant designs have been studied and used, the most widely used designs have converged to favor a tapered screw shape with an internal connection.
6. Implant microstructure, or surface: The surface of the implant and the response elicited from the patient's soft and hard tissues is the topic of this chapter. The surface structure of dental implants has proven to be critical for adhesion and differentiation of cells during the bone remodeling process essential to osseointegration.[2]

It is important to note that each of these factors is critical in treatment success; no single factor in isolation should be considered the keystone or most important determinant. In addition, it is notable that the last three determinants are controlled by the manufacturer of the implant, whereas the first three factors depend on patient characteristics and the skill of the treatment team. Although this chapter will deal with the macroscopic and microscopic nature of the implant surface and discuss its role in osseointegration and survival of dental implants, it is important to place this topic in the proper context of the overall treatment.

Surface Roughness

The process of osseointegration begins with the interaction of the cells in the immediate area with the implant surface. The surface roughness of dental implants has a significant effect on the process of osseointegration; it is crucial in the formation of bone because, although fibroblasts and epithelial cells adhere more strongly to smooth surfaces, rougher surfaces enhance the adhesion and differentiation of osteoblastic cells allowing for the deposition of bone.[3,4]

Osseointegration is a series of coordinated events, which include cell proliferation, transformation of osteoblasts, and bone formation. All of these are affected by different surface topographies.[5,6] Commonly used scientific parameters to describe the surface roughness are the two-dimensional Ra (profile roughness average) and the three-dimensional Sa (area roughness average).[7] Ra and Sa are considered to be valid and reliable parameters of surface roughness and are commonly used to describe the magnitude of the pits and fissures on implant surfaces. Ra is the arithmetic mean deviation of a linear profile, and Sa is the corresponding three-dimensional deviation. Surface roughness measurements are divided into the categories of smooth, minimally rough, moderately rough, and rough surfaces (Table 9.1).[8]

Smooth (Sa 0–0.4 µm) and minimally rough (Sa 0.5–1 µm) surfaces show weaker bone integration than rougher surfaces. Moderately rough (Sa 1–2 µm) surfaces showed stronger bone responses than rough (Sa > 2 µm) in some studies 43. Although the ideal surface roughness is undetermined, according to Albrektsson and Wennerberg,[9] moderately rough surfaces with Sa in the range of 1 to 2 µm seem to provide the optimal degree of roughness to promote osseointegration.

Structural features in the extracellular matrix are on the nanometer scale, and it is thought that biomaterials that mimic this environment might more effectively promote the processes of bone regeneration.[10] As nanotechnology advances, nanoscale surfaces have been introduced in dentistry as well. Nanotechnology involves materials with a surface roughness range between 1 and 100 nm, which are thought to influence the adsorption of proteins, adhesion of osteoblastic cells, and therefore the rate of osseointegration (Fig. 9.1).[11-14]

Review of Implant Surfaces

After the machining of a cpTi or titanium alloy implant, contact with air causes the immediate development of a titanium oxide surface on the implant. The first generation of osseointegrated dental implants, such as the Bränemark System (Nobel Biocare, Kloten, Switzerland), featured this surface. After being manufactured, these implants are subjected to cleaning, decontamination, and sterilization procedures. Scanning electron microscopy analysis showed that the surfaces of machined implants have grooves,

ridges, and marks from the tools used for their manufacturing. These surface defects provide mechanical resistance through bone interlocking. Treatment performed with this type of surface requires a longer healing time between surgery and implant loading and should follow the original protocol suggested by Bränemark, with a 3- to 6-month healing time before loading.[15]

Until the late 1980s, further surface treatments were rarely performed. Since that time, several surface modifications have been developed in an effort to modify the surface roughness of the implant to promote the process of osseointegration, particularly in poor bone quality.[2]

Pits, grooves, and protrusions characterize the microtopography and contribute to an increase in surface area. Studies have shown increased levels of bone-to-implant contact (BIC) for microrough surfaces.[7,16] These modifications can be divided into subtractive and additive processes, depending on whether material is removed or deposited on the implant surface in the development of the surface.

Subtractive Processes

Etching with Acid

Acid treatment of a titanium implant removes the surface oxide and any contamination resulting in a clean and homogenous surface. The acids used include hydrochloric acid, sulfuric acid,

TABLE 9.1	Classification of Rough Surfaces
Surface Roughness Category	**Sa Range**
Smooth	0–0.4 μm
Minimally rough	0.5–1 μm
Moderately rough	1–2 μm
Maximally rough	>2 μm

hydrofluoric acid, and nitric acid. Acid etching of titanium and titanium alloy implants results in uniform roughness with micro pits ranging in size from 0.5 to 2 μm, and an increase in surface area. Acid treatment of implant surfaces enhances osseointegration through improved migration and retention of osteogenic cells at the implant surface.[17]

Blasting with an Abrasive Material

Blasting the implant surface with hard ceramic particles projected through a nozzle at high velocity is another method of surface roughening. Different surface roughnesses can be achieved based on the size of the blasting media particles. Several materials have been used, including alumina, titanium oxide, and hydroxyapatite (HA). Wennerberg and colleagues compared blasted surfaces with different roughnesses and compared them with turned surfaces.[9,18-20] The blasted surfaces demonstrated a stronger bone response than the turned implants in rabbit bone.

Some blasting techniques involve the use of a resorbable blast media (RBM) that is biocompatible, such as HA, β-tricalcium phosphate ceramic particles, and biphasic calcium phosphates (CaPs). These biomaterials are resorbable, creating a textured surface. In the event that some of the blasting media remains on the implant surface, the media is resorbed during the healing process without affecting the biocompatibility.[8] Several studies have reported that the extent of the BIC in RBM implants is greater than that in machined implants.[21-23]

Implants with the RBM surface treatment, in which HA is used as the blast media, offer particular advantages because, unlike blasting with aluminum oxide, grit, or sand, any particles remaining on the surface are resorbable and do not affect healing in the immediate vicinity because of the presence of foreign particles. HA is also a component of bone; thus blasting with HA is not only biocompatible and resorbable but also osteoinductive. This produces a surface in the moderately rough category with an Sa of 1.49, which is in Wennerberg's recommended range of roughness. Blasting with alumina particles in the size range of 25 to 75 μm results in mean surface roughness in the range 0.5 to 1.5 μm,[18,24,25] whereas roughness in the range of 2 to 6 μm is
• **Fig. 9.1** Interactions between bone and the implant surface at different topographic scales. (From Gittens RO, McLachlan T, Olivares-Navarrette R, et al. The effects of combined micron-/submicron-scale surface roughness and nanoscale features on cell proliferation and differentiation. *Biomaterials.* 2011;32(13):3394–3403.)

reported for surfaces blasted with particles sized between 200 and 600 μm.[26,27] Use of fine particle size glass particles of 150 to 230 μm results in relatively smooth surface with an Ra value of 1.36 μm, whereas the use of coarse alumina particles of 200 to 500 μm provides a much rougher surface with an Ra value of 5.09 μm (Fig. 9.2).[28,29]

Treatment with Lasers

Lasers can also be used to modify implant surfaces by using an ablation technique. During laser ablation, the substrate material vaporizes and forms a crater. Depending on the material properties, a resolidified material forms a rim along the periphery of the crater. Laser ablation technology results in titanium surface microstructures with increased hardness, corrosion resistance, and purity with a standard roughness and thicker oxide layer.[30,31] Biological studies evaluating the role of titanium ablation topography and chemical properties showed the potential of the surface to orient osteoblast cell attachment and control the direction of ingrowth.[12,32]

Additive Processes

Additive processes share the same goal, which is to roughen the implant surface to accelerate osseointegration, particularly in lower bone densities:

Hydroxyapatite Coating and Titanium Plasma Spraying

Plasma spraying is an industrial technique in which the desired coating, in powder form, is injected through a plasma torch to melt the powder and shoot it onto the substrate surface, in which it is deposited and fuses with the surface. Plasma-sprayed coatings can be deposited with thicknesses ranging from a few micrometers to a few millimeters.

Plasma spraying has been used for applying titanium and HA coatings on the surfaces of titanium implants. This serves to roughen the surface of the implant, usually into the range of Ra 7 μm. This was considered to be an improvement over the machined surface because of the increased BIC. Additional studies[33] found that HA-coated implants stimulated bone growth during the healing phase (Table 9.2).
- **Fig. 9.2** Resorbable blast media surface of the Hahn tapered implant. (From http://www.Hahnimplant.com.)

Despite the healing advantages found with HA-coated implants, in recent years they have fallen out of favor because of increased risk of complications. Implant failure can be caused by microbial infection and occlusal trauma.[35-37] It has been suggested that HA-coated implants are more susceptible to bacterial colonization than uncoated implants or natural teeth.[38] Enhanced growth of biofilm on HA-coated implant surfaces may result from the increased roughness, which then contributes to peri-implantitis.[39,40]

If marginal bone loss occurs, it will lead to the HA surface implant becoming exposed to the oral environment with resultant contamination. In this case it would also be more difficult for the patient to maintain the implant, resulting in increased risk of peri-implant disease.[41,42] Another concern associated with HA-coated implants is dissolution of the HA layer or fracture of the HA coating–titanium interface, which leads to loss of the coating with subsequent implant mobility and loss.[39,43-45]

Overall, there are major concerns with the use of plasma-sprayed coatings. In the case of both HA and titanium plasma spray (TPS)–coated implants, the surface roughness is at a higher level than the moderately rough that is currently considered optimal. Such rough surfaces are also thought to contribute to the spread of peri-implantitis when the surface is exposed to the oral cavity and facilitates the formation and retention of plaque. As with the HA coatings, delamination of the titanium particles in TPS implants has been observed leading to mobility and eventual loss of the implants.

Oxidation or Anodization

Although all cpTi and titanium alloy implants develop an oxide layer on exposure to air, oxidized implants have been subjected to additional treatment to significantly thicken this layer. In the process of anodic oxidation, the titanium surface to be treated serves as the anode in an electrolytic cell with acid solutions serving as the electrolyte. The thickness of the oxide layer is controlled by altering the voltage and the electrolyte solution.

After such treatment, the surface oxide increases from an approximately 5-nm thickness to 3 μm or more. A positive correlation was found between increasing height deviation of the treated surface and implant healing when oxidized implants prepared at different voltages were compared. This means that implants with a thicker oxidation layer had greater BIC compared with those with a thinner oxide layer. However, an oxide layer greater than 3 μm in thickness did not cause any further increase in bone implant contact (Table 9.3).[46]

Biological Responses and Interaction with the Implant Surface

Osseointegration of a dental implant after placement into a prepared osteotomy follows three stages of repair:[12] (1) initial formation of a blood clot, (2) cellular activation, and (3) cellular response.[47] After implant placement, blood components interact with dental implant surfaces, leading to the adsorption of plasma proteins such as fibrin on the implant surface. The migration of bone cells necessary for osseointegration then occurs through the fibrin clot. The ability of an implant surface design to retain fibrin during the wound contraction phase of healing is critical in determining whether the migrating cells will reach the implant. Bone cells reach the implant surface by migration through fibrin and other early structural matrix proteins and lay down bone on the implant surface itself. Moderately rough and rough surfaces

TABLE 9.2	Different Techniques to Deposit Hydroxyapatite Coating[34]		
Technique	**Thickness**	**Advantages**	**Disadvantages**
Plasma spraying	<20 µm	Rapid deposition; sufficiently low cost; fast bone healing, less risk for coating degradation	Poor adhesion, alternation of HA structure caused by the coating process; nonuniformity in coating density; extreme high temperature up to 1200°C, phase transformation and grain grow of substance caused by high-temperature procedure; increase in residual stress; unable to produce complete crystalline HA coating
Thermal spraying	30–200 µm	High deposition rates; low cost	Line-of-sight technique; high temperatures induce decomposition; rapid cooling produces amorphous coatings; lack of uniformity; crack appearance; low porosity; coating spalling and interface separation between the coating and the substrate
Sputter coating	0.5–3 µm	Uniform coating thickness on flat substrates; dense coating; homogenous coating; high adhesion	Line-of-sight technique; expensive and time-consuming; produces amorphous coatings; low crystallite, which accelerates the dissolution of the film in the body
Pulsed laser deposition	0.05–5 mm	Coating that is crystalline and amorphous; coating that is dense and porous; ability to produce wide range of multilayer coatings from different materials; ability to produce high crystalline HA coating; ability to restore complex stoichiometry; high degree of control on deposition parameters	Line-of-sight technique; expensive and time-consuming; produces amorphous coating; low crystalline, which accelerates the dissolution of the film in the body line-of-sight technique splashing or particle deposition; needs surface pretreatment; lack of uniformity
Dip coating	<1 µm	Inexpensive; coatings applied quickly; can coat complex substrates; high surface uniformity; good speed of coating	Requires high sintering temperatures; thermal expansion mismatch; crack appearance
Sol-gel	0.1–2.0 µm	Can coat complex shapes; low processing temperatures; relatively cheap because coatings are very thin; simple deposition method; high purity; high corrosion resistance; fairly good adhesion	Some processes require controlled atmosphere processing; expensive raw materials; not suitable for industrial scale; high permeability; low wear resistance; hard to control the porosity
Electrophoretic deposition	0.1–2.0 mm	Uniform coating thickness; rapid deposition rates; can coat complex substrates; simple setup, low cost, high degree of control on coating morphology and thickness; good mechanical strength; high adhesion for n-HA	Difficult to produce crack-free coatings; requires high sintering temperatures; HA decomposition during sintering stage
Hot isostatic pressing	0.2–2.0 mm	Produces dense coatings; produces net-shape ceramics; good temperature control; homogeneous structure; high uniformity; high precision; no dimensional or shape limitation	Cannot coat complex substrates; high temperature required; thermal expansion mismatch; elastic property differences; expensive; removal/interaction of encapsulation material
Ion beam–assisted deposition	<0.03 µm	Low temperature process; high reproducibility and reliability; high adhesion; wide atomic intermix zones are coating-to-substrate interface	Crack appearance on the coated surface

HA, Hydroxyapatite.

From Mohseni E, Zalnezhad E, Bushroa AR. Comparative investigation on the adhesion of hydroxyapatite coating on Ti-6Al-4V implant: a review paper. *Int J Adhes.* 2014;48:238–257.

promote this activity by providing surface features with which fibrin can become entangled and by increasing the available surface area for fibrin attachment.[48] This leads to greater BIC and improved osseointegration. Implant surface properties also have the potential to alter ionic interactions, protein adsorption, and cellular activity at the implant surface (Fig. 9.3).[49]

Bone cell migration and bone formation observed on titanium implant surfaces are also thought to be related to the similarity between the microroughness of the surface and the pit irregularities found in natural bone surfaces resulting from osteoclast activity.[50,51]

After implant placement, remodeling of the surrounding bone occurs by osteoclastic activity, which removes some of the existing bone around the implant. The natural surface of the demineralized bone matrix created by osteoclast resorption processes is rough and pitted. This becomes the recipient surface for new bone formation. Submicron scale features <1 µm with undercuts allow the deposition of bone matrix, micron scale surface features <10 µm mimic a single osteoclast resorption pit, and macroscale cavities >10 µm are similar to resorption activity of one or more osteoclasts.[52-54] As with natural bone, osteoblasts find these surface irregularities and begin depositing matrix in and around them to form bone.

HA, Hydroxyapatite; *RBM,* resorbable blast media.
From Bullis G, Shreya S. Implant surface treatments: a literature review. *Inclusive Mag.* 2014;5(2).

In summary, microroughness on implant surfaces helps in retention of the fibrin clot. This in turn enables the migration of bone progenitor cells that deposit bone in close proximity to the implant improving the BIC. Pits on the implant surface mimic naturally occurring osteoclastic activity and lead osteoblasts to deposit bone on the surface of the implant, leading to improved osseointegration.

Role of Surface Roughness in Peri-implant Disease

Several studies recognized surface roughness as an important factor in the formation of biofilm on implant surfaces.[55,56] By their nature, rougher surfaces encourage more biofilm formation.[57-60]
• **Fig. 9.3** Cellular phenomena at the implant–bone interface during healing of implant. (From Anil S, et al. Dental implant surface enhancement and osseointegration. In Turkyilmaz I, ed. *Implant Dentistry: A Rapidly Evolving Practice*. London, UK: InTech; 2011.)

Biofilm formation is directly proportional to surface roughness; the greater the roughness, the higher the rate of biofilm formation is around the implants. The wettability and surface free energy (SFE) of a specific surface also influence the biofilm formation on implants.[57]

Future Directions

Several additional surfaces are being explored as options to improve osseointegration and the rate of bone healing.

Bisphosphonate Surfaces

Bisphosphates are antiresorptive agents known to inhibit osteoclast activity that are used in the treatment of osteoporosis. Bisphosphate-loaded implant surfaces have been reported to improve implant osseointegration.[61,62] It has been shown that bisphosphonate incorporated onto titanium implants increased bone density locally in the peri-implant region[63] with the effect of the antiresorptive drug limited to the vicinity of the implant.[12] An animal study conducted by Peter and colleagues showed a positive effect of zoledronate-coated implants on the peri-implant bone volume fraction in osteoporotic rats.[64]

Abtahi and colleagues conducted a double-blind split-mouth study in which each patient received one bisphosphonate-coated implant and one uncoated implant. After 6 months of osseointegration, resonance frequency analysis indicated better fixation of the coated implants. The implants were coated by using a nanometer-thin fibrinogen coating containing minimal amounts of bisphosphonates that improved early implant fixation with an effect that was maintained at 5 years after prosthetic loading. Reduced marginal bone resorption was also seen. All implants functioned well.[65] At 5 years, the bisphosphonate-coated implants showed only a small amount of resorption (median 0.20 mm). The present data suggest that bisphosphonate-coated implants enable prolonged preservation of the marginal bone.[66] Histologic analysis of test implants removed en bloc at the 6-month follow-up showed mature lamellar bone trabeculae in intimate contact with the implants.[67]

Bisphosphonates inhibit the resorption and renewal of bone mediated by osteoclasts, retaining existing bone, which may increase mineralization under normal function, resulting in an

increase in bone mineral density.[68] The prevention of osteoclast-mediated bone resorption and renewal influenced by bisphosphonates results in retention of old bone. Old bone lives out its natural life span and becomes brittle.[69] This may create a nonideal local environment for increased BIC. Bisphosphonates can work as a bony shield to protect the early formed bone, which may explain better fixation seen in some studies.[70]

Statins

Statins are commonly prescribed drugs that decrease cholesterol synthesis by the liver. This reduces serum cholesterol concentrations and lowers the risk of heart attack.[71] Simvastatin induces the expression of bone morphogenetic protein 2 (BMP-2) mRNA that promotes bone formation.[72] Ayukawa and colleagues[73] confirmed that topical application of statins to alveolar bone increased bone formation and concurrently suppressed osteoclast activity at the bone-healing site. In addition, clinical studies reported that statin use is associated with increased bone mineral density.[74-78]

Antibiotic Coating

Antibacterial coatings on the surface of implants that provide antibacterial activity to the implants themselves have been studied as a possible way to prevent surgical site infections associated with implants. Gentamycin, along with the layer of HA, can be coated onto the implant surface, which may act as a local prophylactic agent along with the systemic antibiotics in dental implant surgery.[79] Tetracycline enhances blood clot attachment and retention on the implant surface during the initial phase of the healing process, promoting osseointegration.[12,80]

Functionalization with Biologically Active Substances

The purpose of functionalization of the implant surface with biologically active substances is to diminish the initial inflammatory response after torquing in of the implant and encouraging rapid bone growth. Growth factors and fragments of the organic matrix of bone and other known biologically active peptides are used to coat the surface of implants.[81,82]

There are several growth factors involved in osteogenesis. Four growth factors have potential use in implantology: BMP-2 and BMP-7, fibroblast growth factor (FGF-2), and platelet-derived growth factor (PDGF-B).[83,84]

PDGF-B is a potent mitogen and chemotactic agent for a variety of mesenchymal cells, including osteoblasts.[85] Recently, Chang and colleagues[85] have demonstrated that PDGF stimulates osseointegration of dental implants in vivo. On the other hand, it has been reported that the isolated recombinant PDGF may affect bone formation adversely.[85]

In clinics, the use of platelet-rich plasma or platelet-fibrin clot is the equivalent of pure PDGF usage. This method is gaining popularity because it is safe, and it is possible to use autologous source of growth factors. The method has shown good results in a number of clinical studies.[86-88]

BMPs are a family of growth factors that are present during early stages of bone healing and play an important role in the growth and differentiation of several cell types, including osteoblasts.[89,90] BMP-2 is often used in bone-implant interaction

studies because it seems to possess the highest osteoinductive potential among the BMPs.[91] BMPs may be applied to bone sites through various delivery systems such as an absorbable collagen sponge used to augment the bone ridge before implant placement or implants with porous structures coated with rhBMP-2.[92] However, coating an implant is an unreliable way of delivering similar dosages uniformly. The rhBMPs and BMPs are costly, have a high dose requirement (several micrograms up to milligrams), and have a poor distribution profile.[93,94] High doses of BMP-2 have been associated with localized and temporary bone impairment[95] or increased bone resorption caused by stimulation of osteoclast formation.[96] However, once the levels drop, normal bone formation is observed.[70]

Usage of Biologically Active Peptides

Proteins of extracellular bone matrix also have potential use as functional coatings. For example, fibronectin stimulated osteoblastic differentiation and tissue mineralization and contributed to strong osseointegration of implants in experimental models in vivo.[97-99]

Common problems associated with the use of growth factors and biologically active peptides are increase in the cost of implants treated with them, complications with usage, and preservation of the bioactive material before implantation. There are also concerns about the release profile of these components into surrounding tissues (rate of release, area of release, etc.).

Zirconia Implants

In recent years, yttria-stabilized tetragonal zirconia polycrystal (Y-TZP), a high-strength zirconia, has become an attractive new material for dental implants. Zirconia has a tooth-like color and the ability to transmit light, improving the overall esthetic outcome.[100] Moreover, it has a high chemical resistance, high flexural strength (900–1200 MPa), a favorable fracture toughness (KIC; 7–10 MPa/m$^{1/2}$), and a Young's modulus of 210 GPa, which makes it a strong material.[101] Zirconia also has a low affinity for dental plaque, which reduces the risk of inflammatory changes in the peri-implant soft tissues.[102-104]

Zirconia implants are often one-piece implants, which means that both the implant body and the permucosal portion can be digitally designed to fit the local anatomic conditions and individually machined. One-piece implants have the advantage of no implant-abutment movement.[105] Zirconia implants perform well in areas with thin soft tissue biotype and in cases in which soft tissue recession might expose some part of the implant. These advantages make Y-TZP implants a potential alternative to titanium implants in certain clinical situations,[100,105] as well as opening up the possibility for computer-aided design and computer-aided manufacturing (CAD/CAM) of customized zirconia implants.[104]

Surface modifications of zirconia implants such as sandblasting and acid etching trigger tetragonal-to-monoclinic (t → m)phase transformation.[105] This transformation is associated with 3% to 4% phase volume expansion and induces compressive stresses that shield the crack tip from the applied stress.[106] This unique characteristic is known as transformation toughening.[107] However, the surface flaws introduced by sandblasting and acid etching act as stress concentrators and may become potential sites for crack initiation and propagation, causing strength degradation and the possibility of implant fracture.[108,109]

Depprich and colleagues[52] conducted an animal study to compare the osseointegration of acid-etched titanium and zirconia implants of similar macrostructure and found that the BIC during the process of osseointegration was very similar. Langhoff and colleagues[110] conducted a study in sheep using six types of implants with identical implant geometry. All titanium and zirconia implants were sandblasted and partially etched before the surface treatments, similar to the reference. The surfaces of the chemically modified implants were either plasma anodized or coated with CaP. The pharmacologically modified implants were either coated with bisphosphonate or collagen type I. An acid-etched and sandblasted implant made of titanium (grade 4; SPI 1 ELEMENT, Thommen Medical AG, Waldenburg, Switzerland) served as the reference and control for the surface modifications.

The collagen coating was based on an extracellular matrix containing chondroitin sulfate, prepared by fibrillogenesis of the collagen in the presence of chondroitin sulfate, and performed as dip coating in a collagen/chondroitin sulfate solution. The bisphosphonate-coated implants were immobilized with an alendronate solution to a final concentration of 10 mg/cm^2. The zirconia implants were manufactured from yttrium partially stabilized zirconia, medical grade. The zirconia implants were sandblasted and etched in an alkaline bath.

Results of the BIC measurements showed that all titanium implant types were nearly similar at 2 weeks (59%–62% BIC) and increased with time (78%–83%), except the plasma-anodized surface (58%). The two chemical surface modifications performed very differently. The CaP surface showed similar values, with the main increase at 2 to 4 weeks, similar to the reference, and a slight increase toward week 8. In contrast, the plasma-anodized surface lost 2% bone contact initially and did not improve after 4 weeks. Pharmacologically modified surfaces performed close to the reference. The collagen with chondroitin sulfate surface showed slightly higher values than the reference implant at 2 weeks and continued nearly equally, whereas the bisphosphonate-coated surface was higher at 2 and 4 weeks. The zirconia implant presented 20% more bone contact than the titanium implants at 2 weeks, improved toward 4 weeks, then reduced at 8 weeks to below the level of the reference surface. The overall performance of the new surfaces, except the plasma-anodized surface, was better than the reference. Statistically significant differences for BIC were not found.

Biomimetic Formation of Hydroxyapatite on the Implant Surface

The use of coatings with similar composition of the human bone provide an accelerated osseointegration during the earliest healing stages. In particular, CaP apatite has the same chemical composition as the mineral bone phase, which means there is no inflammatory reaction.[111] Many researchers have applied coatings on titanium implants by using techniques like HA plasma spraying.[112] In some clinical studies,[113] this treatment produced a quicker osseointegration at early stages after implant placement, but an accelerated bone loss caused by a bacterial microleakage between the HA layer and the titanium has been observed in the long term.[114] Furthermore, additive techniques such as HA plasma spraying do not allow the formation of crystalline apatite such as in human bone, but amorphous CaP can be caused by high elaboration temperatures.[114] The properties of this layer are not considered appropriate for dental implants because they are extremely soluble, and titanium only achieves mechanical retention and not true adhesion.[115]

Osseointegration of dental implants can be improved by the application of CaP coating by plasma spraying and biomimetic and electrophoretic deposition. Although plasma-sprayed HA-coated dental implants have disadvantages related to coating delamination and heterogeneous dissolution rate of deposited phases, an electrochemical process consisting of depositing CaP crystals from supersaturated solutions releases calcium and phosphate ions from these coatings. This process helps in the precipitation of biological apatite nanocrystals with the incorporation of various proteins, which, in turn, promotes cell adhesion, differentiation into osteoblast, and the synthesis of mineralized collagen (the extracellular matrix of bone tissue).[12,116]

Osteoclast cells are also able to resorb the CaP coatings and activate osteoblast cells to produce bone tissue. Thus these CaP coatings promote a direct bone–implant contact without an intervening connective tissue layer leading to a proper biomechanical fixation of dental implants.[12] Osteoclast cells are also able to resorb the CaP coatings and activate osteoblast cells to produce bone tissue. Thus these CaP coatings promote a direct bone–implant contact without an intervening connective tissue layer, leading to a proper biomechanical fixation of dental implants.[12]

Implants coated with CaP have a better BIC compared with currently available titanium implants. Implants coated with CaP claim to offer a physicochemical matrix for the deposition of new bone by osteoclasts, which could explain the increased BIC. It also leads to an increased attachment of osteogenic cells.[117] Ions released from CaP coating have been reported to control the cellular signals that improve osteoblast differentiation.[118] These ions have a potential to stimulate numerous intracellular signaling pathways in osteoblasts and support the bone formation process.[70,119] Even though it has been suggested that CaP coatings can enhance adhesion/activation of bone cells on the surface of implants,[120] possible delamination of the coating from the surface of the titanium implant and failure at the implant/coating interface may happen when the coating is rather thick.[121]

The hope of developing bioactive implant surfaces is to significantly reduce the time required for osseointegration. The most important mechanisms involved are the protein adsorption capacity, wettability, and an optimized zeta potential, which reduces the electrostatic dispersion between particles. These procedures also aim to increase adhesion, proliferation, and differentiation of osteoblast cells compared with other current surface treatments to facilitate bone formation around the implants.[122]

Alenezi and colleagues investigated the effects of the use of local drug and chemical compound delivery systems on the osseointegration of endosseous implants in animal models. They looked at chemical agents incorporated, coated, or immobilized on implant surfaces and also at chemical agents that were locally delivered at the implant site using carrier materials such as injectable gels, microsphere hydrogel, or collagen sponges. BIC was evaluated for CaP, bisphosphonates, and BMPs. They found that implants coated with CaP and BMPs showed statistically significant bone growth compared with uncoated implants.[70] Well-designed clinical trials will help us better understand the effect of these coatings of implant surfaces and their interaction with bone, as well as the long-term success of these biochemical modifications.

Summary

Our understanding of the role played by dental implant surfaces in the process of osseointegration continues to evolve as research provides additional insights. Research continues in the areas of surface treatments, chemical modifications, and how they both influence the cellular and biological processes. With current reported success rates well above 90%, it is unlikely that new surfaces will provide incremental improvement of these overall rates. However, improvements in outcomes in poor bone quality and in medically compromised patients may well be enhanced by future developments.

Medical Evaluation of the Dental Implant Patient

RANDOLPH R. RESNIK AND ROBERT J. RESNIK

The medical evaluation of patients considering dental implant treatment is an important and vital aspect of the treatment planning process. A retrospective analysis of Veterans' Administration Registry data found that the medical status of patients (i.e., medical history, American Society of Anesthesiologists [ASA] category, and medication history) correlated with dental implant failure.[1] It is the primary goal of the clinician to assess the inherent risks associated with the treatment of patients. There exist many factors associated with evaluating the patient's health status and risk including the patients current and past medical and dental history, current and past use of medications, history of allergies, social history, type of treatment, length of treatment, invasiveness of treatment, degree of urgency of treatment, and the past use of sedation (Box 10.1).

Patients presenting for dental implant treatment may apparently appear "healthy"; however, they may actually have serious systemic diseases or taking medications that may increase the morbidity of treatment. Patients today, even those with life-threatening diseases, are more socially active and have a better quality of life because of advances in surgical and medical care. Studies have shown that 30% of dental patients have some type of relevant medical condition.[2] Evaluating patients over the age of 60 years old, 40% have been shown to be on five or more prescription medications, 15% are taking 10 or more prescription medications, and 67% are taking a combination of five or more prescription and over-the-counter (OTC) medications.[3]

Although difficult in many situations, the clinician should do everything possible to identify the medically compromised patient. The goal is for every patient to be treated in a safe and efficient manner. Increased risk to patients may arise from procedures that are too invasive or outside the patient's tolerance in an office setting. Therefore it is imperative for the clinician to make an assessment of risk based on medical and dental history and be conscious of the extent of trauma and stress to the patient with the anticipated procedures.

This chapter is specific for an implant candidate and focuses on the importance of the initial medical evaluation with primary emphasis on the medical history questionnaire and the physical examination. Relevant systemic diseases along with medications that directly affect the dental implant patient are addressed with recommendations on the treatment plan, intraoperative treatment, and postoperative care modifications.

Medical Evaluation

The medical evaluation remains of paramount importance in implant dentistry, perhaps more so than in other disciplines of dentistry. Dental implant treatment is well accepted today as a surgical, prosthetic, and maintenance discipline for patients ranging from adolescence to the elderly population. The need for implant-related treatment increases with the age of the patient; as a result, the implant dentist treats more elderly patients than other specialists in dentistry.

An estimated 12% of the US population is 65 years of age or older; this number is expected to reach 21% (64.6 million) in the year 2030.[4] A 65-year-old person has a life expectancy of another 16.7 years, and an 80-year-old person can expect to live an additional 8 years.[5] These patients often request implant support for their failing fixed restorations or to improve the conditions of their removable prostheses. An increased life span indicates that the number of elderly patients in the dental practice is highly likely to increase in the future. Therefore it is important to design the medical and physical evaluations to accommodate the special conditions of these patients.

Medical History

An extensive written medical history is mandatory for every dental implant candidate. The review of the patient's medical history is the first opportunity for the dentist to speak with the patient. The

---

> • BOX **10.1** **Factors Affecting the Risk Assessment of the Implant Patient**

- Current and past medical history
- Current and past dental history
- Current and past use of medications
- History of allergies
- Social history and use of recreational drugs
- Type of required treatment
- Length of treatment
- Invasiveness of treatment
- Psychological status
- Degree of urgency of treatment
- Use and type of sedation

time and consideration taken at the onset will set the tone for the entire subsequent treatment. This first impression should reflect a warm, caring practitioner who is highly trained to help patients with complex medical and dental histories. A sincere interest and active note-taking process are beneficial. The practitioner should not underestimate the value of the medical history interview. Asking questions that show an understanding of listed medical conditions and related common problems offer several benefits.

The two basic categories of information addressed during the review of the medical history include the medical history and a review of the patient's systemic health. The dental office uses a medical evaluation form to obtain most of this information (Fig. 10.1). Of particular importance is the history of medication usage including OTC medications, herbs and supplements, allergies, and a review of the body systems. The pathophysiology of the systems, the degree of involvement, and the medications being used to treat the conditions are evaluated. It is important to review this form with the patient to ensure that comprehension is adequate to answer all questions accurately and truthfully.

Extraoral and Intraoral Examinations

After the medical history is reviewed, the medical physical examination is initiated because this is the first physical contact the office staff has with the patient. A gentle, caring approach should continue throughout the examination. A complete evaluation of the head and neck is important initially and at all subsequent preventive maintenance (recall) appointments.

The extraoral and intraoral examinations are similar to those addressed in any oral diagnosis textbook. The exposed areas of the patient need to be evaluated (face, neck, arms, and hands) and documented accordingly. Features and facial symmetry are observed, including the ears, nose, and eyes. If the midline, occlusal plane, or smile line of the natural teeth or existing prosthesis is not harmonious, the etiology should be determined. The temporomandibular joint should be evaluated along with maximum occlusal opening because this may complicate or contraindicate surgical and prosthetic procedures. Patients are very receptive to critical evaluation and treatment limitations

Fig. 10.1 (A–D) Medical history form.

About Your Medical History

		Date ___/___/___	Date ___/___/___
Endocrine System	EN1. Do you have diabetes? controlled/uncontrolled	❑ Yes ❑ No	❑ Yes ❑ No
	EN2. Does anyone in your family have diabetes?	❑ Yes ❑ No	❑ Yes ❑ No

relating to facial esthetics before reconstruction begins. The high smile should be evaluated, because this may pose esthetic complications related to dental implants. Visible signs of anxiety, abnormal body movements, tremors, lethargy, or difficulty in breathing should be noted along with any abnormalities in the face (e.g., expression, pallor, cyanosis or jaundice, drooping eyelids), neck (e.g., lumps, swelling), arms (e.g., bruising or petechiae), or hands (e.g., finger clubbing, Raynaud phenomenon, rashes, dexterity issues).

The submental, submandibular, parotid, and cervical areas are palpated for lymphadenopathy or unusual swelling. The area between the cricoid notch and the suprasternal notch is palpated for enlargement of the thyroid gland. Thyroid disorders may influence bone metabolism and implant management. Intraoral examination of the lips, labial and buccal mucosa, hard and soft palate, tongue, and oral pharynx is then performed. Any lesions or disease states must be further evaluated before implant procedures commence.

Vital Signs

The recording of vital signs (blood pressure, pulse, temperature, respiration, weight, and height) is also part of the physical examination. Trained dental auxiliary personnel can often gather this information before the patient's history is reviewed by the dentist. If any findings are unusual, the doctor can repeat the evaluation as needed.

Blood Pressure

Blood pressure is a critical component of the medical examination and is often neglected in dental offices. Studies have shown that approximately 10% of dental offices record the patient's blood pressure.[6] The importance of obtaining and recording the blood pressure in every implant patient is twofold. First, the initial recording may serve as a baseline measurement, which, if too high, may indicate an underlying cardiovascular disease that may contraindicate a surgical procedure. Second, when in

an acceptable range, the initial blood pressure acts as a baseline measurement specific for that patient. If the patient has a future problem during treatment, the blood pressure difference between baseline and the current situation may alter the medical risk of the patient.

Blood pressure is measured in the arterial system. This makes using a wrist cuff more difficult and less accurate, as the arteries in the wrist are narrower than in the elbow. It is always advisable to use a cuff that measures the blood pressure just above the elbow. Using a cuff that is too small will give you an artificially higher blood pressure, and using a cuff that is too large will give an artificially low blood pressure. Bladder length is a helpful guide in choosing the appropriate cuff size. The American Heart Association (AHA) recommends the cuff to be 80% of the patient's arm circumference and 40% for ideal width.

There are several standard-size cuffs. The small adult size is for an arm circumference of approximately 7 to 9 inches. Regular adult-sized cuffs can be used for arm circumferences that are between 9 and 13 inches. A large adult cuff can be used when the arm circumference exceeds 13 inches but is less than 17 inches.

Blood pressure may be directly influenced by the cardiac output, blood volume, viscosity of the blood, condition of blood vessels (especially the arterioles), and heart rate. The systolic blood pressure is the maximum amount of pressure in your arteries during the contraction of your heart muscle. The diastolic blood pressure is the pressure in the arteries between beats. The difference between the diastolic and systolic blood pressure is the pulse pressure. The pulse pressure is the amount of pressure the heart creates every time is beats. For example, a blood pressure of 120/80 would have a pulse pressure of 40 mm Hg. The average pulse pressure is 30 to 50 mm Hg. A high pulse pressure is greater than 60 mm Hg and is more common in the elderly. Along with age, a high pulse pressure can be indicative of accelerated hypertension or atherosclerosis of the arteries. Blood pressure may be directly influenced by the cardiac output, blood volume, viscosity of the blood, condition of blood vessels (especially the arterioles), and heart rate.

In 2017, the standards for evaluating blood pressure readings were updated with the release of the "Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure" (Joint National Committee [JNC] 7).[7] Blood pressure is now divided into four different categories: normal, elevated, stage 1, and stage 2. Normal blood pressure is defined as <120/<80 mm Hg; elevated blood pressure is defined as 120 to 129/<80 mm Hg; stage 1 hypertension is defined as 130 to 139 or 80 to 89 mm Hg; and stage 2 hypertension is defined as >140 or ≥90 mm Hg. A diagnosis of hypertension is not made on a single reading. The diagnosis should be confirmed on at least two or more readings on at least two or more occasions. If the blood pressure reading exceeds a systolic of 140 or diastolic of 90 on two separate readings, then the patient should be referred to their primary care physician.[8]

White-coat hypertension in a medical office can occur with some patients. This is especially true for patients in a dental office, who may be anxious or apprehensive about the pending dental procedure. Before making a diagnosis of hypertension in these individuals, the patient should monitor the blood pressure at home or out of the office. Hypertension tends to have a higher prevalence in African Americans compared with Caucasians. The risk of death from a stroke or heart disease can be doubled for every 20 mm Hg of elevation in systolic blood pressure and every 10 mm Hg in elevation of diastolic blood pressure.

Only personnel that have been trained and retrained on a regular basis in the standardized technique should perform blood pressure monitoring. It is advised to record the blood pressure in both arms and provide at least 2 to 3 minutes between repeating the blood pressure readings. You should always verbally give the patient their blood pressure reading in addition to recording it in their chart. Usually giving the patient at least 5 minutes to rest before checking their blood pressure is advisable. Most dental offices will use an automatic electronic cuff, which will inflate the cuff to the appropriate pressure and automatically measure the blood pressure. It is important that the cuff is in the appropriate position, with the tubes from the cuff running directly over the brachial artery. The patient's feet should be supported on the floor and the arm supported on a table or chair arm at the level of the heart. Do not use one measurement to determine whether a patient has blood pressure issues. Repeat the reading to confirm elevated blood pressure, and refer the patient to their primary care provider when appropriate.

Low blood pressure can also create issues for dental implant surgery. Blood pressure readings of less than 90 mm Hg systolic or less than 60 mm Hg diastolic is considered abnormal, and elective dental implant surgery should be postponed until consultation with the patient's physician. It is always important to recheck the blood pressure to verify the low readings. Low blood pressure can result from dehydration, hypothyroidism, or the patient being over-medicated with antihypertensive medications.

Note: If a female patient presents with a history of a mastectomy, blood pressure should be taken on the arm opposite the side of the mastectomy to avoid possible lymphedema. If a patient relates a history of a double mastectomy, blood pressure should be taken on the ankle (this will usually result in an elevated blood pressure reading).

Pulse

The second vital sign of importance is the pulse. The pulse represents the force of the blood against the aortic walls for each contraction of the left ventricle. The pulse wave travels through the arteries and reaches the wrist 0.1 to 0.2 seconds after each contraction. The actual blood flow takes longer to travel this distance. The usual location to record pulse is the radial artery in the wrist. However, other locations, such as the carotid artery in the neck and the temporal artery in the temporal region, are convenient to use during implant surgery or dental treatment. Pulse monitors are easy to use and are beneficial during surgery or long prosthetic appointments.

Pulse Rate. The normal pulse rate varies from 60 to 90 beats/min in a relaxed, nonanxious patient. Many of the automated blood pressure machines will check the pulse. If there is any significant variation in the blood pressure readings or there is an error on the automated machine, you should check a manual pulse in the brachial or radial artery to ensure the rhythm is regular. The pulse rate can be verified manually for a minimum of 30 seconds to 1 minute.

If you feel any irregularities in the pulse, you should refer the patient back to their primary care provider before proceeding. Sometimes premature ventricular or atrial contractions are normal and can be felt manually with the pulse rate. These extra beats will usually be infrequent. More frequent irregular beats or beat that seem to be just erratically irregular without any particular pattern may indicate a need for primary care provider consultation before proceeding with dental surgery.

Some patients with chronic atrial fibrillation will have an erratically irregular heart rate. These patients are usually on blood

thinners (anticoagulants). A rate greater than 100 or less than 60 in these patients can also be problematic and should indicate the need for physician consultation.

The normal cardiac rhythm originates in the sinoatrial node; the pulse reflects the ventricular contractions. The upper limit of normal is considered 100 beats/min; patients in excellent physical condition may have a pulse rate of 40 to 60 beats/min. A pulse rate less than 60 beats/min in a nonathlete or higher than 110 beats/min in a relatively calm patient could be suspect and warrant further medical consultation.

A decreased pulse rate of normal rhythm (less than 60 beats/min) indicates a sinus bradycardia. Naturally, some patients may reach as low as 40 beats/min, although most patients become symptomatic with lightheadedness, dizziness, or can experience syncope with a rate lower than 40 beats/min. An adult pulse rate lower than 60 beats/min in a nonathlete mandates medical evaluation before surgical procedures. Patients receiving beta-blocker medications may have lower than normal pulse rates. These patients may be asymptomatic, but consultation with their physician should be considered. During implant surgery, inappropriate bradycardia may indicate a very serious problem. If the pulse rate of the patient decreases to less than 60 beats/min and is accompanied by sweating, weakness, chest pain, or dyspnea, the implant procedure should be stopped, oxygen administered, and immediate medical assistance obtained. If the resting pulse of the patient is greater than 60 beats/min and drops into the 40s or lower, the dental procedure should be suspended, even if the patient is asymptomatic, until the pulse returns closer to the resting rate.

An increased pulse rate of regular rhythm (more than 100 beats/min) is termed sinus tachycardia. This rate is normal if experienced during exercise or anxiety. However, a medical consultation is suggested when a nonanxious patient has a resting pulse rate higher than 100 beats/min. In patients with anemia or severe hemorrhage, the heart rate increases to compensate for the depletion of oxygen in the tissues. Therefore when increased bleeding during surgery is observed, evaluate the pulse rate and blood pressure.

Pulse rate and temperature are also related, with the pulse rate increasing 5 beats/min for each degree that the body temperature rises. Hyperthyroidism and acute or chronic heart disease also may result in sinus tachycardia. Some patients may be asymptomatic and experience a condition called paroxysmal atrial tachycardia. This condition is characterized by episodes of very fast heartbeats that may last a few minutes or several weeks. All of these conditions affect the surgical procedure and may increase postoperative swelling. The increased swelling favors the occurrence of infections and complications during the first critical weeks after implant placement. This can lead to increased morbidity and failure of the implants.

Pulse Rhythm. As described previously it is critical to not only rely on the automated pulse calculation but also to manually check the pulse for regularity or irregularity for at least 30 seconds in the radial or brachial artery. Extremely anxious patients can have accelerated pulse rates, which can then become irregular with a premature ventricular contraction (PVC) or premature atrial contraction (PAC). Stress reduction protocols can be implemented, and implant procedures may even be contraindicated if the causal conditions are severe.

The presence of an extra pulse beat may indicate a PVC. This condition may be associated with fatigue, stress, or excessive use of tobacco or coffee, but it is also observed during myocardial infarction (MI). If the PVCs are more frequent over a short period of time, physician consultation should be initiated. If during implant surgery, five or more PVCs are recorded within 1 minute, especially when accompanied by dyspnea or pain, the surgery should be stopped, oxygen administered, the patient placed in a supine position, and immediate medical assistance obtained. If the health history includes cardiovascular disease, including hypertension, the pulse rhythm should be recorded. Sudden death in persons older than 30 years with PVC is six times more frequent than in younger persons.[9]

Pulse Strength. The patient's pulse rate and rhythm may be normal, yet the blood volume can affect the character of the pulse. In anxious patients, the pulse may be bounding as the heart is forced to pump large amounts of blood. If the pulse seems to be strong then weak with some alteration back and forth, this could indicate pulsus alternans, which is frequently observed in left ventricular failure, severe arterial high blood pressure, and advanced coronary disease. Implant surgery is contraindicated, and medical consultation with an electrocardiographic examination is needed to obtain a diagnosis.

Temperature

Technology has altered the way we can now check a patient's temperature. Automated thermometers allow for an accurate temperature by placing a probe under the tongue. Another option is a digital ear thermometer. These devices give quick and reliable temperature measurements of the infrared radiation or heat coming from the tympanic membrane. Axillary and forehead measuring devices are much less sensitive and probably have no utility in a dental implant office. For every degree of fever, the pulse rate raises 5 beats/min and the respiratory rate increases 4 beats/min. If the patient's temperature is greater than 100.5°F, implant surgery should be postponed. If the temperature is greater than 102°F or higher, medical consultation is suggested.

The usual cause of elevated body temperature is bacterial infection and its toxic by-products. Other causes can be exercise, hyperthyroidism, MI, congestive heart failure (CHF), and tissue injury from trauma or surgery. Dental conditions causing an elevated temperature include severe dental abscess, cellulitis, and acute herpetic stomatitis. Elective dental treatment (such as implant surgery or bone grafting) is contraindicated when the patient is febrile (>100.5). The cause of the fever may complicate the postsurgical phase of healing. In addition, because elevated temperature increases the patient's pulse rate, the risks of hemorrhage, edema, infection, and postoperative discomfort are greater. Special attention must be given to a prolonged, sustained fever after surgery because sepsis or possible brain abscess could be present. Very low body temperatures can also be problematic but can also result from inaccurate measurement. If the body temperature is less than 97°F, an alternative method of testing should be used to verify the reading or at a minimum the reading should be repeated. More elderly patients can have normal body temperatures that run just higher than 97°F. Low body temperature can be found in hypothyroidism.

Respiration

Respiration is evaluated while the patient is at rest. The normal rate in the adult varies between 16 and 20 breaths per minute and is regular in rate and rhythm. Patients with advanced respiratory conditions including chronic obstructive pulmonary disease (COPD), CHF, and some forms of asthma may use accessory muscles in the neck or shoulders for inspiration, whether before or during surgery. This is considered a form of dyspnea (difficult

or labored breathing). During dental implant surgery, the use of intravenous (IV) drugs including narcotics can cause patients to develop dyspnea.

If dyspnea occurs during surgery, it is important to evaluate the patient's airway for swelling or obstruction. The pulse should immediately be evaluated to rule out the presence of PVCs or irregularity. This could indicate a more serious condition such as a MI.

Hyperventilation is the result of both an increased rate and depth of respiration and may be preceded by frequent sighs, such as is seen in the anxious patient. A respiratory rate greater than 20 breaths per minute requires investigation. Anxiety may increase this rate, in which case sedatives or stress reduction protocols are indicated before implant surgery. Other causes for an increased respiration rate are severe anemia, advanced bronchopulmonary disease, and CHF. All three can affect the surgical procedure or healing response of the implant candidate.

Having a portable pulse oximeter available is always advisable to measure oxygen concentration. It is important to keep the oxygen saturation greater than 90%. This may require supplemental oxygen. There was previous concern regarding oxygen supplementation in patients with chronic COPD depressing the hypoxemic drive. Currently the accepted use of supplemental oxygen in COPD patients is to keep the oxygen level at their baseline or greater than 90%. It is important that every dental office have supplemental oxygen and both a nasal cannula for routine oxygen supplementation and a nonrebreather mask to deliver higher levels of oxygen.

Hypoventilation can also occur from IV sedation. However, the initial evaluation of a patient that is experiencing hypoventilation with or without IV sedation should always be the airway for possible obstruction. If the airway is clear and hypoventilation persists, then pharmaceutical reversal of the sedative agent should be considered.

Height

The height of the patient should be determined, especially in an adolescent patient, to evaluate their growth and development in the determination of when dental implants would be appropriate. Ideally, growth cessation must occur before implant placement is initiated.

Weight

Weight is an important factor when using sedation for implants procedures, because there exists a direct correlation between dosage of sedative drugs and body weight. Additionally, significant changes in weight (gain or loss) should be evaluated to assess malnutrition, obesity, or retention of fluid from either kidney or heart dysfunction. Unintentional loss of weight may be a sign of malignancy, diabetes, or various other systemic diseases. A significant increase in weight may be a sign of cardiovascular disease such as CHF, hypothyroidism, or possible systemic diseases. Of special concern are patients with a history of gastric bypass because absorption rates of certain medications may be affected.

Laboratory Evaluation

Routine laboratory screening of patients in a general dental setting who previously reported a normal health history have found that 12% to 18% have undiagnosed systemic diseases.[10,11] Many of these disorders may influence implant surgery protocol or long-term success rates. The percentage of implant patients with unreported systemic illnesses is most likely higher because the average implant patient is older than those in these general studies. Implant therapy consists of an elective surgery that involves a considerable investment of time and money by the patient.

Although clinical laboratory tests are not a required component of the physical examination in the dental setting, the implant clinician must be well versed in the interpretation of results. In general, the implant clinician should never prescribe laboratory procedures. The reason for this is twofold. First, the patient's physician should be the first to interpret laboratory results because they are more knowledgeable about the specific medical condition of their patients. Second, there exists a medicolegal issue because the implant clinician would be responsible for interpretation of the entire laboratory tests requested.

The most common clinical laboratory evaluation is obtained from urinalysis and venous blood samples and may include a complete blood count (CBC), basic metabolic panel (BMP), comprehensive metabolic panel (CMP), and bleeding disorder tests such as prothrombin time (PT) or partial prothrombin time (PTT). An A1c should also be obtained if the patient relates prediabetic or diabetic conditions because this test gauges how well the patient's diabetes is managed.

Urinalysis

A simple dipstick urinalysis can serve as a valuable screening tool for systemic disease. Urine is a by-product of the kidney and performs several critical functions: filters wastes from the bloodstream; maintains water balance; and reabsorbs or conserves vital proteins and minerals that the body needs. Anything the body does not need is excreted in the urine. For the most part, urine is generally yellow and clear rather than cloudy. However, the color and consistency of urine can change, especially in the presence of systemic disease, infection, or focal urinary tract infection. Glycosuria or sugar spilling in the urine would be one of the most concerning findings for a dentist because this could indicate the presence of diabetes. In normal individuals sugar is absent from the urine. Many individuals with diabetes may not show sugars in the urine; therefore blood screening is the most sensitive way to screen for diabetes.

A urinalysis is not indicated as a routine procedure for dental patients and is rarely used in implant dentistry. The major uses for the urinalysis are a screening for diabetes, renal cancer with the presence of blood, kidney damage evidenced by the presence of protein or microalbumin, issues involving the liver with elevated levels of bilirubin, and infection with the presence of leukocytes or nitrates. Women that are menstruating will frequently have blood in their urine sample.

Complete Blood Cell Count

A CBC is a common screening test that evaluates the cells that circulate in the blood. There are three types of cells suspended in blood plasma: white blood cells (WBCs), red blood cells (RBCs), and platelets. The bone marrow produces these cells and allows them to mature before releasing them into the bloodstream.

The blood sample is read by an automated machine that the cells present and performs a number of other measurements including the physical characteristics of the cells. This would include the size of RBCs; which can be abnormal in cases of anemia (smaller), or vitamin deficiencies like B_{12} or folate (larger). The CBC is a good general screening test, but it may not be required unless major blood loss is anticipated.

However, in implant dentistry, CBCs would be important in patients with a history of anemia or bleeding disorders. CBCs are also useful for patients with chronic renal conditions, which can cause anemia or those that have been on recent (<3 months) steroid or glucocorticoid therapy. Any patient that received chemotherapy for cancer, cured or in remission, or history of WBC disease such as neutropenia (low WBC) or chronic leukemia (markedly elevated WBC) would also require a CBC.[12]

White Blood Cell Count

WBCs are also referred to as leukocytes. The normal total WBC count ranges from 4500 to 11,000 cells/mm^3, and the normal range can vary between laboratories. An increase in WBCs, or leukocytosis, is not specific to one WBC type. Some of the more common issues that create an elevated WBC are acute infection, inflammation, steroid therapy, or abnormal bone marrow production.

There are five different types of WBCs. Neutrophils, which help fight infection, are the most numerous. Lymphocytes, which are usually less than 25 % of the total cell count, help form antibodies and help the body get rid of foreign substances. They can be elevated in viral infections and decreased in immunocompromised patients such as in HIV. One of the first signs of immunodeficiency including HIV may be low lymphocyte count. Basophils are less than 1% of the total count and can increase or decrease based on certain disease states. Infections, severe allergies, and an overactive thyroid can cause abnormally high counts of basophils. Eosinophils, which are usually less than 3% of the total cell count, are elevated in the presence of allergic responses or parasitic infections. Monocytes, making up less than 10% of the count, are responsible for ingesting bacteria or foreign particles. Monocyte counts can be elevated in inflammatory bowel disease (IBD), endocarditis, or bacterial infections of heart, and parasitic or viral infections. A decrease in the number of total WBCs is referred to as leukopenia. Decreased WBC counts usually are the result of a viral infection, immune disorder, or bone marrow disease.

From an implant dentistry perspective, abnormalities in WBC counts can have significant implications. Inflammatory processes can be present with normal WBC counts, but certain types of cells, when increased, can indicate ongoing inflammation or possibly infection. Elevation in band neutrophils or absolute neutrophil counts (ANCs) usually indicates a more serious process like infection or severe inflammation.

When using a WBC count to monitor infection level, it is important to realize that early in the disease process the WBC counts may be normal. It is important to pay attention to shifts in the number of specific WBCs, such as neutrophils, basophils, or monocytes, which is reported as the differential (the breakdown of the five different types of WBCs). WBC counts are critical to dental outpatient care, particularly for patients with immune diseases or undergoing chemotherapy. The counts can indicate infections, leukemic disease (myeloproliferative), immune diseases, and toxicity of drugs (especially chemotherapeutic drugs). The ANC is very important in evaluating a patient's ability to fight infection. This count is calculated by multiplying the WBC count by the percentage of neutrophils. When not using antibiotic prophylaxis, the ANC must be greater than 2000. Counts less than 1500 are considered neutropenia. These individuals should be seen and evaluated by a hematologist or primary care physician and should be given clearance before continuing with implant surgery.

Consideration for antibiotics should begin at an ANC of less than 2500 and most definitely should be used for ANC levels of 1000 to 2000. Dental implant procedures should never be considered in a patient with an ANC of less than 1000.

Red Blood Cell Count

RBCs are responsible for the transport of oxygen and carbon dioxide throughout the body and for control of the blood pH. These cells represent the largest segment of the formed elements of the blood. The normal RBC count is higher in men than in women. Increases may result from polycythemia, smoking, testosterone use, congenital heart disease, or Cushing syndrome. The most common finding is a decreased cell count, which usually indicates anemia.

Hemoglobin

Hemoglobin (Hb) is responsible for carrying oxygen throughout the bloodstream. Each Hb protein carries up to four molecules of oxygen that can be delivered to various cells in the body. The normal level of Hb is 13.5 to 18 g/dL in men and 12 to 16 g/dL in women. The preoperative threshold of 10 g/dL is often used as a minimum baseline for surgery. However, many patients can undergo surgical procedures safely at 8 g/dL as long as their anemia has been chronic and stable.

It is critical for patients with Hb values less than 10 that the history of the rate of decrease be evaluated. Levels that have been consistently decreasing over time could indicate chronic blood loss in the gastrointestinal (GI) tract or through other means including malformation of blood vessels. Patients with a chronic stable anemia can have consistently lower Hb levels as their baseline. Women with heavy periods can develop low Hb counts over time that can sometimes drop below 10 and require supplementation with iron.

It is always a good idea to check with the patient's physician to confirm the chronicity of their anemia and baseline Hb. Significant acute decreases can be just as important at indicating a new process that may need to be addressed before the implant.

Hematocrit

White and red blood cells are suspended in serum and make up the contents of blood. The hematocrit is the percentage of RBCs in a given volume of blood. The hematocrit is a significant indicator of anemia or blood loss. Adult males have a normal value of about 42% to 54% and women 38% to 46%. Values within 75% to 80% of normal are required before sedation or general anesthesia.

Bleeding Tests

Bleeding disorders are the underlying cause of critical bleeding episodes in any type of dental surgery. Blood changes from liquid to solid through the coagulation cascade, which is a complex series of steps that result in a fibrin clot. The body uses platelets to plug the site of injury, and clotting factors then help form the fibrin clot that maintains the platelets in place.

It is important to realize that the platelet count alone does not necessarily provide all the information needed to evaluate a patient for a potential clotting disorder. It is critical to screen the patient for other signs such as easy bruising, heavy menstrual

cycles, frequent nosebleeds, and prolonged bleeding after small cuts. The patient's medical history may be a better detector than platelet counts.

Understanding the normal clotting process determines which bleeding test to evaluate. Whenever the integrity of a vessel wall is altered surgically, hemostasis is achieved in three phases: vascular spasm, formation of the platelet plug, and then blood coagulation, which through the formation of fibrin stabilizes the platelet plug. For hemostasis to be maintained or achieved, the blood vessels must be normal, and functional platelets must be present in sufficient number with all clotting factors in the coagulation cascade working properly. In a normal, healthy individual, coagulation is initiated within 20 seconds of blood vessel damage. This is accomplished by two phases of hemostasis: primary and secondary. Primary hemostasis is initiated when platelets adhere to collagen fibers in the vascular endothelium and form the platelet plug. The platelets become inactivated, which results in additional platelet activation and expansion of the platelet plug. The secondary phase consists of a coagulation cascade that has two pathways (Fig. 10.2): contact activation pathway (formerly the intrinsic pathway) and the tissue factor pathway (formerly the extrinsic pathway). These pathways involve a series of enzymatic reactions in which an inactive coagulation factor is converted to an active form, which then activates the next coagulation factors in a series of reactions that result in the formation of fibrin to strengthen the clot. The clotting cascade requires cofactors such as calcium and vitamin K to assist with the synthesis of additional clotting factors.

The tissue factor pathway (extrinsic system) and the contact activation pathway (intrinsic system) lead to completion of hemostasis along a common pathway. Both systems are necessary for normal coagulation. The extrinsic system is activated outside the blood vessels; the intrinsic system is activated within the blood vessels.

Three ways to detect potential bleeding problems are (1) to check the medical history, including any family history of bleeding disorders; (2) to review the physical examination; and (3) to screen the clinical laboratory tests. More than 90% of bleeding disorders can be diagnosed on the basis of the medical history alone.[13]
● **Fig. 10.2** Secondary phase of hemostasis is a coagulation cascade.

Bleeding problems in relatives are significant because they indicate inherited coagulation disorders. Hemophilia is a rare inherited condition that can cause minor or major bleeding. It is classified as hemophilia A (lacking clotting factor VIII) and hemophilia B (lacking clotting factor IX, the Christmas factor). Hemophilia B is mostly a hereditary disorder, but 33% of the cases are caused by a spontaneous mutation. The von Willebrand factor is needed to properly carry factor VIII and help blood clot. Without sufficient levels of this factor, blood will not clot properly, resulting in prolonged bleeding after damage to tissue. This hereditary disorder is classified as type 1, 2, or 3 depending on the level of deficiency of the von Willebrand factor. Type 1 is the mildest and type 3 is the most serious. In all of these conditions, WBC, RBC, Hb, and hematocrit most likely will be normal.

It is important to obtain a history of complications from any previous dental or other surgeries. These acquired disorders are present from birth, so uncomplicated previous surgeries most likely indicate there are no inherited disorders. A full personal and family history is still needed, especially in the case of milder forms of the acquired deficiencies. Milder forms of the disease may not cause excessive bleeding in certain conditions but could still create issues during dental implant surgery.

Anticoagulants prevent the production of certain clotting factors and do not break up clots that have already formed. Examples include warfarin, rivaroxiban (Xarelto), apixaban (Eliquis), edoxapan (Savaysa), and dabigatran (Pradaxa). Vitamin K can be used to reverse the effects of Coumadin or warfarin. The newer anticoagulants require more specific reversal medication such as Praxbind for Pradaxa. Currently the Food and Drug Administration (FDA) is evaluating a reversal agent for the other, newer anticoagulant medications like Xarelto and Eliquis. Many times, within 5 days of stopping the medications, the anticoagulant effect of the drug is minimal or eliminated.

Antiplatelet medications decrease platelet aggregation for up to 2 weeks and inhibit the formation of the thrombus. Examples of these medications include aspirin, clopidogrel (Plavix), prasugrel (Effient), ticagrelor (Brilinta), and dipyridamole/aspirin (Aggrenox). Nonsteroidal antiinflammatory drugs (NSAIDs) such as ibuprofen and naproxen may interfere with platelets by blocking platelet aggregation for up to 1 week. This can directly affect clotting during dental surgery.

Any blood dyscrasia history, such as anemia, leukemia, thrombocytopenia (too few platelets), and liver diseases, such as hepatitis or cirrhosis, can be associated with current bleeding disorders. The liver is responsible for synthesizing certain clotting factors and causing defects in both in the quantity and quality of platelet production. Vitamin K is essential for productions of PT, which is required for normal clotting. Therefore it is important that individuals consume daily foods such as green leafy vegetables, such as spinach, lettuce, broccoli, and cabbage, which are high in vitamin K.

Physical Examination

The second method by which the implant dentist can detect a patient with a bleeding disorder is the physical examination. The exposed skin and oral mucosa must be examined for objective signs. Petechiae, ecchymosis, spider angioma, or jaundice may be observed in liver disease patients with bleeding complications. Intraoral petechiae, bleeding gingiva, ecchymosis, hemarthroses, and hematomas may be present in patients with genetic bleeding disorders. Patients with acute or chronic leukemia show signs of oral mucosa ulceration, hyperplasia of the

gingiva, petechiae or ecchymosis of the skin or oral mucosa, or lymphadenopathy. Macular or nodular lesions could be a sign of multiple myeloma.

Clinical Laboratory Testing

The third option for detecting a bleeding disorder is clinical laboratory testing. If a patient's health history and physical examination do not reveal potential bleeding disorders, routine screening with a coagulation profile is not indicated. However, if extensive surgical procedures are expected, a coagulation profile is indicated.

Screening tests for bleeding disorders should include a platelet count, bleeding time, international normalized ratio (INR; formally PT), activated partial thromboplastin time (aPTT), and a thrombin time (TT). In the near future, more sophisticated platelet function analytic studies could replace the bleeding time. NSAIDs (example ibuprofen) and aspirin used within 10 days of this test can affect the results.[14]

International Normalized Ratio and Prothrombin Time. In many cases the most appropriate tests to evaluate patients that are on anticoagulant therapy are the INR and PT. The PT is a test that determines how long it takes blood to clot. Until the early 1990s, the PT was used exclusively to measure the effect of Coumadin on blood clotting. The PT was the test used to measure the effectiveness of the tissue factor pathway (extrinsic system) and common pathways of coagulation. However, because of the variability in laboratory reporting, the World Health Organization (WHO) developed a more standardized system called the INR. In a normal individual, the INR value should be 1.0. The recommended therapeutic range of continuous anticoagulation is an INR between 2.0 and 3.0 for all conditions except artificial heart valves, for which the INR should be between 2.5 and 3.5 (Table 10.1).[15] Each 0.1 increase in the INR means the blood is slightly thinner. An INR > 1.2 in patients not on blood-thinning medication may require additional workup including liver function.

Partial Thromboplastin Time. The PTT is another coagulation test that measures the contact activation pathway (intrinsic system) and common pathways. A more sensitive version of the PTT is the aPTT, which has a normal range of 30 to 40 seconds and is used to monitor heparin therapy. The normal range of the PTT is 25 to 35 seconds and should be used as a routine screening test. Low-dose aspirin only has a minimal effect of INR/PT or PTT.

TABLE 10.1	Target International Normalized Values for Specific Medical Conditions	
Patient Condition	**INR Value**	
Normal	1.0	
Prevention of myocardial infarction	2.0–3.0	
Treatment of pulmonary embolism	2.0–3.0	
Treatment of atrial fibrillation	2.0–3.0	
Pulmonary embolism	2.0–3.0	
Prosthetic heart valves	2.5–3.5	
Prevention of venous thrombosis	2.5–3.5	

INR, International normalized ratio.

Bleeding Time. The bleeding time test is used to evaluate platelet function The Ivy method is the standardized test usually used. In this test, a blood pressure cuff is placed on the upper arm and inflated to 40 mm Hg. A lancet or scalpel blade is used to make a cut on the underside of the forearm, and the time is measured until bleeding has stopped. Normal values fall between 2 and 9 minutes depending on the method used. The bleeding time measures both coagulation pathways and platelet function and capillary activity. Bleeding time will be elevated in the presence of aspirin for 2 weeks or NSAIDs for up to 10 days. It is important to realize that clotting time is different from bleeding time. Clotting time takes longer because it is the time for blood to actually coagulate or form a clot. Normal values are between 8 and 15 minutes.

Platelet Count. The platelet count is part of the CBC and is usually in range of 150,000 to 450,000 cells/mL of blood. This test identifies the number of platelets (thrombocytes), which is vital to the formation of the blood clot. If the count falls below 150,000 cells/mL, the patient is said to have thrombocytopenia. As platelet counts drop below 100,000, there can be significant bleeding problems in implant patients. Low platelet counts will not affect the PT/INR or PTT tests.

Thrombin Time. The enzymes in thrombin help fibrinogen form fibrin, which help form and strengthen the clot. The TT measures the activity of factor Xa (FXa), which activates prothrombin to thrombin. Thrombin then helps form fibrin and also helps stabilize the clot through cross-linking by activating factor XIII. The reference range for TT is usually less than 20 seconds depending on the test kit used. This test in conjunction with the other coagulation tests can provide valuable information about the patient's ability to form clots.

Additional Oral Anticoagulants. In the United States there are several approved novel oral anticoagulants (NOACs) including rivaroxaban (Xarelto), apixaban (Eliquis), edoxaban (Savaysa), and dabigatran (Pradaxa). These drugs were approved for the treatment of venous thromboembolism, pulmonary embolism, and nonvalvular atrial fibrillation. Because their pharmacokinetics is more predictable than Coumadin/warfarin, they do not require laboratory monitoring. In the studies to approve these drugs they were shown to be as or more effective and safe than Coumadin/warfarin. These drugs are not approved for patients with artificial heart valves or atrial fibrillation related to a defective heart valve.

The previously mentioned coagulation studies do not adequately provide information on the effective inhibition of clotting potential for these drugs. Activity of these NOACs is difficult to measure because of several variables including the reagent and analyzer used. Each NOAC affects the PT/INR test differently, which is more dependent on the time when the blood sample was drawn relative to the time of the most recent dose. In contrast, the INR/PT measurement for Coumadin/warfarin demonstrates activity based on the cumulative effect of several of the most recent doses.

Pradaxa (dabigatran) has almost no effect on coagulation studies and does not correlate to the measurement of INR/PT and PTT until supertherapeutic levels are taken. A normal aPTT usually indicates there are no excess drug levels. The TT is also sensitive to Pradaxa, and a normal TT usually indicates normal blood drug levels.

In contrast, Rivaroxaban (Xarelto) has a sensitivity to INR/PT, and a normal INR/PT usually excludes significant drug levels. Rivaroxaban has no effect on aPTT or TT. Apixaban (Eliquis)

cannot be measured by and has no effect on INR/PT, aPTT, or TT. Edoxaban (Savaysa) has almost no effect on INR/PT or TT, but it is sensitive to measurement by aPTT.[16-18]

Dialysis patients pose a number of challenges to the implant dentistry. There are just a few infections that alter drug metabolism and bone lesions. Dialysis patients may be at increased risk for bleeding as well. If the PTT is more than 1.5 times the normal value, surgery should be postponed until physician approval.

Long-term antibiotic therapy can affect the intestinal bacteria that help produce vitamin K, which is necessary for prothrombin production in the liver. Therefore if the implant patient has used long-term administration of antibiotics, then a PT should be obtained to evaluate possible bleeding complications.

It is very important to suspect bleeding disorders in a patient that consumes excessive amounts of alcohol for prolonged periods of time or who has a history of alcohol abuse, because this can lead to liver dysfunction. The liver is the primary site of synthesis of the vitamin K–dependent clotting factors II, VII, IX, and X. Patients with intestinal absorption issues or a diet low in vitamin K can exacerbate this problem.

Alcoholism, independent of liver disease, has been shown to decrease platelet production by megakaryocytes and increased platelet destruction. Most coagulation factors are produced in the liver; 50% of patients with liver disease have hypersplenism resulting from the destruction of platelets. The PT is the single most useful test used to evaluate impaired hepatocyte synthesis of prothrombin complex factors and to assess hemostasis in patients with liver disease. Factor VII has the shortest half-life and is the first to decrease. Factor VIII and the von Willebrand factor tend to increase in chronic hepatic disease patients.

The PT and PTT may be used together to determine coagulation factor defects. A normal PT and abnormal PTT suggest hemophilia. An abnormal PT and a normal PTT suggest factor VII deficiency. If both PT and PTT are longer, then a deficiency of factors II, V, or X or fibrinogen should be considered.

No surgical procedures should be performed on a patient suspected of having a bleeding problem based on history, examination, and clinical laboratory tests without proper preparation, understanding, and concerted management by the dentist and the physician. If the bleeding disorder has been previously undiagnosed, the underlying cause should be addressed before the elective implant surgical procedures begin.

Biochemical Profiles (Serum Chemistry)

The tenets of laboratory diagnosis should be understood, particularly as they relate to implant dentistry. The interpretation of biochemical profiles and the ability to communicate effectively with medical consultants will enhance the treatment of many patients.

The decision to proceed with oral implant treatment may be affected by the results of biochemical profiles by contraindicating the procedure completely, altering the type of implant surgery and reconstruction, postponing the treatment until therapy controls the disease entity, or simply changing the sequence of medications normally used during treatment. Biochemical sanguine profiles are a more necessary part of the medical evaluation for an implant candidate in the presence of systemic diseases or advanced surgical procedures.[19] They are not indicated for every potential implant patient.

The most common metabolic screening assays are the BMP and CMP. The BMP measures the blood levels of the calcium, carbon dioxide (bicarbonate), chloride, creatinine, glucose, potassium, sodium, and blood urea nitrogen (BUN). The CMP measures all of the same tests in the BMP with the addition of albumin, total bilirubin, protein, and the liver enzymes alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase (ALP).

It is imperative that dental implant clinicians have a strong understanding of the more common blood chemistry tests. With an understanding of the basic blood profiles such as the BMP and CMP, a dental implant surgeon can have greater insight into the biochemical parameters reflecting the patient's health.

To be comfortable in interpreting the biochemical profile, some time must be spent in learning the BMP/CMP pattern of systemic diseases. This pattern recognition is similar to the tissue patterns a pathologist looks at during a biopsy. The BMP/CMP profile has been described as a "biochemical biopsy" of the blood. These profiles include normal and abnormal values that have interrelationships in the diagnosis of systemic diseases. It is not wise to single out one value to establish a diagnosis. The data should be related with other values obtained in the profile before further determinations are rendered.

Normal Range

The normal values found on the BMP/CMP represent a statistical norm. Any population characteristically shows a bell-shaped curve for a particular measurement. It has been shown that 56% of a sample fall within one standard deviation of the mean and 95% are within two standard deviations. The normal value in the biochemical profile represents two standard deviations. Thus "normal" in the statistical sense does not necessarily mean healthy; instead, the word merely describes the typical range of values expected in any given population. Approximately 1 in 20 results will be outside the two standard deviation ranges. The further from the average value a particular value falls, the more certain its clinical significance. Different laboratories can have different normal results.

As biochemical profiles are compiled for an individual patient over several years, the deviation in a given test may indicate a radical change for that individual, although the result should never deviate from the normal population range. The implant dentist should remember that the healthy patient of today might have a systemic disease in the future. Therefore when evaluating long-term complications, it is of interest to relate a recent biochemical profile to the one first reviewed before the initial surgery.

The patient should fast for at least 6 to 8 hours before the blood is collected to avoid artificial elevations of blood glucose. Most of the other elements of the profile will not be affected. This chapter will limit discussion to the most common tests that are beneficial to the implant dentist (Table 10.2): glucose, calcium, inorganic phosphorus, ALP, lactic dehydrogenase (LDH), creatinine, and bilirubin.

Serum Glucose

The normal range of glucose found in the blood is 70 to 100 mg/mL and is maintained within fairly narrow limits. It is important when evaluating the serum glucose to make sure the specimen has been collected after the patient was fasting for at least 6 to 8 hours. If not, the serum blood level may exceed 120 to 140 depending on the timing of the test from the last meal. Elevated fasting blood sugars are becoming more common as our population ages. Sugars between 100 to 120 fasting can be consistent with the beginning of glucose intolerance, which is a precursor for diabetes (Table 10.3).

TABLE 10.2 Laboratory Evaluation of Disease Indicators

Chemistry	Disease
Glucose	Diabetes, steroid dysfunction
Calcium	Renal disease, diet, bone diseases, (carcinoma, parathyroid disease, Paget disease)
Inorganic phosphorus	Renal disease, endocrine (parathyroid, thyroid, steroids), antacids
Alkaline phosphatase	Liver disease, bone diseases (Paget disease, metastases, fractures, hyperparathyroidism)
Lactic dehydrogenase	Hemolytic disorders, liver disorders, myocardial infarction
Creatinine	Renal function
Bilirubin	Liver disease

TABLE 10.3 Hemoglobin A1c Values versus Blood Glucose Levels (Approximate)

Hemoglobin A1c (%)	Average Blood Sugar (mg/dL)
6	120
7	150
8	180
9	210
10	240
11	270
12	300

The most common cause of hyperglycemia is diabetes mellitus. If fasting levels of glucose are found to be greater than 120, then a referral to a physician may be warranted. If fasting sugar is greater than 100, then an HbA1c should be added to the blood profile. This test is also referred to as glycosylated Hb and provides average blood sugar concentrations for the past 90 days. For most diabetics the target is less than 7.0%; however, recent studies now show that targets are individualized based on other factors. Patients with longer life expectancy, monotherapy with metformin, and no cardiovascular complications have a target of <6.5%. Patients with frequent hypoglycemic episodes, advanced vascular disease, other comorbidities, and longer history of having diabetes may have a target of <8.0%. An HbA1c greater than 8% should be considered an absolute contraindication to dental implant surgery, and a consultation between the physician and the patient is warranted.

Other causes of hyperglycemia include obesity, insulin resistance, chronic pancreatitis, Cushing syndrome (excess corticosteroid production), polycystic ovary disease, acromegaly, and hemochromatosis (excess iron stores). High fasting blood sugars can be seen in patients that have taken recent or concurrent oral steroids. Hypoglycemia can occur but is much more rare and can be associated with liver damage or excessive insulin production from an insulinoma tumor in the pancreas.

Serum Calcium

Calcium plays a role in several important body functions including nerve impulse transmission, blood coagulation, and muscle contraction. The overwhelming majority of calcium (>99%) is present in the skeleton and teeth. Calcium in the bone provides strength to the skeleton and supplies the intracellular and extracellular calcium. Serum calcium ranges from about 8.8 to 10.4. Bone balance of calcium changes over time. Kids have a positive bone balance (formation > resorption) for skeletal growth. Young adults are usually in neutral bone balance (formation = resorption). Elderly individuals are usually in negative balance during which formation is greater than resorption.

The implant dentist may be the first to detect diseases affecting the bones. Serum calcium levels are influenced by the parathyroid hormone and calcitonin. Serum calcium levels are increased by bone resorption, intestinal absorption, and renal reabsorption of calcium. Vitamin D helps with intestinal reabsorption of calcium and is activated by the parathyroid hormone to allow the intestine to double and even quadruple the absorption of calcium.

Decreased levels of calcium are primarily seen in hypoparathyroidism, decreased dietary or absorptive conditions, hypoproteinemic conditions, and renal disease. Renal disease is much more common, but the diet of the potential implant patient may be severely affected by the lack of denture comfort and stability. The cause and treatment of hypocalcemic serum levels should be addressed before implant reconstruction.

Elevated levels of serum calcium are associated with carcinoma in bones, dietary or absorptive disturbances, and hyperparathyroidism. The osteoporosis that accompanies this disorder has been observed in the mandible. Hyperparathyroidism also causes hypophosphatemia. Hypercalcemia associated with a significant elevation of ALP suggests Paget disease. With all other biochemical values being normal, an elevated calcium value may be the result of laboratory error.[20] If phosphorus or ALP levels are also affected, medical evaluation and treatment are indicated before implant surgery. Calcium levels greater than 11 should be investigated immediately. It is important that lower elevations of calcium also are evaluated, and the patient should be referred back to his or her physician.

Inorganic Phosphorus

Parathyroid hormone also regulates serum levels of phosphorus because of the relationship between calcium and phosphorus in the blood serum. The normal level is between 3 to 4 mg/100 mL. Similar to calcium, it is readily absorbed through the GI tract and can be increased with vitamin D intake. Phosphorus maintains a reciprocal relationship with calcium: as the level of one increases, the other decreases. The most common cause of hyperphosphatemia is renal disease. Low levels of calcium accompany high levels of phosphorus. This results in increased level of parathyroid hormone (PTH), which then increases bone turnover resulting in significant bone mass and density loss.

If an increase in phosphorus is associated with a decrease in calcium and normal renal function, hypoparathyroidism is suspected. If kidney function is abnormal (high BUN/creatinine ratio), the increased phosphorus level is most likely caused by

kidney dysfunction. Other endocrine disorders associated with an increased phosphorus level include hyperthyroidism, increased growth hormone secretion, and Cushing syndrome.

Decreased levels of phosphorus may appear in patients with hyperparathyroidism, especially when it is associated with hypercalcemia. The chronic use of antacids containing aluminum hydroxide also may induce hypophosphatemia and warrants investigation for a peptic ulcer.

Alkaline Phosphatase

ALP is an enzyme that is present in the liver, bones, kidneys, and digestive system. The normal ranges are from 44 to 147 IU/mL. There is a rise in ALP levels in all forms of cholestasis (reduction of bile flow), especially in obstructive jaundice. Any damage to the liver can raise the ALP level because damaged cells release ALP into the bloodstream.

In the absence of liver disease, elevations of ALP are often a sign of osteoblastic activity in the skeletal system. Therefore bone metastases, fractures, Paget disease, multiple myeloma, and hyperparathyroidism increase the level of this serum enzyme. Serum ALP is normal in patients with adult osteoporosis. Low levels of ALP are usually not of clinical significance for the dentist.

Lactic Dehydrogenase

LDH is an intracellular enzyme present in all tissues (normal 100–190 U/L) including blood, muscles, brain, kidneys, and pancreas. This enzyme helps convert sugar into energy. If cells become damaged, then LDH is released into the bloodstream. Falsely elevated LDH levels occur as a result of hemolyzed blood specimens. Therefore if all other blood values including liver function tests (LFTs) are normal, LDH testing should be repeated before further investigation.

Because LDH is in many cell types, high levels of LDH can indicate a number of conditions including a cerebrovascular accident (CVA)/stroke, certain cancers, MI, hemolytic anemia, mononucleosis, liver disease (hepatitis), muscle injury, pancreatitis, and sepsis. Elevated levels can be further differentiated to their source as isoenzymes: LDH-1 and LDH-2 are found in the heart and RBCs; LDH-3 is found in lymph tissue, lung, and pancreas; and LDH-4 and LDH-5 are found in the liver and muscle tissue.

When LDH values are elevated, the isoenzyme test should be performed to determine the etiology of the elevation, and the CBC and a blood smear should be evaluated for any abnormalities.

Bilirubin

Bilirubin is a pigment formed by the liver as it breaks down Hb and excretes it into the bile. There are two types of bilirubin: indirect (unconjugated), which is not attached to glucuronic acid; and direct (conjugated), which is attached to glucuronic acid. These values are added together to give the total bilirubin. The level of bilirubin can be an indicator of liver health. Normal serum values of total bilirubin typically are 0.2 to 1 mg/dL. Direct bilirubin should be no more than 0.2 mg/dL.

When evaluating an elevated bilirubin, it is important to differentiate the source of the elevation (indirect, or direct, or both). Some patients are born with a condition called Gilbert syndrome in which the liver does not properly conjugate bilirubin, leading to elevated unconjugated (indirect) bilirubin levels. This condition is present at birth, and most patients will be told some time early in life that they have this harmless condition. Acute elevations of

indirect bilirubin are usually a result of hemolytic anemia. The increase in indirect bilirubin in both of these diseases is caused by excess production of bilirubin.

High levels of bilirubin can be associated with jaundice, which can be a result of acute or chronic liver disease or failure, cancer, dysfunction of the bile duct including gallstones, or acute inflammation of the liver such as in hepatitis.

When evaluating liver function, it is important to look at all the tests available in the BMP or CMP because proper liver function is important for healing, drug metabolism, and long-term health.

Aminotransferases

The most sensitive tests to indicate liver damage are liver enzymes referred to as the aminotransferases. The two most common and included in a CMP and LFT profile are the AST (or SGOT) and ALT (or SGPT). An injury to the liver will cause the release of these enzymes into the bloodstream.

AST is less specific for liver damage because it can be found in other tissues outside the liver such as the heart, kidneys, muscles, and brain. Damage to these cells will cause release of AST. ALT or SGPT elevation is more specific for liver disease such as hepatitis or cirrhosis. Some patients have chronic higher than normal levels from conditions like fatty liver, which are usually benign. Some may have mild elevation from medications they take, such as statins. Higher than normal levels should not always be assumed to be from liver damage. The levels are a marker that may or may not demonstrate damage to the liver. Elevation in levels can occur from muscle damage. The level of increase may not be directly proportional to the amount of liver disease or prognosis. Some patients with end-stage liver disease may have only mildly elevated levels. In viral hepatitis A from food these levels can reach the thousands, but recovery is usually full and complete. Patients with chronic hepatitis C infections may have no elevation or only minimal elevation and still develop chronic liver disease or failure.

Creatinine

Creatinine levels are one of the ways to monitor kidney function or kidney disease. If the kidneys become impaired, the blood level of creatinine will rise because the kidneys are unable to excrete enough creatinine into the urine. There is a fairly constant production and excretion of creatinine, which provides a reasonable way to monitor kidney function. The normal creatinine range is 0.6 to 1.1 mg/dL in women and 0.7 to 1.3 mg/dL in men. Diabetics have a high incidence of kidney dysfunction but may have a normal creatinine. In diabetics, a microalbumin screen of the urine can pick up early kidney dysfunction. Microalbumin in the urine is the earliest form of nephropathy or damage from diabetes.

The renal system should not be impaired during implant surgery. Kidney dysfunction may lead to osteoporosis and decreased bone healing. The kidney is required for appropriate activation of Vitamin D to aid in Calcium absorption. Medications can alter pharmacokinetics, and normal healing can also be affected by kidney disease.

Low creatinine levels could be from an issue with the muscles or liver. In older adults reduced muscle mass can cause a low creatine level.

Estimated Glomerular Filtration Rate

The estimated glomerular filtration rate (eGFR) is often included in the BMP or CMP blood panel and can provide more detailed information on kidney function. This test can detect early kidney

damage and help with the diagnosis of chronic kidney disease (CKD). More important is a consistent way to monitor kidney status. Normal kidney (stage 1) will have a GFR of 90 or more. Stage 2 kidney disease demonstrates some mild loss of kidney function and has an eGFR between 60 and 89. Stage 3 kidney disease indicates more moderate to severe loss of kidney function and has values of 30 to 59. Stage 4 disease indicates severe loss of kidney function and has values between 15 and 29. Stage 5 indicates kidney failure and has an eGFR of 15 or less. The eGFR will decline with age, even when kidney disease is absent. For example, ages 40 to 49 have an average eGFR of 99, whereas ages 60 to 69 have an average eGFR of 85. A reduced eGFR may require a reduction in dosages of medications metabolized by the kidney.

Blood Urea Nitrogen

Urea is produced mainly in the liver. It enters the bloodstream and is excreted by the kidney in the renal tubules; sweat also can excrete a very small amount of urea. The BUN level can be used as an indicator of kidney and/or liver function. The usual range is 3 to 20 mg/dL. Elevated levels can be seen in a urinary tract obstruction, CHF, a GI bleed, dehydration, use of some medications including some antibiotics, and a high-protein diet.

The BUN can be used in conjunction with the creatinine level and is usually between a ratio of 10 to 1 and 20 to 1. A ratio of greater than 20 can indicate dehydration or GI bleeding. This condition is referred to as prerenal and can also be a result of hypoperfusion of the kidney. When the ratio is less than 10 to 1, it can indicate polyuria such as in diabetes insipidus or Cushing disease and liver disease or failure (Table 10.4).

Systemic Disease and Oral Implants

Systemic diseases play a vital role in treatment planning and implant therapy for patients. There are specific systemic diseases and conditions that undeniably affect bone metabolism, wound

TABLE 10.4	Diagnostic Laboratory Test Summary		
Test Name	**Description**	**Elevated Levels**	**Decreased Levels**
Albumin (blood)	Is produced by liver and most abundant protein in blood; can be used to judge changes in overall health, liver, or kidney function	Dehydration	Inflammation, liver disease, malnutrition, kidney disease, malabsorption
Alkaline phosphatase	Produced by several organs including liver, bone, and kidney	Bone disease such as metastatic cancer, Paget disease, multiple myeloma, liver disease	Malnutrition, hypophosphatemia, hypothyroid, B_{12} deficiency
ALT (SGPT)	Used to access function of the liver	Liver disease (hepatitis, necrosis, cirrhosis, tumor); medications (statins, antibiotics, chemotherapy, narcotics); mononucleosis, obesity (fatty liver)	N/A
Amylase	Enzyme produced by pancreas and used to detect issues with pancreas	Pancreatitis	N/A
ANA	Used as a screen for connective tissue disease; positive test occurs in some individuals without specific disease	Requires further specific tests to confirm lupus, scleroderma, Sjögren syndrome, or myositis	N/A
AST (SGOT)	Used to detect liver disease and provide assessment of liver function	Liver disease, medications, mononucleosis, obesity (similar to AST) AST:ALT >2:1 shows alcoholic liver	Acute renal disease, beriberi, diabetic ketoacidosis, pregnancy, chronic renal dialysis
BMP	Blood panel that measures sodium, potassium, glucose, BUN, creatinine, chloride, CO_2	N/A	Dependent on test (refer to each component)
Bilirubin indirect	Level of bilirubin that is product of liver that is not conjugated (have sugar molecules attached)	Hemolytic anemia, cirrhosis, transfusion reaction, Gilbert disease (lack enzyme to conjugate)	N/A
Bilirubin direct	Level of bilirubin that is conjugated with a sugar molecule but cannot be secreted through blocked bile ducts	Viral hepatitis, drug reactions, alcoholic liver disease, gallstones, tumors, bile duct scarring	N/A
Bleeding time	Measure clot time focused on function of platelets	von Willebrand disease, thrombocytopenia, DIC, medications	N/A
BUN	Measure urea nitrogen formed when protein is broken down; help measure kidney and liver function	Kidney dysfunction, GI bleed, dehydration, shock, medications, CHF, or urinary outlet obstruction	Liver disease, SIADH, malnutrition
BUN/creatinine ratio	Ratio of BUN to creatinine, usually between 10:1 and 20:1	Dehydration, acute kidney failure or injury, diet high in protein (ratio can be normal in chronic kidney disease)	diet low in protein, muscle injury (rhabdomyolysis), pregnancy, cirrhosis, or (SIADH)

TABLE 10.4	**Diagnostic Laboratory Test Summary—cont'd**		
Test Name	**Description**	**Elevated Levels**	**Decreased Levels**
Calcium	Checks blood level calcium not in bones and para-thyroid function	Hyperparathyroidism, lung/breast cancer metastasis to bone, Paget disease, excessive intake of vitamin D	Chronic renal failure, vitamin D deficiency, magnesium deficiency, bisphosphonate therapy
Carbon dioxide	Level of carbon dioxide in the blood and important buffer of acid/base regulation	Vomiting, COPD, anorexia, dehydration, hypoventilation	Diarrhea, hyperventilation, kidney or liver disease
Chloride	Important in the monitoring of acid/base disorders	Dehydration, diarrhea, renal tubular acidosis, diuretics, hyperparathyroidism	Overhydration (SIADH), Addison disease, chronic vomiting, heart failure
Creatinine	Important measurement of kidney function	Kidney disease, dehydration, diuresis, medication, radiocontrast induced, hypertensive kidney disease	Decreased muscle mass
Creatinine clearance	Used to estimate glomerular filtration rate and overall kidney function	90+: stage 1 (normal kidney function) 60–89: stage 2 (mildly reduced kidney function) 30–59: stage 3 (moderately reduced kidney function) 15–29: stage 4 (severe kidney disease) <15: end-stage kidney disease	
ESR	Nonspecific marker for inflammation	Collagen vascular disease (lupus, rheumatoid arthritis), vasculitis, infections, malignancy, renal failure, inflammatory bowel disease, anemias	Polycythemia, sickle cell anemia, spherocytosis
Ferritin	Measures amount of iron stored in body	Hemochromatosis, porphyria, liver disease, multiple blood transfusions, liver disease, Hodgkin lymphoma	Hemodialysis, iron deficiency anemia
Glucose	Measurement of blood sugar level that is best interpreted fasting <100	Diabetes, nonfasting level, illness, infection, stress response	Excess insulin secretion, excessive alcohol, Addison's disease (adrenal insufficiency), reactive hypoglycemia
Hematocrit	Ratio of red blood cell volume to the total volume of the blood	Dehydration, diuresis, polycythemia vera, high altitude exposures	Anemia, pregnancy, excessive blood loss
Hemoglobin	Carries oxygen to tissues	Polycythemia, high altitude exposure, extreme exercise program	Anemia, hemolysis, excessive blood loss
Hemoglobin A1c	Measurement of percentage of hemoglobin coated with sugar and provides average of blood sugar over a 3-month period	Poorly controlled diabetes, iron deficiency anemia, vitamin B_{12} deficiency, uremia, alcoholism	Hemolysis, recent blood transfusion, chronic liver disease, excess treatment of diabetes, hypertriglyceridemia
Iron level	Measures amount of iron in blood	Hemochromatosis, hemolysis, liver necrosis, hepatitis, vitamin B_{12} deficiency, excessive blood transfusions	Low dietary intake, heavy menstrual bleeding, GI blood loss, intestinal malabsorption, pregnancy
LPL	Enzyme produced by pancreas to help break down fats and used to help determine disease of the pancreas	Pancreatitis, tumors of pancreas, gallbladder infection, high triglycerides, excessive alcohol, gallstones or infection of gallbladder	May indicate chronic damage to pancreas
LFTs	Measurement of liver functioning (AST, ALT, bilirubin, albumin, alkaline phosphatase)	See Individual Tests	See Individual Tests
MCV	Red blood cell average size	Vitamin B_{12} or folic acid deficiency, ETOH abuse, liver disease, bone marrow dysfunction, hypothyroidism	Anemias, iron deficiency, chronic disease, sideroblastic, chronic renal failure, lead poisoning, thalassemia
PTT	Measures time for blood to clot for intrinsic pathway (factors IX, X, XI, and XII)	Similar to PT	Similar to PT
Platelets	Number of circulating platelets	Acute bleeding, cancer, renal failure, infections, iron deficiency, splenectomy, inflammatory bowel disease, lupus	Hemolytic uremic syndrome, autoimmune disease, pregnancy, ITP, TTP

Continued

TABLE 10.4 Diagnostic Laboratory Test Summary—cont'd

Test Name	Description	Elevated Levels	Decreased Levels
Potassium	Measure level of potassium in blood, essential for proper function of organs and all cells	Acute/chronic kidney disease, Addison's disease (adrenal insufficiency) rhabdomyolysis (breakdown of muscle), HTN medications (ACE/ARB), excessive intake, burn injury	Diabetic ketoacidosis, diarrhea, excessive alcohol or laxative use, hyperhidrosis (excessive sweating), diuretics, folic acid deficiency, primary aldosterone tumor, vomiting
PSA	Measure blood level of PSA released by prostate gland; PSA normally increases with age as prostate enlarges	Prostate cancer, prostatitis, catheter insertion, BPH, UTI, age-related, prolonged bike riding	<0.1 in patients treated for prostate cancer
PT	Measures time for blood to clot by the extrinsic pathway (tissue factor, Xa); INR is standard measure	Liver disease, alcohol abuse, DIC, vitamin K deficiency, clotting factor deficiency, medication induced	Vitamin K supplementation, estrogen therapy, thrombophlebitis
RBC	Measures number of RBCs	Thalassemia trait, altitude exposure, cigarette use, polycythemia	Anemia (including hemolytic), acute blood loss, bone marrow dysfunction
RF	Measures Rheumatoid Factor (RF antibody) level which are proteins that attack healthy tissue	Rheumatoid arthritis, cancer, chronic infections or liver disease, lupus, scleroderma, Sjögren syndrome; also found in individuals with no disease	N/A
Sodium (Na)	Measure level of circulating sodium (important for fluid balance and functioning of nerves and muscles)	Increased dietary intake, Cushing syndrome	Medications (diuretics), CHF, liver disease, SIADH, chronic vomiting, adrenal insufficiency, drinking too much water
TSH	Released by pituitary and causes thyroid gland to release T4 and T3; used to diagnosis thyroid disease	Hypothyroidism, Hashimoto's thyroiditis (antibody attach thyroid), lithium, amiodarone	Hyperthyroidism, subacute thyroiditis (inflammation thyroid), excess thyroid replacement therapy, thyroid cancer (low normal)
T4 free or total	Total T4 measures the amount of T4 in blood released by thyroid and used to diagnose hyper/hypothyroid disease and respond to thyroid replacement; total T4 is protein bound and can be abnormal because of protein levels; free T4 more accurate and not influenced by protein levels	Hyperthyroidism (Graves' disease), pituitary adenoma, excessive thyroid replacement therapy, thyroiditis, birth control pills, pregnancy, excessive iodine intake	Hypothyroidism, pituitary insufficiency, malnutrition, chronic illness, low intake of iodine
T3 free or total	Measure the amount of circulating T3 produced by thyroid; T3 is bound to thyroxine binding globulin; T3 not bound to protein is free T3 and this is thought to be responsible for biologic activities in the body	Hyperthyroidism (Graves' disease), pituitary adenoma, excessive thyroid replacement therapy, thyroiditis, birth control pills, pregnancy, excessive iodine intake; free T3 levels stable in pregnancy and with birth control pills	Hypothyroidism, pituitary insufficiency, malnutrition, illness, medications (amiodarone, phenytoin)
WBC	Measures total number of white blood cells	Bacterial infection, sepsis, steroids very high in CLL	Immunosuppression, viral infections, chemotherapy, antibiotics

Types of WBCs

Test Name	Description	Elevated Levels	Decreased Levels
Neutrophils	Most abundant type of white blood cell	Bacterial infections, "shift to left," more neutrophils, acute infection	Malignancies, aplastic anemia, severe infections
Lymphocytes	Made up of B cells that produce antibodies and T cells produced in thymus and are part of immune response	Viral infections including mononucleosis and hepatitis	Bone marrow dysfunction, chemotherapy, TB, lupus, rheumatoid arthritis, drug induced
Monocytes	Participate in phagocytosis; produce macrophages to help fight bacteria, fungi, and viruses	TB, chronic inflammatory disorders such as Crohn disease, ulcerative colitis, lupus	Vitamin B_{12} deficiency, bone marrow dysfunction, certain leukemias
Eosinophils	Produced in response to allergens and diseases	Allergic reactions, parasites	Cushing disease, treatment with steroids, stress reactions
Basophils	Least abundant WBC; contain heparin and histamine related to hypersensitivity reactions	Viruses, lymphoma, hypothyroidism, inflammatory bowel disease	Pregnancy, steroid use, hyperthyroidism

ASA I: A normal, healthy patient, without systemic disease.
ASA II: A patient with mild to moderate systemic disease.
ASA III: A patient with severe systemic disease, which limits or alters activity but is not incapacitating.
ASA IV: A patient with severe systemic disease, which is incapacitating and is a constant threat to life.
ASA V: A moribund patient not expected to live more than 24 hours without an operation.
[a]Elective implant surgeries are not indicated for ASA IV or V patients.

TABLE 10.5   Classifications of Dental Treatment

Classification Type	Treatment
1	Examinations, radiographs, study cast impressions, treatment planning, oral hygiene instruction, stage 2 uncovery with minimum tissue reflection, simple restorative dentistry
2	Extractions, single-tooth implants, multiple implants with minimum tissue reflection, minor augmentation procedures
3	Difficult extractions, multiple implants with more extensive reflection, ridge augmentation, unilateral sinus graft
4	Full-arch implants, autogenous block bone augmentation, large membrane grafts, bilateral sinus graft

healing, and ultimately the success of implant therapy. The implant clinician should use the specific systemic disease information with the planning and management phases of treatment. It is the responsibility of the implant dentist to understand the interrelationship of systemic diseases and implant dentistry. Common conditions that may affect the implant treatment are discussed in three steps. The first section describes the entity in general. The second section discusses dental implant treatment implications. The last section reviews dental implant management.

American Society of Anesthesiologists Physical Status Classification

Systemic diseases have a wide range of effects on a patient, depending on the severity of the disease. There are relatively few systemic diseases that always contraindicate implant surgery or prosthetic rehabilitation. However, several metabolic disorders have contraindications when the conditions are uncontrolled or severe. In 1962, the ASA adopted a classification system for the severity of disease, and the system still is widely used today in medicine. The classification system was designed to estimate the medical risk presented by a patient receiving general anesthesia for a surgical procedure. However, the classification system is valuable for determining any medical risk, regardless of the method of anesthesia or type of surgery (Box 10.2).

The systemic conditions listed in this chapter are those most commonly observed in an implant practice; it is not the intent of this chapter to include all conditions. The diseases discussed are classified as mild, moderate, or severe. A disease entity affects the host with varied intensity. For example, mild diabetes may permit implant treatment, but the same disease in the severe form may contraindicate most implant therapy. As a result, a mild diabetic patient should be treated differently from the severe diabetic patient.

In addition to the range of disease expression, the authors have presented a variety of implant treatments delivered to a patient.[21] In Table 10.5, four levels of surgical and prosthetic dental treatments are established. A systemic condition may contraindicate one class of treatment, yet a more simplified implant procedure can still be performed. The four levels of treatment range from noninvasive procedures with little or no risk of gingival bleeding to those that are most complicated and invasive.

Type 1 procedures can be performed on most patients regardless of systemic condition. Type 2 procedures are more likely to cause gingival bleeding or bacterial invasion of the bony structures. Type 3 procedures are surgical procedures that require more time and technique. Type 4 procedures are advanced surgical procedures with more bleeding and greater risk of postoperative infection and complications.

A relationship can be established between the severity of the disease (mild to severe) and the maximum involvement of the dental implant procedure (Table 10.6). For the more extensive procedure, the patient should be healthier; for a more severe form of the disease, the surgical procedure should be less invasive.

Cardiovascular Diseases

Hypertension

Hypertension is the most common primary diagnosis in the United States and accounts for more than 35 million health care visits per year. In 2018, new statistics from the AHA showed that there is an estimated 103 million adults, or almost half (46%) of the entire adult population, in the United States that have high blood pressure. The death rate from high blood pressure continues to rise each year and still remains the most common cause of cardiovascular deaths.[22]

Untreated, undiagnosed, and uncontrolled hypertension is a serious problem in society today. With increasing age, the prevalence of hypertension increases. More than half of people aged 60 to 69 years and approximately three-quarters of those age 70 and older are affected with hypertension.[2] A recent study showed that the lifetime risk of hypertension is 90% for men and women who were nonhypertensive at age 55 to 65 and live to age 80. Failure to diagnose and detect hypertensive patients can result in life-threatening conditions such as stroke or MI.

Because implant dentists treat a high percentage of elderly patients and there is such a high prevalence in the general population, the incidence of treating dental patients with uncontrolled or undiagnosed hypertension is very high. This places the implant clinician at risk because intraoperative hypertensive episodes may result in cardiac arrhythmias with possible myocardial ischemia issues, which may lead to cardiovascular events such as MI or cerebrovascular events.

TABLE 10.6	Evaluation of Risk in Systemic Diseases				
Risk (Disease)	ASA Category	Type 1	Type 2	Type 3	Type 4
Normal (disease)	I	+	+	+	+
Mild	II	+	SRP	Sedation, SRP	Sedation, SRP
Moderate	II	+	Medical consult	Medical consult	Medical consult
Severe	III	Medical consult	Postpone all elective procedures	Postpone all elective procedures	Postpone all elective procedures

+, Procedure may be performed with regular protocol *ASA,* American Society of Anesthesiologists; *SRP,* stress reduction protocol.
Note: ASA IV patients: no treatment.

Classification Guidelines. In late 2017, the American College of Cardiology (ACC) and the AHA released new guidelines for the diagnosis and treatment of high blood pressure. These recommendations show that blood pressure readings greater than 130 mm Hg systolic or 80 mm Hg diastolic should be treated earlier with lifestyle changes and, in some patients that have associated risk factors, with medication. This is a change from the previous guidelines that recommended intervention at blood pressure greater than 140/90. By lowering the definition of high blood pressure, the new guidelines account for complications that can begin with lower readings and now allow for earlier intervention. Although the number of patients now classified as having hypertension will increase, there will be a relatively smaller increase in the need to medicate these patients as opposed to instituting diet, exercise, cholesterol therapy, and other treatment recommendations earlier to prevent future complications from high blood pressure.

The new guidelines define normal blood pressure as less than 120/80 mm Hg. The category of prehypertension has been eliminated; instead these patients are now classified as having elevated blood pressure at 120 to 129/80 mm Hg or stage 1 with a blood pressure between 130 and 139 systolic or 80 and 89 diastolic. In previous guidelines, stage 1 hypertension was classified as 140/90 mm Hg, but in the new classification, this is now stage 2 hypertension. Hypertensive crisis has been redefined as a blood pressure systolic over 180 and/or diastolic over 120 mm Hg. If medically stable, these patients require immediate intervention via consultation with their physician and change of medication. Those patients with chest pain, headache, visual changes, or other somatic complaints may require immediate hospitalization.

Always ensure that proper technique is used to measure blood pressure and use home monitoring with devices that can be validated. White coat hypertension in a medical office is still a concern and should be confirmed by having the patient obtain a blood pressure outside the medical office (i.e., pharmacy, grocery store, home).

Although the definition of Stage 1 hypertension has changed, medication is usually not required for many individuals. The recommendations state that only those individuals that have already had a cardiovascular event like a stroke or heart attack or those at high risk for stroke or heart attack based on factors such as age, presence of diabetes, CKD, or at higher risk for atherosclerotic disease with elevated low-density lipoprotein (LDL) cholesterol or low high-density lipoprotein (HDL) cholesterol should begin medications. Stage 2 hypertension in most cases should be treated with medications.

Hypertension is usually asymptomatic and is the major risk factor for coronary heart disease and CVAs leading to cardiovascular morbidity and mortality for people older than 50 years of age. The medical history should focus on predisposing factors to hypertension such as excessive alcohol intake, history of renal disease, stroke, other cardiovascular diseases, diabetes, increased dietary sodium intake, obesity, and smoking.

Special attention should be given to patients with a history of obstructive sleep apnea (OSA). Sleep apnea has been associated with a number of cardiovascular diseases including dysthymias, MI, and stroke.[23] Greater than 50% of patients with sleep apnea also have hypertension.[24] In contrast to past knowledge that diastolic pressure is more important than systolic pressure, studies have shown that with the aging population, uncontrolled systolic hypertension causes increased rates of cardiovascular and renal diseases.[7]

The side effects of blood pressure medications may alter treatment or require special precautions. For example, orthostatic hypotension affects a patient brought from a supine to an upright position, which can result in syncope and falling, with possible injuries. The patient may feel lightheaded or even faint; these symptoms can be avoided by allowing patients to sit upright for several minutes after the completion of their dental procedure. Patients at high risk include the elderly, those with anxiety, patients taking multiple medications, and those who have undergone lengthy dental procedures.

Patients with difficult-to-control blood pressure may be prescribed multiple classes of antihypertensive medications. Even though these patients are being treated with various antihypertensive medications, they are prone to possible elevation and spikes in blood pressure. With these patients, the clinician should seek medical evaluation and consultation, which may include a postoperative blood pressure–monitoring plan.

Severe hypertension or elevation in blood pressure may lead to angina pectoris, CHF, MI, retinal hemorrhage, or even a cerebrovascular episode. These conditions may be precipitated by a rapid increase in blood pressure during a local anesthetic injection or the inherent stress associated with the surgical procedure. A stress reduction protocol is paramount with hypertensive patients.

Dental Implant Management. Because a high percentage of patients have hypertension, the implant clinician and staff members must be knowledgeable about the measurement, detection, and treatment of hypertension. The accurate measurement of blood pressure, along with a review of all medications including herbal and OTC medications, should be an integral part of the implant consultation and examination (Box 10.3).[25]

An elevated blood pressure is common in the dental office setting because stress associated with treatment (i.e., white coat syndrome) leads to increased levels of catecholamine, which causes an increase in blood pressure and heart rate. Two important steps to decrease the stress in the dental office are a well-monitored stress reduction protocol and proper management of pain and discomfort. Stress reduction protocol may include premedication the night before the appointment with diazepam [Valium] 5 to 10 mg, oral or conscious sedation for the procedure, setting an early morning appointment, minimizing waiting room time, and ensuring the duration of treatment does not exceed the patient's limits. Adequate pain control is also important, including preemptive analgesia, profound anesthesia during the procedure, and sufficient postoperative pain control including long-acting anesthetics. A resting systolic pressure greater than 180 or a diastolic pressure greater than 110 should indicate that all elective procedures be delayed until blood pressure can be reduced to a safer level (Box 10.4).

The use of NSAIDs has been shown to lessen the effectiveness of various antihypertensive medications by inhibiting prostaglandin production, leading to intraoperative hypertensive episodes. Blood pressure regulation is highly prostaglandin dependent, especially as it relates to kidney function through the

vasodilatory effects. NSAIDs possess a higher degree of interaction with diuretics angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blocker (ARB) inhibitors, and beta-blockers, which may modify prostaglandin-dependent pathways more than drugs that alter non–prostaglandin-sensitive pathways such as calcium channel blockers and central-acting drugs. Therefore the interaction with hypertensive medications and NSAIDs results in a higher propensity to increase blood pressure.[26] Studies have shown that approximately 50 million patients are being treated with antihypertensive therapy, and 12 million use NSAIDs concomitantly. However, the short-term use of NSAIDs has not been shown to have a clinically significant effect.[27]

The implant clinician must take into consideration that beta-blockers may potentiate the cardiovascular effects of epinephrine used in local anesthetics. The nonselective beta-adrenergic drugs, such as propranolol (Inderal) and nadolol, pose the greatest risk of adverse interactions.[10] The cardioselective beta-blockers (Lopressor, Tenormin, and Bystolic) carry less risk of adverse reactions; however, there is competitive clearance through the liver between both classes of beta-blockers and the local anesthetic. This may lead to an increase in serum levels of the local anesthetic.[28] To avoid intraoperative hypertensive episodes, decreasing the dose and increasing the time interval between epinephrine-containing injections is recommended.[29]

Calcium channel blockers (amlodipine, nifedipine, and diltiazem) used to treat hypertension or CHF may lead to gingival hyperplasia around natural teeth or implants (similar to Dilantin). Additionally, this drug classification has been associated with erythema multiforme (a benign rash characterized by patches of red raised skin) and other types of oral ulceration. Gingival overgrowth can result in pain, gingival bleeding, and difficulty in mastication, especially around implant prostheses. The incidence of gingival hyperplasia is approximately 1.7% to 3.8% of patients taking calcium channel blockers[30] (Tables 10.7 and 10.8).

Angina Pectoris

Angina is chest pain that is a result of decreased blood flow to the heart. Atherosclerotic disease of the heart blood vessels is usually responsible for the interruption of blood flow to the heart muscle. There are some other causes of angina including coronary artery spasm and severe aortic valve disease. The classic symptoms are a crushing pain in the substernal area that can radiate across the chest or into the neck or jaw. It can be accompanied by shortness of breath, nausea, diaphoresis, and fatigue. Pain is usually relieved with rest and caused by an imbalance between the amount of oxygen the heart requires and the amount delivered by the coronary arteries, especially with exertion or physical activity.

Men tend to develop coronary disease in the larger vessels and have more classic symptoms. Women tend to develop coronary disease in the smaller vessels, which can lead to variations of the classic symptoms. Women may still experience chest pain but can have the other symptoms of pain into the jaw or neck, fatigue, and shortness of breath.

Angina can be classified as stable, unstable, or Prinzmetal. Stable angina is triggered by exertion such as exercise (i.e., climbing stairs), which results in chest pain that is relieved by resting and/or taking nitroglycerin. Unstable angina is the typical substernal chest pain that is not brought on by exertion or exercise, occurs at rest, can last longer, and sometimes may not be relieved by rest

TABLE 10.7a Common Antihypertensive Medications

Thiazides Diuretics	Mechanism of Action	Ace Inhibitors	Mechanism of Action	Calcium Channel Blockers Nondihydropyridines	Mechanism of Action
Hydrochlorothiazide	Decrease BP by Decrease Blood Volume	Captopril, Enalapril, Quinapril, Lisinopril, Ramipril	Decrease BP by decreasing peripheral vascular resistance, Blocks Angiotension Converting enzyme in kidney, Results in decrease level of angiotensin which decreases levels of aldosterone, Lower levels of aldosterone result in less sodium and water retention which lowers BP, Can cause dry cough or angioedema	Diltiazem, Verapamil	Acts to vasodilate peripheral vascular system through smooth muscle relaxation Decreases heart rate and stroke volume of heart and can cause blockade of AV node in heart resulting in symptomatic bradycardia
Chlorthalidone	Decrease reabsorption of Sodium in Distal Kidney	Enalapril	Blocks Angiotension Converting enzyme in kidney	Verapamil	Decreases heart rate and stroke volume of heart and can cause blockade of AV node in heart resulting in symptomatic bradycardia
Metolazone	Can cause hypokalemia and hypomagnesemia	Quinapril	Results in decrease level of angiotensin which decreases levels of aldosterone		
		Lisinopril	Lower levels of aldosterone result in less sodium and water retention which lowers BP		
		Ramipril	Can cause dry cough or angioedema		
Loop Diuretics		**Angiotensin II Receptor Antagonist (ARB)**		**Calcium Channel Blockers Dihydropyridines**	
Bumetanide (Bumex)	Inhibits absorbtion of Sodium in Loop of Henle	Candesartan (Atacand), Losartan (Cozaar), Olmesartan (Benicar), Telmisartan (Micardis), Valsartan (Diovan)	lowers BP by vasodilation produced by inhibiting aldosterone production In renal insufficiency can cause worsening renal function and hyperkalemia In renal insufficiency can cause worsening renal function and hyperkalemia Can cause cough or angioedema Decrease Aldosteron decreases sodium absorption and water reabsorption	Amlodipine (Norvasc)	Block movement of calcium in smooth muscle heart and peripheral smooth muscle
Furosemide (Lasix)	Can cause hypokalemia and hypomagnesemia	Losartan (Cozaar)	Decrease Aldosteron decreases sodium absorption and water reabsorption	Felodipine (Plendil)	Lowers BP through smooth muscle relaxation and vasodilation
Torsemide	Increase Prostaglandin synthesis (NSAIDS can interfere and decrease effectiveness of loop diuretics)	Olmesartan (Benicar)	Can cause cough or angioedema	Nifidipine (Procardia)	Can make heart failure worse and cause leg and peripheral edema

Demadex		Telmisartan (Micardis)	In renal insufficiency can cause worsening renal function and hyperkalemia	
		Valsartan (Diovan)		**Beta Blocker**
Vasodilators				**Nonselective : Block beta receptor at both B1 (heart) and B2 (lungs) receptors**
Hydralazine (Apresoline)	Produce Relaxation of Vascular Smooth Muscle			Propranolol — Decrease Cardiac output which decreases cardiac O_2 consumption by blockade of B1 receptors and lowers BP
Minoxidil	Causes decrease in peripheral vascular resistance lowering BP			Timolol — Causes Peripheral Vasoconstriction and Bronchoconstriction
	Can cause reflex stiumation of heart increasing heart rate, cardiac contractility and O_2 consumption			Nadolol — Blocks effects of epinephrine (adrenaline)
	Minoxidil reserved for severe hypertension			Carvdilol — Decrease Heart Rate and sexual dysfunction
				Labetalol — Can cause disturbances in glucose metabolism:
Central alpha-Agonist in brain				**Cardio selective Beta blockers block only B1 (heart) receptors**
Clonidine (Catapress)	Stimulate alpha receptors in brain			Acebutolol
Methyldopa (Aldomet)	Results in decrease vasoconstriction, heart rate, systemic vascular resistance which then lowers BP			Atenolol — Works specifically on Beta receptors in heart
				Esmolol — BP decreases because of lower Heart Rate and Decrease in cardiac contractility and force of blood flow
				Metoprolol Succinate
				Cardiovil (Coreg)
				Nebivolol (Bystolic) — Coreg and Bystolyic are 3rd generation beta blockers
				Much more specific for working only on beta receptors in heart

TABLE 10.7b **Common Antihypertensive Medications**

Thiazides Diuretics	Mechanism of Action
Hydrochlorothiazide Chlorthalidone Metolazone	Decrease BP by Decrease Blood Volume Can cause hypokalemia and hypomagnesemia Decrease reabsorption of Sodium in Distal Kidney
Loop diuretics	**Mechanism of Action**
Bumetanide (Bumex) Furosemide (Lasix) Torsemide(Demadex)	Inhibits absorbtion of Sodium in Loop of Henle Can cause hypokalemia and hypomagnesemia Increase Prostaglandin synthesis (NSAIDS can interfere and decrease effectiveness of loop diuretics)
Ace Inhibitors	**Mechanism of Action**
Captopril Enalapril Quinapril Lisinopril Ramipril	Decrease BP by decreasing peripheral vascular resistance, Blocks Angiotension Converting enzyme in kidney, Results in decrease level of angiotensin which decreases levels of aldosterone, Lower levels of aldosterone result in less sodium and water retention which lowers BP, Can cause dry cough or angioedema
Angiotensin II Receptor Antagonist (ARB)	**Mechanism of Action**
Candesartan (Atacand) Losartan (Cozaar) Olmesartan (Benicar) Telmisartan (Micardis) Valsartan (Diovan)	Blocks the binding of of angiotension II on muscle receptors surrounding blood vessels Results in lowers BP by vasodilation and inhibition of aldosterone production In renal insufficiency can cause worsening renal function and hyperkalemia In renal insufficiency can cause worsening renal function and hyperkalemia Can cause cough or angioedema Decrease Aldosteron decreases sodium absorption and water reabsorption
Calcium Channel Blockers Nondihydropyridines	**Mechanism of Action**
Diltiazem (Cardiazem) Verapamil (Calan)	Acts to vasodilate peripheral vascular system through smooth muscle relaxation Decreases heart rate and stroke volume of heart Can cause blockade of AV node in heart resulting in symptomatic bradycardia
Calcium Channel Blockers Dihydropyridines	**Mechanism of Action**
Amlodipine (Norvasc) Felodipine (Plendil) Nifidipine (Procardia)	Block movement of calcium in smooth muscle heart and peripheral smooth muscle Lowers BP through smooth muscle relaxation and vasodilation Can make heart failure worse and cause leg and peripheral edema
Beta blocker Non-Selective **Block beta receptor at both B1 (heart) and B2 (lungs) receptors**	**Mechanism of Action**
Cardiovil (Coreg) Labetalol (Normodyne) Nadolol (Corgard) Pindolol (Visken) Propranolol (Inderol) Sotolol (Betapace) Timolol (Blocardren)	Decrease Cardiac output which decreases cardiac O_2 consumption by blockade of B1 receptors and lowers BP Causes Peripheral Vasoconstriction Blocks effects of epinephrine (adrenaline) Decrease Heart Rate and can cause sexual dysfunction Can cause disturbances in glucose metabolism Can Cause Bronchorestriction as these agents block Beta 2 receptors in lungs
Cardio selective Beta blockers block only B1 (heart) receptors	**Mechanism of Action**
Acebutolol (Sectral) Atenolol (Tenormin) Bisoprolol (Zebeta) Esmolol (Brevibloc) Metoprolol Succinate (Toprol) Nebivolol (Bystolic)	Works specifically on Beta 1 receptors in heart BP decreases because of lower Heart Rate and Decrease in cardiac contractility and force of blood flow Reduce systolic pressure and heart rate Decrease contractility of heart which decrease cardiac output and reduces oxygen demand by the heart Can cause some sexual dysfunction and less likely to cause bronchocontriction
Vasodilators	**Mechanism of Action**
Hydralazine (Apresoline) Minoxidil	Produce Relaxation of Vascular Smooth Muscle Causes decrease in peripheral vascular resistance lowering BP Can cause reflex stiumation of heart increasing heart rate, cardiac contractility and O_2 consumption Minoxidil reserved for severe hypertension
Central alpha-Agonist in brain	**Mechanism of Action**
Clonidine (Catapress) Methyldopa (Aldomet)	Stimulate alpha receptors in brain Results in decrease vasoconstriction, heart rate, systemic vascular resistance which then lowers BP

TABLE 10.8	**Blood Pressure Treatment Guidelines**			
			TREATMENT	
Category	Systolic (mm Hg)	Diastolic (mm Hg)	Preoperative	Intraoperative
Ideal	<120	<80	None	None
Prehypertension	120–139	80–89	Recheck, possible medical consultation	Recheck, stress reduction protocol
Grade 1 hypertension	140–159	90–99	Recheck, possible medical consultation, (relative)	Monitor, stress reduction protocol
Grade 2 hypertension	160–179	100–109	Recheck, medical consultation, (absolute)	Monitor, discontinue procedure, possible emergency room referral
Hypertensive crisis	>180	>110	Recheck, emergency care, (absolute)	Monitor, abort immediately, emergency care

or nitroglycerin. This indicates more advanced coronary disease that requires immediate attention. Prinzmetal angina is caused by coronary artery spasm. Stress and drug use, especially cocaine, are the main causes of this type of angina.

Treatment of angina involves many different medications. Beta-blockers are used to reduce the workload of the heart. Nitroglycerin works to dilate coronary blood vessels, which decrease myocardial oxygen consumption and also reduce the workload of the heart. Aspirin and other antiplatelet agents are critical to prevent thrombus formation. Progressive angina requires cardiac catheterization. If there is significant narrowing, an angioplasty and stent may be used to relieve the blockage and improve symptoms. If the blockage is more severe or not amenable to angioplasty, then bypass surgery may be indicated.

Risk factors for angina pectoris are smoking, hypertension, high cholesterol, obesity, and diabetes. Patients with a history of angina may be taking long-acting nitrates to prevent the occurrence of acute episodes. Sublingual or spray nitroglycerin is recommended for the treatment of acute episodes. It is important to ask any patient with angina about their most recent symptoms including frequency, exacerbating factors, worsening symptoms, how long the chest pain lasts, and what relieves the chest pain. Patients with increased symptoms or more frequent or longer-lasting attacks should be referred to the physician for evaluation. Patients with pain at rest should be immediately referred to their physician.

Dental Implant Management. The major concern for the implant clinician is the precipitation or management of the actual angina attack. Precipitating factors are exertion, cold, heat, large meals, humidity, psychological stress, and dental-related stress. All of these factors cause catecholamine release, which in turn increases the heart rate, blood pressure, and myocardial oxygen demand.[31]

The dental emergency kit should include nitroglycerin tablets (0.3–0.4 mg) or sublingual nitroglycerin spray, which are replaced every 6 months because of their short shelf-life. During an angina attack, all dental treatment should be stopped immediately. Nitroglycerin is then administered sublingually, and 100% oxygen is given at 6 L/min, with the patient in a semisupine or 45-degree position.

Vital signs should be monitored after nitroglycerin is administered because transient hypotension may occur. If the systolic blood pressure falls below 100 mm Hg, then the patient's feet should be elevated. If the pain is not relieved in 8 to 10 minutes with the use of nitroglycerin at 5-minute intervals, emergency medical assistance should be initiated.

Patients with mild angina (up to one attack per month) may undergo most nonsurgical dental procedures performed with the normal protocol (type 1). General cardiac precautions are advised, such as vital signs monitoring, and patients are instructed to bring their own nitroglycerin. Advanced restorative procedures and minor implant surgery (type 2) are performed with nitrous oxide or oral sedation. For more advanced implant procedures (types 3 and 4), appropriate sedation techniques should be used. Appointments should be as short as possible. This may require more than one surgical or restorative appointment. Use of vasoconstrictors should be limited to a maximum of 0.04 to 0.05 mg epinephrine, and concentrations greater than 1/100,000 should be avoided.

Patients with moderate angina (up to one attack per week) tolerate examination and most simple operative procedures (type 1). Prophylactic nitroglycerin (0.3–0.4 mg) or long-acting nitrates are given sublingually just before advanced operative or simple to moderate implant surgery (types 2 and 3). Antianxiety sedation with supplemental oxygen is required. Advanced surgical procedures may require a hospital setting (type 4).

Patients with unstable angina (daily episodes) are limited to examination procedures performed under normal protocol. Medical consultation is recommended for any additional treatment. This form of angina has been represented as an absolute contraindication for elective dental surgery (ASA IV).

The side effects of nitroglycerin are important to recognize because prophylactic administration is in order for the patient with moderate to severe angina because there is a decrease in blood pressure, which causes a decrease of the blood flow to the brain. Fainting is often a possibility; therefore the patient should be sitting or lying down during nitroglycerin administration. The heart attempts to compensate for the decreased blood pressure, and the pulse rate may increase to as much as 160 beats/min. Flushing of the face and shoulders is common after administration of nitroglycerin. If the patient has been taking long-acting nitrates, tolerance to the drug may occur; therefore two tablets may be needed at a time. A headache may occur after administration, which may be treated with OTC analgesics (Table 10.9).

Dental Implant Management in Patients with Angina Pectoris

Risk	Symptoms	Type 1	Type 2	Type 3	Type 4
Mild	≤1/month; ASA II	+	+	Sedation, supplemental oxygen	Sedation, supplemental oxygen
Moderate	≤1/week; ASA III	+	Sedation, premedication, nitrates, supplemental oxygen	Sedation, premedication, nitrates, supplemental oxygen	Premedication, sedation, outpatient hospitalization
Severe	Daily/more; ASA IV; unstable	+	Physician consultation	Elective procedures contraindicated	Elective procedures contraindicated

+, Procedure may be performed with regular protocol; *ASA,* American Society of Anesthesiologists.

Myocardial Infarction

An MI is a prolonged ischemia or lack of oxygen resulting from a deficiency in the coronary arterial blood supply that causes injury to the myocardium or heart muscle. The end result is cellular death and necrosis of the heart muscle.

About every 40 seconds someone in the United States has a heart attack. Just under 800,000 individuals suffer a heart attack each year in the United States, and three of every four heart attacks are an initial event.[32] One in five heart attacks are silent and there is heart muscle loss, but the individual is unaware of the event.

An acute MI may be precipitated when the patient undergoes unusual stress, either physical (painful stimuli) or emotional (anxiety). The patient usually has severe chest pain in the substernal or left precordial area during an MI episode. The pain may radiate to the left arm or mandible, and is similar to angina pectoris but more severe. Cyanosis, diaphoresis, weakness, nausea or vomiting, and irregular and increased pulse rate are all signs and symptoms of MI.

The complications of MI include arrhythmias and Congestive Heart Failure (CHF), and if a complete occlusion or malignant arrhythmia occurs, then sudden death results. The larger the ischemic area, the greater the risk of heart failure or life-threatening arrhythmias. Any history of MI indicates significant problems in the coronary vessels. Recent infarctions correspond to higher morbidity and death rates with even simple elective surgery.

The risk of MI is less than 1% in the general population in a perioperative setting. Approximately 18% to 20% of patients with a recent history of MI will have an increase of complications, which have a high mortality rate of 40% to 70%. If general anesthesia and surgery are performed within 3 months of MI, the risk of another MI is 30%, and if performed within 3 to 6 months, the risk is 15%. After 12 months, the incidence of recurrent MI stabilizes at about 5%.[33] Acute coronary syndrome consists of three different types of coronary blockages that can result in sudden rupture of plaque inside one of the coronary arteries. When the plaque ruptures, it causes exposure of the soft fatty tissue, which then causes platelets to migrate to the area of rupture and form a clot around the plaque to cover the fatty tissue. When the clot blocks the entire blood supply to the heart muscles, there is coronary occlusion. This can result in one of three scenarios that result in ischemia: unstable angina (as previously described), non-ST segment elevation MI (NSTEMI), or ST elevation MI (STEMI).

There are several variables that determine the type of acute coronary syndrome: length of time blood flow is blocked, and location of the blockage. Unstable angina is a change from stable angina when the pain starts occurring at rest as opposed to occurring with exertion. If the MI does not cause ST-elevation (classic electrocardiogram [ECG] finding of MI) on the ECG but the clinical markers in blood enzymes demonstrate damage has occurred, then this is considered an NSTEMI. The blockage is partial or temporary, so the damage done to heart muscle is usually much smaller. This is still considered a heart attack or MI. Serial troponin and or creatine-kinase (CK)-MB blood levels are drawn and repeated over several hours. Both of these markers indicate damage to the myocardial muscle. Troponin levels may be the earliest indicator of an MI.

If the interruption to the blood supply is more abrupt and prolonged, it will affect a much larger area of the heart and demonstrate ST-segment elevation on the ECG and damage by the serum chemical makers.

Dental Implant Management

Medical Consultation. A medical consultation should precede any extensive restorative or surgical procedure. Even though there are recommendations based solely on the length of time after an MI, the deciding factor on elective dental implant treatment is not only time but also the amount of myocardial damage. The implant clinician should follow the recommendation of the physician concerning treatment options, modifications, or contraindications.

Stress Reduction Protocol. Dental implant surgery after MI may induce arrhythmias or aggravate cardiac ischemia. An increased blood pressure is common in the dental office setting, because stress associated with treatment (i.e., white coat syndrome) leads to increased levels of catecholamine, which cause an increase in blood pressure and heart rate. The most important step in decreasing stress in the dental office is to integrate a comprehensive stress reduction protocol.

Reduction in the Use of Vasoconstrictors. Epinephrine and other vasoconstrictors have several properties that can potentially result in adverse outcomes in patients that have not fully recovered from a recent MI. Epinephrine is chronotropic, which results in an increased heart rate and force of contraction. Both of these result in an increased oxygen demand and could potentiate ischemia. Epinephrine does have some arrhythmogenic properties that could provoke ventricular fibrillation or tachycardia in recovering myocardial muscle. It is best to minimize complications by consulting the patient's treating physician and closely monitoring vital signs when vasoconstrictors are used.

Myocardial Infarction Treatment Summary. The patient's physician should be consulted before elective dental implant treatment to verify the patient's current cardiac status (Table 10.10).

TABLE 10.10	Dental Implant Management in Patients With Myocardial Infarction			
Risk	**Type 1**	**Type 2**	**Type 3**	**Type 4**
Mild (>12 months)	+	+	Physician	Physician hospitalization if general anesthesia required
Moderate (6–12 months; ASA III)	+	Postpone all elective procedures	Postpone all elective procedures	Postpone all elective procedures
Severe (<6 months; ASA IV)	Physician consultation	Postpone all elective procedures	Postpone all elective procedures	Postpone all elective procedures

+, Procedure may be performed with regular protocol; *ASA,* American Society of Anesthesiologists.

Absolute (surgical): Recent MI (depending on doctor's recommendation).

Relative (surgical): History of MI (depending on doctor's recommendation).

Congestive Heart Failure

CHF is a pathophysiologic state in which an abnormality in cardiac function is responsible for failure of the heart to pump blood in adequate volume to meet the needs of the metabolizing tissues.[34] Over the past 10 years the number of adults living with heart failure has increased significantly. The most recent data from the AHA's "2017 Heart Disease and Stroke Statistics" update states that about 6.5 million Americans were living with heart failure by the end of 2014. That number may jump to 8 million in the next 10 to 12 years because more people are now surviving heart attacks, leaving the heart weaker and more susceptible to heart failure.[35]

Total direct medical costs for heart failure were over $21 billion in 2012, and it is expected that by 2030 we could see that cost rise to over $53 billion. The overwhelming majority of the cost for health failure is in patients aged 65 years and older; these patients currently account for over 80% of costs related to heart failure and are projected to be responsible for 88% or more of the total costs by 2030.[36]

CHF usually develops over time because the muscles in the heart wall lose their ability to generate appropriate contractile forces and can continue to deteriorate with continuous exposure to volume overload. This results in high levels of pressure in the heart and eventual weakening of the stretched contractile muscles in the heart. Because of the diminished output of the heart, the body responds by increasing vascular resistance (increased blood pressure) throughout the circulatory system, which is initially beneficial to the peripheral tissues. However, this leads to further reductions in cardiac output, because the weakened heart must pump against this increased pressure. The kidney acts to retain sodium and fluid, which continues to exacerbate the problem.

There are many acceptable pharmacologic interventions including diuretics, inotropic drugs, beta-blockers, and ACE/ARB blood pressure medications, among others. Spironolactone has now become the diuretic of choice in treating heart failure. Digoxin was one of the most common drugs used for years to treat heart failure; however, recent CHF treatment algorithms have been updated and digoxin has been replaced by the use of beta-blockers and spironolactone. Digoxin is appropriate for some patients, so implant dentists should be aware of the more common side effects

---

• BOX 10.5 Diagnostic Criteria for Congestive Heart Failure

- Paroxysmal nocturnal dyspnea or orthopnea
- Neck vein distention
- Rales
- Cardiomegaly
- Acute pulmonary edema
- S3 gallop
- Increased venous pressure >16 cm of water
- Hepatojugular reflux.

Minor Criteria:
- Ankle edema
- Night cough
- Dyspnea on exertion
- Hepatomegaly
- Pleural effusion
- Vital capacity reduced one third from maximum
- Tachycardia (≥120 bpm)

Major or Minor Criteria:
- Weight loss of 4.5 kg or more in 5 days in response to treatment.

---

of elevated levels like nausea, vomiting, anorexia, headaches, confusion, and visual changes including halos around objects. Patients on digoxin should be questioned about their most recent blood level and stability of blood level over the past several months.

One of newest and most revolutionary treatments for CHF is the medication Entresto. Entresto contains a combination of sacubitril and valsartan. Valsartan (which is classified as an ARB) is used as a single agent to treat hypertension. The drug works in the kidney to block receptors that cause constriction resulting in dilatation of blood vessels, which lowers the resistance against which the heart must pump. Sacubitril is a neprilysin inhibitor that improves blood flow to the kidneys and helps in diuresis and removal of excess volume in the bloodstream.

Symptoms of CHF are listed in Box 10.5, and they include abnormal tiredness or shortness of breath (dyspnea) brought on by slight activity or even occurring at rest (these symptoms are caused by excess fluid in the lungs and partly caused by the excess work required of the heart); wheezing caused by fluid in the lungs (pulmonary edema); peripheral edema or swelling of the ankles (pedal edema) and lower legs; frequent urination at night; jugular venous distension; sounds at auscultation (S₃ gallop); and paroxysmal nocturnal dyspnea (the sensation of being

• BOX 10.6 | **Classification of Congestive Heart Failure (New York Heart Association)**

I. No symptoms and no limitation in ordinary physical activity.
II. Mild symptoms and slight limitation during ordinary activity. Comfortable at rest.
III. Marked limitation in activity caused by symptoms, even during less than ordinary activity. Comfortable only at rest.
IV. Severe limitations. Experiences symptoms even while at rest.

unable to breath), which may interrupt sleep. This symptom is caused by the effect of gravity on fluid that has spent the day down at the feet. As the fluid flows back up, it may pool in the lungs, causing a feeling of suffocation. Excessive weight gain, as much as 20 to 30 pounds, with no change in diet, is also a symptom. This increase, purely from fluid retention, gives some indication of how poorly the heart is pumping. The most common way to make the diagnosis is by using the Framingham criteria. CHF can be diagnosed in patients with two major or one major and two minor criteria.

The most common classification system for heart failure is the New York Heart Association (NYHA). Class 1 is asymptomatic, class II has mild symptoms with moderate exertion, class III has symptoms with minimal activity, and class IV failure has symptoms at rest[37] (Box 10.6).

There are several types of heart failure. Left-sided heart failure involves dysfunction of the left atrium and left ventricle. The left ventricle must function correctly to pump blood to the rest of the body. Left-sided heart failure can be divided into two different subtypes. Systolic failure is when the left ventricle loses its ability to contract fully. This is referred to as heart failure with reduced ejection fraction (HFrEF). Diastolic failure or dysfunction is when the left ventricle cannot relax properly because with the increased pressure and volume the muscle is very stiff. This limits the heart's ability to fill properly between beats, confining the amount of blood that can be pumped out with each beat. Drug treatments are not the same for these two types and are directed at the issue causing the heart failure.

As blood returns to the heart from the venous system in the body, it needs to be reoxygenated. It is collected on the right side of the heart and pumped into the lungs before returning to the left side of the heart. Right-sided heart failure usually occurs as a result of left-sided failure. As the left side increases pressure, the pressure is transferred back through lungs to right side of the heart. Eventually the right side loses contractile power and then backs up into the veins of the body. This results in venous congestion and swelling in the neck or jugular vein distention (JVD). This also causes swelling in the legs, feet, ankles, abdomen, and even in the liver, causing ascites.

In CHF, as the left side of the heart becomes overloaded with fluid, this pressure will be transferred to the lungs, resulting in shortness of breath, dyspnea on exertion, and orthopnea (difficulty breathing when lying down). Heart failure affects the kidney's ability to dispose of sodium and water, leading to edema of the extremities.

An echocardiogram of the heart is the preferred test to gauge the actual output capacity of the heart. Patients with more advanced levels of heart failure such as NYHA class III or class IV may require an implantable defibrillator to prevent sudden death from heart arrhythmias. Most of these patients have heart ejection fractions of less than 30%.

In heart failure there are two proteins, B-brain natriuretic peptide (BNP) and N-terminal-pro-BNP (NT-pro-BNP), which go up when heart failure worsens and down when heart failure improves. BNP (not to be confused with BMP blood panels) levels can be used to monitor the severity of heart failure. Levels <100 are usually not associated with heart failure. In conditions such as sepsis, cirrhosis, and hyperthyroid disorders there is increased or high cardiac output. This can increase levels of BNP and make the test less reliable in gauging the degree of heart failure. Before any dental surgery in a patient with a history of heart failure who is having symptoms, it would be good to review the most recent BNP compared with the patient's baseline. Elevated levels may indicate acute worsening of symptoms and warrant consultation with the patient's physician.

Dental Implant Management. In patients classified as NYHA I and II, no medical consultation is indicated unless there exist additional systemic diseases. In NYHA III and IV, medical consultation is highly recommended for all implant type 3 and 4 procedures. A comprehensive stress reduction protocol is indicated for all patients with CHF. Intraoperatively and postoperatively, pain and anxiety control is important because increased stress can produce an increased myocardial workload with an increase in the degree of heart failure.

Intraoperative Complications. CHF patients are very susceptible to intraoperative cardiovascular morbidity issues. Stress reduction protocol and strict monitoring should be followed. It is advisable to discuss the current condition of the patient with their treating physician. Patients with CHF can be classified as compensated or uncompensated. In uncompensated heart failure, the pulmonary circulation is expanded and congested because the heart is unable to fully compensate. The classic symptoms are seen including shortness of breath, especially with exertion; fatigue; or lying supine. When the CHF patient is treated for heart failure through medical management and the symptoms are controlled, the patient is referred to as compensated.

Patient Positioning. CHF patients should be positioned in the most recumbent position in which they can breathe comfortably and efficiently. This is usually a semireclined or sitting upright position. Usually, the more upright the patient is, the easier it is for the patient to breathe.

Oxygen Supplementation. Oxygen supplementation (≈2 L/min) during implant procedures is highly recommended to minimize the possibility of hypoxia. The use of nitrous oxide in these patients is not advised.

Stress Reduction Protocol. A stress reduction protocol should be implemented prior to the procedure to prevent increased myocardial workload with a damaged heart

Subacute Bacterial Endocarditis and Valvular Heart Disease

Bacterial endocarditis is an infection of the heart valves or the endothelial surfaces of the heart. The infection is the result of the growth of bacteria on damaged or altered cardiac surfaces. The microorganisms most often associated with endocarditis after dental treatment are alpha-hemolytic *Streptococcus viridans* and less frequently staphylococci and anaerobes. The disorder is serious, with a mortality rate of approximately 11%.[38] Dental procedures causing transient bacteremia has been shown to be an etiologic factor of bacterial endocarditis. Patients with gingivitis and certain cardiac conditions are at highest risk. When inflamed gums bleed during dental procedures, bacteria can be introduced into

the bloodstream and infect heart valves and the lining of the heart. These bacteria continue to replicate at the infected site. Depending on the type of bacteria infecting the heart tissue, endocarditis can develop quickly or more slowly. Some symptoms include fever, chills, fatigue, muscle aches, night sweats, shortness of breath, edema, and chest pain with inspiration. As a result, the implant dentist should identify the patient at risk for endocarditis and implement prophylactic procedures.

However, endocarditis after a dental procedure is not as common as once believed. New guidelines suggest prophylactic antibiotics for patients only at the highest risk levels. Scientific evidence has shown that the risk of adverse reactions to antibiotics may exceed any benefit for prophylactic treatment based on previous guidelines. This can also increase the likelihood of drug-resistant bacteria.[39]

In 2007, several organizations including the American Dental Association (ADA) and the AHA released updated guidelines for the prevention of infective endocarditis. In 2017, these guidelines were confirmed by a joint review by the AHA and ACC. These groups published a new update to their 2014 guidelines on the management of valvular heart disease.[40]

The updated recommendation states that patients who have routinely taken prophylactic antibiotics in the past are no longer required to do so. The more specific updated infective endocarditis prophylaxis recommendations for dental procedures are only for patients with underlying cardiac conditions that have been linked to the highest risk for developing an adverse outcome. These include patients with prosthetic heart valves, prosthetic material used for cardiac valve repair, a history of endocarditis, a cardiac transplant with abnormal valves, and certain congenital defects of the heart including cyanotic heart disease with shunts and any repaired defects with residual shunts, or other defects that remain at the site of the prosthetic patch.[41]

The risk of bacterial endocarditis increases with the amount of intraoral soft tissue trauma. There is a correlation between the incidence of endocarditis and the number of teeth extracted or the degree of a preexisting inflammatory disease of the mouth.[42] An incidence of bacteremia is six times higher in patients with severe periodontal disease.[43] However, if scaling and root planing are performed before subsequent soft tissue surgery, the risk of endocarditis is greatly reduced. Bacteremia after traumatic tooth brushing, endodontic treatment, and paraffin chewing has also been reported.[44] Endocarditis may even occur in an edentulous patient with denture sores.[45] Chlorhexidine use on isolated gingiva or irrigation of the sulcus 3 to 5 minutes before tooth extraction reduces postextraction bacteremia.

However, these new guidelines suggested that preventative treatment should be initiated in patients with the listed cardiac conditions but not for all dental procedures. The guidelines suggested prophylactic antibiotics only for dental procedures that involve manipulation of gingival tissue and bleeding. Antibiotics are not recommended for routine anesthesia through noninfected tissues or placement or adjustment of removable prosthodontic or orthodontic appliances.

The oral regimen in adults is 2 g amoxicillin orally, 60 minutes before the procedure. A second dose is not necessary because of the prolonged serum levels above the minimal inhibitory concentration of most oral streptococci[46] and the prolonged serum inhibitory activity induced by amoxicillin against such strains (6–14 hours).[47] For patients unable to

---

• **BOX 10.7** **Endocarditis Prophylaxis Recommendation**

The American Dental Association, American Medical Association, and the American Heart Association have recommended antibiotic coverage in patients with the following conditions receiving elective surgery:
- Artificial heart valves
- Past history of infectious endocarditis
- Cardiac transplant that develops a heart valve problem
- Congenital heart disease with shunts or conduits[a] repaired
- Congenital heart defect with residual defect
  - Able to take oral medication: Amoxicillin 2 g (50 mg/kg)
  - Unable to take oral medication: Ampicillin 2 g IM or IV (50 mg/kg IM or IV); cefazolin or ceftriaxone 1 g IM or IV (50 mg/kg IM or IV)
  - Allergic to penicillin or ampicillin: Cephalexin 2 g (50 mg/kg); clindamycin 600 mg (20 mg/kg); azithromycin or clarithromycin 500 mg (15 mg/kg)
  - Allergic to penicillin or ampicillin and unable to take oral medication: Cefazolin or ceftriaxone 1 g IM or IV (50 mg/kg IM or IV); clindamycin 600 mg IM or IV (20 mg/kg IM or IV)

[a]Functional murmurs and organic heart murmurs do not require prophylactic antibiotic.
IM, *intramuscular;* IV, *intravenous.*

---

take oral medications, 2 g ampicillin is administered intramuscularly (IM) or IV 30 minutes before the procedure. If the patient is allergic to penicillin, clindamycin 600 mg or cephalexin (or cefadroxil) 2 g are administered orally l hour before the procedure. For patients allergic to penicillin and not able to take oral medications, clindamycin 600 mg IV within 30 minutes of the procedure or cefazolin 1 g IM or IV 30 minutes before the procedure are the recommended regimens for oral procedures.[48] Erythromycin is no longer included because GI upset and complicated pharmacokinetics of various formulations make its use problematic.

In patients who are classified in the high-risk category for development of endocarditis, elective implant therapy may be contraindicated. Edentulous patients restored with implants must contend with transient bacteremia from chewing, brushing, or peri-implant disease. Endosteal implants, with an adequate width of attached gingiva, are the implants of choice for patients in this group who need implant-supported prostheses. Implants may be contraindicated for patients with a limited oral hygiene potential and for those with a history of multiple endocarditis events.

Implant surgery in patients with aortic stenosis is usually contraindicated until after aortic valve replacement. It has been recommended that patients with valve replacements postpone any elective implant surgery until 15 to 18 months after surgical completion because these patients are at high risk for bacterial endocarditis and because of the use of high doses of anticoagulants.[49] Special precautions should always be adhered to in valve replacement patients because their therapeutic bleeding times are usually high (INR 2.5–3.5).

Dental Implant Management. The implant clinician must be familiar with the antibiotic regimens for heart conditions requiring prophylaxis. A similar regimen is suggested for any person requiring antibiotic coverage. There may be future updates, but currently the 2017 AHA and ACC guidelines for endocarditis prophylaxis should be used (Box 10.7).[50]

Cerebrovascular Accident

A stroke is a CVA characterized by a sudden interruption of blood flow to the brain, causing oxygen deprivation. It is most frequently seen in patients with current cardiovascular diseases and is the fourth leading cause of death in the United States and a major cause of adult disability. The majority of strokes are ischemic, resulting from narrowing or blocking of the blood supply to the brain. The etiology of ischemic strokes is embolic and thrombotic. Thrombotic strokes are the result of clots that form inside one of the brain's arteries. The clot blocks blood flow to the brain, causing cell death. Usually, these clots result from plaque or other fatty deposits from atherosclerosis, which break off and become lodged in the blood vessel. Embolic strokes are the results of clots that form in other parts of the body and travel to the brain via the bloodstream. The clot eventually will lodge in a blood vessel and block flow of blood to the brain.

It is important to ask patients if they have ever been diagnosed or treated for "ministrokes" or transient ischemic attacks (TIAs). These attacks are the result of brief (usually less than 24 hours) interruptions in blood flow causing strokelike symptoms. These episodes can be a precursor for a much larger stroke. Unlike a CVA, the blockage is temporary and the clot may dissolve or get dislodged in a very brief time causing the temporary symptoms. TIAs usually cause symptoms for less than 10 minutes and should completely resolve within 24 hours. Unlike a CVA, there is no permanent injury to the brain.

Dental Implant Implications

Bleeding. Although it is important to control blood pressure and treat elevated cholesterol in the management of individuals with a history of strokes, caution should be taken because most patients are on blood-thinning medication. Antiplatelet agents such as aspirin or clopidogrel may be used as single agents or in combination as part of a stroke prevention treatment. Both of these medications irreversibly affect platelets' clotting ability and have been shown to cause increased bleeding. In some cases, warfarin (Coumadin) may also be used, which directly interferes with the body's clotting mechanisms. Evaluation and bleeding control are essential in these types of patients.

Limited Dexterity. Patients who have suffered a compromise in dexterity as the result of a stroke require alternative treatment planning for their final prostheses. A fixed prosthesis is usually the best solution for these patients, because an implant-retained prosthesis may lead to the inability to remove for routine hygiene. Additionally, poor oral hygiene, when combined with xerostomia, causes additional oral problems such as candidiasis, dental caries, periodontal issues, and mucositis lesions, which increase implant prostheses morbidity.

Current Anticoagulant Medications. The goal of anticoagulation medication is to keep the blood thinned so clotting is more difficult. However, it is important to understand these medications work by various pathways and can affect clotting at different points in the clotting cascade or by directly inhibiting platelet function. The antiplatelet agents such as aspirin or clopidogrel have been shown to have a minimal effect on bleeding, both intraoperatively and postoperatively.[19] A number of studies have found no increased risk of bleeding during dental procedures when patients on Coumadin have a therapeutic treatment range INR (below 3.0). In patients with mechanical heart valves, the upper limit of the therapeutic range can reach 3.5 to 4.0. In patients with artificial valves, the INR may be checked 24 hours

TABLE 10.11	Additional Cardiovascular Issues and Treatment Implications	
Positive Response	**Treatment Implications**
Abdominal aneurysm	Rupture leading to high mortality, medical consultation (absolute)
Atrial fibrillation	Thrombin inhibitors, hemostatic measures
Prosthetic heart valve	Maintained at high INR, hemostatic measures
Pacemaker	Cardiovascular issue, stress reduction protocol, no electrosurgery
Fainting/lightheadedness	Orthostatic hypotension
Congenital heart defect	Cardiovascular issue, medical consult to determine extent
Ankle edema	Congestive heart failure, possible varicose veins

INR, International normalized ratio.

before the implant surgery. Under no circumstances should a patient with a mechanical valve on Coumadin be instructed to stop or hold a dose without input from the patient's treating physician.

Hemostatic Agents/Surgical Technique. Ideal surgical technique should be followed, which consists of nontraumatic incision and reflection of tissue. The surgical procedures should be minimized with a decreased surgical duration. The implant clinician must have experience with the use of active and passive hemostatic agents.

Treatment Summary

Absolute (surgical): Recent CVA incident (medical consult)
Relative (surgical): History of CVA + anticoagulants (medical consult)

Additional Cardiovascular Disorders

See Table 10.11.

Endocrine Disorders

Diabetes Mellitus

The most recent Diabetes Statistics Report of 2017 from the Centers for Disease Control and Prevention (CDC) estimated that over 30 million Americans (1 in 10) now have diabetes, with another 84 million (1 in 3) with prediabetes. The majority of new cases of diabetes are in adults 45 to 64 years of age, and there also has been an increase in diabetes in the American youth population. New cases were more prevalent in African Americans. Almost 90% of adults diagnosed were overweight and 40% were not physically active. The diagnosis of diabetes usually involves having an HbA1c (glycosylated Hb) of >6.4%. Glucose tolerance tests have been used previously and still have utility in the diagnosis of gestational diabetes. Using the Hba1c in combination with random fasting an post-prandial sugars has now become the accepted standard of care.[51]

• BOX 10.8   Medication Management of Diabetes

Biguanides: These drugs decrease glucose release from liver and act to block intestinal absorption of glucose. They are in the peripheral system to improve insulin sensitivity by increasing glucose uptake. They are considered euglycemic and should not cause hypoglycemia. Example: Metformin (Glucophage). Many newer medications combine metformin with one of the following categories of medications:
  - Sulfonylureas (SFUs). These drugs increase insulin secretion from the pancreas and can cause hypoglycemia. Skipping meals will significantly increase the risk of hypoglycemia. Examples: Amaryl (glimepiride), Glucotrol (glipizide), Micronase (glyburide), Prandin (repaglinide), and Starlix (nateglinide)
  - Thiazolidinediones (glitazones or TZDs): These drugs work to decrease insulin resistance in the muscle and fat tissues creating increased utilization of blood glucose. Examples: Actos (pioglitazone), Avandia (rosiglitazone)

GLP-1 Analogs: These drugs work on several systems to increase insulin secretion and inhibit the release of glucose from the liver after eating. They also can delay emptying of food from the stomach, creating a feeling of satiety. They have been shown to also promote weight loss. These medications require injections and are not oral. Examples: Byetta (exenatide), Victoza (liraglutide), and Trulicity (dulaglutide).

DPP-4 Inhibitors: These drugs also increase insulin secretion and limit glucose release from the liver after eating. Examples: Januvia (sitagliptin), Onglyza (saxagliptin), and Trajenta (linagliptin).

SGLT2 inhibitors: These drugs work specifically in the kidney in patients with normal renal function to increase glucose excretion in the urine. Patients on these medications will usually show levels of glucose on a urinalysis. Examples: Invokana (canagliflozin), Farxiga (dapagliflozin), and Jardiance (empagliflozin).

The most current classification of diabetes includes three general clinical categories: type 1 diabetes, type 2 diabetes, and gestational diabetes (pregnancy). In type 1 diabetes, insulin is not produced from the pancreas. This type of diabetes develops most frequently in children or before age 21. However, there is now a form of type 1 diabetes that develops a bit later in life in which the pancreas does not produce insulin. The incidence of type 2 diabetes in the older population is increasing. This type is much more common and accounts for approximately 95% of the diabetic cases and almost always occurs in adults. Initially the defect is coming from the body's inability to respond properly to the action of insulin, which is produced from the pancreas. The incidence of type 2 diabetes is estimated to double by the year 2025 because of aging, unhealthy diets, and obesity.[52] An increased body mass index (BMI) and advanced age can be predictors of undiagnosed diabetes. In patients for whom the clinician has a higher suspicion of diabetes, questions concerning frequent urination (polyuria) or excessively thirst (polydipsia) may be appropriate (Box 10.8).

Diabetes and Dental Implant Healing

Studies have shown that hyperglycemia has a negative effect on bone metabolism, reducing bone mineral density, affecting bone mechanical properties, and impairing bone formation, leading to poor bone microarchitecture.[53] There is a direct correlation between implant osseointegration and glycemic control.[54] Osseointegration is more predictable in anatomic areas with abundant cortical bone, which is why the mandible has shown a greater bone formation than the maxilla.[55]

Implant Failure

Human clinical studies have indicated that no contraindications exist for patients who are well controlled by diet and oral hypoglycemic. However, for insulin-controlled patients, a contraindication for implants may exist depending on the state of control. Researchers have concluded that implants have a high success rate provided the diabetes is controlled (monitor to ensure that glycosylated Hb [HbA1c] < 7.0). An increased failure rate of dental implants has been associated with poor metabolic control.[56] It is imperative that uncontrolled diabetics or patients exhibiting an elevated HbA1c are treated before and during the implant surgery healing period.

Dental Implant Management

Hypoglycemia. The most serious intraoperative complication for diabetic patients is hypoglycemia, which usually occurs as a result of an excessive insulin level, hypoglycemic drugs, or inadequate food intake. Weakness, nervousness, tremor, palpitations, or sweating are all signs of acute hypoglycemia. Mild symptoms can be treated with sugar in the form of orange juice or candy. If the symptoms are not addressed, then they may evolve from minor warning signs to seizure, coma, and, in rare cases, death. In these severe cases, patients may become unconscious or barely arousable. For these symptoms, the emergency administration of 50% IV dextrose should be completed. Additionally, glucagon should be available because this hormone may raise blood sugar through a direct effect on the liver. Glucagon may also be administered IM in a dose of 1 mg for adults over 20 kg. Patients taking sulfonylurea medications for diabetes (including glyburide, glipizide, and glimepiride) who do not have adequate carbohydrate intake before their procedure are at an increased risk of hypoglycemia. It is important that patients on these medications follow their regularly prescribed diet before the dental procedure.

Hyperglycemia. The stress of surgery may provoke the release of counterregulatory hormones that will impair insulin regulation and may result in hyperglycemia and a catabolic state. The cause of hyperglycemia is multifactorial and may include any of several medications such as corticosteroids, beta-blockers, epinephrine, diuretics, and some antipsychotic drugs. Hyperglycemia is usually slower to develop and may not necessarily demonstrate any physical symptoms. Patients should be instructed to monitor their blood sugars in the postsurgical period and contact their physician if their readings remain elevated from their normal baseline. In the acute setting, hyperglycemia can be treated with insulin or by increasing fluids in noncardiac patients. Emergency services should be called for patients who experience erratic breathing and/or fluctuating levels of consciousness associated with high blood sugar levels.

Infection. Diabetic patients are prone to developing infections and vascular complications. The healing process is affected by the impairment of vascular function, chemotaxis, and neutrophil function, as well as an anaerobic milieu. Protein metabolism is decreased, and healing of soft and hard tissue is delayed, which may lead to the susceptibility to infection. Neuropathy and impaired nerve regeneration may be altered as well as angiogenesis.[57]

Determine Glycemic Control. The glycemic control should be evaluated via an HbA1c test (HbA1c, glycated Hb, A1c, or HbA1c) in conjunction with a consultation with the patient's physician. Ideally, the A1c should be maintained at less than 7% when appropriate. The HbA1c test is ideal for evaluation of glycemic control because it will show the glycemic control

over the past 3 months. The HbA1c measures the glucose bound to Hb within the RBCs. The test is a weighted average of blood glucose levels during the life of the RBCs (120 days). This test is more accurate in the assessment of diabetic control compared with a fasting blood glucose, which can give a false-positive or false-negative result. It is important to note that target levels for diabetic patients are now individualized rather than generalized. Many times diabetics can be maintained at HbA1c levels greater than 7.0% but less than 8%. The new Medicare quality guidelines consider diabetics less than 9.0% as controlled and greater than 9.0% as uncontrolled. However, it is important to understand studies show that the healing process is much better and complication rate lower in patients with an HbA1c < 7.0%. Because this is an elective procedure, proceeding with surgery in patients with an HbA1c > 7% and ≤8% should be individualized and discussed with their physician and the patient with full disclosure of the increased risks of infection, implant failure, and other complications. Patients with HbA1c > 8% should probably not undergo elective implant surgery because of the higher risk of infection and complications (Table 10.12).

Medication Prophylaxis. Because of the reciprocal relationship between infection and glycemic control, the use of antibiotic prophylaxis is highly recommended. Ideally, a β-lactam antibiotic should be used preoperatively and postoperatively. When antibiotic prophylaxis is administered to diabetic patients, studies have shown a 10.5% reduction in failure rate. Further reduction is achieved by maintaining a strict aseptic technique in combination with good surgical technique. Additionally, it has been reported that the use of a chlorhexidine gluconate (0.12%) rinse at the time of implant placement reduced the failure rate from 13.5% to a remarkable 4.4% in type 2 diabetic patients.[58] A preoperative and postoperative chlorhexidine regimen will decrease morbidity with implants in diabetics. These patients must practice meticulous oral hygiene and be recalled at regular intervals to minimize the possibility of peri-implantitis.

Steroids. Oral steroids like dexamethasone, prednisone, and methylprednisolone will increase blood sugar and should be used with extreme caution in diabetics. A physician consult is recommended for patients under treatment for oral hypoglycemic or insulin-related medications.

Treatment Summary (Diabetes)

Diet-controlled diabetic: Determine/maintain diabetic control.
Hypoglycemic-controlled diabetic: Determine/maintain diabetic, stress reduction protocol; HbA1c < 7%; and individualized treatment recommendations of HbA1c > 7.0% and ≤ 8.0%.
Insulin-controlled diabetic: Determine diabetic control, stress reduction protocol; HbA1c < 7%; individualized treatment recommendations of HbA1c > 7.0% and ≤ 8.0%.

Thyroid Disorders

Thyroid disorders are the second most common endocrine problem, affecting approximately 1% of the general population, principally women. Synthroid (levothyroxine), is one of the most commonly prescribed drugs in the United States.[59,60] Because the majority of patients in implant dentistry are women, a slightly higher prevalence of this disorder is seen in the dental implant practice.

The thyroid gland is one of the larger endocrine glands in the body and is situated at the level of C5 and T1 vertebral bodies, just below the laryngeal prominence. The main function of the thyroid gland is to produce hormones, and the most common are thyroxine (T4) and triiodothyronine (T3). Thyroxine is responsible for the regulation of carbohydrate, protein, and lipid metabolism. In addition, the hormone potentiates the action of other hormones such as catecholamines and growth hormones.

Abnormalities in the anterior pituitary gland or the thyroid can result in disorders of thyroxine production. Excessive production of thyroxine results in hyperthyroidism. Symptoms of this disorder include increased pulse rate, nervousness, intolerance to heat, excessive sweating, weakness of muscles, diarrhea, increased appetite, increased metabolism, and weight loss. Excessive thyroxine may also cause atrial fibrillation, angina, and CHF. Palpation of the patient's neck often reveals an enlarged thyroid gland (goiter) between the cricoid cartilage and the suprasternal notch.

TABLE 10.12	**Hemoglobin–Blood Glucose Treatment Regimen**		
Risk	**Hemoglobin (A1c)**	**Blood Sugar Level (mg/dL)**	**Treatment Plan**
Low	<6.0	<140	Stress reduction protocol, maintain glycemic control
Low/ medium	6.0–7.0	140–180	Stress reduction protocol, maintain glycemic control Patients with neuropathy, nephropathy, peripheral vascular disease, history of coronary disease, or ophthalmologic manifestation of diabetes (retinopathy) may be at higher risk despite controlled HbA1c. Medical consultation may be appropriate (relative contraindication)
Medium high	7.0–8.0	180–215	Patients without any secondary manifestations of diabetes such as neuropathy, nephropathy, peripheral vascular disease, or ophthalmologic (retinopathy), medical consult may be obtained (relative) Patients with coronary disease or other diabetic related conditions require medical consult (relative/absolute)
High risk	>8.0	>215	Medical referral and better glycemic control (absolute contraindication)

HbA1c, Glycosylated hemoglobin.
From Resnik RR, Resnik RJ. Medical/medication complications in oral implantology. In Resnik RR, Misch CE, eds. *Misch's Avoiding Complications in Oral Implantology.* St Louis, MO: Elsevier; 2018.

The most common form of hypothyroidism is Hashimoto's thyroiditis, which is an autoimmune disease where by the immune system produces antibodies that attack the thyroid gland and create chronic inflammation, which in turn leads to insufficient levels of circulating thyroxine. The related symptoms are a result of a decrease in metabolic rate. The patient complains of cold intolerance, constipation, dry skin, fatigue, and weight gain. In severe cases the patient can develop hoarseness or enter what is termed a myxedema coma. This is a medical emergency with compromised mental activity and hypothermia.

Thyroid function tests are used to confirm the diagnosis of hypothyroidism. The best screening test for thyroid function is to measure the thyroid-stimulating hormone (TSH) level. An increased level indicates underactivity of the thyroid gland, whereas decreased or very low levels indicate over activity of the thyroid. An overactive thyroid gland can cause palpitations, weight loss, tremor, nervousness, and diarrhea. If the TSH level is abnormal, then a free T3 and free T4 can help determine further functioning of the thyroid. T4 and T3 both circulate in the blood, and T4 is converted in the more active form of thyroid hormone T3 in multiple tissues in the body. High levels of T3 and/or T4 indicate an overactive thyroid gland, and low levels indicate an hypofunctioning thyroid gland.

Most people with hypothyroidism are treated with synthetic thyroid replacement medications such as levothyroxine (Synthroid), and the TSH is the best way to monitor this therapy. Some individuals are treated with animal versions of thyroid hormone (Armour Thyroid). The TSH can be artificially low in treatment with Armour Thyroid; therefore a measurement of free T3/T4 is the better way to monitor adequate levels of this treatment.

Dental Implant Management

Hyperthyroidism

Catecholamine Sensitivity. Patients with hyperthyroidism are especially sensitive to catecholamines such as epinephrine in local anesthetics. When exposure to catecholamines is coupled with stress (often related to dental procedures) and tissue damage (dental implant surgery), an exacerbation of the symptoms of hyperthyroidism may occur. This can result in a condition termed thyrotoxicosis or thyroid storm, which is an acute, life-threatening hypermetabolic state clinically presenting with symptoms of fever, tachycardia, hypertension, and neurologic and GI abnormalities. Treatment of thyroid storm in the dental setting includes immediate medical attention. If left untreated, these symptoms may result in CHF and life-threatening cardiac arrhythmias.

Bleeding. The increased blood pressure and heart rate that accompany hyperthyroidism may increase bleeding at the surgical site and require additional hemostatic techniques. It is also important to note that propylthiouracil (PTU) is used to treat hyperthyroidism. This drug is an antagonist of vitamin K, which has an adverse effect on the clotting cascade and may result in significant bleeding or postoperative hemorrhage.

Aspirin/Nonsteroidal Antiinflammatory Drug Use. Use of aspirin or NSAIDs requires extreme caution in the hyperthyroid patient. Aspirin can increase free levels of the T4 hormone because of an interaction with protein binding. Additionally, many hyperthyroid patients are on beta-blockers for heart rate and blood pressure control, and the use of NSAIDs can decrease the efficacy of beta-blockers. Alternative pain medications should be considered in patients with hyperthyroidism (e.g., Ultram).

Hypothyroidism

Central Nervous System Depressants Use. The hypothyroid patient is particularly sensitive to central nervous system (CNS)–depressant drugs, especially narcotics and sedative drugs, such as diazepam or barbiturates. The risk of respiratory depression, cardiovascular depression, or collapse must be considered. Patients with long-standing hypothyroidism may have prolonged bleeding requiring hemostatic control for excessive bleeding. Additionally, hypothyroid patients may exhibit delayed wound healing and predisposition to postoperative infection.

Bone Healing. T4 affects bone metabolism by decreasing recruitment and maturation of bone cells and reducing the bone growth factor of insulin-like growth factor. Studies have shown that medically treated hypothyroid patients exhibit greater bone loss and a less favorable soft tissue response after stage I surgery but with no significant increased risk of failure[59] (Table 10.13).

Adrenal Gland Disorders

The adrenal glands are endocrine organs located just above the kidneys. Epinephrine and norepinephrine are produced by chromaffin cells in the adrenal medulla, which forms the central portion of the gland. These hormones are largely responsible for the control of blood pressure, myocardial contractility and excitability, and general metabolism.[61] The outer portion of the gland or adrenal cortex produces three different types of hormones. Glucocorticoids regulate carbohydrate, fat, and protein metabolism and also help decrease inflammation. Synthetic glucocorticoid medications may be used by the implant dentist to decrease swelling and pain. The mineralocorticoids maintain sodium and potassium balance. A third category of hormones is produced that are

TABLE 10.13 Dental Implant Management in Patients With Thyroid Disorders

Risk		Type 1	Type 2	Type 3	Type 4

mainly sex hormones (testosterone and dehydroepiandrosterone [DHEA]). The hypothalamus stimulated the anterior pituitary gland to produce adrenocorticotropic hormone (ACTH), which then stimulates the adrenal glands to produce cortisol.

Cortisol is one of the most important glucocorticoids secreted by the adrenal cortex. Insufficient production and secretion of cortisol leads to primary adrenocortical insufficiency, also termed Addison's disease. A patient with Addison's disease shows symptoms of weakness, weight loss, orthostatic hypotension, nausea, and vomiting. The physical signs of primary insufficiency do not manifest until 90% of the gland is destroyed. Signs and symptoms develop insidiously over months. When these signs are noted, the implant dentist should require a medical consultation. These patients cannot increase their steroid production in response to stress and in the midst of surgery or long restorative procedures may have cardiovascular collapse. During the physical examination, the dentist can notice hyperpigmented areas on the face, lips, and gingiva.[62] An increase in serum potassium level (hyperkalemia) and decrease in serum glucose level are characteristic of Addison's disease.

When adrenal hypersecretion of cortisol is present, patients will show signs of Cushing syndrome. The characteristic changes associated with this disease are moon facies, truncal obesity or "buffalo hump," muscle wasting, and hirsutism. Patients are hypertensive, and long-term excess function of the cortex decreases collagen production. These patients bruise easily, have poor wound healing, experience osteoporosis, and are also at increased risk for infection. These elements are especially noteworthy to the implant dentist. Laboratory studies show an increase in blood glucose related to an interference with carbohydrate metabolism. The CBC often shows a slight decrease in eosinophil and lymphocyte counts.

Corticosteroids are potent antiinflammatory drugs used to treat a number of systemic diseases and are one of the most prescribed drugs in medicine. Steroids are used for more than 80 conditions such as arthritis, collagen and vascular disorders, kidney diseases, asthma, and dermatologic disorders. However, the continued administration of exogenous steroids suppresses the natural function of the adrenal glands and causes a condition equivalent to Cushing disease. As a result, patients under long-term steroid therapy are placed on the same protocol as patients with hypofunction of the adrenal glands.

Aldosterone is the main mineralocorticoid produced by the adrenal gland and it is essential for sodium conservation by the body. It is regulated by the renin angiotensin system in the kidney. Renin is secreted in response to variations in blood pressure, volume, and sodium and potassium levels by the kidney. Aldosterone works to enhance the reabsorption of sodium and water in the kidneys and secrete potassium, which increases blood pressure. ARB and ACE inhibitor high blood pressure medications block the production of the angiotensin–renin system in the kidneys, thus lowering aldosterone production and sodium retention and leading to the lowering of blood pressure. Overproduction of aldosterone can lead to low levels of potassium and uncontrolled hypertension

Dental Implant Management. Patients with a history of adrenal gland disease, whether hyperfunctioning or hypofunctioning, face similar problems related to dentistry and stress. The body is unable to produce increased levels of steroids during stressful situations, and cardiovascular collapse may occur. As a result, additional steroids are prescribed for the patient just before the stressful situation. These doses are stopped within 3 days. The healthy patient will accelerate steroid production three to five times higher than regular levels to respond to the stress of surgery or dental procedures. Therefore for patients with known adrenal disorders, the physician should be contacted for consultation. The nature of the disorder and the recommended treatment should be evaluated.

The patient on regular maintenance doses of steroid in excess of prednisone 5 mg/day is at high risk of adrenal suppression. Adrenocortical suppression should be suspected if a patient has received a dose of 20 mg or more of cortisone or equivalent daily via the oral or parenteral route for a continuous period of 2 weeks or longer, within 2 years of dental treatment.[63] Consultation with the patient's physician is indicated, and any modification of medication should only be adjusted by the patient's physician. For simple to advanced operative procedures and simple extractions, and for periodontal or implant surgery (types 1 and 2), the steroid dose should be doubled up to 60 mg of prednisone or equivalent (10 mg dexamethasone). The day after the procedure, the maintenance dose is returned to normal. Oral or IV conscious sedation is used to reduce stress. For moderate to advanced implant surgery or the very anxious patient, general anesthesia may be indicated. The day of the procedure, 60 mg prednisone is administered. This dose is reduced by 50% each day over a 2- to 3-day period to the maintenance dose. Antibiotics are also administered for 3 to 5 days.

Patients at significant or moderate risk for adrenal suppression are those formerly on steroid therapy of 20 mg prednisone or more for longer than 7 days within the preceding year. Simple to complex restorative procedures or simple surgery (types 1 and 2) suggest administration of 20 to 40 mg of prednisone the day of the procedure. Sedation techniques and antibiotics for 3 to 5 days are suggested. The next day the steroid dose is reduced by 50%, and by the third day the dosage is reduced by an additional 50% or returned to normal. For types 3 and 4, moderate to advanced surgical procedures, the protocol is further modified. Prednisone 60 mg or equivalent is administered the day of the surgery. This dose is reduced 50% the next day, and another 50% on the third day. General anesthesia may be used to reduce anxiety in the apprehensive patient.

Patients at low risk for adrenal suppression are those on alternate-day steroid therapy or those whose steroid therapy ended 1 year or more before the implant procedure. For these, dental procedures are scheduled the day steroids are taken or up to 60 mg of prednisone is administered. On the second day the dose is reduced 50%; on the third day, the patient resumes the alternate-day schedule. Sedation and antibiotics are also used.

Steroids act in three different ways that affect implant surgery. They decrease inflammation and are useful in decreasing swelling and related pain. However, steroids also decrease protein synthesis and therefore delay healing. In addition, they decrease leukocytes, reducing the patient's ability to fight infection. Therefore whenever steroids are given to patients for surgery, it may be reasonable to prescribe antibiotics. After a loading dose, amoxicillin or clindamycin are given three times per day for 3 to 5 days (Table 10.14).

Hyperparathyroidism

Hyperparathyroidism is an excess of PTH in the bloodstream caused by overactivity of one or more of the parathyroid glands that maintain calcium balance. The clinical manifestations of this disease vary widely depending on the severity. Mild forms may

TABLE 10.14 Dental Implant Management in Patients With Adrenal Disorders

Risk	Dosage	Type 1	Type 2	Types 3 and 4
Mild	Equivalent of prednisone on alternate days for >1 year	+	Surgery on day of steroids	Sedation and antibiotics steroids: <60 mg prednisone on day 1 Dose x/2 on day 2 Maintenance dose on day 3
Moderate	Equivalent of prednisone >20 mg or >7 days in past year	+	Sedation and antibiotics: 20–40 mg day 1 Dose x2 on day 2 Dose x4 on day 3	Sedation and antibiotics: 60 mg day 1 Dose x2 on day 2 Dose x4 on day 3
Severe	Equivalent of prednisone 5 mg/day	Physician consultation	Elective procedures contraindicated	Elective procedures contraindicated

+, Procedure may be performed with regular protocol.

be asymptomatic, whereas severe hyperparathyroidism can cause bone, renal, and gastric disturbance. It has been noted that skeletal depletion occurs as a result of stimulation by the parathyroid gland, which results in alveolar bone being affected before bones such as the ribs, vertebrae, or long bones. In the oral and maxillofacial regions, altered trabecular bone patterns may be present that result in mobility of the teeth and compromised bone density. Hyperparathyroidism falls into three categories: primary, secondary, and tertiary. Primary hyperparathyroidism involves one of the parathyroid glands becoming overactive and releasing excess parathyroid hormone. This results in high levels of calcium being released into the bloodstream from the bone, which leads to osteoporotic bones.

Secondary hyperparathyroidism is a chronic condition in which the parathyroid glands release an excess amount of parathyroid hormone because of chronically low blood calcium levels. Secondary hyperparathyroidism is usually caused by conditions such as CKD, vitamin D deficiency, and some GI issues that affect calcium absorption.

Tertiary hyperparathyroidism can occur when the condition causing secondary hyperparathyroidism is treated. This is similar to vitamin D deficiency; however, the parathyroid glands continue to produce excess parathyroid hormone.

Dental Implant Management

Bone Involvement. Dental implants are contraindicated (absolute) in areas of active bony lesions; however, implant placement may be initiated after treatment and healing of the affected areas. Altered trabecular bone pattern with the appearance of ground glass may also occur. In animal studies, secondary hyperparathyroidism affects alveolar bone more than any other bone of the skeleton, and central or peripheral giant cell tumors may be present in active lesion areas.[64]

Parathyroid Control. When the PTH is elevated, a serum calcium level is obtained to determine whether the hyperparathyroidism is primary or secondary, and the condition is usually treated with surgery or medication. In advanced disease, there are certain oral changes that can be present to suggest hyperparathyroidism. These patients have an increased risk for tori, and reduction in the radicular lamina dura is evident on dental radiographs. Many patients with higher levels of PTH develop loose teeth and widening of the periodontal ligament space surrounding the teeth. Additionally, cortical bone loss at the angle of the mandible has been noted in this disorder.

• BOX 10.9 Xerostomia Treatment Regimens

- Drink water frequently: Helps moisten mucosa and loosen mucus.
- Gum/candy: The use of sugarless gum or candy helps stimulate saliva flow.
- Avoid commercial mouth rinses containing alcohol or peroxide: Further desiccates the mucosa.
- Avoid salty foods, dry foods (for example, crackers, toast, cookies, dry breads, dry meats/poultry/fish, dried fruit, bananas), and foods and beverages with high sugar content.
- Avoid drinks containing alcohol or caffeine. Alcohol and caffeine increase urination and desiccate the mucosa.
- Over-the-counter saliva substitutes: Products containing xylitol (e.g., Mouth Kote, Oasis Moisturizing Mouth Spray, or ones containing carboxymethylcellulose).
- Prescription medications, after physician consultation (Evoxac [cevimeline], Salagen [pilocarpine]).

From Resnik RR, Resnik RJ. Medical/medication complications in oral implantology. In Resnik RR, Misch CE, eds, Misch's Avoiding Complications in Oral Implantology. St Louis, MO: Elsevier; 2018.

Xerostomia

Xerostomia (dry mouth) may directly or indirectly have effects on dental implants. A decrease in salivary flow is also accompanied by a change in its composition. An increase in mucin and a decrease in ptyalin result in a more viscous and ropy saliva. Plaque formation is increased, and the reduced antibacterial action of the saliva results in a favorable environment for bacteria growth (Box 10.9).

Dental Implant Management

Oral Complications. Dental implants are not contraindicated in patients suffering from xerostomia. Case reports have been documented with successful implant placement with no increase in failure rate.[65] However, with the lack of saliva, implant patients may be susceptible to more oral lesions and the possibility of irritation from tissue-borne implant prostheses. Additionally, patients are at higher risk for incision line opening.

Oral Bacterial Infections. Patients with xerostomia are at a higher risk for oral infections such as periodontitis, caries, and fungal infections. A comprehensive oral and periodontal examination must be completed with emphasis on a low periodontal

pathogen bacterial count to reduce possible postoperative complications.

Increase Saliva Flow. Stimulation of salivary flow may be achieved either by physiologic or pharmacologic means. Mouth rinses, chewing gum, or salivary substitutes may be used.

Final Prosthesis. When planning treatment for patients with xerostomia, a final prosthesis that is not tissue borne is recommended. A fixed-detachable (FP-3) prosthesis is highly recommended because of the lack of soft tissue coverage. If a removable prosthesis is warranted, an RP-4 is recommended because of the lack of soft tissue coverage. Additionally, removable prostheses worn in patients with xerostomia are associated with a high prevalence of fungal infections. If fungal infection is diagnosed, the use of a Nystatin medication is warranted.

Pregnancy

Elective dental implant surgery procedures are contraindicated for the pregnant patient. Not only is the mother the responsibility of the dentist, but so is the fetus. The radiographs or medications that may be needed for implant therapy and the increased stress are all reasons the elective implant surgical procedure should be postponed until after childbirth. However, after implant surgery has occurred, the patient may become pregnant while waiting for the restorative procedures, especially because modalities may require 3 months to 1 year of healing. Periodontal disease is often exacerbated during pregnancy. All elective dental care, with the exception of dental prophylaxis, should be deferred until after the birth. The only exceptions to this are caries control or emergency dental procedures. In these instances, medical clearance should be given for all drugs, including anesthetics, analgesics, and antibiotics to be administered to the patient. In most cases, physicians will approve the use of lidocaine, penicillin, erythromycin, and acetaminophen (Tylenol). Aspirin, vasoconstrictors (epinephrine), and drugs that cause respiratory depression (e.g., narcotic analgesics) are usually contraindicated. Diazepam (Valium), nitrous oxide, and tetracycline are almost always contraindicated.

Dental Implant Management. Elective dental implant therapy should be delayed until after pregnancy. A medical clearance should be obtained before any invasive treatment.

Additional Endocrine Disorders and Treatment Implications

See Table 10.15.

Hematologic System

Erythrocytic (Red Blood Cell) Disorders

In a healthy patient, 4 to 6 million RBCs per milliliter of blood are in circulation. RBCs make up the largest portion of the formed elements in blood. There are two main categories of erythrocyte disorders: polycythemia (increased erythrocyte count) and anemia (decrease in Hb).

Polycythemia. Polycythemia is defined as an increased concentration of Hb in body. It is either the result of increased RBC production or can it be caused by reduction in plasma volume. Most cases of polycythemia are the result of other underlying medical conditions or medications and referred to as secondary polycythemia. Hb levels >16.5 g/dL in women or 18.5 g/dL in men can suggest a diagnosis of polycythemia. Any condition that

TABLE 10.15	Additional Endocrine Issues and Treatment Implications
Positive Response	**Treatment Implications**
Frequent urination	Diabetes (undiagnosed)
Increased thirst	Diabetes (undiagnosed)
Recent weight loss	Anxiety, depression, GI disease, diabetes, hyperthyroidism
Recent weight gain	Heart failure (water retention), corticosteroids, Cushing syndrome, hypothyroidism
Increased appetite	Diabetes, hyperthyroidism
Fatigue	Anxiety, depression, anemia, vitamin B deficiency, hyper/hypothyroidism, chronic pulmonary/cardiovascular disease
Frequent kidney stones	Hypercalciuria from hyperparathyroidism
Increased head/hand shoe size	Paget disease
Nontraumatic bone fractures	Osteoporosis, hyperparathyroidism, myeloma
Slow healing infections/sores	Undiagnosed diabetes, Cushing syndrome, coagulation factor deficiency, vitamin C deficiency, adrenal insufficiency
Pigment changes in skin (dark spots)	Undiagnosed diabetes, Addison disease, melanoma, hemochromatosis

GI, Gastrointestinal.

causes chronic hypoxemia like COPD or even sleep apnea can be a secondary cause of polycythemia. Patients undergoing testosterone replacement can also develop a secondary polycythemia. Complicated implant or reconstruction procedures are usually contraindicated. Very high concentrations of Hb can cause infarcts in tissue such as the heart and stroke. Any patient with an elevated Hb having chest pain or any neurologic symptoms including headache, visuals issues or numbness, and weakness or tingling of extremities should be referred to their physician immediately.

Dental Implant Implications

Thrombus Formation. Because of the higher viscosity of the blood in polycythemic patients, an increased possibility of stroke, MI, or pulmonary embolism may occur.

Bleeding. Excessive bleeding and clotting issues are common with polycythemia patients; good surgical technique and strict hemostatic control measures must be followed to minimize intraoperative and postoperative bleeding episodes.

Treatment Summary

Unless cleared by a physician, polycythemia is an absolute contraindication for dental implant treatment.

Anemia

Anemia is the most common hematologic disorder. Almost all blood dyscrasias may at one time or another be associated with

anemia. Anemia is not a disease entity; rather, it is a symptom complex that results from a decreased production of erythrocytes, an increased rate of their destruction, or a deficiency in iron. It is defined as a reduction in the oxygen-carrying capacity of the blood and results from a decrease in the number of erythrocytes or the abnormality of Hb. Hb levels <13.5 g/dL in men or <12.0 g/dL in women can be indicative of anemia. Levels less than 10 g/dL require immediate attention, especially in patients that are symptomatic with shortness of breath, extreme fatigue, or dizziness.

There are a number of different types of anemia, and the most common type is iron-deficiency anemia and relative bone marrow failure. Iron-deficiency anemia may be caused by a decreased intake of iron, a decreased absorption of iron, or an increase in bleeding. Vitamin C increases the absorption of iron. The female patient may normally be anemic in menses or pregnancy. Mild anemia in a man, however, may indicate a serious underlying medical problem. The most common causes of anemia in men are peptic ulcers or carcinoma of the colon. These serious complications warrant medical evaluation of any male patient found to be anemic.

Other forms of anemia include sickle cell anemia (predominant in African Americans), pernicious anemia (low B_{12} or folate levels), and thalassemia (chronic hereditary hemolytic anemia as a result of defective Hb production). These types of anemia are chronic and many patients are well adapted to lower levels of Hb without many symptoms. Sickle cell anemia has different levels of severity, which requires a thorough history and consultation with the patient's physician may be warranted.

The general symptoms and signs are all a consequence of either a reduction of oxygen reaching the tissues or alterations of the RBC. The symptoms of mild anemia include fatigue, anxiety, and sleeplessness. Chronic anemia is characterized by shortness of breath, abdominal pain, bone pain, tingling of extremities, muscular weakness, headaches, fainting, change in heart rhythm, and nausea. The general signs of anemia may include jaundice, pallor, spooning or cracking of the nails, hepatomegaly and splenomegaly, and lymphadenopathy. The oral signs of anemia affect the tongue; symptoms include a sore, painful, smooth tongue; loss of papillae; redness; loss of taste sensation; and paresthesia of the oral tissues.

Complications associated with implant patients with anemia may affect both short-term and long-term prognoses. Bone maturation and development are often impaired in the long-term anemic patient. A faint, large trabecular pattern of bone may even appear radiographically, which indicates a 25% to 40% loss in trabecular pattern. Therefore the initial character of the bone needed to support the implant can be affected significantly. The decreased bone density affects the initial placement and may influence the initial amount of mature lamellar bone forming at the interface of an osteointegrated implant. The time needed for a proper interface formation is longer in poor density bone.[66] However, after the implant is loaded successfully, the local strain environment will improve the bone density at the interface.

Abnormal bleeding is also a common complication of anemia; during extensive surgery, a decreased field vision from the hemorrhage may occur. Increased edema and subsequent increased discomfort postsurgically are common consequences. In addition, the excess edema increases the risk of postoperative infection and its consequences. Not only are anemic patients prone to more immediate infection from surgery; they are also more sensitive to chronic infection throughout their lives. This may affect

the long-term maintenance of the proposed implant or abutment teeth.

Approximately 0.15% of the African American population has sickle cell anemia.[67] Patients with such a disorder usually show marked clinical manifestations and often die before the age of 40. Secondary infections are a common consequence with frequent history of osteomyelitis and bone infection. Because of these complications, implants are contraindicated in patients with sickle cell anemia.

The laboratory tests that diagnose anemia or polycythemia are in the CBC. An accurate test for anemia is the hematocrit, followed by the Hb; the least accurate is the RBC count. The hematocrit indicates the percentage of a given volume of whole blood composed of erythrocytes. The normal values for men range from 40% to 50%, and those for women from 35% to 45%. Hb composes almost 95% of the dry weight of RBCs. Abnormal Hb may result from its combination with substances other than oxygen (e.g., carbon monoxide) or genetic diseases (e.g., sickle cell diseases). Normal values for men are 13.5 to 18 g/dL, and those for women are 12 to 16 g/dL. The minimum baseline recommended for surgery is 10 mg/dL, especially for elective implant surgery. For the majority of anemic patients, implant procedures are not contraindicated. However, preoperative and postoperative antibiotics should be administered, and the risk of bleeding in anemic patients should not be potentiated by the prescription/use of aspirin. Hygiene appointments should be scheduled more frequently for these patients.

Dental Implant Implications

Bleeding. Some anemias are associated with abnormal bleeding. During extensive surgery, the increased bleeding may cause a decreased field of view for the clinician and possible postoperative issues. Most often iron-deficiency anemia and other vitamin-dependent anemias are associated with increased bleeding.

Edema. Increased edema and subsequent increased discomfort postsurgically are common consequences. In addition, the excess edema increases the risk of postoperative infection and morbidity. Anemic patients are prone to more immediate infection from surgery, and they are also more sensitive to chronic infection throughout their lives. This may affect the long-term maintenance of the proposed implant or abutment teeth.

Oral soft tissue issues. The oral signs of anemia affect the tongue. Symptoms include a sore, painful, smooth tongue; loss of papillae; redness; loss of taste sensation; and paresthesia of the oral tissues.

Bone Healing. Bone maturation and development are often impaired in the long-term anemic patient. A faint, large trabecular pattern of bone may even appear radiographically, which indicates a 25% to 40% loss in trabecular pattern. Therefore the initial quality of the bone required to support the implant can be affected significantly. The decreased bone density affects the initial placement and may influence the initial amount of mature lamellar bone forming at the interface of an osseointegrated implant. The time needed for a proper interface formation is longer in poor density bone.[68] However, after the implant is loaded successfully, the local strain environment will improve the bone density at the interface.

Leukocytic Disorders

Leukocyte disorders are an important consideration in hematologic diseases. The WBC count normally ranges from 4500 to 11,000/mm^3 in the adult. Leukocytosis is defined as an increase in circulating WBCs in excess of 11,000/mm^3. The most common

cause of leukocytosis is infection. Leukemia, neoplasms, acute hemorrhage, and diseases associated with acute inflammation or necrosis (e.g., infarction, collagen diseases) are more serious causes of leukocytosis. Physiologic conditions such as exercise, pregnancy, and emotional stress can also lead to leukocytosis. Any patient receiving recent or continuous oral steroids will most likely have an elevated WBC count.

Most oral implant procedures are contraindicated for the patient with acute or chronic leukemia. Acute leukemia can be a fatal disease, but some patients with aggressive therapy including stem cell transplants do have more favorable outcomes. These patients experience serious oral problems, either secondary to the disease process or as complications after chemotherapy. The patient with chronic leukemia will experience anemia and thrombocytopenia. Although the infection is less severe than in acute leukemia, radiolucent lesions of the jaws, oral ulcerations, hyperplastic gingiva, and bleeding complications develop in these patients

Leukopenia is a reduction in the number of circulating WBCs to less than $4500/mm^3$. Many times, a low WBC count can be caused by a recent viral infection; however, this should be temporary and past WBC counts should have been normal. Cancer, certain autoimmune diseases (lupus and rheumatoid arthritis [RA]), severe infections, and even some antibiotics can cause a low WBC. There is a subset of patients that have a chronically low WBC count and are otherwise completely healthy. However, these patients require additional testing to confirm that the decrease is in WBCs is benign. These patients should be evaluated by a hematology specialist.

In the potential implant candidate with leukocytosis or leukopenia, many complications can compromise the success of the implants and prosthesis. The most common is infection, not only during the initial healing phase but also long term. Delayed healing is also a consequence of WBC disorders. For most implant procedures, the first few months are critical for long-term success. Delayed healing may increase the risk of secondary infection. Treatment-planning modifications should shift toward a conservative approach when dealing with leukocyte disorders. Complications are more common than in erythrocyte disorders. If the condition is temporary, such as an acute infection, surgical procedures should be delayed until the infection has been controlled and the patient has returned to a normal condition.

Platelet Disorders

A normal platelet count is between 150,000 and 450,000/μL. Thrombocytopenia is a lower than normal platelet count caused by decreased production, increased destruction, or sequestration of platelets in the spleen, which results in potential bleeding complications during surgery. A platelet count should always be obtained in patients with this history, and a value lower than 50,000 U/L contraindicates elective dental surgery because of a significant risk of postoperative bleeding.[69]

It should also be noted that platelet counts can be reduced or normal but bleeding time can be prolonged in the presence of platelet dysfunction. Acquired platelet dysfunction can be the result of a systemic illness like liver or connective tissue disease. Drugs like aspirin or clopidogrel cause an acquired platelet dysfunction that can last 7 days or longer, and concurrent use in the presence of lower than normal platelet counts can prolong

bleeding. Consultation with the patient's physician is indicated in this situation.

Idiopathic thrombocytopenic purpura is a platelet disorder that may present with a number of findings including petechiae, blood in the urine, ecchymosis, and spontaneous prolonged bleeding. Implant dentists need to recognize this condition because it may create prolonged life-threatening bleeding. Oral manifestations include spontaneous gingival bleeding. There may be scattered petechiae on the palate tongue or oral mucosa. There should be consultation with the patient's physician before any dental implant surgery.

Thrombotic thrombocytopenic purpura (TTP) is a rare blood disorder characterized by anemia, neurologic dysfunction, and thrombocytopenia. Neurologically patients will have changes in vision, speech, and mental status as well as fatigue from the anemia and bleeding from the low platelet counts. TTP can be the result of certain medications, including chemotherapy. Any patient with a history of TTP should not undergo any dental implant procedure without clearance from their physician.

Essential thrombocythemia is a condition when the body produces too many platelets. This condition can result in abnormal blood clotting, but because many times the overproduced platelets are dysfunctional, it can also cause abnormal bleeding. Platelet counts can also be elevated from inflammation and caused by several conditions including recent blood loss, infections, pancreatitis, splenectomy, and certain anemias. The platelet counts in these conditions usually resolve as the underlying condition is treated.

It is recommended that patients that have a history of low or high platelet counts be closely evaluated for elective implant surgery.

Dental Implant Management. When treating patients with any hematologic disease, a medical consultation and clearance is warranted, including those with current or past history of reduced or elevated platelet counts because many times there may be an associated platelet dysfunction, which could lead to issues with perioperative and postoperative bleeding. The patient's physician should be presented with a comprehensive summary of the proposed procedure, medications to be prescribed, and the extent of anticipated bleeding.

Additional Hematologic Disorders and Treatment Implications

See Table 10.16.

Pulmonary System

Chronic Obstructive Pulmonary Disease

COPD refers to a group of pulmonary diseases that block airflow, resulting in breathing difficulties. The two most common conditions that make up COPD are chronic bronchitis and emphysema. Chronic bronchitis is an inflammation of the bronchial tubes that produces an increase in mucous production and coughing.

There are close to 15 million American adults that have been diagnosed with COPD and about 10 million of them have chronic bronchitis with about 5 million with emphysema. COPD is now the third most common cause of death behind only cancer and heart disease in the United States. The annual costs to our health care system for COPD-related illness is over $30 billion each year.[70]

TABLE 10.15	Additional Hematologic Issues and Treatment Implications
Positive Response	**Treatment Implications**
Sickle cell anemia	Secondary infections are a common consequence with frequent history of osteomyelitis and bone infection (absolute contraindication)
Leukemia	Experience anemia and thrombocytopenia. Although the infection is less severe than in acute leukemia, radiolucent lesions of the jaws, oral ulcerations, hyperplastic gingiva, and bleeding complications develop in these patients (absolute contraindication)
Thalassemia	Multiple types (alpha, beta) and degrees of severity (major, minor) More severe forms can present some issues such as erythroid mass expansion directly into facial bones causing malocclusions Medical consultation is recommended to determine severity of disease Major (severe forms): absolute contraindication Minor (less severe): relative contraindication
Frequent nosebleeds (epistaxis)	Hypertension, sinus disease, bleeding disorders such as von Willebrand Spontaneous or frequent nosebleeds should have bleeding time and INR
Easy bleeding gums	Gingival disease, bleeding disorder, thrombocytopenia, leukemia, liver disease Further investigation may be warranted with platelet, CBC, bleeding time, PT, PTT
Heavy menstrual periods	Thyroid disease, dysfunctional uterine bleeding (fibroid, polyps, and hormone imbalance), bleeding disorders, platelet dysfunction If no obvious medical reason, check CBC, INR, bleeding time
Family history of bleeding disorder	If family history of bleeding issues, check CBC, INR, PTT, bleeding time to rule out hereditary bleeding disorders such as von Willebrand, hemophilia, and coagulation factor deficiencies
Prolonged bleeding after cuts	Rule out coagulation defect, hereditary bleeding disorder, or platelet dysfunction; check CBC, INR, PTT, bleeding times
Easy bruising or spontaneous bruising	Platelet deficiency, coagulation factor issue, leukemias, vitamin K deficiency, chemotherapy, anticoagulation medication
History of excessive bleeding after dental surgery	If no definitive diagnosis correlates with prolonged bleeding, check CBC, INR, PTT, bleeding time

CBC, Complete blood count; *INR,* international normalized ratio; *PT,* prothrombin time; *PTT,* partial thromboplastin time.
From Resnik RR, Resnik RJ. Medical/medication complications in oral implantology. In Resnik RR, Misch CE, eds. *Misch's Avoiding Complications in Oral Implantology.* St Louis, MO: Elsevier; 2018.

Emphysema occurs when the alveoli in the bronchioles of the lungs become damaged or destroyed, creating symptoms of dyspnea (shortness of breath) that may worsen with mild activity. Patients with COPD may have a combination of both conditions. These patients usually present with fatigue, history of recurrent respiratory infections, wheezing, and shortness of breath. In advanced disease states, patients may become oxygen dependent with tachypnea being present with some audible wheezing and shortness of breath even at rest. The various levels of COPD are classified via the Global Initiative for Chronic Obstructive Lung Disease (GOLD), which classifies patients on their degree of airflow limitation. The airflow limitation is measured during pulmonary function tests (PFTs) and measured as forced expiratory volume (FEV_1).

These guidelines use an ABCD grading system with A being better and D being worse. Treatment involves using long-acting bronchodilators that are beta-agonists (LABA) or muscarinic antagonist (LAMA) and work directly on the lung to improve oxygenation through dilation of the bronchioles. Inhaled corticosteroids (ICS) are not usually used as a single therapy, but many times are used in combination with bronchodilators. More common LABA/IC combinations include Advair, Dulero, Breo, and Symbicort. Common LAMA drugs include Spiriva and Incrusel. Albuterol is a short-acting bronchodilator and is not indicated for continuous monotherapy. It is used as a "rescue" to help treat acute symptoms or exacerbations. Short-acting bronchodilators can have a profound effect on increasing heart rate, especially if used just before an elective dental surgery. Any COPD patient using a long- or short-acting bronchodilator is considered grade A. Patients using a long-acting bronchodilator LABA or LAMA, or both, with persistent symptoms are considered grade B. Grade C is the addition of a LAMA or switching to a LABA and LAMA combination or adding an inhaled corticosteroid to control exacerbations. Grade D patients are the more complex patients requiring more specialized treatment because they do not respond to conventional combinations. Although it is important to get a detailed history of a patient with COPD, there should be specific focus on their current use of medications to control symptoms because they can vary seasonally and under other situations. Patients with grade D symptoms should always get clearance from their physician for elective dental surgery. However, there should be consideration for physician consultation for any grade C or recent worsening of respiratory symptoms in patients with COPD.

Dental Implant Management. Patients with difficulty breathing only on significant exertion and who have normal laboratory blood gases are at minimal risk and may follow all restorative or surgical procedures with normal protocols (types 1–4). Dental management of COPD patients may require repositioning the patient from the normal supine position. Depending on the severity of the disease, orthopnea may result. The patient can be placed in the most recumbent position so that breathing is comfortable. Supplemental oxygen (2–3 L) should be administered throughout the dental procedures.

Patients with difficulty breathing on exertion in general are at moderate risk, as are patients on chronic bronchodilator therapy or who have recently used corticosteroids. These patients may follow examination procedures with normal protocol (type 1). A recent medical examination is recommended for all other procedures. Type 2 procedures should be performed in a hospital setting. If the patient is on bronchodilators, no epinephrine or vasoconstrictors should be added to the anesthetics or gingival retraction cord. Adrenal suppression should be evaluated for any patient on steroid therapy within the past year.

Patients at high risk are those with previously unrecognized COPD, acute exacerbation (e.g., respiratory infection), dyspnea at rest, or a history of carbon dioxide retention. Dental management

of patients with COPD is staged according to the severity of the disease. If a patient has been hospitalized for respiratory difficulties, then a medical consultation is warranted. The dentist should inquire regarding the carbon dioxide retention capability of these patients. Patients who retain carbon dioxide have a severe condition and are prone to respiratory failure when given sedatives, oxygen or nitrous oxide, and oxygen analgesia.

Examination procedures may be performed under normal protocol (type 1). Elective moderate procedures or advanced surgical or prosthetic procedures are usually contraindicated. However, if surgery or prosthetic procedures are needed to repair a previously inserted implant, then they should be performed in the hospital. The use of epinephrine should be limited. Drugs that depress respiratory function, such as sedatives (including nitrous oxide), tranquilizers, and narcotics, should be discussed with the physician.

Anesthetic selection. In rare instances, patients with COPD receiving local anesthetics have exhibited adverse reactions. Increased doses of anesthetic solutions that contain sulfites may increase the risk of bronchospasm or allergic reactions. Most local anesthetics that are vasopressor anesthetics (e.g., epinephrine, levonordefrin) will contain the antioxidant sodium (meta) bisulfite. For COPD patients with a known allergy to bisulfites, a local anesthetic without a vasopressor (e.g., mepivacaine HCL 3%, prilocaine HCL 4%) should be used.

Adrenal Suppression. Adrenal suppression may occur with long-term corticosteroid treatment, which is common with more advanced COPD patients.

Cardiovascular Event. For patients who have had a cardiovascular event, the patient's functional capacity should be ascertained (physician consultation) and a stress reduction protocol implemented. The implant clinician should avoid long or extensive surgical procedures.

Oxygen Supplementation. High flow rates of oxygen can result in respiratory depression in patients that are oxygen dependent or have more severe COPD disease. However, there is now supporting evidence that titration of oxygen therapy to maintain saturations between 88% and 92% is the correct approach. Avoid using higher levels of oxygen that would increase pulse oximetry levels to >92%, creating hyperoxia in a COPD patient, which could result in hypercapnia (retention of COPD which can diminish respiratory rate). Nitrous oxide is also contraindicated because of the negative affect on the respiratory drive. Low–flow rate oxygen supplementation (<2 L/min) during implant procedures is highly recommended to minimize the possibility of hypoxia.

Bronchodilators/Inhaled Corticosteroids. Bronchodilators and inhaled corticosteroids are the hallmark of treatment for COPD; however, they have been associated with an adverse effect on oral tissues. β_2-agonists such as albuterol have been associated with a decrease in saliva production and subsequent secretion resulting in xerostomia. Patients should always be instructed to bring their rescue inhaler (usually albuterol) to the procedure or, for more advanced COPD patients, their nebulizer and albuterol solution in case of an emergency.

Use of Sedation. Sedation should be carefully evaluated in patients with COPD, and discussion with their treating physician is recommended. Potent sedatives such as narcotics and barbiturates should be avoided unless approved by the treating physician. These drugs can further depress the respiratory drive in more advanced COPD patients. Antihistamines may desiccate respiratory secretions, which may lead to compromised airflow. Additionally, nitrous oxide should not be used in COPD patients because it can lead to further respiratory depression (Table 10.17).

Additional Pulmonary Disorders and Treatment Implications

See Table 10.18.

Digestive System

Liver Disease (Cirrhosis)

Cirrhosis of the liver is characterized by irreversible scarring and is usually caused by excessive alcohol intake, viral hepatitis B and C, and certain medications. Although patients with advanced disease can present with jaundice and itching, the diagnosis is usually confirmed by liver biopsy and blood tests. Cirrhosis may cause excessive bleeding, mental confusion, kidney failure, and accumulation of fluid in the abdomen (ascites). Cirrhosis is irreversible, and transplantation is becoming the most successful treatment for advanced disease states.

Cirrhosis is the third leading cause of death in young men between the ages of 35 and 54 years. It occurs as a result of injury to the liver with resultant loss of liver cells and progressive scarring. The major cause of cirrhosis is alcoholic liver disease. In 2015, approximately 6.2% of the population met the diagnostic criteria for alcohol abuse and alcohol dependence, but as many as 15 to 20 million may be considered alcoholics. More than 25 million Americans have alcohol-related liver or gallbladder disease, and an estimated 900,000 Americans have cirrhosis.[71,72]

Patients with cirrhosis have several significant issues that can affect dental treatment, including dysfunctional synthesis of clotting factors and the inability to detoxify drugs. Hemostatic defects of liver disease cause not only reduced synthesis of clotting factors but also an abnormal synthesis of fibrinogen and clotting proteins, vitamin K deficiency, enhanced fibrinolytic activity, and quantitative and qualitative platelet defects. Of patients with liver disease,

TABLE 10.17	Dental Implant Management in Patients With Chronic Obstructive Pulmonary Disease			
Risk	Type 1	Type 2	Type 3	Type 4
Mild (ASA II)	+	+	+	+
Moderate (ASA III)	+	Physician	Physician/moderate treatment	Physician/moderate treatment
Severe (ASA IV)	Physician consultation	Postpone (hospitalization)	Elective procedures contraindicated	Elective procedures contraindicated

+, Procedure may be performed with regular protocol; *ASA*, American Society of Anesthesiologists.

50% have a prolonged PT and possible significant clinical bleeding. The inability to detoxify drugs may result in oversedation or respiratory depression. The laboratory evaluation of the implant candidate gives much insight into hepatic function. A basic panel of LFTs or a CMP can provide the needed information. In most patients with liver disease, it is recommended that a CBC, LFT, BMP, bleeding time, and an INR/PT test should be performed.

Of special note, patients with normal LFTs can present with constant itching or pruritus. This may be the first symptom of early liver disease, especially primary biliary cirrhosis. This is a progressive disease that causes cholestasis (buildup of bile in the liver) and damages the small bile ducts and over time destroys the ducts, resulting in liver damage. Because this is a progressive disease, it can be fatal, but early diagnosis of the disease can have more favorable outcomes. For baby boomers, hepatitis C has been a significant issue, and until recently many chronic hepatitis C patients were undiagnosed until new screening protocols were instituted. Risk factors include transfusions of blood products (mostly from the 1970s and 1980s), IV drug use, sexual transmission, and tattoos. Because of the opioid and injection drug use epidemic, hepatitis C

infections have increased dramatically since 2005. Many infected individuals can have spontaneous resolution of their infection, but almost 50% of persons with hepatitis C infections are unaware they have or have had the disease. Seventy-five percent of individuals currently with hepatitis C were born between 1945 and 1965 and may be current candidates for elective dental implant surgery. Asking patients at risk, or in this age group, about previous screening through a blood test for hepatitis C is recommended. Newer treatments have now essentially cured this disease for many patients. Individuals affected by hepatitis C can have normal or slightly elevated LFTs, but screening with a hepatitis C antibody blood test should be considered for patients at risk.

Dental Implant Management. Patients with no abnormal laboratory values on CMP, CBC, PTT, and PT are at low risk, and a normal protocol is indicated for all procedures (types 1–4). Patients with an elevated PT of less than 1.5 times the control value, or bilirubin slightly affected, are at moderate risk. These patients should be referred to their physician for evaluation and treatment. The use of sedatives may require physician clearance. Nonsurgical and simple surgical procedures may follow normal protocols (types 1 and 2). However, strict attention to hemostasis is indicated. Bovine collagen such as CollaTape, topical thrombin, or additional sutures may be indicated. Moderate to advanced surgical procedures may require hospitalization (types 3 and 4). Postsurgical close surveillance is indicated. Elective implant therapy is a relative contraindication in the patient with symptoms of active alcoholism.

Patients with a PT greater than 1.5 times the control value, mild to severe thrombocytopenia (platelets lower than 140,000/mL), or several liver-related enzymes or chemicals affected (bilirubin, albumin, ALP, SGOT, and SGPT) are at high risk.

Elective dental procedures such as implants are usually contraindicated. If surgical procedures must be performed on a preexisting implant, hospitalization is recommended. Platelet transfusion may be required for even scaling procedures and administration of mandibular nerve blocks. Fresh frozen plasma may be used to correct PT to under half the control value.

Medications. Many drugs such as local anesthetics (lidocaine, prilocaine, mepivacaine, and bupivacaine), sedatives (lorazepam, valium, and alprazolam), and antibiotics (erythromycin and clindamycin) are metabolized primarily in the liver. Therefore in some patients a dosage reduction may be warranted based on the current liver functioning.

Nonsteroidal Antiinflammatory Drugs. In patients with cirrhosis, NSAIDs have been associated with renal failure and should be avoided. In patients with chronic liver disease, NSAIDs and opioids may be used at reduced doses but only after consultation with the patient's physician. Acetaminophen at a reduced dosage is a possible alternative consideration. New FDA recommendations suggested a maximum dosage of 2 g/day is reasonable. An accepted school of thought is that codeine and opioids should not be used or, if so, used at very infrequent and lower dosages to avoid hepatic encephalopathy.[73] Additionally, tetracycline, erythromycin, and metronidazole should never be used in patients with advanced liver disease.

Stomach Ulcers

Approximately 1 in 10 Americans will suffer from a version of gastritis or ulcer disease during their lifetime. Ulcers form when there is a break or breach of the lining of the stomach or intestine.

Peptic ulcers form in the duodenum of the small intestine from being in contact with stomach acids. Duodenal ulcers are

TABLE 10.18	Additional Pulmonary Issues and Treatment Implications
Positive Response	**Treatment Implications**
Asthma	Inflammatory process in lung is IgE/allergen mediated Determination of trigger: asthma or bronchospasm, including anxiety Albuterol on hand for surgery Approximation of severity determined by number of medications and frequency of use of albuterol rescue inhaler
Shortness of breath (dyspnea)	Asthma, COPD, heart disease, cardiomyopathy, CHF, arrhythmias, anemia, obesity, heart valve disease
Wheezing	Allergies, asthma, bronchitis, GERD, vocal cord dysfunction
Hemoptysis (blood in sputum)	Bronchitis, pulmonary embolism, CHF, lung cancer, blood thinners, TB
Cough	Postnasal drainage, asthma, GERD, ACE/ARB blood pressure medications, chronic bronchitis in COPD, other respiratory processes like bronchiectasis
Change in exercise tolerance	Any changes walking upstairs or walking more than 50 yards Cardiovascular, pulmonary, poor conditioning
Weight loss	Poorly controlled COPD, malignancy, TB, hyperthyroid, ethyl alcohol abuse
Dysphagia from stroke or other neuromuscular diseases	Risk of aspiration during dental procedure

the most common type of ulcer. Ulcers that occur in the stomach are referred to as gastric ulcers. In rare cases, esophageal reflux can cause esophageal ulcers. There are several main causes for ulcer disease, including excessive alcohol intake, stress, medications (NSAIDs and aspirin), and a bacterium (*Helicobacter pylori*).

Although there are no direct contraindications to the use of prophylactic antibiotics in patients with ulcer disease (except allergies), some patients may be more sensitive to certain types of antibiotics that may irritate their stomach. Pain management may be hampered by the inability to use NSAIDs or certain narcotics. To prevent bleeding from stomach ulcers, analgesics and antibiotics should be cautiously used (medical clearance) in the treatment of implant surgical patients.

Inflammatory Bowel Disease

IBD is a chronic inflammation of all or part of the digestive tract. The number of people afflicted with this condition continues to increase. The two major forms of IBD are ulcerative colitis and Crohn's disease. Patients will usually have symptoms of chronic or severe diarrhea, fatigue, rectal bleeding, and anemia. Ulcerative colitis is characterized as an inflammatory disease of the rectum and large intestine mainly affecting the mucosal lining. Crohn's disease is an inflammatory disease of the entire digestive tract from mouth to anus, resulting in lesions of healthy tissue in between areas of inflammation. Most cases of Crohn's disease originate within the terminal ileum.

Patients with a history of stomach ulcers are susceptible to infections and healing issues usually associated with the immunosuppressive drugs. Also, their dietary restrictions may affect both of these issues, and postoperative antibiotics are usually indicated.

During dental procedures, stress reduction protocol is essential. Excess stress can affect adrenal function and require additional corticosteroid augmentation. Postoperative pain episodes may increase stress on the adrenal gland, resulting in possible adrenal suppression complications.

Many digestive disorder patients are anemic and, because of malabsorption, may not absorb all the necessary components of clotting factors and certain vitamins. Care should be taken to minimize bleeding.

There are many differences in the oral lesions that manifest in patients with Crohn's disease and those with ulcerative colitis. Many of these patients present with a glossitis, aphthous ulcerations, or a more classic marker of ulcerative colitis, pyostomatitis vegetans. This condition is characterized by pustules with thickened oral mucosa and surrounding erythema with some erosions. Ulcerative colitis has extra GI manifestations that have been associated with erosive temporomandibular joint disease. Crohn's disease has been shown to have oral symptoms such as cobblestoning of the oral mucosa accompanied by ulcerations usually in a linear pattern along with hyperplastic folds of the buccal vestibules (mucosal tags).

A physician consultation is recommended to determine the extent of the patient's digestive disorder along with the current immune status. Most notably, an evaluation of delayed wound healing and postoperative infection susceptibility should be ascertained.

Antibiotics that have a high incidence of antibiotic-associated diarrhea or pseudomembranous colitis should be avoided (e.g., amoxicillin/clavulanic acid, erythromycin, clindamycin). Patients with IBD, especially those with ulcerative colitis, may benefit from the use of probiotics, especially when antibiotics are prescribed. Probiotics are live microorganisms that are added to food to change the intestinal microbial balance. The mechanism of action is controversial; however, theories include strengthening of the gut barrier, pathogen growth inhibition, and enhancement of mucosal and systemic immune responses. Most NSAIDs may precipitate these disease states and should be avoided unless authorized by a physician.

Additional Digestive Disorders and Treatment Implications

See Table 10.19.

Bone Diseases

Diseases of the skeletal system and specifically the jaws often influence decisions regarding treatment in the field of oral implants. Bone and calcium metabolisms are directly related. Approximately 99% of the calcium in the body is held in the bones and teeth. Calcium equilibrium is influenced by several different processes in the body, which then could directly affect bone health. PTH has the most important influence on calcium by impacting the storage of calcium on bones. Even though vitamin D is important for small intestine absorption of calcium, the renal tubules in

TABLE 10.19 Additional Digestive Issues and Treatment Implications

Positive Response	Treatment Implications
Jaundice	Hepatitis, bile duct disorders, sickle cell anemia, autoimmune hemolytic disease pancreatic cancer
Hepatitis	Medical consultation, aseptic technique, preventive measures
Esophageal reflux	Infection, increased tooth decay/erosion
Hiatal hernia	Appointment duration not to exceed patient's tolerance
Nocturnal cough	Gastric reflux disease, chronic sinusitis, allergies
Dark, tar-colored stools	GI bleeding (avoid anticoagulants, NSAIDs; need GI evaluation)
Frequent foul-smelling stools	Crohn disease, pancreatic cancer (gum disease), lactose intolerance (tooth decay, bone demineralization), celiac (gluten intolerance) disease (enamel erosion, aphthous ulcers)
Dysphagia (solid/liquid)	Reflux, esophageal spasm, stricture, esophageal mass, multiple sclerosis, Parkinson disease, stroke, poor oral clearance, high-volume suction, aspiration during treatment, protect airway rubber dam
Persistent pruritus (itching)	Celiac disease, liver disease, biliary disease (sclerosing cholangitis) All can lead to coagulopathy and excessive bleeding

GI, gastrointestinal; *NSAIDs,* nonsteroidal antiinflammatory drugs.

From Resnik RR, Resnik RJ. Medical/medication complications in oral implantology. In Resnik RR, Misch CE, eds. *Misch's Avoiding Complications in Oral Implantology.* St Louis, MO: Elsevier; 2018.

the kidneys reabsorb 95% of the calcium. In the elderly there is increasing evidence to support that lower levels of vitamin D have the most influence on calcium levels.[74]

There exist many diseases that directly affect the dental implant treatment.

Osteoporosis

The most common disease of bone metabolism the implant clinician will encounter is osteoporosis, which is an age-related disorder characterized by a decrease in bone mass, increased microarchitectural deterioration, and susceptibility to fractures. The WHO defines osteoporosis as a bone mineral density level more than 2.5 standard deviations below the mean of normal young women.[75] Forty percent of postmenopausal women in the United States have bone mineral density levels denoting osteopenia, and 7% have scores correlated with osteoporosis.[76] As the population ages, the incidence of osteoporosis will continue to increase in both women and men. Women with osteoporosis are three times more likely to experience tooth loss than those who do not have the disease. It has been shown that dental x-rays may be used as screening for osteoporosis.[77]

After age 60, almost one-third of the population has osteoporosis; it occurs in twice as many women as men. This condition is common in postmenopausal women or those with a history of a premenopausal oophorectomy. The lack of estrogen increases the likelihood of osteoporosis; the addition of estrogen is the single most effective treatment to increase calcium absorption in these women. However, current concerns about the development of breast, ovarian, or endometrial cancer and an increased incidence of stroke, heart attack, and blood clots in these patients have almost eliminated the use of supplemental estrogen.

Many times, if estrogen therapy is initiated, it is at much lower doses and for shorter duration. Half of all women present with bone mineral density below the normal fracture threshold of a 20-year-old woman by the age of 65 years. It is estimated that 1.3 million fractures overall and 133,000 hip fractures occur every year as a result of osteoporosis. Most patients fail to recover normal activity; 24% die of complications related to the fracture within the first year.[78]

The osteoporotic changes in the jaws are similar to other bones in the body. The structure of the bone is normal; however, because of the uncoupling of the bone resorption and formation processes with emphasis on resorption, the cortical plates become thinner, the trabecular bone pattern becomes more discrete, and advanced demineralization occurs. The bone loss related to osteoporosis may be expressed in both the dentate and edentulous patient. In one study of osteoporotic women who had their teeth at age 50, 44% had a complete denture by the age of 60, whereas only 15% of nonosteoporotic women had dentures.[79] A strong correlation was shown between periodontal disease and skeletal osteoporotic changes. In addition, women represent a greater percentage of patients with residual ridge resorption than do men.[80] The loss of trabecular bone is accelerated in the edentulous patient because the factors involved in resorption are already established.

Bone remodeling is a continuous process; however, bone mass increases during youth and diminishes with aging. The peak bone mass is usually reached by the age of 35 to 40 years and is usually 30% higher in men than in women. In the first 3 to 10 years after menopause, bone loss is rapid. Trabecular bone loss in a women 80 years old reaches 40%, but is only 27% in men of the same age. Persons most at risk of osteoporosis are thin, postmenopausal, Caucasian women with a history of poor dietary calcium intake, cigarette smoking, and British or Northern European ancestry.

Estrogen therapy can halt or retard severe bone demineralization caused by osteoporosis and can reduce fractures by about 50% compared with the fracture rate of untreated women. For those patients taking an estrogen supplement, there have been studies to evaluate the effect of estrogen replacement therapy on dental implant failures. Osteoporotic patients not taking estrogen have nearly twice the failure rate of maxillary implants in comparison to patients who were receiving estrogen therapy.[81]

Recent advances in radiology, such as dual-energy x-ray absorptiometry, can measure as little as 1 mg of bone mass change at such sites as the hip, spine, and wrist. Such measurements may accurately predict future fracture risk and identify the patients at risk. The actual diagnosis and treatment of osteoporosis should be attained by the patient's physician. The implant dentist can best assist the patient by noting the loss of trabecular bone and early referral.

Treatment of osteoporosis remains controversial. Its management concentrates on prevention. Regular exercise has shown to help maintain bone mass and increase bone strength. Adequate dietary calcium intake is essential. The advanced demineralization and consequent increase in bone loss of the completely edentulous may become a vicious circle. The denture is less secure, and the patient may not be able to follow the diet needed to maintain proper calcium absorption levels.

The recommended calcium intake is 800 mg/day. The average person in the United States ingests 450 to 550 mg. In postmenopausal women, 1500 mg may be required to maintain a positive calcium balance.[82] Calcium supplements of 1 to 2 g of elemental calcium per day have been shown in several studies to reduce the rate of bone loss. However, there is no evidence that these supplements lead to recovery of bone mass. Plain calcium carbonate tablets contain the greatest fraction of elemental calcium and are relatively inexpensive. It is insoluble and is absorbed after conversion into calcium chloride by gastric hydrochloric acid. Patients with achlorhydria (lack of hydrochloric acid) should be given salts other than calcium carbonate. If the patient has a lactate deficiency, lactate salts are contraindicated. Several food–drug interactions have been reported. Tetracycline and iron do not work effectively with calcium doses. Patients should also avoid phosphate (found in some dairy products or diet soda) or oxalic acid (in spinach and rhubarb) and the phytic acid in bran and whole grains because these decrease calcium absorptions. Patients with a history of renal calculi should avoid calcium supplements. Patients with renal dysfunction need periodic serum and urine calcium level checks, and their serum pH should be monitored to avoid hypercalcemia and metabolic alkalosis.

Vitamin D is also important in treating and preventing osteoporosis because it is required for proper calcium absorption. Without proper levels of vitamin D calcium supplementation may have no effect on bone health; this is especially true in older patients. Calcium and vitamin D supplements may help prevent tooth loss in older adults. Vitamin D is normally made in the skin after exposure to sunlight; however, given the concerns for skin cancer, most individuals are now avoiding direct sun exposure or overexposure. At least 800 IU of vitamin D per day are recommended for postmenopausal women or men over age 70. For more severe cases of vitamin D deficiency higher daily doses

of one to several thousand international units of vitamin D may be required. For patients with established osteoporosis, treatment options include bisphosphonates and calcitonin. Bisphosphonates are inhibitors of bone resorption. Calcitonin, which is normally secreted by the thyroid gland, inhibits bone resorption and alters calcium metabolism.

Dental Implant Implications

Surgical Technique. Underpreparation of the osteotomy site (or use of osteotomes) will result in the implant having more bone at the implant interface. Although not contraindicated, immediate stabilization of dental implants is a common concern because of decreased trabecular bone mass. Healing periods and implant surface characteristics should be selected for poorer-quality bone.

Bisphosphonates Use. Oral/IV bisphosphonates are common medications for osteoporosis. (See the section "Bisphosphonates.")

Length of Healing. In osteoporotic patients, there is a decrease in cortical and trabecular bone; the repair process (implant healing) may be compromised. Sufficient time for healing should be adhered to with progressive prosthetic bone loading is highly recommended.

Peri-implantitis. A strong correlation has been shown between periodontal disease and skeletal osteoporotic changes. Strict postoperative recall and periodontal evaluation should be adhered to.

Progressive Bone Loading. Because of poorer bone quality, healing is compromised, necessitating progressive bone loading throughout the prosthetic rehabilitation. The poorer-quality bone is progressively increased to better-quality bone, which results in better bone quality at the implant interface.

Implant Design. Implant design should include greater-width implants. Surface conditions of implant bodies should be designed to increase bone contact and density. Bone stimulation to the healed interface will increase bone density, even in advanced osteoporotic changes (Box 10.10).

Fibrous Dysplasia

Fibrous dysplasia (FD) is a rare, nonheritable, genetic disorder characterized by normal bone being replaced by immature, haphazardly distributed bone and fibrous tissues. The etiology of this bone disease is a gene mutation that prevents the differentiation of cells within the osteoblastic formation. FD can be further classified to involve one site (monostotic FD [MFD]), multiple sites (polyostotic FD [PFD]), or multiple locations (craniofacial FD [CFD]). CFD lesions are usually unilateral and occur twice as often in the maxilla versus mandible. The diagnosis of CFD should be determined from the clinical evidence, histopathologic analysis of the biopsy specimen, and radiologic findings.[55] Most individuals with this disorder are diagnosed early in childhood.

The radiographic appearance is highly variable because of the disproportionately mineralized tissue and fibrous tissue in the lesion. This variability results in radiographic images depicting the typical "ground glass" appearance to early-stage radiolucencies and late-stage radiopacities.[83] Additionally, severe malocclusion, dental abnormalities, and facial asymmetry have been shown to be highly prevalent in CFD patients, which further complicates the prosthetic rehabilitation of these patients.[84]

Dental Implant Implications

Postoperative Healing. Healing after trauma in patients with FD is much different than for those with normal bone. The tissue

• BOX 10.10 Common Medications and Implications for Treatment of Osteoporosis

Bisphosphonates
- Alendronate (Fosamax, Fosamax Plus D)
- Alendronate (Binosto)
- Denosumab (Prolia)
- Ibandronate (Boniva)
- Risedronate (Actonel)
- Risedronate (Atelvia)
- Zoledronic acid (Reclast)

Calcitonin
- Calcitonin (Fortical, Miacalcin)
- Calcitonin (Miacalcin injection)

Estrogen (Hormone Therapy)
- Estrogen (multiple brands)

Estrogen Agonists/Antagonists (Also Called Selective Estrogen Receptor Modulators)
- Raloxifene (Evista)
- Bazedoxifene (Duavee)

Anabolic Agents Parathyroid Hormone (Anabolic Agent)
- Teriparatide (Forteo)

Parathyroid Hormone-Related Protein Analog (Anabolic Agent)
- Abaloparatide (Tymlos injection)

Rank Ligand Inhibitor
- Denosumab (Prolia injection)

---

is hypocellular, which leads to slow healing and an increased infection rate. These local infections may spread through the bone and result in more advanced complications.

Informed Consent. Because of the lack of research and studies, patients need to be well informed of possible morbidity and complications.

Treatment Summary

Active lesion areas: Absolute contraindication
Nonlesion areas: Relative contraindication

Vitamin D Disorders (Osteomalacia)

Osteomalacia results in softer than normal bones and is directly related to calcium deficiencies. Lack of vitamin D is the most common cause of osteomalacia. Vitamin D is synthesized by the body in several steps involving the skin, liver, kidney, and intestine. The kidney, in conjunction with PTH, activates vitamin D. With this deficiency, the intestinal uptake and mobilization of calcium from the bone is altered, resulting in hypocalcemia. This will lead to an increased PTH secretion, which increases the clearance of phosphorus from the kidneys. This resultant decrease in the concentration of phosphorus prevents a normal mineralization process. Anticonvulsant drugs, especially diphenylhydantoin and phenobarbital, may cause drug-induced osteomalacia. Many GI disorders also may result in osteomalacia. Osteoporosis is different from osteomalacia. In osteoporosis the bones become more porous and brittle, whereas in osteomalacia the bones are just softer because of

demineralization caused by the lower levels of phosphorus and calcium.

The oral findings of osteomalacia are usually not dramatic. A decrease in trabecular bone, indistinct lamina dura, and an increase in chronic periodontal disease have been reported. The treatment for osteomalacia is supplemental oral vitamin D (50,000 IU) usually at weekly doses.

Dental Implant Implications. Treatment for osteomalacia is usually successful, with radiographic changes seen months after treatment. There are no known reports of implant complications in osteomalacia patients; however, there is no contraindication as long as the disease is not active and well controlled.

Hyperparathyroidism

Hyperparathyroidism is caused by overactivity of the parathyroid glands. There are four of these tiny glands located just behind/beside the thyroid gland. Primary hyperparathyroidism results when one or more of the glands become hyperactive, which leads to increased levels of PTH. Surgical intervention is usually required. Vitamin D deficiency, kidney failure, and other disease that results in lower calcium levels will cause a secondary hyperparathyroidism. The treatment for this condition is targeted at the secondary cause. The diagnosis is confirmed with an elevated level of intact PTH.

The clinical manifestations of this disease vary widely, depending on the severity. Mild forms may be asymptomatic. Renal colic disorders often occur with moderate disease. Severe hyperparathyroidism can cause bone, renal, and gastric disturbance. It has been noted that when skeletal depletion occurs as a result of stimulation by the parathyroid gland, alveolar bone may be affected before that of the rib, vertebrae, or long bones.

Oral changes related to this disorder occur only with advanced disease. The loss of lamina dura is the most significant finding. Clinically, patients with this disorder develop loose teeth. Altered trabecular bone pattern with the appearance of ground glass may also occur. In animals, secondary hyperparathyroidism affects alveolar bone loss greater than any other bone of the skeleton.[85] Central or peripheral giant cell tumors may also develop.

Dental Implant Implications. Dental implants are contraindicated in areas of active bony lesions. However, implant placement may be initiated after treatment and healing of the affected areas. Medical consultation is highly recommended.

Osteitis Deformans (Paget Disease)

Osteitis deformans, or Paget disease, is a common metabolic disease characterized by slow, progressive, uncontrolled resorption and deposition of bone. This disease is usually seen in Caucasian men older than 40 years. It is estimated that the rates of Paget disease in the United States are approximately 2% to 3% among patients 55 years and older.[86]

The etiology is unknown and usually affects the maxillary alveolar ridge twice as frequently as the mandibular ridge. Because of the enlargement of the middle one-third of the face, the appearance of a "lionlike" deformity is often noted. Diastemas, tooth mobility, and bone pain are additional characteristics. Radiographically, a decreased radiodensity, large circumscribed radiolucencies, patchy areas of coalesced sclerotic bone (cotton-wool appearance), and marrow spaces that are replaced by fibrous tissue are observed. During the active phases of this disease, bone is highly vascular with the possibility of arteriovenous shunts, which may cause hemorrhagic complications.

Paget disease is marked by high elevations of serum ALP, normal or elevated calcium, and normal phosphate levels. Radionuclear bone scans are used to determine the extent of the disease throughout the body. Edentulous patients are often unable to wear their prostheses without discomfort. There is no specific treatment for Paget disease, and these patients are predisposed to develop osteosarcoma and possibly osteomyelitis.

This disease has a wide spectrum of treatment ranging from no treatment to the use of bisphosphonates. For patients who are symptomatic, IV bisphosphonates are usually the preferred treatments. These drugs help decrease further bone breakdown, formation, and remodeling.

Dental Implant Implications

Bleeding. During the active phases of this disease, bone is highly vascular with the possibility of arteriovenous shunts, which may cause hemorrhagic complications.

Infection. Bone areas that are affected by this disorder are predisposed to develop osteosarcoma and possible osteomyelitis.

Treatment Summary

Oral implants are contraindicated in the regions affected by this disorder or in patients on IV bisphosphonates for the treatment of their Paget symptoms.

Multiple Myeloma

Multiple myeloma is a plasma cell neoplasm that originates in the bone marrow and is characterized by the abnormal proliferation of B cells. Multiple myeloma causes severe hypercalcemia, immune suppression, anemia, and thrombocytopenia because it causes widespread bone destruction. The disease is usually found in patients between 40 and 70 years of age. Usually it affects several bones in the body, with symptoms of skeletal pain. Pathologic fractures may occur. Punched-out lesions appear radiographically. Some patients with early disease may not have any symptoms, but there are increasing examples of the first manifestation of multiple myeloma being an oral gingival or mandibular soft mass.[87]

Secondary oral manifestations of the disease are common (80%) and may affect both the maxilla and the mandible. Paresthesia, swelling, tooth mobility, and tooth movement may occur. Gingival enlargements are also possible. The diagnosis is usually determined through both a urine and serum protein electrophoresis test. The presence of light-chain proteins (Bence-Jones) can also be found. In the past the disease was almost always fatal within a short time after being diagnosed. However, there are now more aggressive treatments including improved chemotherapy and stem cell transplants that have prolonged survival. Although it is rarely curable, the disease is now more manageable.

Dental Implant Implications. Dental implants are usually an absolute contraindication in patients with multiple myeloma because of the severity of this disease; however, a case report has described successful implant placement in a patient with this disease.[88] Although the disease is rarely curable, it is now more manageable, and in just the past few years the 5-year survival rate for these patients has doubled. Given the recent success in treating this disease and the longer survival time, new studies will most likely be done to evaluate the use the of dental implants in patients that have undergone successful treatment for multiple myeloma.

Osteomyelitis

Osteomyelitis is an infection with or without inflammation of the bone. Most always the infection is caused by a bacteria or fungi entering the bone. Open wounds or recent surgery around a bone are the most common sources, but an abscessed tooth is also a potential source for the infection. The radiographic appearance is a poorly defined, radiolucent area with isolated fragments of bone (sequestra) that can exfoliate or become surrounded by bone (involucrum). Osteomyelitis in the oral cavity is usually in the mandible and rarely in the maxilla, most likely because of the increased vascularization. This disorder can also be caused by odontogenic and periodontal infections, trauma, dental implants, immunocompromised states, and hypovascularized bone. The treatment includes aggressive surgical drainage, with possible IV antibiotic intervention.

Dental Implant Implications

Implant Placement. Implant placement in surgical sites that have been previously affected with osteomyelitis leads to an increased morbidity. Because of the lack of vascularity, endosseous implants have a greater chance of bone loss, infection, and failure.

Treatment Summary

Osteomyelitis is usually an absolute contraindication unless the etiologic factors are corrected and adequate blood supply to the affected area is restored. A physician clearance should be obtained along with a comprehensive informed consent on the possible complications that may arise from implant placement into these sites.

Osteogenesis Imperfecta

This is a genetic disorder in which bones break with ease many times with almost no apparent cause. Bone quality is poor, with a thin cortical bone and thin, fine trabeculae. Bones are extremely fragile. Some forms are more severe, but overall the disease is relatively rare. However, osteogenesis imperfecta is the most common inherited bone disease. Bone fractures along with skeletal deformities are common, with very poor healing. Histologically, defective osteoblasts lead to a reduction in bone matrix and abnormal collagen.

Dental Implant Implications. Dental implants are not contraindicated; however, caution should be given to the very poor bone quality and questionable osseous healing.

Cemento-Osseous Dysplasia

This disease usually manifests with lesions in the upper and or lower jaw. Normal bone is replaced with bone that is mixed with connective tissue and abnormal bone. Cemento-osseous dysplasia seems to be more common in middle-aged women, with a higher incidence in African American and Asian women. Most of the time, the lesions are symmetric on both sides of jaw. There is variability in shape, size, and number of lesions. The lesions can expand and may cause some pain, but for the most part the disease is asymptomatic. Many times, the diagnosis is found by accident on a radiograph. There are three types of cemento-osseous dysplasia (i.e., focal, periapical cementoma, florid) that can vary radiographically as radiolucent, radiopaque, or a combination. The lesions are usually associated with the mandibular anterior teeth.

Dental Implant Implications. Dental implants are not contraindicated unless in the sclerotic phase of the disease in which the bone is hypovascular. This bone has the ability to become infected

easily, with questionable healing. Special attention must be given so that the disease does not progress to osteomyelitis.

Ectodermal Dysplasia

Ectodermal dysplasia (ED) is a genetically inherited disorder that occurs in 1 per 100,000 live births.[89] Clinically, ED has been divided into two broad categories: an X-linked hypohidrotic form (Christ–Siemens–Touraine syndrome) characterized by the classical triad of hypodontia, hypohidrosis, and hypotrichosis, and by characteristic facial features such as prominent supraorbital ridges and a depressed nasal bridge; and an autosomal inherited hidrotic form (Clouston syndrome), which usually spares the sweat glands but affects teeth, hair, and nails.[90]

In this condition, there is abnormal development of the skin, hair, nails, sweat glands, or teeth. The most common intraoral feature of ED is hypodontia or anodontia. In these patients, conventional prosthodontic procedures often are not successful because of anatomic abnormalities that result in poor retention and stability. Because of this, dental implant therapy aimed at restoring function, esthetics, and psychological rehabilitation is an integral part in the management of adolescent patients with ED. Numerous studies have been completed on dental implants in patients with ED. A 3-year study showed impressive success rates in preadolescents (ages 7–11, 87%), adolescents (ages 12–17, 90%), and adults (older than 17, 97%). Other positive case reports have shown dental implants as a successful adjunct to oral rehabilitation.[91,92]

Dental Implant Implications. Dental implants are not contraindicated in patients with ED. Although not ideal, implants may be placed in preadolescents (i.e., usually anterior mandible), with with functional, esthetic, and psychological advantages. Alveolar bone has been shown to continue to grow after implants have been placed in edentulous ridges of children with ED. Transverse and sagittal growth is not restricted; however, vertical growth may result in submersion of the implants, necessitating prosthetic revision or possible use of longer abutments.

Radiation

Although the survival rate of patients with head and neck cancer has increased over the last 20 years, it still remains one of the deadliest forms of cancer. Aggressive treatment includes surgery, radiation, chemotherapy, or a combination therapy that inevitably leaves the patient with compromised anatomy and physiologic functioning. Patients are left with many deficits including oral mucositis, xerostomia, compromised healing, and reduced angiogenesis. This is a direct result of changes in the vascularity and cellularity of hard and soft tissue, damage to the salivary glands, and increased collagen synthesis that results in fibrosis. Because of these detrimental effects on the bone, wound repair and healing are significantly reduced after surgical procedures. When exposed to high levels of radiation, bone undergoes irreversible physiologic changes that include narrowing of the vascular channels (endarteritis), diminished blood flow, and loss of osteocytes. In time the bone becomes nonvital, which leads to limited remodeling and healing potential.

Dental Implant Implications

Osteoradionecrosis. The most significant risk in placing implants into irradiated bone is osteoradionecrosis (ORN), which is an irreversible devitalization of irradiated bone characterized by necrotic, soft bone that fails to heal properly. The pathophysiologic mechanism is an imbalance in oxygen demand

and oxygen availability, which is caused by endarteritis of the blood vessels. Clinical symptoms include pain, exposed necrotic bone, pathologic fractures, and suppuration. Studies have shown the overall incidence of ORN after radiotherapy to be from 3% to 22%.[93]

Radiotherapy to Previously Placed Implants. There are very few studies on the effects of radiotherapy on preexisting dental implants. Short-term data show very minimal complications and failures. However, in longer-term studies, failure rates seem to be higher.[74] At this time, more studies need to be conducted for conclusive results.

Implant Placement After Radiotherapy. The time between radiotherapy to implant placement seems to affect the prognosis of implants. Most studies have shown that the longer the period for implant placement after radiotherapy, the higher the success rate and the lower the risk of ORN (Box 10.11).[94]

Irradiation Patient Prosthetics. Because of the oral effects of radiotherapy (mucositis and xerostomia), an implant-supported prosthesis (FP-1, FP-2, and FP-3) is recommended over a soft tissue prosthesis (RP-4 and RP-5). This will reduce the possibility of soft tissue irritation associated with postradiotherapy patients wearing removable prostheses.

Past Radiation Treatment. Caution must be emphasized to patients with past radiation therapy because earlier forms of radiation therapy (pre-1980s) were of lower energy, in contrast to current higher energy levels that are less destructive. Because of this lower-energy radiation and associated higher destructive radiotherapy, progressive endarteritis has been shown to take place, which increases over time.[95]

Amount of Radiation Exposure. The presently available literature states that implant placement surgery may be completed on patients who have been irradiated at doses lower than 50 Gy.[96] Unfortunately, very few patients receiving doses greater than 50 Gy have been rehabilitated with implants. Studies have shown that implants placed in patients with a cumulative radiation effect of 18 to 20 (approximately 48–65 Gy standard fractionation) have a rather high success rate. Other reports have shown that doses greater than a cumulative radiation effect of 40 (approximately 120 Gy standard fractionation) exhibit a high degree of failure.[97]

Hyperbaric Oxygen. One treatment proposed to minimize the possibility of ORN is the use of hyperbaric oxygen. Prophylactic hyperbaric oxygen has been advocated to increase oxygen tension in irradiated bone, which will promote capillary angiogenesis and bone formation. Recent data show that oxygen under hyperbaric conditions acts synergistically with growth factors, which stimulates bone growth and turnover and also may act as a growth factor itself. Hyperbaric oxygen also has been shown to act as a stimulator of osseointegration by increasing new bone formation, increasing bone turnover, and increasing the vascular supply to irradiated bone.[98]

Additional Bone Diseases
See Table 10.20.

Systemic Autoimmune Diseases

Autoimmune diseases refer to a group of more than 80 serious, chronic illnesses that can affect almost any organ in the body. Approximately 75% of autoimmune diseases occur in women; these diseases are thought to have a genetic predisposition. However, autoimmune diseases are among the most poorly understood diseases, with symptoms extremely variable among individuals.

Sjögren Syndrome

Sjögren syndrome is an autoimmune disease in which immune cells attack and destroy exocrine glands that produce saliva and tears. This disorder affects an estimated 4 million people in the United States (90% are female), with an average age of onset in the late 40s. The classic symptoms of Sjögren syndrome are xerostomia and xerophthalmia (dry eyes). Because of the xerostomia, patients are more susceptible to decay and the mucous membranes become atrophic and friable. Because of the lack of salivary secretions, complications may arise with the use of a tissue-borne prosthesis.

The healing response and integration of implants has been shown to be successful in patients with Sjögren syndrome.[99] These implant-supported prostheses decrease soft tissue–borne prosthetic sore spots and discomfort.

• BOX 10.11 Treatment Protocol for Implant Placement in Radiation Sites

- For sites that have been previously treated with radiotherapy, the authors recommend referral to a dental school, hospital, or clinic that has experience in treating radiotherapy patients.
- If the clinician has experience or can treat the associated complications, the following is recommended.

Ideal Implant Placement
- Preradiation: More than 14 days before radiation
- During radiation: Absolute contraindication[a]
- Postradiation: <6 month or >24 months—relative/absolute contraindication
- 6 to 24 months: Relative contraindication[b]

[a]Radiation therapy medical consultation, possible >20 years ago referral to cancer institution or hospital treatments, for 90 minutes before placement followed by 10 minutes after placement.
[b]Medical consultation, hyperbaric oxygen, informed consent, aseptic technique (<20 Gy cumulative, approximately <50 Gy technique fractionation).

TABLE 10.20 Additional Bone Disease Responses and Treatment Implications

Positive Response	Treatment Implications
Orthopedic prosthetic device	Antibiotic prophylaxis
Ectodermal dysplasia	Many studies completed showing successful treatment in ectodermal dysplasia patients
Cemento-osseous dysplasia (periapical cemental dysplasia)	Bone quality is questionable because of avascular cementum–like lesions (relative contraindication)
Osteomalacia	Hypomineralized bone, questionable bone quality (relative contraindication)

From Resnik RR, Resnik RJ. Medical/medication complications in oral implantology. In Resnik RR, Misch CE, eds. Misch's Avoiding Complications in Oral Implantology. St Louis, MO: Elsevier; 2018.

Dental Implant Implications

There are no contraindications for dental implants in patients with a history of Sjögren syndrome. However, it is advantageous for the prosthesis to be non–tissue-borne (FP-1, FP-2, FP-3, and RP-4) to minimize soft tissue complications associated with xerostomia.

Systemic Lupus Erythematosus

Systemic lupus erythematosus is a chronic, potentially fatal autoimmune disease in which the immune system attacks cells and tissue in almost any part of the body. There are three main types of lupus in adults. The majority of patients have systemic lupus (eight times higher incidence than other forms) in which the immune system attacks cells and tissue in several areas of the body. In the United States, over 50% of the time, patients with systemic lupus have a major organ such as the heart, lung, kidney, or brain affected. Cutaneous lupus affects only the skin and accounts for a small number of cases (1 of 8). Certain drugs producing symptoms similar to systemic lupus can induce lupus. This category is referred to as drug-induced lupus, and the major contributors are hydralazine, procainamide, and isoniazid. The remaining cases of lupus are neonatal lupus. Lupus occurs in both men and women, but almost 90% of the cases are in women, and most of those cases are women of childbearing age between 14 and 45.[100]

There is no one test to diagnosis lupus. The antinuclear antibody (ANA) test provides some suggestion of lupus; it important to realize that most people with lupus have a positive ANA test, but most people with a positive ANA test do not have lupus. Positive ANA can occur with certain drugs, cancer, and a viral infection. It is interesting to note that those with a positive ANA, but no signs of lupus, may have a false positive test for other diseases like Lyme disease. A positive ANA blood test requires a more sophisticated panel of antibody testing to further differentiate the etiology of the positive ANA and help confirm a diagnosis of lupus. There is no cure for lupus, but symptoms can be controlled in many cases with corticosteroids and immunosuppressive drugs.

Dental Implant Implications

There is no direct contraindication to dental implant treatment in systemic lupus erythematosus patients. However, caution should be taken for possible associated organ damage and the use of high doses of corticosteroids and immunosuppressive drugs, which may contraindicate dental implants in those individuals.

Scleroderma

Scleroderma is a rare, chronic disease characterized by excessive deposits of collagen that causes musculoskeletal, pulmonary, and GI involvement. There are about 75,000 to 100,000 people in the United States that have this disease. The disease is most common in women between the ages of 30 and 50. There are two main types, localized and systemic. Localized scleroderma usually attacks the skin and on occasion the muscle and joints, but it spares the internal organs. These patients usually have discolored patches on the skin (morphea). They can have streaks or bands of thick, hard skin. This is called linear scleroderma and it affects the arms and legs. The more serious type is systemic scleroderma. This form attacks the skin, joints, blood vessels, lungs, kidneys, heart, and other organs and in many cases significantly shortens one's life span. CREST syndrome is a version of systemic scleroderma that manifests as skin thickening in fingers and toes and as calcified nodules under the skin. Raynaud phenomenon is also associated with CREST, as are esophageal motility issues. A blood test for anticentemere antibodies is usually positive in CREST syndrome. There is no cure for scleroderma. Treatment is aimed at the affected organs, including NSAIDs and immunosuppressant drugs. ACE inhibitors are a mainstay of scleroderma affecting the kidney.[101]

Dental Implant Implications

Numerous reports have discussed the successful treatment of scleroderma patients with dental implants. A fixed prosthesis is recommended because of the inability to retrieve a removable prosthesis due to possible dexterity problems. However, a high percentage of these patients are being treated with immunosuppressive drugs, which may contraindicate the implant therapy.

Rheumatoid Arthritis

RA is a chronic, inflammatory autoimmune disease that causes the patient's immune system to attack the muscles and joints of the body. It is more prominent in the early stages in the fingers, wrist, feet, and ankles rather than the larger joints such as the shoulder, hip, or knee. RA is different from osteoarthritis, which is caused by wear and tear and previous injuries. In RA, the disease affects the lining of the joints, which increases pain and swelling and results in significant bone erosion and deformity of the joints. The inflammation in RA can affect other organs in the body. In most cases the affected joints are symmetric, so if one side of the body is affected, then the other side usually will demonstrate similar manifestations. Life expectancy of patients with RA is shortened by approximately 5 to 10 years.[102]

RA is treated with a wide range of medications including disease-modifying antirheumatic drugs, antiinflammatory drugs, and analgesic medications.

Methotrexate, a drug used to treat cancer, is commonly used to treat RA. Studies have shown the detrimental effect of this medication on bone by delaying bone healing. However, other studies have concluded that that low-dose methotrexate treatment does not affect titanium implant osseointegration.[103]

Dental Implant Implications

There is no direct contraindication for dental implants in patients who have RA. Because of the lack of mobility and dexterity, a fixed-implant restoration is indicated. Special attention should be given to the treatment medications because immunosuppressive, glucocorticoid therapy and biologics may contraindicate implant treatment.

Human Immunodeficiency Virus

Human immunodeficiency virus (HIV) is a retrovirus that is responsible for acquired immunodeficiency syndrome (AIDS), which causes the immune system to be depressed, leading to life-threatening opportunistic infections. According to the US government (https://www.hiv.gov), there are more than 1.1 million in the United States living with HIV and almost 1 in 7 may not be aware they have the disease. Just less than 40,000 individuals were diagnosed with HIV in 2016. The number of new HIV infections did decline between 2008 to 2014, but over the past several years an increase in new cases has been seen. It is most common in homosexual and bisexual men.

Initially, most diagnosed with HIV died from the disease, but a lot has changed in the past 20 years. In 1996, the life expectancy for a 20-year-old with HIV increased to almost 39 years. In 2011, the total life expectancy increased to almost 70 years.[104]

There is no cure for either HIV or AIDS; however, revolutionary new antiretroviral medication and protease inhibitors developed since 1996 have now been able to eliminate active viral load titers from the bloodstream. Many patients demonstrate complete suppression of the virus while taking the medication. Although not a cure, the inactivity improves survival and limits the effect on other organs. These newer medications have slowed or even stopped the damage caused by the HIV infection. They also prevent the virus from developing into more virulent forms and attacking other organs in the body. A postexposure prophylaxis (an antiretroviral) has been shown to reduce the risk of infection after exposure.

Dental Implant Implications

Numerous reports have shown successful dental implant therapy in HIV patients.[105,106]; however, there is insufficient data to determine the association between HIV infection and the success of dental implants. Special care must be taken to evaluate the current status of the patient's immune system and the potentially toxic medications the patient is taking.

Miscellaneous

Sleep Apnea

Obstructive sleep apnea (OSA) occurs when there is partial or complete obstruction of the upper airway during sleep. This in turn causes the chest wall muscles and diaphragm to work harder to clear the obstruction. OSA has both significant medical and dental implications. During the period of obstruction, the oxygen levels in the bloodstream decrease, resulting in diminished delivery of oxygen to vital organs, which can precipitate an MI or stroke.

Patients that are obese, have a larger, thicker neck, deviated septum or smaller nasal canals, enlarged tonsils, large uvula, or large tongue may be at increased risk during surgery, especially if sedation is used. There are many symptoms that can be associated with OSA. Daytime sleepiness, early morning headaches, restless sleep, loud snoring, and waking up feeling like one is choking or gasping are some of the more common ones.

One study demonstrated that "among the associated sleep symptoms and disorders OSA was the highest risk factor for tooth grinding during sleep and was reduced with proper treatment."[107] Untreated patients will most likely have increased morbidity, and implants will be subject to higher related mechanical force issues.

The diagnosis of OSA is made through the use of a sleep study. Sleep studies can be done at home or in a sleep clinic. Home sleep studies are better used as screening tools to confirm the diagnosis. To fully evaluate the potential treatment options, a titration study in a sleep laboratory may be required. The test records the number of slower or apneic (stopped breathing) episodes and oxygen saturation in the bloodstream. The test also monitors arm and leg movements. A sleep specialty physician evaluates the test and makes the diagnosis and recommendations for treatment.

Treatment options include continuous positive airway pressure (CPAP). The CPAP machine uses a hose and mask to deliver constant steady air pressure. Newer devices are much more compact, including Federal Aviation Administration (FAA) travel sizes, and are much quieter. Some individuals find these devices cumbersome and uncomfortable and sometimes give up on this treatment method. It is important to ask patients diagnosed with sleep apnea if they are using their CPAP or other treatment on a regular basis. A variation of the CPAP is bilevel positive airway pressure (BiPAP). This machine supplies BiPAP and coordinates more pressure during inhalation versus exhalation. In less severe cases, oral appliances may be a reasonable option and are much easier to use than CPAP. Most open the airway by bringing the jaw more forward. CPAP machines may place an increased force on the implant-related area. Oral airway devices may not be appropriate for patients with more significant apnea.

It is important to remember that OSA is a medical condition that has a complex pathophysiology. It can be seen as a factor in other medical conditions including CHF and asthma. OSA is not limited to just maxillofacial structural abnormalities. The diagnosis goes beyond just a test on the number of apnea-hypopnea spells. The diagnosis must be considered in conjunction with other of the patient's comorbid conditions. OSA should be diagnosed and treated by a physician, and preferably by a sleep medicine specialist.[108]

OSA has been shown to be a secondary cause of hypertension. Apnea creates significant increases in systolic and diastolic pressure, which creates higher blood pressure levels at night. However, this elevation can continue into the daytime. It has been shown that 50% of patients with hypertension may have OSA (p. 20). More important OSA causes more secondary hypertension than any other source. This same study implies that OSA may be one of the modifiable factors to help prevent hypertension. It is reasonable to consider that patients with resistant hypertension may have untreated sleep apnea.[109]

Elderly (Increased Age)

According to WHO, most developed countries have accepted the chronologic age of 65 years as the definition of an elderly or older person. The treatment of elderly patients is definitely challenging, and because more patients are living longer and are more socially active, they will continue to be a significant part of the implant dentist's practice. Studies have shown that elderly patients are more prone to systemic diseases, more medically compromised, have potentially longer healing periods, more challenging bone conditions (quality and quantity), increased susceptibility to drug interactions, and increased dental implant morbidity.

Dental Implant Implications

Decreased Renal Function. There is an age-related decline in renal functions accelerated by comorbid conditions such as hypertension, heart disease, and diabetes. The age-related decline is more physiologic, whereas the pathologic decline is associated with many medical conditions. In elderly patients, the glomerular filtration rate (GFR) and creatine will give insight into the patient's kidney function. As kidney function declines, especially in stage 3 (GFR 30–59) and above, there is a decreased metabolism and excretion of drugs. Therefore the intervals between drug administration should be longer and dosages should be decreased, except for lipid-soluble drugs and antibiotics, to compensate for the increase in body fat and the reduced immune response. In the presence of significant kidney disease (stage 4 or above), antivirals (acyclovir), β-lactams (amoxicillin), and cephalosporins should be reduced. Nonsteroidal analgesics should not be prescribed in those with stage 3 or greater impairment without consultation with the patient's physician. Caution should be exercised with the use of sedation drugs because they can have more pronounced and longer-lasting effects.

Decreased Gastric Motility. The decreased gastric motility of the elderly patient affects the use of oral analgesics such as

hydrocodone and oxycodone. In addition, the use of narcotics in the elderly can cause significant changes in bowel habits, especially constipation. If not contraindicated, a stool softener may be recommended concurrently with use of analgesics. Also, when using antibiotics for any prolonged period, the use of probiotics may help maintain normal gut flora.

Medications. Medications and the number of prescribed drugs usually increase with age, with over 75% of patients 65 years and older taking medications. Many of these drugs are often the cause of adverse or significant drug reactions. Studies have shown more than 70% of drugs taken by elderly patients have potentially adverse effects in the dental practice.[29] Although the incidence of severe drug interactions with commonly prescribed pain medications is relatively low, caution should be used in reviewing the elderly patient's complete medication history before prescribing any analgesics.

Isolated Systemic Hypertension. A major cardiovascular health issue with the elderly is isolated systolic hypertension (ISH). In ISH, systolic blood pressure elevates above 140 mm Hg while the diastolic pressure remains below 90 mm Hg. The difference between the systolic and diastolic is termed the *pulse pressure,* which is a significant risk factor for stroke and heart disease. Recent meta-analysis studies have shown a 10-mm Hg increase in pulse pressure will increase the risk of major cardiovascular events by 20%.[110]

Bone Healing. Clinical studies have shown a direct correlation between delayed bone healing with increasing age. Most likely the etiology results from a reduced number of osteogenic cells and reduced systemic and localized blood flow to the healing site. Therefore longer healing periods along with progressive loading are recommended in older patients.

Bone Quality/Quantity. Both the quality and quantity of bone is affected by aging. Histomorphometric and microradiographic studies have shown that after the age of 50, a marked increase in the cortical porosity leading to decreased bone mass is present. Loss of bone mineral content has been estimated to be approximately 1.5% per year in females and 0.9% in males.[111]

Increased Implant Failure Rate. Studies have shown an increased risk of implant failure as a result of many age-related factors including compromised bone quality and quantity, implant length, treatment protocol, and edentulous locations. Other studies have shown patients older than 60 years were twice as likely to have adverse outcomes.[112]

Prosthetic Treatment. Elderly patients have been shown to have increased difficulty in adapting to the final implant prostheses. Postinsertion issues such as general adaptation, muscle control, hygiene difficulty, tissue inflammation, and overdenture seating were significant in the older population study. Patient education and final expectations should be discussed in detail before initiating treatment.[113]

Treatment Summary. The implant clinician must understand the physical, metabolic, and endocrine changes and the effects associated with the elderly patient before initiating implant treatment. Age is most certainly a prognostic factor in implant failure and morbidity. However, advanced age is not an absolute contraindication to implant therapy. It is imperative that the clinician obtain a detailed medical history and list of medications before devising the dental treatment plan. Patient education along with modification in medication use, surgical technique, soft and hard tissue healing times, and careful assessment of postoperative complications must be strictly enforced.

Adolescent (Decreased Age)

Dental implants are commonly used to correct the congenital absence of teeth in adolescents, and studies have shown this to be a very reliable and predictable treatment option. When a clinician is presented with an adolescent patient, there must be a degree of caution as to the ideal time that implant therapy should be commenced. The concern is that placement of implants too early may lead to the implants interfering with normal growth development and potential esthetic issues. No age-related surgical issues exist unless there are systemic contraindications or psychological issues. If placement of an implant is completed before craniofacial growth is complete, possible interruption of facial growth and esthetic (infraocclusion or labioversion) issues can result.

Dental Implant Implications

Early Consultation. In determining the ideal time for implant placement, the patient/family must be educated on craniofacial growth compared with chronologic age. Chronologic age is a poor indicator of dental development/facial growth; timing of implant placement should coincide with growth cessation.

Determination of Growth Cessation. In the literature, there exist many methods of determining completion of craniofacial/skeletal growth: chronologic age, complete dental development, voice changes, hand–wrist radiographs, cervical vertebral maturation, and superimposition of lateral cephalometric radiographs. The most reliable and safest (no radiation exposure) method has been shown to be when the patient begins to exhibit a lack of growth in stature (0.5 cm/year). When implants are treatment planned in adolescents, clinicians must take into consideration the timing, site development, esthetics, and possible prosthetic limitations including malposition that may develop with age. Most importantly, the determination of growth cessation should be determined by the lack of growth in stature. This method involves no radiographs (decreased radiation exposure) and is the most benign method. The patient's pediatrician should be consulted in the determination of growth cessation (Fig. 10.3).

Smoking

In the United States, an estimated 42.1 million people, or 18.1% of all adults (age 18 years or older), smoke cigarettes. Overall, smoking prevalence has declined from 2005 (20.9%) to 2012 (18.1%); however, tobacco is still the most preventable cause of death and disease in the United States.

Smoking has been directly related to many oral diseases including periodontal disease, malignancies, and dental implant–related complications. Studies have shown that over 7000 different gases and chemicals are found in cigarette smoke (e.g., nitrogen, carbon monoxide, carbon dioxide, ammonia, hydrogen cyanide, benzene, nicotine). In tissues, carbon monoxide displaces oxygen from Hb molecules because of its stronger affinity.[114] Hydrogen cyanide has been shown to cause hypoxia in tissues. The adverse effects that smoking has on successful outcomes in implant surgery are well documented. Multiple retrospective studies have shown that smokers experienced almost twice as many implant failures compared with nonsmokers.[115]

Dental Implant Implications

Increased Incision Opening. Studies have shown that smoking is directly related to increased incision line opening. Possible mechanisms for poor wound healing include the vasoconstrictive nature of nicotine; increased levels of fibrinogen, Hb, and blood viscosity; increased platelet aggregation; and impaired polymorphonuclear neutrophil leukocyte function.[116] Therefore additional sutures along with tension-free closure are recommended.
• **Fig. 10.3** Growth cessation chart. Consultation with the patient's pediatrician should be completed to ascertain growth cessation, which usually coincides with <0.5 cm of growth in stature *(arrows).*

Infection. Tobacco smoke decreases polymorphonuclear leukocyte activity, resulting in lower motility, a lower rate of chemotactic migration, and reduced phagocytic activity. These conditions contribute to a decreased resistance to inflammation and infection.[117]

Implant/Bone Grafting Failure. Meta-analysis studies have shown a definite correlation between smoking and failure rates of implants and bone grafts.

Peri-implantitis. Studies have shown in smokers a strong correlation between peri-implantitis and dental implants.

Informed Consent. With the possible detrimental effects of smoking on implants, it is recommended that patients be informed in detail about the risks of smoking. These possible consequences include increased marginal bone loss after implant placement and the presence of peri-implantitis. Additionally, there is a direct effect on the success rates of bone grafts, with almost double the failure rate in implants placed in grafted maxillary sinuses.

Smoking Cessation. A strong recommendation on smoking cessation before and after implant surgery is recommended because it has been shown to decrease implant morbidity.[118] Ideally, the patient is instructed to cease smoking for 2 weeks before surgery to allow for reversal of increased blood viscosity and platelet adhesion. Smoking cessation is continued for 8 weeks after implant surgery, which coincides with the osteoblastic phase of bone healing.[119] This has been shown to increase wound healing capabilities and reverse subgingival microflora[120] (Table 10.21).

Ideally, smoking cessation should be a gradual process because withdrawal symptoms are less severe in patients who quit slowly. There exists the concept of the "five As" in smoking cessation:
1. Ask: All patients should be asked about possible tobacco use.
2. Assess: Determine whether the patient has ever quit smoking or is interested in smoking cessation.
3. Advise: Every smoking patient should be advised of complications that may arise from continued smoking.
4. Assist: The smoking patient must be instructed on ways to quit smoking or be given a relevant physician referral.
5. Arrange: Make arrangements to evaluate the success of the smoking cessation.[121]

Treatment Summary

Any amount of smoking: Relative contraindication
Excessive smoking (>1.5 packs/day): Absolute contraindication until smoking sessation

Alcohol

Ethyl alcohol is one of the most widely used mood-altering drugs in the world. Approximately 17 million adults aged 18 and older have an alcohol use disorder. This is more common in men than women. Many with alcohol dependence disorders go undiagnosed. Because of the adverse effect of alcohol on dental implants, screening for undiagnosed alcohol-related disorders

TABLE 10.21	Smoking Cessation Techniques		
Technique	**Instructions**	**Possible Side Effects**
Nicotine gum (Nicorette)	Chewing gum that releases nicotine	TMJ, gastric irritation, difficulty for patients wearing removable prostheses
Nicotine inhaler (Nicotrol inhaler)	Puffing for approximately 20 minutes/hour	Dizziness, nausea/vomiting, confusion, blurred vision, palpitations
Nicotine lozenge (Nicorette)	Dissolving	Dizziness, nausea/vomiting, confusion, blurred vision, palpitations
Nicotine nasal spray (Nicotrol)	1–2 doses per hour for 2 months	Nasal mucosa irritation, dizziness, nausea/vomiting, confusion, blurred vision, palpitations
Nicorette microtab sublingual tablets	1–2 tabs hourly	Dizziness, nausea/vomiting, confusion, blurred vision, palpitations
Nicotine patch (Nicoderm CQ)	Worn during day	Skin irritation, dizziness, nausea/vomiting, confusion, blurred vision, palpitations
Rx medication: bupropion SR (Zyban), varenicline tartrate (Chantix)	As directed	Bupropion SR: dry mouth, nausea, headache, dizziness, changes in appetite, weight loss or gain, worsening of anxiety, insomnia Varenicline tartrate: chest pain, dizziness, severe headache, easy bruising, vivid nightmares, sleep disturbance
Hypnosis	Mixed results supporting effectiveness	N/A
Acupuncture	Mixed results supporting effectiveness	N/A

TMJ, Temporomandibular joint dysfunction.

is beneficial. Excessive alcohol intake has been associated with surgical and dental implant-related issues such as liver and metabolic dysfunction, bone marrow suppression resulting in bleeding complications, predisposition to infection, and delayed soft tissue healing.[122]

Dental Implant Implications

Bleeding Problems. Alcohol interferes with coagulation on multiple levels, leading to decreased platelet production (thrombocytopenia), impaired platelet function (thrombocytopathy), and diminished fibrinolysis. Patients who abuse alcohol are more susceptible to intraoperative and postoperative bleeding complications associated with dental implant surgery.

Infection. Alcohol use leads to significant alterations of cell-mediated immune systems. Alcohol-induced immunosuppression results in a decrease in delayed-type hypersensitivity (DTH), which is a preoperative indicator for postoperative infectious complications.[123] Therefore patients consuming alcohol (especially those who consume it immediately after surgery) are more susceptible to incision line opening and infection.

Increased Bone Loss. Alcohol use also leads to decreased bone formation, increased resorption, and decreased osteoblast function, resulting in decreased bone density and integration issues. The use of alcohol has a direct effect on dental implant healing; studies have shown greater marginal bone loss and implant failure associated with alcohol consumption.

Informed Consent/Decrease Comorbidities. The patient must be well informed of potential consequences of alcohol use, especially immediately after implant surgery.

Cessation Program. Abstinence can reverse many of alcohol's effects on hematopoiesis and blood cell functioning; the patient should be instructed on possible cessation treatments and programs. Ideally, patients should refrain from using alcohol for a minimum of 2 weeks or after incision line closure occurs.

Psychological

Providing dental implant care to patients with psychological problems is very challenging for clinicians. This group of patients is prone to oral health issues because of poor oral hygiene, poor compliance, and adverse medication effects. Providing comprehensive dental implant care to patients requires good communication skills, perseverance, and flexibility in both the surgical and prosthetic phases of treatment. Additionally, many of the drugs used to treat these patients, including tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), and monoamine oxidase inhibitors, are associated with many drug interactions. Oral manifestations of these diseases and medications include an increase in caries and periodontal disease, increased smoking, xerostomia, chronic facial pain, parafunction (bruxism/clenching), and temporomandibular joint dysfunction.

Dental Implant Implications. Many psychotherapeutic drugs interact with medications that are commonly prescribed in implant dentistry. Clinicians must be aware of drug–drug and drug–disease interactions with respect to the patient's medical history. Most interactions are related to the potentiation of the sedative and anticholinergic actions of the psychotherapeutic drugs. It is important to identify patients taking monoamine oxidase inhibitors or tricyclic antidepressants. Although these are no longer the mainstay of treatment for psychiatric illness, many patients will be placed on these medications to potentiate the effect of other medications. Common examples include amitriptyline, doxepin, nortriptyline, and imipramine. These medications are also being used to treat nonpsychiatric illnesses such as chronic pain and sleep disorders. The main concern is

TABLE 10.22	Medications Linked to Drug-Induced Osteonecrosis of the Jaw			
Drug	**Classification**	**Use**	**Dose**	**Route**
Alendronate (Fosamax)	Bisphosphonate	Osteoporosis	70 mg/week	Oral
Risedronate (Actonel)	Bisphosphonate	Osteoporosis	35 mg/week	Oral
Ibandronate (Boniva)	Bisphosphonate	Osteoporosis	150 mg/month	Oral
Zoledronate acid (Reclast)	Bisphosphonate	Osteoporosis	5 mg/year	IV
Zoledronate acid (Zometa)	Bisphosphonate	Osteoporosis	4 mg/month	IV
Pamidronate (Aredia)	Bisphosphonate	Osteoporosis	90 mg/month	IV
Denosumab (Prolia, Xgeva)	Monoclonal antibody	Osteoporosis, cancer	60 mg/6 months	Subcutaneous
Bevacizumab (Avastin)	Monoclonal antibody	Metastatic cancer	100–400 mg/14 days	IV
Sunitinib (Sutent)	Tyrosine kinase inhibitor	Cancer	5 mg/year	IV
Etidronate (Didronel)	Bisphosphonate	Paget disease	300–750 mg/6 months	Oral
Tiludronate (Skelid)	Bisphosphonate	Paget disease	400 mg daily/3 months	Oral

IV, Intravenous.

the interaction of tricyclic medications and epinephrine because they produce anticholinergic effects on the heart. There is no contraindication to using them together, but patients should be followed more closely for adverse interactions. A physician consult and the implementation of a stress reduction protocol are recommended steps to follow when initiating treatment with these patients.

Medications of Interest to Implant Dentistry

Bisphosphonates

Since the first reported cases of necrotic, exposed bone in patients taking bisphosphonates, there has been much debate over treatment implications regarding dental implants. Bisphosphonates are a group of drugs that are widely used for several bone disorders and have been approved by the FDA for treatment of osteoporosis, metastatic bone cancer, and Paget disease. However, what was once termed bisphosphonate osteonecrosis has now been renamed drug-induced or medication-induced osteonecrosis of the jaws (DIONJ) by the American Medical Association. This has been renamed because of the incidence of osteonecrosis cases involving additional drug classifications such as monoclonal antibody drugs, antiangiogenic drugs, and tyrosine kinase inhibitors (Table 10.22).

Bisphosphonates are mainly used for the treatment of osteoporosis (oral form) and metastatic cancer (IV form) by inducing osteoclastic death or apoptosis at the cellular level. As an osteoporosis drug, bisphosphonates reduce bone resorption via a direct effect on the osteoclast. In osteoporotic patients undergoing bisphosphonate treatment, old bone is retained because bone turnover is suppressed, preventing normal remodeling in this area, which results in the formation of brittle bone. Additionally, bisphosphonates kill functionally resorbing osteoclasts not only at the peripheral sites but also in the bone marrow.

Diagnosis of Drug-Induced Osteonecrosis of the Jaw

Marx has defined characteristics of patients who are diagnosed as having drug-induced osteonecrosis of the jaw (DIONJ). These characteristics include (1) current or previous treatment with a systemic drug that affects bone homeostasis, (2) exposed alveolar bone in the jaws that persists for more than 8 weeks, (3) no history of radiotherapy to the jaws, and (4) no known diagnosis of osteopetrosis or cemento-osseous dysplasia. The definitive symptom of DIONJ is bone exposure in the mandible or maxilla that does not heal. Pain and inflammation are present, with possible secondary infection of the soft tissue. In severe cases, drainage and progressive extension of bone involvement or sequestration result.[124]

Active Lesions

Osteonecrosis may remain asymptomatic for weeks and possibly months. Lesions usually develop around sharp, bony areas and previous surgical sites, including extractions, retrograde apicoectomies, periodontal surgery, and dental implant surgery. Symptoms include pain, soft tissue swelling, infection, loosening of teeth, and drainage. Radiographically, osteolytic changes are seen, and tissue biopsy has shown the presence of actinomyces, which is possibly caused by secondary infection.

Testing

C-Terminal Telopeptide Test (CTx). It has been proposed that assays to monitor markers of bone turnover may help in the diagnosis and risk assessment of developing bisphosphonate-associated osteonecrosis. CTx are fragments of collagen that are released during bone remodeling and turnover. Because bisphosphonates reduce CTx levels, it is believed that serum CTx levels can be a reliable indicator of risk level. The CTx test (also called C-terminal telopeptide and collagen type 1 C telopeptide) is a serum blood test obtained by laboratories or hospitals (ICD-9 diagnostic code 733.40). However, today, the use of the CTx test to determine the possibility of osteonecrosis is controversial.[125,126]

CTx Value	Risk for Drug-Induced Osteonecrosis of the Jaw
300–600 pg/mL (normal)	None
150–299 pg/mL	None to minimal
101–149 pg/mL	Moderate
Less than 100 pg/mL	High

Drug Holiday. Marx has suggested a preoperative protocol for administering possible DIONJ drugs to patients who are undergoing oral surgical procedures. This protocol takes into consideration the type and duration of drug use and radiographic and clinical risk factors. Depending on the laboratory values obtained, a "drug holiday" may be indicated, which includes temporary interruption of bisphosphonate treatment. However, improvement of bisphosphonate levels may not be observed, because measurable levels have been shown to persist in bone for up to 12 years after cessation of therapy.

Drug Holiday Recommendation[125]

Presurgical: Medication stoppage 9 months before surgery
Postsurgical: Medication stoppage 3 months after surgery

Additional Recommendations

Medical History. A comprehensive medical history is essential before any elective treatment is initiated. The most important history of bisphosphonates is the use of IV nitrogen-containing bisphosphonates such as pamidronate (Aredia) and zoledronic acid (Zometa) and new osteoporotic drugs, which have very limited data on the association with DIONJ. In the dental setting, the most common bisphosphonates that implant dentists are exposed to will most likely belong to the family of oral nitrogen-containing bisphosphonates such as risedronate, ibandronate, and alendronate. The latest studies show that oral bisphosphonates have a very low probability of causing osteonecrosis.[127] However, because of the long half-life and short duration of the studies, future long-term complications may become problematic. With this in mind, the implant dentist should be cautioned regarding the possibility of developing osteonecrosis side effects. The risks versus benefits of dental treatment must be discussed with the patient in detail. A well-documented consent form is recommended with possible medical consultation if the patient has been on this medication for more than 3 years.

Reclast. As stated previously, most drugs used to treat osteoporosis are oral, nitrogen-containing bisphosphonate drugs. Reclast (IV: Zoledronate) is given in 5-mg IV doses once a year. Studies have shown that a significant risk occurs after the fourth yearly dose, which is caused by the accumulation of the medication and its 11-year half-life. Elective dental implant surgery or bone graft surgery are best scheduled 9 months after the most recent Reclast dose and 3 months before the next planned dose. However, at this time, very little research has been conducted on the relationship between Reclast and DIONJ. The FDA has placed a warning on the Reclast package inserts that states, "avoid having any type of dental surgery while you are being treated with Reclast." Therefore patients under treatment with Reclast should not be considered for elective dental implant surgery.

Comorbidities. Comorbidities are systemic diseases, medical conditions, medications, gender, and age, all of which can predispose the patient to a greater chance of developing DIONJ. Many chemotherapeutic drugs, diabetes, immune diseases, anemia, smoking, obesity, female gender, and renal dialysis have been noted as comorbidities for DIONJ. Additionally, the use

• BOX 10.12 Bisphosphonate Protocol and Suggestions[a]

ORAL BISPHOSPHONATE
Use <3 Years:
1. Proceed with surgery with detailed oral and written informed consent for bisphosphonate-associated osteonecrosis and possible decreased implant healing.
2. Decrease co-morbidities: periodontal disease, infections, smoking, etc.
3. Strict adherence to antibiotic prophylaxis and antimicrobial use (0.12% chlorhexidine)
4. No prophylactic corticosteroids
5. Elective: CTx Test or Drug Holiday
*Early learning curve: Referral

Use >3 Years
1. Proceed with surgery with detailed oral and written informed consent for bisphosphonate-associated osteonecrosis and possible decreased implant healing.
2. Decrease co-morbidities: periodontal disease, infections, smoking, etc.
3. Medical Clearance
4. Strict adherence to antibiotic prophylaxis and antimicrobial use (0.12% chlorhexidine)
5. No prophylactic corticosteroids
6. CTx Test (>150 pg/mL) or Drug Holiday
*Early learning curve: Referral

Drug Holiday (by physician only)
9-month presurgical + 3 month post-surgical

Laboratory Risk Assessment

CTx Value (pg/mL)	Risk for Osteonecrosis
300–600 (normal)	None
150–299	None to minimal
101–149	Moderate
<100	High

IV BISPHOSPHONATE
Absolute Contraindication

[a] Marx RE: Oral and intravenous bisphosphonate-induced osteonecrosis of the jaws: history, etiology, prevention, and treatment. *Chicago, IL: Quintessence; 2007.*

---

of glucocorticosteroids may be contraindicated in patients taking the DIONJ medications discussed previously because these drugs have been associated with an increased occurrence of osteonecrosis.

Treatment Summary

Oral bisphosphonates: Relative contraindication (informed consent, good surgical technique, CTx test, drug holiday)

IV bisphosphonates: Absolute contraindication (Reclast: absolute/relative contraindication depending on physician clearance) (Box 10.12).

New Therapies for Osteoporosis

Monoclonal Antibodies

Monoclonal antibodies work by inhibiting receptor activator of nuclear factor κ-B (RANK) ligand, which is a type II membrane protein that acts as a primary signal for bone removal. Monoclonal antibodies have a direct effect on the immune system and

control bone regeneration and remodeling. These drug molecules irreversibly bind to mineral matrix in bone and have a half-life of approximately 26 days, which is much shorter than bisphosphonates (11 years).

Denosumab (Prolia) is a biyearly subcutaneous injection for the treatment of osteoporosis. This is a human monoclonal antibody that functions as a RANK ligand inhibitor. Inhibition of the RANK ligand results in diminished osteoclast functional and bone resorption. Denosumab recognizes the specific protein that normally activates osteoclasts, inhibiting their activation and preventing them from breaking down bone. Denosumab has also been used to treat metastatic bone disease. These inhibitors do not bind to bone, and their effect on bone remodeling decreases after treatment is stopped. Prolia has a short half-life (26 days) and does not accumulate in the bone like bisphosphonates. It has been shown to be completely inert within 6 months of administration.[128] Osteonecrosis of the jaw has been observed in patients receiving denosumab, and all patients should receive an oral examination before therapy. The risk of developing osteonecrosis of the jaw is less studied compared with the bisphosphonates; however, this has been shown to be a relevant concern.[129]

Immunosuppressive Drugs

Immunosuppressive drugs are medications that are used to inhibit or prevent activity of the immune system. They are usually used to minimize rejection of transplanted organs and tissues and for treatment of autoimmune diseases. These drugs have many side effects, with the majority of them acting nonselectively (acting on normal cells also). There are many classes of immunosuppressive drugs including corticosteroids, calcineurin inhibitors, mTOR inhibitors, IMDH inhibitors, biologics, monoclonal antibodies (Box 10.13).

Glucocorticoids (Long-Term Use)

Glucocorticoids have potent antiinflammatory and immunosuppressive properties. Because these drugs are widely used in the treatment of inflammatory and autoimmune diseases, special attention must be given to patients who are on long-term high doses of glucocorticoids. These drugs impair many healthy anabolic processes in the body and suppress the immune system, which can lead to severe complications in dental implant patients. The long-term use has been shown to have deleterious effects on bone remodeling and repair.

Cytostatics

Cytostatics are common medications in the treatment of malignant disease. These drugs cannot discriminate between malignant and normal tissues and become cytotoxic to normal tissue. Most chemotherapeutic agents are known to have cytotoxic effects on bone, especially on grafted bone in which the blood supply is compromised. Because chemotherapeutic agents have a high affinity for cells that have a high turnover rate, the oral mucosa is often affected. These mucosal ulcerations can become secondarily infected.

Several studies have shown that cyclosporin may negatively influence bone healing around dental implants and may even impair the mechanical retention of dental implants previously integrated in bone.[130]

• BOX 10.13 Immunosuppressive Drugs

Corticosteroids
- Prednisone (Deltasone, Orasone)
- Budesonide (Entocort EC)
- Prednisolone (Millipred)

Calcineurin Inhibitors
- Cyclosporin (Neoral, Sandimmune, SangCya)
- Tacrolimus (Astagraf XL, Envarsus XR, Prograf)

mTOR Inhibitors
- Sirolimus (Rapamune)
- Everolimus (Afinitor, Zortress)

IMDH Inhibitors
- Azathioprine (Azasan, Imuran)
- Leflunomide (Arava)
- Mycophenolate (CellCept, Myfortic)

Biologics
- Humira (Adalimumab): Rheumatoid arthritis, Crohn's disease, ulcerative colitis, psoriatic arthritis, ankylosing spondylitis
- Remicade (Infliximab): Rheumatoid arthritis, Crohn's disease, ulcerative colitis, psoriatic arthritis, ankylosing spondylitis
- Enbrel (Etanercept): Rheumatoid arthritis, psoriatic arthritis
- Herceptin (Trastuzumab): HER2+ breast cancer
- Lucentis (Ranibizumab): Age-related macular degeneration
- Avonex (Interferon beta-1a): Multiple sclerosis
- Glatiramer acetate (Copaxone): Multiple sclerosis
- Brodalumab (Siliq): Psoriatic arthritis
- Ixekizumab (Taltz): Psoriatic arthritis
- Secukinumab (Cosentyx): Psoriatic arthritis, ankylosing spondylitis
- Ustekinumab (Stelara): Psoriatic arthritis, Crohn's disease

Monoclonal Antibodies
- Basiliximab (Simulect)
- Daclizumab (Zinbryta)
- Muromonab (Orthoclone OKT3)

Tamoxifen

Tamoxifen is a standard treatment for hormone receptor–positive breast cancer in premenopausal women. Because tamoxifen mimics the effects of estrogen, it has a very beneficial side effect that preserves bone mass and prevents bone loss. However, there exist drug-induced osteonecrosis concerns with the administration of this drug, even though there is a very low prevalence.[131]

Aromatase Inhibitors

In postmenopausal women diagnosed with estrogen receptor–positive breast cancer, aromatase inhibitors (AIs) are the mainstay of adjuvant therapy. These medications inhibit the conversion of androgens to estrogens, which results in estrogen deficiency and may accelerate bone loss. There has been an association with an increase in drug-related osteonecrosis of the jaws with this class of medications.[132] However, in patients on AIs, the incidence of osteonecrosis is still significant, and consultation with the treating physician should be considered in these patients.

Treatment Summary of Immunosuppressive Drugs

Most immunosuppressive medications affect the entire immune system, having a higher incidence of adverse effects (e.g., bone

marrow suppression leukopenia, thrombocytopenia, anemia). Therefore patients are susceptible to increased infectious episodes, intraoperative bleeding, and compromised bone healing. A medical consult and evaluation are highly recommended before any proposed implant treatment. For most immunosuppressive drugs, concurrent use and the placement of implants are an absolute contraindication. Additionally, patients on long-term corticosteroid use should be evaluated for possible adrenal insufficiency symptoms.

Past immunosuppressive therapy: Relative contraindication after medical consultation
Concurrent immunosuppressive therapy + implant therapy: Absolute contraindication

Biologics

A newer class of therapeutic drugs is termed *biologics*, and it is used to treat an array of medical conditions such as autoimmune diseases and cancers. Biologics use living organisms (genes) and are manufactured by using recombinant DNA technology in the form of vaccines, antitoxins, growth hormones, gene therapy, and recombined proteins and allergens. Biologic medications are advantageous because they specifically target cells that are involved in the pathogenesis of the disease. Some of the most common biologics used today are tumor necrosis factor-α (TNF-α) inhibitors Cimzia (certolizumab pegol), Enbrel (etanercept), Humira (adalimumab), Remicade (infliximab), and Simponi (golimumab). These drugs block the protein TNF-α that stimulates the body to initiate the inflammation process. In conditions such as psoriasis and psoriatic arthritis, TNF-α is produced in excess in the skin and joints, which stimulate accelerated growth of skin cells and may damage joint tissue. Blocking TNF-α stops the inflammatory cycle. Other biologics include the following:

Interleukin (IL)-12 and IL-23 inhibitors Stelara (ustekinumab): These drugs work by specifically targeting IL-12 and IL-23, which create inflammation.
IL-17 inhibitors Cosentyx (secukinumab) and Taltz (ixekizumab): These drugs block IL-17, which is involved in inflammatory and immune responses; Siliq (brodalumab) blocks the receptor for IL-17, which then inhibits the inflammatory process created by IL-17.
T-cell inhibitors Orencia (abatacept): These drugs target T cells, which are involved in the immune and inflammatory response. Blocking T-cell activation leads to reduced inflammation.

Common Disorders Using Biologics for Treatment

Age-Related Macular Degeneration

Age-related macular degeneration (AMD) is an incurable disease that is the most common cause for blindness in the United States. The macula is the central portion of the eye, which is responsible for the central vision in reading, driving, recognizing color, and seeing objects in fine detail. Over 11 million people in the United States have some form of AMD. This number is expected to double to nearly 22 million by 2050. Worldwide the number may exceed 200 million by 2020 and approach 300 million by 2040. Advancing age is the greatest risk factor. In those less

than 59, the risk is only about 2%, but the risk is 30% for those over age 75.[133] A newer, more aggressive treatment option to slow the progression of AMD is to inject medications that block vascular endothelial growth factors (VEGFs). With AMD, abnormally high levels of VEGF may be found that can be reduced by injections with anti-VEGF medications such as Lucentis (ranibizumab). These intraocular injections, which may be administered multiple times a month, have been linked to a significant increase in nonocular hemorrhagic events. This may include bruising, GI hemorrhages, formation of hematomas, and subdural hematomas. Despite being injected directly into the eye intravitreally, anti-VEGF agents have demonstrated high levels in the bloodstream. This provides the basis for the potential occurrence of significant systemic adverse events.[134]

Psoriatic Arthritis

Psoriasis is an autoimmune disease that usually affects the skin. Approximately 33% of patients with psoriasis may develop a very painful form of debilitating inflammatory autoimmune arthritis called psoriatic arthritis. The body's immune system attacks healthy tissue mostly in the skin as well as the joints. This defective process creates inflammation that leads to joint pain with swelling and stiffness. Psoriatic arthritis is usually treated very aggressively to avoid permanent joint damage. In most patients, skin symptoms develop before joint problems. This disease most prevalently affects people who have psoriasis and are 30 to 55 years of age. There exist multiple forms including the following:

Symmetric psoriatic arthritis: This makes up about half of the cases of psoriatic arthritis. This creates symptoms in the same joints on both sides of the body simultaneously. This type is very similar to RA.
Asymmetric psoriatic arthritis: A milder form that affects about 35% of patients with psoriatic arthritis but does not appear in the same joints on both sides of body.
Spondylitis: This form creates pain and stiffness in neck and spine.
Distal psoriatic arthritis: The inflammation in this form occurs near distal portion of fingers and toes, and there can be changes in the toenails and fingernails, including lifting from the nail bed and pitting.
Arthritis mutilans: This is only about 5% of the cases and is the most severe. In this form, the inflammation is more aggressive, causing destruction and deformities of the distal joints in the finger and toes.
Ankylosing spondylitis (AS): This is a form of arthritis that primarily creates pain in the lower lumbosacral area of the spine, but it can also affect the ribs, hips, knees, feet, eyes, and bowel. There is a genetic predisposition to development of this disease, and the main gene associated with this condition is *HLA-B27*. Frequently, patients are given steroids and/or methotrexate to treat the symptoms. New treatment options include biologics.

Rheumatoid Arthritis

See "Autoimmune" section.

Polymyalgia Rheumatica

Polymyalgia rheumatica (PMR) is an autoimmune inflammatory disease that directly affects the muscles and joints, mainly in the shoulders and hips. The disease also causes muscle pain and stiffness in the neck, buttocks, and arms. Most of patients diagnosed

with PMR are over 50, and the average age is about 70. Onset of symptoms can be abrupt without warning and is usually bilateral. One of the most common complaints is that patients have trouble raising their arms above their shoulders and have aching in joints including the hands and wrists. The stiffness is always worse after prolonged sitting, sleeping, or inactivity. There is no joint swelling. There is no specific test that confirms the diagnosis. Almost all patients with the shoulder and other symptoms have elevated inflammatory markers including elevated sedimentation rate and C-reactive protein. Treatment many times includes steroids, methotrexate, and various biologics.

Eczema (Atopic Dermatitis)

Eczema is a dermatitis that causes dry, itchy, inflamed patches of skin. The etiology of eczema is not fully understood, but it is related to an overactive immune system that many times can be associated with other allergy type symptoms and asthma. There are several types of eczema. (1) Contact dermatitis is caused by contact with chemicals, soaps, plants, or other irritants. (2) Dyshidrotic dermatitis, which is more common in women, affects fingers, the bottom of the feet, and palms. This condition causes itchy, inflamed patches of skin that become erythematous, cracked, and eventually painful. (3) Nummular dermatitis is more prevalent in the winter, with round dry patches mostly on the legs. (4) Seborrheic dermatitis causes scaly, red flaky rashes mostly in the scalp or around the eyes. It can also be seen on the sides of the nose or behind the ears.

For the most part, eczema has been treated with topical steroids, which have very little effect on dental implant surgery. However, recently new biologics have been introduced to treat eczema. Dupixent (dupilumab) is the first biologic medication used to treat eczema. Dupixent works by blocking interleukins from attaching to cell receptors. Interleukins help the immune system combat infection, but when the immune system becomes dysfunctional, the interleukins can cause immune disorders such as eczema. The injection schedule for Dupixent is usually every 2 weeks.

Multiple Sclerosis

Multiple sclerosis (MS) is a chronic disease of the CNS that results in damage to the nerves in the brain, spinal cord, and optic nerves. Symptoms can be mild to severe, from numbness in extremities to complete paralysis or even vision loss. There are over 400,000 people in the United States that have MS. Each year approximately 10,000 new cases are diagnosed. It is over twice as prevalent in women as men, and the diagnosis is usually made after age 20 and before age 50.

Nerves rely on myelin to successfully transmit electrical impulses. MS attacks the myelin sheath, resulting in damage to the nerves and resulting in plaques or lesions that can show up on imaging such as magnetic resonance imaging (MRI). As the nerves lose myelin, impulses from the brain are no longer transmitted to the muscle, causing the symptoms of MS.

Most of the cases of MS are relapse–remitting, which results in new attacks with increasing symptoms, but there are periods of remittance with the periods of relapse. Progressive MS does not have any relapse or remissions; symptoms worsen progressively. These symptoms include muscle weakness, vision problems, coordination and balance issues, memory issues, and numbness in extremities. Difficulty emptying the bladder, constipation, fatigue, dizziness, and muscle spasms are also common symptoms. The exact cause in unknown, but MS is thought to be an autoimmune disorder. There are almost a dozen drugs approved to treat MS, and the most common biologics are Avonex (interferon beta-1a) and glatiramer acetate (Copaxone).

Fibromyalgia

Fibromyalgia causes diffuse musculoskeletal pain accompanied by exhaustion/fatigue, sleep disturbances, mood swings, and sometimes memory issues. Although the etiology of fibromyalgia is unclear, many researchers believe there exists a dysfunctional amplification of pain sensation by the brain, which results in the patient being more sensitive to pain. The disease is much more common in women than men and there is no real cure; however, the symptoms may be treated. Most of the treatment involves relaxation, stress reduction techniques, and exercise. In the United States, fibromyalgia affects about 4 million, or about 2% of the adult population. Although there is no specific test for fibromyalgia, the diagnosis is usually made by combining a detailed history and physical with laboratory and radiologic evaluation.[135] Duloxetine (Cymbalta) and other SSRIs are common treatment options for fibromyalgia. Tricyclic antidepressants like amitriptyline (Elavil) and nortriptyline (Pamelor) are used to help treat fatigue and sleep disturbances. The greatest concern regarding tricyclic antidepressants in implant dentistry is the production of anticholinergic actions on the heart. Epinephrine and levonordefrin are not contraindicated in these patients, but they should be used cautiously. For example, heart rate and blood pressure should be reassessed after each 20- to 40-μg dose of epinephrine administered.[136] Muscle relaxants like cyclobenzaprine, tizanidine, or carisoprodol (Soma) are used to help relieve the muscle pain. These drugs can cause xerostomia. Of greatest concern for dental implant patients is the potential for chronic pain after the implant surgery. There are numerous studies demonstrating chronic persistent pain after dental implant surgery without any neurosensory deficits or evidence of an organic cause. Dental implant surgeons need to take this potential postsurgical complication into consideration when determining whether patients are candidates for implant treatment.[137]

Breast Cancer

The American Cancer Society estimates just over 250,000 new cases of invasive breast cancer will be diagnosed in the United States in 2018. In addition, about 64,000 cases of carcinoma in situ (CIS), which is the earliest form of breast cancer, will be also diagnosed. About 41,000 women will die of breast cancer this same year. The incidence of breast cancer has been stable over the past couple of years, but it remains more common in African American women. Breast cancer remains the second leading cause of cancer death in women, and rates from 1989 to 2015 have dropped almost 40%. Since 2007, deaths from breast cancer have continued to drop in women over age 50. There are currently about 3.1 million breast cancer survivors in the United States, including those that are still being treated.[138]

It is important to recognize that women with breast cancer may be considered cancer free after treatment but, for up to 10 years after the diagnosis, patients may be taking adjuvant therapy (treatment given after chemotherapy and surgery) with medications that could affect dental implant success. This therapy is targeted for hormone receptor–positive breast cancer (the most common type of breast cancer). Approximately 75% of breast cancers express the estrogen and/or progesterone receptors (ERs, PRs).[139] Certain breast cancer cells are stimulated by progesterone and/or estrogen

to grow. Medications such as tamoxifen or other similar drugs classified as Aromatase Inhibitors block the hormones from getting to these cells. AIs stop tissues and organs other than the ovaries from making estrogen and are used in postmenopausal women only. In premenopausal women, the AI medications actually stimulate estrogen production from the ovary. Tamoxifen, on the other hand, blocks a cell's ability to use estrogen so it can be used in premenopausal and postmenopausal women. Women that have hormone receptor–positive cancer and are premenopausal will take tamoxifen for 5 years. If they have not entered menopause after 5 years, then they can continue tamoxifen for up to 10 years total. Women that go through menopause while on Tamoxifen can switch to an AI for 5 more years or a total of 10 years of hormone treatment.

The oral cavity can be directly affected by estrogen. Antiestrogen therapies can create issues that can influence dental implant success. There are associated side effects with these types of prolonged hormonal therapies. The complications include oral/pharyngeal mucositis, pain, xerostomia, and dental caries. Of increased concern is the risk for opportunistic bacterial, fungal, and viral infections from the immunosuppressive effect of these drugs as a result of chemotherapy-induced immune suppression.[140] Patients are also at risk for osteonecrosis and the therapies may affect the periodontal tissue, causing gingivitis, gingival bleeding, and periodontal infection.[141]

Treatment Summary for Biologic Medications

Although biologic medications have become very popular in the treatment of many systemic disorders, caution must be exercised in patients that have been treated in the past or are currently being treated. Patients may be susceptible to increased infectious episodes, intraoperative bleeding, and compromised bone healing. A medical consult and evaluation are highly recommended before any proposed implant treatment. For most biologic drugs, concurrent use and the placement of implants is an absolute contraindication. Because of the lack of history and studies with these types of medications, severe caution must be exercised with past biologic use and future implant treatment. Physician consultation and approval is highly recommended.

Past biologic therapy: Relative contraindication after medical consultation
Concurrent biologic therapy + implant therapy: Absolute contraindication

Oral Antithrombotic Medications

Oral antithrombotic medications have been used successfully to treat a variety of thrombotic diseases such as MI, stroke, and deep venous thrombosis, and are frequently used in the prevention of cardiovascular diseases. For decades, clinicians and patients have been conscious of the adverse side effects of these medications, primarily spontaneous bleeding or perioperative bleeding. Many have advocated for years to temporarily discontinue these medications before invasive dental treatments such as dental implant surgery. However, because discontinuation of these drugs may result in serious thrombus complications, a thorough knowledge of the mechanism of action needs to be understood (Table 10.23).

Warfarin Sodium

Warfarin sodium (Coumadin) is used as an anticoagulant in a wide range of conditions such as ischemic heart disease, deep

venous thrombosis, pulmonary emboli, and artificial heart valves. Warfarin sodium has a half-life of 40 hours, which has been known to vary from 20 to 60 hours in some individuals. The mode of action of warfarin sodium is the interference of the synthesis of vitamin K, which is a cofactor in many reactions within the coagulation cascade. Coumadin has been the mainstay of anticoagulant treatment options; however, in the past 3 years there has been a shift to a new class of blood thinners in the treatment of nonvalvular atrial fibrillation and deep venous thrombosis. With an aging population, the number of individuals diagnosed with nonvalvular atrial fibrillation continues to climb, with over 2 million Americans now undergoing treatment. The major concern of atrial fibrillation is the formation of blood clots, so most of these patients will be maintained on blood-thinning medications.

Medication Modification

Until recently, most medical practitioners have believed that anticoagulants should be discontinued before dental surgery to prevent possible bleeding problems. However, there exist many documented cases of embolic complications in patients who discontinue the use of warfarin sodium and develop thrombosis from rebound hypercoagulability. In addition, studies have shown that dental surgery may be performed safely on patients receiving anticoagulant therapy as long as their INR values are within the therapeutic range (2.0–3.5). A brief periprocedural interruption of warfarin therapy is associated with a low risk of thromboembolism (0.7%) and risk of clinically significant bleeding (1.7%); however, the risk versus benefit of interruption is not warranted in most cases.[142]

Medical Consultation

Practitioners should consult with the patient's physician to determine the most recent INR before the surgery (ideally 24–48 hours before surgery). If the INR values are within the therapeutic range (2–3.5) then there is no need to discontinue use of the anticoagulant. If the INR value is higher the therapeutic range (especially higher than 3.5), the physician should take appropriate steps to lower the INR to a safer level or possibly discontinue the warfarin and supplement with heparin therapy or vitamin K. It is important to remember with all anticoagulant patients that special attention should be given to good surgical technique and use of appropriate local measures to control bleeding (hemostatic agents). In addition, many antibiotics can increase the effect of Coumadin thus increasing the chance of bleeding. In general cephalosporins, penicillins, quinolones, and macrolides can increase INR and have a moderate class C rating, which means patient should have their INR checked a bit more frequently while on these antibiotics. Sulfonamides and metronidazole are considered to have more severe interactions and are considered as class D drugs, which usually require reduction in Coumadin dosages. Consultation with a physician for use of any class D drug is absolutely indicated. For class C drugs it is suggested but imperative that the patient also understand the relative increased risk. NSAIDs should not be used in patients on Coumadin.

Aspirin

Aspirin or salicylic acid has been used as an antiinflammatory, analgesic, and antipyretic medication. However, in the 1980s, it

TABLE 10.23   Common Anticoagulant Medications

Drug	ASA (81 mg)	ASA (325 mg)	Clopidogrel (Plavix)	Coumadin (Warfarin)	Dabigatran (Pradaxa)	Rivaroxaban (Xarelto)	Apixaban (Eliquis)

From Resnik RR, Resnik RJ. Medical/medication complications in oral implantology. In Resnik RR, Misch CE, eds. *Misch's Avoiding Complications in Oral Implantology.* St Louis, MO: Elsevier; 2018.

was discovered that aspirin also had an antiplatelet effect at very low doses (0.5–1 mg/kg) versus higher doses needed for an antipyretic effect (5–10 mg/kg) and antiinflammatory response (30 mg/kg). Because of this research, low-dose aspirin has become a secondary preventive drug for patients who have cardiovascular and peripheral vascular disease. Aspirin works by inhibiting the formation of prostaglandin thromboxane A$_2$ within the platelet, affecting thrombus formation by irreversibly decreasing platelet aggregation.

Studies

Aspirin inhibits platelet function and can be much more severe in the presence of decreased platelet counts. Studies have shown that this risk is minimal unless a 325-mg aspirin is being used. In a study of tooth extractions, 36 patients were randomized to 325 mg of aspirin or placebo for 2 days before and 2 days after. There

was no significant association between those that took the aspirin and perioperative or postoperative bleeding.[143]

Recommendations

Low-Dose (81 mg) Aspirin. There exists no study supporting the recommendation of low-dose aspirin discontinuation for routine dental implant procedures. In most patients, interruption is not warranted because it may expose the patient to the risk of developing thromboembolism, MI, or CVA.

High-Dose (325 mg) Aspirin. When patients are advised by their physician to take 325 mg of aspirin or doses higher than 100 mg, a physician consultation is recommended. This is especially true of patients on aspirin (any dose) with other anticoagulants such as clopidogrel or dipyridamole. Bleeding times may be appropriate in these patients in combination with physician consultation. Usually aspirin is stopped 7 to 10 days before

surgery and can be continued after adequate hemostasis has been confirmed.[144]

Plavix (Clopidogrel)

Clopidogrel is a platelet inhibitor that is approved for the reduction of atherosclerotic events in patients with recent stroke, MI, or peripheral arterial disease. The recent literature has supported longer treatment times for patients with coronary stents and acute coronary syndrome from 3 to 12 months or more in combination with aspirin. The literature does not support the routine discontinuation of this medication in relation to dental implant treatment, but it is important to remember that many patients treated with clopidogrel will be on aspirin or another antiplatelet medication, especially those with cardiac stents.

Recommendation: This regimen should never be discontinued unless under the recommendation of a physician.

Novel Oral Anticoagulants

Pradaxa, Xarelto, and Eliquis are a class of medications termed Novel Oral Anticoagulants (NOAC). NOACs. Orally administered anticoagulants have recently been developed to eliminate the disadvantages associated with warfarin. Dabigatran etexilate (Pradaxa) and rivaroxaban (Xarelto) have been shown to have a more favorable (wider) therapeutic index, fewer drug–drug and drug–food interactions, and a predictable anticoagulant response without the need for anticoagulants. Dabigatran reversibly inhibits thrombin, so the duration of action is predictable and correlates well with plasma drug concentrations. Rivaroxaban is an FXa inhibitor that produces reversible inhibition of FXa activity.[145]

Bleeding

In contrast to the many studies on oral surgery and the use of warfarin, no clinical trials have been completed to offer recommendations on the management of patients on these newer anticoagulants with relation to dental implant surgery. However, there exist several case studies suggesting that, with physician consultation, these drugs can be temporarily discontinued 24 hours before elective oral surgery and restarted the following day, resulting in minimal complications. Because these drugs have a short half-life, brief interruption of usage is usually acceptable. It is imperative that physician consultation be obtained prior to any of these medications being temporarily discontinued. Good surgical technique and the use of hemostatic agents should be adhered to during oral surgery. Currently Praxbind is available to help reverse the effects on Pradaxa and control excessive bleeding. AndrexXA is awaiting final approval to help reverse the excessive or uncontrollable bleeding that may occur from the FXa inhibitors (Xarelto, Eliquis, and Savaysa). Currently there is no approved treatment to control excessive bleeding caused by the FXa inhibitors.

Treatment Summary

Currently there is no accepted reduction protocol for NOACs. Based on the information available, the clinician should consult the patient's physician concerning the proposed implant procedure and the invasiveness of the surgery, anticipated hemostasis complications, and amount of bleeding to be expected. If physician recommendation is for the temporary discontinuation of these drugs, then the typical discontinuation recommendation is for 24 hours before surgery, and the drug should not be restarted until the risk of postoperative bleeding is minimal (usually within 24 hours of surgery).[146] Patients should be closely monitored

postoperatively because bleeding may reoccur after initial hemostasis and continuation of the medication.

Herbal Supplements

OTC herbal and dietary supplements are being consumed at a record pace for general health improvement and treatment of chronic conditions. It is an important part of taking a medical history that you specifically ask about any OTC supplements, herbal medications, or any pills a patient may be taking that are not prescribed by a physician.

Herbs have been known to be associated with unwanted side effects and can cause drug interactions, as well as being associated with surgical complications. Many of these supplements contain active ingredients that exhibit strong biologic effects. The doses are usually unregulated and variable among patients. The *Journal of the American Medical Association* estimates that 15 million adults are at risk for adverse interactions between herbs and prescription medications.[147] The risks of these medications associated with dental implant surgery are increased bleeding, drug interactions, and possible infection.

Recommendation: Patients should discontinue the use of these herbal supplements for at least 2 weeks before implant surgery (Box 10.14).

Selective Serotonin Reuptake Inhibitors

Depression is a prevalent mental illness disorder that is a significant disability with a reduced quality of life. Low levels of serotonin (chemical and neurotransmitter) have been associated with depression. SSRIs have been used to successfully treat depression.

SSRIs have a very low adverse-effect profile because they do not affect blood pressure or heart rate. SSRIs inhibit serotonin reuptake from the synaptic cleft into presynaptic nerve terminals, increasing serotonin neurotransmission. However, SSRIs have been directly associated with lower bone mineral density.[148]

Serotonin found in bone cells (osteocytes, osteoblasts, and osteoclasts) can be activated by SSRIs, which results in altered function. Wu and colleagues stated that SSRIs might have a negative effect on dental implant healing. Their data demonstrate an increased risk of failure with most complications occurring from the anabolic response, which inhibits the bone-remodeling processes triggered by mechanical loading.[149]

Treatment Summary

The concomitant use of SSRIs and dental implants is a relative contraindication. A medical consult and evaluation should ideally be completed before dental implant treatment.

Allergies

Hypersensitivity to titanium is an ever-increasing reportable complication in medicine today that has been associated with a wide range of situations. In orthopedic medicine, there exist many case reports of titanium alloy hypersensitivity. Witt and Swann reported 13 cases of failed total hip prostheses and concluded the tissue reaction in response to metal-wear debris may have been the etiology of the failed implants. This process has been termed *repassivation* and may produce an oxide that surrounds and turns the peri-implant tissues black.[150]

Yamauchi and colleagues reported a titanium-implanted pacemaker developing an allergic reaction. The patient developed a distinct erythema over the implantation site, which

resulted in a generalized eczema. Titanium sensitivity was confirmed by intracutaneous and lymphocyte stimulation testing.[151] In the dental literature, allergic reactions to pure titanium are rare. However, many authors have suggested there is a higher incidence of titanium alloy allergy with respect to dental implants, and it is most likely underreported because of a poor understanding of failure or allergy.[152] du Preez and colleagues have reported a case of implant failure caused by a suspected titanium hypersensitivity reaction around a dental implant. Histologic results showed a chronic inflammatory reaction with concomitant fibrosis.[153] Egusa and colleagues reported

a titanium implant overdenture case that resulted in generalized eczema that fully resolved after implant removal.[154] Sicilia and colleagues, in a clinical study of 1500 consecutive implant patients, reported approximately nine implants with a positive reaction to titanium allergy.[155]

Sensitivity to titanium has been shown to be a result of the presence of macrophages and T-lymphocytes with the presence of B-lymphocytes, which results in a type IV hypersensitivity reaction.[156] All metals, when in a biologic environment, undergo corrosion, which may lead to the formation of metallic ions that trigger the immune system complex with endogenous proteins.[157] Titanium alloy dental implants have been shown to contain many "impurities" that may trigger type IV hypersensitivity reactions. Harloff used spectral analysis to investigate various Ti alloy implants. The results showed that all the Ti alloy samples contained small amounts of other elements such as beryllium (Be), cobalt (Co), chromium (Cr), copper (Cu), iron (Fe), nickel (Ni), and palladium. These impurity elements have been shown to be the etiology of the hypersensitivity reactions.[158]

Treatment Summary

When titanium hypersensitivity is suspected, the implants should be removed and the patient should be referred to their physician for appropriate testing. Case reports have shown that, after complete removal of the implants, complete resolution results.[154] Metal sensitivity is usually diagnosed using a "patch-test," which involves placement of titanium (allergen) to the skin for approximately 3 to 4 days. A positive test would include the appearance of an erythematous reaction. However, there is a possibility of false negatives because of the sealing qualities of the skin against direct contact, which may make the test unreliable (Fig. 10.4).

Medical Consultation and Clearance

Oral implantology is a complex specialty with many factors that must be taken into consideration to decrease morbidity and increase the probability of successful treatment. Medical clearance is a necessity with respect to patients who present with complicated systemic conditions, medications, and predisposing factors that may lead to complications. The implant clinician must relay to the physician all necessary information, including
1. A detailed summary of what the patient related as their medical history
2. A list of all current and recent medications
3. A list of all allergies
4. Any medications that will be prescribed by the implant dentist
5. The invasiveness of the intended procedure

The physician will provide with the following:
1. Most recent physical examination: To determine whether the patient is compliant with keeping up with their medical health
2. Documentation of medical health: Very important to determine whether there exists any misinformation or missing health issues that the patient failed to represent on the medical/dental history
3. Medication modification: The physician will recommend any modifications to physician-prescribed medications or dental surgery proposed medications.
4. Acceptable candidate: The physician will clear the patient for dental implant treatment in writing.
5. Contacting the physician: The physician will document whether their recommendation is for the implant dentist to contact them before treatment and, last, to make sure the physician signs and dates the form (Fig. 10.5).

MEDICAL CONSULTATION FOR DENTAL IMPLANT SURGERY

Patient: _____ **Date:** _____

The above patient is tentatively scheduled for dental implant surgery. The outpatient surgery will be performed in my office under intravenous conscious sedation. The following information has been provided by the patient.

Medical History: _____

Current Medications: _____

Allergies to Medications: _____

THE FOLLOWING MEDICATIONS ARE PROPOSED FOR THE DENTAL IMPLANT SURGERY:

ANTIMICROBIAL	ANTI-INFLAMMATORY	ANALGESIC	ANESTHESIA	SEDATION
____ Amoxicillin	____ Ibuprofen	____ Hydrocodone	____ 2% Lidocaine 1/100k Epi.	____ Halcion
____ Cephalosporin	____ Dexamethasone	____ Codeine	____ 2% Carbocaine 1/20k Neo.	____ Valium
____ Clindamycin		____ Acetaminophen	____ 3% Carbocaine	____ N20
____ Augmentin		____ Percocet	____ .5% Marcaine 1/200k Epi	____ IV Rx"s
_____		____ Ultram	____ 4% Articaine 1/100k Epi	(Versed,Fentanyl)

- -

PLEASE PROVIDE ANSWERS TO THE FOLLOWING QUESTIONS

1. Date of most recent physical exam:_____
2. Significant medical condition, treatment, disease, injury or comments:

_____
_____
_____
_____

3. Any Recommendations or Modifications of Medications   YES ——— NO ———

   Current Medications _____

   Proposed Medications (Listed Above) _____

4. The above patient is an acceptable candidate for outpatient dental implant surgery   YES ——— NO ———

5. Please contact me prior to treating this patient   YES ——— NO ———

_____   _____
Signature of Physician   **Date**

Radiographic Evaluation in Oral Implantology

RANDOLPH R. RESNIK

Advances in radiologic imaging technology have had a significant impact on the surgical and prosthetic phases of oral implantology. Comprehensive and accurate radiographic assessment is crucial and one of the most important aspects of dental implant treatment planning. In the past, various imaging techniques have been used to evaluate bone quality, quantity, and location of anatomic structures in relation to proposed implant sites. Traditionally, implant clinicians have relied on two-dimensional (2D) conventional radiographic modalities in implant dentistry that have inherent shortcomings. However, with the advent of computed tomography (CT) and cone beam computed tomography (CBCT), a new era in all phases of the radiographic imaging survey of implant patients has become available to the implant clinician. These technological advances have significantly increased the level of detailed information available to implant clinicians in the diagnosis, treatment planning, surgical, and prosthetic phases of dental implant treatment. This chapter will comprehensively review the use of various radiographic modalities and technology in the presurgical evaluation, treatment planning, and surgical, prosthetic, and postoperative assessments of implant treatment.

Imaging Objectives in Oral Implantology

The objectives of diagnostic imaging depend on a number of factors, including the amount and type of information required and the anatomic location of interest. The decision of when to image, along with which imaging modality to use, depends on the integration of these factors and can be organized into three phases.

Phase 1

Phase 1 is termed presurgical implant imaging assessment and involves all past radiologic examinations and new radiologic examinations selected to assist the implant team in determining the patient's final and comprehensive treatment plan. The objectives of this phase of imaging include all necessary surgical and prosthetic information to determine the quantity, quality, and angulations of bone; the relationship of critical structures to the prospective implant sites; and the presence or absence of disease at the proposed surgery sites.

Phase 2

Phase 2 consists of surgical and intraoperative implant imaging, and is focused on assisting in the surgical and prosthetic phases of intervention of the patient. The objectives of this phase of imaging are to evaluate the surgery sites during and immediately after surgery, assist in the optimal position and orientation of dental implants, evaluate the healing and integration phase of implant surgery, and ensure that abutment position and prosthesis fabrication are correct.

Phase 3

Phase 3 is the final phase comprising the postprosthetic implant imaging. This phase commences just after the prosthesis placement and continues as long as the implants remain in the jaws. The objectives of this phase of imaging are to evaluate the long-term maintenance of implant rigid fixation and function, including the crestal bone levels around each implant, and to evaluate the implant prosthesis.

Presurgical Imaging (Phase 1)

In the field of oral implantology numerous radiographic imaging modalities are available for the presurgical assessment of patients with dental implants. Before cone beam computerized tomography, intraoral radiographs, along with 2D panoramic images, were used as the sole determinants of implant diagnosis and treatment planning. With the advancement of radiographic technology, various three-dimensional (3D) imaging systems are now common place in the dental profession, allowing an unlimited amount of diagnostic information to be available to the implant team.

The presurgical imaging phase of treatment is one of the most important in the implant process. The goal of presurgical radiographic evaluation is to assess the available bone quality and quantity, angulation of bone, and selection of potential implant sites, and to verify the absence of pathology. With the popular use of CBCT, the presurgical phase has become more user-friendly and allows a comprehensive evaluation of the patient. In comparison with CBCT, other types of radiographic modalities (e.g., panoramic, periapical, cephalometric, conventional tomography)

have inherent advantages and disadvantages, and have been shown to exhibit false-negative and false-positive results.[1]

In dental and medical radiology a recommended principle when selecting the appropriate radiographic modality is based on radiation dosage. Dental professionals should always adhere to the "as low as reasonably achievable" (ALARA) principle. ALARA basically states that the diagnostic imaging technique selected should include the lowest possible radiation dose to the patient. The American Academy of Oral and Maxillofacial Radiology published guidelines stating that all implant site surveys should be evaluated with a 3D imaging technique such as CBCT or CT.[2] This phase of implant imaging is intended to evaluate the current status of the patient's teeth and bony anatomy, and to develop and refine the patient's treatment plan. Evaluation of the patient by members of the dental implant team is accomplished with a review of the patient's history, a thorough clinical examination, and a review of the patient's radiologic examinations. At this point the clinician should be able to rule out dental or bone disease, and establish a tentative clinical objective that meets the patient's functional and esthetic needs. If the dentist cannot rule out dental or bone disease, then a further clinical or radiologic examination is necessary. The ideal objective of this phase of treatment is to develop and implement a treatment plan for the patient that enables restoration of the patient's function and esthetics by the accurate and strategic placement of dental implants. The patient's functional and esthetic needs can be transformed physically into a 3D diagnostic template that allows the implant team to identify the specific sites of prospective implant surgery in the imaging examinations. The specific objectives of preprosthetic imaging are listed in Box 11.1.

All of the modalities identified in Box 11.2 have been used in the first diagnostic phase of treatment in oral implantology.[3,4] However, dental implant cases are inherently 3D with respect to the final prosthetics, occlusion, and function of the patient's 3D anatomy. A 3D treatment plan ideally identifies at each prospective implant site the amount of bone width, the ideal position and orientation of each implant, its optimal length and diameter, the presence and amount of cortical bone on the crest, the degree of mineralization of trabecular bone, and the position or relationship of critical structures to the proposed implant sites. Therefore the modalities of choice for presurgical implant treatment planning most commonly utilize CBCT which provides high-resolution and dimensionally accurate 3D information about the patient at the proposed implant sites.

Radiographic Modalities Used in Oral Implantology

Periapical Radiograph

Periapical radiography (digital), one of the most commonly used radiographic modalities in dentistry, has many advantages, such as high resolution, low radiation, convenience, and image modification via digital software capability. However, the implant clinician must understand the inherent disadvantages of this radiologic technique when used in oral implantology.

1. *Image distortion:* Intraoral radiographs are inherently susceptible to image distortion and magnification because the object of interest does not have the same focal spot-to-object distance. When determining the location of anatomic structures the clinician should note that the image may contain distortion, and relying on exact measurements from these images should be cautioned. If the x-ray beam is perpendicular to the image receptor (film or sensor), but the object is not perpendicular to the image receptor and object, then dimensional changes such as foreshortening and elongation will occur (Fig. 11.1). Edentulous sites/quadrants are especially predisposed to these errors because flat maxillary palatal vaults, along with high muscle

attachments in the mandible, make accurate positioning of the image receptor difficult.

2. *Two-dimensional radiographic modality:* A true evaluation and determination of the buccal-lingual available bone must be ascertained to evaluate the osseous contours of the existing bone. Because periapical radiography is 2D, vital information on the width of available bone is not obtained. Therefore when attempting to estimate width distances in close approximation to maxillary and mandibular anatomic structures with 2D radiographs, the implant clinician must be conscious of the inherent inaccuracies associated with 2D images.

3. *Poor identification of vital structures:* When evaluating the position of vital structures with intraoral radiographs, extreme caution should be exercised. In the evaluation of the true location of the mental foramen, studies have shown less than 50% of periapical radiographs depict the correct location of the mental foramen.[5] Other studies have concluded that because of insufficient cortical bone around the mandibular canal (MC), only 28% of periapical radiographs will accurately identify the MC.[3] Therefore periapical radiographs exhibit relatively high false-positives and false-negatives with respect to the identification of vital anatomic structures.

Uses in Oral Implantology

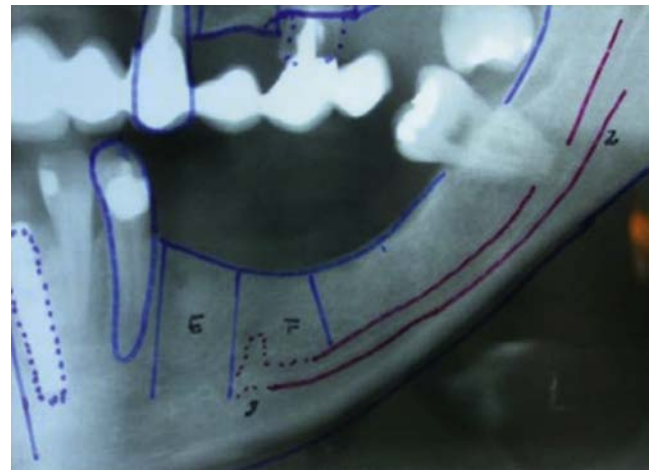
Periapical radiographs have many inherent disadvantages, most notably providing only a 2D image of a 3D object. The inability to determine the buccal-lingual bony dimensions is a major shortcoming with respect to implant treatment planning. These radiographs are of little value in determining quantity and quality of bone, identifying vital structures, and depicting the spatial relationship between structures within proposed implant sites. In summary, periapical radiographs should be limited to an initial evaluation of a proposed implant site, intraoperative evaluation, and postoperative assessment.

In terms of the objectives of presurgical imaging, periapical radiography is:

- a useful high-yield modality for ruling out local bone or dental disease;
- limited value in determining quantity because the image is magnified, may be distorted, and does not depict the third dimension (bone width);
- limited value in determining bone density or mineralization (the lateral cortical plates prevent accurate interpretation and cannot differentiate subtle trabecular bone changes); and
- has poor ability in depicting the spatial relationship between the anatomic structures and the proposed implant site.

Panoramic Radiograph

Panoramic radiography is a curved plane tomographic radiographic technique used to depict the body of the mandible, maxilla, and the maxillary sinuses in a single image. Its convenience, speed, and ease have made this type of radiography a popular technique in evaluating the gross anatomy of the jaws. However, the implant clinician must understand the inherent fundamental limitations characteristic of this type of radiograph.

1. *Magnification/Distortion:* All panoramic radiographs exhibit vertical and horizontal magnification, together with a tomographic section thickness that varies according to the anatomic position. Because the x-ray source exposes the jaws using a negative angulation (~8%) to avoid superimposing the occipital bone/base of the skull over the anterior dental region,


● **Fig. 11.2** All two-dimensional panoramic radiographs exhibit magnification, distortion, overlapping of images, and ghost images, making these images inaccurate as the sole determination for dental implant diagnosis. Therefore panoramic radiographs should not be used for final measurements or determination of vital structures.

variable magnification will always be present on panoramic radiographs. Increased magnification stems from variances in patient positioning, focal object distance, the relative location of the rotation center of the x-ray system, and variations in normal anatomic form and size from one patient to the next. Zarch et al.[4] have shown that 83% of panoramic measurements are underestimated, with the greatest magnification being present in the anterior region (Fig. 11.2).

a. *Horizontal magnification* is determined by the position of the object within the focal trough. The degree of horizontal magnification depends on the distance of the object from the focal trough center and is influenced by the patient's anatomy and positioning within the panoramic machine. In the anterior region the horizontal magnification will increase significantly as the object moves away from the focal trough. This results in anterior magnification being far greater and more variable than posterior magnification.

b. *Vertical magnification* is determined by the differences between the x-ray source and object. Because the beam angle is directed at a negative [upward] angulation, structures positioned closer to the source are projected higher within the image in relation to structures positioned farther from the x-ray source. Therefore the vertical plane spatial relationships between objects projected on a panoramic radiograph are inaccurate.

2. *Two-dimensional radiographic modality:* The panoramic radiograph is a 2D image depicting 3D structures. Accordingly, it does not demonstrate the buccal-lingual dimension of maxillofacial structures; therefore bone width and vital structures cannot be determined. In addition, it produces a flattened, spread-out image of curved structures, which results in significant distortion of the vital structures and their relationship in space.

3. *Identification of vital structures:* Panoramic radiography does not exhibit an accurate assessment of bone quality/mineralization and the true identification and location of vital structures.

a. *Visibility of Mental Foramen:* Caution must be exercised in using panoramic images as the definitive diagnostic modality in evaluating the location and visibility of the MC.

Lindh et al.[6] have shown that the MC cortical walls were visible in only 36.7% of panoramic radiographs.

b. *Mental foramen location:* The location of the mental foramen has high patient variability. Yosue and Brooks,[7] in evaluation of the mental foramen, concluded that more than 50% of radiographs will not depict the true location of the mental foramen.

c. *Linear measurements:* Because of the inherent panoramic magnification and distortion disadvantages, calculating linear measurements on panoramic images is inaccurate. Sonic et al.[8] reported in determination of linear measurements for bone assessment with respect to vital structures, an inaccuracy rate of 24% has been shown.

d. *Anterior loops:* The anterior course of the mental nerve in relation to the mental foramen must be identified to prevent neurosensory impairment. Studies completed by Kuzmanovic et al.[9] of anterior loops (mental nerve courses anteriorly to the mental foramen) concluded panoramic radiographs exhibit a high incidence of false-positives and false-negative results, thus being totally inaccurate.

e. *Location of septa:* Septum in the maxillary sinus complicate bone grafting and implant placement. In evaluation of maxillary sinus floor bony septa by Krennmair et al.,[10] correct identification and location have been shown to be approximately 21.3%.

f. *Identification of accessory foramina:* A common anatomic variant in the mandible is the presence of two mental foramen. Accessory (double) foramina have been shown to be identified accurately in less than 50% of panoramic radiographs.[11]

Use in Oral Implantology

Although panoramic radiographs have historically been the gold standard in evaluating potential implant sites, many disadvantages are associated with these types of radiographs. A lower resolution prevents evaluation of the fine detail that is required for the assessment of osseous structures and anatomy. The magnification in the horizontal and vertical planes are nonuniform; thus linear measurements are inaccurate. Often the image has superimposition of real, double, and ghost images, which result in difficulty in visualizing anatomic and pathologic details. The true positions of important vital structures, which are crucial in dental implant treatment, are not easily seen or incorrectly depicted. Therefore panoramic radiographs have value for initial evaluation; however, caution should be exercised when using these types of radiographs for the sole determinant of implant placement because they predispose the implant clinician to many surgical, prosthetic, and medical-legal complications (Fig. 11.3).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a cross-sectional imaging technique that produces images of thin slices of tissue with excellent spatial resolution. This imaging modality developed by Lauterbur[12] in 1972 uses a combination of magnetic fields that generate images of tissues in the body without the use of ionizing radiation. MRI allows complete flexibility in the positioning and angulation of image sections and can reproduce multiple slices simultaneously. Digital MRI images are characterized by voxels, with an in-plane resolution measured in pixels and millimeters, and a section thickness measured in millimeters (2–3 mm) for high-resolution imaging acquisitions. The image sequences used
● **Fig. 11.3** Panoramic showing nonuniform magnification in the vertical and horizontal plane depicting inaccurate measurements. Magnification is highly variable, especially in the horizontal plane. (*From Resnik RR, Preece JW. Radiographic complications and evaluation. In: Resnik RR, Misch CE, eds.* Misch's Avoiding Complications in Oral Implantology. *St. Louis, MO: Elsevier; 2018.*)

to obtain magnetic resonance images can be varied to obtain fat, water, or balanced imaging of the patient's anatomy. The images created by MRI are the result of signals generated by hydrogen protons in water or fat such that cortical bone will appear black (radiolucent) or as having no signal. Cancellous bone will generate a signal and will appear white because it contains fatty marrow. Metal restorations will not produce scattering and thus will appear as black images. Therefore MRI has been shown to be less prone to artifacts from dental restorations, prostheses, and dental implants than CT or CBCT scans.[13] As with CT, MRI is a quantitatively accurate technique with exact tomographic sections and no distortion.

Numerous authors have suggested the use of MRI for dental implant evaluation and treatment planning.[14] Vital structures are easily viewed, such as the inferior alveolar canal and the maxillary sinus. In cases where the inferior alveolar canal cannot be differentiated by conventional tomography or CT, MRI would be a viable alternative because the trabecular bone is easily differentiated with the inferior alveolar canal. In cases of nerve impairment or infection (osteomyelitis), MRI may be used because of added advantages including differentiation of soft tissue with respect to CT. Studies have shown that the geometric accuracy of the mandibular nerve with MRI is comparable with CT and is an accurate imaging method for dental implant treatment planning.[15] MRI may be used in implant imaging as a secondary imaging technique when primary imaging techniques such as complex tomography or CBCT fail. Complex tomography fails to differentiate the inferior alveolar canal in 60% of implant cases, and CT fails to differentiate the inferior alveolar canal in about 2% of implant cases. Failure to differentiate the inferior alveolar canal may be caused by osteoporotic trabecular bone and poorly corticated inferior alveolar canal.[16] MRI visualizes the fat in trabecular bone and differentiates the inferior alveolar canal and neurovascular bundle from the adjacent trabecular bone. Double-scout MRI protocols with volume and oriented cross-sectional imaging of the mandible produce orthogonal quantitative contiguous images of the proposed implant sites. Oriented MRI of the posterior mandible is dimensionally quantitative and enables spatial differentiation between critical structures and the proposed implant site. Recent advances in MRI have allowed for higher image resolution, similar to the resolution produced on CBCT scans, with voxel sizes of 300 to 400 μm³. In addition, technology has allowed for shorter image acquisition times of only 3 to 4 minutes.[17] However, there exist numerous disadvantages for the use of MRI for implant dentistry.

MRI is not useful in characterizing bone mineralization or as a high-yield technique for identifying bone or dental disease. In addition, no commercially available reformatting programs are available to use as reference points.

Use in Oral Implantology

In oral implantology, because of the imaging artifacts associated with CBCT scans, MRI is a possible alternative for the postoperative evaluation of dental implants, especially if associated with a neurosensory impairment (Fig. 11.4).

Cone Beam Tomography (CBCT)

With the advent of cone beam computerized tomography, many of the disadvantages of 2D radiographs and conventional medical CT scanners have been overcome. CBCT has been one of the most significant technological breakthroughs in oral implantology today. Because of the low radiation dose inherent with cone beam technology, the limitations of medical computerized tomography have been overcome. This scanning technology has many advantages, including "in-office" installation and use, which allow the clinician and patient the convenience of on-site scanning capabilities and treatment planning. In addition, the scanning speed (<5 seconds) and integration of interactive software programs have brought an unparalleled advantage to the implant clinician for the evaluation and assessment of potential implant sites.

Today CBCT imaging has become the gold standard for dental implant treatment planning. However, many implant clinicians lack the background and knowledge in evaluating and treatment planning with CBCT, thus predisposing to possible complications. Therefore the implant clinician must have a thorough understanding of inherent disadvantages of CBCT scans, together with knowledge of applied head and neck anatomy, anatomic variants, incidental findings, and pathologic conditions with respect to implant treatment planning.

CBCT images are a result of data collected by numerous detectors and ionizing chambers in the CBCT unit. The data collected by the detectors correspond to a composite of the absorption characteristics of the tissues and structures imaged. This information is transformed into images (raw data) that are reformatted into a voxel (digital) volume for evaluation and analysis. The integration of digital imaging systems in the field of implant dentistry has significantly increased clinicians' diagnostic capabilities. A digital 2D image is described by an image matrix that has individual picture elements called *pixels*. A digital image is described by its width, height, and pixels (i.e., 512 Å~ 512). For larger digital images (i.e., 1.2 M Å~ 1.2 M, where M is megapixels), the image is alternatively described as a 1.5-M image. Each picture element, or pixel, has a discrete digital value that describes the image intensity at that particular point. The value of a pixel element is described by a scale, which may be as low as 8 bits (256 values) or as high as 12 bits (4096 values) for black and white imaging systems, or 36 bits (65 billion values) for color imaging systems. Nine to 11

black and white digital images are displayed optimally on a dedicated black and white monitor. Generally 8 bits, or 256 levels, can be displayed effectively on a monitor. A digital 3D image is described by an image matrix that has individual image or picture elements called *voxels*. A digital 3D image is described not only by its width and height of pixels (i.e., 512 Å~ 512) but also by its depth and thickness. An imaging volume or 3D characterization of the patient is produced by contiguous images, which produce a 3D structure of volume elements (i.e., CT, MRI, and interactive computed tomography [ICT]).

Each volume element has a value that describes its intensity level. Typically 3D modalities have an intensity scale of 12 bits, or 4096 values. The 2D digital images are composed of pixels (2D) and voxels (3D) picture elements. Pixels and voxels possess attributes of size, location, and grayscale value. Each voxel and pixel displayed is characterized by a numerical value that represents the density of the tissues. This is termed the *CT number*. A specific shade of gray or density value is assigned to each CT number that comprises the images (Fig. 11.5).

CT images are inherently 3D images that are typically 512 Å~ 512 pixels with a thickness described by the slice spacing of the imaging technique. Each voxel has a value, referred to in Hounsfield units (HUs), that describes the density of each image. The range of these units is –1000 (air) to +3000 (enamel) HUs (Box 11.3). Most CT scanners are standardized with a Hounsfield value of 0 for water. The CT density scale is quantitative and meaningful in identifying and differentiating structures and tissues (Box 11.4).

Types of Computed Tomography Scanners

Medical

In medical radiology departments the CT scan is the most common diagnostic imaging modality to evaluate hard and soft tissues.

From Patrick, S., Birur, N. P., Gurushanth, K., Raghavan, A. S., & Gurudath, S. (2017). Comparison of gray values of cone-beam computed tomography with hounsfield units of multislice computed tomography: An in vitro study. Indian Journal of Dental Research, 28(1), 66.

Advances in speed and image quality were apparent in the early 1990s with the advent of spiral and helical CT scanners. However, since its introduction in 1998, multislice (multirow detector CT) has revolutionized the field of medical CT. These CT scanning units are tomographic machines that are classified as 4-, 8-, 12-, 16-, 32-, or 64-slice machines. The number of slices corresponds to the number of times the x-ray beam rotates around the patient's head to acquire the CT data. The CT numbers, or Hounsfield units, are then reconstructed mathematically and formatted into images. However, because these images consist of a series of incremental images grouped together, CT spiral slices produce "average" reconstructed images based on multiple x-rays transversing the scanning area. With this reconstruction of images, a small gap between each slice is present, which contributes to an inherent error within medical scanners.

In the 1980s cross-sectional reconstruction of the CT images dramatically improved the diagnosis and treatment planning in oral implantology. These reformatted images allowed 3D evaluation of vital structures and related oral anatomy. However, even though these advances enhanced diagnostic skills, there were inherent shortcomings to medical scanners used for dental purposes. Because medical scanners were not developed for dental reformatting, there existed inherent errors such as distortion, magnification, and positioning problems that led to inaccuracies when reformatted. In addition, no prosthetic information could be gathered to predict the final prosthetic outcome. This was overcome with the advent of sophisticated scanning appliances, stereolithographic resin bone models, virtual teeth technology, interactive software, computer-generated surgical guides, and CT-based image-guided navigation systems, which allowed for ideal placement and prosthetic outcome to be established.
• **Fig. 11.6** (A) A conventional computed tomography (CT) scan uses a very narrow "fan beam" that rotates around the patient, acquiring one thin slice (image) with each revolution. Because of the numerous revolutions needed, the radiation dose is increased. (B) Cone beam volumetric tomography captures all data in one rotation, thus reducing radiation and avoiding distortion and errors in reformatting. (*From Resnik RR, Misch CE. Radiographic imaging in implant dentistry. In: Misch CE, ed.* Dental Implant Prosthetics. *2nd ed. St. Louis, MO: Elsevier; 2015.*)

Although the clinical problems of medical scanners have been remedied, numerous disadvantages remain, including radiation exposure and availability. The amount of radiation exposure of medical scans has been a controversial topic for many years and has been shown to be excessive. The availability has dramatically improved over the years with the advent of cone beam computed technology (Fig. 11.6A).

To overcome some of the disadvantages of conventional medical CT scanners, CBCT has become extremely popular (Table 11.1 and Fig. 11.6B). Because conventional CT is associated with high radiation doses, this medical imaging technique has always been under significant criticism when used for implant treatment planning. However, with the advent of cone beam technology, the limitations of medical CT have been overcome. With cone beam technology, there exists the ability to provide more accurate diagnostic images, along with a fraction of the radiation exposure with conventional CT and adherence to the ALARA principle.[18] Cone beam scanners are made for "in-office" installation and use, allowing the doctor and patient the convenience of on-site scanning capabilities (Fig. 11.7).

CBCT scanners use a rotating x-ray source that generates a conical-shaped beam that can be modified to acquire a desired area of interest. The attenuated x-ray beam data are collected by a

• **Fig. 11.7** Cone beam computed tomography (CBCT) unit: I-Cat Unit with only minimal space requirements (4 × 4 foot footprint).

single collector. These data are then converted to various shades of gray, which are displayed on a computer screen. Reconstruction of these images can be in any plane by simply realigning the image or voxel data. This allows viewing of the data in axial, sagittal, coronal, panoramic, 3D, and soft tissue images (Fig. 11.8).

Focal Spot. The clarity of CT scan images is not dependent on the voxel size. Actually a CBCT unit may have a very small voxel size; however, image quality may be compromised because of a large focal spot. The focal spot is the area of the x-ray tube that emits the x-rays. In general the smaller the focal spot, the sharper the final image quality. Thus a larger source or focal spot will result in projections of shadows of the scanned area, which will result in blurring of the object. This penumbra or blurring of the edges creates a shadow with resultant poor image quality and clarity.

Current CBCT units have focal spots ranging from 0.15 to 0.7 mm (Fig. 11.9).

Field of View. CBCT units vary on the area of interest or what is commonly termed the *field of view* (FOV) in radiology. The FOV describes the scan volume, which is dependent on many factors, including the detector size and shape, beam projection geometry, and beam collimation. Beam collimation is paramount in decreasing radiation exposure to the patient and ensuring only the area of interest to be radiated. Usually smaller scan volumes produce higher resolution images. Currently, CBCT units are classified as small, mid, or large FOVs (Fig. 11.10).

Effective Dose Range of Cone Beam Computed Tomography Scanners. Because of the increasing number of CBCT units being developed and released on the market, it is difficult to generalize radiation dose of CBCT. These units exhibit a wide variation of exposure parameters, such as x-ray spectrum (voltage peak and filtration), x-ray exposure (mA and number of projections), and FOV. Thus the range of units and imaging protocols will result in different absorbed radiation doses.

The effective dose measured in microsieverts is still the most accepted way to determine radiation risk for patients. A number of studies have measured the effective dose on dental CBCT units using thermoluminescent dosimeters with dosimetry phantoms. The phantoms are placed into multiple layers along the axial plane to allow for access to internal anatomy. The thermoluminescent dosimeters are placed on the radiosensitive area to be tested (i.e., ramus, symphysis, thyroid, salivary glands). The operator may control the FOV, kVp, mA, and scanning times to reduce the effective dose. However, these reductions result in a decreased signal and poorer image quality (Fig. 11.11).

Sensor (Detector) Type. The x-ray sensor receives the x-rays and converts them into electrical data, which are then converted to various images via special computer programs. Two types of sensors are used today in CBCT technology: (1) image intensifiers (IIs) with charged coupling devices, and (2) flat panel detectors. Image intensifiers have many disadvantages in comparison with flat panel detectors, including having poorer resolution, being bulkier, and requiring a higher patient radiation dose. Flat panel detectors, although more expensive than image intensifiers, produce images with much higher quality and resolution. Most flat panel detectors used today in CBCT units utilize cesium iodide as the scintillator crystal screen. Cesium iodide scintillators produce the highest spatial resolution possible among various CBCT screens.

Voxel Size. The unit element in the 3D image is termed the *voxel*, which is analogous to the 2D pixel. Images comprised of multiple voxels are stacked in rows or columns that are isotropic. Isotropic correlates to equal dimensions in the x, y, and z planes, and ranges in size from 0.075 to 0.6 mm. Each individual voxel is assigned a grayscale value that corresponds to the attenuation value of the anatomic structure. Thus the smaller the voxel size, the greater the resolution and quality of the image; however, the greater the resultant radiation dose. A voxel size of 0.2 to 0.3 mm is considered ideal because it allows for an equitable trade-off between image quality and absorbed radiation dose (Fig. 11.12).

Spatial Resolution. Spatial resolution is measured in lines per millimeter (lp/mm) and relates to the ability to distinguish two anatomically close objects. On a CBCT image the higher the spatial resolution, the greater the ability to delineate two different objects from one another. Normally, CBCT scanners (voxel size, 0.075–0.6 mm) are most commonly associated with higher spatial resolution than medical-grade scanners (voxel size, 0.6–1 mm). However, decreased spatial resolution on CBCT images may result from: (1) the use of a higher voxel size (>0.4; use of voxel sizes > 0.3 mm for implants is not recommended because of

• **Fig. 11.11** Effective dose (microsieverts [mSv]) from cone beam computed tomography (CT) compared with other dose metrics. FOV, field of view. (*From Aanenson JW, Till JE, Grogan HA. Understanding and communicating radiation dose and risk from cone beam computed tomography in dentistry.* J Prosthet Dent. *2018;120:353-360.*)
- **Fig. 11.12** Comparison of volume data sets obtained isotropically (left) and anisotropically (right). Because cone beam computed tomography data acquisition depends on the pixel size of the area detector and not on the acquisition of groups of rows with sequential translational motion, the compositional voxels are equal in all three dimensions, rather than columnar, with height being different from the width and depth dimensions. (*From Scarfe WC, Farman AG. What is cone-beam CT and how does it work?* Dent Clin North Am. *2008;52:707-730.*)

the lower spatial resolution); (2) decreased radiation (kVp or mA), which results in increased noise; (3) metallic restorations or dental implants resulting in artifacts; and (4) increased focal spot size.

Contrast Resolution. Contrast resolution is defined as the ability to differentiate tissues of different radiodensities. Ideally, in implant dentistry the ability to produce different shades of gray is important for a clearly diagnostic image. Because CBCT images use less radiation and are produced with lower kVp and mA settings in comparison with MDCT (Multi-Detector Computerized Tomography) units, dental CBCT is associated with slightly higher image contrast, modifiable through software settings. Dental CBCT generally has increased noise and image scatter compared with medical units. A smaller FOV may be used to minimize noise and scatter. However, smaller FOVs are usually associated with slightly higher radiation settings.

Bit Depth. The quality of CBCT images is directly related to the number of shades of gray (bit depth). CBCT units today produce up to 16-bit images, which corresponds to 2^{16} (65,536 shades of gray). However, computer monitors may display up to only 8 bits (2^8; 256 shades of gray). The monitor brightness and contrast may be adjusted to display 8 bits per image, to increase the quality of the image.

Bone Density

MDCT/CBCT. Medical CT data have inherently higher contrast resolution in comparison with dental CBCT images, and medical units permit differentiating between tissues that have a physical density of less than 1%. In contrast, conventional radiography requires a minimum of 10% difference in physical density to be seen.[19] Each medical CT image is composed of pixels and voxels, which are characterized by a given numerical value, which reflects the x-ray beam attenuation. These values are directly affected by the density and thickness of the tissue. These HUs or CT numbers correlate with the density of the medical CT image and range in value from –1000 (air) to +3000 (enamel). A specific shade of gray or density number is assigned to each CT number, which ultimately forms the image. The correlation of these CT numbers has been used to associate the density of the area of interest with various bone densities used for surgical and prosthetic treatment planning. Thus the gray values depicted on medical CT images are considered true attenuation x-ray values (HUs) (Fig. 11.13). When evaluating dental CBCT images in regard to bone density, a direct correlation (accuracy of measurement) does not exist compared with medical CT. Most dental CBCT systems
- **Fig. 11.13** Hounsfield unit correlation with the Misch bone density classification (D1–D4).

inherently have an increased variation and inconsistency with density estimates. The density estimates of gray levels (brightness values) are not true attenuation values (HUs), thus inaccuracies in bone density estimates result.[20] This is mainly due to the high level of noise in the acquired images and the slight inconsistencies in the sensitivity of the CBCT detectors. Dental imaging software frequently provides attenuation values (HUs); however, such values should be recognized as approximations lacking the precision of HU values derived from medical CT units.

Scanning Technique

1. *Imaging protocol:* The patient should be positioned within the CBCT unit as per manufacturer's recommendations. When taking the scan, the teeth should be slightly separated so that the different arches may be easily differentiated on re-formation. Cotton rolls, tongue depressors, or a bite registration may be used. In addition, cotton rolls may be placed in the vestibule to separate the lips and cheeks from the buccal mucosa. This will allow for a more accurate representation of the contour and thickness of the gingival tissues.
2. *Position of the scanning template:* The position of the scanning template/radiographic markers in the mouth during CBCT examination is crucial for the accuracy of fabrication of the surgical template. First, it is recommended that an index be used to position and maintain the scanning template in the correct position. This will prevent inaccuracies and help stabilize the template in the mouth. In addition, tissue conditioner or denture adhesive may be used for CBCT templates that are ill fitting or have associated movement.
3. *Mucosal thickness:* When fabricating mucosa-supported surgical guides, the thickness of the mucosa may have a direct effect on the accuracy of the of the planning of the implant sites. Increased mucosa thickness may lead to inaccurate placement of the mucosa-borne guides during the surgical placement procedure. Vasak et al.[21] showed a 1.0-mm buccal mucosa thickness may result in a buccal-lingual deviation larger than 0.41 mm. This will inevitably cause inaccurate measurements and possible misalignment of the surgical guide when placing the implants.

Artifacts

1. *Beam hardening:* Because metallic objects in the oral cavity are associated with higher attenuation coefficients than soft tissue, dental CBCT images inherently are predisposed to these artifacts. One of the most common types of artifacts is termed *beam hardening.* Beam hardening occurs when x-rays travel through the bone/implant, resulting in more low-energy photons being absorbed than high-energy photons. Because of this, the image will have compromised image quality.[22] The titanium alloy
• **Fig. 11.14** Beam Hardening Artifacts. These radiolucent areas next to an implant are caused by the dense nature of titanium implants and the exposure of more low-energy photons (red arrows).
• **Fig. 11.15** Motion artifact due to movement of the patient, leading to overlapping "double images." Usually stand-up CBCT units have a higher incidence of motion-related artifacts. (*From Resnik RR, Preece JW. Radiographic complications and evaluation. In: Resnik RR, Misch CE, eds.* Misch's Avoiding Complications in Oral Implantology. *St. Louis, MO: Elsevier; 2018.*)

surface is highly susceptible to these types of artifacts because of the high-density nature of the metal. This results in inaccuracies, especially when viewing peri-implant bone levels. Conventional intraoral images will not exhibit these beam hardening artifacts and may appropriately be used to better evaluate the quality and quantity of bone mesial and distal to an implant when beam hardening artifacts may obliterate visualization of interproximal bone, especially when multiple implants are present in the same quadrant. In addition, higher density materials commonly found in the oral cavity (i.e., dental implants, metal based restorations) will lead to complete absorption of the beam and beam hardening artifacts.[23]

Two types of beam hardening artifacts exist that result in linear areas of dark bands or streaks between dense objects and cupping artifacts. Cupping artifacts occur when x-rays pass through the center of a highly dense object and are absorbed more than the peripheral x-rays. This results in an image in which a uniformly dense object appears to be less dense (darker, lower CT numbers) at its center and appears as a "cup" (Fig. 11.14).

2. *Motion-related artifacts:* Motion artifacts are usually the result of patient movement and result in the inaccurate depiction of bony landmarks, measurements, and implants.[24] Patient movements and incorrect patient positioning create blurring problems, double-density line artifacts adjacent to major bony structures, which result in nondiagnostic images. Patients should be instructed to not move and avoid swallowing throughout the scan. The motion blurring causes "double contours" of anatomic structures that result in decreased scan quality and spatial resolution. This may lead to improper implant placement and possible damage to neural structures.[25] Motion-related artifacts may be decreased by using sit-down CBCT units, head restraints, or decreasing scanning times (Fig. 11.15).

3. *Streak (scatter) artifacts:* CBCT images are susceptible to streak artifacts that are caused by x-rays traveling through objects with a high atomic number (metallic restorations). Streak artifacts usually are seen as light and dark lines that arise from the source object, resulting in images with decreased quality and obscuring of anatomic structures. This is caused by photons (x-rays) that are deflected from their original path by metallic objects. When these deflected photons reach the sensor (detector), the intensity of the signal is magnified in a nonuniform magnitude. The end result is an image with decreased resolution and image quality, which ultimately lead to inaccuracies in the reconstructed CT number or voxel density.[26] The FOV of the CBCT is proportional to the amount of scattering, thus smaller FOVs are associated with less scattering. In comparison of scattering with MDCT and CBCT, CBCT images have inherently greater scatter radiation than medical-grade CT images[27] (Figs. 11.16 and 11.17).

4. *Noise:* Two types of noise are associated with CBCT images: additive (results from electrical noise) and photon count (quantum noise). Because CBCT scanners operate at much
● **Fig. 11.16** Image depicting "streaks" that result from the metal restorations.
● **Fig. 11.17** Image showing significant streak artifacts that result in total obliteration of the associated anatomy. These artifacts result from full-arch porcelain fused to metal restoration.

● **Fig. 11.18** Image showing resultant noise (grainy appearance).
● **Fig. 11.19** Bone dehiscence on three-dimensional images that is caused by reformatting with too high of Hounsfield unit threshold.

lower amperage (mA) settings than MDCT scanners, CBCT images are associated with greater quantum noise. The noise is displayed as a "graining" of the image and is the result of inconsistent distribution of the signal, which results in inconsistent attenuation (gray) values in the projection images (Fig. 11.18).

5. *Bone dehiscence on 3D reformatted images:* MDCT and dental CBCT data have the ability to be reformatted by software algorithms to represent 3D images by projecting only the voxels that represent the surface of the object (surface). The pixels are illuminated on the screen as if a light source is present in the front of the object. The closer the pixels, the brighter they appear. This shading effect allows the object to be projected as a 3D object with depth. However, some 3D images appear to have large voids or no bone present on the surface because of the software averaging volume elements, and the voids appear when the software attempts to reconstruct portions of the image covered by a very thin layer of bone. When evaluating the cross-sectional images, bone will be present. This is a direct result of the reformatting process, which usually selects

a higher HU re-formation, which results in decreased scatter on the 3D image. Therefore the implant clinician should be aware that 3D images *do not accurately* depict the bone in an area; it is only a stylized representation of the facial skeleton (Fig. 11.19).

Incidental Findings

The role of CBCT is rapidly emerging in all aspects of diagnosis and treatment planning with dental implants. Because of varying FOVs, the implant clinician is placed in a position to evaluate maxillofacial areas which he or she may not be familiar. Therefore it is crucial the implant clinician be able to interpret anatomic structures and pathology outside his or her primary area of interest. In radiology an incidental finding is defined as an unexpected discovery found on a radiologic examination performed for an unrelated reason. Unfortunately many normal anatomic variants, developmental anomalies, and imaging artifacts may be misidentified as possible pathologic conditions by inexperienced clinicians.[28] This may lead to unnecessary concern and stress for patients, and embarrassment for the clinician. In addition, possible significant pathologies may exist that go undiagnosed. This problem results in many professional, ethical, clinical, and potential legal issues for the implant clinician.

Complication Prevention

Understanding Incidence of Incidental Findings. Incidental findings on CBCT scans have been well documented in the literature. The exact frequency of incidental findings varies from study to study depending on age, gender, race, and FOV. Price et al.[29] showed a high incidence (3.2 findings/scan) of incidental findings, with approximately 16% requiring intervention or referral. These incidental findings ranged from common benign findings to significant pathologic conditions. Miles[30] reported a minimum of two reportable findings per CBCT and also showed a high incidence of periapical lesions that went undetected on conventional radiographs. Cha et al.[31] determined after evaluation of 500 scans an incidence rate of 24.6% of incidental findings, mostly in the airway region. Arnheiter et al.[32] showed that patients 40 to 49 years old had the largest percentage of reportable incidental findings (70%), with patients aged 20 to 29 years with the lowest percentage (40%).

Obtaining a Radiology Report. Radiology reports immediately after CBCT examinations, before surgery, minimize the liability that may present to the implant clinician. Formal radiology reports may be obtained from many sources, preferably from an appropriately qualified, board-certified maxillofacial radiologist. Unfortunately the geographic distribution of maxillofacial radiologists is not uniform within states or regions within a state, and a careful search will be required. Several, but not all, states require that the report be made by a maxillofacial radiologist licensed in the state, and it is therefore crucial to check with your local dental board or dental practice act to determine whether in-state licensure is required. The implant clinician must be able to recognize and evaluate variations from normal and refer for appropriate medical consultation any significant incidental finding that may be contained in the radiology report.

Use of the Smallest Field of View as Possible. Ideally the smallest FOV should be used for scans when treatment planning for dental implants. A smaller FOV (~mid FOV) will reduce radiation dose to the patient, thus adhering to the ALARA principle. However, caution should be exercised to not take an inadequate FOV that includes insufficient view of the anatomic area of concern. The most common anatomic area for this to occur is the maxillary posterior region, because many practitioners will set the limits of the scan superiorly to exclude the maxillary ostium. When placing implants or bone grafting in the posterior maxilla area, confirming the patency of the ostium is important to minimize complications associated with an obstructed ostiomeatal complex (Fig. 11.20).

Normal Radiographic Anatomy

Due to the complex nature of implant treatment and the potential for complications throughout the surgical and prosthetic phases, the clinician must have a thorough understanding of the normal anatomy of the maxillofacial region. Traditional dental education has focused on the interpretation of conventional 2D radiographic images for diagnosis, but with the introduction and rise of CBCT images, a deeper understanding of anatomy is necessary to examine the patient's structures in three dimensions. This section will address the basic radiographic anatomy as viewed in the three planes (axial, coronal, sagittal) typically shown on a CBCT image.

Mandibular Anatomy

The mandible is the largest, strongest, and lowest bone in the human face area.[33] The mandible is formed by the fusion of the right and left processes, and join in the midline area. It consists of the body (symphysis) and the right rami (ramus). The innervation of the mandible is via the inferior alveolar nerve, which is a branch of the trigeminal nerve. It enters the mandibular foramen on the lingual aspect of the ramus and courses anteriorly, where it divides into two branches: mental nerve and incisive nerve. The mental nerve exits the mental foramen, which gives sensory innervation to the chin, lip, and anterior gingiva. The incisive nerve courses anteriorly to supply the anterior teeth.

Mandibular Canal and Associated Anatomy

The position of the MC as it courses through the mandible from posterior to anterior is highly variable. Although the pathways of the inferior alveolar nerve and the mental nerve have been well described in the literature, it is paramount the implant clinician have a clear understanding of their anatomic features. When evaluating the intraosseous course of the MC buccal-lingually and inferior-superiorly within the mandible, many variations exist based on gender, ethnicity, amount of bone resorption, and age.

The inferior alveolar canal or MC contains the neurovascular bundle, which consists of the inferior alveolar nerve, artery, vein, and lymphatic vessels. The inferior alveolar nerve bundle enters the mandibular foramen, where it transverses anteroinferiorly from lingual to buccal within the body of the mandible. A 3D evaluation of the MC position is recommended when implant placement is going to be positioned in proximity to the nerve. The most accurate assessment of the anatomic position is with CBCT, because images may be enhanced via viewing software

• **Fig. 11.20** Newer cone beam computed tomography units allow for collimation or customized field of views that decrease radiation exposure.

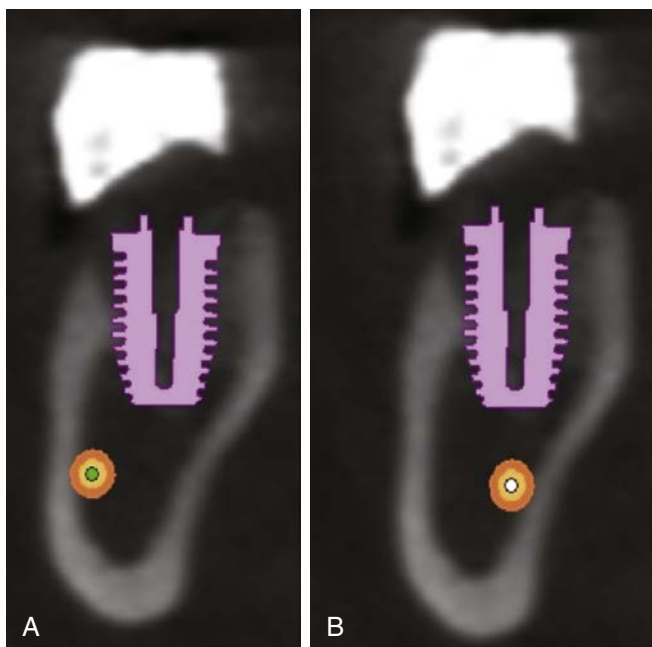
adjustments for contrast, brightness, and grayscale to help depict the anatomic location of the MC.

Image Evaluation. Radiographically the MC appears as a linear, radiolucent shadow, with or without inferior and superior radiopaque borders. Studies have shown the total length to be approximately 62.5 mm, with slightly longer measurements in male individuals (~2.5 mm).[34] The average diameter of the MC is approximately 2.0 to 3.4 mm, with the diameter being the greatest in the posterior near the mandibular foramen.[35] The foramen is triangular in nature near the mandibular foramen, and as it progresses anteriorly, becomes more ovoid in shape.[36] Location is variable depending on the patient's race, gender, and amount of bone resorption. Usually the MC is located on a bony ledge, the lingula, which is located on the medial surface of the ramus. Studies have shown the foramen to be located approximately 19.7 mm from the anterior border of the ramus.[37]

The CBCT data are used with appropriate viewing software to identify and trace the MC. The depiction of the MC enables the implant clinician to assess the position in various multiplanar and 3D re-formations. Initially the MC is most easily drawn on the CBCT reconstructed panoramic view with location confirmation on the cross-sectional images. In most cases the endpoints are first identified (e.g., mandibular foramen, mental foramen), then the location of the MC is extrapolated between these two landmarks.

Buccal-Lingual Path of Mandibular Canal

Radiographic Evaluation. In the posterior region of the mandible the inferior alveolar nerve enters the mandibular foramen on the lingual surface of the mandible and progresses anteriorly in the body of the mandible. In between the MC and the mental foramen, the buccal-lingual position is extremely variable. Studies have shown the buccal-lingual location is dependent on such variables as the amount of bone resorption, age, and ethnicity.[38] The buccal-lingual position of the MC is easily depicted on cross-sectional images after canal location is verified and highlighted (Fig. 11.21).

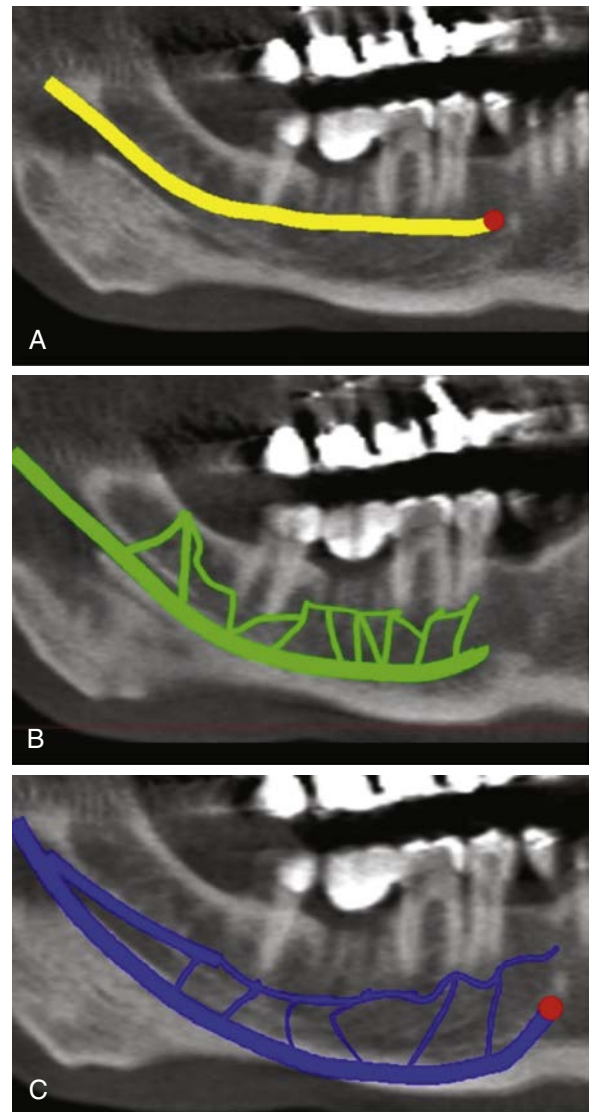
Clinical Significance. The intraosseous path of the MC is variable in the buccal-lingual position within the mandible, and a comprehensive radiographic survey (CBCT) ideally should be completed before implant osteotomy initiation to determine the anatomic path.


• **Fig. 11.21** Variable Buccal-Lingual Position. (A) Buccal positioned. (B) Lingual positioned. (*From Resnik RR, Preece JW. Radiographic complications and evaluation. In: Resnik RR, Misch CE, eds.* Misch's Avoiding Complications in Oral Implantology. *St. Louis, MO: Elsevier; 2018.*)

A 2-mm safety zone between the implant and the MC should always be adhered to. Attempting to place an implant buccal or lingual to the neurovascular bundle may result in neurosensory impairment.

Inferior-Superior Path of Mandibular Canal

Evaluation. The vertical position of the MC below the apices of the natural teeth within the mandible is highly variable. Thus generalizations cannot be made because the distance of the canal to the root apices is *not* consistent.[39] An early classification of the vertical positions of the course of the alveolar nerve was reported by Carter and Keen.[40] They described three distinct types: (1) in close approximation to the apices of the teeth, (2) a large nerve approximately in the middle of the mandible with individual nerve fibers supplying the mandibular teeth, and (3) a nerve trunk close to the inferior cortical plate with large plexuses to the mandibular teeth. After the MC is located and drawn on the reconstructed panoramic image using CBCT viewing software, the vertical position of the intraosseous path may be determined by scrolling through the cross-sectional images. The vertical position is then easily seen on individual cross sections or CBCT-generated reconstructed panoramic images (Fig. 11.22).

Clinical Significance. The intraosseous path of the MC is variable in the inferior-superior position within the mandible, and a


• **Fig. 11.22** Inferior Mandibular Nerves. Type 1 (A), type 2 (B), and type 3 (C) nerves. (*Adapted from Resnik RR, Preece JW. Radiographic complications and evaluation. In: Resnik RR, Misch CE, eds.* Misch's Avoiding Complications in Oral Implantology. *St. Louis, MO: Elsevier; 2018.*)

comprehensive radiographic survey (CBCT) ideally should be completed before implant osteotomy. Special care should be exercised in type 1 nerves because their close approximation to the root apexes results in compromised bone height for implant placement. Type 3 nerves are most favorable for implant placement in the posterior mandible because there exists the most ideal amount of bone height. In many instances the MC may not be easily depicted on the CBCT image; thus identification can be extremely challenging. The visibility of the MC varies significantly, even within the same individual.

The MC walls usually are not made up of compact bone, showing only a coalescence of trabecular bone with varying degrees of density.[41] This complicates the determination and location of the true identification of the canal. Studies have shown the unreliability of identifying the entire MC course being a direct result of minimal to no dense cortical plates surrounding the nerve bundle, which has been shown to occur in approximately 30% of cases. The MC has an increased wall density in the posterior (~mandibular foramen > third molar region) in comparison with the anterior region.[42]

With CBCT, images are susceptible to noise and artifacts, with resulting low contrast. Because of these inherent quality issues, distinguishing the MC from other aspects of the internal trabecular components of the mandibular image is difficult. Thresholding, the inability of the software to distinguish between two closely related densities, results in the inability to determine the correct position because of the increased noise. If a highly accurate assessment of the mandibular canal is warranted, the implant clinician may order an MRI survey, which has been shown to depict the soft tissues much better than CBCT.

Mental Foramen

The mental foramen is an opening in the anterolateral aspect of the mandible, commonly in the interproximal space between the first and second premolars; however, individuals may rarely exhibit the position of the foramen as anterior to the cuspid area and as far posteriorly as the bifurcation of the first molar. One of the two terminal branches of the inferior alveolar nerve is the mental nerve, which exits the mental foramen with sensory innervation to the chin, lip, and anterior gingiva. The mental foramen completes after the 12th gestational week, when the mental nerve separates into several fascicles. If the mental nerve separates before the formation of the mental foramina, the formation of accessory foramen results.[43] The mental foramen location, size, and number are highly variable, with many dependent factors, including gender, ethnic background, age, and skeletal makeup.

Image Evaluation. The mental foramen may be most easily identified on axial, coronal, and cross-sectional images. The relationship between the mental foramen and teeth or vital structures can be evaluated most easily on volumetric 3D images. The location of the mental foramen on 2D periapical and conventional panoramic radiographs has been shown to be inaccurate because they do not show the true location in most cases. In addition, when placing immediate implants in the premolar region, angulation and avoidance of the foramen should be noted because the mental foramen has been shown to be located coronal to the root apex of premolars in 25% to 38% of patients. Thus anytime an implant is to be treatment planned in approximation of the foramen, a CBCT evaluation is recommended.[44] However, the low contrast in CBCT images may make it difficult to do this without obscuring the canal or including too much noise in the process (Fig. 11.23).

Incisive Canal

The mandibular incisive canal is a bony canal within the anterior mandible that is a continuation of the MC. This canal contains the terminal branch of the inferior alveolar nerve, which travels inferiorly to the mandibular anterior teeth and terminates in the midline. In approximately the first molar region, the inferior alveolar nerve bifurcates into the mental and incisive nerves. The mandibular incisive canal terminates as nerve endings within the anterior teeth or bone near the lateral incisor region and will extend only to the midline in 18% of patients and in some cases will anastomosis with the contralateral side.[45]

Radiographic Evaluation. The incisive canal is not always seen radiographically on CBCT. The incisive nerve may be differentiated from the mental nerve by determination of any canal that is anterior to the mental nerve/foramen exit. When present, this radiolucent canal will continue anteriorly from the mental foramen and can be seen as a bifurcation (Fig. 11.24).

Clinical Significance. The incisive canal is often mistaken for an anterior loop of the mental nerve; however, this nerve
● **Fig. 11.23** (A) The mandibular canal is easily seen when a thick cortical component is present. (B) However, in approximately 30% of patients, the mandibular canal will not have a cortical component.
● **Fig. 11.24** Incisive Canal. (A and B) The incisive canal is a continuation of the inferior alveolar canal that contains the incisive nerve, which innervates the mandibular anterior teeth.

innervates the anterior teeth and has no sensory innervation to the soft tissue. However, if the incisive canal is traumatized, cases of excessive bleeding have been reported.

Anterior Loop

As the mental nerve proceeds anteriorly in the mandible, it may on occasion extend beyond the anterior boundary of the mental foramen. This endosteal curved loop is proximal to the mental foramen and exits distally through the mental foramen, and is termed an *anterior loop*. Studies have shown a prevalence rate of approximately 35% to 50%, with a mean distance of 1.16 mm anteriorly to the foramen.[46] Clinically an anterior loop may be determined by probing within the mental foramen in a posterior direction; however, this necessitates full reflection of the mental foramen.

Radiographic Evaluation. The determination of an anterior loop is difficult to identify and cannot be determined accurately with 2D radiography. High false-positive and false-negative results have been noted on conventional panoramic and periapical radiographs. To identify an anterior loop on a reformatted CBCT image, the MC must be highlighted, including the cross-sectional image depicting the mental foramen slice. The anterior part of the mental foramen is marked with a constant perpendicular line (see Fig. 11.25a). In axial images, scrolling from superior to inferior is evaluated for any part of the nerve anterior to the line. If an anterior loop exists, the highlighted nerve will be anterior to the perpendicular line (Fig. 11.25).
● **Fig. 11.25** An anterior loop is determined by evaluating axial images in a superior to inferior direction. (A) The anterior aspect of the foramen should be marked (line that remains constant in the vertical plane). (B) As the axial images are sequentially evaluated from superior to inferior, if any part of the marked canal extends anterior to the line (C and D, arrows), an anterior loop exists. (*From Resnik RR, Preece JW. Radiographic complications and evaluation. In: Resnik RR, Misch CE, eds.* Misch's Avoiding Complications in Oral Implantology. *St. Louis, MO: Elsevier; 2018.*)

Clinical Significance. The importance of determining the presence of an anterior loop is critical when placing implants anterior to the mental foramen. Inability to establish the existence of an anterior loop may result in implant placement too close to the mental nerve, resulting in possible neurosensory impairment.

A

B
● **Fig. 11.26** (A) 3D CBCT image depicting a small accessory foramen inferior to primary mental foramen. (B) Coronal Image showing large main foramen and smaller accessory foramen.

Accessory and Double Foramina

In approximately 6.6% to 12.4% of patients, an accessory (double) foramen is present, with an average diameter of 1.0 mm.[47-49] Special care should be noted to evaluate for an accessory canal because it may contain components of one of the three branches of the mental nerve. Accessory foramina are believed to be the result of early branching of the inferior alveolar nerve, before exiting the mental foramen during the 12th week of gestation.[50]

Radiographic Evaluation. The ideal technique to determine an accessory foramen is evaluation of coronal images, along with evaluation of the 3D image. In the coronal image the mandibular foramen will be shown bifurcating into two canals, resulting in the presence of two foramina. The evaluation of 3D images will easily depict two canals. Normally, accessory canals are located distal to the mental foramen (Fig. 11.26). In some cases, small openings which represent nutrient vessels may perforate through the buccal plate. These aberrant vessels are of no neural consequence.

Clinical Significance. In the majority of patients, small accessory foramina usually contain a small branch of the mental nerve, which is not problematic because of cross-innervation. However, in some cases a larger branch of the mental nerve (equal or larger size foramen) may exit the mental foramen. If a larger accessory foramen is present and resultant damage to the nerve exists, possible neurosensory impairment is possible. However, usually these accessory foramina are smaller and do not result in any disturbances because of collateral innervation.

Hypomineralization of the Mandibular Canal

When locating the MC, approximately 41% of the time the canal is not seen because of hypomineralization of the bone.[51] Studies have shown that in 20.8% of CBCT scans the MC walls are hypomineralized.[52] This often results in poor localization of the MC and is sometimes an early indication of osteopenia or osteoporosis (Fig. 11.27).

Radiographic Evaluation. The brightness and contrast may be altered using imaging software to more clearly define the canal walls.

Clinical Significance. Lack of identification of the MC may result in the inability to properly locate the MC. This may result in increased morbidity, leading to placement of implants too close to the nerve, with resultant nerve damage. In cases where a CBCT cannot differentiate the canal, an MRI survey is a reasonable alternative.

Mandibular Ramus (Donor Site for Autogenous Grafting)

The mandibular ramus area has become a popular donor site for autogenous onlay and trephine bone grafting. This anatomic area of

A

B
● **Fig. 11.27** (A) Accessory (Double) Foramina which are easily seen on 3D images. (B) Nutrient Canals are small openings which represent nutrient vessels (*green arrow*, mental foramen; *blue arrow*, nutrient canal). (*A: From Resnik RR, Preece JW. Radiographic complications and evaluation. In: Resnik RR, Misch CE, eds.* Misch's Avoiding Complications in Oral Implantology. *St. Louis, MO: Elsevier; 2018.*)

the mandible is extremely variable in the amount of bone present, as well as the buccal-lingual and inferior-superior position of the MC. Most commonly the lateral aspect of the ramus is harvested as a block graft, which is used for ridge augmentation procedures.

Image Evaluation. The mandibular ramus is quadrilateral in shape and contains two surfaces, four borders, and two processes. The lateral surface is flat with two oblique ridges, the external and internal. The masseter muscle attaches on the entire lateral ramus surface. The medial surface gives rise to the lingula, which is the entrance of the inferior alveolar nerve and associated vessels. The antegonial notch, anterior to the angle of the mandible, when present, is significant for the presence of parafunction.

The relationship between the lateral cortical plate in the ramus area and the position of the MC is easily seen on cross-sectional images, after nerve location identification. In addition, 3D images and bone models assist in the determination of the osseous morphology in this region to help the clinician select the most appropriate graft site.

Historically, standard 2D radiographs for evaluation of the ramus area as a donor site included conventional panoramic images, in which the location of the external oblique and the MC may be noted. However, 2D evaluation of this area can be difficult to use for determination of the amount of bone present and position of the MC. With this procedure, it is vital that the implant clinician be able to completely determine the exact position of the MC with respect to the external oblique ridge and the lateral cortical bone. Thus overestimation of available bone can result in increased morbidity, so a more accurate representation of this area is with the use of CBCT (Fig. 11.28).
● **Fig. 11.28** The mandibular ramus area can be evaluated. (A and B) Cross-sectional (outline for ramus block graft) (A) and axial 3D image (B) allowing for the evaluation of the proximity of the mandibular nerve to the facial cortical plate. (*A: From Resnik RR, Preece JW. Radiographic complications and evaluation. In: Resnik RR, Misch CE, eds.* Misch's Avoiding Complications in Oral Implantology. *St. Louis, MO: Elsevier; 2018.*)

Lingual Concavities (Posterior)

The trajectory/angulation of the mandible, along with inherent undercuts, poses a significant problem to the implant clinician. Lingual concavities may occur in the anterior region as an hourglass or constriction of the mandibular bone. Butura et al.[53] have shown the incidence to be approximately 4% of patients, which is most likely genetic or developmental in origin.

In the posterior region, concavities are much more common, resulting in undercuts in approximately 35% of patients.[54] Because of these undercuts, implant placement may be difficult, and perforation of the lingual plate may result.

Radiographic Evaluation. Posterior undercuts are most easily seen in cross-sectional and 3D images.

Clinical Significance. In the posterior region, overestimation of available bone is a common complication. If an implant osteotomy is completed in this area, perforation of the lingual plate may result, leading to possible bleeding and possible implant morbidity. Life-threatening lingual bleeding may occur as a result of blood vessel injury, leading to bleeding into the soft tissues. In addition, damage to the lingual nerve may occur on perforation of the lingual cortical plate (Fig. 11.29).

Retromolar Canal/Foramen

The retromolar fossa of the mandible forms a triangular depression, which borders the temporal crest medially and the anterior border of the mandibular ramus laterally. Within this fossa an anatomic variant termed the *retromolar foramen* is present in approximately 14% of patients.[55] The retromolar foramen on the alveolar surface is the terminal end to the retromolar canal, which branches from the MC.

Radiographic Evaluation. The retromolar foramina are not located in a constant position and usually are not bilateral. Most commonly, retromolar foramina should be initially evaluated via CBCT sagittal slices and then verified with cross-sectional images.

Clinical Significance. It is important to confirm the retromolar foramen and canal locations before surgical procedures, because this area is a common donor site for bone grafts. If perforation of the retromolar canal results, excessive bleeding may result (Fig. 11.30).

Mandibular Symphysis (Implant Placement and Bone Donor Site)

The mandibular symphysis area is a common area for implant placement, as well as a donor site for autogenous block grafting. This anatomic region has been shown to be one of the most ideal intraoral donor sites for bone harvesting. However, the mandibular symphysis is susceptible to nonuniform bone resorption and contains various anatomic variations that may lead to surgical complications.

Image Evaluation. The anterior surface of the mandible is termed the mandibular symphysis. A ridge divides the right and left sides, which inferiorly forms the triangular eminence of the mental protuberance. The elevated center of this depressed area forms the mental tubercle, which is the origin of the mentalis muscles. This area should be evaluated on cross-sectional, axial, and 3D images. Two-dimensional imaging of this area should be used only as a preliminary evaluation for bone quantity determination. Poor angulation, bony undercuts, and measurements cannot be determined with 2D radiography. CBCT imaging is highly recommended to prevent implant malposition or overestimation of available bone for harvest procedures, which may lead to increased complications (Fig. 11.31).
• **Fig. 11.29** (A) Three-dimensional images depicting sublingual undercut. (B) Cross section depicting significant undercut. (C) Nonideal placement of implant perforating the lingual plate that may predispose the patient to possible sublingual bleeding. (*A and B: From Resnik RR, Preece JW. Radiographic complications and evaluation. In: Resnik RR, Misch CE, eds.* Misch's Avoiding Complications in Oral Implantology. *St. Louis, MO: Elsevier; 2018.*)
• **Fig. 11.30** Cone beam computed tomography image showing large retromolar canal.

Anterior (Hourglass Shaped)

Radiographic Evaluation. Anterior undercuts are most easily seen in cross-sectional and 3D images.

Clinical Significance. In the anterior region, perforation of the bony plates of the mandible during implant osteotomies may lead to extensive bleeding from sublingual vessels. A significant plexus of sublingual and submental arteries may lead to life-threatening floor of the mouth hematoma formation. Therefore a thorough CBCT examination will determine the exact location and angulation for safe implant placement (Fig. 11.32).

Lingual Foramen/Canal. The interforaminal region in the anterior mandible is usually a relatively safe area for implant placement and bone grafting procedures. However, on the lingual aspect of the mandible, in the midline, lies the lingual foramen or foramina.
● **Fig. 11.31** (A and B) The symphysial area can be evaluated on cross-sectional images, along with axial slices.
● **Fig. 11.32** Anterior Mandible. (A) Cone beam computed tomography three-dimensional image depicting large undercuts. (B) Cross-sectional image showing hourglass mandibular shape. (C) Interactive treatment plan displaying perforation of an implant if placed in an hourglass mandible. (*A and C: From Resnik RR, Preece JW. Radiographic complications and evaluation. In: Resnik RR, Misch CE, eds.* Misch's Avoiding Complications in Oral Implantology. *St. Louis, MO: Elsevier; 2018.*)

This anatomic structure houses the terminal branches of the lingual artery (sublingual artery), facial artery (submental artery), or the anastomosis of both. As the blood vessels enter within the mandible, they are termed the *mandibular median vascular canal.*

Radiographic Evaluation. Lingual canals and foramina may be seen radiographically as a radiolucent canal in the midline of the mandible and easily depicted on cross-sectional or axial views. Studies have verified the median vascular canal is present in 96% to 100% of patients. The median vascular canal size is proportional to the diameter of the arteries entering the foramen. The average diameter has been shown to be approximately 0.84 mm, with the average distance from the inferior mandibular border to be 11.2 mm. With consideration to the extent of penetration within the mandible, 19.4% of canals end within the lingual third, 52.8% reached the middle third of the mandible, and 27.8% penetrated to the buccal third[56] (Fig. 11.33).

Significance. Potentially, these vessels may cause extensive bleeding in the mandible during endosseous implant placement or symphysial bone grafts. When larger lingual canals exist (>1.0 mm), significant bleeding issues may present with a possible compromised integration because of a potential soft tissue interface with the implant.

Maxillary Anatomy

The maxilla is composed of paired bones, which unite to form the upper jaw, and is composed of four processes: posterolateral (zygomatic, horizontal and medial), palatine (arch and inferior), alveolar, and the superior projecting frontal process. In oral implantology the maxilla presents a difficult and demanding challenge in the treatment and placement of implants with its complex osseous makeup, anatomy, and anatomic variants.

Premaxilla

The anterior premaxilla is one of the most difficult areas for the implant clinician in preoperative assessment, surgical placement, esthetic, and prosthodontic demands. Numerous factors affect the anatomic makeup of the premaxilla that may predispose to surgical complications and result in a decrease in implant survival.

Biomechanics. As a result of the alveolar ridge resorption after tooth loss, the residual available bone migrates to a more palatal position.[57] This leads to difficulties in implant positioning that place the implant clinician at risk because of esthetic issues. Because bone resorption occurs at the result of the buccal plate, implant placement usually occurs in a more palatal position. This

● **Fig. 11.33** Mandibular Vascular Canal. (A) The mandibular vascular canal that contains the sublingual artery anastomosis, which is usually present in the mandibular midline. (B and C) Canal that extends to the facial plate and superiorly (B), and off the midline lingual vascular canal (C).

will create a greater moment force leverage on the bone-implant interface, abutment screws, and implants. Coupled with an angled force in both centric and excursions, more stress is transmitted to premaxillary implants than those in anterior mandibles. Often, more implants and larger-diameter implants are indicated, with bone augmentation by bone spreading or bone graft procedures before or in conjunction with implant placement.

Poor Bone Density. In most patients the bone is less dense in the anterior maxilla than in the anterior mandible. The maxilla most often presents thin porous bone on the labial aspect, very thin porous cortical bone on the floor of the nasal and sinus region, and denser cortical bone on the palatal aspect.[58] The trabecular bone in the premaxilla is usually fine and less dense than the anterior region of the mandible. Due to this poor bone quality, increased difficulty in implant placement and a higher probability of overload implant failures or crestal bone loss may result.

Accelerated Bone Loss. Because of the poor bone quality in the premaxilla, preexisting bone after extractions is predisposed to significant resorption. After tooth loss, the facial cortical plate rapidly resorbs during initial bone remodeling, and the anterior ridge has been shown to lose up to 25% of its width within the first year, as well as 40% to 50% within the next 3 to 5 years, mostly at the expense of the labial contour (Fig. 11.34).

Nasopalatine Canal/Incisive Foramen

The nasopalatine canal (also termed the incisive canal or anterior palatine canal) is a passageway within the anterior maxilla midline that connects the palate to the floor of the nasal cavity. The entrance of the canal into the oral cavity is via the incisive foramen, which is posterior to the central incisor teeth. The vital structures passing through the canal include the terminal branch of the internal maxillary artery and the nasopalatine nerve, which communicates with the sphenopalatine artery and the greater palatine nerve. The anatomic structures in the nasopalatine canal may present with wide variation in the location, shape, dimensions, and its existence.

Radiographic Evaluation. The location and dimension of the nasopalatine canal is most likely seen on axial and coronal images. Cross-sectional and 3D images may also depict the size, shape,
• **Fig. 11.34** The premaxilla presents a challenging area for the implant clinician because of the (A) significant vertical and horizontal bone loss, and (B) minimal bone for implant placement, along with trajectory issues.
• **Fig. 11.35** The nasopalatine canal area should be evaluated as to the size and location because implant placement in this area may predispose to placement within soft tissue. (A) Very large canal leading to minimal available bone. (B) Implant placement impinging on nasopalatine canal.

and location of the nasopalatine canal, along with evaluation of implant impingement on this space.

Clinical Significance. Determining the morphology of the nasopalatine canal via CBCT images allows the clinician to ascertain whether available bone is present for dental implantation. Placing implants in the anterior maxilla (central incisor area) is the most challenging anatomic location for the implant dentist because of biomechanical, functional, esthetic, and phonetic demands. Especially with immediate implant placement, consideration must be given to the presence of the nasopalatine canal, including a careful evaluation of its morphology and position to minimize implant placement complications.

Implant Placement. The incisive foramen often expands laterally within the palatal bone, and the central incisor implant osteotomy may inadvertently encroach on this structure, resulting in the formation of fibrous tissue at the interface in the mesiopalatal region. If the osteotomy invades the incisive canal, treatment options include tissue removal within the canal and bone graft and/or implant placement. When a large nasopalatine canal exists, a more distally placed implant placement in the central incisor region prevents encroachment on this area. Because most restorations in an edentulous premaxilla are FP-2 or FP-3, the most favorable sites for bone width are selected, even when they are in the interproximal region of central and lateral incisor sites.

Enlarged Incisive Foramen/Canal. When there exists an enlarged canal, the lack of available bone will most likely not

permit ideal implant placement. However, it is important to differentiate enlarged canals from incisive canal cysts. Incisive canal cysts are known to cause localized dilation of the canals, with possible displacement of the teeth. In edentulous patients the nasopalatine canal has been shown to be significantly larger in comparison with dentate patients (Fig. 11.35).

Implant Failure/Bleeding. When implants are positioned in contact with neural tissue, lack of osseointegration and failure of the implant may result. In addition, placement of implants in close approximation to nasopalatine blood vessels may cause excessive bleeding during surgical procedures; however, this is usually self-limiting and controlled by local hemostatic techniques.

Infraorbital Foramen

The infraorbital foramen is located in the anterior aspect of the maxillary bone below the infraorbital margin of the orbit. The infraorbital artery, vein, and nerve exit the foramen. On average the infraorbital foramen to infraorbital margin distance is approximately 6.1 to 10.9 mm.[59]

Radiographic Evaluation. The infraorbital foramen is easily seen on coronal images, along with 3D reformatted images.

Clinical Significance. Anatomic variants have been reported to be as far as 14 mm from the orbital rim in some individuals. In the severely atrophic maxilla the infraorbital neurovascular structures exiting the foramen may be close to the intraoral residual ridge and should be avoided when performing sinus graft procedures, to
• **Fig. 11.36** (A) Normal location for infraorbital nerve. (B) Variation closer to ridge that may result in neurosensory impairment from retraction or possible transection on reflection of the tissue. (*From Resnik RR, Preece JW. Radiographic complications and evaluation. In: Resnik RR, Misch CE, eds.* Misch's Avoiding Complications in Oral Implantology. *St. Louis, MO: Elsevier; 2018.*)

minimize possible nerve impairment. This is of particular concern on soft tissue reflection and the bone preparation of the superior aspect of the window. Because the infraorbital nerve is responsible for sensory innervations to the skin of the upper cheek; mucosa of the maxillary sinus; maxillary incisors, canines, and premolars; and gingiva, skin and conjunctiva of the eyelid, lateral nose, and mucosa of the upper lip, damage to this nerve may cause significant discomfort to the patient. Most often the nerve is not severed, and a neurotmesis presents that usually resolves within 1 month after the surgery (Fig. 11.36).

Paranasal Sinuses

Frontal. The frontal sinuses are bilateral and funnel-shaped on each side of the midline superior to the orbital bones. The borders of the frontal sinus are inferior, orbital portion of the frontal bone; posterior, separates the dura of the frontal lobe from the lining mucosa; and posterior, separates the dura of the frontal lobe

from the lining mucosa. The frontal sinuses extend to the middle meatus, and drain through the nasofrontal duct and into the frontal recess. The location of the frontal ostia is approximately two-thirds high on the posterior medial wall, which anatomically complicates clearing of the sinus after infection.[60] The frontal recess, which is the drainage pathway of the frontal sinus, drains into the middle meatus or ethmoid infundibulum. On coronal CBCT images, the frontal recess is superior and medial to agger nasi cells.

Ethmoid. The ethmoid sinuses are within the ethmoid bone and divided into two compartments, the anterior and posterior. The anterior ethmoid sinus drains into the middle meatus, and the posterior ethmoids drain into the sphenoethmoidal recess. The borders of the ethmoid sinuses include:

Anterior ethmoid
   Lateral: lamina papyracea of the orbit
   Medial: middle turbinate
   Superior: fovea ethmoidalis, cribriform plate
Posterior ethmoid
   Lateral: lamina papyracea of the orbit
   Medial: superior turbinate
   Superior: fovea ethmoidalis, cribriform plate

The ethmoid sinuses have various radiographic anatomic markers, which are termed *air cells*. The *ethmoid bullae* are the largest and most prominent radiographically in the anterior region. *Agger nasi cells* are usually the most anterior of the anterior air cells and are located in anterior/superior to the middle turbinate. Along the inferior border of the orbits are the *Haller cells*, which may impair mucociliary clearance when they enlarge and impinge on the ethmoid infundibulum. The *Onodi cells* derive from the posterior ethmoid and are located lateral and superior to the sphenoid sinus.[61]

Sphenoid Sinus. The sphenoid sinus is located within the sphenoid bone and contains superiorly the pituitary fossa and olfactory nerves. Inferiorly the pterygoid canal courses beneath the mucosa, with the cavernous portion of the internal carotid artery within the lateral wall. The ostium lies in the superior aspect and drains into the sphenoethmoidal recess.[62]

Maxillary Sinus. The maxillary sinuses are the largest of the paired paranasal sinuses and are often a problematic area for implant clinicians. The posterior maxilla has many inherent disadvantages, including poor bone density, the anatomic minimal interocclusal space, and insufficient bone quantity for ideal implant placement. Thus the implant clinician must have comprehensive knowledge of normal versus abnormal anatomy in association with the maxillary sinus and paranasal sinus anatomy. The maxillary sinus has a high prevalence of anatomic variants and pathology, which predispose the patient to increased morbidity. Thus a comprehensive knowledge and understanding of this area is important for implant clinicians. Radiographically the maxillary sinus has the following borders: Superiorly, the maxillary sinus is bordered by the orbital floor, which houses the infraorbital canal. Inferiorly, the floor of the maxillary sinus approximates the roots of the maxillary teeth. The medial wall coincides with the lateral wall of the nasal cavity and is the location of the maxillary ostium, the area of drainage of the ethmoid infundibulum (Fig. 11.37).

Nasal Cavity

The borders of the nasal cavity are:

Inferior: hard palate
Lateral: medial walls of the right and left maxillary sinus
Superior: nasal, ethmoid, and sphenoid bones
Medial: nasal septum
• **Fig. 11.37** Diagram of Maxillary Sinus Anatomy.

The lateral walls of the nasal cavity are made up of turbinates (concha), which are epithelium-lined bony structures that protrude into the nasal cavity and function to warm/cool and filter inspired air. Below each turbinate are spaces, termed *meatuses*. The middle meatus is most important because this is the area of drainage for the frontal, anterior ethmoid, and maxillary sinuses. The inferior meatus is the drainage site for the nasolacrimal duct. The superior meatus interconnects with the posterior ethmoid and sphenoid sinuses through the sphenoethmoidal recess.[63]

Maxillary Sinus Membrane

The maxillary sinus is lined by the Schneiderian membrane, which is identical to respiratory epithelium. This pseudostratified columnar epithelium is continuous with the nasal epithelium through the maxillary ostium in the middle meatus. The membrane has an average thickness of 0.8 mm and is usually thinner and less vascular than nasal epithelium.[64]

Radiographic Evaluation. A CBCT scan of normal, healthy paranasal sinuses reveals a completely radiolucent (dark) maxillary sinus. Any radiopaque (whitish) area within the sinus cavity is abnormal, and a pathologic condition should be suspected. The normal sinus membrane is radiographically invisible, whereas any inflammation or thickening of this structure will be radiopaque. The density of the diseased tissue or fluid accumulation will be proportional to varying degrees of gray values (Fig. 11.38).

Ostiomeatal Complex

The ostiomeatal unit is composed of the maxillary ostium, ethmoid infundibulum, anterior ethmoid cells, uncinate process, and the frontal recess.
• **Fig. 11.38** The maxillary sinus membrane (Schneiderian membrane) in health should be invisible (red arrow). When inflammation or pathology is present, it will be depicted as an increase in density/radiopacity or a visible increase in thickness (green arrow).

Radiographic Evaluation. The ostiomeatal complex can be evaluated radiographically and most easily seen on a coronal scan that includes the following structures:
1. maxillary sinus ostium
2. infundibulum
3. ethmoid bulla
4. uncinate process
5. hiatus semilunaris
● **Fig. 11.39** (A and B) Maxillary sinus ostium patency is the mucociliary drainage area of the maxillary sinus. (C) Nonpatent ostium (*red arrow*, non-patent ostium; *white arrow*, membrane inflammation).

Maxillary Ostium

The main drainage avenue of the maxillary sinus is through the ostium. The maxillary ostium is bounded superiorly by the ethmoid sinuses and inferiorly by the uncinate process. The maxillary sinus ostium is on the superior aspect of the medial wall of the sinus, approximately halfway between the anterior and posterior walls. The ostium is usually oval shaped and oriented horizontally or obliquely.[65]

Radiographic Evaluation. The maxillary ostium is visualized on coronal images usually in the anterior third of the maxillary sinus. This opening is located in the superior aspect of the maxillary sinus medial (lateral wall of nasal cavity). The patency of the maxillary ostium should always be ascertained when placing implants or bone grafts into the maxillary sinus. The opening can be verified by scrolling through various coronal images (Fig. 11.39).

Clinical Significance. If the maxillary ostium is nonpatent, the mucociliary clearance of the maxillary sinus may be affected. This can lead to an increased morbidity to implant-related procedures.

Uncinate Process

The uncinate process is an important structure in the lateral wall of the nasal cavity. This finger-like bony projection helps form the boundaries of the hiatus semilunaris and ethmoid bulla, which allow the draining of the frontal and maxillary sinuses.

Radiographic Evaluation. On coronal or cross-sectional CBCT images, the uncinate process is bordered by the medial wall

of the maxillary sinus and articulates with the ethmoid process and inferior nasal turbinate. Inferiorly it borders the semilunar hiatus, and posteriorly it has a free margin (Fig. 11.37).

Clinical Significance. A deflected uncinate process (either laterally or medially) can narrow the ethmoid infundibulum, thus affecting the ostiomeatal complex. Perforations may also be present within the uncinate process, leading to communication between the nasal cavity and ethmoid infundibulum. In addition, the uncinate process may be pneumatized. Although this is rare, it may compromise adequate sinus clearance. Uncinate process variations should be evaluated and treated before any procedure in which the physiology of the maxillary sinus is altered (e.g., implant placement or bone grafting).

Hiatus Semilunaris

The hiatus semilunaris is a curved fissure on the lateral wall of the nasal cavity, inferior to the ethmoid bulla. It connects the middle meatus to the anterior ethmoidal air cells and contains the openings for the frontal, maxillary, and anterior ethmoidal sinus (Fig. 11.37).

Radiographic Evaluation. The hiatus semilunaris gains its name from its arched appearance and is best identified in sagittal and cross-sectional images. This anatomic structure is bordered superiorly by the ethmoid bulla and posteriorly by the ethmoid process of the inferior nasal turbinate.

Clinical Significance. Because three different sinuses drain into the hiatus semilunaris, any mechanical blockage in this region may cause inflammation and possible disease into one of the sinuses.

Anatomic Variants

Concha Bullosa

The middle turbinate plays a significant role in proper drainage of the maxillary sinus. Normally the middle turbinate is a thin, bony structure; however, it can be aerated, which is termed a *concha bullosa*. This anatomic variant may be unilateral or bilateral, and it has been shown to have a prevalence rate of up to 53.6% of the population.[66] In addition, there exists a strong association with conchae bullosae and a deviated septum of the contralateral side.[67]

Radiographic Evaluation. Conchae bullosa are easily identified on a CT/CBCT coronal image depicting a radiolucent air space in the center of the middle meatus and surrounded by an ovoid bony rim.

Clinical Significance. In most cases of concha bullosa, no paranasal sinus pathology results. The larger the concha bullosa, the more likely the probability of compromising the drainage of the middle meatus. When enlarged, pressure against the uncinate process may occur, decreasing the infundibulum drainage, and thus affecting the physiology of the maxillary sinus, leading to an increased drainage problem. Caution must be exercised because patients with concha bullosa are more predisposed to postoperative complications from bone grafting and implants in the sinus area (Fig. 11.40).

Paradoxical Middle Turbinate

A paradoxical middle turbinate is an anatomic variant of the middle turbinate, with a prevalence rate of approximately 15% of the population.[68] This anomaly is a reversal of the normal medially directed convexity of the middle turbinate. The inferior edge of the middle turbinate may have various shapes exhibiting excessive curvature, which may predispose the patient to blockage in the nasal cavity, infundibulum, and middle meatus.[69]
● **Fig. 11.40** An anatomic variant that may predispose the implant patient to postoperative mucociliary impairment is a concha bullosa, which is an aerated middle turbinate.

Radiographic Evaluation. A paradoxical middle turbinate is most easily seen on a coronal CT/CBCT scan image. In certain cross-sectional images, it may also be seen. The convexity of the paradoxical middle turbinate is directed laterally, instead of medially toward the nasal septum.

Clinical Significance. When present, the implant clinician must take into consideration the possibility of postoperative mucociliary complications after bone grafting or implant placement in the maxillary sinus from blockage of the ostium (Fig. 11.41).

Deviated Septum

One of the most common anatomic variants in the oral region is a deviated septum, which may be congenital or traumatic in origin. Studies have shown a prevalence rate of 70%, which increases the possibility of ostiomeatal complex blockage. This occurs when the nasal septum is displaced laterally toward one side of the nasal cavity. When the deviation is severe, the flow of air through the nasal cavity is redirected and may cause nasal obstruction, hypoplasia of the ipsilateral turbinates, or hyperplasia of the contralateral turbinates.

Radiographic Evaluation. A deviated septum can be seen most easily via the coronal and axial image scans. In addition, a 3D image of the midline structure will allow direct evaluation. The nasal septum will be displaced toward one side of the nasal cavity (Fig. 11.42).

Clinical Significance. When the deviation is severe, the airflow through the nasal cavity is compromised, manifesting as nasal congestion. Patients with deviated septums are predisposed to sinus clearance issues, which increase morbidity of bone grafting and implant placement procedures in the maxillary posterior area on the side of deviation. Usually the contralateral side will have normal mucociliary clearance.

Haller Cells

Haller cells are infraorbital ethmoidal air cells that project from the maxillary sinus roof and the most inferior portion of the lamina papyracea. The Haller cells are usually present unilaterally, with a prevalence rate of approximately 6% of the population.[70] The origin of Haller cells is the anterior ethmoid (88%) and posterior ethmoid (12%).[71]
● **Fig. 11.41** Paradoxical Middle Turbinate (A) An anatomic variant that may predispose the implant patient to postoperative mucociliary impairments is termed a paradoxical middle turbinate. The convex side of the middle turbinate is directed laterally, instead of medially. (B) Image depicting no right or left middle turbinates, which is a recent treatment for patients exhibiting chronic rhinosinusitis to improve mucociliary flow.
● **Fig. 11.42** An anatomic variant that may predispose the implant patient to postoperative mucociliary impairments is a deviated septum. The side of deviation may cause blockage of the maxillary ostium.

Radiographic Evaluation. Haller cells are identified on coronal images and are located inferior to the ethmoid bulla and adher to the medial roof of the orbit, lateral to the uncinate process.

Clinical Significance. These air cells may expand into the orbit and narrow the ostium of the maxillary sinus, especially in the presence of an infection. Haller cells have been associated with a high incidence of chronic rhinosinusitis because they may impinge on the patency of the maxillary ostium, thus inhibiting ciliary function. Procedures (implants, bone grafts) that may involve the maxillary sinus have an increased morbidity when Haller cells are present.

Agger Nasi Cells

Agger nasi cells are the most anterior ethmoidal air cells that extend anteriorly into the lacrimal bone. They can be identified
● **Fig. 11.43** Agger nasi cells that are anterior aerated ethmoid air cells (arrows). (*From Koenig LJ, et al. Diagnostic Imaging: Oral and Maxillofacial. 2nd ed. Philadelphia: Elsevier; 2017.*)

on CT/CBCT in more than 90% of patients and are associated with a high incidence of frontal sinusitis.[72]

Radiographic Evaluation. Agger nasi cells are most easily seen in CT/CBCT coronal images lateral to the nasal wall (Fig. 11.43).

Clinical Significance. Agger nasi cells may predispose the patient to postoperative sinus complications.

Maxillary Sinus Septa

Antral septa (of buttresses, webs, and struts) are the most common osseous anatomic variant seen in the maxillary sinus. Underwood, an anatomist, first described maxillary sinus septa in 1910. Krennmair et al.[73] further classified these structures into two groups: primary, which are a result of the development of the maxilla; and secondary, which arise from the pneumatization of the sinus floor after tooth loss. The prevalence rate of septa has been reported to be in the range of 33% of the maxillary sinuses in the dentate patient and as high as 22% in the edentulous patient. The most common location of septa in the maxillary sinus has been reported to be in the middle (second bicuspid to first molar) region of the sinus cavity. CT scan studies have shown that 41% of septa are seen in the middle region, followed by the posterior region (35%) and the anterior region (24%). For diagnosis and evaluation of septa, CT scan is the most accurate method of radiographic evaluation.[74] Sinus septa may create added difficulty at the time of surgery.

Radiographic Evaluation. Three-dimensional images depict the anatomic features of septa most easily on CBCT images. They may also be easily seen on reformatted panoramic and axial and sagittal images (Fig. 11.44).

Clinical Significance. Maxillary septa complicate sinus graft surgery and can prevent adequate access and visualization to the sinus floor; therefore inadequate or incomplete sinus grafting is possible. In addition, a higher incidence of membrane perforation results when septa are present.

Maxillary Sinus Hypoplasia

Hypoplasia of the maxillary sinus may be a direct result from trauma, infection, surgical intervention, or irradiation to the maxilla during the development of the maxillary bone. These or other congenital developmental conditions interrupt the maxillary growth center, thus producing a smaller-than-normal maxilla. A malformed and positioned uncinate process is associated with this disorder, leading to chronic sinus drainage problems.

Radiographic Evaluation. Dimensionally smaller than normal maxillary sinus can be seen on panoramic, cross-sectional, coronal, axial, or 3D images.

Clinical Significance. Most often maxillary sinus hypoplasia patients have adequate bone height for endosteal implant placement, and a sinus graft is not required to gain vertical height. If implant placement or bone grafting involves the maxillary sinus,
• **Fig. 11.45** Hypoplasia of the maxillary sinus with inflammation (white arrow).
• **Fig. 11.44** The Maxillary Sinus Inferior Floor. (A) Flat and smooth maxillary sinus floor. (B) Narrow maxillary sinus floor with septum separating the sinus cavity.

caution should be exercised, because this condition has been associated with chronic sinus disease (Fig. 11.45).

Inferior Turbinate and Meatus Pneumatization (Big-Nose Variant)

A rather uncommon anatomic variant is when the inferior third of the nasal cavity exhibits pneumatization within the maxilla and resides over the alveolar residual ridge. Studies have shown an incidence rate of approximately 3%. Because the maxillary sinus is lateral to the edentulous ridge, inadequate bone height exists.

Radiographic Evaluation. Big-nose variants may be determined by evaluation on reconstructed CBCT panoramic images, as the nasal cavity will extend distal or posterior to the premolar area.

Clinical Significance. If unaware of this condition, the implant may be placed into the nasal cavity above the residual ridge, often penetrating into the inferior meatus and contacting the inferior turbinate. A sinus graft maybe contraindicated with this patient condition, because the sinus is lateral to the position of the implants. Most likely an onlay graft is required to increase bone height (Fig. 11.46).

Buccal Thickness of Bone in Premaxilla

On average, maxillary buccal cortical plates are less than 1 mm thick, significantly thinner than the mandibular alveolar bones, which are greater than 1 mm. Thin cortical plates (similar to voxel size) tend to become indistinguishable from adjacent cementum or titanium implants on CBCT images.

Radiographic Evaluation. Studies have shown that spatial resolution limitations of CBCT limit bone visibility of thickness less than 0.6 mm, meaning this is the minimum thickness for bone to be measurable. In addition, clinical studies show when bone dehiscence is present, a true dehiscence was present only 50% of the time, and a fenestration was present 25% of the time.[75]
● **Fig. 11.46** (A and B) Big-nose variant, which results in the nasal cavity extending into the first molar region, leaving inadequate bone for implants in the bicuspid region.
● **Fig. 11.47** Buccal Image Thickness. (A) The buccal bone can be very deceiving as depicted in this cone beam computed tomography cross section showing no buccal bone thickness and (B) photo image after full reflection showing buccal bone is present.

Clinical Significance. Because of the high degree of false-positive results, diagnosis and treatment planning can be problematic. The bone thickness should be correlated with all CBCT images, especially the cross-sectional views (Fig. 11.47).

Intraosseous Anastomosis

Within the lateral wall of the maxilla sinus is the intraosseous anastomosis, which is comprised of the posterior superior alveolar and infraorbital arteries. The vertical component of the lateral access wall for the sinus graft often severs these blood vessels.

Radiographic Evaluation. The intraosseous anastomosis is easily seen on cross-sectional or coronal views of a CBCT scan as a discontinuation of the lateral wall with a radiolucent notch. On average, this structure is approximately 15 to 20 mm from the crest of a dentate ridge.

Clinical Significance. When lateral wall sinus augmentation is indicated, evaluation of the CBCT scans should be completed to determine location and size. If bleeding does occur during the lateral wall osteotomy, this can be addressed by cauterization by the handpiece and diamond bur without water, electrocautery, or pressure on a surgical sponge while the head is elevated (Fig. 11.48).

Canalis Sinuosus

The anterior superior alveolar nerve branches from the infraorbital canal, just lingual to the cuspid area. This radiolucent canal is denoted as the canalis sinuosus. The canal runs forward and inferior to the inferior wall of the orbit and follows the lower margin of the nasal aperture and opens to lateral to the nasal septum.[76] The canalis sinuosus transmits the anterior superior alveolar nerve, artery, and vein.

Radiographic Evaluation. If the clinician is unaware of the canalis sinuosus, this anatomic structure may be misinterpreted as apical pathology on 2D radiographs. Therefore on CBCT scans, this bilateral anatomic structure should be evaluated for its presence. It may be depicted on axial, cross-sectional, or 3D images.
• **Fig. 11.48** Intraosseous anastomosis (arrow) shown on a cross-sectional image seen as discontinuity of the lateral wall and ovoid radiolucency.

Studies have shown the canalis sinuosus to be present on 87.5% of CBCT scans[77] (Fig. 11.49).

Clinical Significance. Because the anterior maxillary region is a common area for dental implant placement, the presence of canalis sinuosus may lead to a high degree of implant morbidity. Impingement into the canal may lead to a soft tissue interface and failure of the implant, and temporary or permanent sensory dysfunction and possible bleeding issues.[78] However, significant sensory impairments are rare because of cross-innervation.

Calcified Carotid Artery Atheroma

Calcified carotid artery atheromas are calcifications located in the common carotid, usually near the bifurcation of the internal and external carotid arteries. These calcifications give radiographic evidence of atherosclerosis, which is an indicator of possible stroke or metabolic disease. It has been shown that approximately 80% of strokes are ischemic and due to atherosclerotic disease in the carotid bifurcation.[79]

Radiographic Evaluation. Carotid artery calcifications are small, multiple radiopacities in the carotid space anterior and lateral to cervical vertebrae C3-C4. These multiple and irregularly shaped calcifications may be vertical in orientation and are usually easily distinguished from the adjacent soft tissue. They can easily be seen on axial and 3D images (Fig. 11.50). An additional common site to evaluate for carotid artery calcifications in large-volume CBCT images is lateral to the pituitary fossa.

Clinical Significance. Because of the significant complications that may arise from the presence of carotid calcifications (ischemic cerebrovascular disease is the second leading cause of death in most developed countries), the patient should be referred to his or her physician for assessment of carotid artery stenosis and possible ultrasound evaluation.

Pathologic Conditions in the Paranasal Sinuses

Pathologic conditions observed on CBCT scans taken for other indications appear to be increasing in prevalence. Signs of inflammation or serious pathologic conditions are a concern when bone augmentation procedures or dental implants are planned for the area. Therefore the implant clinician must have a strong knowledge base for various pathologic conditions in the sinus to understand when proper referral is recommended. In the next part of this chapter, a comprehensive evaluation of maxillary sinus pathology will be discussed, with emphasis on differential diagnosis and clinical relevance.

Odontogenic Rhinosinusitis (Periapical Mucositis)

Odontogenic rhinosinusitis occurs when the sinus membrane is violated by infection of teeth and pathologic lesions of the jaws. The intimate approximation of the roots of the maxillary posterior teeth to the floor of the sinus results in inflammatory changes of the periodontium or surrounding alveolar bone, which promotes the development of pathologic conditions in the maxillary sinus.

Radiographic Appearance. Odontogenic rhinosinusitis will usually produce generalized sinus mucosal hyperplasia, which is seen as a radiopaque band that follows the contours of the sinus floor. A localized periapical mucositis reveals a thickening of the mucous membrane adjacent to the offending tooth and, on occasion, a perforation through to the floor of the sinus. This radiographic appearance has been termed a halo effect (Fig. 11.51).

Differential Diagnosis. Odontogenic rhinosinusitis may be confused with acute rhinosinusitis or mild mucosal thickening.
• **Fig. 11.49** Canalis Sinuosus. (A) CBCT panoramic image depicting the canalis sinuosus, which transmits the anterior superior alveolar vessels. (B) Cross-sectional image highlighting in red the nerve. (C) 3D image showing course of the canal.
• **Fig. 11.50** (A and B) Carotid calcification atheroma at the level of cervical vertebrae C3-C4 (arrows).

However, in odontogenic rhinosinusitis the patient will most likely have pathology associated with an existing tooth (e.g., pain from a posterior tooth or a recent extraction, exudate around the existing natural posterior teeth) and radiographic evidence.

Acute Rhinosinusitis

A nonodontogenic pathologic condition may also result in inflammation in the maxillary sinus in the form of rhinosinusitis. The most common type of rhinosinusitis in the maxillary sinus is acute rhinosinusitis. The signs and symptoms of acute rhinosinusitis are rather nonspecific, making it difficult to differentiate from the common cold, influenza type of symptoms, and allergic
• **Fig. 11.51** Odontogenic rhinosinusitis (A and B) associated with pathologic teeth that extends into the sinus cavity.

rhinitis. However, the most common symptoms include purulent nasal discharge, facial pain and tenderness, nasal congestion, and possible fever. Acute maxillary rhinosinusitis results in 22 to 25 million patient visits to a physician in the United States each year, with a direct or indirect cost of $6 billion dollars. Although four paranasal sinuses exist in the skull, the most common involved in sinusitis are the maxillary and frontal sinuses.[80]

Radiographic Appearance. The radiographic hallmark in acute rhinosinusitis is the appearance of an air-fluid level. A line of demarcation will be present between the fluid and the air within the maxillary sinus. If the patient is supine (CBCT), then the fluid will accumulate in the posterior area; if the patient is upright during the imaging, the fluid will be seen on the floor and horizontal in nature. Additional radiographic signs include smooth, thickened mucosa of the sinus, with possible opacification. In severe cases the sinus may fill completely with supportive exudates, which gives the appearance of a completely opacified sinus. The terms *pyocele* and *empyema* have been applied with these characteristics (Fig. 11.52).

Differential Diagnosis. The differential diagnosis of acute rhinosinusitis and prolonged viral upper respiratory infection are similar. However, a classic air-fluid level in the maxillary sinus will give rise to the confirmation of acute rhinosinusitis. In addition, viral rhinosinusitis will usually improve within 7 to 10 days, whereas acute bacterial rhinosinusitis persists for longer than 10 days.[81]
● **Fig. 11.52** Cone beam computed tomography coronal image depicting an air-fluid level that is a classic radiographic sign of acute bacterial rhinosinusitis.

Chronic Rhinosinusitis

If the symptoms of acute rhinosinusitis do not resolve in 12 weeks, it is then termed *chronic rhinosinusitis*. It is the most common chronic disease in the United States, affecting approximately 37 million people. Symptoms of chronic rhinosinusitis are associated with periodic episodes of purulent nasal discharge, nasal congestion, and facial pain.[82]

Radiographic Appearance. Chronic rhinosinusitis has the characteristic feature of sclerotic, thickened cortical bone from long-lasting mucoperiosteal inflammation. In addition, it may appear radiographically as thickened sinus mucosa to complete opacification of the antrum.

Allergic Rhinosinusitis

Allergic rhinosinusitis is a local response within the sinus caused by an irritating allergen in the upper respiratory tract. Therefore the allergen may be the cause of the allergic rhinosinusitis. This category of sinusitis may be the most common form, with 15% to 56% of patients undergoing endoscopy for sinusitis showing evidence of allergy. Allergic rhinosinusitis often leads to chronic rhinosinusitis in 15% to 60% of patients.[83] The sinus mucosa becomes irregular or lobulated, with resultant polyp formation.

Radiographic Appearance. Polyp formation related to allergic rhinosinusitis is usually characterized by multiple, smooth, rounded, radiopaque shadows on the walls of the maxillary sinus. Most commonly, these polyps are located near the ostium and are easily observed on a CBCT scan. In advanced cases, ostium occlusion, along with displacement or destruction of the sinus walls, may be present, with a radiographic image of a completely opacified sinus (Fig. 11.53).

Fungal Rhinosinusitis (Eosinophilic Fungal Rhinosinusitis)

Granulomatous rhinosinusitis is a very serious (and often overlooked) disorder within the maxillary sinus. Patients who have fungal sinusitis are thought to have had an extensive history of antibiotic use, chronic exposure to mold or fungus in the environment, or are immunocompromised.

Differential Diagnosis. Three possible clinical signs may differentiate fungal sinusitis from acute or chronic rhinosinusitis: (1) no response
● **Fig. 11.53** (A) Bilateral polyposis, usually associated with allergies, showing the circumferential, polypoid nature of the lesions. (B) Bilateral partially opacified sinuses representing a severe case of allergic rhinosinusitis; severe cases may lead to complete opacification.

to antibiotic therapy; (2) soft tissue changes in sinus associated with thickened reactive bone, with localized areas of osteomyelitis; (3) and association of inflammatory sinus disease that involves the nasal fossa and facial soft tissue. In some cases a positive diagnosis may require mycological and histologic studies.

Radiographic Appearance. Fungal rhinosinusitis is usually unilateral (78% of cases), with bony destruction being rare. Within the sinuses the presence of mild thickening to complete opacification may be present. In most cases varying degrees of density ("double densities") are seen (Fig. 11.54).

Cystic lesions are a common occurrence in the maxillary sinus, and studies have reported a prevalence rate of 2.6% to 20%.[84] They may vary from microscopic lesions to large, destructive, expansile pathologic conditions that include pseudocysts, retention cysts, primary mucoceles, and postoperative maxillary cysts.

● **Fig. 11.54** Coronal image showing a progressive fungal rhinosinusitis of the left paranasal sinus area. Note the dense radiopacity, which is termed a *fungal ball*.

Pseudocysts (Mucous Retention Cyst)

The most common cysts in the maxillary sinus are mucous retention cysts. After much controversy, in 1984 Gardner[85] distinguished these cysts into two categories: pseudocysts and retention cysts. Pseudocysts are more common and of much greater concern during sinus graft surgery, compared with retention cysts. Pseudocysts reoccur in approximately 30% of patients and are often unassociated with sinus symptoms. As a consequence, many physicians do not treat these lesions. However, when their size becomes large in diameter, pseudocysts may occlude the maxillary ostium during a sinus graft procedure and increase the risk for postoperative infection.

Radiographic Appearance. Pseudocysts are depicted radiographically as smooth, homogenous, dome-shaped, round to ovoid, well-defined homogeneous radiopacities. Pseudocysts do not have a corticated (radiopaque) marginal perimeter and are always on the floor of the sinus cavity (Fig. 11.55).

Retention Cysts

Retention cysts may be located on the sinus floor, near the ostium, or within antral polyps. Because they contain an epithelial lining, researchers consider them to be mucous secretory cysts and "true" cysts. Retention cysts are often microscopic.

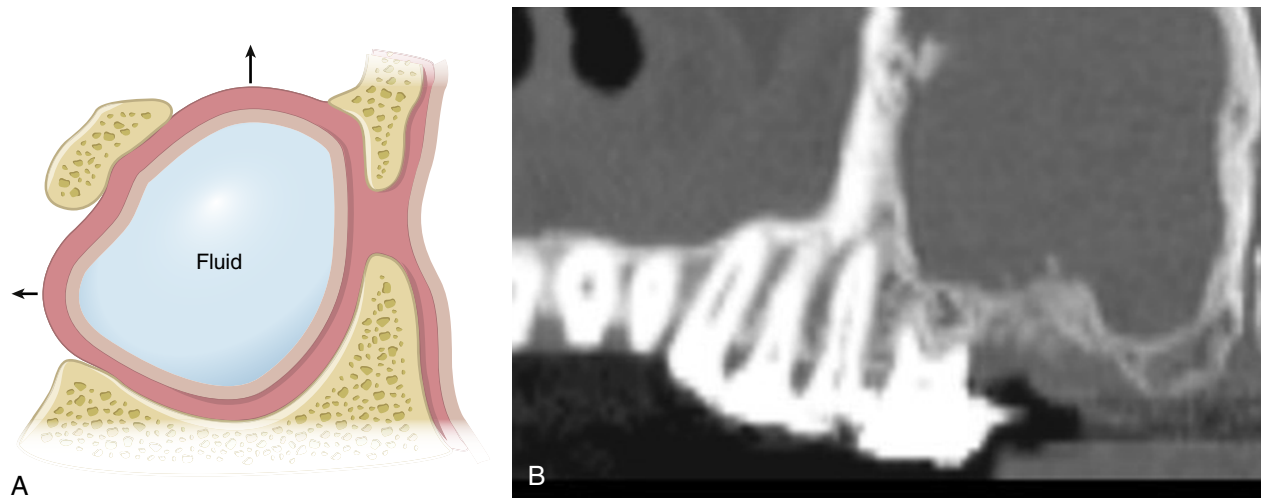
Radiographic Appearance. Retention cysts are usually very small and not seen clinically or radiographically. In rare instances they may achieve adequate size to be seen in a CT image and may resemble the appearance of a small pseudocyst.

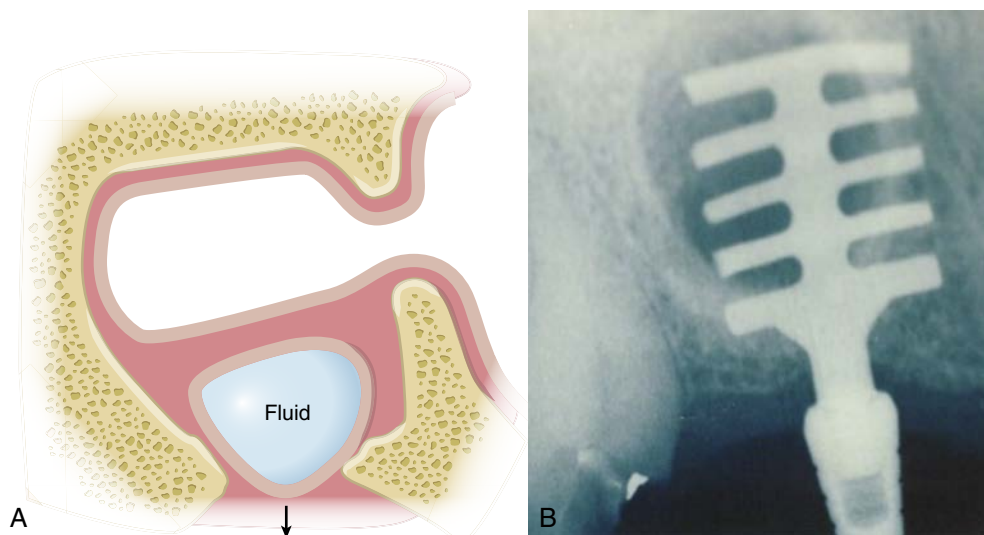
Primary Maxillary Sinus Mucocele

A primary mucocele is a cystic, expansile, destructive lesion that may include painful swelling of the cheek, displacement of teeth, nasal obstruction, and possible ocular symptoms.[86]

Radiographic Appearance. In the early stages the primary mucocele involves the entire sinus and appears as an opacified sinus. As the cyst enlarges, the walls become thin and eventually perforate. In the late stages, destruction of one or more surrounding sinus walls is evident (Fig. 11.56).

Postoperative Maxillary Cyst

A postoperative maxillary cyst of the maxillary sinus is a cystic lesion that usually develops secondary to a previous trauma or
● **Fig. 11.55** Pseudocyst. (A–C) Small pseudocyst (mucous retention cyst) located on the floor of the sinus (A), larger cyst (B), and very large pseudocyst that may lead to obstruction of the sinus (C).


• **Fig. 11.56** Primary Mucocele. (A) Expansile nature of lesion causes destruction of sinus walls. (B) Clinical image depicting right side of a complete radiopaque sinus with expansion of walls.


• **Fig. 11.57** (A) Secondary mucocele is a well-defined radiolucent lesion that separates the sinus cavity into two separate compartments, which is usually fluid filled. (B) Radiograph depicting cystic area surrounding the implant.

surgical procedure in the sinus cavity. It has also been termed a surgical ciliated cyst, postoperative maxillary sinus mucocele, or secondary mucocele.[87]

Radiographic Appearance. The cyst radiographically presents as a well-defined radiolucency circumscribed by sclerosis. The lesion is usually spherical in the early stages, with no bone destruction. As it progresses, the sinus wall becomes thin and eventually perforates. In later stages it will appear as two separated anatomic compartments (Fig. 11.57).

Squamous Cell Carcinoma and Adenocarcinoma

Malignant tumors of the paranasal sinuses are rare, with a poorly differentiated squamous cell carcinoma comprising approximately 80% of tumors. Seventy percent of these tumors are found in the maxillary sinus.[88] Symptoms can vary; however, neoplasms of the maxillary sinus usually include nasal obstruction, rhinorrhea, epistaxis, cranial neuropathies, and pain. Advanced cases may include visual disturbances, paresthesias, and possible malocclusion.

Radiographic Appearance. Radiographic signs of neoplasms may include various sized radiopaque masses, complete opacification, or bony wall changes. A lack of a posterior wall on a radiograph should be a sign of possible neoplasm (Fig. 11.58).

Maxillary Sinus Antroliths

Maxillary sinus antroliths are the result of complete or partial encrustation of a foreign body that is present in the sinus. These masses found within the maxillary sinus originate from a central nidus, which can be endogenous or exogenous.[89]

Radiographic Appearance. The radiographic appearance of a maxillary antrolith resembles either the central nidus (retained root) or appears as a radiopaque, calcified mass within the maxillary sinus (Fig. 11.59).

Differential Diagnosis. Because the calcified antrolith is composed of calcium phosphate ($CaPO_4$), calcium carbonate salts, water, and organic material, it will be considerably more radiopaque than an inflammatory or cystic lesion.[90] The central nidus
• **Fig. 11.58** Squamous cell carcinoma of the right maxillary sinus showing complete radiopacity with associated expansion and destruction of sinus walls.

of the antrolith is similar to its usual radiographic appearance (Fig. 11.60).

Radiology Reports

A typical radiographic report template will include the following basic information elements.[91]

Patient/Office Identification Section

This section records: date of report, patient name, date of birth, gender, name of the referring doctor, date of the scan, and the name of the scanning center or dental office taking the scan/volume.

Clinical Significance. This section has critical patient record information.

Images Provided

Enter the type of images provided for review. A typical entry would be: "Cone Beam CT images with bone window; Axial, coronal and sagittal planes." Optional information would include the name of the CBCT unit, pixel resolution (e.g., 0.3 mm, size of the volume: small, medium, or large).

Clinical Significance. *Critical/patient record information.* When volume size and pixel resolution are included, patient dose reconstruction is possible when the specific CBCT unit is identified.

Clinical Information

This section would include a brief relevant history and/or clinical note. Entries might include such elements as: "Implant evaluation for edentulous areas of maxilla," "Relationship of endosseous implant to the mandibular canal," etc.

Clinical Significance. This includes critical/patient record information providing the clinician's rationale for taking the diagnostic image.

Diagnostic Objectives

The referring clinician enters his or her specific objectives for the report such as: (1) sinus evaluation; (2) rule out pathology; (3) implant measurements #3,10, 14, 19, 29; (4) rule out osteomyelitis; and (5) mandibular/maxillary pathology.
• **Fig. 11.59** Antrolith or calcified masses present in the sinus (arrows). (A) Tooth root, and (B) Restorative material.

Clinical Significance. This includes the clinician's specific request or potential concern for the radiologist to look for as a priority.

Radiographic Findings

This section of the template provides the radiologist/volume interpreter with a list of specific areas within the volume to be evaluated. A standard listing would include:

- maxilla
- paranasal sinuses
- nasal cavity
- air space
- temporomandibular joint (TMJ)

Dental Findings. The radiologist will provide limited comments in this section and typically *will not* report on caries, calculus, and periodontal disease associated with individual teeth. Typically third molar positions will not be reported unless

Deflected ucinate process

Nonpatent ostium

Polyps

Mucous retention cyst

Concha bullosa

Big-nose variant

Deviated septum

Paradoxical middle turbinate
● **Fig. 11.60** Summary of the most common pathologic conditions that occur in the paranasal sinuses.

specifically requested by the clinician. The interpretation of these anomalies is within the diagnostic skill set of the dentist.

Clinical Significance. This provides a summary of radiographic findings for the clinician to quickly identify areas of normality and abnormality within the patient volume.

(NOTE: With a digital template for reports, these areas may have a "normal" response listed and subsequently edited as necessary when variations from the normal appearances are identified. For example: "Maxilla: no abnormalities detected; Sinuses: no abnormalities detected, the right and left ostiomeatal complexes were patent; Nasal Cavity: no abnormalities detected, etc." for each area on the list.)

Radiographic Impression

This section of the report template will identify specific variations and deviations from "normal" for each of the areas listed under the radiographic findings and provide the radiologist's impression of the deviation from normal.

Clinical Significance. This gives a summary of radiographic findings providing the clinician with a differential radiographic interpretation of deviations from normal.

Recommendations

This section may be combined with the radiographic impression noted earlier. However, it may be separated to provide general recommendations for clinician guidance related to the findings listed within the radiographic impression section earlier.

The "Recommendations" section would most likely include statements such as: "Physician referral for more thorough evaluation of: … (Included here would refer any anomaly *not* within the dental scope of practice as defined by your state licensing board.) Other recommendations might include: "Biopsy suggested/recommended for more thorough evaluation of the biological processes involved in …" (e.g., a large, cystlike lesion in the anterior dental area could represent a cyst of the incisive canal/foramen, large radicular/periapical cyst, ameloblastoma, or central giant cell

tumor, and a biopsy would be helpful in identifying the specific biological nature of the lesion.)

Clinical Significance. This provides the clinician with general guidance related to a specific anomaly and basis for referral.

(NOTE: In general, the radiologist *will not* recommend a specific type of treatment for any finding because this is a consultative report that the clinician must integrate into the patient's overall treatment plan and outcome assessment.)

Radiologist Name and Signature

Level 4: Clinical Significance. This is critical patient record information.

Typical Radiographic Descriptions

Descriptions and entities should be reported as radiographic findings.

Radiographic Findings

Maxilla

Asymmetries between right and left maxillae or sinuses are noted, as well as, changes in bone pattern or texture.

Typical report findings might read:

An asymmetry was noted between the right and left maxillary sinuses; the right maxillary sinus and maxilla exhibit a smaller volume and size than the left, potentially suggestive of maxillary hypoplasia. Correlation of the radiographic observation with the patient's clinical evaluation is suggested.

Clinical Significance. This includes identification of possible hemimaxillary hypoplasia, previous trauma, fibrous dysplasia, etc.

Sinuses

This section will report on findings within all major sinus groups: right and left maxillary, and ethmoid, frontal, and

sphenoid sinuses. Under "normal" circumstances the linings of the sinuses are not radiographically visible and are reported as "no abnormalities detected." When the lining becomes visible, sinus pathology is present and reported if the lining is 3 mm or more in thickness.

Common Findings and Sinus Descriptions

Mucositis/sinusitis: "The right maxillary and sphenoid sinuses exhibited an increase in the thickness and density of the sinus lining."

Mucous retention pseudocyst: "A homogeneous ovoid/dome-shaped increase in density was noted within the left maxillary sinus."

Sinusitis: "The right maxillary sinus was partially occupied by homogeneous area of increased density containing bubbles."

Ostiomeatal complex: If the opening is not clearly visible, it should be reported as obstructed/blocked.

Other, less common sinus findings: A thickening, irregularity, and sclerosis of the walls of the sinus may potentially represent a long-standing chronic inflammation of the sinuses. Small, irregular calcifications within the homogeneous density of the tissues of the sinus may be an indication of antrolith formation and an indication of a long-standing chronic sinusitis, small osteomas within the ethmoid sinus.

Typical report findings might read:

The radiographic findings appear consistent with a mild chronic sinusitis of the right and left maxillary sinuses. Review of patient's history for chronic sinusitis/allergy is suggested. Physician referral for more thorough evaluation is suggested if merited by clinical findings and symptoms.

Clinical Significance. This includes identification of potential changes on the sinus region meriting potential physician referral in the presence of symptoms.

Nasal Cavity

This section will include any findings of asymmetry associated with the nasal cavity, including: inferior, middle, and superior turbinates; deviations of the nasal septum; and absence of internal nasal structures potentially associated with previous ear, nose, and throat surgery. A variation in normal anatomy is a dilation within the middle turbinate referred to as a concha bullosa.

Typical report findings might read:

A mild deviation of the nasal septum to the right; enlargement of the middle turbinate consistent with a concha bullosa is considered a variation in normal anatomic form. Deviation of the nasal septum is considered a variation in normal anatomy; referral and treatment are not indicated unless the patient provides a history of difficulty breathing through his nose.

Clinical Significance. This includes identification of possible changes in the nasal cavity potentially influencing breathing patterns.

Air Space

Variations in the size of the airway are noted in the section, as well as potential enlargements of the adenoid and pharyngeal tonsils.

Typical report findings might read:

Narrowing of the airway has been associated with a variety of respiratory disorders, including an increased risk for obstructive sleep apnea. Correlation of the radiographic observation with the patient's clinical history is suggested. Clinical evaluation of the soft tissues of the oral pharynx is suggested.

Clinical Significance. This includes identification of possible airway changes that affect patient breathing patterns.

TMJ

This section reports on variations and deviations in symmetry between the right and left condyles, articular fossae, and joint spaces.

Typical report findings might read:

The right condyle, articular fossa, and joint space exhibited normal bony profiles and contours; the left articular fossa and joint space exhibited normal radiographic contours; the left condyle exhibits a localized discontinuity of the cortical outline, the presence of resorption lacunae, and sclerosis of the underlying bony trabecular pattern consistent with degenerative joint disease (DJD). Correlation of the radiographic observation with the patient's clinical findings and symptoms, if any, is suggested.

Clinical Significance. This includes identification of possible radiographic changes within the bony structures of the TMJ region that affect patient symptoms/occlusion. TMJ-positive findings may predispose the patient to prosthetic rehabilitation complications.

Other Findings

This section is used to report radiographic changes in anatomic structures not associated with the maxilla and mandible but included within the volume, including, but not limited to: calcifications within the carotid artery lateral to the pituitary fossa and within the lower neck, radiographically visible changes within the cervical vertebra, including osteophyte formation, sclerosis, narrowing, and irregularity of intervertebral disc space width with potential bone-to-bone contact; generalized loss or thinning of cortical bone and an absence of internal bony trabeculation suggestive of systemic metabolic disorders of bone/osteoporosis; and increased density noted within one or both mastoid processes. Common incidental radiographic findings included here would be: calcification of the stylohyoid ligament, calcifications of pineal gland and cavernous sinus (middle cranial fossa area), idiopathic soft tissue calcifications within the soft tissues of the skin or soft tissues of the oral pharynx (tonsilloliths), salivary gland/duct calcifications, metallic foreign bodies, ear wax, among others.

Typical report findings might read:

(1) The small areas of increased density noted lateral to the pituitary fossa are anatomically associated with the carotid arteries and are consistent with calcification of the carotid arteries. Vascular calcifications have been associated with an increased risk for cardiovascular disease and stroke. Review of patient's medical history for increased risk factors, such as high blood pressure, elevated cholesterol, stress, and smoking, is suggested. Physician referral is suggested with findings of elevated risk factors or if patient is not currently under the care of a physician. (2) Sclerosis and osteophyte formation within the cervical vertebra may be early indications of DJD of the cervical spine. Correlation of the radiographic observation with the patient's clinical findings and symptoms of chronic neck/muscle pain/headache or other neurologic symptoms is suggested. Physician referral is suggested

for more thorough evaluation if merited by clinical findings and symptoms. (3) Calcification of the pineal gland is considered to be a common incidental radiographic finding that does not require treatment or referral.

Clinical Significance. This provides identification of potential changes indicative of systemic conditions that affect overall patient health and welfare.

Dental Findings

This area provides a summary of radiographic findings that affect dental structures immediately adjacent to the teeth. This area typically reports periapical pathology or other maxillary/mandibular pathology involving the teeth. Evaluation of impacted canines, resorptive changes of adjacent teeth and, dilaceration roots potentially preventing eruption of teeth are noted.

Typical report findings might read:

The maxillary right canine is impacted adjacent to the lingual surface of the apex of the maxillary right lateral incisor; moderate to severe resorptive changes were observed in the root of the lateral incisor.

Clinical Significance. This provides identification of potential changes/conditions that affect treatment planning decisions.

Reporting Implant information

The radiology report template may include separate sections that delineate existing implants or the evaluation of prospective implant sites.

Existing Implants

This section would include a brief notation of the areas that exhibit existing implants and whether the implant exhibits integration with the adjacent bone or the presence of potential changes associated with peri-implantitis.

Implant Measurements

This section typically corresponds to illustrations within the report that exhibit measurements of requested implant sites and will typically state: "Implant measurements have been provided for the requested sites." NOTE: It is important for the clinician to be very specific about the possible sites for which measurements are being requested; it should not be assumed that the radiologist will know the sites for implant placement.

Alternative Report Style for "Incidental Radiographic Findings"

Most incidental findings are unlikely to compromise patient health or dental treatment outcomes, typically do not require referral to a physician, and are found in a high percentage of volumes. They may be provided as a separate list without illustrations depending on the radiologist.

Typical report findings using this format might read:

Incidental findings: deviated nasal septum, concha bullosa, tonsilloliths, ear wax, elongated/calcified stylohyoid ligaments, faint/small calcifications within the pineal gland and cavernous sinuses.

Clinical Significance. This includes identification of potential changes/conditions that will not affect treatment planning decisions or require outside referral.

Styles of Radiology Reports

Each radiologist has her own style and format she uses to construct a report, and it is appropriate for the referring clinician to do his "due diligence" and select the radiologist who will provide the type of report he is comfortable using as a basis for treatment planning decisions (Fig. 11.61). For example, some radiologists specify that their review of the volume is through the assessment of "axial cross sections only," which limits the potential of visualization of radiographic anomalies when CBCT volumes and the software used easily provide axial, coronal, and sagittal cross sections. Our suggestion is to identify a radiologist who provides interpretation based on a complete analysis of the volume using axial, coronal, and sagittal cross sections.

Intraoperative Imaging

The use of surgical imaging has dramatically changed the way that surgical implantology is completed. In the past the disadvantage of periapical radiography perioperatively has been time inefficiency. To verify positioning and location of an osteotomy site or for identification of a vital structure, processing of standard radiograph film can take up to 6 minutes. Because of this, practitioners rarely verified positioning of anatomic structures during surgery. With digital radiography technology, instantaneous images are achieved, allowing for multiple images to be completed in a fraction of the time. Additional advantages of digital intraoperative imaging include manipulation of images, calibration, accurate measurements and positioning, and maintenance of aseptic protocol (Fig. 11.62).

Immediate Postsurgical Imaging

A plain film radiograph (periapical or panoramic) or CBCT should be taken postsurgically so that a baseline image may be used to evaluate against future films. With the ease of image acquisition after surgery, an immediate assessment of positioning and displacement of implants can be evaluated. Because the radiation dose with CBCT has become user-friendly with significantly reduced time and radiation levels (i.e., less than 5 seconds and as low as 15 mSv), immediate postoperative CBCT imaging is a common procedure in implant dentistry today.

Abutment and Prosthetic Component Imaging

When evaluating transfer impressions along with two-piece abutment component placement, radiographs should be taken to verify ideal seating. Intraoral radiographs should be used because of their high geometric resolution to evaluate for any fit discrepancy. However, care must be taken so that the x-ray beam is directed at a right angle to the longitudinal axis of the implant. Even a slight angulation may allow a small opening gap to be unnoticed. When positioning is difficult for intraoral periapical radiographs, bitewing or panoramic radiographs may be used (Figs. 11.63 and 11.64).

Postprosthetic Imaging

In the past, postprosthetic imaging has been limited to intraoral and panoramic radiographs. However, with the advancements in CBCT technology, more accurate CBCT scans with less scattering are available in oral implantology. Therefore CBCT scans are gaining acceptance for use in postprosthetic imaging. There exists no conclusive scientific evidence that low-level ionizing radiation

A. Minimal Information Report:

Patient Name: xxxx xxxxxxx   DOB: 8/20/1991   Date: xx-xx-xxxx

Scanning Center: or dental office taking volume   Gender: xxxx

Referring Doctor: xxxx xxxxxx   Date of Scan: 5/26/15

Images provided: Cone Beam CT images in the bone window. Axial, coronal and sagittal planes. Closed and open scans provided.

Clinical Info: chronic headaches, jaw pain
Relevant History: not available
Client Notes: implant #3

Diagnostic Objectives:
Rule out pathology

Findings:
Axial, coronal, and sagittal cross-sections of the patient volume were reviewed. Radiographic findings potentially affecting your proposed treatment objectives were not identified.

Radiologist name and signature:
Thank you for the referral of this patient and the opportunity to serve your practice.

B. Medical Style [written only, no illustrations] Report:

Patient Name: xxxx xxxxxxx   DOB: 8/20/1991   Date: xx-xx-xxxx

Scanning Center: or dental office taking volume   Gender: xxxx

Referring Doctor: xxxx xxxxxx   Date of Scan: 5/26/15

Images provided: Cone Beam CT images in the bone window. Axial, coronal and sagittal planes.

Clinical Info: chronic headaches, jaw pain
Relevant History: not available
Client Notes: implant #3

Diagnostic Objectives:
Rule out pathology

Findings:
Maxilla: no abnormalities detected
Sinuses: a small dome shaped area of increased density was noted within the right maxillary sinus; the right and left osteomeatal complexes were patent.
Nasal Cavity: a deviation the nasal septum to the left was noted.
Mandible: no abnormalities detected
Air Space: no abnormalities detected
TMJs: Both condyles, their articular fossae and eminences exhibit good symmetry and apparently normal bony anatomy; no abnormalities of the bony structures were noted.
Other findings: Sclerosis and osteophyte formation, narrowing and irregularity of intervertebral disc space width with bone to bone contact was noted within the cervical vertebra.
Dental findings: no abnormalities detected

Radiographic Impression:
Sinuses: the radiographic findings appear consistent with a mild chronic mucositis/sinusitis/mucus retention pseudocyst. Review of patient's history for chronic sinusitis/allergy is suggested. Physician referral if merited by clinical findings and symptoms.
Nasal Cavity: deviation of the nasal septum is considered a variation in normal anatomy; referral and treatment is not indicated unless the patient provides a history of difficulty breathing through their nose.
Other Findings: Sclerosis and osteophyte formation, narrowing and irregularity of intervertebral disk space width with bone to bone contact within the cervical vertebra may be indications of DJD of the cervical spine. Correlation of the radiographic observation with the patient's clinical findings and symptoms of chronic neck/muscle pain/headache or other neurological symptoms is suggested. Physician referral is suggested for more thorough evaluation if merited by clinical findings and symptoms.

Radiologist name and signature:
Thank you for the referral of this patient and the opportunity to serve your practice.

Comment: Using the medical model style of radiology report, the radiologist provides a written description of radiographic findings but does not provide illustrations of the various findings or implant measurements.

C. Hybrid Medical with Illustrations

Thank you for the referral of this patient and the opportunity to serve your practice.

Comment: Many maxillofacial radiologists provide a hybrid medical model style of report that will include selected images illustrating various radiographic findings. The referring clinician values this kind of report because the illustrations provided allow them to evaluate the severity of the conditions the radiologist has identified and can be used to educate the patient with regard to the radiographic findings.

Patient referral to a physician for additional evaluation based on a radiology report does not have clearly defined guidelines and clearly professional clinical judgment is the key, taking into consideration and integrating clinical findings and patient symptoms. We as healthcare providers have an underlying responsibility to refer patients for additional evaluation when considered appropriate; however, we cannot force our patients to go to physicians if they do not choose to. As a result, documenting in the patient's chart that the radiology report indicated the presence of potential pathology in an area outside of our scope of practice and that the patient was requested to seek a more thorough examination from a physician regarding the condition is prudent and critical.

has a detrimental effect on bone metabolism and healing. A post-prosthetic radiograph needs to be taken to act as a baseline for future evaluation of component fit verification and also for marginal bone level evaluation.

Recall and Maintenance Imaging

For the evaluation of implant success, immobility and radiographic evidence of bone adjacent to the implant body are the two most accurate diagnostic aids in evaluating success. Follow-up or recall radiographs should be taken after 1 year of functional loading and yearly for the first 3 years.[92] Multiple studies have shown that, in the first year, marginal bone loss and a higher rate of failure are seen.

Evaluation of Alveolar Bone Changes

Radiographically, lack or loss of integration is usually indicated as a radiolucent line around the implant. However, false-negative diagnoses may be made when the soft tissue surrounding an implant is not wide enough to overcome the resolution of
• **Fig. 11.62** Intraoral Radiographs. (A) Initial pilot orientation with slight mesial inclination. (B) Angulation corrected and verified with final depth indicator. (C) Implant placement. Note poor angulation of radiograph leading to distorted measurements. (D) Ideal implant placement radiograph. Note perpendicular orientation of x-ray beam as all threads are seen without distortion. (*From Resnik R, Kircos LT, Misch CE. Diagnostic imaging and techniques. In: Misch CE, ed.* Contemporary Implant Dentistry. *St. Louis, MO: Elsevier; 2008.*)
• **Fig. 11.63** Verification of direct transfer coping placement before final impression. Note ideal angulation from thread alignment.

the radiographic modality used (i.e., the implant may not have a direct bone-implant interface). Also, false-positive diagnoses may be made when a "Mach band effect" results from an area of lower radiographic density adjacent to an area of high density (implant), which results in a more radiolucent area than is actually present.[93] However, studies have shown that the possibility of the Mach band effect is significantly reduced with digital image processing. In addition, digital radiography has been shown to have the advantage over conventional radiography with respect to "edge enhancement," which is the ability to detect space between the implant and the surrounding bone. Because of the variability of operator-controlled problems, a strict quality-assurance protocol should be used to maintain ideal image quality over time. Proper positioning, along with kVp and mA settings, should be documented for future reference.

Periapical Radiographs. In recall radiographic examinations the marginal bone level is compared with the immediate postprosthetic films. Therefore radiographs similar in geometry, density, and contrast are paramount. Standardized periapical radiographs are essential to ensure accuracy. However, reproducing positioning is difficult. Numerous film-holding devices have been documented that attach to the implant, abutment, or prosthesis to standardize image geometry. When proper projections are achieved, implant threads on both sides of the implant are clearly seen. If the threads are not clearly seen in the radiographs, modification of the beam angle needs to be made. If diffuse threads are present on the right side of the implant, then the beam angle was positioned too much in the superior direction. If the threads are diffuse on the left side, then the beam angle was from an inferior angulation (Fig. 11.65). With digital enhanced radiographs, numerous techniques have been postulated to measure bone levels around implants. Computer-assisted measurements, rulers, calipers, and suprabony thread evaluation have been shown to have highly reproducible results.[94]

Bitewing Radiographs. In cases where the x-ray source cannot be positioned perpendicular to the implant because of oral anatomy or existing prosthesis, horizontal or vertical bitewings may be taken to evaluate the crestal bone area. With this projection the central beam is perpendicular to the implant and alveolus, the object-film distance is relatively small, and very minor distortions are present. The only limitation of bitewing radiographs is that the apical portion cannot be seen.

Panoramic Radiographs. Panoramic radiographs usually are not used routinely for evaluation of osseous bone levels and recall examinations. Because panoramic radiographs use intensifying screens, resolution is not as good as with intraoral radiographs. However, when film positioning or when multiple implants need to be evaluated, panoramic radiography is the imaging technique of choice.

Computed Tomography. Two-dimensional radiographs (periapical, panoramic) have limitations in that they relay no buccolingual information about the present condition of alveolar bone. CBCT does allow 3D information about the osseous status around an implant. Resolution and scattering have always been a problem in evaluation of implants; however, with the advent of cone beam technology, this is greatly improved. CBCT can be of great benefit in the evaluation of sinus augmentation graft prognosis. With the advantage of bone density evaluation using Hounsfield units, important information on bone maturation may be determined. Also, this radiographic modality is the image
• **Fig. 11.64** Seating of Final Prosthesis. (A) Poor x-ray angulation showing a false-negative or complete seating of the prosthesis. Note the diffuse threads. (B) A corrected angulation image exposes the seating problem.

of choice for evaluation of sinus infection or postsurgical sinusitis complications (Figs. 11.66 and 11.67).

Legal Issues and Cone Beam Computed Tomography

With CBCT becoming more prevalent in diagnosis and treatment planning for dental implants, many legal issues are coming to light. The implant clinician, as a medical professional, is liable for nondiagnosis of any abnormality on the CBCT scan. Dentists are held to a standard when diagnosing and treating patients. To help meet this standard, the implant clinician must use the CBCT survey in a proper and ideal manner, thus maximizing diagnostic accuracy. Therefore it is imperative for the practitioner to stay current with some of the many potential legal issues associated with CBCT.

To Take a Scan or Not

In medicine, radiographic equipment is usually not approved for a particular purpose or indication. Nor is there any actual standard of care or universally accepted guidelines for the use of CBCT technologies. Instead, any applicable standard of care is mandated by the legislature, a court, or dental board.[95] On
● **Fig. 11.66** Maxillary sinus evaluation. (A) Preoperative cone beam computed tomography (CBCT). (B) Postoperative CBCT depicting maxillary rhinosinusitis after sinus augmentation.

the other hand, even in the absence of an express guideline, an implant clinician is more likely to be questioned for failing to use available CBCT technologies preoperatively if a complication arises.

Technical Parameters

The doctor ordering the scan must be careful to select the correct parameters of the scan. Inadequate or improper CBCT settings and settings may lead to liability. Examples include ordering a scan with low resolution when a high resolution is indicated (e.g., tooth fracture).

Field of View

The FOV (anatomic limits of the scan) is crucial in the preoperative assessment of an implant patient. Ideally the FOV should be the smallest possible to reduce the patient x-ray dosage and improve spatial resolution. However, if the FOV is too small, inadequate sufficient evaluation of the anatomic area will result. This is most commonly seen in the posterior maxillary augmentation when too small a field of view is used. If there is any type of pathology in the sinus and the scan is not taken high enough to determine the patency of the ostium, the doctor is at risk of causing serious sinus issues because of the inability to determine the patency of the ostium and the nature of the pathology.

Interpreting the Scan

There is no current consensus on the legal ramifications of interpreting CBCT scans. However, as a general proposition the implant dentist remains responsible for interpreting the entire scan.[96] The implant clinician has three options. The implant clinician may: (1) interpret the scan themselves; (2) send the CBCT data to a licensed radiologist, or (3) have the CBCT data evaluated by the hospital or imaging center radiologist.

Referral to Radiologist

Ideally, most clinicians will decrease their liability by referring their CBCT scans to a radiologist for evaluation. However, if the doctor sends the scan to a radiologist who is unqualified to interpret the scan, the dentist may have liability for the negligent referral.[97] In addition, the CBCT scan must be read by a radiologist licensed in the same state as the implant clinician. Otherwise, the dentist may be subject to disciplinary action by the state dental board for aiding and abetting the radiologist's unlicensed practice of medicine and for negligent referral of the patient's scan to the unlicensed provider.[98] The implant clinician also should confirm that the radiologist's malpractice insurance covers the reading of CBCT scans.

Waiver of Liability

Many implant clinicians who are untrained in CBCT interpretation request their patients sign a waiver of liability regarding the interpretation of the CBCT scans or a waiver of the right to have the scan read by a radiologist. In general, a patient cannot consent to the negligence of their dentist or other health care provider.[99] Waivers of liability typically have no legal effect and are inadmissible.

Summary

One of the keys to preventing potential complications during the surgical and prosthetic phases of implant treatment is to have as clear a picture of the patient's current anatomic makeup as possible. Identifying deficiencies of bone allows the clinician to modify the bony architecture to achieve optimal implant location for prosthetic success. Knowing the exact locations of vital structures allows us to plan safe zones during treatment to avoid potentially catastrophic complications. Proper planning is absolutely paramount to success in any endeavor, and having a strong plan in place before the initiation of implant treatment is no exception.

Cone beam technology has ushered in a new era of accuracy in treatment planning. Clinicians are no longer having to rely on "guesswork" by extrapolating anatomic measurements from a distorted 2D image. Templates may be made based on these new 3D images to assist clinicians during tough surgical cases, especially early on respective learning curves. There are just so many benefits to using CBT technology that it is hard to distinguish a reason not to possess one before the initiation of implant treatment. The present legal climate is beginning to echo this sentiment, as CBT is closer to becoming the standard of care across the board.

With the combination of 3D imaging and a thorough knowledge of the anatomic areas that are focused on in this chapter, a clinician can acquire a further degree of confidence that the likelihood of complications has been reduced, which makes the implant treatment process less stressful for both patient and provider.

Applied Anatomy for Dental Implants

MOHAMED SHARAWY

The surgical anatomy of the maxilla and mandible provide the foundation required to safely insert dental implants. The anatomy is also a requisite to the understanding of complications that may inadvertently occur during surgery, such as injury to blood vessels or nerves, as well as postoperative complications such as infection. This information also provides the operator with the confidence needed to deal with these complications. This chapter addresses those issues important in the field of oral implantology.

Surgical Anatomy of the Maxilla as an Organ

The maxilla is pyramidal in shape, with the root of the zygoma as its apex (Figs. 12.1 and 12.2). The latter can be palpated in the buccal vestibule of the oral cavity. The root of the zygoma divides the facial surface of the maxilla into anterolateral and posterolateral surfaces of the pyramid. The third surface of the pyramid is the orbital plate of the maxilla. The base of the pyramid is the lateral wall of the nose or the medial wall of the maxillary sinus. The alveolar process of the maxilla related to the anterolateral surface carries the incisors, the canines, and the premolars, whereas that of the posterolateral surface carries the molars and ends as the maxillary tuberosity. The intraoral part of the maxilla is limited by the mucobuccal fold and the orbicularis oris muscle anteriorly and by the buccinator muscle posteriorly. The posterolateral surface of the maxilla above the mucobuccal fold forms the anterior wall of the infratemporal fossa and is difficult to palpate. However, the anterolateral surface of the maxilla beyond the mucobuccal fold can be palpated easily under the skin along with the anterior nasal spine, the anterior nasal aperture, and the frontal process of the maxilla. Intraorally, it is possible to palpate the canine eminence, the canine fossa (distal to the canine eminence and a common site for facial access to the maxillary sinus), the maxillary tuberosity, and the hamular notch. The maxilla extends as a horizontal plate medially to form the anterior two-thirds of the hard palate. The horizontal plate of the palatine bone forms the posterior one-third of the hard palate. The palatine bone has a vertical plate that articulates with the base of the maxilla; it also has a pyramidal process that interposes between the maxillary tuberosity and the pterygoid processes of the sphenoid bone. Mucosal incision

at the maxillary tuberosity that extends into the hamular notch may expose the pyramidal process of the palatine bone. Distal to this point, one may expose the medial pterygoid muscle, which takes origin from the tuberosity and the lateral pterygoid plate of the sphenoid. The medial wall of the maxilla begins at the sharp edge of the anterior nasal aperture and extends posteriorly, with a concavity that bounds the nasal fossa and continues distal to the canine. Once there, it forms the medial wall of the maxillary sinus and continues all the way back to the maxillary tuberosity. The medial wall of the maxilla provides attachment to the inferior nasal concha and to the vertical plate of the palatine bone. The opening of the maxillary sinus is found in the medial wall of the maxilla, close to the floor of the orbit. The opening is reduced in diameter by the uncinate process of the ethmoid bone. The latter provides the superior and middle conchae of the lateral nasal wall. The orbital plate of the maxilla forms the floor of the orbit and also the roof of the maxillary sinus. The infraorbital canal carries the infraorbital nerve and vessels, and it forms a ridge that can be seen in the sinus cavity.

Muscles Attached to the Maxilla

As the maxillary alveolar bone resorbs, the crest of the residual ridge migrates toward the muscles that take their origin from the basal bone of the maxilla. Descriptions of muscles of surgical importance to oral implantologists follow (Figs. 12.3–12.5).

Orbicularis Oris Muscle

The orbicularis oris muscle originates from the modiolus at each corner of the mouth. The muscle fibers fan out into the upper and lower lips, in which they form upper and lower peripheral portions under the skin and marginal portions under the vermilion zone of the lips. Some of the orbicularis oris fibers attach to the ala of the nose and to the nasal septum. In the midline of the upper lip, the peripheral portions from both sides interdigitate to create the philtrum. The marginal portions interdigitate and create the labial tubercle. Although unattached to the bone of the maxilla, the muscle limits the depth of the upper and lower facial vestibule. The orbicularis oris receives innervation from the buccal and mandibular branches of the facial nerve.

Incisivus Labii Superioris Muscle

The incisivus labii superioris muscle originates from the floor of the incisive fossa of the maxilla above the eminence of the lateral incisor and deep to the orbicularis oris. To expose the bone of the premaxilla between the canines, a mucoperiosteal flap reflection may detach the incisivus labii superioris. It may also detach the septalis and oblique fibers of the nasalis muscle. The first fiber is attached to the skin of the nasal septum and the latter fiber to the ala of the nose. These small muscles will reattach after placement of the flap. However, if the muscles were damaged, then drooping of the septum and flaring of the ala of the nose may result.

Buccinator Muscle

The buccinator muscle originates from the base of the alveolar process opposite to the first, second, and third molar of both jaws. This muscle also takes origin from the pterygoid hamulus of the medial pterygoid plate of the sphenoid bone, bridging the gap

between the maxillary tuberosity anteriorly and the hamulus posteriorly. Extension of a subperiosteal frame design into the pterygoid plates may interfere with the fibers of these muscles without adding too much to the retention of the implant. When incising and reflecting the mucosa overlying the areas of the maxillary tuberosity and hamular notch before taking impressions for maxillary subperiosteal implants, avoid injuring the tendon of the

tensor veli transact muscle, which passes around the pterygoid hamulus. The tendon moves on an underlying bursa whenever the soft palate moves; therefore it may become irritated by the subperiosteal frame and result in inflammation and pain. Fibers of the buccinator and medial pterygoid muscles are also found in the area of reflection. The majority of the fibers of the medial ptery-goid muscle originate from the medial surface of the lateral ptery-goid plate of the sphenoid bone, whereas the rest of the fibers form the tuberal head, which takes origin from the maxillary tuberosity. Near the pterygoid hamulus, a fibrous tissue raphe or, in some cases, a broad fascialike structure is found between the transaction and the superior pharyngeal constrictor muscles. In some cases, no raphe or fascia is found. Injury to the latter muscle should be avoided during reflection of the mucosa, particularly on the pala-tal aspect of the area of the hamulus.

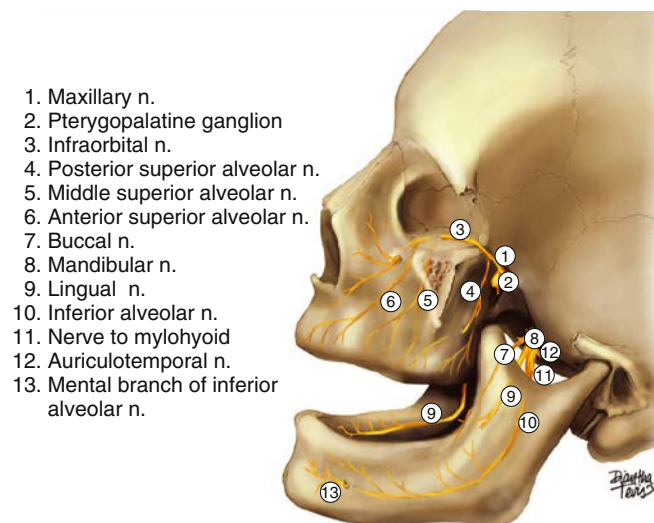
Levator Labii Superioris Muscle

The levator labii superioris muscle takes origin from the infraor-bital margin above the infraorbital foramen; therefore it is rarely of concern to the implant surgeon. The zygomatic branch of the facial nerve innervates this muscle.

Levator Anguli Oris (Caninus) Muscle

The levator anguli oris muscle originates in the maxilla below the infraorbital foramen. The infraorbital nerve and vessels arise between this muscle and the levator labii superioris. In the severe atrophic division D maxilla, the infraorbital foramen is relatively close to the crest of the ridge. Reflection of the tissues for autog-enous grafts and implant placement into sinus grafts may approxi-mate this region and cause paresthesia. In subperiosteal implant cases that require extensive framework extension for retention, the operator should be aware of the location of the infraorbital neuro-vascular bundle in relation to the caninus and levator labii superi-oris muscles. The zygomatic branch of the facial nerve innervates the caninus muscle.

Sensory Innervation of the Maxilla

The maxillary nerve (V2) innervates the maxilla (Fig. 12.6). The nerve leaves the middle cranial fossa by passing through the foramen rotundum and appears in the pterygopalatine fossa. It exits the fossa


and passes briefly into the infratemporal fossa; from there it enters the floor of the orbit or the roof of the maxillary sinus by passing through the infraorbital fissure. The nerve then exits the orbit via the infraorbital foramen. The pterygopalatine portion of the max-illary nerve provides the descending palatine and sphenopalatine branches. The sphenopalatine nerve enters the nasal cavity from the pterygopalatine fossa by passing through the sphenopalatine fora-men. The nerve supplies the nasal cavity and becomes the incisive nerve that supplies the palatine mucosa opposite to the upper six anterior teeth. The descending palatine nerve terminates as the great palatine nerve, which supplies the mucosa of the hard palate, and the lesser palatine nerves, which supply the mucosa of soft palate. These sensory nerves also carry parasympathetic fibers from the spheno-palatine ganglion that innervate the mucous glands of the palate. The infratemporal portion of V2 branches into the posterior alveolar nerve and zygomatic nerve. The latter divides into the zygomati-cofacial and zygomaticotemporal cutaneous nerves. The posterior superior alveolar nerve supplies the buccal gingiva, buccal alveolar bone, second and third molars, and two roots of the first molar. The infraorbital portion of V2 gives rise to anterior superior alveo-lar and occasionally middle superior alveolar nerves. These nerves run in bony grooves in the facial wall of the maxillary sinus under the Schneiderian membrane. The nerves supply the sinus wall and the premolars; the canine, lateral, and central incisor on the same side; and the central incisor at the contralateral side. The infraorbital nerve exits the maxilla at the infraorbital foramen and supplies cuta-neous branches to the lower eyelid, side of the nose, and upper lip. Implantologists often need to block V2 or several of its branches. Luckily this can be achieved by an intraoral route. V2 can be reached via the great palatine foramen and descending palatine canal, or via the pterygomaxillary fissure by following the slope of the posterolat-eral surface of the maxilla into the pterygopalatine fossa.

Posterior Superior Alveolar (Dental) Nerve

The nerve arises within the pterygopalatine fossa, courses down-ward and forward, passing through the pterygomaxillary fissure, and enters the posterior aspect of the maxilla. It runs between the bone and the lining of the maxillary sinus. This nerve supplies the sinus, the molars, the buccal gingiva, and the adjoining portion of the cheek; it may be injured during a sinus augmentation with

a lateral approach. Clinically this does not appear to be of major consequence.

Infraorbital Nerve

This nerve is a continuation of the main trunk of the maxillary division. It leaves the pterygopalatine fossa by passing through the inferior orbital fissure to enter the floor of the orbit. It runs in the infraorbital groove and then in the infraorbital canal. The nerve exits the orbit through the infraorbital foramen to give cutaneous branches to the lower eyelid, the ala of the nose and the skin, and the mucous membrane of the lip and cheek. The infraorbital foramen is located between the levator labii superioris muscle, which takes origin above the foramen, and the levator anguli oris (caninus) muscle, which takes origin below the foramen. The foramen and neurovascular contents are within 5 to 10 mm of an extremely resorbed maxilla. When applying onlay grafts, which expose the entire maxilla, the implant dentist must be very aware of this situation. Fixation screws or implants may cause paresthesia when inserted through the graft and into this structure. Subperiosteal implants designed for an atrophied maxilla should not extend into the site of the infraorbital nerve and vessels. In some cases of maxillary sinus disorder, the site of the infraorbital foramen becomes tender, probably as a result of inflammation of the infraorbital nerve. This is an important diagnostic test for possible postoperative involvement after sinus augmentation procedures.

Middle Superior Alveolar (Dental) Nerve

This branch of the infraorbital nerve is given off as the infraorbital nerve passes through the infraorbital groove. The middle superior alveolar nerve runs downward and forward in the lateral wall of the sinus to supply the maxillary premolars. This region is routinely violated in the lateral approach to sinus grafts, with apparently no consequence.

Anterior Superior Alveolar (Dental) Nerve

This branch of the infraorbital nerve arises within the infraorbital canal. It initially runs laterally within the sinus wall and then curves medially to pass beneath the infraorbital foramen. The branch turns downward to supply the maxillary anterior teeth. A nasal branch passes into the nasal cavity to supply the mucosal lining of a portion of the nasal cavity. Before elevation of nasal mucosa and placement of grafts, this nerve must be anesthetized. The infraorbital nerve block or V2 block anesthesia is suggested. Implant dentists must also anesthetize this branch before placement of implants in the incisor region. The anterior, middle, and posterior superior alveolar nerves intermingle to form the superior dental plexus. The posterior, middle, and anterior superior alveolar nerves run in the facial wall of the maxillary sinus between its lining membrane and the bone. During antrostomy procedures to augment the floor of the sinus, the operator should be aware of these structures, which are present even in the absence of teeth.

Palatine Nerve

The greater (anterior) and lesser (posterior) palatine nerves supply the hard and soft palate, respectively. They exit the pterygopalatine fossa through the superior opening of the descending palatine canal, travel downward, and enter the oral cavity by way of the greater and lesser palatine foramina. The greater palatine nerve runs forward in a groove on the inferior surface of the hard palate to supply the palatal mucosa as far forward as the incisor teeth. Here the nerve communicates with the nasopalatine nerve. The nerve supplies the gingiva, mucous membrane, and glands of

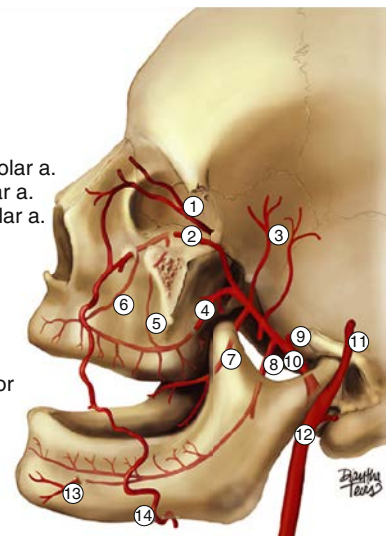
the hard palate. The greater palatine artery and vein accompany the nerve during its course in the hard palate. As the maxillary alveolar process atrophies, it shifts to the palate and brings the crest of the ridge closer to the groove in which the greater palatine neurovascular bundle is found. The restoring dentist should be aware that an incision too palatal to the crest of the ridge in the atrophied maxilla might injure these vital structures. This foramen is entered for a V2 block anesthesia. One may find it by taking a blunt instrument and pressing firmly along the alveolar palatal bone angle. The instrument will depress over the foramen when in the correct position.

Nasopalatine (Sphenopalatine) Nerve

The nasopalatine nerve leaves the pterygopalatine fossa through the sphenopalatine foramen located in the medial wall of the fossa. The nerve enters the nasal cavity and supplies portions of the lateral and superior aspects of the nasal cavity. The longest branch reaches the nasal septum, in which it turns downward and forward, traveling on the surface of the septum. While on the septum it forms a groove on the vomer bone. The nerve supplies the nasal mucosa, descends to the floor of the nose near the septum, passes through the nasopalatine canal, and then exits onto the hard palate through the incisive foramen. The latter opening is deep in the incisive papilla. The nerve communicates with the greater palatine nerve. The incisive nerve should be anesthetized before elevation of the mucosa of the floor of the nose for subnasal grafts or implants that engage the nasal floor in the incisor region.

Arterial Supply to the Maxilla

The majority of arterial blood supply (Fig. 12.7) comes from the maxillary artery, which is one of the terminal branches of the external carotid artery. The artery starts deep in the neck of the mandibular condyle (mandibular portion) and then proceeds either superficial or deep to the lateral pterygoid muscle (pterygoid portion). It then branches close to the pterygomaxillary fissure, in which one branch enters the fossa (pterygopalatine portion). The other branch, called the *infraorbital artery,* enters the floor of the orbit via the infraorbital fissure; it proceeds in the infraorbital canal and exits on the face by passing through the infraorbital foramen. Branches of the maxillary artery are as follows:

1. Ophthalmic a.
2. Infraorbital a.
3. Deep temporal a.
4. Posterior superior alveolar a.
5. Middle superior alveolar a.
6. Anterior superior alveolar a.
7. Buccal a.
8. Inferior alveolar a.
9. Middle meningeal a.
10. Maxillary a.
11. Superior temporal a.
12. External carotid a.
13. Mental branch of inferior alveolar a.
14. Facial a.


• **Fig. 12.7** Arterial supply of the maxilla and mandible.

1. Mandibular portion: deep auricular, tympanic, middle meningeal, and inferior alveolar arteries
2. Pterygoid portion: deep temporal, lateral pterygoid, medial pterygoid, and masseteric arteries
3. Pterygopalatine portion: posterior superior alveolar, descending palatine, and sphenopalatine arteries
4. Infraorbital portion: anterior and middle superior alveolar, palpebral, nasal, and labial arteries

Supplemental arterial blood supply reaches the maxilla via two branches from the cervical portion of the facial artery (ascending palatine and tonsillar arteries), two dorsolingual arteries from the lingual artery, and the ascending pharyngeal branch of the external carotid artery. All the collateral circulation reaches the maxilla from the area of the soft palate. During orthognathic surgery to correct maxillary prognathism, the surgeon often cuts the posterior, middle, and anterior superior alveolar arteries, as well as the descending palatine arteries, without compromising the blood supply to the maxilla because of the presence of supplemental blood supply from the branches mentioned previously. It is important to note that the maxillary artery supplies blood to the bone of the mandible via its inferior alveolar artery and its branches to the muscles of mastication. Detaching the masseter and medial pterygoid muscles without reattaching it could result in necrosis of the ramus of the mandible. In addition, all the arterial branches mentioned previously arise from the external carotid; therefore bilateral arteriosclerosis of the carotids, which is common in old age and in uncontrolled diabetic patients, may compromise the blood supply to the maxilla and could result in delay of healing after insertion of implants or bone grafting to the area. More detailed consideration of applied anatomy of the arterial supply to both the maxilla and mandible is presented at the end of this chapter.

Venous Drainage of the Maxilla

The veins follow the arteries and carry the same names. The maxilla drains into the maxillary vein. The latter communicates freely with the pterygoid plexus of veins and then joins the superficial temporal vein to form the posterior facial vein within the parotid gland. Infection from the maxilla may follow the maxillary vein to the pterygoid plexus veins and then to the cavernous sinuses via emissary veins, causing infected cavernous sinus thrombosis. Adequate arterial supply and healthy venous drainage are essential for bone regeneration and remodeling of bone grafts.

Lymphatic Drainage

The maxilla, including the maxillary sinuses, drains its lymphatics into the submandibular lymph nodes. In addition, the posterior portion of the maxilla and soft palate drain into the deep facial lymph nodes, which are part of the deep cervical nodes. Palpation of lymph nodes is an essential part of the physical examination of the head and neck.

Surgical Anatomy of the Mandible

The clinician should be familiar with the anatomical features of dentulous and edentulous mandibles, not only from radiographs but also from physical examination (see Figs. 12.1–12.4). The symphysis, inferior border, premasseteric notch, gonial angle, lateral pole of condyle, and coronoid process are all palpable under the skin. Intraoral palpable features of the mandible from the facial surface include the external oblique ridge and retromolar triangle, with the coronoid process at its tip, the external oblique ridge bordering it laterally, and the internal oblique ridge bordering it medially. The latter is called the *temporal crest* because this is the site for insertion of the medial tendon of the temporalis muscle. The mental foramen can be located at the midpupillary line at the apices of the premolars. From the lingual aspect, palpate the internal oblique ridge and torus mandibularis at the premolar region. Reflection of the mucoperiosteal flap beyond the mucobuccal fold facially exposes the mentalis muscles lateral to the midline, the mental foramen with the mental neurovascular bundle, the depressor labii inferiori, and the triangularis close to the inferior border in the premolar region, the transaction at the base of the alveolar process opposite to the molars, and the temporalis tendons at the anterior border of the ramus. An atrophied edentulous mandible loosens the alveolar process, and the crest of the ridge may be found at the same level as the external and internal oblique ridge. It is possible to palpate the superior genial tubercle with its genioglossus muscle attachment. Reflection of the mucoperiosteal flap after a midcrest incision may expose the mental neurovascular bundle, which is abnormally located at or occasionally lingual to the crest of the ridge. The transact muscle may loosen its attachment to the external oblique ridge, whereas the mylohyoid may rise above the level of the ridge. The lingual nerve, which has a close relationship to the alveolar bone of the third molar in the dentulous mandible, may run close to the crest of the edentulous ridge; in some cases it may be found under the retromolar pad.

Muscle Attachment to the Mandible

The loss of teeth begins a cascade of events that leads to alveolar bone loss in width and height. As the mandibular alveolar bone resorbs, the residual ridge migrates toward many of the muscles that originate or insert on the mandible (see Figs. 12.3–12.5). The origin, insertion, innervation, and function of the muscles of surgical importance to the implant dentist are discussed.[1-7]

Lingual or Medial Attachments

Mylohyoid Muscle. The mylohyoid muscle is the main muscle of the floor of the mouth. It takes origin from the entire length of the mylohyoid lines on the medial aspect of the mandible bilaterally. The most posterior fibers of the mylohyoid insert into the body of the hyoid bone, whereas the other fibers meet in the midline to form a median raphe that extends from the mandible to the hyoid bone. The structures above the mylohyoid muscle are sublingual or intraoral in location, and the structures below the mylohyoid muscle are extraoral or subcutaneous. With a severely resorbed residual ridge, the origin of the mylohyoid muscle approximates the crest of the ridge, especially in the posterior mandible. In these cases surgical manipulation at the crest of the ridge may injure the mylohyoid muscle. A mandibular periosteal reflection for subperiosteal implant often reflects this muscle to the second molar region. The substructure of the implant then has a permucosal site in the first molar area and a lingual primary strut above and below the mylohyoid muscle. Surgical manipulation of the tissue of the floor of the mouth may lead to edematous swelling of the sublingual space (above the mylohyoid muscle), swelling of the submandibular space (below the mylohyoid muscle), or both. Ecchymosis resulting from blood accumulation may occur

subcutaneously and/or submucosally. In some cases, infection may start and spread lingually and lead to an abscess or cellulitis either sublingually (intraoral) or submandibularly (extraoral), depending on the site of origin of the infection in relation to the origin of the mylohyoid muscle. Extensive bilateral cellulitis of the sublingual spaces may push the tongue backward or compress the pharynx, which may result in airway obstruction and necessitate a tracheotomy or cricothyroidotomy to maintain the airway. Functionally, the mylohyoid muscle raises the hyoid bone and floor of the mouth, or it can depress the mandible if the hyoid bone is fixed. The mylohyoid nerve that innervates the muscle is a motor branch of the inferior alveolar nerve. The latter is a branch of the mandibular nerve (V3).

Genioglossus Muscle. The genioglossus muscle forms the bulk of the tongue. It takes origin from the superior genial tubercle. The anterior fibers insert into the dorsal surface of the tongue from the root to its tip, and the posterior fibers insert into the body of the hyoid bone. The genioglossus muscle is the main protruder of the tongue. The genial tubercles, particularly the superior pair, may be located near the crest of the alveolar ridge in divisions C to D of the atrophic mandible. During the elevation of the lingual mucosa and before making an impression for a subperiosteal implant, one should be aware of the origin of this structure to avoid causing injury during the procedure. A portion of this muscle may be reflected from the genial tubercle. However, the muscle should not be completely detached from the tubercle because this may result in retrusion of the tongue and possible airway obstruction. A branch of the hypoglossal nerve (cranial nerve XII) supplies the genioglossus.

Medial Pterygoid Muscle. The majority of the fibers of the medial pterygoid muscle take origin from the medial surface of the lateral pterygoid plate of the sphenoid bone. A small slip of muscle originates from the tuberosity of the maxilla. The muscle inserts on the medial surface of the angle of the mandible. The medial pterygoid muscle bounds the pterygomandibular space medially. This space is entered when an inferior dental nerve block is administered. Furthermore, during surgical procedures medial to the medial tendon of the temporalis muscle, such as in preparation for the insertion of a unilateral subperiosteal implant, the pterygomandibular space is usually involved. Infection of this space is dangerous because of its proximity to the parapharyngeal space and the potential for spread of the infection to the mediastinum. Surgical exposure of tissue posterior to the maxillary tuberosity may also involve the medial pterygoid muscle because a portion of the muscle takes origin from the maxillary tuberosity. However, the numbers of fibers originating from the tuberosity are few compared with the fibers from the medial surface of the lateral pterygoid plate. A branch of the mandibular division (V3) of the trigeminal nerve innervates the muscle.

Lateral Pterygoid Muscle. Although the lateral pterygoid muscles rarely are involved in surgery for implants, their possible action in mandibular flexure or adduction during opening, as well as the effect of this phenomenon on subperiosteal implants or prosthetic full-arch splitting of mandibular implants in the molar region, warrants their consideration. The lateral pterygoid muscle consists of superior and inferior heads. The superior head takes origin from the infratemporal surface and crest of the greater wing of the sphenoid bone (roof of the infratemporal fossa), whereas the inferior head takes origin from the lateral surface of the lateral plate of the pterygoid process of the sphenoid bone. The fibers of the superior head run downward to insert on the anterior band of the temporomandibular joint (TMJ) disk (about 15% of its fibers)

and the pterygoid fovea on the neck of the mandible. The fibers of the inferior head run upward to insert on the pterygoid fovea and also on the medial pole of the condyle, median capsule, and median collateral ligament of the TMJ disk. Because of the angulation of the lateral pterygoid muscles, many authors believe that the mandibular flexure causing alteration in the mandibular arch width, and sometimes pain in patients with a full-arch subperiosteal implant or prosthetic splint, may be caused by contraction of the lateral pterygoid muscles. The muscles normally function in protraction of the mandible and are innervated by a branch of the mandibular nerve (V3).

Temporalis Muscle. The temporalis is a fan-shaped muscle of mastication. It takes origin from the temporal fossa and inserts into the coronoid process of the mandible and the anterior border of the ramus as far inferiorly as the last molar at the site of the retromolar fossa. The muscle has two tendons that insert into the mandible. The superficial tendon is located laterally, and the deep tendon is inserted medially. The temporalis tendons and their associated fascia project anteromedially and inferiorly and serve as a common point for attachment for the temporalis, masseter, and medial pterygoid muscles, as well as for the transaction and superior pharyngeal constrictor muscles. The long buccal nerve and vessels are also located in this area. This temporalis tendon–fascial complex extends into what is traditionally called the *retromolar triangle.* Surgical exposure of the mandibular ramus medially would involve this tendon–fascial complex, with its contents of muscle fibers, nerves, and vessels, and may lead to transaction and postoperative pain. Incisions placed on the anterior ascending ramus for subperiosteal implants or harvesting bone from the external oblique and ramus should be inferior to the insertion of the two tendons of the temporalis muscle. The temporalis muscle is a powerful elevator and retractor of the mandible and, like all the major muscles of mastication, is innervated by a branch of V3.

Buccal or Facial Muscle Attachments

Mentalis Muscle. The external surface of the mandible in the midline presents a ridge indicative of the location of the symphysis menti (see Fig. 12.5). The ridge leads inferiorly to a triangular elevation known as the *mental protuberance.* The base of the triangle is raised on either side into the mental tubercles. The mentalis muscles take origin from the periosteum of the mental tubercles and the sides of the mental eminence and insert into the skin of the chin and superiorly interdigitate with the orbicularis oris of the lower lip. Above the mentalis origin, the incisivus muscles take origin from small fossae called the *incisivus fossae.* Complete reflection of the mentalis muscles for the purpose of extension of a subperiosteal implant or symphyseal intraoral graft may result in "witch's chin," probably caused by the failure of muscle reattachment. If the muscle is completely detached to expose the symphysis, then an elastic bandage is applied externally to the chin for 4 days to help in the reattachment of the muscle. Another approach is to incise the muscle and leave a proximal portion attached to bone and reflect the distal portion. The distal and proximal portions should be approximated with resorbable sutures before suturing the mucosa. The mentalis muscle receives its nerve supply from the marginal (mandibular) branch of the facial nerve.

Buccinator Muscle. The fibers of the transaction muscle (cheek muscle) take origin from the lateral surfaces of the alveolar processes of the maxilla and the mandible in the area of the molars, the maxillary tuberosity, the pterygoid hamulus, the pterygomandibular raphe, and the retromolar fossa of the mandible. The insertion of the muscle is complex. The upper and lower fibers of

the transaction blend with the fibers of the orbicularis oris at the upper and lower lips. The central fibers decussate at the modiolus before they insert into the orbicularis oris. The modiolus is the site of crossing and intermingling of fibers from the transaction muscle with fibers from the elevator and depressor muscles of the angle of the mouth. The modiolus forms a palpable node inside the angle of the mouth opposite the upper first premolar tooth. The parotid duct opposite the maxillary second molar pierces the transaction muscle. The buccopharyngeal fascia, which is a part of the visceral fascia of the neck, covers the muscle. Lateral to the fascia is the buccal pad of fat.

Some patients wearing lower subperiosteal implants complain of episodic swelling and pain at the site of origin of the transaction muscle, particularly after periods of heavy mastication or bruxism. Incision of these swellings does not usually yield exudate or purulence. The condition responds well to heat application, transactionary drugs, and rest. Although the cause for this condition is not known, one may speculate that myositis of a detached transaction muscle may cause it. The process of muscle reattachment to the implant surface or to a new site should be investigated. The buccal branch of the facial nerve innervates the muscle.

Masseter Muscle. This strong muscle of mastication covers the lateral surface of the ramus and angle of the mandible. The masseter has a dual origin from superficial and deep heads. The superficial head takes origin from the anterior two-thirds of the lower border of the zygomatic arch. The deep head originates from the posterior one-third of the zygomatic arch and the entire deep surface of the arch. The muscle inserts into the outer surface of the ramus of the mandible from the sigmoid notch to the angle. However, the muscle can be deflected easily during surgery to expose the bone for the ramus extension needed for lateral support of a subperiosteal implant. The space between the masseteric fascia and the muscle is a potential surgical space, known as the *masseteric space,* into which an infection may spread, causing myositis and trismus. The masseter is one of the main elevators of the jaw. The masseteric nerve provides the innervation of the muscle and is a branch of the mandibular division (V3) of the trigeminal nerve.

Innervation of the Lower Jaw and Associated Structures

Inferior Alveolar (Dental) Nerve
This nerve arises as a branch of the mandibular nerve (V3) in the infratemporal fossa (see Fig. 12.6). It appears at the inferior border of the inferior head of the lateral pterygoid muscle, courses downward, and enters the mandibular foramen on the medial aspect of the ramus. Before the nerve enters the mandibular foramen, it gives numerous sensory branches that innervate the mandibular bone. These small nerves are in association with small vessels in neurovascular channels. The inferior dental nerve can run as one unit through the mandibular canal until it reaches the premolar region, in which it divides into the mental and the incisive nerves. The mental nerve exits the canal through the mental foramen. In an excessively resorbed ridge, the mental foramen, with its contents of mental nerve and vessels, can be found on the crest of the ridge. When making an incision or reflection of the mucosa in this area, avoid injury to these vital structures. Knowledge of the position of the inferior dental canal in vertical and buccolingual dimensions is of paramount importance during site preparation for implants. The potential use of reconstruction techniques on computed tomographic scans and magnetic resonance imaging may increase clinicians' ability to locate the inferior dental canal precisely within the jawbone. Much less expensive techniques using panoramic cross-sectional tomographic imaging are also available. In some cases the inferior dental nerve may divide into two or three rami that occupy separate canals as the nerve travels in the mandible to supply the bone. These variations can be determined by conventional radiographic techniques, and the operator should modify the surgical approach and type of implant to avoid injury to the portion of the nerve that exits the foramen. Injury to the portion of the inferior alveolar nerve that remains in the atrophied bone and does not innervate soft tissues is of far less consequence. The nerves in the bone, when in contact with an implant, may account for the rare but occasional observation of tenderness, even though the implant is rigid and appears healthy. In addition, the fibrous tissue around these nerves may cause an increase in the amount of fibrous tissue around an implant that is inserted in contact with these structures.

Lingual Nerve
The lingual nerve is a branch of the mandibular nerve that is given off in the infratemporal fossa. It appears at the inferior border of the inferior head of the lateral pterygoid muscle anterior to the inferior alveolar nerve. It passes downward and forward between the ramus of the mandible and the medial pterygoid muscle. The nerve enters the oral cavity above the posterior edge of the mylohyoid muscle close to its origin at the third molar region. Because the nerve lies just medial to the retromolar pad, incisions in this region should remain lateral to the pad, and the mucosal reflection should be done with the periosteal elevator in constant contact with bone to prevent injury to the nerve. The nerve proceeds on the surface of the hyoglossus muscle and then crosses the duct of the submandibular gland medially to enter the floor of the mouth and the tongue. While in the infratemporal fossa, the nerve is joined by the chorda tympani nerve, which is a branch of cranial nerve VII. The chorda tympani nerve carries taste fibers from the anterior two-thirds of the tongue and parasympathetic preganglionic fibers to the submandibular autonomic ganglion. The ganglion is connected to the lingual nerve on the surface of the hyoglossus muscle. The postganglionic neurons from the submandibular ganglion supply the submandibular and sublingual salivary glands. The branches of the lingual nerve in the oral cavity carry sensory information from the lingual mucosa, the mucosa of the floor of the mouth, and the anterior two-thirds of the tongue. Improper reflection of a lingual mucoperiosteal flap may injure the lingual nerve and produce ipsilateral paresthesia or anesthesia of the innervated mucosa, loss of taste, and reduction of salivary secretion. The extent of involvement depends on the degree of injury to the nerve.

Nerve to the Mylohyoid
The mylohyoid motor branch of the inferior dental nerve is given off just before the nerve enters the mandibular foramen. This branch descends in a groove on the medial surface of the mandibular ramus and then appears in the submandibular triangle at the posterior border of the mylohyoid muscle. The nerve supplies the mylohyoid muscle and then proceeds on its surface with the submental artery (branch of the facial artery) until it reaches the anterior belly of the digastric muscle, which it also supplies. Because the nerve is so closely related to the ramus of the mandible, surgical intervention in this area may lead to injury of this important motor nerve.

Long Buccal Nerve

This nerve is a sensory branch of the mandibular division of the trigeminal nerve and is distributed to the skin and mucous membrane of the cheek and the buccal transact opposite the mandibular molar region. The nerve courses between the two heads of the lateral pterygoid muscle, then precedes medial to, or sometimes within, the medial temporalis tendon to gain access to the surface of the buccinator muscle. The nerve supplies the skin of the cheek and runs down to the level of the external oblique ridge, penetrates the buccinator, and spreads its branches under the cheek mucosa, alveolar mucosa, and attached gingivae opposite to molar teeth. The implantologist who is planning to access the ramus for the purpose of excising a block graft should be aware of the buccal nerve and avoid injuring it. In addition, surgical manipulation in this area (e.g., during insertion of a subperiosteal implant) may injure this nerve.

Blood Supply to the Maxilla and Mandible

The head and neck region has an abundant blood supply, with many anastomoses (see Fig. 12.7). The upper and lower jaws are no exception. The blood supply to both the mandible and maxilla is derived from a common source, the external carotid artery. The external carotid artery is a branch of the common carotid artery, which is a direct branch off the arch of the aorta on the left side and a branch of the brachiocephalic artery on the right side of the body.

The main artery supplying the mandible is the inferior alveolar (dental) artery, which serves as the nutrient artery to the bone and other tissues within the lower jaw. The bone tissue of the maxillae is supplied by branches of two major vessels, the posterior superior alveolar (dental) artery, and the infraorbital artery. The major branch of the infraorbital artery that supplies the maxilla is the anterior superior alveolar (dental) artery. The posterior superior alveolar and infraorbital arteries are branches of the maxillary artery, which is one of the two terminal branches of the external carotid artery.

General Concepts

The circulation of blood within long bones is centrifugal; that is, the blood circulates from the marrow (medullary) region outward through the cortical bone to end in vessels located in the periosteum and soft tissues associated with the bone.[8,9] The blood supply to the medullary region is by way of nutrient arteries, which are relatively large vessels that pass through the bone by way of nutrient canals to enter the marrow spaces. Within the marrow spaces, the nutrient artery forms a network of vessels called the *endosteal* or *medullary plexus*. Vessels from this plexus enter the cortical bone through Volkmann canals and eventually reach the surface of the bone. While blood is passing through the cortical bone, numerous vessels are given off at right angles to these intraosseous vessels within Volkmann canals. These branches are the vessels that are found within the haversian canals of the osteons.[8,9] Osteonal bone is the major type of bone found in the cortical bone of the jaws. Once the intraosseous vessels reach the outer surface of the bone, they anastomose with vessels within the fibrous layer of the periosteum or with arteries supplying the soft tissues. The network of vessels associated with the periosteum is called the *periosteal plexus*. The periosteal plexus in turn communicates with vessels that are supplying arterial blood to muscles and other soft tissues in the area.

The mandible and maxilla are membrane bones and as such do not develop in the same manner as long bones. Most researchers agree that the circulation of blood within the body of the mandible[10] and in the maxilla[11,12] is centrifugal under normal conditions. As in the long bones, endosteal and periosteal plexuses exist that are connected with one another.[12,13] In addition to these vascular networks, a periodontal plexus is found associated with the teeth.[12,13] When teeth are present, intraosseous vessels send branches into the alveolar processes (intraalveolar arteries), to the teeth (apical arteries), and to branches of the periodontal plexus. The intraalveolar arteries and periodontal plexus in turn connect with vessels of the periosteal plexus, as well as with vessels within the soft tissues surrounding the bone. Once a tooth is removed, its periodontal plexus is lost. When abnormal circulatory conditions exist within the mandible or maxilla, such as occlusion of the nutrient artery, the blood supply to the bone is reversed so that the direction of flow is from the outside to the inside of the bone.[10,11,14] This is called *centripetal circulation.*

Maxilla

The vessels that supply the maxilla are branches of the third part of the maxillary artery. The posterior superior alveolar artery leaves the maxillary artery and travels on the infratemporal portion of the maxilla, in which it divides into several branches. Some of the branches enter alveolar canals within the posterior aspect of the maxilla to become intraosseous arteries, which supply the molar and premolar teeth and the lining of the maxillary sinus. Other branches of the posterior superior alveolar artery travel on the surface of the maxilla to supply the transact of the posterior maxillary teeth. Injury to this artery within the bone during lateral-approach sinus elevation procedures may cause hemorrhage, which requires coagulation or the use of bone wax to control the bone bleeding.

The infraorbital artery leaves the maxillary artery and enters the orbital cavity by way of the inferior orbital fissure. The artery runs in the infraorbital groove and later in the infraorbital canal. Both of these structures are located in the floor of the orbit. The infraorbital canal opens on the face as the infraorbital foramen. Within the canal the artery gives off the anterior superior alveolar artery, which descends through anterior alveolar canals to supply the maxillary anterior teeth and the mucous membrane of the maxillary sinus. The anterior and posterior superior alveolar arteries join together to form an arterial loop. The middle superior alveolar artery is rarely a separate branch.[15] The infraorbital artery also supplies branches to the maxillary sinus.[16]

Gingival, buccal, labial, palatal, nasal, and maxillary sinus blood vessels anastomose with the arterial networks associated with the maxilla. These vessels not only join with the periosteal plexus, but they also penetrate the bone to connect with vessels of the endosteal and periodontal plexuses. In addition, abundant midline crossover is possible in the soft tissues of the palate and face.[13]

The mucoperiosteum of the anterior maxilla is supplied by branches of the infraorbital artery and the branches of the superior labial artery, which is a major branch of the facial artery.[13] The buccal mucoperiosteum of the maxilla is supplied by vessels of the posterior superior alveolar, anterior superior alveolar, and buccal arteries. Branches from the greater (anterior) palatine and the nasopalatine arteries supply the mucoperiosteum of the hard palate. The lesser (posterior) palatine artery supplies the soft palate. Communications of the lesser palatine arteries with the ascending pharyngeal branch of the external carotid artery and the ascending palatine branch of the facial artery are critical in many

of the surgical orthognathic procedures that are performed on the maxilla.[12] In these surgical procedures, the major nutrient arteries to the maxilla are sometimes severed, but the blood supply is maintained by means of the anastomoses present in the soft palate. The vessels of the soft palate unite with vessels of the hard palate, which in turn communicate with the periosteal, periodontal, and endosteal plexuses of the upper jaw. Thus the vitality of the tissues of the maxilla is maintained through an arterial supply derived entirely from vessels that normally supply the soft palate.

Mandible

The major artery supplying the blood of the mandible is the inferior alveolar artery. The artery enters the medial aspect of the ramus of the mandible and courses downward and forward within the mandibular canal to enter the body of the mandible. The artery branches in the premolar region to give rise to two terminal branches: the mental and incisive arteries. The incisive artery continues medially within the body to anastomose with the artery of the opposite side. This artery is often severed during the harvest of a monocortical symphyseal block of bone for grafting resorbed ridges. Crushing bone around the vessel or using bone wax easily controls the bleeding. The mental artery exits the body of the mandible through the mental foramen and supplies the region of the chin and anastomoses with the submental and inferior labial arteries. Near its origin the inferior alveolar artery gives off a lingual branch, which supplies blood to the oral mucosa.[16]

Studies in animals have demonstrated that the coronoid process, the condylar process, and the angle of the mandible are supplied by arteries that provide blood to the muscles that attach to these sites.[16] Studies of human cadaver material show that the condylar process is supplied by the vascular network of the TMJ joint capsule and the lateral pterygoid muscle. In addition, researchers found that vessels from the temporalis muscle supplied the coronoid process exclusively, and the inferior alveolar artery supplied the angle of the mandible, as well as the muscles attached to the area. The same researchers found that the vessels that supply the pterygomasseteric sling (i.e., the medial pterygoid and masseter muscles) also supply the anterior portion of the ramus.[17] Empirical findings from mandibular osteotomy procedures in humans support many of these findings.[18] Thus the repositioning of the inferior alveolar artery laterally, which is a procedure that may be needed in some cases before implant insertion, should not eliminate the blood supply to the bone in this region (see the discussion that follows).

Changes in Blood Supply to the Mandible with Age. Although the normal circulation within the body of the mandible is centrifugal in young individuals, the direction of blood flow may reverse with aging. It has been shown that the inferior alveolar artery is susceptible to arteriosclerotic changes and tends to become tortuous and narrow with age.[19,20] Blockage of the inferior alveolar artery occurs years before any clinical evidence of blockage in the carotid vessels is found. Angiographic studies of living human subjects of all ages demonstrated blockage of the inferior alveolar artery in 79% of all individuals studied, and in 33% of the patients arterial flow was absent.[20] The incidence of absence of flow in the inferior alveolar artery increased with age. The reduction or absence in flow within the inferior alveolar artery may be associated with tooth extraction.[20] Studies in completely edentulous humans indicated that the inferior alveolar artery degenerates to such an extent as to be negligible in the supply of blood to the mandible.[19] In these cases the blood supply to the bone and internal structures was dependent on the connections with the external

blood supply located within the periosteum and soft tissues associated with the mandible.[19,20] Major arteries that probably supply blood to the mandible after the interruption of the inferior alveolar artery blood flow include the mental artery,[14] the mandibular branch of the sublingual artery,[14] the facial artery,[10] and muscular branches of the maxillary artery. These anastomoses are critical in surgical procedures in which mucoperiosteal flaps are created in the mandible. The changes in pattern of blood flow to the atrophic mandible are of special importance to implant dentistry. Mucoperiosteal flap reflection for subperiosteal implant usually exposes 75% of the body of the mandible and approximately 50% of the inferior one-third of the rami. Dehiscence of the mucosa at the incision lines has been reported. The reduction in atrophied bone blood supply may be a contributing factor. Onlay grafts from the iliac crest to severely atrophied mandibles are also associated with occasional incision line opening postoperatively. Limitation of surgical reflection of muscles that attach to the bone improves blood supply but may complicate primary closure without tension. However, muscle attachments at the basal bone of the mandible, which are not in the way of the graft placement, should not be reflected. In addition, endosteal implants placed in an atrophied anterior mandible may have less blood supply to the interface and may require longer time for load-bearing bone to develop. Misch has suggested 5 months of healing in very dense bone when found in an atrophied anterior mandible.[21] These speculations, of course, require experimental verification. Similar blood flow reversal with age has not been reported in the maxilla, but final comment concerning blood flow in the aged edentulous maxilla awaits further investigation.

Implantologists may encounter neurovascular bundles such as the infraorbital, incisal, greater palatine, anterior, middle, and posterior superior alveolar nerves in the maxilla (e.g., during antral augmentation procedures or mucoperiosteal flap reflection) and the mental nerve, inferior dental nerve, and the lingual nerve in the mandible (e.g., during placement of root or blade implants or reflection of microperiosteal flaps). Stretching, compression, partial resection, or total transaction can mechanically injure the nerve.

Factors that affect nerve response to mechanical injury include the following:
1. Size and number of funiculi (nerve bundles) within the nerve trunk.
2. Funicular pattern: The branching within the nerve trunk will lead to an increase in density or number of nerve fibers per cross section of the nerve. Therefore injury to the nerve at one spot may cause damage to more fibers than to the adjacent area of the nerve that has less funicular branching.
3. The amount of epineural tissue: The connective tissue that surrounds the nerve is called the *epineurium*. The thinner the epineurium is, the greater the possibility is that partial injury to the nerve could damage the nerve fibers.
4. Position of the nerve fibers in the nerve trunk: The peripheral fibers leave the nerve first, whereas the central fibers innervate the most distal tissue. If a patient develops paresthesia of the lower lip after surgical placement of implants in the molar region, then it means that the nerve damage went through the center of the nerve to affect the mental nerve fibers.
5. Physiologic susceptibility: For an unknown reason, the motor fibers respond differently when subjected to mechanical deformation compared with sensory fibers.

Nerve fibers of the peripheral nervous system (PNS) show greater capacity for regeneration than nerves of the central nervous

system (CNS). The axons of both myelinated and unmyelinated fibers in the PNS are surrounded by Schwann cells, which are covered by basal lamina. They later provide a continuous tube, even after the nerve fiber is cut into distal and proximal segments. The proximal segment is still connected to a living nerve cell body, whereas the distal segment gradually degenerates and eventually disappears. This is known as *Wallerian degeneration.* The Schwann cells of the distal segment proliferate and form a cell strand known as a *Schwann cell column* or *band of Büngner* within the basal lamina tube.[22] The Schwann cells also become phagocytic, and along with macrophages they clean the distal segment from degenerating axons. Sprouting of new axons takes place approximately 4 weeks after injury, and it takes 5 weeks for a sizeable number of axons to occupy the distal segment. The excess sprouts degenerate, and one fiber finds its way into the distal segments. If regenerating axons evade the Schwann cell column and enter the connective tissue, then they cease to grow after elongation of a few millimeters. The Schwann cells and the basal lamina are indispensable for axonal regeneration because they retain growth factors. The Schwann cells also provide new myelin for the regenerating fibers, although the conduction property is less efficient and the functional recovery may never be complete. The sprouting stage may cause pain to the patient, and the area may be sensitive to touch. The rate of recovery will depend on the type of injury (e.g., a crushed nerve regenerates faster than a severed nerve).

Dental Implant Infections

JOSEPH E. CILLO, JR.

Introduction

Dental implants are a contemporary solution to tooth loss and oral reconstruction with a known high success rate of osseointegration. It is estimated that between 100,000 and 300,000 dental implants are placed per year.[1] Although the success rate is high, dental implant infections may occur that lead to lack or loss of osseointegration and may result in subsequent implant failure. These failures may be divided into either early or late based on the time of their occurrence during a dental implant's life span. Early dental implant failure occurs before osseointegration and prosthetic loading, whereas late failures occur after loading and may occur years to decades later. Early dental implant failure may be attributed to bacterial contamination, such as pellicle or biofilm formation, and inflammation that prevents or prolongs osseointegration. Similarly, long-term survival of dental implants depends, in part, on control of bacterial infection in the peri-implant region. Peri-implant disease may contribute to increased bone loss and eventual dental implant failure. The capability to diminish the potential early deleterious effects of bacterial contamination during both the surgical and prosthetic aspects of dental implant therapy and later effects of bacterial involvement in the peri-implant tissues begins with the understanding of the microenvironment and its denizens. This understanding of the oral microenvironment and its influence on dental implant surgery and prosthetics may allow for strategies to decrease the occurrence and spread of dental implant infections.

Overview of Oral, Head, and Neck Infection and Spread

Dental implants are uniquely engineered biomaterials ubiquitously used to replace teeth for restoration of oral function. The most common form of dental implant is the screw-type, or endosseous, implant comprised of a single implant unit that is inserted within a dentoalveolar or basal bone osteotomy. An implant's presence in the bacteria-laden milieu of the oral cavity would indicate the high likelihood of an increase in infection risk. However, the failure rate because of infection for dental implants (0.0%–1.1%) placed in this contaminated environment is similar to that of orthopedic joint arthroplasties performed in a near-sterile environment (0.1%–1.3%).[2] Conversely, orthopedic device placement that breaches the immune barrier of the epidermis and exposes the underlying sterile tissue to an unsterile external environment results in much higher infection-associated failure rates of up to 23.0%.[2]

The success of dental implant resistance to infection-associated failure may be caused by the ability of oral tissues to heal rapidly in the continuous presence of commensal bacteria and opportunistic pathogens, and the tolerance of the oral immune system. The main cause of infection-associated dental implant failure is when local tissue is unable to adhere, spread, and heal in the presence of microbial contaminants and an intolerant immune system. The role of saliva in the development of dental implant infection is complicated. Saliva has been shown to have antimicrobial[3,4] and antifungal[5] properties that may be a contributing factor to infection prevention. However, saliva is responsible for pellicle formation to which viable bacteria may adhere and mature to hinder healing and yield infection.

Signs and Symptoms of Oral Infection

The signs and symptoms of surgical site infections (SSI) have remained consistent and are generally similar throughout the human body. Diagnosis is based on the clinical signs of infection such as hyperplastic soft tissues, suppuration, color changes of the marginal peri-implant tissues, and gradual bone loss. The four fundamental signs of infection are pain or tenderness (*dolor*), localized swelling (*tumor*), redness (*rubor*), and heat or fever (>38°C) (*calor*) are the hallmark signs of infection.[6] This may or may not be associated with purulent drainage (pus) or fistula formation.

The occurrence of hematologic bacterial seeding with dental implant surgery is common and may occur as soon as 30 minutes after placement. Hematologic spread of oral microorganisms caused by this transient bacteremia may result in bacterial colonization in extraoral sites and is a proposed mechanism for systemic injury by free toxins and systemic inflammation caused by soluble antigens of oral pathogens. Some of the numerous species involved include *Staphylococcus epidermidis, Eubacterium* spp., *Corynebacterium* spp., and *Streptococcus viridans, Fusobacterium nucleatum, Porphyromonas gingivalis, S. mutans,* and *Campylobacter rectus.*[7,8] Systemic hematologic spread of oral commensals and pathogens to distant body sites may cause extraoral infections and inflammation, leading to cardiovascular disease, such as infective endocarditis with early colonizers *S. gordonii, S. sanguinis,* and *S. oligofermentans,*[9-11] adverse pregnancy outcomes, rheumatoid arthritis, inflammatory bowel disease, and colorectal cancer (direct and specific carcinogenesis of colonic adenomas from *F. nucleatum* induces tumor growth,[12] respiratory tract infections, organ inflammation, and abscesses by virulent oral species). Development of dangerous and life-threatening conditions, such as Ludwig angina, airway compromise, or carotid cavernous sinus fistula may also occur.[13]

Spread of Head and Neck Infection

Regardless of their pathogenic potentials in the oral cavity, once colonized in the extraoral sites, oral bacteria often become bona fide pathogens, especially in immunocompromised individuals, causing disease manifestation (Figs. 13.1–13.4).[7] Spread of infection from a dental implant, or any oral source, will travel through the path of least resistance, which is generally fascial spaces. Fascial spaces are potential spaces that exist without the presence of pathology or infection and lay between loose fibrous connective tissue fasciae and underlying organs and other tissues. The loose fibrous connective tissue that makes up the fascia of the head and neck is found in varying degrees of density with a tensile strength somewhat less than dense fibrous connective tissue located elsewhere in the body. In the head and neck, fascia may be divided into the superficial and deep layers with 16 fascial spaces divided into four subtypes. These four subtypes are the fascial spaces of the face, suprahyoid fascial spaces, infrahyoid fascial spaces, and the fascial spaces of the neck.

The superficial fascia of the head and neck lies just under the skin (as it does in the entire body), invests the superficially situated mimetic muscles (platysma, orbicularis oculi, and zygomaticus major and minor), and, located in distinct anatomic areas, is composed of two layers, an outer fatty layer and a thin inner membrane.[14] The deep fascia is absent in the face and scalp and begins at the anterior border of the masseter muscle and invests the muscles of mastication

The fascial spaces of the face are subdivided into five spaces: canine, buccal, masticatory (further divided into the masseteric, pterygomandibular, and temporal spaces), parotid, and infratemporal. The canine space is located between the levator anguli oris and the levator labii superioris muscles. Infection may spread to this space from dental abscess or dental implant–related procedures performed in the anterior maxillary region. Direct surgical access is achieved by incision through the maxillary vestibular mucosa above the mucogingival junction. The buccal space is bounded anterior to the masticator space and lateral to the buccinator muscle with no true superior or inferior boundary and consists of adipose tissue (the buccal fat pad that fills the greater part of the space), Stensen duct, the facial artery and vein, lymphatic vessels, minor salivary glands, and branches of cranial nerves VII and IX.[15] The buccal space frequently communicates posteriorly with the masticator space where it joins the buccopharyngeal fascia.[16]

When infection is involved in the buccal space, the buccal space can serve as a conduit for spreading disease between the mouth and the parotid gland. The lack of fascial compartmentalization in the superior, inferior, and posterior directions permits the spread of pathology both to and from the buccal space.[17] Surgical access to the buccal space infections may be easily accomplished through the intraoral approach. However, more complicated infections, directed by location within the buccal space and suspicion of malignancy, may require a preauricular and/or submandibular approach. The masticator space is a well-defined fibrous tissue that surrounds the muscles of mastication and contains the internal maxillary artery and the inferior alveolar nerve. Most masseteric space infections result from spread in the mandibular molar region,[18] with trismus being the most pronounced clinical feature, and often precludes intraoral examination. Computed tomography (CT) and/or magnetic resonance imaging (MRI) may be an invaluable resource in the assessment of masseteric space infections because they can often influence the surgical approach and distinguish abscess from cellulitis.[18] Abscess formation in this area is easily reached by intraoral surgical access for simple, isolated abscesses for incision and drainage, but with extension into adjacent spaces, an external approach may be required. The pterygomandibular space is bounded by the mandible laterally and by the medial pterygoid muscle medially and inferiorly. The posterior border is formed by parotid glandular tissue, which curves medially around the posterior mandibular ramus and anteriorly by the pterygomandibular raphe, the fibrous junction of the buccinator, and superior constrictor muscles. Other structures in this space are important in the administration of local anesthesia, including the inferior alveolar vessels, the sphenomandibular ligament, and the interpterygoid fascia.[19] Surgical access to this space for incision and drainage may be achieved intraoral in the case of simple infections, but it may require extraoral access when multiple adjacent spaces are involved.[20] The temporal fascia surrounds the temporalis muscle in a strong fibrous sheet that is divided into clearly distinguishable superficial and deep layers that originate from the same region, with the muscle fibers of the two layers intermingled in the superior part of the muscle.[21]

The sublingual space is bounded between the mylohyoid muscle and the geniohyoid and genioglossus muscles. This space contains the lingual artery and nerve, the hypoglossal nerve, the glossopharyngeal nerve, Wharton duct, and the sublingual salivary gland, which drains into the oral cavity through several small
• **Fig. 13.1** (A) Extraoral and intraoral edema and fluctuance involving the floor of mouth and (B) submental and submandibular spaces from dental implant infection.

• **Fig. 13.4** Postoperative recovery from extraoral incision and drainage of dental infection.

excretory ducts in the floor of the mouth and a major duct known as the Bartholin duct. The submental space is bounded anteriorly by the symphysis of the mandible, laterally by the anterior bellies of digastric muscles, superiorly by the mylohyoid muscle, and inferiorly by the superficial fascia of the platysma muscle. There are no vital structures that traverse the submental space. This space is usually involved in odontogenic infections from the anterior mandibular teeth with surgical access for drainage of infection generally through an extraoral incision below the chin.[22] The submandibular space extends from the hyoid bone to the mucosa of the floor of the mouth and is bound anteriorly and laterally by the mandible and inferiorly by the superficial layer of the deep cervical fascia. The mylohyoid muscle separates it superiorly from the sublingual space, which communicates with it freely around the posterior border of the mylohyoid. Most oral infections that perforate the lingual mandible above the mylohyoid line will involve the sublingual space. When infection has spread to the bilateral submandibular, sublingual, and submental spaces, it represents Ludwig angina, a potentially life-threatening condition that requires immediate surgical drainage and intravenous antibiotic therapy.

The lateral pharyngeal space (also called the parapharyngeal space) is an inverted cone with its base at the base of skull and apex at the hyoid bone and is bounded posteriorly by the prevertebral fascia, anteriorly by the raphe of the buccinator and superior constrictors muscles, and laterally by the mandible and parotid fascia. The lateral pharyngeal space can be divided into anterior (prestyloid) and posterior (retrostyloid) compartments by the styloid process. The anterior compartment contains only fat, lymph nodes, and muscle, whereas the posterior compartment contains the carotid artery, the internal jugular vein, and cranial nerves IX through XII. Infections in the anterior space may present with pain, fever, and neck swelling below the angle of the mandible and trismus. Rotation of the neck away from the side of the swelling causes severe pain from tension on the ipsilateral sternocleidomastoid muscle. Because this space communicates with the other fascia spaces, spread of infection may also arise from numerous sources,

including the tonsils, parotid, and submandibular, peritonsillar, masticator, or retropharyngeal spaces. Airway impingement caused by medial bulging of the pharyngeal wall and supraglottic edema may occasionally occur, which may require the procurement of a stable airway by either tracheotomy or intubation.[23] The treatment of lateral pharyngeal space infections requires surgical drainage through either a transoral or extraoral approach.[24]

Fascial Spaces of the Neck

The fascial spaces of the neck all lie between the deep cervical fascia surrounding the pharynx anteriorly and the spine posteriorly. The retrovisceral space is divided into the retropharyngeal and danger spaces by the alar fascia and serves as the main route for oropharyngeal infections to descend into the mediastinum. The other fascial spaces of the neck include the prevertebral and carotid sheath spaces.

The retropharyngeal space is bounded anteriorly by the constrictor muscles and posteriorly by the alar layer of the deep cervical fascia and connects posteriorly to the danger space. Infections in this space may present with symptoms of fever, stiff neck, drooling, dysphagia, and bulging of the posterior pharyngeal wall. They may be complicated by the development of supraglottic edema with airway obstruction, aspiration pneumonia caused by rupture of the abscess, and acute mediastinitis that may lead to empyema or pericardial effusions. Proximity to the danger space may allow infection to spread to the mediastinum to the level of the diaphragm and possibly posteriorly to the prevertebral space. Surgical drainage should be performed in the operating room via a transoral approach with the head down to prevent rupture during intubation and septic aspiration.

The danger space is bounded superiorly by the skull base, anteriorly by the alar fascia, and posteriorly by the prevertebral fascia, ending at the level of the diaphragm. Danger space infections may track from the anteriorly located retropharyngeal space between the buccopharyngeal fascia and alar fascia and pass inferiorly to the mediastinum and the pericardium and may result in conditions such as purulent pericarditis.[25]

Microbiology of Dental Implant Infection

The oral cavity is awash in a milieu of different microbial species and colonies. More than 19,000 types of eukaryotic and prokaryotic bacteria, fungal, protozoan, and viral species coexist in the oral microenvironment.[26-28] This diverse microbiome consists of beneficial, pathologic, and opportunistic organisms, and when in balance may produce a benign or even beneficial result to the individual. When development of dysbiotic polymicrobial communities ensue with a misrepresentation between normally dominating species and normally outcompeted or contained species, more deleterious microbial species may increase in number to fill the void. Longitudinal studies have shown that successful implants are colonized by a predominantly gram-positive, facultative flora, which is established shortly after implantation, with no change in composition in patients with clinically stable implants over 5 years.[29] The transition from a gram-positive, facultative flora in health to a gram-negative, anaerobic flora in disease is the hallmark of impending dental implant infection and failure. In patients with bone loss and pocket formation around implants, significantly different flora develops consisting of gram-negative anaerobic bacteria, particularly fusobacteria, spirochetes, and black-pigmenting organisms such as high proportions of *Prevotella*

intermedia. Although there may be nonmicrobial primary causes for implant failure, gram-negative anaerobes play a role in peri-implant infections, and their elimination may lead to improvement of the clinical condition. The introduction and growth of deleterious microorganisms may also occur within the implant and on the prosthesis because the dental implant/abutment interface cannot totally seal the passage of microorganisms. Therefore the implant interior may become a reservoir of pathogenic microorganisms that produce and maintain chronic inflammation in the tissues around implants.

The numerically predominant species in the oral microbiota is the streptococci species. Most of the oral streptococci are commensal, nonperiodontopathogenic bacteria, but some are known to cause local and distant disease. Oral streptococci are divided into five different groups: (1) Mutans group (prominent members are *S. mutans* and *S. sobrinus*), (2) Salivarius group (*S. salivarius*), (3) Anginosus group (*S. anginosus* and *S. intermedius*), (4) Sanguinis group (*S. sanguinis* and *S. gordonii*), and (5) Mitis group (*S. mitis* and *S. oralis*).[30-32] These oral streptococci species are known to be the early colonizers for oral biofilm formation and heavily influence the development of further infection and biofilm formation. As an early colonizer, oral streptococci have been found to have metabolic interactions between other members of the oral biofilm, which may develop either a corporative or disobliging relationship. Symbiotic relationships exist between oral streptococci and the genus *Veillonella, V. atypica,* and *V. parvula* most prominently[33,34]; *Actinomyces naeslundii*[35,36]; *F. nucleatum*[37]; and the periodontal pathogen *Aggregatibacter actinomycetemcomitans.*[38] These symbiotic relationships include such events as coaggregation between *S. cristatus* and *F. nucleatum* and lactic acid–based cross-feeding between *S. gordonii* and the late colonizer and periodontal pathogen *A. actinomycetemcomitans.*

Anaerobic bacteria genera in the oral cavity include *Actinomyces, Arachnia, Bacteroides, Bifidobacterium, Eubacterium, Fusobacterium, Lactobacillus, Leptotrichia, Peptococcus, Peptostreptococcus, Propionibacterium, Selenomonas, Treponema*, and *Veillonella.* In adults, anaerobes are always present with greatest proportions found in the gingival sulcus rather than in the gingival margin, tooth surfaces, buccal mucosa, tongue, or saliva.[39] Proportions of anaerobic bacteria from the healthy gingival sulcus consist of gram-positive bacilli (5%–14%), gram-negative bacilli (13%–29%), *Veillonella* (2%–8%), and gram-positive cocci (1%–15%) of the cultivable flora.[39] Marginal plaque and tooth surface plaque consist mainly of gram-positive bacilli and gram-positive cocci, whereas *Veillonella* is the most numerous anaerobe in saliva.

Spirochetes are distinctive double-membrane bacteria that generally have characteristic helically coiled or spiraled cells and are known to be an abundant phylum in periodontitis.[40] *Treponema denticola,* a gram-negative, obligate anaerobic, motile, and highly proteolytic bacterium, is the most common spirochete in both periodontitis and peri-implantitis. Once spirochetes have developed in the dental implant site, they are responsible for bone loss and may be extremely difficult to eradicate. Spirochetes have developed a defense mechanism against antibiotic administration by transformation into spherical dense granular bodies, which make them highly resistant to antibiotics.[41] This phenomenon is seen with serial infections treated by multiple rounds of oral antibiotics that seem to resolve and then recur repeatedly.

Genera of fungi frequently found in the mouth include *Candida, Cladosporium, Aspergillus, Fusarium, Glomus, Alternaria, Penicillium,* and *Cryptococcus.*[42] Interactions between the mycobiome and the bacterial microbiome may play a role in health

and disease. In some cases, the occurrence of bacteria correlates positively with the presence of fungi, such as when *Mycobacterium* superinfection occurs occasionally with aspergillosis[43] or when bacteria compete with fungi, such as when the growth of *Candida* species and possibly other fungi is suppressed when *Pseudomonas aeruginosa* dominates.[44] These microorganisms are known to colonize dental implants, dental implant prostheses surfaces, and internal components that may lead to peri-implant mucositis and peri-implantitis.[45,46]

Archaea are prokaryotic organisms (which means they do not possess nuclei) that have been isolated in the oral cavity as a source of disease. The presence or increase in level of methanogenic Archaea alters the composition of the polymicrobial community, resulting in changes in virulence and composition of microflora at diseased sites. Antagonistic interactions of methanogenic Archaea and treponemes,[47] and *Synergistes* spp. have been suggested to be possible syntrophic partners of the methanogens.[48] *Methanobrevibacter oralis* is a species of coccobacillary, nonmotile, gram-positive, methane-producing archaeon considered to be the major methanogenic archaea found in the oral cavity and associated with severe periodontitis.[49] It has a high prevalence in subgingival plaque of chronic periodontitis patients while being undetectable in healthy subjects.[50] An increase in the inoculum of methanogenic Archaea and sulfate-reducing bacteria have been reported to be associated with the severity of periodontitis[51,52] and has a significant increased prevalence in peri-implantitis sites.[53] *Methanobacterium congelense/curvum* is also an archaeon that is found in peri-implantitis sites but at a significantly lower volume.

Periodontal pathogens such as *Porphyromonas gingivalis, Tannerella forsythia, Prevotella intermedia,* and *Capnocytophaga ochracea* have been shown clustered together in peri-mucositis sites, suggesting that periodontal pathogens may play important roles in the pathogenesis of peri-implant diseases. Progression to peri-implantitis reveals a relative abundance of *Eubacterium minutum, Prevotella intermedia,* and *Propionibacterium acnes* in peri-implantitis.[54,55] Various microorganisms have been identified as possible pathogenic determinants in the multispecies infection of peri-implantitis. Some, such as *Enterococcus faecalis,* are persistent and may vegetate in bone after tooth extraction and colonize a dental implant after placement in the healed site that may cause fixture loss, marginal bone loss, or progression to osteomyelitis.[56]

Recent evidence has suggested that the peri-implant crevice may be immunologically, histologically, and microbiologically distinct from the subgingival sulcus.[57-59] Certain periodontal pathogens (such as *P. gingivalis* and *T. denticola*) may be shared between tooth and implants in certain individuals.[60-64] However, most of the flora, especially the abundant species, remain distinct between the two ecosystems, which may indicate that proximity is not sufficient to fully determine the local environmental microbiology. The diverse anatomy of the oral cavity has allowed unique microenvironments that shape the evolution of a diverse bacterial flora. The buccal epithelium, subgingival crevice, maxillary anterior vestibule, tongue, soft and hard palate, tonsils, and the tooth surface are all colonized by different combinations of bacterial species or phylotypes.[27] As such, the periodontal microbiome tends to be more diverse than the peri-implant microbiome, particularly in health. The disease process appears to shape the microbial populations through increased diversity in the diseased microenvironments in both periodontal and peri-implant healthy and diseased individuals.[58] Not all species present in the subgingival sulcus are capable of surviving and thriving in the peri-implant sulcus, and evidence to support that bacteria can translocate from diseased

teeth to healthy teeth and do not necessarily colonize the niche[65] and the architecture, surface energy, and surface characteristics of abiotic structures such as dental implants dictates the composition of the ecosystem around them.[66,67]

Causes and Risks of Dental Implant Infection

Infection is one of the most important causes of early dental implant failure and may be an indication of a much more critical result than if the same complications occur later because of disturbance of the primary bone healing process. Several authors have defined the criteria for implant failure and postoperative infection. Esposito and colleagues[68,69] defined dental implant failure and infection as implant mobility measured manually and/or any infection directing implant removal with any biologic complications such as wound dehiscence, suppuration, fistula, abscess, and osteomyelitis. Similarly, Abu-Ta'a and colleagues[70] defined dental implant failures caused by infection as the presence of signs of infection and/or radiographic peri-implant radiolucencies that could not respond to antibiotics and/or judged a failure after performing explorative flap surgery by an experienced surgeon. Quirynen and colleagues classified dental implant infection failures into one of four groups: infection before the implant placement, perisurgical infection, severe postsurgical infection, and peri-implant disease.[71]

Infection Before the Implant Placement

Active Infection Site

Immediate dental implant placement and function after tooth extraction has become a widely accepted practice in contemporary dental implantology (Fig. 13.5).[72] Whether completed with or without immediate function, comparative clinical studies have found that implant survival rates (SRs) after immediate dental implant placement are similar to rates seen with delayed dental implant placement. Immediate dental implant placement has several advantages, such as reduction in the number of surgical treatments, reduction of the time between tooth extraction, and placement of a definitive prosthesis and maintenance of alveolar ridge dimensions. However, there are certain situations that may endanger the success of the immediate dental implant placement, including periodontal disease or periapical lesions. Active infection in a fresh extraction site may be considered a harbinger for immediate dental implant placement failure. Placement of a dental implant in the presence of an active infection has traditionally been considered a contraindication because of the possibility of septic embolism that may cause immediate or late postsurgical infection, such as osteomyelitis or peri-implant abscess, and may increase the risk of implant nonintegration. This remains a controversial subject in dental implantology because of a lack of high-level prospective research to substantiate these claims[73] and a body of literature that consists mainly of retrospective case reports and series.[74]

Clinical case series have shown favorable results in immediate dental implant placement into chronically infected sites.[75-83] High implant SRs have been reported even when implants were placed immediately in infected extraction sockets and provisionalized within 36 hours. Early or immediate loading of dental implants placed into periodontally or endodontically infected sites produced no statistically significant difference in failure rates between chronically infected or noninfected sites.[82] In immediately placed and loaded dental implants into chronically infected sites in the esthetic zone of the anterior maxilla, Anitua and colleagues[75] found no failures and a success rate of 93%, leading them to conclude that immediate loading of implants inserted into fresh and infected extraction sockets is not a risk factor for implant survival. Systematic reviews of the literature reveal a high SR and support the hypothesis that implants may be successfully osseointegrated when placed immediately after extraction of teeth that present with endodontic[76,81] or periodontal lesions.[77] This was contingent on appropriate clinical decontamination procedures being performed before dental implant placement, such as meticulous cleaning, socket curettage/debridement, and chlorhexidine (0.12%) rinse/irrigation.[78,80,83] Nonocclusal loading on implants placed in cleaned periodontically or endodontically infected

• **Fig. 13.5** Periapical radiographs of (A) nonrestorable tooth #9 with periapical radiolucency, (B) extraction of tooth #9 with immediate implant placement, and (C) 1-year postprosthesis loading.

extraction sites has shown complete initial primary stability (100%) and a 98.7% success rate on postoperative reverse torque testing of osseointegration at 3 and 4 months.[84] Similarly, Bell and colleagues[79] found high, comparable, and statistically insignificant success rates, defined as successful osseointegration and restoration, and absence of evidence of bone loss or peri-implantitis at last follow-up, between implants placed in fresh extraction sockets with chronic periapical pathology (97.5%) and healed sites (98.7%). A statistically significant higher failure rate is seen for dental implants placed adjacent to retained teeth with periapical pathology. Placement of dental implants in sockets affected by chronic periapical pathology can be considered a safe and viable treatment option, but placement adjacent to teeth with periapical radiolucencies carries a high risk of failure.

A metaanalysis of dental implant failure and marginal bone loss after immediate placement into infected versus noninfected sites found that immediate placement into an infected site showed 116% increase in the risk of implant failure, with no statistically significant difference in marginal bone loss.[85] However, the reviews and analyses used have been found to be of low or moderate methodological quality[86] and with the presence of uncontrolled confounders, respectively, and should also be interpreted with caution.[85] It would be recommended that sound clinical judgment be used in determining whether immediate dental implant placement into an actively infected site is prudent, despite decontamination procedures, and whether a delayed protocol until proper site healing has been achieved should be followed.

Periodontal Disease

Periodontal disease is a chronic infectious and inflammatory response to pathologic changes in periodontium to an anaerobic microenvironment. These changes generally result in an imbalance and aggregation of deleterious microorganisms that may lead to the development of peri-mucositis, peri-implantitis, and bone loss. Comparisons of clinical, microbiologic, and host response characteristics between healthy dental implants and healthy teeth and between infected implants and periodontally diseased teeth have been found to be similar, respectively, with subjects at risk for periodontal disease also at risk for peri-implantitis.[87] The bacteria associated with periodontal diseases are predominantly gram-negative anaerobic bacteria and may include *A. actinomycetemcomitans, P. gingivalis, P. intermedia, B. forsythus, C. rectus, E. nodatum, P. micros, S. intermedius,* and *Treponema* sp., with bacterial numbers associated with disease up to 100,000 times larger than those associated with healthy teeth. The frequency of four periodontopathogenic bacteria in tooth sulci (*A. actinomycetemcomitans, P. gingivalis, T. forsythia,* and *T denticola*) are significantly higher around natural teeth with deeper periodontal pockets but not in peri-implant sulci in partially edentulous subgroups or in the peri-implant sulci or the alveolar gingiva of completely edentulous patients. Cytokine and interleukin creation from periodontal pathogens stimulate the production of inflammatory mediators secreted in peri-implant sulcus fluid, leading to peri-implant tissue destruction.[88]

A systematic review of implant failure rates, postoperative infection, and marginal bone loss from dental implant placement in periodontally compromised patients compared with periodontally healthy patients found some evidence that patients treated for periodontitis may experience more implant loss and complications around implants, including higher bone loss and peri-implantitis, than patients without periodontitis.[89] Similarly, individuals with both aggressive or chronic periodontal disease have a greater significant risk for implant loss, peri-implant bone loss, and peri-implantitis compared with patients without periodontal disease. The risk is greater for patients with aggressive periodontitis compared with patients with chronic periodontitis.[90]

There are different types of periodontal disease, including gingivitis, which is the mildest form, and aggressive periodontitis, which is a form of periodontitis that occurs in patients who are otherwise clinically healthy and may include rapid attachment loss, bone destruction, and familial aggregation. Another type is chronic periodontitis, which results in inflammation within the supporting tissues of the teeth, progressive attachment and bone loss, and is characterized by pocket formation and/or gingival recession (Fig. 13.6). Necrotizing periodontal diseases are another type and are characterized by necrosis of gingival tissues, periodontal ligament, and alveolar bone. General and local periodontitis have been implicated as "microbial reservoirs" in the etiology of peri-implant diseases.

Gingivitis is a reversible inflammatory process in the soft tissue surrounding teeth. When this phenomenon surrounds an osseointegrated dental implant without the loss of marginal bone beyond normal resorption it is known as peri-implant mucositis. Gingivitis is ubiquitous in the adult population and if left untreated may progress to periodontal disease and bone loss. Gingivitis is generally very treatable and, regarding dental implants, rarely leads to implant loss or infection; it is not a contraindication for implant surgery or prosthetics when an appropriate oral hygiene regimen is established.

Dental implant placement in patients with a history of generalized aggressive periodontal disease might be considered a viable option to restore oral function despite the aggressive nature of this

• **Fig. 13.6** Aggressive periodontal disease consisting of (A) generalized pathologic migration, calculi deposits, purulent exudate, gingival inflammation, grades II and III mobility, greater than 5-mm probing depths, and (B) radiographic signs of severe bone resorption with multiple bone defects.

disease and its assault on local bone levels. Outcomes similar to those seen in chronic periodontal disease and healthy periodontium[91] with high SRs and low marginal bone loss[92] have been found in generalized aggressive periodontal disease subjects. A systematic review of the literature revealed that the 3-year SR was high but statistically significantly lower in generalized aggressive periodontal disease subjects (SR 97.98% versus 100%) compared with healthy periodontal and chronic periodontitis subjects.[93] The only significant difference seen at the 3-year time point between these groups was an increased probing depth and attachment loss in the generalized aggressive periodontal disease subjects.[91] At 10-year follow-up, bone and attachment loss were higher with a lower SR, 83% compared with 100% in generalized aggressive periodontal disease subjects compared with healthy individuals.[94] Similarly, the probability of a dental implant infection failure in individuals with a history of aggressive periodontal disease is significantly higher (almost four times as great) compared with individuals with either healthy or chronic periodontal disease.[95] Long-term dental implant success may be achievable with post-periodontal treatment long-term stability with excellent patient cooperation and strict periodontal maintenance protocol.[96] Several case reports have detailed medium-term dental implant reconstruction success in aggressive periodontal management, involving scaling and root planning and periodontal surgery, in the treatment and implant maintenance.[96-98] The functioning SRs of fixtures and superstructures of osseointegrated implants also tend to be generally high in subjects with aggressive periodontal disease (between 95.9% and 100%) over short- and long-term follow-up.[99]

Immediate dental implant placement into fresh extraction sockets with periodontal infection has been evaluated at single- and multiple-tooth reconstruction and shown to be a valid option with predictable results. Single dental implants placed into periodontally infected extraction sites have shown, at 12-month follow-up, to be asymptomatic with no signs of infection or bleeding on probing, no decrease in radiographic bone–implant contact, and no loss of clinical attachment level or keratinized mucosa width at the midbuccal location per implant.[100]

Chronic Periodontitis

There is conflicting evidence over medium- and long-term success between dental implants placed to restore periodontitis- and nonperiodontitis-associated tooth loss. Over a 10-year period, dental implants have lower SRs and more biologic complications between periodontitis- and nonperiodontitis-associated tooth loss.[101] However, although this difference was significant between these two groups, the success rate was still high between the chronic periodontitis group (90.5%) and nonperiodontitis group (96.5%). Similarly, dental implant suprastructures and dental implant survival are not significantly different over a 10-year period, but they have significantly increased incidences of peri-implantitis at 10 years and peri-implant marginal bone loss at 5 years with periodontitis-associated tooth loss.[102] The important aspect of dental implant treatment associated with existing periodontitis or a history of chronic periodontitis is proper periodontal therapy. Implant reconstruction can be successfully accomplished in patients with periodontitis when appropriate regular periodontal therapy and maintenance are achieved. Residual pockets, non-attendance to a periodontal maintenance program, and smoking are negative factors for long-term dental implant outcomes in periodontitis-associated tooth loss.[103]

Immediate Loading in Periodontal Disease

Immediately placed and immediately loaded dental implants have been shown to be predictable and successful.[104] Immediate implant loading of complete mandibular implant–retained prostheses may be a viable treatment option for edentulous individuals with a history of chronic periodontal infection. Dental implants immediately placed in chronically infected sockets and immediately loaded with a fixed full-arch maxillary and mandibular prosthesis have been shown to have excellent short-term success[105] and a 3-year cumulative surgical and prosthetic SR.[106] Crestal bone height is also an indicator of dental implant success because increased bone loss may lead to a change in the microenvironment and microorganism composition. This will eventually lead to dental implant failure and need for removal. Immediately restored dental implants in patients with periodontal disease, after 1 year, exhibit crestal bone loss rates similar to those seen for conventionally restored implants.[107] Immediate dental implant rehabilitation in subjects with untreated periodontitis may also be feasible when appropriate periodontal therapy is provided and regularly maintained.[108] This shows that immediate dental implant placement and restoration is possible in individuals with periodontal disease as long as periodontal maintenance is regularly and consistently sustained.

Perisurgical Infection

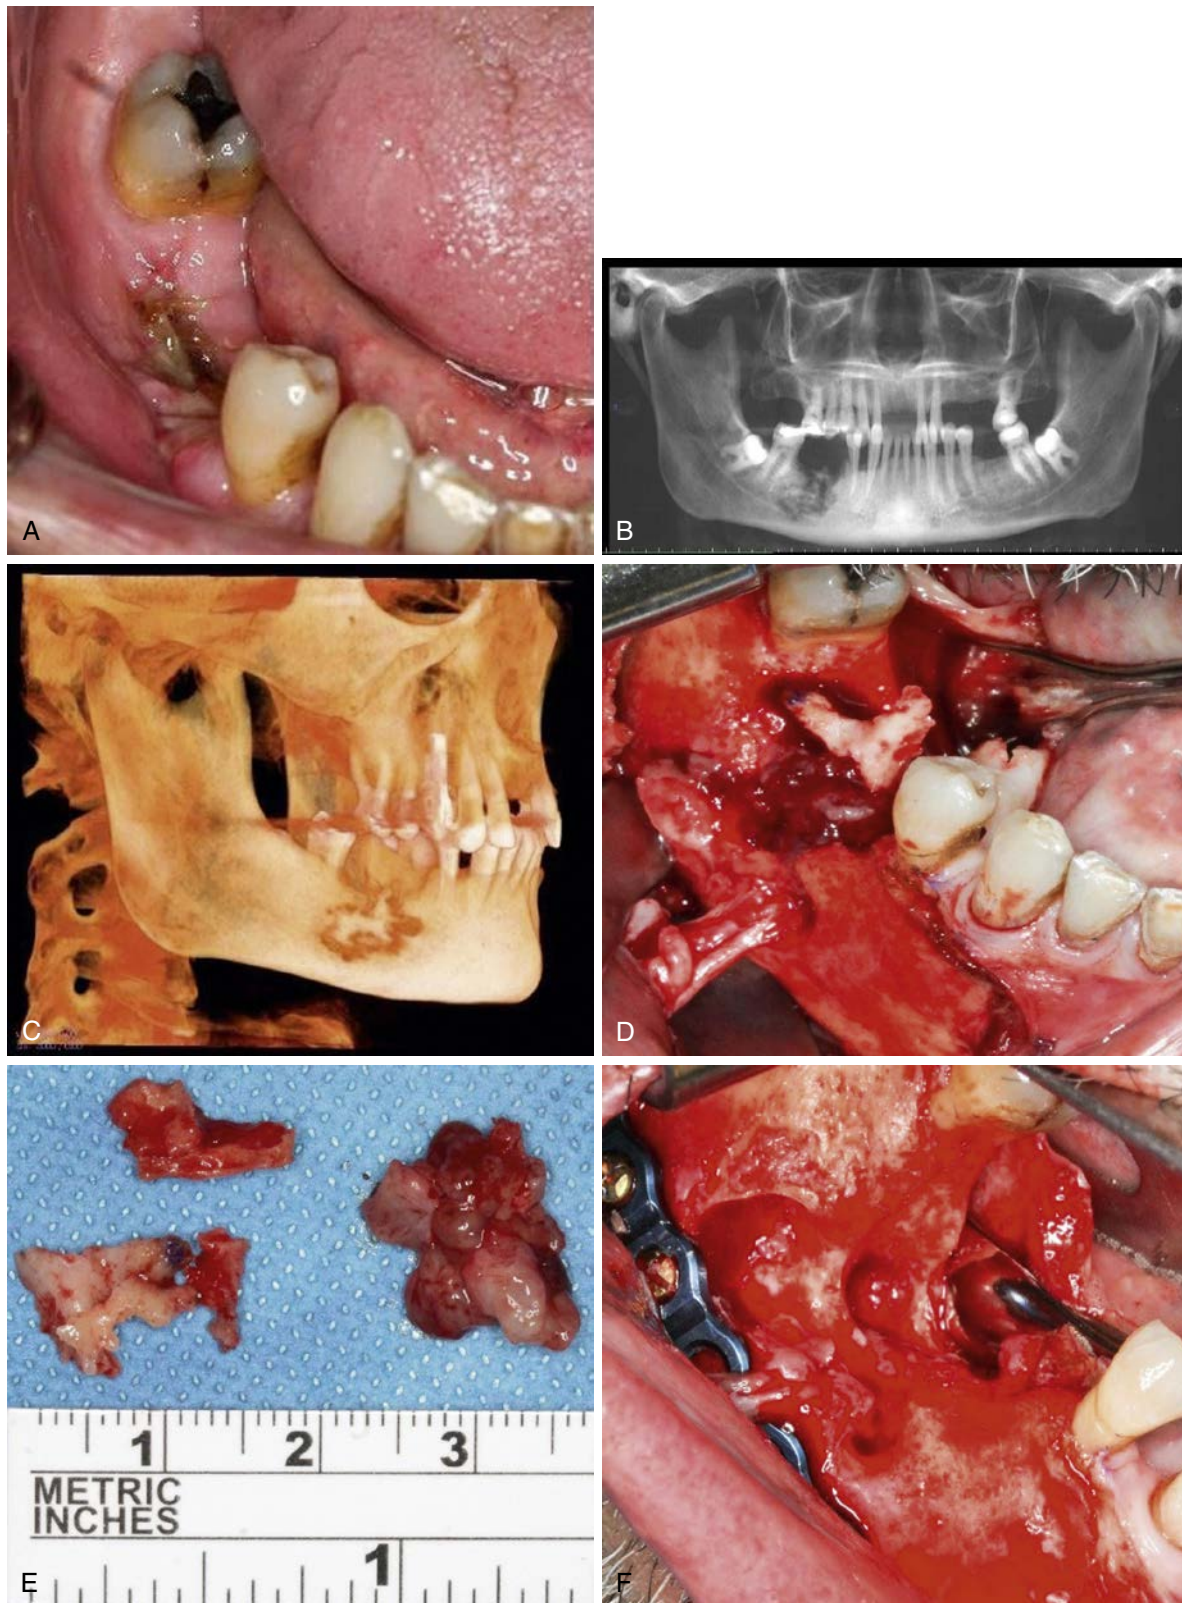
Intraoral surgery, in general, and dental implant surgery, specifically, are classified as clean-contaminated surgery because the surgical field may be contaminated by many sources of microorganisms that can easily infiltrate the surgical site. There are numerous sources of potential perisurgical-site infections. Several specific potential sources of perisurgical contamination are mostly derived from surgical instrumentation, such as air, aspiration, instrumentation, and saliva in the surgical field, and its relationship with the skin of the face, lips, and nose.[109] Several techniques have been used to avoid perisurgical cross-contamination of the surgical field, including saliva secretion reduction with atropine,[110] double aspiration to avoid salivary contamination of surgery, and chlorhexidine rinses to reduce oral microbial load.[71] Chlorhexidine has been shown to have effective antibacterial activity on the salivary flora and development of oral biofilms[111-113] but not on developed and mature biofilms.[114] Additionally, chlorhexidine has been shown to be affected by its local salivary environment, such as pH. Chlorhexidine is more effective in alkaline than in acidic environments,[115] and the presence of organic substances and food compounds will reduce antimicrobial activity.[116] However, the effect of saliva on the antimicrobial activity of chlorhexidine has been shown to be weak but statistically significant.[117] Extraoral microbial organism presentation has been suggested in perisurgical contamination, such as from the nose. A meshed nose guard to prevent contact with the highly contaminated nasal skin is highly recommended for field isolation to prevent infection; otherwise, covering the nostrils by a mask and sterile adhesive plastic film is not essential in avoiding airborne microbial contamination during dental implant surgery.[118] Clinical manifestations of the infections caused by perioperative contamination are usually in the form of peri-implant abscesses, periapical radiolucency, marginal bone loss, orocutaneous fistulas, and/or osteomyelitis.

Severe Postsurgical Infection

Postoperative infections are rare complications that usually occur within the first month after dental implant placement, with an incidence as high as 11.5%. These infections generally occur during the osseointegration period. Dental implant placement in the mandible and submerged healing are more prone to postoperative infections.[119] Signs and symptoms of postoperative dental implant infection are similar to other oral infections and include pain, swelling, heat, and redness. If the infected implant is not removed and the area debrided and decontaminated, an orocutaneous fistula[120,121] and/or osteomyelitis may develop.

Osteomyelitis

Dental implant–related osteomyelitis of the jaws is a rare complication that has been reported in the literature (Figs. 13.7 and 13.8).[122-130] The incidence of dental implant–related

• **Fig. 13.7** (A–E) Advanced osteomyelitis from a mandibular subperiosteal implant resulting in significant bone loss, implant mobility, chronic infection, and pain. After removal, note the amount of calculus and slime layer as evidence of suspected developed biofilm.


• **Fig. 13.8** (A–F) Clinical and radiographic presentation of dental implant–related mandibular osteomyelitis. Extension of osteomyelitis necessitated placement of a mandibular fracture plate to prevent pathologic fracture during debridement.

osteomyelitis of the jaws has ranged from 5%[131] to 26%[130] of all cases. Osteomyelitis of the jaws is an acute and chronic inflammatory process in the medullary spaces or cortical surfaces of bone that extends away from the initial site of involvement. Several local and systemic factors are generally involved in the development and spread of osteomyelitis of the jaws. Local factors, such as trauma from tooth extraction or dental implant placement, can decrease vascularity and vitality of bone in the area. Systemic factors, such as immunosuppression or diabetes mellitus, can impair host defense mechanisms.

The mandible is a much more prevalent location for osteomyelitis than the maxilla because of the latter's rich vascularity.[124,130,132-135] Introduction of bacterial pathogens into the bone, such as in the surgical placement of a dental implant, allows the bacteria access into the jaw bone to initiate a local infection and inflammatory response. The inflammatory response developed toward these pathogens leads to a compromise of local blood flow. Medullary infection then spreads throughout the marrow spaces and vessel thrombosis leads to extensive bone necrosis. Lacunae in the bone then empty the osteocytes, fill with purulence, and proliferate in the necrotic tissue. Suppurative inflammation may then extend through cortical bone to the periosteum, which further compromises vascular supply. This predisposes the bone to further become necrotic, which leads to sequestrum that separates from the surrounding vital bone.

Local and systemic host factors may increase the patient susceptibility. Comorbidities such as chronic systemic diseases, alcoholism, immunosuppression, malnutrition, diabetes mellitus, intravenous drug abuse, malignancy, and diseases can result in hypovascularized bone (such as osteopetrosis, Paget disease, florid cemento-osseous dysplasia, and radiation therapy), or, more recently, medication-related osteonecrosis of the jaw (MRONJ) caused by antiresorptive and antiangiogenic therapies has also been associated with an increased frequency of osteomyelitis.

The classic presentation of osteomyelitis of the jaws indicates an acute phase that can present either as a suppurative or nonsuppurative infection causing vascular compromise, which results in local tissue ischemia and necrosis with bony sequestrum. The two major groups of osteomyelitis (acute and chronic) are differentiated by the clinical course of the disease after onset, relative to surgical and antimicrobial therapy with an arbitrary time limit of 1 month used to differentiate the two groups.[135-138]

Chronic osteomyelitis of the jaws is classified into various types based on clinical characteristics by the Zurich classification system, which is primarily based on the clinical course and appearance of the disease and on imaging studies.[134] Chronic osteomyelitis of the jaws can be divided into primary and secondary chronic osteomyelitis, with secondary types further subclassified into three major clinical types: suppurative chronic osteomyelitis, osteoradionecrosis of the jaw, and MRONJ. Suppurative chronic osteomyelitis has major symptoms of abscess/purulence formation, sequestration, and exposed bone.[134] This is in contrast to primary chronic osteomyelitis, which may present with nonsuppurative chronic inflammation of the jawbone, the absence of causative dental infection, pus formation, fistula formation, or sequestration.

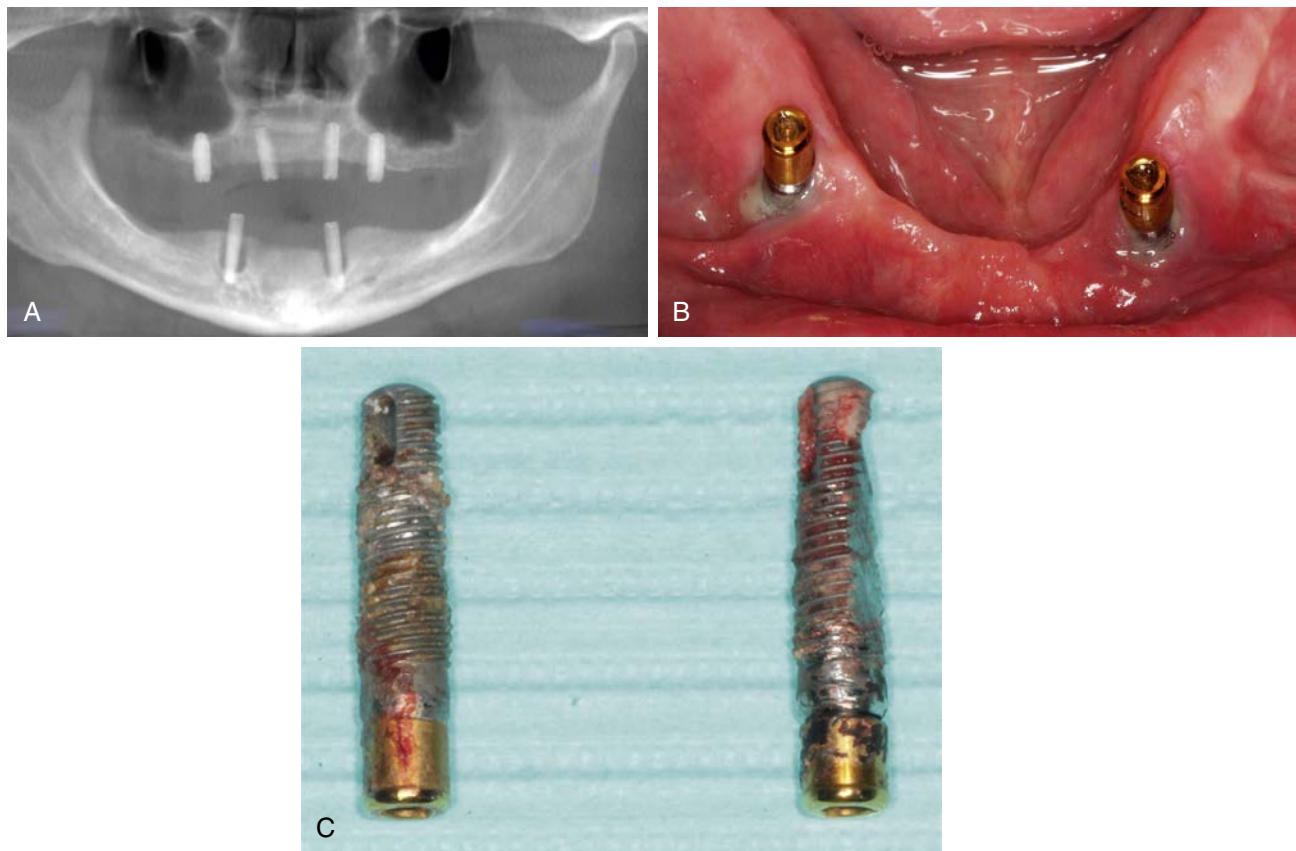
Radiologic features of mandibular dental implant–related osteomyelitis are generally similar to other types of osteomyelitis of the jaws. Early stages may initially appear normal radiographically and may not manifest itself until at least 10 days after initiation of the inflammatory process. Progression of the infection may include radiolucent or mixed radiolucent-radiopaque lesions with poorly defined borders that may be limited to the area of the failed implant or may extend to a large part of the mandible.[123] After sufficient bone resorption has occurred, an irregular moth-eaten area of radiolucency may appear, which is generally pathognomonic for osteomyelitis.

Histopathologic findings may range from acute osteomyelitis and chronic osteomyelitis with features of a fibroosseous-like lesion and occasional rimming of atypical osteoblasts.[123] Routine histology will show loss of osteocytes from lacunae in addition to peripheral resorption, bacterial colonization, and acute inflammatory infiltrate consisting of polymorphonuclear leukocytes in haversian canals and peripheral bone. Furthermore, inflamed connective tissue in the intertrabecular bone, scattered sequestrum, and pockets of abscess are generally seen.

Progression of dental implant–related osteomyelitis involves a host of virulent causative organisms. These may include *Streptococcus, Peptococcus,* and *Peptostreptococcus* species in general[128] and *S. anginosus*[130] and *S. intermedius,*[134,139] specifically. Osteomyelitis of the jaw may also exhibit large areas of bone occluded with well-developed biofilms that comprise microbial organisms embedded in an extracellular polymeric substance with a predominance of the *Actinomyces* genus.[140]

Conservative treatment alone is often insufficient to provide a cure for chronic osteomyelitis.[141,142] Progression of an incorrectly diagnosed or treated osteomyelitis of the jaws can result in serious complications such as pathologic fracture and/or osteolytic extension to the inferior border of the mandible. This generally will require an aggressive surgical intervention to include debridement of the infected area until bleeding bone is visualized. The condition may progress to the point in which it will require either marginal mandibulectomy or segmental mandibular resection. The resultant continuity defect from mandibular resection may also require titanium reconstruction plate stabilization with or without hard- and soft-tissue reconstructive procedures.[125]

Medication-Related Osteonecrosis of the Jaws

Although the reason remains unknown, current literature reveals a low rate of MRONJ in dental implant patients taking antiresorptive medication compared with other invasive procedures, such as tooth extraction.[143-145] Although the mechanism in the development of dental implant–related MRONJ is believed to be mainly mechanical, such as in dental implant placement,[146] a microbial biofilm component has been identified.[147] These cases have shown large areas of necrotic bone occluded with biofilms that compromise many bacterial morphotypes and species, such as *Fusobacterium,* bacillus, *Actinomyces,* staphylococcus, streptococcus, *Selenomonas,* and treponemes and yeast (*Candida* species), all with observed coaggregation.[147] This represents some more diverse bacterial organisms in addition to fungal organisms not generally seen in osteomyelitis of the jaws,[140] which may provide an important therapeutic implication because microorganisms present in biofilm represent a clinical antibiofilm target for prevention and treatment efforts.


• **Fig. 13.9** (A and B) Advanced peri-implantitis involving two mandibular overdenture dental implants. Note the excessive amount of peri-implant bone loss. (C) Although stable, the implants required removal because of chronic infection.

Biologics

"Biologics" are monoclonal antibodies used against specific targets in the treatment of autoimmune diseases such as rheumatoid arthritis, psoriatic arthritis, and ulcerative colitis. Commonly prescribed medications include adalimumab (Humira), infliximab (Remicade), and certolizumab (Cimzia). Serious postoperative infections may occur when biologic drugs that suppress the immune system have been used and are more likely when combined with other drugs that also suppress the immune system. Individuals that are to undergo any oral or dental implant surgical procedures should have prior consultation with their prescribing physician to evaluate infection risks and the possible need for discontinuation of the medication in question.

Peri-implant Disease

Peri-mucositis and Peri-implantitis

Peri-implant mucositis is characterized by biofilm-induced inflammation localized on the soft peri-implant mucosa but with no evidence of destruction of the supporting bone (Fig. 13.9). Progression of the inflammation may lead to gradual destruction of the bone, manifesting as peri-implantitis. Peri-implant mucositis and peri-implantitis are analogous to gingivitis and periodontitis of natural teeth.[148] Mucositis occurs in

approximately 80% of patients with dental implants and in 50% of the implants. The prevalence of peri-implantitis has varied reportedly from 28% to 56% among patients, and 12% to 43% among implants.[149] Evidence indicates that peri-implant mucositis occurs in 50% to 90% of implants, whereas 20% of implants with an average function time of 5 to 11 years develop peri-implantitis.[149] Putative pathogens associated with peri-implantitis are present at a moderate relative abundance in peri-implant mucositis, suggesting that peri-implant mucositis is an important early transitional phase during the development of peri-implantitis.[54] Peri-implant mucositis and peri-implantitis are analogous to gingivitis and periodontitis of natural teeth.[148] The current literature does not warrant development of a correlation of potential bacterial initiators or promoters of peri-implantitis.

Peri-implantitis is an irreversible inflammatory reaction in the soft and hard peri-implant tissues. Plaque accumulation around dental implants has been shown to result in the development of peri-implant inflammation. Contributing factors for the development of peri-implantitis include periodontal disease, smoking, excess cement, and lack of supportive therapy.[150] Periodontopathogenic bacteria that have been implicated in peri-implantitis include *P. gingivalis, P. intermedia, Prevotella nigrescens,* and *A. actinomycetemcomitans.*[151,152] Peri-implantitis has more floral clinical symptoms because in the initial phase it may present the same signs as peri-implant mucositis, but these are later accompanied by the symptoms of bone loss itself.

The most common signs of peri-implantitis are the presence of bacterial plaque and calculus, edema and redness of peri-implant tissues, peri-implant mucosal hyperplasia with a lack of keratinized gingiva, increased probing depths that may reach the apex of the implant, bleeding and purulence on probing and/or palpation, vertical bone destruction in relation to a peri-implant pocket, radiologic presence of bone reabsorption, implant mobility, and possibly pain.[153]

Lack of treatment of peri-implantitis will progress to marginal bone loss. A continuously moving implant and peri-implant radiolucency indicate that the disease is reaching its outcome, characterized by total loss of the bone–implant interface. Radiologic examination is very important because although radiographs only show bone on mesial and distal implant surfaces, the bone defects have a circular or funnel-shaped form; therefore they are larger than those observed on radiographs.

Biofilm

Most infections of the oral cavity are caused by bacteria, fungi, and yeast organized into biofilms. Oral microbial flora comprises one of the most diverse human-associated biofilms that is heavily influenced by oral streptococci as the main group of early colonizers. Oral streptococci species are believed to make up over 80% of the early biofilm constituents.[154] Their initial attachment determines the composition of later colonizers in the oral biofilm. Biofilms are a complex, multispecies, highly communicative community of multilayered accumulations of bacteria or fungi, immersed in an extracellular polymeric matrix.[155,156] Biofilms form in a rapid sequence of events and mature into a complex, interacting community of microorganisms that have different properties than when present in isolation, resulting in a community that is more resistant to antimicrobial agents, stress, and host defenses. This makes the treatment of biofilm infections with traditional antibiotics alone ineffective, and surgical removal of diseased tissue is required.

The earliest stage of biofilm formation is adhesion of microbial cells to a surface, such as dental implant or prostheses, with an acquired salivary pellicle. The salivary pellicle is a thin acellular organic film that forms on any type of surface on exposure to saliva. The role of the pellicle is diverse, with functions known to be highly influenced by the physicochemical properties of both substrata and ambient media, which include protection, lubrication, remineralization, hydration, and acting as a diffusion barrier and buffer.[157] The next stage involves development of an irreversible bond between bacterial adhesins and the acquired salivary pellicle surface with the degree of adherence dependent on the microbial species, the number of cells, and the physicochemical properties of a given surface. Secretory IgA, α-amylase, and cystatins have been identified as dominant proteins in the salivary pellicle that strengthen adherence to smooth titanium surfaces and cause an upregulation of metabolic activity in early oral microbial colonizers, such as *S. oralis*.[158] Once colonized, the involved microorganisms begin to produce an extracellular polysaccharide matrix.[156] Within this matrix, the subsequent growth in layers of biofilm depend on many factors such as salivary flow, nutrient content, iron availability, pH, osmolarity, oxygen content, concentration of antibacterial agents, and ambient temperature.[159] As microcolonies form, maturation of the biofilm ensues such that the structure and function of microorganisms within the biofilm

may resemble multicellular organisms caused by interactions and communication between cells, even of different species, which function as a consortium, cooperating in a relatively complicated and coordinated manner.[156] Once established, biofilm may cause a pathogenic process even in anatomically distant sites because of dislodged fragments that contain aggregates of bacterial cells, production of endotoxin, evasion of the immunologic response of the host, and formation of a niche for replication of bacterial cells resistant to antimicrobials.

Microbial samples obtained by traditional methods tend to destroy the three-dimensional structure of biofilm, resulting in mixtures of bacteria from unspecified districts of biofilm associated with peri-implant diseases. Advances in microbial analyses methods indicate that peri-implant disease may be viewed as a mixed anaerobic infection, and in most cases the composition of the flora is comparable to subgingival flora of chronic periodontitis dominated by gram-negative bacteria, such as *P. gingivalis, P. intermedia, B. forsythus,* and gram-positive bacteria, such as *peptostreptococci* or s*taphylococci.*[61]

The presence of biofilm also effects dental implant restorative materials. Biofilm may lead to a friction coefficient and threaten the biomechanical behavior of a single implant-supported restoration and lead to infection-related failure.[160] Effects of dental implant restorative material/surface properties (such as surface charge, hydrophobicity, roughness, topography, and chemistry) on bacterial adhesion and biofilm formation have shown that negatively charged surfaces, super-hydrophobic surfaces, super-hydrophilic surfaces, and nanometer-scale surface roughness reduce bacterial adhesion. The presence of an acquired pellicle-containing host and bacterially derived proteins poses a great challenge to the control of bacterial adhesion and biofilm formation based on surface modifications. Factors other than surface properties, such as dietary intake and complex oral microbiome, also affect biofilm formation.

Biofilms may act as directors or promoters of cell-mediated (osteoclast) bone resorption or induce bone resorption via various microbial mechanisms. Once established, local host defenses and repair mechanisms act to wall off and eradicate the dead bone via sequestration.[161] Therefore biofilms play an important role in the pathogenesis of osteonecrosis of the jaw (ONJ) in addition to explicating the septic nature of this condition.

Prophylactic Antibiotics

Administration of preoperative, perioperative, or postoperative systemic antibiotics is generally undertaken to prevent dental implant infection. Although numerous prophylactic systemic antibiotic regimens have been suggested to minimize failure, the role of antibiotics in implant dentistry remains contentious. There appears to be no consensus regarding antibiotics in association with routine dental implant placement, the type of regimen to use, or effectiveness in preventing early implant loss. Furthermore, most of the antibiotic regimens used are not in accordance with the recommendations current in the published data.[162,163] Systematic antibiotic administration in patients that receive dental implants significantly reduces implant failure, but there are no apparent significant effects of prophylactic antibiotics on the occurrence of postoperative infections in healthy patients receiving implants.[164,165]

Pharmacology in Implant Dentistry

RANDOLPH R. RESNIK

Because of the increase in demand and use of dental implants in dentistry today, a thorough understanding of the indications and protocol for the use of pharmacologic agents in implant dentistry is essential for the implant clinician. The morbidity of implant-related complications may on occasion be significant; therefore ideal medication selection and sufficient dosage levels of medications are preoperatively and postoperatively indicated. In addition, the scope of implant treatment often encompasses an older population with more complex cases and medical histories. As a result, treatment requires a greater understanding of the use of pharmacologic agents to decrease implant morbidity and possible complications.

Currently in implant dentistry, no consensus exists on the pharmacologic protocol based on both the patient's health status and procedure type. Many practitioners use medications empirically or generically with respect to all procedures with little basis on scientific facts and studies. The author has developed a pharmacologic protocol with the goal of decreasing complications and increasing the success rate of implants with an emphasis on the patient's health status and the invasiveness of the procedure. Therefore this chapter will provide the implant dentist with an overview of the pharmacokinetics and pharmacodynamics of various classifications of medications, together with an understanding of the proper prescribing protocol used in implant dentistry today with respect to different patient and procedure characteristics.

Antimicrobials

An important complication to prevent after implant surgery is infection. Infectious episodes may lead to a multitude of problems, including pain, swelling, loss of bone, and possible failure of the implant. Because of the risk for morbidity resulting from infections, antimicrobial therapy is an essential component of the surgical protocol. Although adverse effects are associated with antibiotic therapy, these are usually mild and infrequent. The most common antimicrobials used in implant dentistry today consist of antibiotics (local and systemic) and antimicrobial rinses (0.12% chlorhexidine gluconate).

Antibiotics

The use and understanding of the various antibiotic regimens available in implant dentistry are beneficial for the initial success and long-term maintenance of implant therapy. Antibiotic therapy in implant dentistry may be classified as either prophylactic (prevent infection) or therapeutic (treat infection). The field of dentistry has been shown to prescribe a considerable amount of antibiotics administered in the United States (7%–11%).[1]

Prophylactic Antibiotics

In general surgery, including its subspecialties, principles of antibiotic prophylaxis are well established. Guidelines are specifically related to the procedure, the type of antibiotic, and the dosage regimen.[2,3] The use of prophylactic antibiotics in dentistry has also been documented in the prevention of complications for patients at risk for development of infectious endocarditis and immunocompromised patients. However, in oral implantology, there exists no consensus on the use and indications for prophylactic antibiotics. Disadvantages with the use of antibiotics include cost, development of resistant bacteria, adverse reactions, and possible resultant lax surgical technique.[4-6] As a result the need for prophylactic antibiotics in healthy patients, type of antibiotic, dosage, and duration of coverage is controversial. On the other hand, postoperative surgical wound infections can have a significant impact on the well-being of the patient and the survival of the implant or bone graft. Documented cases of potential consequences of infection range from increased pain and edema to even patient death. According to Esposito and Hirsch,[7] one of the main causes of dental implant failure is due to bacterial contamination at implant insertion.

A local inoculum must be present for a surgical wound infection to occur, to overcome the host's defenses and allow growth of the bacteria. This process has many variables, including various host, local tissue, systemic and microbial virulence factors. Antibiotic prophylaxis is only one component of this complex cascade; however, the efficacy and impact of antimicrobial prophylaxis has been proven to be significant.[4]

Several studies have concluded there is a benefit of preoperative antibiotics for dental implantology.[8-10] In the most comprehensive and controlled study to date, 33 hospitals formed the Dental Implant Clinical Research Group and concluded the use of preoperative antibiotics significantly improved dental implant survival, both in early and later stages. In the evaluation of 2973 implants, a significant difference was found with the use of preoperative antibiotics (4.6% failure) compared with no antibiotics (10% failure).[8,9]

• BOX 14.1 **Surgical Wound Classifications with Associated Infection Rates**

Class 1: clean (<2%)
- Elective, nontraumatic surgery; no acute inflammation; respiratory, gastrointestinal (GI), and biliary tracts not entered

Class 2: clean-contaminated (10%–15%)
- Elective opening of the respiratory, GI, and biliary tracts entered
- Elective dental implant and bone graft procedures

Class 3: contaminated (20%–30%)
- Inflammation, gross spillage from GI and biliary tracts, along with fresh traumatic injuries

Class 4: dirty/infected (50%)
- Established clinical infection; perforation of respiratory, GI, and biliary tracts

---

• BOX 14.2 **Factors Associated with Increased Risk for Infection with Dental Implant Procedures**

Systemic Factors
- Diabetes
- Long-term corticosteroid use
- Smoking, Alcohol Abuse
- Immunocompromised systemic disorders
- Malnutrition, obesity
- Elderly population
- American Society of Anesthesiologists score 3 or 4

Local Factors
- Use/type of grafting material (autogenous, allograft, alloplast)
- Periodontal disease
- Tissue inflammation
- Odontogenic infections
- Ill-fitting provisional prosthesis
- Incision line opening
- Inadequate hygiene

Surgical Factors
- Poor aseptic technique
- Skill/experience of the surgeon
- Increased duration of surgery
- Wound contamination during surgery
- Foreign body (implant)

The main goal of the use of prophylactic antibiotics is to prevent infection during the initial healing period from the surgical wound site, thus decreasing the risk for infectious complications of the soft and hard tissues. Although there is no conclusive evidence on the mechanism of preoperative antibiotics, most likely a greater aseptic local environment is achieved. A landmark study by Burke[11] defined the scientific basis for the perioperative use of antibiotics to prevent surgical wound infection. From this work, several accepted principles have been established in the perioperative use of prophylactic antibiotics.[12]

Principle 1: The Procedure Should Have a Significant Risk for and Incidence of Postoperative Infection. To evaluate the risk for postoperative wound infection, the American College of Surgeons (Committee on Control of Surgical Wound Infections) developed a classification of operative wounds and risk for infection. All surgical procedures were classified according to four levels of contamination and infection rates (Box 14.1). Within these classifications, it is generally accepted that all class 2, 3, and 4 procedures warrant the use of prophylactic antibiotics.[13] By definition, elective dental implant surgery falls within the class 2 (clean-contaminated) category. Class 2 medical and dental surgical procedures have been shown to have an infection rate of approximately 10% to 15%. However, with proper surgical technique and prophylactic antibiotics, the incidence rate of infection may be reduced to less than 1%.[14,15] In a healthy patient, risk for infection after dental implant surgery is influenced by numerous factors, such as type and location of surgery, skill of the surgeon, methods of intraoperative management, patient factors, and aseptic technique.[14,16] Moreover, additional patient-related (systemic and local) risk factors that are not addressed in these classifications have also been correlated with increased susceptibility to infection. These factors must be addressed in reference to evaluation for the use and duration of antibiotic prophylaxis (Box 14.2).

One of the most significant surgical factors that may contribute to infection is poor aseptic technique. Various routes of transmission of virulent bacteria include: (1) direct contact with the patient's blood or other body fluids; (2) indirect contact with contaminated objects; (3) contact of infected nasal, sinus, or oral mucosa; and (4) inhalation of airborne microorganisms. To prevent these conditions, a controlled, well-monitored aseptic setting should be achieved for the surgical procedures that are at high risk of infection. The aseptic surgical site includes proper disinfection and draping procedures of the patient, hand scrubbing, sterile gowns worn by all surgical members, and maintenance of complete sterility of the instrumentation.

Another important surgical factor related to postoperative infection is the duration of the surgical procedure. This factor has been shown to be the second most critical risk factor (after wound contamination) affecting postoperative infection rates.[17] In general, surgical operations lasting less than 1 hour have an infection rate of 1.3%, whereas those lasting 3 hours increase the rate to more than 4%.[18-20] It is postulated that the rate of infection doubles with every hour of the procedure.[21] The skill and the experience of the surgeon with the placement of implants has been shown to be significant in postoperative infections and implant failures. A recent study has shown that less-experienced surgeons (<50 implants placed) have a 7.3% increase in failure rates in comparison with experienced surgeons.[9]

In the medical literature it is well documented that the insertion of any prosthetic implant or device increases the chance of infection at the surgical site. A dental implant can act as a foreign body, and the host's defenses may therefore be compromised. The surface of the implant has been shown to facilitate bacterial adherence, and the presence of an implant can compromise the host's defenses. This may result in normal flora with low virulence potential to cause infections at the implant-host interface, which has been shown to be very difficult to treat.[22-24]

The probability of risk for infection for a given procedure is related to local, systemic, and surgical factors. The patient's American Society of Anesthesiologists (ASA) score may be used as the systemic factor and then correlated with various local and surgical factors. A risk index may then be modified from the literature to correlate these factors to dental implant surgeries (Table 14.1). The probability of wound infection may then be correlated with the type of wound contamination (class 1–4) and the risk index. Therefore a class 2 wound with a risk index 2 has a greater risk for complications, and a class 1 wound with risk index 0 has the least risk for postoperative infection.[18,25]

TABLE 14.1　Probability of Wound Infection by Type of Wound, Risk Index, and American Society of Anesthesiologists Status

Operation Classification	RISK INDEX		
	0	1	2
Clean	1.0%	2.3%	5.4%
Clean-contaminated	2.1%	4.0%	9.5%

Risk index classification: 0: ASA 1 or ASA 2, and no local or surgical factors; 1: ASA ≥2, at least one of the local or surgical factors is present; 2: ASA ≥2, both local and surgical factors are present.

ASA, American Society of Anesthesiologists.

Data are from Cruse PJ, Foord R. A 5-year prospective study of 23,649 surgical wounds. *Arch Surg.* 1973;107:206-210.

• BOX 14.3　Microorganisms Most Commonly Associated with Peri-implant Complications

- *Staphylococcus* spp.
- *Actinomyces* spp.
- Surface translocating bacteria
- *Wolinella* spp.
- *Capnocytophaga* spp.
- *Fusobacterium* spp.
- *Entamoeba gingivalis*
- Motile rods
- Fusiforms
- Spirochetes
- Enteric gram-negative bacteria
- *Candida albicans*

Principle 2: The Appropriate Antibiotic for the Surgical Procedure Must Be Selected. The prophylactic antibiotic should be effective against the bacteria that are most likely to cause an infection. In the majority of cases, infections after surgery are from organisms that originate from the site of surgery.[12] Most postoperative infections are caused by endogenous bacteria, including aerobic gram-positive cocci (streptococci), anaerobic gram-positive cocci (peptococci), and anaerobic gram-negative rods (bacteroides)[14] (Box 14.3).

Although oral infections are usually mixed infections in which anaerobes outnumber aerobes 2:1, it has been shown that anaerobes need the aerobes to provide an environment to proliferate.[26] Subsequent studies have shown that the early phase of intraoral infections involves streptococci that prepare the environment for subsequent anaerobic invasion.[27,28] With that in mind, the ideal antibiotic must be effective against these pathogens.

The second factor in selecting the correct antibiotic is to use the antibiotic with the least amount of adverse effects. These effects may vary from mild nausea to the extreme allergic reaction.

The final selection factor is that the antibiotic should ideally be bactericidal. The goal of antibiotic prophylaxis is to kill and destroy the bacteria. Bacteriostatic antibiotics work by inhibiting growth and reproduction of bacteria, thus allowing the host defenses to eliminate the resultant bacteria. However, if the host's defenses are compromised in any way, the bacteria and infection may flourish. Bactericidal antibiotics are advantageous over bacteriostatic antibiotics in that: (1) there is less reliance on host resistance, (2) the bacteria may be destroyed by the antibiotic alone, (3) results are faster than with bacteriostatic medications, and (4) there is greater flexibility with dosage intervals.[14]

Principle 3: An Appropriate Tissue Concentration of the Antibiotic Must Be Present at the Time of Surgery. For an antibiotic to be effective, a sufficient tissue concentration must be present at the time of bacterial invasion. To accomplish this goal, the antibiotic should be given in a dose that will reach plasma levels that are three to four times the minimum inhibitory concentration of the expected bacteria.[29] The minimum inhibitory concentration is defined as the lowest antibiotic concentration to destroy the specific bacteria. Usually the antibiotic must be given at twice the therapeutic dose and at least 1 hour before surgery to achieve this cellular level.[16] It has been shown that normal therapeutic blood levels are ineffective to counteract bacterial invasion. If antibiotic administration occurs after bacterial contamination, no preventive influence has been seen compared with taking no preoperative antibiotic.

Principle 4: Use of the Shortest Effective Antibiotic. In a healthy patient, continuing antibiotics after surgery often does not decrease the incidence of surgical wound infections.[3,30,31] Therefore, depending on the procedure and infection risk, in some patients a single dose of antibiotics is usually sufficient. However, for patients or procedures with increased risk factors (see Box 14.2), a longer dose of antibiotics is warranted.[12] With the high degree of morbidity associated with dental implant infections, one must weigh the benefits versus risk involved for the extended use of antibiotics.

Complications of Antibiotic Prophylaxis

With the use of prophylactic antibiotics for dental implant procedures, many side effects may develop. It is estimated that approximately 6% to 7% of patients who are taking antibiotics will have some type of adverse event.[32] Incidence of significant complications with the use of prophylactic antibiotics are minimal; however, a small percentage can be life-threatening. The risks associated with antibiotics include gastrointestinal (GI) tract complications, colonization of resistant or fungal strains, cross-reactions with other medications, and allergic reactions.

Allergic reactions have a wide range of complications, ranging from mild urticaria to an anaphylaxis and death. Studies have shown that 1% to 3% of the population receiving penicillin will exhibit the urticaria type of reactions, with 0.04% to 0.011% having true anaphylactic episodes. Of this small percentage of anaphylactic reactions, 10% will be fatal.[33]

An unusual but increasing complication in the general population after antibiotic use is pseudomembranous colitis (PMC). This condition is caused by the intestinal flora being altered and colonized by *Clostridium difficile*. Penicillin and clindamycin use have been significantly associated with PMC; however, all antibiotics have been shown as potential causative agents. The risk levels of colitis related to antibiotics are outlined in Table 14.2. The most common treatment for antibiotic-induced colitis is vancomycin or metronidazole.

The most recent concern of antibiotic use is the development of resistant bacteria. It has been observed that the overgrowth of resistant bacteria begins only after the host's susceptible bacteria are killed, which usually takes at least 3 days of antibiotic use. Therefore short-term (1 day) use of antibiotics has been shown to have little influence on the growth of resistant bacteria.[14]

• Amoxicillin	• Erythromycin	• Metronidazole
• Cephalosporin	• Quinolones	• Vancomycin
• Clindamycin		

Antibiotics Used in Implant Dentistry

Beta-Lactam Antibiotics. The most common beta-lactam antibiotics used in implant dentistry are the penicillins and cephalosporins. These antibiotics have similar chemical structures, and the mechanism of action is by inhibiting bacterial cell wall synthesis (bacteriocidal) via the interruption of the cross-linking between peptidoglycan molecules.

Penicillin V. Penicillin V is one of the more common antibiotics currently used in dentistry. It is well absorbed and will achieve peak serum levels within 30 minutes of administration with detectable blood levels for 4 hours. Penicillin V is effective against most *Streptococcus* species and oral anaerobes. The main disadvantages of penicillin are four times per day dosing and susceptibility to resistant bacteria.

Amoxicillin. Amoxicillin is a derivative of ampicillin, with the advantage of superior absorption and a bioavailability of 70% to 80% with a very low toxicity. It has excellent diffusion in infected tissues, and adequate tissue concentrations are easily achieved. Amoxicillin is considered broad spectrum and is effective against gram-negative cocci and gram-negative bacilli. This antibiotic also has greater activity than penicillin V against streptococci and oral anaerobes.

Amoxicillin/Clavulanic Acid (Augmentin). A combination of two antibiotics was synthesized to counteract the activity of beta-lactamase destruction of penicillins by resistant bacteria such as *Streptococcus aureus*. Clavulanic acid, a beta-lactam antibiotic, was added to amoxicillin to form Augmentin. This combination antibiotic has an affinity for penicillinase-producing bacteria. It functions as a "suicide molecule" that inactivates the resistant bacteria. As a result of an increase in the prevalence of these specific bacteria (especially in the sinus), Augmentin is becoming more popular in oral implantology. This antibiotic is used mainly in cases in which penicillinase bacteria are suspected (or known by culture) and is practical as a perioperative antibiotic for sinus augmentation procedures (Fig. 14.1 and Box 14.4).

Cephalosporins. The cephalosporin family is designated according to their generation (generations 1–5), with increasing generation equaling increasing spectrum activity. The first generation (cephalexin) has coverage similar to amoxicillin (i.e., gram-positive cocci with a limited activity against gram-negative pathogens). The second-generation cephalosporins have greater gram-negative pathogen and anaerobic coverage. Third-generation cephalosporins exhibit even greater gram-negative activity, with the fourth generation demonstrating efficacy against most gram-positive and -negative activity. Fifth-generation cephalosporins have activity against methicillin-resistant *Staphylococcus aureus*.

A disadvantage that is often discussed is the cross-reactivity with patients who are allergic to penicillin. They are often used in dentistry as an alternative for the patient who is allergic to penicillin, although cross-reactivity between these two drugs may
• **Fig. 14.1** Beta-lactamase inactivation by the addition of clavulanic acid to amoxicillin (Augmentin). Because of the high binding affinity of clavulanic acid, beta-lactamase will be inactivated, allowing penicillin to destroy the bacteria.

• BOX 14.4	Common Penicillin Antibiotics
Generic	**Brand Name**
Amoxicillin	Amoxil, Polymox, Trimox, Wymox
Ampicillin	Omnipen, Polycillin, Polycillin-N
Bacampicillin	Spectrobid
Carbenicillin	Geocillin, Geopen
Cloxacillin	Cloxapen
Dicloxacillin	Dynapen, Dycill, Pathocil
Flucloxacillin	Flopen, Floxapen, Staphcillin
Mezlocillin	Mezlin
Nafcillin	Nafcil, Nallpen, Unipen
Oxacillin	Bactocill, Prostaphlin
Penicillin G	Bicillin L-A
Penicillin V	Beepen-VK, Betapen-VK, V-Cillin K
Ticarcillin	Ticar

occur. Rates of cross-reactivity to first-generation cephalosporins with patients who are allergic to penicillin have been cited to be approximately 8% to 18%. The most recent gram-positive and -negative bacteria studies have shown that only patients who have had type I (immunoglobulin E: immediate hypersensitivity reactions) should not be administered a cephalosporin. If the patient has a previous history of a reaction that was not immunoglobulin E mediated (types II, III, or IV, or idiopathic reactions), a first-generation cephalosporin may be administered. Newer second- and third-generation cephalosporins exhibit a broader spectrum, less cross-reactivity, and a greater resistance to beta-lactamase destruction (Box 14.5).[34]

Macrolides

For years the most common macrolide used in dentistry was erythromycin. It is active against most streptococci, staphylococci, and some anaerobes, and it is an alternative for patients who are allergic to penicillin. Erythromycin has the advantage of excellent absorption and, unlike many drugs, is affected by the presence of food. It is administered primarily by the oral route and has a relatively low toxicity. However, this antibiotic has a high incidence

Generic	Brand Name

• Erythromycin	
• Clarithromycin	Biaxin

(300 mg/2 mL) solution that is sometimes used in the incorporation of graft material for sinus augmentation procedures. However, it is bacteriostatic in normal concentrations and has a rather high toxicity in larger concentrations. As a result the main disadvantage of clindamycin is the occurrence of diarrhea in 20% to 30% of patients treated. This antibiotic also has a higher incidence of antibiotic-associated PMC caused by *C. difficile* when administrated for extended periods. PMC has been reported to occur with most long-term antibiotics.

The toxicity of antibiotics related to PMC is elevated with ampicillin, amoxicillin, cephalosporin, and clindamycin. Penicillin, erythromycin, and quinolones are moderate risk, and the lowest occurrence is with tetracycline, metronidazole, and vancomycin. The latter group is often used even to treat PMC conditions.

The patient should be informed that if either diarrhea or abdominal cramping occurs during or shortly after antibiotic therapy, the drug should be discontinued and the physician should be notified. Antidiarrheal medications should be avoided in these cases because they hinder the fecal elimination of the pathogen. If it is necessary to continue management of the dental infection, consultation with the patient's physician is warranted.

Tetracyclines

Tetracycline is a bacteriostatic antibiotic that inhibits protein synthesis. Tetracycline has been available since the 1950s and has a wide spectrum of activity against streptococci, staphylococci, oral anaerobes, and gram-negative aerobic rods. Because this antibiotic has been so extensively used in the past, there exists a high degree of bacterial resistance. Tetracycline is an attractive adjunct for the treatment of gingival and periodontal disease with a high bioavailability in the gingival sulcus. For these reasons tetracyclines are primary agents for treating implant disease and infections around implant posts. Their efficacy for managing infrabony infections is questionable, considering their inactivity when chelated with calcium complexes. The disadvantages of this antibiotic include a high incidence of promoting *Candida* spp. infections, and it may be associated with photosensitivity reactions. Tetracycline has been shown to be advantageous in allowing for reosseointegration resulting from peri-implant disease. Case reports have shown that application of 50 mg/mL tetracycline for 5 minutes and then bone grafting resulted in bone growth fill in the peri-implant defects.[35]

of nausea and is bacteriostatic rather than bacteriocidal, and it is therefore not an ideal first-line choice for infections in the oral cavity.

Erythromycin has questionable use when a severe infection exists or when the patient is immunocompromised and requires bacteriocidal activity. Even more disturbing is its implication in numerous drug interactions, including its proclivity for elevating serum levels of digoxin, theophylline, and carbamazepine. Erythromycin has also been found to retard conversion of terfenadine (Seldane), a nonsedating antihistamine, to its active metabolite. As a result, elevated serum concentrations of the predrug may result and lead to cardiotoxicity, presenting a particular form of ventricular tachycardia called *torsades de pointes*.

Therefore two novel macrolides have shown to be advantageous over erythromycin (i.e., clarithromycin [Biaxin] and azithromycin [Zithromax]). Unlike other macrolides, they do not appear to inhibit hepatic cytochrome P450 isozymes, which account for most drug interactions inherent with erythromycin. Biaxin has been shown to produce less nausea and has better gram activity; Zithromax appears to be more effective against *Haemophilus influenzae* (Box 14.6).

Clindamycin

The use of clindamycin is popular for the treatment of dental infections primarily because of its activity against anaerobic bacteria. It also is active against aerobic bacteria, such as streptococci and staphylococci, and it has superior effects against Bacteroides fragilis. Clindamycin (Cleocin phosphate) is supplied as an aqueous

Fluoroquinolones

Fluoroquinolones are bactericidal antibiotics and have a broad antibacterial spectrum, which may be used either orally or parenterally. Ciprofloxacin is one of the first-generation quinolones and is the prototype antibiotic for this antibiotic classification. Newer third-generation (Levaquin, Avelox) quinolones have been developed with great activity against resistant bacteria and anaerobic bacteria. However, the U.S. Food and Drug Administration has placed warnings on this antibiotic class because of the potential for disabling and potentially permanent side effects related to tendon damage. Therefore these antibiotics are no longer used to

• Trovafloxacin	Trovan

treat dental implant–related issues unless no other options exist. Physician consultation and approval are recommended in these situations (Box 14.7).

Metronidazole

Metronidazole is a bacteriocidal antibiotic that is most often used for anaerobic infections. Because metronidazole has no activity against aerobic bacteria, it is seldom used for mixed infections unless it is combined with another antibiotic. However, it may be combined with penicillin when managing severe infections. Patients should be cautioned against drinking alcoholic beverages while taking this medication, because disulfiram-like reactions have been reported. These consist of severe nausea and abdominal cramping caused by the formation of a toxic compound resembling formaldehyde. Metronidazole should not be prescribed for patients who are taking the oral anticoagulant warfarin (Coumadin).

The more common antibiotics and dosages used in oral implantology for prophylaxis, grafting and implant insertion, postoperative infection, and long-term complications are listed in Table 14.3

TABLE 14.3 Commonly Used Antibiotics in Oral Implantology

Generic Name	Brand Name	Bactericidal/Bacteriostatic	Usual Adult Dosage	Maximum Adult Dosage	Prophylactic Dosages

Prophylactic Antibiotics in Oral Implantology

Postoperative wound infections can have a significant effect on the success of dental implants and bone-grafting procedures. The occurrence of surgical host defenses allows an environment conducive to bacterial growth. This process is complex, with interactions of host, local, systemic and microbial virulence factors. Various measures attempt to minimize infection by modifying the host and local tissue factors. The use of antimicrobials has been shown to be significant in reducing postoperative infections and decreases failure rate in implant dentistry.[36-38]

The antibiotic chosen for prophylaxis should encompass the bacteria most known to be responsible for the type of infection related to the surgical procedure. Therefore the following antibiotics are suggested against pathogens known to cause postoperative surgical wound infections in bone grafting or implant surgery:
1. **Amoxicillin** is the usual drug of choice; however, if the patient is allergic to amoxicillin, use
2. **Cephalexin** (nonanaphylactic allergy to penicillin) or
3. **Clindamycin** (anaphylactic allergy to penicillin).

For sinus involvement procedures (e.g., sinus grafts) the following antibiotics are suggested:
1. **Augmentin**
2. **Ceftin** (if history of recent use of antibiotics [within 4 weeks]) or doxycycline

Therapeutic Use of Antibiotics: Postoperative Infections

Acute postoperative infections have been shown to most commonly occur on the third to fourth day after surgery. The most common microorganisms associated with peri-implant, postoperative complications have been previously listed in Box 14.3.

Local signs of infection are pain, inflammation, bleeding, and exudate at the site of surgery. Systemic signs include fever, headache, nausea, muscle aches, vomiting, and weakness. When surgical wound infections arise, a specific diagnosis is advantageous to treat the complication. When evaluating the various antibiotics that are possibly effective against the bacteria in question, a broad-spectrum beta-lactam antibiotic is most often the first-line medication. The duration of treatment should include antibiotic administration for 3 days beyond the occurrence of significant clinical improvement (i.e. usually the fourth day), and therefore for a minimum of 7 days.[39]

Therapeutic Antibiotics in Implant Dentistry

The recommended treatment for intraoral infections associated with grafting or implant therapy includes:
1. **Surgical drainage**
2. **Systemic antibiotics**:
   Amoxicillin (500 mg): two immediately, then one tablet three times daily for 1 week or if penicillin allergy exists
   Clindamycin (300 mg): two immediately, then one tablet three times daily for 1 week
   NOTE: If no improvement is seen after 4 days, a culture and sensitivity test may be obtained to select the antibiotic that is most effective against the responsible organisms.
3. **0.12% chlorhexidine gluconate rinse** (½ oz twice daily for 2 weeks)

Prescription: 0.12% chlorhexidine gluconate (16 oz)
1. Patient presurgical rinse: used in the aseptic protocol before surgery for reduction of bacterial load
2. Surface antiseptic: intraoral and extraoral scrub of patient, scrubbing of hands before gowns and gloves
3. Postsurgical rinse: rinse twice a day until incision line closure
4. Peri-implant maintenance on daily basis
5. Treatment of postoperative infections

Chlorhexidine

Another medication used for antimicrobial prophylaxis for implant surgery is the use of an oral rinse, 0.12% chlorhexidine digluconate (Peridex; Procter & Gamble, Cincinnati, OH). Chlorhexidine gluconate is a potent antibacterial that causes lysis by binding to bacterial cell membranes. It has high substantivity that allows it, at high concentrations, to exhibit bacteriocidal qualities by causing bacterial cytoplasm precipitation and cell death.[40,41] In the oral cavity, chlorhexidine has been shown to have a slow release from tissue surfaces over a 12-hour period.[42,43]

In vitro studies have shown an inhibitory effect of chlorhexidine on cultured epithelium and cell growth; however, clinical studies have not shown this effect.[44-46] To the contrary, the use of chlorhexidine has been shown to be an effective adjuvant in reducing plaque accumulation, enhancing mucosal health,[46-48] improving soft tissue healing,[49,50] treating periodontal disease, preventing alveolar osteitis,[51,52] improving tissue healing after extractions,[53] and reversing peri-implantitis,[54] and has been shown to have no adverse effect on implant surfaces.[55]

When evaluating the effect of preoperative chlorhexidine before dental implant surgery, a significant reduction in the number of infectious complications (2 to 1) and a sixfold difference in implant failures in comparison with no use of chlorhexidine have been shown.[56]

Use of Chlorhexidine in Oral Implantology

As a consequence of many reported benefits of chlorhexidine, this antiseptic has been advocated for many uses in oral implantology (Box 14.8).

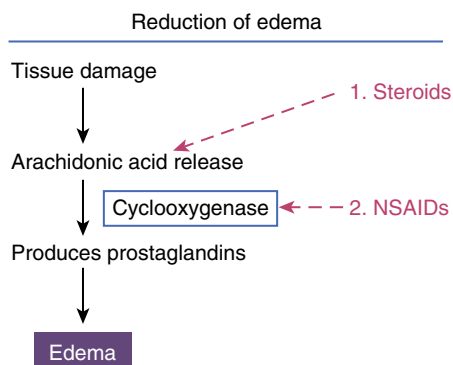
Miscellaneous

Citric Acid

Citric acid has been reported in the literature for the detoxification of exposed implant surfaces resulting from bone loss. Citric acid is stated to remove the smear layer, lipopolysaccharides, and exposure of collagen fibrils. The detoxification results in the improvement of the blood clot formation with a greater fibrin retention fibrin.[57,58] Numerous articles have evaluated the in vitro and in vivo effectiveness of citric acid; however, there is no agreement on the ideal concentration and duration for application. In a rhesus monkey study, implants were decontaminated with citric acid with a 40% concentration and developing reosseointegration 40 months after surgery.[59] In most detoxification protocols, citric acid is used in different concentrations (10%, 20%, or 40%) with a cotton pellet to burnish the exposed surfaces (Fig. 14.2).

Management of Postoperative Inflammation

The management of postsurgical swelling is crucial to pain management, control of edema, and incidence of postoperative

• **Fig. 14.2** Citric Acid. (A) 40% citric acid solution. (B) Citric acid is used to detoxify implant surface before bone grafting in the treatment of peri-implantitis.


• **Fig. 14.3** Mechanism of action for nonsteroidal antiinflammatory drugs (NSAIDs) and steroids in the reduction of inflammation.

infection. In most dental implant surgeries, tissue is traumatized, which results in some degree of an inflammatory reaction. By controlling the extent of inflammation associated with surgical procedures, edema, trismus, pain, and infection may be reduced.

The mediators of the inflammatory process include cyclooxygenase (COX) and prostaglandins, which play a significant role in the development of postoperative inflammation and pain (Fig. 14.3). When tissue manipulation or damage occurs, phospholipids are converted into arachidonic acid by way of phospholipase A_2. Arachidonic acid, which is an amino acid, is released into the tissue, which produces prostaglandins by enzymatic breakdown by COXs. The end result is the formation of leukotrienes, prostacyclins, prostaglandins, and thromboxane A_2, which are the mediators for inflammation and pain. For postoperative treatment, medications such as ibuprofen (nonsteroidal antiinflammatory drugs [NSAIDs]) and glucocorticosteroids (steroids) are used, which play an integral part in counteracting the negative effects of this cascade.

Nonsteroidal Antiinflammatory Drugs

NSAIDs have an analgesic effect, as well as an antiinflammatory effect. This drug class reduces inflammation by inhibiting the synthesis of prostaglandins from arachidonic acid. Therefore the use of the popular analgesic drug ibuprofen has a secondary beneficial antiinflammatory effect. NSAIDs do not have a ceiling effect for inflammation; however, higher doses to achieve antiinflammatory qualities are accompanied by serious side effects. In implant dentistry the use of ibuprofen is suggested as a preemptive analgesic agent, because it has antiinflammatory properties in type 1 to 5 procedures.

Glucocorticosteroids

The adrenal cortex, which uses cholesterol as a substrate, synthesizes and secretes two types of steroid hormones—androgens and corticosteroids. The corticosteroids are classified by their actions: (1) glucocorticoids, which have effects on carbohydrate metabolism and have potent antiinflammatory actions; and (2) mineralocorticoids, which have sodium-retaining qualities. The use of synthetic glucocorticosteroids has become popular in the postoperative management of pain and inflammation after oral surgical procedures. These synthetic glucocorticoids have greater antiinflammatory potency in comparison with natural steroids with very little sodium and water retention. Most of these steroids have similar chemical structures; however, they differ in their milligram potency.[60] Their antiinflammatory effects are achieved by altering the connective tissue response to injury, thus causing a decrease in hyperemia, which results in less exudation and cellular migration, along with infiltration at the site of injury.[61,62]

A wide range of glucocorticoid preparations are available for local, oral, and parenteral administration. In relation to the naturally occurring cortisol (hydrocortisone), synthetic glucocorticoids are longer acting and more potent. The main differences are based on the classification as short-acting (<12 hours),

TABLE 14.4	Synthetic Glucocorticoids		
Glucocorticoids	Antiinflammatory Potency	Equivalent Dose (mg)	Duration (hr)
Short-acting			
Hydrocortisone	1.0	20	<12
Cortisone	0.8	25	<12
Intermediate-acting			
Prednisone	4.0	5	24–36
Prednisolone	4.0	5	24–36
Long-acting			
Dexamethasone	25	0.75	>48

intermediate-acting (12–36 hours), and long-acting (>36 hours). A summary of the most common glucocorticosteroids is shown in Table 14.4.[60]

Mechanism of Action

Glucocorticoids bind to glucocorticoid receptors within cells and form a glucocorticoid-GR complex. This complex alters the synthesis of messenger RNA from the DNA molecule, thus affecting the production of different proteins. By suppressing the production of proteins that are involved in inflammation, glucocorticoids also activate lipocortins, which have been shown to inhibit the action of phospholipase A$_2$. Phospholipase A$_2$ is a key enzyme involved in the release of arachidonic acid from cell membranes.

Arachidonic acid is an omega-6 fatty acid that is incorporated into cell membranes. When a cell is damaged, arachidonic acid is released from cell membranes and is converted into inflammatory and pain prostaglandins by cyclooxygenase-2 (COX-2) enzymes. The release of arachidonic acid requires the activation of the enzyme phospholipase A$_2$. However, lipocortins, which cause the inhibition of phospholipase A$_2$, prevent the release of arachidonic acid, thereby reducing the amounts of inflammatory prostaglandins.

Adrenal Suppression

Glucocorticoids are essential for the body to adapt to stressful situations. Adrenal insufficiency may predispose a person to an inability to respond to stress. Adrenal suppression has been shown to occur after 7 to 10 days of steroid administration. In stressful situations, cardiovascular collapse may occur and, if not treated appropriately, may be life-threatening. Because most dental implant procedures maintain a high level of stress, the implant dentist must be able to assess the level of adrenal suppression on patients taking glucocorticoid replacement therapy.

Prolonged, long-term steroid therapy causing adrenal suppression is a well-known phenomenon. The amount of suppression is a function of both the duration of treatment and the dose administered. Studies have shown that short-term use of corticosteroids does not significantly affect the hypothalamus-pituitary-adrenal (HPA) axis, and normal levels of cortisol, which are initially suppressed, recover to normal levels after 7 days.[63] The conclusion is that the HPA axis, although altered by the initial dexamethasone therapy, is restored completely. In addition, the amount of surgical stress involved with oral surgical procedures appears to be of insufficient magnitude to overcome the HPA suppression of the negative feedback mechanism caused by the steroid administration. Therapeutic levels of steroid are present at a cellular level to prevent any manifestations of adrenal insufficiency.[64]

Timing

The use of synthetic steroids should be based on the production of the natural steroid cortisol (hydrocortisone) in the body. Normally, cortisol is produced from plasma cholesterol at a rate of 15 to 30 mg/day.[65] Under stressful situations (e.g., infection, illness, trauma), as much as 300 mg of cortisol can be secreted. Plasma concentrations of cortisol are several-fold higher in the morning compared with the afternoon. Studies have shown that a dose of dexamethasone given in the morning (8:00 a.m.) does not significantly alter the level of endogenous circulating cortisol. However, the same dose in the late afternoon (4:00 p.m.) can cause complete suppression of the HPA cycle.[66] This secretion rate is dictated by the pituitary-adrenal axis with a feedback-inhibition cycle.[67] Therefore administration of glucocorticoids should ideally be given in the early morning so that simulation of normal diurnal rhythm is achieved, thus minimizing the possibility of HPA suppression.[68]

Glucocorticoid Use in Implant Dentistry

Since the advent of glucocorticoids in 1942, these medications have been used clinically in two ways: (1) therapeutic treatments in various inflammatory diseases and autoimmune diseases, and (2) prophylactic treatment of inflammation and associated pain. They are still used for an array of autoimmune diseases. Glucocorticoids have been well documented in the dental literature as being advantageous in the prevention of postoperative complications after traumatic oral surgery,[69] intraoral sagittal osteotomy,[70] vestibuloplasty with palatal mucosal grafts, and reduction of edema and pain after oral surgical procedures.[61,62,71,72] In addition, they have been shown to be associated with less need of pain medication after oral surgical procedures.[73,74] These drugs have been shown to have the ability to be long-lasting in duration and cause minimal effects on wound healing, infection, and adrenal suppression, with minimal central nervous system (CNS) alteration.[66]

Antiinflammatory/Analgesic. The use of glucocorticoids is an integral part in the treatment of postsurgical edema after dental implant procedures. The selection of the ideal synthetic glucocorticoid for dental implant surgery should maintain high antiinflammatory potency with minimal mineralocorticoid effects. The glucocorticoid that best suits the requirements is the long-acting glucocorticoid dexamethasone (Decadron). It is imperative that this drug be administered before surgery so that adequate blood levels are obtained. Also, it should be given in the morning in conjunction with the natural release of cortisol. This timing will interfere the least with the adrenocortical system. Because inflammation usually peaks between 48 and 72 hours, the postoperative regimen of dexamethasone should not exceed 3 days after implant surgery unless a nerve impairment is present. The dose should not exceed the equivalence of 300 mg cortisol and with high doses, a decreasing dose the second and third day to reduce possible side effects. This high-dose, short-term glucocorticoid therapy has been shown not to significantly affect the HPA axis.[64,75,76] Studies evaluating the efficacy of dexamethasone have shown positive results with preventing and controlling postoperative pain and discomfort after implant placement surgery (Box 14.9).[77]

• BOX 14.9 Glucocorticoid Use in Oral Implantology[a]

Prescription:
- Dexamethasone (Decadron Tablets 0.5 mg, 0.75 mg, 4 mg, and 6 mg)
- Dexamethasone Injectable (4 mg/mL—30-mL vial)
1. Antiinflammatory/Analgesic: administer 4 mg according to pharmacologic protocol
2. Neurosensory impairment: 8 mg for days 1–3, 4 mg for days 4–6

NOTE: Also may use injectable form to be placed locally at site of nerve injury (1–2 mL of 4 mg/mL)
3. Postoperative nausea and vomiting: 8 mg to be administered in two 4 mg doses intravenously

[a]Methylprednisolone (Medrol) is an alternative to dexamethasone but has significantly less antiinflammatory potency.

Neurosensory Impairment. The use of dexamethasone has been shown to decrease the morbidity of neurosensory impairments. Not only does dexamethasone reduce the inflammation at the site of nerve injury, it has been shown to improve the regeneration of severed and compressed inferior alveolar nerves.[78]

Postoperative Nausea and Vomiting. A significant additional benefit of the administration of dexamethasone is the potent antiemetic effects for the prophylactic treatment of postoperative nausea and vomiting. This is now an accepted medication for hospital-based outpatient surgery, usually given in doses of 8 to 10 mg intravenously.[79-81] When using intravenous (conscious) sedation for dental implant procedures, it is highly effective in reducing pain and inflammation, along with preventing postoperative nausea and vomiting. Usually an 8-mg dose is recommended split into two administrations to reduce the possibility of perineal pain and itching.

Contraindication to Glucocorticosteroids

Contraindications to the use of corticosteroids include active infections (viral, bacterial, fungal), tuberculosis, ocular herpes simplex, primary glaucoma, acute psychosis, and diabetes mellitus. Special attention must be given to patients with diabetes, because glucocorticoids have an antiinsulin action that results in increased serum glucose and glycosuria.[82] Dexamethasone has been reported to induce immunosuppression when prescribed for long periods, which could be a concern with implant therapy.[83] However, the recommended use in our pharmacologic protocol involves only short-term use, thus minimizing the risks for these unwanted complications.

Cryotherapy

An additional therapeutic regimen to help reduce the amount and duration of postoperative inflammation is the application of cold dressings. It is reported that cold dressings in the form of ice bags or premanufactured ice packs applied extraorally to the surgical site will minimize edema.[84] The application of cold dressings is believed to cause vasoconstriction of the capillary vessels, thus reducing the flow of blood and lymph in this region, resulting in less inflammation.[85] Also, with the lower temperature at the surgical site, cell metabolism is reduced. As a result the cells in the region of trauma consume less oxygen, which allows them to survive a longer period of ischemia. Localized hypothermia will induce vasoconstriction and lowers microcirculation by more than 60%, and these effects may last for up to 30 minutes after cessation. In addition, there exists a reduction in pain as a result of less edema as well as restoration of motor and sensory nerve conduction.[86]

• BOX 14.10 Cryotherapy Use in Oral Implantology

Prescription: Ice Packs[a]
1. Ice packs (cold dressings) should be applied extraorally over the surgical site for 20 minutes on/20 minutes off for first 24 to 36 hours.

[a]Caution must be taken to limit the application of ice for no longer than 36 hours, because prolonged use may cause rebound swelling and cell destruction.

When applying ice to the surgical site, caution should be exercised to not cause a thermal necrosis of the tissue from too long of an application. Ideally cryotherapy should be applied for 20 minutes, followed by 20 minutes of rest. The rationale for this protocol includes possible vasodilation (reactive hyperemia) after the initial cryotherapy-induced vasoconstriction. The vasodilation is a compensatory reaction also termed a "hunting response," which results from the blood flow through the arteriovenous anastomoses.[87] Therefore to prevent the possibility of increased edema, the 20 minutes on/20 minutes off protocol is recommended (Box 14.10).

Postsurgical Pain Management

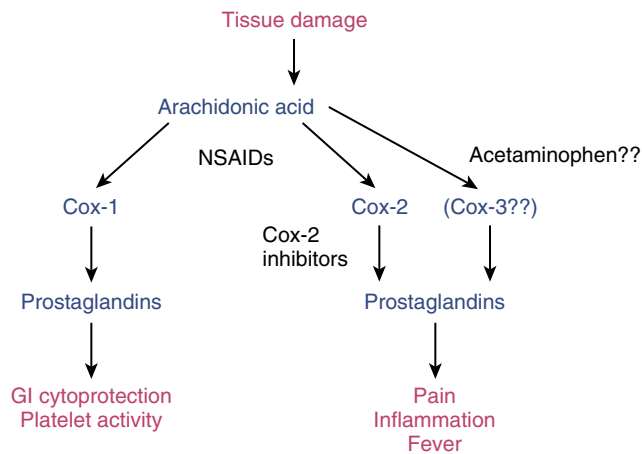
Pain has been documented to be inadequately treated in 50% of all surgical procedures.[88] These painful experiences predispose the patient to amplification of noxious stimuli (hyperalgesia) and cause typically painless sensations to be experienced as pain (allodynia).[89,90] Therefore patients who have had painful experiences may have increased pain and the need for additional analgesic use in future surgeries. The goal for pain control in oral implantology is to obtain analgesic levels before the cessation of local anesthesia and a well-administrated postoperative analgesic regimen for patient comfort.

Mechanism of Pain

The mechanism of painful stimuli is modulated by the peripheral nervous system and CNS. Noxious stimuli (tissue damage) cause peripheral nociceptors to transmit signals along nerve fibers lying in the dorsal root ganglion. Their axons synapse in the dorsal horn of the spinal cord and then travel along the spinothalamic tract of the spinal cord to the thalamus and the cortex. Within the cortex and thalamus, the signals originating from tissue damage form the subjective interpretation of pain.

With repeated noxious stimuli, peripheral nociceptors become more responsive. The sensitivity to these receptors is further enhanced by tissue factors and inflammatory mediators released in the course of tissue damage. Numerous inflammatory mediators are present that include prostaglandins, kinins, leukotrienes, substance P, and histamine. These mediators initiate and magnify the nociceptive impulses that are transmitted to the CNS for the perception of pain.

The most important mediators, prostaglandins, are extremely important in sensitizing peripheral neurons to the local stimuli. Prostaglandins are also synthesized in the spinal cord and brain, and enhance pain sensitivity by recruiting secondary neurons to respond to the primary stimulus.[91]

One of most commonly used analgesics, NSAIDs, works at the site of tissue damage and the spinal cord and brain to prevent prostaglandin formation by inhibiting COX. COX is an enzyme


• **Fig. 14.4** Mechanism of action of the various cyclooxygenase enzymes. *COX,* Cyclooxygenase; *GI,* gastrointestinal; *NSAIDs,* nonsteroidal antiinflammatory drugs.

that breaks down arachidonic acid to prostaglandin synthesis. In the tissue, two well-identified COXs exist, COX-1 and COX-2. COX-1 enzymes support hemostasis (platelet degranulation and adhesion), stomach mucosal integrity, and regulation of kidney function. COX-2 enzymes are an inducible form whose synthesis is activated in damaged tissue, which leads to the formation of proinflammatory prostaglandins that play a major role in inflammation, pain, and fever. A relatively new COX has been described (COX-3) that is found in the brain and is thought to be the site of action of acetaminophen.[92]

In contrast with NSAIDs, opioids have a different mechanism of action to reduce pain. Opioids act on the CNS by binding to specific receptors (μ-opioid), thus preventing transmission of nociceptive pathways, while also activating inhibitory pathways that descend to the spinal cord. By binding to these μ-opioid receptors, substance P is barred from being released, thus preventing painful stimuli.[93]

Protocols Postoperative Pain

In implant dentistry different classifications and mechanisms of pain suppression may be used. The most effective technique to decrease pain is a combination of preemptive analgesia and a multimodal pain management protocol. By using a multimodal therapy protocol, lower dosages of medication can be used, which results in fewer side effects and advantageous outcomes. Therefore the author has developed a pain control protocol that simplifies and standardizes the various aspects of pain relief (Fig. 14.4, Box 14.11, and Table 14.5).

Prophylactic Analgesics
1. Preemptive Analgesia
Postoperative Analgesics
1. Nonopioid Analgesics (Nonnarcotics)
2. Opioid Analgesics (Narcotics)
3. Adjuvants

Preemptive Analgesia

Preemptive analgesia is defined as the introduction of an analgesic regimen before the onset of noxious stimuli. In relation to dental implant surgery, it is advantageous to have adequate analgesic blood levels present before the initiation of surgery. The concept of

TABLE 14.5   Common Analgesic Medications in Oral Implantology

Medication	Advantages	Disadvantages
NSAIDs Nonselective	Inexpensive Over the counter Excellent pain relief Excellent antiinflammatory effects	Many drug interactions Limited use in patients with gastrointestinal issues
Acetaminophen	Inexpensive Over the counter Good pain relief	No antiinflammatory effects
Opioids	Good to excellent pain relief	Addiction potential Drug interactions No antiinflammatory effects
Corticosteroids	Excellent antiinflammatory action	Use in patients with diabetes is restricted Alteration of the hypothalamus-pituitary-adrenal axis

NSAID, Nonsteroidal antiinflammatory drug.

preemptive analgesia is based on advances in evidence-based clinical research. It has recently been refined and evolved to a broader concept that surgical incision alone is not the trigger for central sensitization. The goal is to prevent sensitization of the nervous system to subsequent stimuli that could possibly amplify pain. Dental implant surgery is ideal for this type of treatment because it is usually elective, and the timing of noxious stimuli is known.

Manipulation of hard and soft tissues during implant and bone grafting procedures predisposes the patient to postoperative pain. The extent of tissue reflection, amount of bone preparation, inherent patient factors, and duration of the surgical procedure have an effect on the intensity and duration of postoperative pain. Hyperalgesia is characterized by enhanced sensations of pain, a pain threshold reduction, and an increase in the suprathreshold noxious stimuli. With administration of analgesics before tissue

• BOX 14.12 Preemptive Analgesics

Prescriptions
- Ibuprofen (400 mg)
- Acetaminophen (1000 mg)
- Celecoxib (200mg)

Given 1 hour before the procedure.

• BOX 14.13 Nonopioid Analgesics

Prescriptions
- Ibuprofen (400–600 mg): 400 mg every 4 hours; not to exceed 1200 mg/day
- Acetaminophen (500 mg): 1 g every 6 hours; not to exceed 4 g/day
- Celecoxib (50, 100, 200, 400 mg): 200 mg twice daily as needed
- Tramadol: 50–100 mg oral dose every 4–6 hours as needed; not to exceed 400 mg/day
- Ultram: 50 mg tramadol
- Ultracet: 37.5 mg tramadol/1000 mg acetaminophen
- Ultram ER: 100 mg tramadol–extended release once daily

TABLE 14.6 Relative Risks of Nonsteroidal Antiinflammatory Drugs for Gastrointestinal Complications

NSAID	Relative Risk
None	1
Ibuprofen	2.1
Ketoprofen	3.2
Naproxen	4.3
Indomethacin	5.5

Ketorolac	24.7

NSAID, Nonsteroidal antiinflammatory drug.

damage, the sensitivity of these receptors is dramatically reduced and may be eliminated.[94] Many studies on the ideal medication to use for preemptive analgesia with ibuprofen (400 mg), acetaminophen (1000 mg), or celecoxib (200 mg) show positive results for the reduction of postoperative pain[95] (Box 14.12).

Postoperative Medications

Nonopioid Medications

The nonopioid analgesics used in implant dentistry include acetaminophen, NSAIDs, COX-2 inhibitors, and tramadol (Box 14.13).

Acetaminophen (Paracetamol). The mode of action of acetaminophen is not known; however, it is believed to involve the prostaglandin pathways within the CNS, with little influence on peripheral prostaglandin synthesis. The COX-3 enzyme has been described that is fully expressed in the brain, spinal cord, and heart. The primary function of this enzyme is to regulate pain responses and fever, and it has been postulated to be the site of action of acetaminophen.[96]

Acetaminophen is indicated for mild-to-moderate pain and is a safe alternative to NSAIDs. It has excellent analgesic and antipyretic properties, and is void of side effects that are associated with NSAIDs. Like NSAIDs, acetaminophen also has a ceiling dose (4 g/day) for analgesic effects. However, unlike NSAIDs, acetaminophen is limited in that it has minimal antiinflammatory qualities. The main side effect is liver damage, which is associated with long-term use of this drug.

Nonsteroidal Antiinflammatory Drugs. NSAIDs are one of the most commonly used analgesics in implant dentistry today. Clinical trials have shown that NSAIDs are effective in all levels of pain (mild, moderate, severe).[97,98] The mechanism of action of NSAIDs is thought to arise from the inhibition of the synthesis of prostaglandins from arachidonic acid. With the inhibition of COX, conversion of arachidonic acid to the immediate precursors of prostaglandins is prevented. Thus with the lack of prostaglandins in the tissue, the hyperanalgesia and edema associated with the acute inflammation are minimized.[99]

The main reasons that NSAIDs are so widely used is the fact that they work very well as analgesics and have variable effects on inflammation (drug and dose dependent). Inflammation and pain are two separate entities, with analgesic doses having a ceiling effect[100] and antiinflammatory doses not having a ceiling effect. In regard to the analgesic effect, there exists no reason to exceed the analgesic ceiling for the treatment of acute pain, because higher doses give no additional pain relief while increasing the likelihood of side effects.

There are two classes of NSAIDs: "nonselective" (e.g., ibuprofen) and "selective" (e.g., celecoxib). The COX enzyme is actually present in two different forms, COX-1 and COX-2. COX-1 enzymes protect the gastric mucosa from the acid that the stomach naturally produces and also is involved with platelet aggregation. COX-2 enzymes are responsible for producing prostaglandins that mediate pain and inflammation. The selective NSAIDs target only the COX-2 enzymes, which decrease pain and inflammation while maintaining the protective factors of the stomach, along with not interrupting platelet function. The side effects of NSAIDs are numerous, including GI disturbances (dyspepsia, erosions, ulcerations) and liver, renal, and cardiac effects.[101] This group of medications is responsible for the largest number of serious drug-related complications, surpassing all other drugs by a wide margin.[102] The various types of NSAIDs and their associated risks are listed in Table 14.6.[103] NSAIDs have very little effect on platelet aggregation because bleeding times are not prolonged. With prolonged use of NSAIDs, interference with most classes of antihypertensives has been noted. Therefore if patients take NSAIDs for more than 5 days postoperatively, blood pressure should be monitored. Although NSAIDs have numerous advantages, they may have a potential detrimental effect on bone metabolism. Numerous animal studies have been inconclusive. Some have shown that NSAIDs may impair angiogenesis and osteoblast/osteoclast precursor differentiation, especially in the first month after implant placement. However, other studies have shown no differences in long-term healing outcomes.[104]

Ibuprofen. Ibuprofen was first introduced in 1969 as a new NSAID and has since been the most popular prescribed NSAID.[105] Ibuprofen is a nonselective COX inhibitor because it inhibits two isoforms of COX, COX-1 and COX-2. It is available under a number of different trade names, including Advil and Motrin (200 mg). Ibuprofen is used to treat mild-to-moderate pain and has been proven to significantly reduce postoperative dental pain in clinical studies.[106,107] The analgesic ceiling dose is 400 mg/dose

and 1200 mg/day[108]; at these doses it has been shown to be as safe as acetaminophen, while achieving better analgesia with less nausea and cramping.[109]

Aspirin. Acetylsalicylic acid was the first prototypical NSAID. It has analgesic, antiinflammatory, and antipyretic properties. However, at analgesic doses its relative risk for GI complications is high. Acetylsalicylic acid is not a drug of choice in the management of dental implant surgical patients because of its very significant antiplatelet effects.

COX-2 Inhibitors. An additional type of NSAID specifically targets the COX-2. Because this class of medications is selective for COX-2, the risk for GI side effects is reduced. These drugs do not block COX-1 enzymes, which produce prostaglandins that protect the stomach and promote blood clotting. Because COX-1 is not altered, the possibility of ulcers or increase in bleeding is reduced. Recently rofecoxib (Vioxx) and valdecoxib (Bextra) have been taken off the market because of a possible increase in heart attacks and strokes. Currently celecoxib (Celebrex) 200 mg is available in the United States.

Acetaminophen + Nonsteroidal Antiinflammatory Drugs (Ibuprofen). Prescribing acetaminophen and NSAIDs together has become popular in clinical practice with positive results.[110] Although NSAIDs have few regulatory restrictions, many significant adverse effects may be present at high doses or with longer courses of treatment. Acetaminophen is safe and widely accepted; however, it has minimal pain relief by itself. Combining an NSAID and acetaminophen allows for the benefits of both medications without increasing dose or risk. Typically acetaminophen is given in a dosage regimen of 1 g every 6 hours, and ibuprofen in a dosage of 400 mg every 8 hours. This dosage regimen is advantageous because asynchronous dosing has been shown to be less effective.[111]

Tramadol. Tramadol represents a unique classification of analgesic because it is a synthetic analog of codeine; however, it has a reduced affinity for opioid receptors while having an action on 5-hydroxytryptamine-noradrenaline reuptake inhibitors. Therefore it is a centrally acting analgesic with two complementary characteristics: opioid and antidepressant. It works by inhibition of norepinephrine and serotonin reuptake within pain pathways of the CNS and also by its relative weak affinity for the μ-opioid receptor.[109] Tramadol is a nonscheduled drug and is associated with fewer opioid-like side effects, such as dependence, sedation, respiratory depression, and constipation.[112,113] The analgesic efficacy of tramadol is similar to codeine (60 mg) and is indicated for moderate to moderately severe pain management. This drug is an appropriate analgesic alternative for the treatment of postoperative pain in patients who have NSAID-related GI and opioid intolerance. Tramadol has been shown to be effective in the reduction of pain when used in combination with acetaminophen. Ultracet (tramadol/acetaminophen) has demonstrated excellent efficacy in pain studies and is supplied as a combination analgesic containing 37.5 mg tramadol and 325 mg acetaminophen.[114,115]

Narcotics (Opioids)

Narcotics (opioids) are the primary medications for analgesia of moderate-to-severe pain from dental origin. They are centrally acting analgesics that act as agonists at μ- and κ-opioid receptors. Morphine, which is a naturally occurring opioid, is generally accepted as the prototypical narcotic. All other narcotics are compared in potency to morphine.

Unlike nonopioids, opioids do not have a ceiling effect for analgesia. As the dose increases, the analgesic effect increases. However, in addition to relieving pain by μ-receptor binding, euphoria, nausea, vomiting, and constipation may occur. With high doses, sedation and respiratory depression are possible. With chronic use, physical and psychological dependence are common.

The following section discusses the most commonly used narcotics in oral implantology. Structurally these narcotics are similar to morphine and provide the same degree of pain relief and unlimited efficacy at equipotent doses.

Codeine. Codeine is a naturally occurring alkaloid that is classified as a mild analgesic. Codeine has excellent antitussive properties; however, it is associated with high degrees of nausea and constipation. Orally administered codeine is only 60% bioavailable, which results in only 10% being demethylated to morphine. This 10% is the only part responsible for analgesic properties, thus allowing 90% to have no analgesic efficacy. Because of the side effects and low potency compared with other opioids, codeine is usually not the first choice of narcotics used in oral implantology.

Hydrocodone. Hydrocodone bitartrate is a semisynthetic narcotic analgesic and antitussive with multiple actions qualitatively similar to codeine. It is usually used as a combination analgesic, being combined with either acetaminophen or ibuprofen. For several years this narcotic has been the most frequently dispensed prescription medication in the United States. Hydrocodone is habit forming, and the most frequent adverse reactions are dizziness, sedation, nausea, and vomiting.

Oxycodone. Oxycodone is a semisynthetic opioid with analgesic action similar to morphine. It is recommended for moderate-to-severe pain, with its principal actions being analgesia and sedation. It has excellent oral bioavailability because it retains half of its analgesic activity when administered orally. Oxycodone has the same adverse effects as most other opioids, with an increased potential for abuse and drug dependence. Oxycodone is marketed as a combination narcotic, combined with either acetaminophen (Percocet) or aspirin (Percodan). A slow-release oxycodone (Oxycontin) has recently been released, which has a high abuse potential.

Meperidine. Meperidine is mostly used in hospital settings via intramuscular administration. A majority of meperidine is converted to normeperidine, which is a metabolite that has no analgesic property; however, it is a strong CNS stimulant. Because meperidine in oral form has a poor oral bioavailability (25%), a greater risk evolves with the accumulation of normeperidine. As a result, meperidine is a poor choice for an orally administered opioid.

Combination Analgesic Therapy for Postoperative Pain

A pain management strategy using multiple analgesics with different mechanisms of action is termed *combination analgesic therapy*. The goal of combining different types of analgesics is to increase the analgesic effect while decreasing possible side effects. When multiple drugs are used in combination, synergistic and additive effects allow for the use of lower doses of each individual drug.

With combination therapy, acetaminophen or NSAIDs are used with an opioid. Because of the ceiling effects of acetaminophen and NSAIDs, further increases in dosage will not provide any additional analgesia; however, they will increase side effects (Table 14.7).

Analgesic Agents in Oral Implantology

The selection of an analgesic or analgesic regimen for management of postsurgical pain is ideally related to the expected pain intensity. This may be based on the patient's medical history, past pain threshold, type of procedure, extent of tissue reflection, and

TABLE 14.7 **Combination Analgesics**

Generic Name	Brand Name	Average Adult Dosage	Schedule
5 mg codeine/300 mg acetaminophen	Tylenol #1	1–2 tablets every 4 hr	III
15 mg codeine/300 mg acetaminophen	Tylenol #2	1–2 tablets every 4 hr	III
30 mg codeine/300 mg acetaminophen	Tylenol #3	1–2 tablets every 4 hr	III
60 mg codeine/300 mg acetaminophen	Tylenol #4	1 tablet every 4 hr	III
5 mg hydrocodone/500 mg acetaminophen	Vicodin/Lortab 5/500	1–2 tablets every 4–6 hr (maximum: 8 tablets/24 hr)	III
7.5 mg hydrocodone/750 mg acetaminophen	Vicodin ES	1 tablet every 4–6 hr	III
7.5 mg hydrocodone/650 mg acetaminophen	Lorcet	1 tablet every 4–6 hr	III
10 mg hydrocodone/660 mg acetaminophen	Vicodin	1 tablet every 4–6 hr	III
10 mg hydrocodone/650 mg acetaminophen	Lorcet 10/650	1 tablet every 4–6 hr	III
7.5 mg hydrocodone/200 mg ibuprofen	Vicoprofen	1–2 tablets every 6 hr	III
5 mg oxycodone/325 mg acetaminophen	Percocet 5/325	1–2 tablets every 4–6 hr	II
7.5 mg oxycodone/500 mg acetaminophen	Percocet 7.5/500	1–2 tablets every 4–6 hr (maximum: 8 per day)	II
10 mg oxycodone/650 mg acetaminophen	Percocet 10/650	1 tablet every 4–6 hr	II
5 mg oxycodone/400 mg ibuprofen	Combunox	1 tablet every 6 hr (maximum: 4 per day)	II

duration of procedure. Because of the various agents and numerous options for the treatment of postsurgical pain after dental implant surgery, a pain control protocol was formulated to aid in the proper administration of these agents. According to the World Health Organization guidelines, the procedure and patient must be evaluated and classified as mild, moderate, or severe.

Mild Pain

Mild pain is self-limited and usually will be resolved with regular recommended doses of NSAIDs.

Moderate Pain

Moderate pain involves more intense pain than mild and usually will not be resolved totally by NSAIDs. The expected pain will interfere with function and disrupt the activities of daily living.

Severe Pain

Severe pain is defined as pain that interferes with some or all of the activities of daily living. The patient may be confined to bed, and strong opioid treatment will need to be continued for days. Adjuvant drug therapies may be needed for supplementation.

Control of Postoperative Surgical Pain

Currently in the United States an alarming increase in prescription opioid deaths has been reported. A source of a substantial number of opioids are from leftover postoperative medications that are later shared among friends and family members. Among health care providers who prescribe opioids, dentists have been shown to be the most prevalent providers of these medications.[116] Therefore the dental profession has an obligation to counsel patients on the misuse of opioids and to use caution in the prescribing practices of opioids.

The implant dentist is placed in a challenging position with respect to the management of postoperative pain. Many of the procedures performed are rather invasive, which may lead to

intense pain postoperatively. Identifying patients who may be susceptible to poor pain management or uncontrolled acute pain is difficult. Therefore it is advantageous for implant clinicians to be able to assess patients and propose pain management plans that will minimize the risk and maximize inherent benefits. Thus good practice involves a comprehensive initial assessment, individualized pain management strategy, and reassessment if necessary.

The goal of postsurgical pain management is to optimize patient comfort through pharmacologic and behavioral strategies. The World Health Organization formulated an analgesic "ladder" for the treatment of pain management. The following protocol describes three steps in the treatment of acute pain (Box 14.14)[103]:

1. The first step is to maximize the use of NSAIDs (acetaminophen, ibuprofen) for mild-to-moderate pain.
2. When moderate pain is expected or persists, an opioid (hydrocodone, codeine) should be added to the NSAID. The fixed dose of opioids with the NSAIDs provides additive analgesia. Adjuvant medications such as glucocorticoids and cryotherapy are often suggested.
3. Moderate-to-severe pain that is expected or persists should be treated by increasing the dosage of the opioid. Adjuvant medications such as glucocorticoids and cryotherapy are often suggested.

With the guidelines from the World Health Organization, a pain control protocol was formulated for treatment of procedures based on the expected postoperative pain.

Pain Control Protocol

Preoperative Evaluation

1. A thorough evaluation that includes a comprehensive medical and dental history: This should include screening for past or current use of opioids, benzodiazepines, sedative-hypnotics, antidepressants, or anxiolytics.

2. Access and check the Prescription Monitoring Program for the past and current use of the earlier drug categories. This information can be compared with the patient's medical and dental history, along with determining the extent of a patient's history of chronic opioid or sedative medications. In some cases a physician consultation and clearance may be recommended.

Development of a Pain Control Protocol

After obtaining this information, the following prescribing protocol may be followed:

Step 1: Preemptive analgesics—the use of ibuprofen (400 mg), acetaminophen (1000 mg), or celecoxib (200 mg)—should be taken 1 hour before the procedure.

Step 2: Nonopioid analgesics should be used as the first line of pain control.
  a. NSAIDs are ideally used because they exhibit great pain control together with antiinflammatory effects. Avoid NSAIDs if there exists a known hypersensitivity, GI bleeding, or history of aspirin allergy. For patients at risk for bleeding, a selective COX–2 inhibitor (e.g., celecoxib) may be considered.
  b. If an increased analgesic effect is required, the combination of an NSAID with acetaminophen may be used. Avoid acetaminophen if there is a history of liver disease or hypersensitivity to the medication.
  c. Adjuvant multimodal pain strategies should be integrated into the management of acute postoperative pain (e.g., cryotherapy, long-acting anesthetics, glucocorticosteroids).

Step 3: If an opioid is warranted, the following protocols should be adhered to:
  a. The lowest effective opioid dose of immediate-release opioids should be prescribed.

• BOX 14.14	**World Health Organization Analgesic Ladder**

Three-Step Conceptual Model
1. Nonopioid + adjuvant
2. Nonopioid + adjuvant + opioid (moderate)
3. Nonopioid + adjuvant + opioid (severe)

---

  b. Quantity should be proportional to the expected duration of pain; usually this will cover 3 days, and a quantity exceeding 7 days is rare.
  c. Obtain medical clearance before prescribing opioid medication to any patient with a history of chronic use.

Local Anesthetics

Local anesthetics are an integral component of all dental implant surgical procedures. They are necessary to perform surgery without pain and are effective for decreasing onset and duration of pain. The dental surgeon must have significant knowledge of the pharmacokinetics of the different local anesthetics used in implant dentistry. The most commonly used dental anesthetics are amides, which are known for their low toxicity and relative lack of allergenicity.

Local anesthetics prevent postoperative pain by blocking the generation and conduction of action potentials in sensory neurons. This will prevent surgically induced nociceptive impulses from reaching the CNS and causing centrally mediated postoperative hyperalgesia. Table 14.8 provides local anesthetic dosage information.

Lidocaine

The compound with which most other local anesthetics are compared is 2% lidocaine-1/100,000 epinephrine. This solution is most commonly used in infiltration or block anesthesia, and is considered a medium-duration anesthetic. Lidocaine is supplied in two other forms: a higher-concentration vasoconstrictor (1/50,000 epinephrine) and with no vasoconstrictor (plain).

Mepivacaine

Mepivacaine is an anesthetic that is very similar to lidocaine in onset of action, duration, and toxicity. The usual dosage used in dentistry is a 2% solution with the addition of 1/20,000 levonordefrin (Neo-Cobefrin) as the vasoconstrictor. This local anesthetic is also made in a 3% (plain) solution, which is used for short procedures or when a vasoconstrictor is contraindicated.

Articaine

Articaine is a newer amide type of anesthetic that was approved in 2000 by the U.S. Food and Drug Administration for use in the United States. Articaine differs structurally from other amide anesthetics, allowing it to have a better lipid solubility, which improves permeability of the lipid barriers in nerve membranes. Articaine

also has a very short half-life (20 minutes) in comparison with the other amide anesthetics. This shorter half-life results because it is hydrolyzed over 90% by plasma esterases and not by the liver as with the other amides. As a result, articaine is of less concern in liver-impaired individuals and is a safer drug for reinjections in longer-duration procedures.

Long-Acting Anesthetics

Postoperative dental pain has been shown to reach its maximum intensity during the first 12 hours postoperatively.[117] When comparing analgesia (reduction in the sensation of pain) with anesthesia (complete elimination of feeling and sensation of pain), complete elimination of pain can be beneficial throughout the immediate postoperative period. Local anesthetics play a key role in the postoperative pain experience for the patients. If the implant surgeon can keep the patient comfortable during the initial period, pain and discomfort in the short term will also be minimized. The greater duration of anesthesia and decreased postoperative pain is effective in reducing the amount of analgesics required after surgery.[118]

The most common long-acting amide anesthetic is bupivacaine (Marcaine). This local anesthetic can play a vital role in pain management. Because of its unique pharmacokinetics, bupivacaine has been studied extensively and has been proven to be safe and far superior to other long-acting local anesthetics. Bupivacaine is an amide local anesthetic that is structurally similar to lidocaine and mepivacaine. It is more potent and less toxic than other types of amide anesthetics. Because of its high pKa (8.1), bupivacaine lasts two to three times longer than lidocaine or mepivacaine. The epinephrine concentration of bupivacaine is much lower (1/200,000 epinephrine) than standard anesthetics, thus limiting its ability to affect hemostasis.

Local Anesthetic Overdosage

A serious complication, local anesthetic overdosage, is of great concern in implant dentistry. Because many implant-related surgeries are of longer duration, a greater amount of anesthetic is often administered. Special attention must be taken during implant surgery as to the number of cartridges and type of anesthetic used during a procedure. Table 14.9 lists anesthetics and the manufacturers' maximum recommended dose by weight of patient to carpules. However, the maximum number of cartridges is time

---

• BOX 14.15 Signs and Symptoms of Local Anesthetic Toxicity

Mild Symptoms
- Talkativeness
- Slurred speech
- Apprehension
- Localized muscle twitching
- Light-headedness/dizziness
- Tinnitus
- Disorientation

Progressive Symptoms
- Lethargy
- Unresponsiveness
- Drowsiness/sedation
- Lack of muscle tone
- Mild drop in blood pressure, heart, and respiratory rate

---

dependent. The elimination half-life is not indicative of anesthetic duration; however, it may be used as a guide for repeated anesthetic administration during a lengthy procedure. After one half-life, as much as 50% of the permissible dose can be administered with reasonable safety if liver function is normal.

Special care must be given to the use of combination local anesthetics. In implant dentistry, it is common to use two amide anesthetics together—lidocaine and bupivacaine. Although acceptable, total doses should not exceed combined maximum recommended doses. Calculations should factor in the total dose of the combination and whether sufficient time has elapsed for elimination of the initial dose.[81] If local anesthetic toxicity reactions occur,[119] CNS excitation, convulsions, respiratory depression, and cardiac arrest may occur (Box 14.15).

Most amide anesthetics (except for articaine) are metabolized by the liver by a microsomal enzyme system. Therefore special attention should be given to patients with decreased liver function, especially in elderly patients (e.g., chronic alcoholism, hepatitis). The half-life of lidocaine has been shown to be greater than 2.5 times the normal values in patients with hepatic disease.[120] Special attention must be given to the amount of anesthetic used, and concern for reinjection must be strictly evaluated in these

TABLE 14.10	Most Commonly Used Oral and Intravenous Sedative Agents									
Sedative Agent	Class	Administration	Onset (min)	Duration	Half-Life (hr)	Active Metabolites	Oral Dose	IV Dose	Amnesia	Analgesia
Triazolam	Benzodiazepine	PO	60	1–2 hr	2–3	No	0.125–0.25 mg	—	Yes	No
Diazepam	Benzodiazepine	PO/IV	PO: 60 IV: 1–2	0.25–0.5 hr	21–37	Yes	0.2–0.5 mg/kg (maximum: 15 mg)	0.1 mg/kg	Yes	No
Lorazepam	Benzodiazepine	PO/IV	PO: 120–240	IV: 1–2 hr	10–20	No	0.053 mg/kg (maximum: 4 mg)	0.03–0.04 mg/kg	Yes	No

IV, Intravenous; *PO*, by mouth.

patients. In addition to liver dysfunction, the kidneys are the primary organs responsible for excretion of the local anesthetics and its metabolites. Patients with significant renal impairment will also have difficulty in removing the anesthetics from the blood, resulting in an increased chance of toxicity.

Patients with cardiovascular disease should be well evaluated before the use of epinephrine-containing anesthetics, and care should be taken as to the amount of epinephrine administered. Recommendations on the maximum safe dose for a healthy patient are 0.2 versus 0.04 mg epinephrine for the patient with cardiac impairment. It should be noted that when epinephrine is not included in the anesthetic, the systemic uptake of the drug is more rapid and the maximum number of carpules given is significantly less in comparison with anesthetics with vasoconstrictors.

Post-Surgical Anesthetic Use

To keep the patient as comfortable as possible, the use of long-acting anesthetics is highly recommended both in the beginning and at the end of the procedure. By administering a long-acting anesthetic at the end, the patient will remain "pain free" longer and will have a decrease in the initiation of noxious stimuli. However, care must be given to the number and amount of local anesthetic to avoid overdosage.

Sedative Agents

The use of conscious sedation is a valuable adjunct to dental implant procedures. The American Dental Association defines conscious sedation as a minimally depressed level of consciousness that retains the patient's ability to independently and continuously maintain an airway and respond appropriately to physical stimulation or verbal command, and that is produced by a pharmacologic or nonpharmacologic method or combination thereof.[121] Several sedative agents are currently available for oral and intravenous

sedation. Table 14.10 provides the most commonly used oral and intravenous sedative agents.

Benzodiazepines

The benzodiazepines are the most effective drugs available for dental-related anxiety. These drugs have depressant effects on the subcortical levels of the CNS. Benzodiazepines produce anxiolysis and anterograde amnesia, which are extremely useful for patients undergoing conscious sedation for dental procedures. The exact mechanism is not known, but benzodiazepines are thought to have an effect on the limbic system and the thalamus, which are involved with emotions and behavior.[122]

Diazepam (Valium)

Diazepam is usually not an effective agent for highly apprehensive patients unless administered intravenously. However, it is extremely effective if given orally the night before the procedure with a dose of 5 to 10 mg. Advantages of diazepam for dental procedures are that it reduces salivary flow and relaxes skeletal muscles.

The main disadvantage of diazepam is the 24-hour half-life for adults and an 85-hour half-life for elderly patients. The active metabolites (desmethyldiazepam and oxazepam) are responsible for the prolonged sedation and recovery, along with impaired psychomotor impairment.[122,123]

Midazolam (Versed)

Midazolam is a fast-acting benzodiazepine that is twice as potent as diazepam. It is available as a syrup and also as a formulated injectable solution. Midazolam possesses anticonvulsant properties and also is an excellent muscle relaxant, sedative, and amnesic. The inhibitory effects in the CNS are intensified; therefore midazolam should not be combined with other CNS depressant drugs.

Triazolam (Halcion)

Triazolam is an orally administered benzodiazepine and short-term hypnotic drug. When given orally, this drug is fast acting and has been shown to be safe and effective for dental procedures. Studies have shown that triazolam given in doses of 0.25 to 0.5 mg does not produce adverse effects in respiration, heart rate, or arterial pressure. This drug is also ideal for patients with hypertension, because blood pressure has been shown to decrease by five points.[122,123]

Additional Sedative Anxiolytics

Fentanyl

Fentanyl is a synthetic opioid agonist narcotic that produces analgesia, drowsiness, sedation, and euphoria, but no amnesia. All opioid agonists produce dose-dependent depression of ventilation. Respiratory depression is a result of a decreased response of the ventilatory centers to carbon dioxide. For this reason, care should be taken when administering opioid agonists, especially in combination with other sedatives. Nausea and vomiting are another undesirable effect of opioid agonists. Opioid-induced nausea and vomiting are caused by direct stimulation of dopamine receptors in the chemoreceptor trigger zone in the fourth floor of the fourth ventricle.[122]

Propofol (Diprivan)

Propofol is an intravenous sedative-hypnotic agent commercially introduced in the United States in 1989 by Zeneca Pharmaceuticals. It was the first of a new class of intravenous anesthetic agents: the alkylphenols. Propofol is an ideal sedative anesthetic for dentistry because it is fast-acting and possesses a short half-life. The elimination half-life of propofol has been estimated to be between 2 and 24 hours. However, its duration of clinical effect is much shorter because propofol is rapidly distributed into peripheral tissues. Because of its pronounced respiratory depressant effect and its narrow therapeutic range, propofol should be administered only by individuals trained in airway management.[122,123]

Reversal Agents

Flumazenil (Anexate, Lanexat, Mazicon, Romazicon) is a benzodiazepine antagonist used as a reversal agent for the treatment of benzodiazepine overdose. It reverses the effects of benzodiazepines by competitive inhibition at the benzodiazepine binding site on the $GABA_A$ receptor. It was introduced in 1987 by Hoffman-LaRoche under the name Anexate.

The onset of action is rapid, and usually effects are seen within 1 to 2 minutes. The peak effect is seen at 6 to 10 minutes. The recommended dose for adults is 200 mg every 1 to 2 minutes until the effect is seen, to a maximum of 3 mg per hour. It is available as a clear, colorless solution for intravenous injection, containing 500 mg in 5 mL. It is hepatically metabolized to inactive compounds, which are excreted in the urine.[122,123]

NOTE: Many benzodiazepines have longer half-lives than flumazenil. Therefore repeated doses of flumazenil may be required to prevent recurrent symptoms of overdosage after the initial dose of flumazenil wears off. It is hepatically metabolized to inactive compounds that are excreted in the urine.

Naloxone (Narcan) is a drug used as a reversal for narcotic toxicity. Naloxone is injected intravenously for fastest action. The drug acts after about 2 minutes, and its effects may last about 45 minutes.

Many opioids have a longer half-life than naloxone. Therefore patients who are receiving naloxone should be monitored for resedation and may require repeated doses of naloxone if resedation or respiratory depress occurs.[122,123]

Comprehensive Pharmacologic Protocol

Because of the many variables (e.g., local, systemic, surgical) that need to be considered with the use of pharmacologic agents in implant dentistry, a protocol has been developed to standardize the prophylactic use of these agents. A five-category classification is proposed based on the patient's ASA status and procedure type (Table 14.11).

a. **Patient selection:** Patients are evaluated according to their ASA status: ASA1—normal, healthy patient; ASA2—mild systemic disease; ASA3—severe systemic disease; and ASA4—patient with severe systemic disease that is a threat to life.
b. **Procedures:** The specific procedures are categorized into the protocol according to the extent, invasiveness, surgery duration, and expected bleeding.
c. **Antimicrobials:** The type of antibiotic is selected that is most specific to combat the type of bacteria present in the surgical area. The duration of antibiotic administration can be either a single preoperative dose or extended postoperatively. The duration of antibiotic use is dictated by the patient's health status and invasiveness of the procedure. The first-line antibiotic is amoxicillin for type 1 to 4 categories and Augmentin for type 5 category. Second-line antibiotics include clindamycin (types 1–4) and Ceftin or doxycycline for type 5. The use of chlorhexidine is recommended with all implant procedures before and after surgery.
d. **Glucocorticoid:** Dexamethasone (4 mg) is recommended for type 2 to 5 surgeries, with an increase dose and duration in relation to the extent and invasiveness of surgery.
e. **Analgesic:** Ibuprofen is the ideal preemptive analgesic to be used in all surgeries. Alternatives to ibuprofen would include acetaminophen. See earlier Pain Control Protocol section consisting of maximizing nonopioid medications first and adding narcotics only if warranted.

Possible Drug Interactions in Oral Implantology

See Table 14.12 for possible drug interactions.

TABLE 14.11 Pharmacologic Protocol for Oral Implantology

	Patient Selection	Procedures	Antibiotic	Glucocorticoid	Antimicrobial	Analgesic
CATEGORY 1	ASA1/ASA2 >ASA2 = Category 2	• Single implants with minimal reflection	*Amoxicillin 1 g:* 1 hr before surgery	None	*Chlorhexidine:* ½ oz BID for 2 weeks	Pain control protocol **PCP 1–2**
CATEGORY 2	ASA1/ASA2 >ASA2 = Category 4	• Traumatic extractions with pathology • Socket grafting • Single-tooth implants with extensive reflection • Multiple implants with minimal tissue reflection • SA-1 sinus procedures • Immediate implants without pathology	*Amoxicillin 1 g:* 1 hr before surgery, then 500 mg 6 hours after	*Decadron 4 mg* • 1 tablet a.m. day of surgery	*Chlorhexidine:* ½ oz BID for 2 weeks	Pain control protocol **PCP 1–2**
CATEGORY 3	ASA1/ASA2 >ASA2 = Category 4	• Single implants with bone grafting and excessive tissue reflection • Multiple implants with extensive reflection • Bone grafting (allograft/autograft)	*Amoxicillin 1 g:* 1 hr before surgery, then 500 mg TID for 3 days	*Decadron 4 mg* • 1 tablet a.m. day of surgery • 1 tablet a.m. day after surgery • 1 tablet a.m. 2 days after surgery	*Chlorhexidine:* ½ oz BID for 2 weeks	Pain control protocol **PCP 2–3**
CATEGORY 4	**Any of the following:** • >ASA2 • Long-duration surgery • Less experienced surgeon • Immunocompromised • Active periodontal disease	• Any category 3 procedures with surgical or patient factors • Immediate implants with pathology • Autogenous onlay grafting	*Amoxicillin 1 g:* 1 hr before surgery, then 500 mg TID for 5 days	*Decadron 4 mg* • 2 tablets a.m. day of surgery • 2 tablets a.m. day after surgery • 1 tablet a.m. 2 days after surgery	*Chlorhexidine:* ½ oz BID for 2 weeks	Pain control protocol **PCP 3–4**
CATEGORY 5	All SA-3/SA-4 sinus patients	All SA-2, SA-3, and SA-4 sinus procedures	*Augmentin (875 mg/125 mg):* 1 tablet BID starting 1 day before, then 1 tablet BID for 5 days	*Decadron 4 mg* • 2 tablets a.m. day before surgery • 2 tablets a.m. day of surgery • 1 tablet a.m. day after surgery • 1 tablet a.m. 2 days after surgery	*Chlorhexidine:* ½ oz BID for 2 weeks	Pain control protocol **PCP 2–3**

ASA, American Society of Anesthesiologists; *PCP*, pain control protocol; *SA*, subantral; *SBE*, subacute bacterial endocarditis.

Alternative Medications

Amoxicillin (1 g) = cephalexin (1 g), clindamycin (600 mg)

Augmentin (875/125) = Ceftin (500 mg) = doxycycline (100 mg)

SBE prophylaxis: change preoperative antibiotic dose to amoxicillin (2 g), cephalexin (2 g), or clindamycin

CHAPTER 14   Pharmacology in Implant Dentistry

377

TABLE 14.11	**Pharmacologic Protocol for Oral Implantology—cont'd**

Pain control protocol:

PCP 1: ibuprofen 400 mg 1 hour before surgery

PCP 2: ibuprofen 400 mg + 5 mg/300 mg hydrocodone PRN

PCP 3: ibuprofen 400 mg + 7.5 mg/300 mg hydrocodone

PR PCP 4: ibuprofen 400 mg + 10 mg/300 mg hydrocodone PRN

Recommended Pain Control Protocol:

PCP 1: mild pain expected

Ibuprofen: 400 mg 1 hour before surgery

PCP 2: mild-to-moderate pain expected

Ibuprofen: 400 mg 1 hour before surgery (continue QID for 2 days)

+Hydrocodone (Vicodin): 5 mg/300 mg as needed

PCP 3: moderate pain expected

Ibuprofen: 400 mg 1 hour before surgery (continue QID for 2 days, then PRN)

+Hydrocodone (Vicodin ES): 7.5 mg/350 mg (QID) for 2 days, then PRN

PCP 4: severe pain expected

Ibuprofen: 400 mg 1 hour before surgery (continue qid for 4 days, then PRN)

+Hydrocodone (Vicodin HP): 10 mg/300 mg (QID) for 2 days, then PRN

Alternative Medications:

Ibuprofen (400 mg) > acetaminophen (500 mg) or naproxen sodium (375 mg)

Hydrocodone (5 mg/500 mg) > Tylenol #2/tramadol (50 mg)

Hydrocodone (7.5 mg/750 mg) > Tylenol #3/tramadol (100 mg)/Nucynta (50, 75, 100 mg)

Hydrocodone (10 mg/660 mg) > oxycodone (Percocet) 7.5/500 mg

If the patient cannot take medication by mouth:

1. Ibuprofen oral suspension (over the counter)

2. Lortab Elixir (7.5 mg hydrocodone/500 mg APAP/15 mL)

From Misch International Implant Institute.

APAP, acetyl-para-aminophenol.

TABLE 14.12	Drug Interactions	
Medication	**Interacting Medication**	**Adverse Effects**
All penicillins	Bacteriostatic antibiotics	Static drug will impair action of penicillin
	Methotrexate (Rheumatrex)	Decreases secretion of methotrexate
All cephalosporins	Bacteriostatic antibiotics	Static drug will impair action of penicillin
	Anticoagulants	Risk for bleeding disorders might be increased in anticoagulated patients
Lincomycins Clindamycin (Cleocin)	Erythromycin	Possibility of antagonism AVOID CONCURRENT USE
Macrolides: Dirithromycin (Dynabac) Clarithromycin (Biaxin) Erythromycin	Anticoagulants	Risk for bleeding disorders is increased in anticoagulated patients— monitor patient
	Benzodiazepines	Possible increased benzodiazepine levels resulting in CNS depression, avoid in elderly
	CCBs diltiazem (Cardizem) and verapamil (Isoptin, Calan, Verelan)	QT interval prolongation, could cause sudden death
	Cyclosporine (Sandimmune, Neoral)	Increased cyclosporine renal toxicity
	"Statins" (Lipitor, Zocor, Mevacor)	Increased statin levels with possible muscle toxicity
Metronidazole (Flagyl)	Anticoagulants (Coumadin)	Risk for bleeding disorders is increased in anticoagulated patients
	Ethanol	Severe disulfiram-like reactions
	Tacrolimus (Prograf)	Metronidazole doubles Prograf levels
Quinolones: Ciprofloxacin (Cipro) Gatifloxacin (Tequin) Levofloxacin (Levaquin) Moxifloxacin (Avelox)	Antacids	Decreased quinolone absorption
	Anticoagulants (Coumadin)	Increased risk for bleeding disorders Monitor international normalized ratio
	Antineoplastics	Quinolone serum levels may be decreased
	Cyclosporine (Sandimmune, Neoral)	Cyclosporine renal toxicity may be enhanced
	NSAIDs	Enhanced CNS stimulation
	Caffeine	Increased caffeine effects
		Muscle weakness—tendon damage
NSAIDs and aspirin	Anticoagulants (warfarin [Coumadin])	Increase risk for bleeding disorders in anticoagulated patient, possible GI hemorrhage
	Antihypertensives (all but CCBs) (angiotensin-converting enzyme inhibitor, beta blockers, diuretics)	Decreased antihypertensive effect Monitor blood pressure
	Bisphosphonates	GI toxicity
	Cyclosporine (Neoral, Sandimmune)	Nephrotoxicity of both agents may be increased
	Methotrexate (Rheumatrex, Mexate)	Toxicity of methotrexate may be increased, and increased possibility of stomatitis
	SSRIs	GI bleeding, depletion of platelet serotonin required for aggregation
	NSAID + salicylates	Blockage of antiplatelet action with increased GI effects
Acetaminophen	Barbiturates, carbamazepine, phenytoin, rifampin, sulfinpyrazone	The hepatotoxicity of APAP may be increased by high-dose or long-term administration of these drugs
	Sedatives/anxiolytics	Increased sedation and respiratory depression
	Ethanol	Increased hepatotoxicity of APAP with chronic ethanol ingestion
Tramadol (Ultram, Ultracet)	Any drug that enhances serotonin activity (SSRI antidepressants, "triptans" for acute migraine	Possible serotonin syndrome
	MAOIs (Marplan, Nardil, Parnate)	MAOI toxicity enhanced
	Quinidine	Tramadol increased/metabolite decreased
All opioids	Alcohol, CNS depressants, local anesthetics, anti-depressants, antipsychotics, antihistamines, cimetidine	Increased CNS and respiratory depression may occur Use with caution
Hydrocodone/Codeine	2D6 inhibitors, amiodarone, cimetidine, desip-ramine, fluoxetine, paroxetine, propafenone, quinidine, ritonavir	Inhibition of biotransformation of codeine to active analgesic form Use different narcotic on patients taking 2D6 inhibitor
	SSRI antidepressants and bupropion	Analgesic effect reduced

Continued

TABLE 14.12 Drug Interactions—cont'd

Medication	Interacting Medication	Adverse Effects
Amides (e.g., lidocaine)	Alcohol, CNS depressants, opioids, antidepressants, antipsychotics, antihistamines	Increased CNS and respiratory depression may occur
	Antiarrhythmic drugs	Increased cardiac depression
	Beta blockers, cimetidine	Metabolism of lidocaine is reduced
	Bupivacaine	Toxicity is additive, total dose should not exceed the combined maximum dosages
Vasoconstrictors (epinephrine, levonordefrin)	TCAs—high dose (amitriptyline, desipramine, imipramine, nortriptyline, etc.)	Increased sympathomimetic effects possible. Limit epinephrine to 0.04 mg with high-dose TCAs
	Beta blockers (nonselective) (e.g., propranolol, nadolol)	Hypertensive and/or cardiac prescription possible. Limit epinephrine to 0.04 mg/2 hour visit
	Phenothiazines (e.g., chlorpromazine)	Vasoconstrictor action inhibited, leading to possible hypotensive responses. Use with caution
Antihistamines: Diphenhydramine (Benadryl) Hydroxyzine (Atarax, Vistaril) Promethazine (Phenergan)	Anticholinergics	Increased dry mouth, tachycardia, urinary retention
	CNS depressants (alcohol, narcotics)	Enhanced duration and intensity of sedation. Reduce dosages
Benzodiazepines (Triazolam)	Rifampin, carbamazepine	Increased metabolism leading to decreased sedative response

APAP, Acetyl-para-aminophenol; *CCB*, calcium channel blocker; *CNS*, central nervous system; *GI*, gastrointestinal; *MAOI*, monoamine oxidase inhibitor; *NSAID*, nonsteroidal antiinflammatory drug; *SSRI*, selective serotonin reuptake inhibitor; *TCA*, tricyclic antidepressant.

PART IV

Treatment Planning Principles

15

Interactive Computed Tomography and Dental Implant Treatment Planning

RANDOLPH R. RESNIK

One of the most significant advances in cone beam computed tomography (CBCT) technology is interactive computed tomography (ICT). ICT describes a technique that was developed to bridge the gap between the CBCT radiographic survey and the surgical placement of implants or bone grafts. With this technology, the implant clinician's computer becomes a diagnostic radiologic workstation with unlimited tools to measure the length and the width of the alveolus, determine bone quality, evaluate vital structures, diagnosis pathology, place type and specific sized implants, and evaluate and preplan the final prosthesis. When viewing the data via the interactive software, various views may be obtained that include axial, cross-sectional, panoramic, sagittal, coronal, and three-dimensional (3D). Specific areas or regions of the patient's anatomy can be selected for display, which may be manipulated via magnification or grayscale modifications to facilitate the evaluation of anatomic structures, anatomic variants, or disease processes.

An important feature of ICT is the implant clinician may perform electronic surgery (ES) by selecting and placing various sized implants into specific anatomic areas. With an appropriately designed diagnostic template, ES can be performed to develop the patient's treatment plan electronically in three dimensions. Electronic implants can be placed at arbitrary positions and orientations with respect to each other, the alveolus, vital anatomic structures, and the final prosthesis. ES and ICT enable the development of a 3D treatment plan that can be integrated with the patient's anatomy and visualized before surgery by the implant team and the patient for approval or modification. With the number and size of implants accurately determined, along with the density of bone at the proposed implant sites, the implant clinician can determine the exact specifications of the implants or bone grafting needed before surgery. Recent advances have allowed this technology to go one step further, with the advent of navigational surgery. Navigational surgery allows the clinician to place implants precisely in "real time" with specialized computer software and global positioning system (GPS)–like technology.

Therefore this chapter will discuss an overview of the basic concepts and use of ICT technology in implant dentistry, including:

(1) evaluating and determining the ideal implant position prior to obtaining an CBCT, (2) obtaining a CBCT scan, (3) obtaining a dataset, (4) integrating the dataset into interactive computer software programs (5) developing various treatment plans with the CBCT data (6) designing a surgical template from the treatment plan, and (7) integrating the surgical plan/template into the actual surgical procedure.

Evaluation and Determination of the Ideal Implant Position Prior To Obtaining a CBCT

The ideal location of the final tooth position or prosthesis must be determined to correlate the positioning of the implant in relation to the available bone. Without a known prosthetically driven location, the implant may be surgically placed in an incorrect position, leading to biomechanical issues and future complications. Therefore a relationship between the implant and final prosthesis location must exist in combination with the radiographic survey to achieve this information. If no correlation exists, the ideal implant positioning may be in error and lead to final placement complications (Fig. 15.1). Various methods of radiographic visualization in determination of the ideal location of the planned implants exist in two categories: radiographic templates and virtual restorations.

Fabrication of Radiographic Template (Scanning Template)

In the literature, there exists significant confusion in the use of prosthodontic terminology and nomenclature when describing radiographic and surgical templates. The terms *stent*, *guides*, *model*, and *appliances* have been used interchangeably in the description of these prostheses. Additional terms sometimes used in identifying these prostheses include scan appliance, scan stent, radiographic or surgical appliance, and radiopaque appliance. However, according to the *Journal of Prosthetic Dentistry*'s "Glossary of Prosthodontic Terms," the definition of *template* best describes the purpose of the prosthesis (Box 15.1).
• **Fig. 15.1** (A–C) If no correlation exists between the implant and final prosthesis, the implant may not be planned in the ideal position. (D) With a radiopaque template, the ideal implant position may be correctly transferred to the surgical treatment plan, thereby allowing for implant placement to be directly related to the final prosthesis.

• BOX 15.1   Prosthodontic Glossary of Terms

Template: A thin, transparent form duplicating the tissue surface of a dental prosthesis and used as a guide for surgically shaping the alveolar process; a guide used to assist in proper surgical placement and angulation of dental implants

Stent: Named for the dentist who first described their use, Charles R. Stent, such ancillary prostheses are used to apply pressure to soft tissues to facilitate healing (i.e., periodontal stent, skin graft stent)

Appliance: A device or restoration; something developed by the application of ideas or principles that are designed to serve a special purpose or perform a special function; a broad term applied to any material or prosthesis that restores or replaces lost tooth structure, teeth, or oral tissues

Model: A facsimile used for display purposes; a miniature representation of something

Guide: No definition exists in the "Prosthodontic Glossary of Terms"

Many different types of radiographic templates have been used in implant dentistry. A radiopaque template describes a prosthesis that is fabricated to wear during the CBCT survey that relates the ideal prosthesis position in reference to the bone. Radiopaque templates are usually fabricated through the process of diagnostic tooth positioning via diagnostic waxing, denture teeth arrangement, or duplication of the existing prosthesis. This information is then transferred to the template and used in the radiographic survey (i.e., patient wears radiopaque template during the CBCT survey). In some instances the radiopaque template can be transformed into a surgical placement template for use during implant placement (Fig. 15.2).

Radiopaque Material

A radiopaque material must be used to correlate tooth position and tissue in relation to available bone and vital structures. Many different materials have been described in the literature and may be used in the fabrication of a radiopaque template. The most common material used today in implant dentistry is barium sulfate ($BaSO_4$), which is an inorganic compound that has been used for years as a radiocontrast material in medical diagnostic imaging (Fig. 15.3). This material is ideal for maxillofacial imaging because it may accurately depict the existing contours of the teeth or soft tissue without scattering artifacts. Various techniques to incorporate $BaSO_4$ into the radiographic template include: (1) filling the edentulous area with $BaSO_4$, (2) painting the outside aspects of the buccal and lingual surfaces of the template, and (3) use of preformed $BaSO_4$ teeth. When using $BaSO_4$, care must be made not to use too high of a concentration of $BaSO_4$ because it may cause excessive scatter in the scan. Therefore commercially available monomer and polymer kits are available that include ideal concentrations (i.e., Salvin Dental Inc.). Other radiopaque materials that have been used include gutta percha, amalgam, lead foil, and metal sleeves. However, these materials are useful for delineating the position of the final tooth position but give little information regarding the contours of the restoration.[1,2]

In the literature the radiopaque prosthesis worn during the CBCT scan has been termed many different names (radiopaque template, barium sulfate template or appliance, scanning template, and scanning appliance). The radiopaque prosthesis may be fabricated by various techniques:

1. *Clear vacuum formed:* One of the simplest methods to fabricate a radiopaque template is with the use of a clear vacuum-formed prosthesis from a study cast. After fabrication of a diagnostic wax-up, a duplicate study cast is made. A clear vacuum-formed matrix is created. With the use of $BaSO_4$, the material is added to the edentulous site and allowed to cure. The patient then wears the prosthesis during the scanning process. This prosthesis may be fabricated by a laboratory or with an in-office technique (Box 15.2).

2. *Prosthesis duplication:* If the patient's current prosthesis needs no modification because of esthetics or function, the prosthesis is duplicated via a denture duplicator. The patient wears the fully edentulous radiopaque template during the scanning process. Care must be made so that the prosthesis is stable during the scanning procedure. It is highly recommended to place denture adhesive on the prosthesis before the scan to avoid inaccuracies in the location of the teeth on the scan. Another option would be to make a clear vacuum-form matrix over the existing denture. The matrix is trimmed and barium sulfate is painted over the buccal surfaces of the matrix. The patient wears the denture (with matrix) during
● **Fig. 15.2** Radiopaque template made from a diagnostic wax-up with the correct tooth position and vertical dimension. Note the amount of bone loss (space between the radiopaque template and residual ridge.
● **Fig. 15.3** (A) Barium sulfate monomer and polymer (Salvin Dental Specialties, Inc., Charlotte, N.C.). (B) Homogenous mixture that may be added to the radiographic template before the cone beam computed tomography (CBCT) scan. (C) Barium sulfate complete denture (i.e., scanning appliance), which is worn by patient for the CBCT scan.

the CBCT survey. Once the scan is obtained, the matrix is removed. (Fig. 15.4; Box 15.3).

3. *Virtual teeth:* Most software programs today allow for an alternative to a radiographic template. This technique has been generically termed the "virtual teeth" function. The benefit of this technique is the clinician may design the replacement teeth via the specialized computer program without the fabrication of a radiopaque template. This specialized tool may be used for single tooth replacement and short edentulous spans. However, caution must be exercised because the use of this modality should be limited to ideal cases in which no maxillomandibular changes are required (Fig. 15.5; Box 15.4).

Flapless Template Techniques

1. *Flapless full arch technique (single scan):* Barium sulfate is used to identify the teeth from the diagnostic wax-up in a 20% $BaSO_4$ solution. If a soft tissue (flapless surgery) template is to be made, teeth are ideally identified with a 20% $BaSO_4$ solution, and the base (soft tissue) uses a 10% mix. This allows for differentiation of the teeth from the soft tissue. Poor mixing will result in a nonhomogeneous mixture that exhibits areas of high radiolucency.

2. *Flapless full arch technique (double scan):* The drawbacks of single scan CBCT-generated surgical techniques are associated with increased costs, more time consuming, and a technique sensitive process. To combat these disadvantages, a new scanning technique, referred to as the *dual-scan technique*, has been introduced to the profession for flapless procedures on fully edentulous patients. This scanning technique allows for fast, easy, and accurate scanning data to be obtained at a significantly reduced cost. With the dual-scan technique, the scan can be obtained at the initial appointment, without the need for a duplicate prosthesis or irreversible modification of the existing prosthesis.

The dual-scan technique utilizes two scans to obtain the data to fabricate a fully guides tissue supported template. The first scan is obtained with the patients current prosthesis with added

● BOX 15.3   Laboratory Steps for Radiopaque (Full Edentulism) Denture Template

Option 1: Laboratory-Fabricated Template
1. With the use of a denture duplicator flask (Lang Dental Manufacturing, Chicago, Ill.), mix and fill half of the flask with alginate.
2. Place the denture (teeth first) into alginate with the teeth perpendicular to the bottom of the flask.
3. After alginate is set, trim excess that covers the denture flange.
4. Lubricate the alginate and exposed denture with separating material.
5. Fill the other half of the flask, along with the ridge part of the denture, with alginate.
6. Close the flask, ensuring complete closure. After the alginate is set, open and remove the denture.
7. Pour acrylic clear acrylic resin (Clear Surgical Template) or radiopaque acrylic resin (Radiopaque Template) into the incisal and occlusal surfaces, ensuring no bubbles. Pour the remainder of the mixture into the palate or vestibule area.
8. Cure for a minimum of 20 minutes on the laboratory bench or in a pressure pot at 30 psi.
9. Trim excess and polish.

NOTE: If modifications need to be made to the existing prosthesis, the try-in denture should be duplicated after all necessary changes are made.

Option 2: Immediate Template
1. With the patient's existing complete denture, fabricate a vacuum-formed clear template with clear thermoforming material (~0.060 inch, 5 x 5 inches).
2. Using barium sulfate monomer and polymer, paint the facial and lingual surfaces of the template. Allow it to dry.
3. Administer the cone beam computed tomography scan with the radiopaque template.
4. After scan is completed, the vacuum form matrix is removed from the denture. (Figure 15.4)

---

radiopaque markers along with a bite registration (centric relation). The second scan is obtained only with the current prosthesis with added radiopaque markers. After the scans are obtained, the raw data (Digital Imaging and Communications in Medicine [DICOM] datasets) are reformatted with any of the third-party software programs available today. By superimposing the spherical markers over each other, a 3-D bone model is fabricated along with the radiographic template.

Scanning Process
First Scan: The patients existing prosthesis is modified by adding self-stick radiopaque markers Suremark Clearmarkers (3D Diagnostix) over the flange and palatal areas. A bite registration material is then obtained and is worn during the first scan to allow for stability of the prosthesis. Ideally, specifications of the scan should include a 512-x-512 matrix, thickness of less than 1.0 mm, a high resolution reconstruction computer algorithm, and exported in DICOM format.
Second Scan: For the second scan, the prosthesis (with the markers attached) is removed from the patient's mouth and placed onto a holder (attached to the chin cup holder) that allows the prosthesis to be positioned parallel to the floor. The prosthesis should be placed in relatively the same position as the first scan.

Merging of the Two Datasets
Most software programs today will allow for the merging of the two dataset files. The CBCT dataset files are merged by aligning the radiopaque markers so that the prosthesis will be visible over the available bony anatomy, thereby allowing the radiographic template and patient's anatomy to be viewed together or separately. The virtual planning is then completed on the bone and/or prosthetic

model, which allowing for fabrication of the final treatment plan and surgical template.[3] (Fig. 15.6; Box 15.5).

Obtaining a Cone Beam Computed Tomography Scan

Medical Scan vs. Cone Beam Computed Tomography

The second step in the interactive treatment planning technique is obtaining a CT scan (CBCT or medical). Today medical scans are becoming less popular, mainly because of the availability and benefits of the CBCT units in the office setting. Today a wide range of CBCT machines are available in implant dentistry. With most CBCT units, there are two components of CBCT production: acquisition configuration and image detection.

1. *Acquisition configuration:* The first step in the CBCT process is the acquisition of the data via the x-ray source. With most units a partial or rotational scan originates from the x-ray source, whereas a reciprocating area detector moves around the area of interest via a fixed fulcrum. During this rotation, each projection image x-ray beam is captured by the detector. The dimensions of the data acquisition are dependent on the field of view (FOV), which is dictated by inherent detector size and shape. Most CBCT imaging machines use a 360-degree complete circular arch scan to acquire the data.

2. *Image detection:* Current CBCT units have two types of image detectors: an image intensifier tube/charge-coupled device or a flat panel imager. The resolution of the images is mainly determined by the voxel (individual volume elements) size specified within the CBCT unit. The voxel dimension is dependent on the pixel size of the detector and is displayed in submillimeters (range 0.07 to 0.04 mm). The voxel resolution on CBCT units is isotropic or equal in the x, y, and z dimensions.[4]

For interactive treatment planning, it is imperative to reduce artifacts and increase resolution and accuracy of the scan. Therefore to maximize accuracy, the following should be adhered to:

• Use the smallest FOV that encompasses the area of interest. The FOV are usually classified as either small, mid, or large.
• Patients should wear a radiopaque template when indicated. If there is a lack of retention of the radiographic prosthesis, the patient should wear the prosthesis with denture adhesive to ensure stability. The prosthesis may also be relined with tissue conditioner or soft reline material to improve retention. Any movement or improper seating will result in errors, leading to incorrect implant position.
• Always separate the arches (i.e., cotton roll), so the ideal contours of the teeth can be ascertained and the maxilla and mandible can be differentiated in the reformatting process (Fig. 15.7).

• **Fig. 15.6** Double Scan. (A) Markers are placed on the palate (SureMark Markers). (B) Markers placed on right and left flanges. (C) Cone beam computed tomography (CBCT) scan acquired with patient wearing the existing prosthesis + markers. (D) CBCT scan acquired prosthesis + markers. (E) Final CBCT surgical template fabricated.

Obtain Dataset

The data generated from the CBCT scan include multiple slices with varying thickness (i.e., 1 to 5 mm), which is dependent on the type of scanner. The number of individual projection frames may number from 100 to more than 600, each with greater than a million pixels, with each pixel containing 12 to 16 bits of data per pixel. All of the images are stored in a file termed a *dataset*. To create the volumetric dataset, the acquisition computer will reconstruct the data in a format that will allow transfer to other computers for evaluation and manipulation of the information.

Ideally the dataset should be saved in the Digital Imaging and Communication in Medicine (DICOM) format. This format was developed to create a generalized system for digital image acquisition, storage, and display in medical radiography. If the dataset is saved in a ".dcm" format, the data are easily transferred into the various available CBCT software programs for data evaluation (Fig. 15.8).

Integrate Dataset Into Specialized Software

Most treatment planning software have their own specific protocol; however, all are compatible with DICOM files. These files may be directly generated and downloaded from the scanner. If the dataset is saved in a "viewer" format, in most cases the data will not be able to be extracted for reformation purposes in other third-party software programs.

Reconstruction (Manipulation of Data to Formulate a Treatment Plan)

With the use of CBCT-generated software programs (e.g., SimPlant, Co-Diagnostix), the anatomic relationship can be predictably determined before surgery for ideal treatment planning

purposes. After successful integration of the dataset into the software program, there exist several different methods to evaluate the images.

Determination of Panoramic Curve

The initial viewing window of most CBCT software programs will consist of any of the following images: axial, coronal, sagittal, panoramic, and cross-sectional views, along with 3D representations. In many programs a spline is present that allows the clinician to represent the area or depth of the image in a buccal-lingual orientation. These sagittal cuts allow for anatomic structures to be seen clearly (e.g., mandibular canal [MC]). The clinician can then scroll through the various cross-sectional images that may aid in the visualization of the dimensions of bone (buccal to lingual).

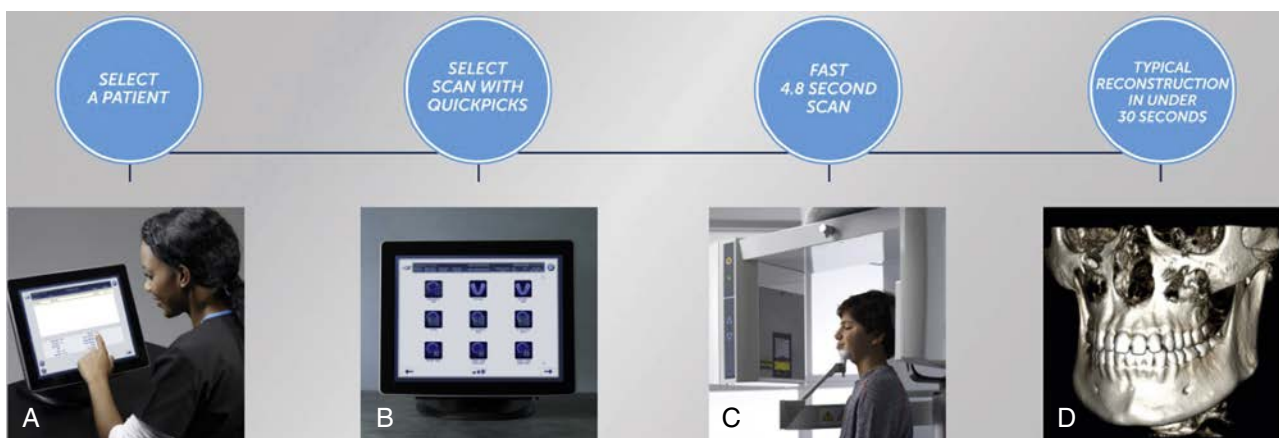
Mandibular Canal Identification

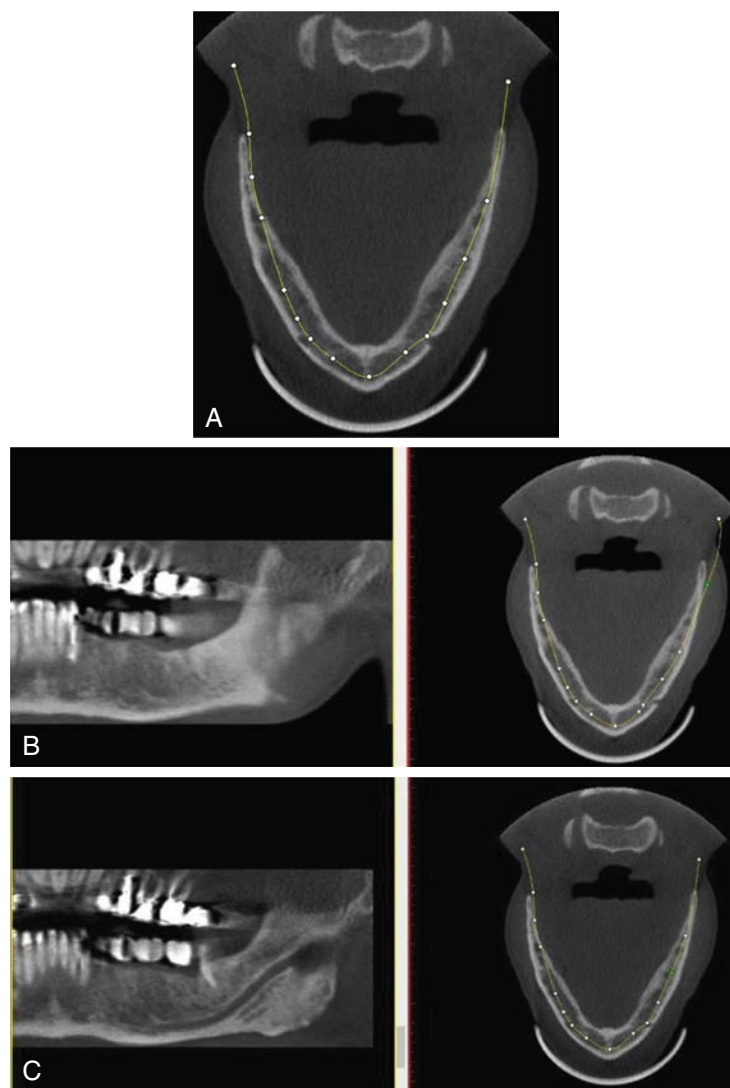
Methods for Identifying the Mandibular Canal

The identification of the MC is manually performed and estimated on multiple endpoints that cross reference in all available image types of the dataset (Fig. 15.9; Box 15.6).[5]

• BOX 15.5   Double Scan

1. The first scan is taken with the patient wearing the radiolucent prosthesis with Dual Scan Markers 3D Diagostix and bite registration. The bite registration is used to stabilize the prosthesis during the scanning procedure.
2. Positioning of the patient is comparable with a standard dental computed tomography scan. The transaxial slice plane must be parallel to the floor.
3. The maxilla and mandible, including the scan template, must be within the FOV.
4. The second scan is taken of the prosthesis alone, applying the same general settings that were used to obtain the first scan.
5. It is important that the position of the prosthesis is in the same position as the mouth position. The materials to hold the prosthesis must be more radiolucent than the prosthesis itself. Polyethylene and polyurethane foam materials may be used. Alternatively, a cardboard box can be used to secure the prosthesis in a vertical position.

• **Fig. 15.8**   Individual image stored in Digital Imaging and Communication in Medicine (DICOM) format. A dataset is made of many dicom images.


• **Fig. 15.7**   Cone Beam Computed Tomography (CBCT) Scan Acquisition (I-cat). (A) Patient information added. (B) Field of view selected. (C) CBCT scan taken (~< 5 seconds). (D) Reconstruction of scan data (~<30 seconds).


• **Fig. 15.9** (A) Panoramic curve outlined in an axial image. (B) Panoramic curve outside the focal trough of the mandibular canal (MC) resulting in no visualization of MC. (C) Panoramic curve changed within the MC allowing for evaluation of MC.

• BOX 15.6 | Identification of Mandibular Canal

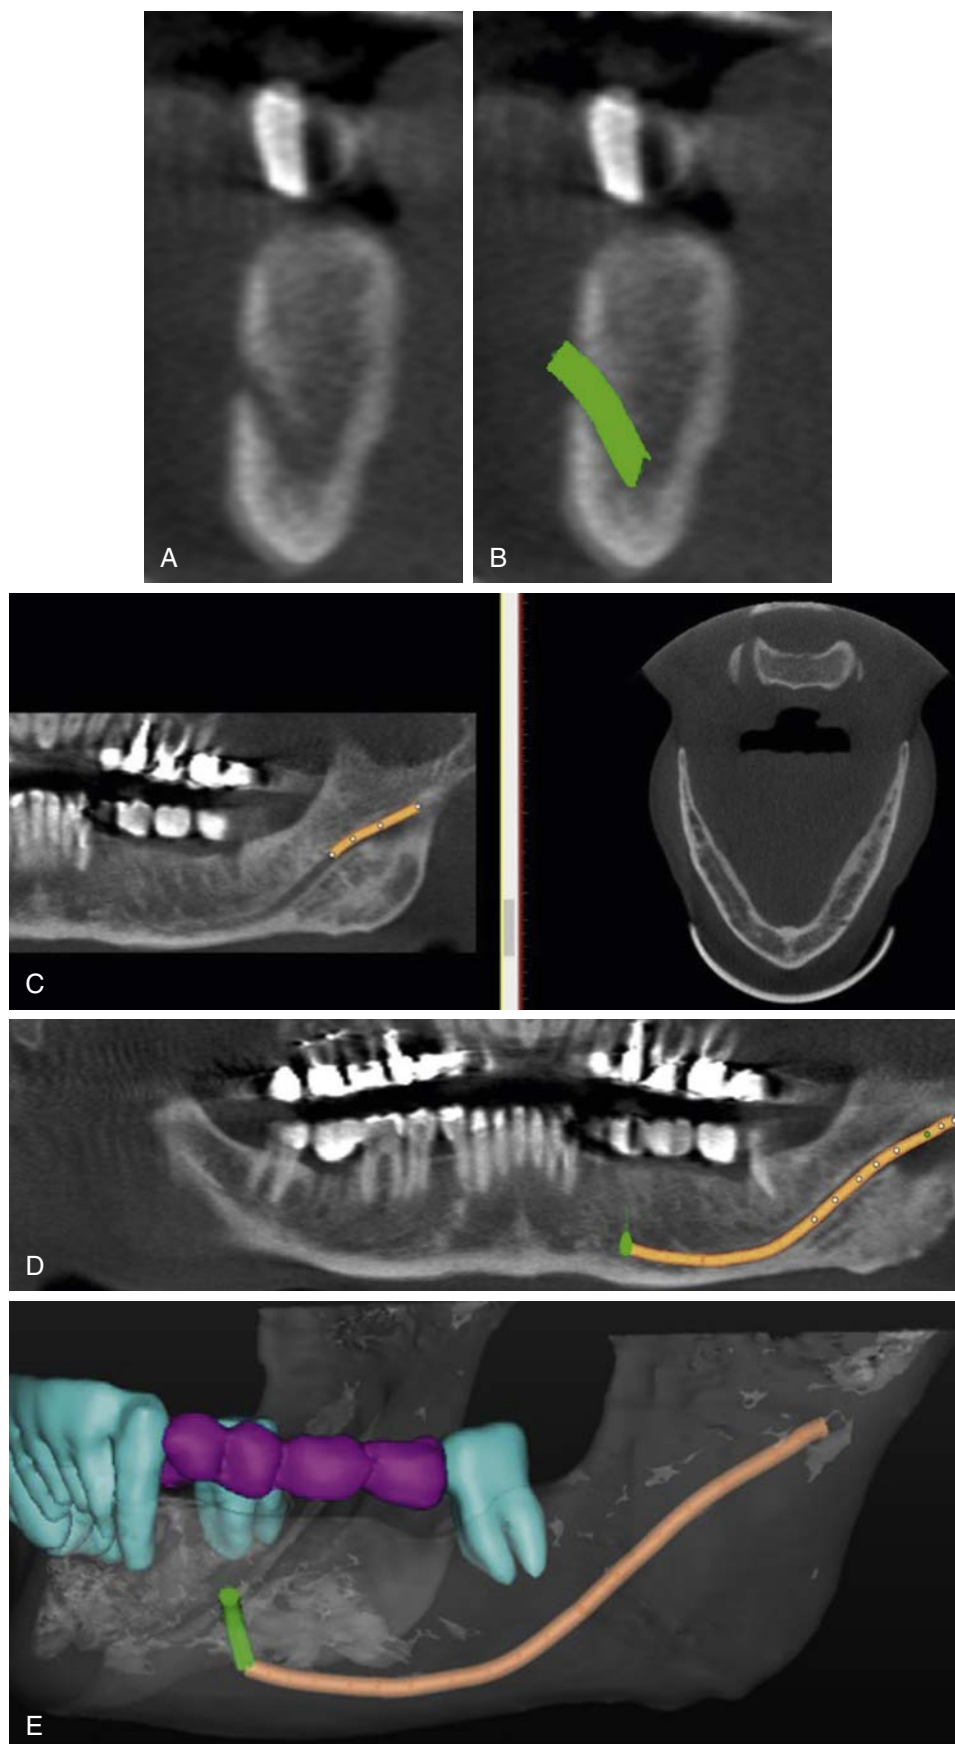
Manipulation of Images

1. Select the reconstructed panoramic view using the CBCT software to access the MC.
2. If the MC is not seen clearly, manipulate the mandibular curve in the axial view buccal-lingually
3. When the MC can be seen clearly, the nerve is drawn (main nerve canal) from the posterior to the mental foramen.
4. In the cross-sectional views, scroll until the mental canal/foramen is seen. Draw the first nerve (green) from the MC to the exit of the mental foramen. Draw the second nerve (orange) from anterior to posterior.
5. If the MC cannot be seen clearly, mark the posterior and anterior limits of the MC and extrapolate via cross-sectional images. The MC can then be drawn, connecting the extrapolating points on the panoramic image.

Additional Techniques

If the CBCT examination does not depict the MC clearly, an MRI examination may be completed to more easily see the cortical and cancellous bone, nerve, and blood vessels. Studies have shown that MRI images provide less variability in determining the locations of the mandibular nerve, the mental foramen, and the mandibular foramen than CBCT images. Even though there exists no ionizing radiation, MRI technology is limited in dentistry because of cost, availability, and no cross referencing.

The accurate identification of the MC is crucial for preoperative treatment planning for implant placement in the posterior mandible. Because the amount of available bone height present between the alveolar ridge and the MC dictates the positioning and size of the dental implant, any inaccuracies may lead to an increased morbidity. Because of the varying inability to ascertain cortical borders in the MC and with different trabecular patterns, in some cases it may be difficult to determine the exact location. Studies have shown the visibility of the MC decreases toward the mental foramen. This unreliability of visualization of the MC near the mental foramen is due to the lack of definite walls in the anterior portion of the canal. Even with the wide variation of CBCT images, the identification of this structure is directly proportional to the density of the bone and the thickness of the cortical bone surrounding the MC.

Lofthag-Hansen et al.[6] determined that the MC is visible on only one-third of cross-sectional images. However, when other images (sagittal and axial) were evaluated, the visibility of the MC increased significantly to approximately 87%. Therefore assessing multiple sequential images increases the localization of the MC[6] (Fig. 15.10).


• **Fig. 15.10** Mandibular Canal (MC) Identification. (A) Mental foramen and canal are identified in the cross-section view. (B) Foramen and canal are marked by using the nerve marking module within the software. (C) In the CBCT panoramic view the MC is marked from the posterior in small segments. (D and E) The canal is marked anteriorly until the MC marking connects with the mental canal.

Evaluation of Bone Density

The determination of the bone density values allows for modification of the surgical (drilling protocol, insertion torque, implant size determination, number of implants) and prosthetic (healing time, progressive bone loading) protocols. The bone density is a relative measurement on CBCT units because it is based on many factors, including gray values, machine calibration and settings, and software interpretation, whereas on medical-grade CT scanners, it is directly related to the Hounsfield units (Fig 15.11; Box 15.7).

Virtual Implant Placement

Manual implant placement may be performed in most of the associated views after reformatting the DICOM images. The digital software will allow the user to place a "virtual implant" in the proposed position according to anatomic factors. Analysis may be made for ideal positioning, and modifications are easily completed. Most software programs have implant libraries that consist of various implant types and allow for the determination of the exact implant dimensions (i.e., the diameter, length, and thread size). The implant position may be evaluated and adjusted accordingly with respect to bony anatomy, prosthesis type, and location of vital structures (Figs. 15.12 and 15.13).

Safety Zone

Most software programs contain safety zone features that prevent implant placement too close to a vital structure (i.e., implant in approximation to the MC). Usually a 2-mm safety zone will be preset within the program that will prevent implant placement too close to the MC (Fig. 15.14).

Bone Graft Simulation

When advanced cases of ridge resorption are present, bone grafting defects may need to be addressed and evaluated. Bone grafting procedures (e.g., sinus augmentation, ridge augmentation) may be simulated and completed via the interactive software programs (Fig. 15.15). With some software programs, actual bone graft volume may be determined.

Treatment Plan to Surgical Placement

The implant profession has seen a major shift and demand from traditional freehand implant placement to computer-guided surgical intervention. This can be accomplished by facilitating the accurate translation from the interactive treatment plan to reality with the use of surgical guides (templates). The three-dimensional computer-assisted interactive implant treatment planning software tools have facilitated an accurate and precise clinical method to ensure proper placement. This computerized transfer process can be accomplished via the use of fabricated stereolithographic drill guides or direct navigation. The use of surgical templates has been shown to be a reliable and proven method to transfer the surgical plan to the surgical field through guided drilling templates.

Surgical Template Fabrication

Commercial

After the treatment plan is verified the clinician can easily upload the saved plan to a third-party site for template fabrication. In most software programs the patient data, type of template, drilling sequence, and drill diameters may be manually inserted into the program (Fig. 15.16).

In-Office

New techniques have allowed for the integration of the following; (1) CBCT, (2) digital scan, and (3) surgical template from a computer-aided design/computer-aided manufacturing (CAD/CAM). This type of template is usually milled or 3D printed (3D additive manufactured). Although the milled guides are the most dimensionally stable and less brittle, cost and the time-consuming nature are disadvantages. Affordable,

high-quality, in-office 3D printers are now available that produce guides with limited waste and minimal polymerization shrinkage, to combat these drawbacks. These 3D printers are highly accurate and produce precise anatomic models and surgical templates (Figs. 15.17 and 15.18).

Surgical Implant Placement With Surgical Template

A surgical template (guide) is defined as a prosthesis used to assist in the surgical placement of implants. In the literature, three different surgical template designs are based on surgical restriction: nonlimiting, partial-limiting, and complete-limiting design.

Surgical Restriction Templates

Non-limiting Design

A non-limiting surgical template is a template that allows for a generalized location of the ideal implant site. No actual directional guide is built into this type of template other than possibly the buccal or lingual contours of the ideal positioning of the teeth. A simple and inexpensive method to fabricate this type of template is duplication of an existing prosthesis or modification of Preston's clear splint for the diagnosis of tooth contours, tooth position, and occlusal form.[7]

The diagnostic wax-up is completed to evaluate the tooth size, position, contour, and occlusion in the edentulous regions where implants will be inserted. A full arch, irreversible hydrocolloid or polyvinyl siloxane impression is made of the diagnostic wax-up and poured in dental stone. On the duplicate cast of the wax-up teeth

a vacuum acrylic shell (0.060 to 0.080 inch) is vacuum formed to fit over the teeth and gingival contours of the buccal aspect of the ridge. If no natural teeth are present in the posterior, then the posterior portion of the template should be maintained to cover the retromolar pads or tuberosities and palate to aid in positioning.

The occlusal surface is trimmed over the ideal and optional implant sites, maintaining the facial and facial-occlusal line angle

of the surgical template. A black line then is drawn on the template with a marker to indicate the center of each implant and the desired angulation. This provides latitude for the implant dentist for implant placement, yet communicates the ideal tooth position and angulation during surgery.

The surgical template should relate to the ideal facial contour. Many edentulous ridges have lost facial bone, and the template can assist in determining the amount of augmentation required for implant placement or support of the lips and face. The surgical template may be used for a bone graft, and later the same template may be used for insertion of implants and again for implant uncovery.

• **Fig. 15.14** Safety Zone. Most software programs have safety zones that prevent placement of implants too close to a vital structure. In this example a 2.0-mm safety zone is present around the implant in the prevention of placement too close to the mandibular nerve.

• **Fig. 15.18, cont'd**

Partial-Limiting Design

The partial-limiting design incorporates a guided sleeve or a slot that allows for angulation of one drill size, usually the pilot drill. Therefore after the first drill is used, the remainder of the osteotomy sites are completed freehand. Various techniques can be used, including manual laboratory-fabricated templates or templates fabricated from a radiographic template, which is then converted into a surgical guide template.

Complete-Limiting Design

With the complete-limiting design, the position, angulation, and depth of the osteotomy are dictated by the guided tubes or sleeves, thus restricting any variation by the implant surgeon.

This type of template prevents any osteotomy error in the buccolingual and mesiodistal planes (i.e., complete-limiting). In addition, drill stops can be incorporated to prevent from over-preparing the site. With the complete-limiting design, the final position of the implant is known before the actual surgery. The complete-limiting design is ideal because the prosthetic final abutment or provisional restoration can be prefabricated for immediate provisionalization after implant placement (Fig. 15.19).

CBCT Templates by Support

When using a CBCT-generated treatment plan, the complete-limited design is the most common. There are three types of CBCT supported guides: tooth, bone, or tissue.

Tooth-Supported Guides

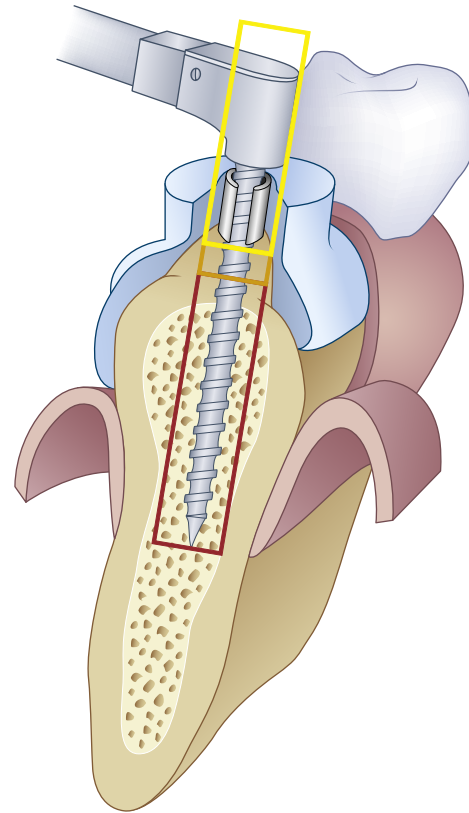
Tooth-supported guides are the most accurate and easiest guide to use.[8,9] These guides are mainly used in partially edentulous patients and are highly dependent on the accuracy of the impression and study cast. These guides typically are translucent, thus allowing visualization of the complete seating of the guide. No gaps should be present between the guide and teeth on the study cast or in the mouth. In addition, the guide must be stable and have no movement when lightly manipulated (Fig. 15.20).

Indications
1. Partially edentulous patients
2. Sufficient number of teeth for guide support

Requirements (one of the following)
1. Study cast + CBCT
2. Stereolithography (STL) STL file of study cast + CBCT
3. Digital impression + CBCT
• **Fig. 15.19** Complete-Limiting Template. Accurate template fabricated from cone beam computed tomography data.
• **Fig. 15.20** Tooth-Supported Guides. Surgical template that is completely supported by adjacent teeth and is the most accurate type of template.

Bone-Supported Guides

Bone-supported guides may be used in partially or fully edentulous patients. These guides require extensive full-thickness reflection to expose the bony ridges to allow proper seating of the guide. If bone modification is indicated, proper seating of the guide may be difficult, resulting in errors in implant placement. In some cases a bone reduction guide may be used before seating the bone-supported guide. It should be noted that small bone protuberances may exist that are below the resolution of the scan. Therefore meticulous evaluation of the bony contours should be evaluated before osteotomy site preparation (Fig. 15.21).

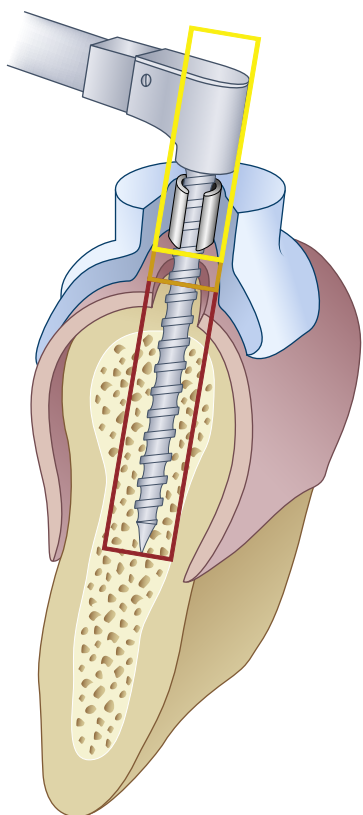
Indications
1. Edentulous patients
2. Partially edentulous patients (minimum of three teeth missing)


• **Fig. 15.21** Bone-Supported Guide. Surgical template that is completely supported by the existing bone. This type of template is often used when existing bone modification is indicated.

Soft Tissue–Supported Guides

Soft tissue–supported guides are usually indicated for completely edentulous patients, and these surgeries are usually termed *flapless*. In some cases the guides are difficult to seat correctly, especially if there exists overextension beyond the vestibule or floor of the mouth. Bite registrations are sometimes used to ensure ideal placement and positioning. In many cases, stabilizing pins or screws are placed to improve stability during osteotomy and implant placement. The most challenging cases for the use of soft tissue guides are the maxilla with flat palatal vaults and mandibles with high floor of the mouth with very little vestibule. Most full arch soft tissue–supported guides are fabricated via the "dual scan" technique (Fig. 15.22).

Indications
1. Only edentulous patients
2. Must have sufficient support
   a. Maxilla (palate)
   b. Mandible: sufficient vestibular or lingual support of prosthesis

Requirements
Dual Scan technique.
Studies: Accuracy studies comparing the three types of guides have shown tooth-supported guides being the most accurate, followed by bone-supported guides. Soft tissue guides are the least accurate, mainly because of the consistency and changes of the soft tissue.[8,10]


• **Fig. 15.22** Soft Tissue–Supported Guide. Surgical template that is completely supported by the soft tissue and is used mainly in flapless surgery.

CBCT by Drill Guidance (Fig. 15.23)

Pilot Guide (Fig. 15.24)

- Ideal for initial position (buccal-lingual, mesial-distal)
- Only first drill used
- Must freehand final drills and implant placement
- May have depth control (guided drills with stop)
  Uses: position and angulation of the implant

Universal Guide (Fig. 15.25)

- Compatible with all implant systems
- Drill guidance
- Depth control
- Finalize osteotomy with surgical system
- Must place implant freehand
  Uses: depth, position and angulation

Fully Guided (Fig. 15.26)

- Brand-specific surgical kits
- Drill guidance with depth control (full sequence)
- Implant guidance with depth control
- Immediate smile possible
  Uses: depth, position, angulation, and implant placement

Requirements of a Surgical Template

1. The template should allow the clinician to place the implant in the ideal position according to the x, y, and

CBCT GUIDED SURGERY

Drill Guidance   Drill Support

1. Pilot	1. Tooth
2. Universal	2. Bone
3. Fully Guided	3. Tissue
• **Fig. 15.23** Summary of Cone Beam Computed Tomography (CBCT) Surgical Templates.

• **Fig. 15.24** Pilot Guide. Surgical template depicting pilot guide placement in the anterior (# 8, # 9). After the first drill the clinician must complete the osteotomies freehand. The premolar implants are for universal guide placement and the molar sites are for fully guided implant placement.
• **Fig. 15.25** Universal Guide. Surgical template that can be used with any implant surgical system. All drills except the last drill are used from a universal surgical kit and special keys that fit directly into the surgical tubes.

z axes (i.e., buccolingual, mesiodistal, and apicocoronal dimensions).
2. The template must be stable and rigid when placed in the correct position. There should exist no "rocking" or incomplete seating of the template.
3. If the arch being treated has remaining natural teeth, the template should encompass as many teeth as possible to stabilize the template in position. When no remaining teeth

● **Fig. 15.26** Fully Guided. Surgical template that allows for all osteotomy drills to be used along with implant placement through the guide.

are present, the template should extend onto nonreflected soft tissue regions (i.e., the palate and tuberosities in the maxilla or the retromolar pads in the mandible) for tissue-borne templates.

4. Access for irrigation must be present because osteotomy drilling without irrigation will result in overheating the bone (necrosis) and lack of implant integration. The surgical guide tube diameter is approximately 0.2 mm larger; therefore adequate irrigation is difficult to achieve.

5. The template must be able to be sterilized to ensure surgical asepsis. Templates should be able to be disinfected with 3.2% glutaraldehyde and immersed in 0.12% chlorhexidine during the surgery.

Surgical Template Fabrication

Surgical guides are computer-generated drilling guides that are fabricated through the process of stereolithography. The surgical guide concept is based on the presurgical treatment plan, using specialized dental implant software for ideal implant positioning. The surgical osteotomy drill guides may be either bone-, teeth-, or mucosa-borne. Surgical templates have metal cylindrical tubes that correspond to the number of desired osteotomy preparations and specific drill diameters. The diameter of the drilling tube is approximately 0.2 mm larger than the corresponding drill, thus making angle deviation highly unlikely.

Clinical data and studies of computer-aided stereolithographic surgical guides have shown that implant placement is improved, and allow precise translation of a predetermined treatment plan directly to the surgical field. Nickenig et al.[9] evaluated the margin of error with freehand vs. guided implant placement and showed an apical deviation of 0.6 to 0.9 mm (guided) and 2.0 to 2.5 mm (freehand).

There are two types of surgical guide fabrication techniques from the treatment planning software: (1) laser photopolymerization of liquid resin, and (2) CAD/CAM.

Additional Types of Templates (Guides)

Stereolithographic Models

The fabrication of stereolithographic models is a laser-dependent rapid polymerization technique using sequential layers of special polymers that can duplicate the exact shape of the osseous anatomy.[10-13] These types of models include:

1. Surgical guide models used in the fabrication of surgical guides
2. Presurgical models used in the preoperative evaluation for implant placement, bone grafting, and orthognathic surgery (Fig. 15.27); and
3. Bone reduction guides: similar to reduction copings in conventional crown and bridge, and used to reduce osseous height before implant placement (Fig. 15.28).

Surgical Guidance Templates and Navigation Systems

Navigational systems, originally developed in neurosurgery, are now available to facilitate dental implant placement procedures during surgery. The navigational implant systems are based on CBCT imaging in combination with optical positioning, which assists in the accurate placement of dental implants.[15] Using preoperative planning software and real-time display, the depth and trajectory of the drilling sequence can be made to the specifics of preplanned position. Navigational systems have been shown to prevent damage to adjacent teeth and vital structures such as the inferior alveolar nerve.[16,17]

Dental implant surgical navigation is comparable with a GPS that is composed of three components: (1) localizer (Satellite in Space), (2) instrument or surgical probe (Tracking waves emitted by the GPS Unit), and (3) CBCT dataset (Road Map).[18]

Two different types of navigational systems are currently available: optical and electromagnetic. With an optical system, also referred to as an infrared system, infrared sensors along with light reflectors are fixed to the patient's head and a handheld probe to track the position of the instruments within the surgical field. Electromagnetic systems use an electromagnetic field and reference points on a device that is attached to the patient's head and a wired surgical instrument.

When placing implants with navigational surgery, a generalized protocol includes:

1. Stent (template) fabrication
   • A thermoplastic stent is fabricated directly on the patient's teeth.
2. CBCT imaging
   • The patient is scanned wearing the prefabricated stent, along with fiducial markers for cross-referencing jaw positions with the CBCT scan.
3. Implant treatment planning
   • The implant and prosthesis are treatment planned using CBCT software.
4. Implant surgery
   • Using the dynamic guidance process, implant placement is completed in real time. The surgical handpiece is equipped with a 3D positioning device, such as electromagnetic digitizers[19] or light-emitting diodes.[20] Extraoral markers attached to the surgical guide are also necessary so that the computer can analyze the positions of the jaw and the handpiece relative to each other. Continuous reevaluation of locations and matching to the CT scan data during surgery allow for visualization of osteotomies and comparison of planning and drilling. Some computer systems are equipped with audible or visual warnings when osteotomies deviate from pre-planned positions or when a vital structure is about to be entered.

• **Fig. 15.28** Bone Reduction Guide. (A) The amount of bone reduction is determined via the prosthetic treatment plan. (B) Outline of bone reduction showing the relationship between implants and bone height.

Studies

Research studies have shown this approach, although complex, can yield favorable results in the vicinity of 0.5 mm.[21,22] Other studies have shown guided surgery with CAD/CAM guides can achieve precision consistently within 1 mm of the planned implant location at the entrance and 5 degrees of the desired angulation[23] (Fig. 15.29).

Stackable Templates for Provisional Restorations (Immediate Smiles)

Taking the CT-generated technology to the next level involves fabricating provisional restorations before implant insertion. First, the virtual treatment plan is created by the implant dentist, followed by the manufacturer developing the computer-generated stereolithographic surgical guides. A dental laboratory uses the surgical guide and articulated diagnostic casts to fabricate provisional and (in some cases, final) prostheses. The implant dentist then uses the surgical guide to place the implants and abutments. The provisional (or final) prosthesis is then inserted immediately after the placement (Fig. 15.30).

Digital Technology

The use of dental CAD/CAM technology has become overwhelmingly popular today in all phases of dentistry. Chairside CAD/CAM systems for dental offices have allowed clinicians the opportunity to design, mill, and place ceramic restorations in a single appointment, along with treatment planning and fabricating implant restorations. The ability to fabricate various prosthetic restorations without using traditional dental laboratory methods has proved to be rewarding in many ways.

• **Fig. 15.30, cont'd**

The prototypic workflow for CAD/CAM typically begins with the accumulation of data either intraorally or from model-based scanners. The acquired digital data are processed using various specialized computer programs that build 3D-specific information via modeling algorithms. The information then can be analyzed and the acquired data altered via dental-specific CAD software to design a full array of restorations (Box 15.8).

Optical Impressions

Digital optical impressions are becoming the ideal and most accurate technique to be integrated into the clinical practice workflow. This technology is user friendly and requires a minimal learning curve. Digital impressions are advantageous over

Computer-navigated surgery (dynamic): use of a surgical navigation system that directly reproduces the virtual implant position from the CBCT data and allows for intraoperative implant position changes

traditional techniques in that they are more efficient, less time consuming, give greater patient comfort, and increase the profitability of the dental practice. The optical scan produces a positive replica of the teeth and tissues, not a negative replica such as a conventional impression. The position of teeth, soft tissue contours, existing restorations, edentulous spaces, and occlusal contacts can be evaluated easily using the high-resolution 3D images.

Studies have shown the accuracy of optical impressions to be far greater than conventional techniques. Because no dimensional discrepancies exist, such as with conventional impressions, the accuracy is far superior. In addition, instantaneous diagnosis and treatment planning can be accomplished, along with user-friendly patient educational resources (Box 15.9).

Digital Systems

Two types of digital systems are used today for clinical dentistry: (1) digital impression systems, and (2) CAD/CAM systems with clinical oriented software. For the dental laboratory, there exists a full spectrum of technology, including scanners, milling machines, and rapid prototype units. The dental laboratory has available greater sophisticated technology that is based on the CAD/CAM workflow of digital data, which are sent by the dental office. The data is usually transmitted electronically to the dental laboratory for use in multiple applications, which may include study cast fabrication, prosthetic design, implant treatment planning, and restoration fabrication. After obtaining the digital impression data, the laboratory may convert the digital impression into an analog model through the milling or rapid prototyping techniques.

Most CAD/CAM systems today require a direct method of data input for capture of intraoral conditions into the CAD software. These systems use a digital intraoral camera or scanner for image acquisition directly in the oral cavity. Some chairside CAD/CAM systems use intraoral camera systems to scan stone master casts produced by the clinician via the traditional technique. However, the goal of the digital impression system is to replace the traditional analog method of recording a patient's intraoral condition through the traditional impression technique.

Most of these digital chairside impression systems include both the hardware for scanning and the software for management of patient data. The learning curves with the various systems differ slightly, with the understanding of the specific imaging modality of the individual scanner (static images versus video streaming) being paramount.[24]

Digital Scanner Process

The digital scanner software will capture and store the digital data from the intraoral scan and also record all of the necessary medical and prescription information. The accumulated data are archived within the computer and then transmitted digitally to the laboratory via the Internet. Once transmitted, the data may be used by the dental laboratory for evaluation, design, or milling for the particular case. The laboratory may convert the digital impression into an analog model through the process of milling or rapid prototyping such as stereolithography.[25] After model fabrication, the laboratory may initiate a direct restoration or use the model as a reference or evaluation of the final CAD/CAM restoration (Fig. 15.31).

For chairside CAD/CAM systems the intraoral camera or scanner is capable of both designing and milling within the office setting; however, greater skill set is required.

Studies have shown that digital systems are more accurate than traditional techniques; however, meticulous care must be exercised in proper setup, consistent protocols, and calibration of milling parameters to ensure accuracy.[26]

Implant Treatment Planning

Significant improvements in CAD/CAM systems have allowed chairside and laboratory workflows to be integrated into implant therapy. CAD x-ray software has led to advancements in implant treatment planning and guided implant surgery. With the use of CBCT data, special implant software has allowed the integration of CAD data from digital impression systems to aid in restorative implant planning and placement. The specialized software may virtually wax-up teeth that is based on a functional and esthetic position, and export the virtual restoration into a CBCT software environment that aids in ideal implant positioning by use of a surgical template.

Restorative Implant Applications

CAD/CAM restorative applications have expanded into implant-level digital impressions, design and milling of custom healing abutments, custom prosthetic abutments, interim restorations, single-tooth prostheses, multiple and full arch prostheses, overdenture bar substructures, and telescopic implant prosthetics (Figs. 15.32–15.34).

Laboratory Implant Applications

Laboratories now have the capability to transition traditional clinical impressions and master casts to CAD/CAM implant prostheses. There exists a full array of laboratory-based benchtop scanners that vary from small scanners for simple impression, die, and model scanning, to large scanners that allow for scanning of fully articulated models.

Materials

Major advancements have been made in CAD/CAM technology, including material type, strength, chemistry, biocompatibility, and esthetics. Glass ceramic materials may be used for chairside fabrication of single-tooth restorations that can be adhesively bonded, with the future allowing for multiple teeth restorations. Materials such as zirconium oxide, commercially pure titanium, titanium alloy, noble metals and alloys, composite resins, wax, and fiber-reinforced acrylics are primarily the mainstay of laboratory-processed restorations. Laboratory-based CAD/CAM materials are supplied in a form where multiple restorations may be milled within one large blank of material (monolithic) to reduce material waste and costs.

Surgical Template Complications

Overheating the Bone

Because of the tolerances between the drill size and the surgical template tubes (i.e., usually less than 0.2 mm), inadequate irrigation often results. It is imperative to use as much irrigation as possible to prevent this complication.

1. This may involve the use of supplemental irrigation in the form of external irrigation (i.e., monoject curved syringe). In most templates the facial aspect may be altered, which allows for the delivery of additional saline solution (Fig. 15.35).
2. "Bone dance" preparation is most important in better quality bone (D1 or D2 bone). Bone dancing includes preparing the osteotomy in a "pumping" motion, which allows irrigation to enter into the template tube and osteotomy.[27]
3. Refrigerate irrigation: Barrak et al.[28] showed that cooling the irrigation fluid to 10°C is a safe method for implant site preparation and drilling through a drilling guide in terms of temperature control. The results showed no mean increase in temperature resulted. Therefore the sterile saline irrigation fluid may be stored in a refrigerator before surgical procedures.[28]

Inadequate Access

A common complication with surgical templates may exist with posterior implant placement. Because most guided drills are longer than standard surgical drills, in many cases the clinician may not have sufficient interarch space to drill the osteotomies (Fig. 15.36). In addition, most tubes used in surgical templates are approximately 5 mm in height, which further increases the difficulty in drill access. Many surgical template manufacturers may fabricate "buccal" or "lingual" accesses within the guides, which allows the clinician greater access (Fig. 15.37).
• **Fig. 15.35** (A) Monoject Curved Syringe, (B) Facial aspect of template altered to allow for external irrigation.

● **Fig. 15.36** (A) Posterior implant placement with cone beam computed tomography (CBCT) template limits available room for access. (B) Standard surgical drill versus guided drill with depth stopper is approximately 10 mm longer.
● **Fig. 15.37** Lateral Access Drilling Tube. Surgical drill is inserted from the lateral access, thereby decreasing amount of interocclusal space by approximately 5 mm. This allows for easier posterior guided implant placement in compromised interocclusal space cases.
• **Fig. 15.38** Difficulty in Seating Template. (A) Incision. (B and C) Reflection for access of template placement. (D) Seating template underneath soft tissue flap.

Difficulty in Template Seating

With bone-supported guides, many clinicians may have difficulty in seating the template because of the extent of required reflection. It is imperative that the template seats completely on bone, and no soft tissue prevents the seating. Therefore the incision and reflection should be preplanned to accommodate the size and peripheral extent of the surgical template (Fig. 15.38).

Summary

Digital technology is responsible for the most innovative advancement that dentistry has ever seen. Being able to obtain a digital replica of the oral-facial structures to enhance diagnosis and treatment planning, along with the use in surgical and prosthetic treatments, has changed implant dentistry forever. Optical scans of the teeth and soft tissue can be combined with 3D CBCT images to even further enhance the scope of implant dentistry. These advances in both CAD/CAM technology and dental material science are paving the future for applications of digital implant dentistry. The digital systems for CAD/CAM dentistry have allowed for the clinical workflow and final clinical outcomes for patient therapy in implant dentistry. As the CAD/CAM systems continue to evolve, the research and clinical evidence of the effectiveness of CAD/CAM dentistry will take implant dentistry to the next level.

Available Bone and Dental Implant Treatment Plans

CARL E. MISCH AND RANDOLPH R. RESNIK

Long-term success in implant dentistry requires the evaluation of more than 50 dental criteria, many of which are unique to this discipline.[1] However, the doctor's training and experience, and the amount and density of available bone in the edentulous site of the patient, are arguably the primary determining factors in predicting individual patient success. Today the prosthodontic requirements and desires of the patient should be determined first; then an array of factors that include patient force factors, bone density, key implant positions, implant number, and size are evaluated. In the past the available bone was not modified and was the primary intraoral factor influencing the treatment plan. Greenfield,[2] as early as 1913, documented the importance of the amount of available bone. However, with the predictability of bone augmentation today, patients with even large osseous defects are becoming candidates for dental implants. Therefore this chapter will describe the three-dimensional concept of available bone and the implant treatment options (Misch classification) for each type of bone anatomy.

Literature Review

The process of bone volume atrophy after tooth loss and loss of alveolus has been fully documented in the literature (Fig. 16.1).[3-19] Characteristic bone volume changes after tooth loss were evaluated in the anterior mandible by Atwood (Fig. 16.2).[4-6] The six described residual ridge stages are beneficial to appreciate the shapes and range of bone loss. Tallgren[7] reported the amount of bone loss occurring the first year after tooth loss is almost 10 times greater than the following years. The posterior edentulous mandible resorbs at a rate approximately four times faster than the anterior edentulous mandible.[8]

It has been suggested that, in the mandibular symphysis, females present higher total reduction and more rapid bone loss during the first 2 years.[9] More recent studies in complete denture wearers have confirmed the higher rate of resorption in the first year of edentulouness.[10,11] The anterior maxilla resorbs in height slower than the anterior mandible. However, the original height of available bone in the anterior mandible is twice as much as the anterior maxilla. Therefore the resultant maxillary atrophy, although slower, affects the potential available bone for an implant patient with equal frequency.[7] The changes in the edentulous anterior maxillary ridge dimension can be dramatic in height and width (up to 70%),

especially when multiple extractions are performed.[12] In addition, many patients lose additional bone by simultaneous alveolectomy procedures after tooth extraction before the delivery of a maxillary denture.[13] Although slight differences exist between different alveolectomy techniques, all are detrimental to the ridge volume.[14]

The residual ridge shifts palatally in the maxilla and lingually in the mandible as related to tooth position, at the expense of the buccal cortical plate in all areas of the jaws, regardless of the number of teeth missing.[15-19] However, after the initial bone loss, the maxilla continues to resorb toward the midline, whereas the mandibular basal bone is wider than the original alveolar bone position and results in the late mandible resorption progressing facially. This, in addition to a marked change in mandibular position, leads to the classical appearance of the denture wearer with a protruding chin and a mandibular lip.[20] The posterior maxilla loses bone volume faster than any other region. Not only can periodontal disease cause initial bone loss before the loss of teeth, the crestal bone loss is substantial after tooth extraction. In addition, the maxillary sinus after tooth loss expands toward the crest of the edentulous ridge. As a result the posterior maxilla is more often indicated for bone augmentation compared with any other intraoral location. In 1974, Weiss and Judy[21] developed a classification of mandibular atrophy and its influence on subperiosteal implant therapy. In 1982, Kent[22] presented a classification of alveolar ridge deficiency designed for alloplastic bone augmentation. Another bone volume classification was proposed by Lekholm and Zarb[23] in 1985 for residual jaw morphology related to the insertion of Brånemark fixtures. They described five stages of jaw resorption, ranging from minimal to extreme (Fig. 16.3). The mandibular resorption was described only in loss of height. All of the five stages of resorption in either arch used the same implant modality, surgical approach, and type of final prosthesis. In addition, as the bone volume decreased, the number of implants decreased.

A maxillary alveolar process of resorption after tooth loss after Atwood's description for the mandible was presented by Fallschüssel[24] in 1986. The six resorption categories of this arch ranged from fully preserved to moderately wide and high, narrow and high, sharp and high, wide and reduced in height, and severely atrophic. The classifications of Atwood, Zarb and Lekholm, and Fallschüssel do not describe the actual resorption process in chronologic order and are more descriptive of the residual bone.[25] Another bone resorption classification, which included the expansion of

the maxillary sinuses, was also proposed by Cawood and Howell[26] in 1988. Although similar to other categories, the bone volume changes are not reflective of the changes required for implant placement or bone-grafting procedures.
• **Fig. 16.1** Maxillary and mandibular atrophy after tooth loss was documented by J. Misch in 1922.

• **Fig. 16.2** Atwood presented a classification of bone loss after tooth loss in the anterior mandible in 1963.
In 1985, Misch and Judy established four basic divisions of available bone for implant dentistry in the edentulous maxilla and mandible, which follow the natural resorption phenomena of each region, and determined a different implant approach to each category.[1,27-33] The angulation of bone and crown height were also included for each bone volume, because they affect the prosthetic treatment. These original four divisions of bone were further expanded with two subcategories to provide an organized approach to implant treatment options for surgery, bone grafting, and prosthodontics (Fig. 16.4). The ability to organize the available bone of the potential implant site into specific related categories of common treatment options and conditions is of benefit to both the beginning and experienced clinician alike. Improved communication among health professionals and the collection of relevant specific data for each category are also beneficial. The Misch-Judy bone classification has facilitated these processes during the past three decades within the profession, universities, implant programs, and international implant societies. To understand the available bone classification, the clinician must first have a knowledge of dental implant size (i.e., width or diameter and height or length).

Implant Size

The category and design of the final prosthesis and key implant positions are first determined after a patient interview and evaluation of existing medical and dental conditions. The patient force factors and bone density are of particular note. The abutments necessary to support the restoration are then established in implant number and size, and without initial regard to the available bone conditions.

Implant Width (Diameter)

Manufacturers describe the root form implant in dimensions of width and length (e.g., Hahn 4.3 mm × 16.0 mm). The implant length corresponds to the height of available bone. Therefore this text refers to root form implant height or length. The width of a root form implant is most often related to the diameter and mesiodistal length of available bone. Most root form implants have a round cross-sectional design to aid in surgical placement; therefore the diameter of the implant corresponds to the implant width. Many manufacturers propose implants with a crest module wider than

• **Fig. 16.3** Lekholm and Zarb presented a classification of bone loss in the edentulous jaws in 1985.

| A | B | B–w | C–w | C–h | D |
● **Fig. 16.4** In 1985, Misch and Judy presented a classification of available bone (Divisions A, B, C, and D), which is similar in both arches. Implant, bone grafting methods, and prosthodontic-related treatment were suggested for each category of bone. *h*, Inadequate height; *w*, inadequate width.
● **Fig. 16.5** Tapered dental implant showing width and length along with distinct difference between crest diameter and body. (*From Glidewell Dental, Newport Beach, California.*)

the implant body dimension. Yet the often-stated dimension of the manufacturer is the smaller body width. For example, the Nobel Biocare 3.75-mm-diameter implant has a 4.1-mm crest module. The clinician should be knowledgeable of all implant dimensions, especially because the crestal dimension of bone (where the wider crest module dimension is placed) is usually the narrowest region of the available bone and where the implant is closest to an adjacent tooth (Fig. 16.5).

All teeth are not equal when considered as abutments for a prosthesis. The restoring dentist knows how to evaluate the surface area of the natural abutment roots. A healthy maxillary first molar with more than 450 mm^2 of root surface area constitutes a better abutment for a fixed prosthesis than a mandibular lateral incisor with 150 mm^2 of root support. The larger-diameter teeth correspond to the regions of the mouth with greater bite force. It is interesting to note the increase in surface area for natural teeth is most dependent on diameter and a change in design, more so than length.

All sizes and designs of implants do not have the same surface area and should not be considered as equals for prosthetic abutments. With a greater surface area of implant–bone contact, less stress is transmitted to the bone, and the implant prognosis improved. For a generic cylinder root form implant design, each 0.25-mm increase in diameter corresponds to a surface area increase of approximately 5% to 8%. Therefore a cylinder root form implant 1 mm greater in diameter will have a total surface area increase of approximately 20% to 30%. Because stress (S) equals force (F) divided by the functional area (A) over which it is applied (S = F/A), the greater diameter decreases the amount of stress at the crestal bone–implant interface. Because early bone loss relates to the crestal bone regions and prosthetic complications may be related to the crest module size of an implant, the width of the implant is much more critical than its height, after a minimum height has been obtained.

Implant Height (Length)

The height of the implant also affects its total surface area. A cylinder root form implant 3 mm longer provides a 20% to 30% increase in surface area. The advantage of increased height does not express itself at the crestal bone interface, but rather in initial stability of the implant, the overall amount of bone–implant interface, and a greater resistance to rotational torque during abutment screw tightening. The increased height of an implant in an
• **Fig. 16.6** Implant Length. Most implant systems include various implant sizes varying in length, with "long" implants being approximately 16 mm and "short" implants being approximately ~8 mm in length. *(From Glidewell Dental, Newport Beach, California.)*

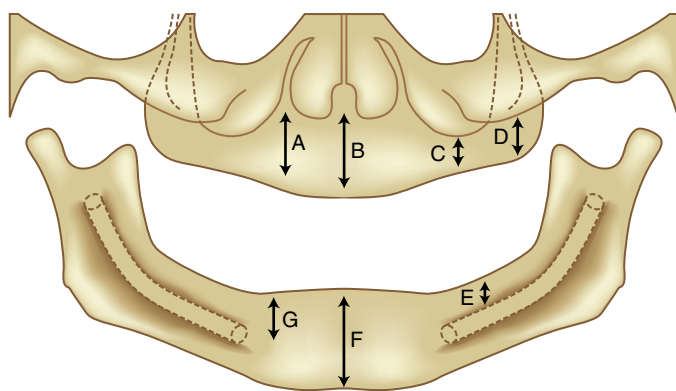
immediate extraction site larger in diameter than the implant also increases the initial bone contact percent, which can decrease the initial risk for movement at the interface. In addition, the crestal bone and opposing anatomic landmark are often composed of cortical bone, which is denser and stronger than trabecular bone. As a result, it may help stabilize the implant while the trabecular woven bone forms. In this way a direct bone–implant interface is encouraged. This may be of particular advantage when an immediate-loading protocol of implants is used for a transitional prosthesis. However, after the implant has healed, the crestal region is the zone that receives the majority of the stress. As a result, implant length is not as effective as the width to decrease crestal loads around an implant (i.e., prevent future bone loss).

The minimum height for long-term survival of endosteal implants is in part related to the density of bone. The denser bone may accommodate a shorter implant (i.e., 8 mm), and the least dense, weaker bone requires a longer implant (i.e., 12 mm). After the minimum implant height is established for each implant design and bone density, the width is more important than additional length. This chapter primarily presents the volume of bone requirements for ideal bone density situations or D2, which is coarse trabecular bone surrounded by porous to dense cortical bone.

Before 1981 the Brånemark screw–type implant body and osteointegrated approach was provided as a single diameter (3.75 mm) and was used only in the completely edentulous anterior maxilla and mandible.[34] The implant drills cut 10 mm deep, and the "10-mm" implant was 9 mm in length. By 1990 this philosophy had been expanded to all jaw regions and many implant sizes. However, failure rates reported in the literature for implants shorter than 9 mm tended to be higher independently from the manufacturer design, surface characteristic, and type of application.[35-50] For many years there existed a 12-mm height minimum that applied to most screw-shape endosteal implant designs in good-density (D2) bone.[51-53] However, with newer implant designs and implant coatings, this has been disproved. Currently many studies are available that discuss the high success of short dental implants (~8 mm). With newer implant designs and implant coatings, shorter length implants are gaining acceptance (Fig. 16.6).

Measurement of Available Bone

Available bone describes the amount of bone in the edentulous area considered for implantation. It is measured in width, height, length, angulation, and crown height space (CHS; Fig. 16.7).
• **Fig. 16.7** Available bone is measured in height (H), width (W), and length (L). Also considered are crown height space and angulation of bone (direction of force to the implant body).
• **Fig. 16.8** Cone beam computed tomographic image of implant placement with 2 mm safety zone to prevent neurosensory impairment.

Historically the available bone was never modified, and it dictated the implant position and size (or contraindicated implant treatment). Today if the bone is inadequate to support an ideal abutment for the intended prosthesis or bone grafting, the ideal site is often indicated, or an alternative site may be considered. As a general guideline, 2 mm of surgical error is maintained between the implant and a vital structure. Unfortunately, today many implants are placed in violation of this principle, leading to complications and morbidity of the patient. For example, implants placed too close to the mandibular canal may result in neurosensory impairment (Fig. 16.8). Implants placed into the nasal cavity or maxillary sinus may result in infection. Therefore, when evaluating an edentulous site, bone may be evaluated in four parameters: (1) height, (2) width, (3) length, and (4) angulation.


• **Fig. 16.9** The height of available bone is measured from the crest of the edentulous ridge to the opposing landmark. The opposing landmark may be in the maxillary canine region (*A*), floor of the nares (*B*), maxillary sinus (*C*), tuberosity (*D*), bone above the inferior mandibular canal (*E*), anterior mandible (*F*), or mandibular canine region (*G*).

• **Fig. 16.10** Minimum bone width for a 4-mm-diameter root form is 7 mm to allow for greater than 1.5 mm on the buccal and a minimum of 1.0 mm on the lingual.

Available Bone Height

The available bone height is first estimated by radiographic evaluation in the edentulous ideal and optional regions, where implant abutments are required for the intended prosthesis. A cone beam computed tomography (CBCT) survey is the most common method for the determination of the available bone height.

The height of available bone is measured from the crest of the edentulous ridge to the opposing landmark. The anterior regions are limited by the maxillary nares or the inferior border of the mandible. Usually the anterior regions of the jaws have the greatest height, because the maxillary sinus and inferior alveolar nerve limit this dimension in the posterior regions. The maxillary canine eminence region often offers the greatest height of available bone in the maxillary anterior.[54] In the posterior jaw region, there is usually greater bone height in the maxillary first premolar than in the second premolar, which has greater height than the molar sites because of the concave morphology of the maxillary sinus floor. Likewise the mandibular first premolar region is commonly anterior to the mental foramen and provides the most vertical column of bone in the posterior mandible. However, on occasion, this premolar site may present a reduced height compared with the anterior region, because of the mental foramen position or the anterior loop of the mandibular canal (when present) as it passes below the foramen and proceeds superiorly, then distally, before its exit through the mental foramen (Fig. 16.9).

The dilemma of available bone in implant dentistry involves the existing anatomy of the edentulous mandible and maxilla. The initial mandibular bone height is influenced by skeletal anatomy, with angle Class II patients having shorter mandibular height, and angle Class III patients exhibiting the greatest height. The initial edentulous anterior maxillary available bone height is less than the mandibular available bone height. The opposing landmarks for the initial available bone height are more limiting in the posterior regions. The posterior mandibular region is reduced because of the presence of the mandibular canal, approximately situated 12 mm above the inferior border of the mandible. As a result, in the areas where greater forces are generated and the natural dentition has wider teeth with two or three roots, shorter implants, if any, are often used and in insufficient number because of the anatomic limiting factors. A study of 431 patients revealed that in the partially edentulous maxilla and mandible, the placement of posterior implants at least 6 mm in length was possible in only 38% and 50%, respectively. The anterior regions of edentulous arches could receive implants 55% and 61% of the time, respectively.[55] The existing bone anatomy of the implant patient often
requires modification to enhance long-term implant success. For example, sinus grafts in the posterior maxilla permit the placement of posterior endosteal implants into restored bone height.

The available bone height in an edentulous site is a crucial dimension for implant consideration, because it affects both implant length and crown height. Crown height affects force factors and esthetics. In addition, bone augmentation is more predictable in width than height, so even when the width is inadequate for implant placement, bone grafting may be used to create a site ideal for restorative and implant insertion requirements.

Available Bone Width

The width of available bone is measured between the facial and lingual plates at the crest of the potential implant site. The crest of the edentulous ridge is most often supported by a wider base. In most areas, because of this triangular-shaped cross section, an osteoplasty can be performed that results in a greater width of bone, although of reduced height. However, the anterior maxilla often does not follow this rule, because most edentulous ridges exhibit a labial concavity in the incisor area, with an hourglass configuration. Crest reduction affects the location of the opposing landmark, with possible consequences for surgery, implant height selection, appearance, and the design of the final prosthesis. This is particularly important when a type 1 fixed prosthesis (FP-1) is planned, with the goal of obtaining a normal contour and proper soft tissue drape around a single tooth replacement.

After adequate height is available, the next most significant criterion affecting long-term survival of endosteal implants is the width of the available bone. Root form implants of 4-mm crestal diameter usually require a minimum of 7 mm of bone width (4.0 mm + 2.0 mm buccal + 1.0 mm lingual) to ensure sufficient bone thickness and blood supply around the implant for predictable survival. These dimensions provide more than 1.5 mm of bone on the buccal side and at least 1.0 mm on the lingual side. When measuring necessary bone width, always determine the true diameter of the implant at the crest module, because many implant systems base the diameter on the root area of the implant, not the neck area. Because the bone usually widens apically, this minimum dimension rapidly increases. For root form implants the minimum bone thickness is located in the midfacial and midlingual contour of the crestal region exclusively (Fig. 16.10). The crestal aspect of the residual ridge is often

cortical in nature and exhibits greater density than the underlying trabecular bone regions, especially in the mandible. This mechanical advantage permits immediate fixation of the implant, provided this cortical layer has not been removed by osteoplasty.

The initial width of available bone is related to the initial crestal bone loss after implant loading. Edentulous ridges that are greater than 6 mm in width have demonstrated less crestal bone loss than when minimum bone dimensions are available. In general, extraction sockets having more width at the crest also lose less bone during initial healing than sites with minimum width of cortical plates on the facial or lingual of the extraction site.

Available Bone Length

The mesiodistal length of available bone in an edentulous area is often limited by adjacent teeth or implants. As a general rule the implant should be at least 1.5 mm from an adjacent tooth and 3 mm from an adjacent implant. This dimension not only allows surgical error but also compensates for the width of an implant or tooth crestal defect, which is usually less than 1.4 mm. As a result, if bone loss occurs at the crest module of an implant or from periodontal disease with a tooth, the vertical bone defect will not spread to a horizontal defect and cause bone loss on the adjacent structure.[56] Therefore in the case of a single-tooth replacement, the minimum length of available bone necessary for an endosteal implant depends on the width of the implant. For example, a 5-mm-diameter implant should have at least 8 mm of mesiodistal bone, so a minimum of 1.5 mm is present on the buccal and 1.0 mm on the lingual. A minimum mesiodistal length of 7 mm is usually sufficient for a 4-mm-diameter implant. Of course the diameter of the implant is also related to the width of available bone and, in multiple adjacent sites, is primarily limited in this dimension. For example, a width of bone of 5.0 mm without augmentation requires a 3.5-mm or smaller implant, with inherent compromises (such as minimal surface area and greater crestal stress concentration under occlusal loads). Therefore in the narrower ridge, it is often indicated to place two or more narrow-diameter implants when possible to obtain sufficient implant–bone surface area to compensate for the deficiency in width of the implant. Because the implants should be 3 mm apart and 1.5 mm from each tooth, 13 mm or more (3.5 mm + 3.5 mm + 3.0 mm between implants + 1.5 mm + 1.5 mm from adjacent teeth) in available bone mesiodistal length may be required when the narrower implant dimensions are used to replace a posterior tooth.

The ideal implant width for single-tooth replacement or multiple adjacent implants is often related to the natural tooth being replaced in the site. The tooth has its greatest width at the interproximal contacts, is narrower at the cement-enamel junction (CEJ), and is even narrower at the initial crestal bone contact, which is ideally 2 to 3 mm below the CEJ (or 3 mm below the free gingival margin).[57] The ideal implant diameter corresponds to the width of the natural tooth 2 mm below the CEJ, if it also is 1.5 mm from the adjacent tooth. In this way, the implant crown emergence through the soft tissue may be similar to a natural tooth. For example, a maxillary first premolar is approximately 8 mm at the interproximal contact, 5 mm at the CEJ, and 4 mm at a point 2 mm below the CEJ. Therefore a 4-mm-diameter implant (at the crest module) would be the ideal implant diameter, if it also is at least 1.5 mm from the adjacent roots (2 mm below the CEJ) (Fig. 16.11).

Available Bone Angulation

Bone angulation is the fourth determinant for available bone. The initial alveolar bone angulation represents the natural tooth root trajectory in relation to the occlusal plane. Ideally it is perpendicular to the plane of occlusion, which is aligned with the forces of occlusion and is parallel to the long axis of the prosthodontic restoration. The incisal and occlusal surfaces of the teeth follow the curve of Wilson and curve of Spee. As such the roots of the maxillary teeth are angled toward a common point approximately 4 inches away. The mandibular roots flare, so the anatomic crowns are more lingually inclined in the posterior regions and labially inclined in the anterior area compared with the underlying roots. The first premolar cusp tip is usually vertical to its root apex.

The maxillary anterior teeth are the only segment in either arch that does not receive a long axis load to the tooth roots, but instead are usually loaded at a 12-degree angle. As such, their root diameter is greater than the mandibular anterior teeth. In all other regions of the mouth the teeth are loaded perpendicular to the curve of Wilson or curve of Spee. Rarely does the bone angulation remain ideal after the loss of teeth, especially in the anterior edentulous arch (Fig. 16.12). In this region, labial undercuts and resorption after tooth loss[12,15,16] often mandate greater angulation of the implants or correction of the site before insertion. In the posterior mandible the submandibular fossa mandates implant placement with increasing angulation as it progresses distally. Therefore in the mandibular second premolar region the angulation may be 10 degrees to a horizontal plane; in the first molar areas, 15 degrees; and in the second molar region, 20 to 25 degrees.

The limiting factor of angulation of force between the body and the abutment of an implant is correlated to the width of bone. In edentulous areas with a wide ridge, wider root form implants may be selected. Such implants may allow up to 25 degrees of divergence with the adjacent implants, natural teeth, or axial forces of occlusion with moderate compromise. The angled load to an implant body increases the crestal stresses, but the greater diameter implant decreases the amount of stress transmitted to the crestal bone. In addition, the greater width of bone offers some latitude in angulation at implant placement. The implant body may often be inserted so as to reduce the divergence of the abutments without compromising the permucosal site.

The narrow yet adequate width ridge often requires a narrower design root form implant. Compared with larger diameters, smaller-diameter designs cause greater crestal stress and may not offer the same range of custom abutments. In addition, the narrower width of bone does not permit as much latitude in placement regarding angulation within the bone. This limits the acceptable angulation of bone in the narrow ridge to 20 degrees from the axis of the adjacent clinical crowns or a line perpendicular to the occlusal plane.

Divisions of Available Bone

Division A (Abundant Bone)

Division A abundant bone often forms soon after the tooth is extracted. The abundant bone volume remains for a varied amount of time that is dependent on many factors. Studies have shown the original crestal width may be reduced by more than 30% within 2 years.[12] Division A bone corresponds to abundant available bone in all dimensions (Box 16.1 and Fig. 16.13). It should be emphasized that the available bone height may be greater than 20 mm for Division A, but this does not mean the implant length must be equal to the bone height. Because the stresses to the implant interface are dependent on bone density, the ideal implant length is bone-density and force-factor driven.
• **Fig. 16.11** (A) Determining ideal position between adjacent tooth roots, (B) measuring spacing between roots, (C) measuring clinical crown space, and (D) verifying ideal position in third dimension.
• **Fig. 16.12** Bone Angulation. (A) Mandibular anterior angulation contraindicating dental implants. (B) Maxillary anterior depicting nonideal bone trajectory issues because of extensive atrophy.

The Division A width of more than 6.5 mm (1.5 mm on buccal, 1.0 mm on lingual) is predicated on an implant diameter of at least 4 mm at the crest module, because abundant long-term data have been published regarding this implant size.[35,43] In abundant bone width (A+ bone) of greater than 7 mm a wider (5-mm-diameter) implant may be inserted, provided that 1.5 mm of bone remains around the buccal and 0.5 mm on the lingual aspects of the implant. Osteoplasty may often be performed to obtain additional bone width.

The implant choice in Division A bone is a root form of 4 mm or greater in diameter. A larger-diameter implant is suggested in the molar regions (5–6 mm in diameter). The length of the implant (8–16 mm) is primarily dependent on the bone density and secondarily dependent on the force factors. Longer implants

- Width > 7 mm
- Height > 10 mm
- Mesiodistal length > 7 mm
- Angulation of occlusal load (between occlusal plane and implant body) < 25 degrees
- CHS ≤ 15 mm
- Prosthesis:
  - Fixed: FP-1 likely, possible FP-2
  - Removable: RP-4 or RP-5

• **Fig. 16.13** Division A Bone. (A) Cone beam computed tomographic image depicting adequate bone width and length. (B) Because of adequate bone, Division A implant inserted ideally in the bone.

- The larger the diameter of an implant, the greater the surface area and the less stress distributed through the crestal bone region.
- The larger-diameter implants are closer to the lateral cortical plates of bone, which have greater density and therefore increased strength, modulus of elasticity, and bone-implant contact percentages.
- The larger-diameter implants are less likely to fracture, because the strength of the material is increased by a power of four related to the radius of the implant. (A 4-mm-diameter implant is 16 times stronger than a 2-mm-diameter implant.)
- The smaller-diameter implants (~ 3.0 mm) are often one piece to decrease the risk for fracture. The one-piece implants require an immediate restoration, rather than a submerged or one-stage approach. As such, likely loading and micromovement may occur at the bone–implant interface, with an increased risk for crestal bone loss and/or implant failure.
- The emergence profile angle of the crown is related to the implant diameter. The larger-diameter teeth can be most esthetically restored with a wider-diameter implant.
- The larger the implant diameter, the less stress applied to the abutment screw, and therefore complications such as screw loosening or fracture are less likely.
- The larger-diameter abutment provides greater cement retention for the final restoration crown.
- Oral hygiene procedures are more compromised around smaller-diameter implants restored with greater emergence profile angles and over contoured restorations.
- The crest module and crestal portion of many two-piece, small-diameter implants are smooth metal to increase the interbody wall thickness, thus creating shear loads to the crestal bone and an increased risk for bone loss.
- Implant costs to the patient are related to implant number, not diameter. Therefore increases in implant numbers for smaller-diameter implants increase the cost to the patient (and the doctor).
- Division A root form implants are designed for variable bone density and can provide the greatest range of prosthetic options.

are usually suggested in immediate placement and loading treatment options. Division A bone ideally should not be treated with smaller-diameter implants for the final prosthesis. There are several advantages to the use of implants equal to or greater than 4 mm in diameter, compared with smaller-diameter implants (Box 16.2).

A patient with Division A bone should be educated that this is the most ideal time to restore his or her edentulous condition with implants. All too often the doctor fails to inform the patient about the rapid decrease in bone volume width and the consequences of delaying treatment. When the bone volume is Division A, there is a decrease in treatment costs, with a reduction in the number and complexity of surgeries to the edentulous area with significant benefits to the patient. Unfortunately, these patients may not have significant problems with their existing restoration and therefore may not be motivated to address the situation. As the bone resorbs and the problems arise, a greater appreciation for the benefits of implant-supported restorations are realized. Just as the restoring dentist explains the need to replace a single tooth before tipping and extrusion of adjacent teeth and the risk for additional tooth loss, the patient should be educated as to the benefit of implant treatment while the area presents abundant bone.

The prosthetic options for Division A can be all fixed and removable options. An FP-1 prosthesis definitely will require a Division A ridge. An FP-2 prosthesis most often also requires a

Division A bone. The FP-2 restoration is the most common posterior restoration supported by multiple adjacent implants in partially edentulous patients, because of either bone loss or osteoplasty before implant placement. An FP-3 prosthesis is most frequently the option selected in the anterior Division A bone when the maxillary smiling lip position is high or a mandibular low lip line during speech exposes regions beyond the natural anatomic crown position.

For removable implant overdentures in Division A bone the final position of the tooth and superstructure bar must be evaluated before surgery. A limited CHS may be present with Division A bone, and a final type 4 removable prosthesis (RP-4) or RP-5 result may require a significant osteoplasty before implant placement. Division A bone may represent a contraindication for high-profile O-ring attachments or superstructures placed several millimeters above the tissue for hygiene considerations, because of a compromised CHS to accommodate prosthetic components (Fig. 16.14). In cases of inadequate CHS, prosthesis complication failure in the form of tooth debonding, fractured prosthesis, or attachment problems may occur.

Division B (Barely Sufficient Bone)

As the bone resorbs, the width of available bone first decreases at the expense of the facial cortical plate, because the cortical bone is usually thicker on the lingual aspect of the alveolar bone,
• **Fig. 16.14** Osteoplasty indicated (only if the crown height space is not compromised) to change a Division B ridge to a Division A.

• **BOX 16.3** **Division B Dimensions**

- 2.5 to 7 mm wide
  - B+: 4 to 7 mm
  - B–w: 2.5 to 4 mm
- Height > 10 mm
- Mesiodistal length > 6 mm

  - Removable: RP-4 or RP-5

---

especially in the anterior regions of the jaws. Studies have shown a possible 25% decrease in bone width the first year and a 40% decrease in bone width within the first 1 to 3 years after tooth extraction.[12,15,16] The resulting narrower ridge is often inadequate for many 4-mm-diameter root form implants. Slight-to-mild osseous atrophy is often used to describe this clinical condition. After Division B bone volume is reached, it may remain for more than 15 years in the anterior mandible.[5] However, the posterior mandibular height resorbs four times faster than the anterior region. The posterior maxillary regions exhibit less available bone height (i.e., as a consequence of sinus expansion) and have the fastest decrease of bone height of any intraoral region. As a result the posterior regions of the jaws may become inadequate in height (C–h) earlier than the anterior regions.

Division B bone offers sufficient available bone height with compromised width (Box 16.3). The Division B available bone width may be further classified into ridges 4 to 7 mm wide and B minus width (B–w) 2.5 to 4 mm wide, where bone grafting techniques are usually indicated (Fig. 16.15). The minimum mesiodistal width of a Division B ridge is less than that of Division A; a smaller-diameter implant (i.e., 3 mm) may be used depending on the area of concern and force factors. Because the ridge width and implant diameter are narrower and forces

• **Fig. 16.15** Osteoplasty contraindicated because bone augmentation is required. If osteoplasty is performed, a compromised crown height space will result.
• **Fig. 16.16** Division B bone ridge may be modified by osteoplasty to increase the width of bone. The osteoplasty increases the crown height space for the prosthesis.

increase as the angle of load increases, the angulation of occlusal load is also less. A CHS of 15 mm or less (similar to Division A) is necessary in Division B to decrease the moment of forces with lateral or offset loads, especially because of the narrower width dimension.

Three treatment options are available for the Division B edentulous ridge:
1. Modify the existing Division B ridge to Division A by osteoplasty to permit the placement of root form implants 4 mm or greater in width (Fig. 16.16). When more than 10 mm of bone height results, the bone converts to Division A. When less than 10 mm of bone height results, the bone converts to Division C–h.
2. Insert a narrow Division B root form implant (e.g., 3.0-mm implant for maxillary lateral incisors or mandibular anteriors).
3. Modify the existing Division B bone into Division A by bone augmentation.

FP-1 FP-3
• **Fig. 16.17** Options to treat a Division B ridge in the anterior mandible include a narrow implant with a final prosthesis closer to anatomic dimensions (FP-1) (left) or osteoplasty with Division A root forms and extended crown heights (FP-2 or FP-3) (right).

The final prosthesis must first be considered to select the ideal approach to this bone category. When a Division B ridge is changed to a Division A by osteoplasty procedures, the final prosthesis design has to compensate for the increased CHS. For example, before surgery the available bone height may be compatible with an FP-1 prosthetic design. If at the time of surgery the ridge is found deficient in width for implant placement, it is not unusual to remove 1 to 3 mm of crestal bone before reaching a Division A width. This will result in the final restoration, requiring an additional 3 mm in height and prosthesis type changing to an FP-2 or FP-3 (Fig. 16.17).

The osteoplasty option is less likely the treatment of choice for an FP-1 prosthesis with a B–w ridge, because even greater bone height reduction is required. Therefore changing a Division B to an A will most likely always result in the fixed prosthesis being a FP-2 or FP-3.

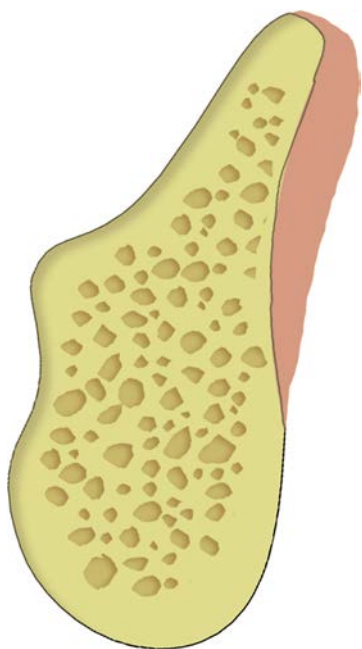
The most common approach is to modify the narrower Division B ridge into another bone division by osteoplasty when the final prosthesis is an implant overdenture (Figs. 16.18 to 16.20). The edentulous ridge crest may be reduced, thereby increasing the width of the ridge. If the CHS is less than 15 mm, the ridge division becomes Division A with a greater width than 6 mm, ideal for a RP-4 or RP-5. If the ridge height is reduced so that the CHS is greater than 15 mm, the bone division may be changed to Division A. However, caution should be exercised to not decrease the height to a Division C–h bone volume, where vertical cantilevers or lateral forces may be present on the prosthesis. An RP-4 or RP-5 restoration most often requires option 1—osteoplasty—where adequate CHS is created to permit the fabrication of the overdenture and superstructure bar with attachments without prosthetic compromise.

The second main treatment option for the narrow available bone Division B is the small-diameter root form implant. Smaller-diameter root form implants (~3.0 mm, not "mini-implants") are designed primarily for Division B available bone. The Division B bone is narrower, so the implant body of the implant must bisect
• **Fig. 16.18** Evaluation of necessary amount of osteoplasty is determined by evaluating the position of the final prosthesis.
• **Fig. 16.19** Osteoplasty completion with ridge reduction bur.

• **Fig. 16.20** Evaluation of necessary interocclusal space for final prosthesis via a diagnostic template fabricated from the patients existing prosthesis or diagnostic wax-up.

the bone and implant angulation becomes less flexible. The Division B root form implants present several inherent disadvantages compared with the larger-diameter implants (Box 16.4).[56-61] As a result of these concerns for the Division B root form, this option is mostly used for single-tooth replacement of a maxillary lateral incisor or mandibular incisors where the restricted available bone is in mesiodistal width and buccal-lingual length.[62,63]

• BOX 16.4   Disadvantages of Division B Root Forms

1. Almost twice the stress is concentrated at the top crestal region around the implant.
2. Less overall surface area means that lateral loads on the implant result in almost three times greater stress than Division A root forms.
3. Fatigue fractures of the abutment post are increased, especially under lateral loads.
4. The crown emergence profile is less esthetic (except for maxillary lateral or mandibular incisors).
5. Conditions for daily care are compromised around the cervical aspect of the crown.
6. The implant design is often poor in the crestal region. To increase implant body wall thickness to reduce fracture, no threads or compressive force design are present, but this further increases stress and the amount of shear loads to bone.
7. The angle of load must be reduced to less than 20 degrees to compensate for the small diameter.
8. Two implants are often required for proper prosthetic support, unless anterior single-tooth replacement for maxillary laterals or mandibular incisors, so surface area ends up being greater because of implant number, *not* size.
9. Implant costs are not related to diameter, so an increase in implant number results in greater cost to the doctor and patient.


• **Fig. 16.21** Division B ridge anatomy may be modified to Division A by augmentation procedures.

The third alternative treatment for Division B bone is to change the Division B ridge into a Division A by grafting the edentulous ridge with autogenous or a combination of autograft and allograft with or without guided bone regeneration techniques (Fig. 16.21). If this graft is intended for implant placement, a healing period of at least 4 to 6 months is needed for maturation of the graft and before endosteal implants should be placed. An FP-1 restoration most often mandates the augmentation option. The emergence profile angle of the final crown, which does not compromise hygiene, requires a Division A root form implant with the exception of maxillary lateral incisors or mandibular incisors.

Stress factors may also dictate the surgical approach to Division B bone. In the presence of unfavorable stress factors, the number and width of abutments should be increased without increasing the CHS to provide a greater surface area of resistance to the magnified forces. Augmentation is indicated in Division B bone to accomplish this goal.

The success of regenerative materials for augmentation correlates with the number of osseous walls in contact with the graft material.[64] Therefore a five-wall bony defect as a tooth socket forms bone more predictable with an allograft versus a one-wall defect as an onlay graft. The distinction between B and B–w is especially important when augmentation is the method of choice. Bone augmentation is most predictable when the volume to augment is minimal and is for width, and least predictable when height is desired. For example, usually a width increase of 1 to 3 mm may be obtained with an allograft and a guided bone regeneration, whereas greater than 3 mm of width is more predictable with an autologous block graft. Some regions of the mouth are better suited than others for height augmentation (e.g., the floor of the maxillary sinus versus the posterior mandible).

Bone Spreading

An alternative for the augmentation approach for Division B bone is bone spreading. A narrow osteotomy may be made between the bony plates, and bone spreaders are sequentially tapped into the edentulous site. The Division B ridge may be expanded to a Division A with this technique and allow a Division A implant or an allograft to be inserted.[65]

The Division B–w ridge requires greater than 2 mm of width increase, and therefore autologous bone is beneficial to predictably grow bone width. If the Division B–w ridge contour should be altered for improved prosthodontic relationships, a block graft of autogenous bone is usually indicated. The autograft may be harvested from an intraoral region (such as the symphysis or ramus) and placed along the lateral aspect of the ridge that corresponds to ideal arch form (Fig. 16.22). The implant placement should be delayed until after the augmentation process to permit ideal implant placement and to ensure complete bone formation before placing the implant. In most cases, Division A root form implants may be placed 4 to 6 months after the autologous bone graft.[64-66]

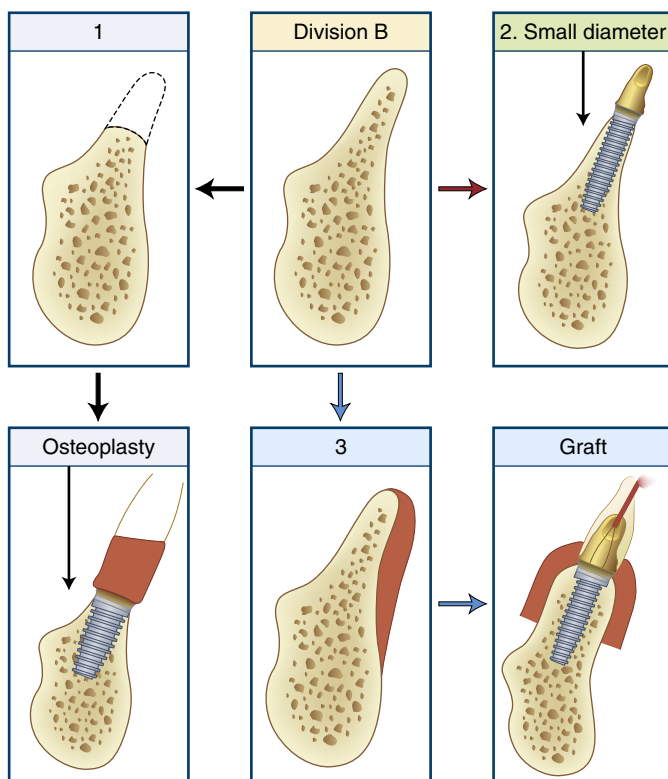
The patient delaying treatment with a Division B bone condition should be notified of future bone volume resorption. The augmentation of bone in height is much less predictable and requires more advanced techniques than the augmentation of width alone. For example, the patient may not be experiencing problems with a maxillary denture, but the Division B bone will resorb in height and decrease the stability and retention of the removable soft tissue–supported prosthesis over time. When treatment is delayed, until patient problems begin, the overall result may be more difficult to achieve and more costly to the patient.

The final prosthesis type for Division B ridges is dependent on the surgical option selected. Grafted ridges will more often be used when a fixed prosthesis is desired, whereas ridges treated with osteoplasty before implant placement are likely to be supporting removable prostheses. The most common osteoplasty driven treatment for a Division B ridge is the anterior mandible. The treatment option may be influenced by the region to be restored. For example, in the partially edentulous anterior maxilla, augmentation is most often selected because of esthetics. In the edentulous anterior mandible, osteoplasty is common because esthetics are less of a concern (Fig. 16.23).

Division C (Compromised Bone)

The Division C ridge is deficient in one or more dimensions (width, length, height, or angulation) (Box 16.5) regardless of the position of the implant body into the edentulous site. The resorption pattern occurs first in width and then in height. As a result the Division B ridge continues to resorb in width, although height of bone is still present, until it becomes inadequate for any design of endosteal implant. This bone category is called Division C minus width (C–w) (Fig. 16.24). The resorption process continues, and the available bone is then reduced in height (C–h).

Moderate-to-advanced atrophy may be used to describe the clinical conditions of Division C. The posterior maxilla or mandible result with Division C–h more rapidly than the anterior regions because the maxillary sinus or mandibular canal limit vertical height sooner than the opposing cortical plates in the anterior regions. When the anterior mandible is C–h, the floor of the mouth is often level or below the residual mandibular crest of the ridge. During swallowing, it may prolapse over the residual crest and implant sites, causing constant irritation of the permucosal implant posts and impairing proper design of the prosthetic superstructures.

• **Fig. 16.22** (A) Reentry of an onlay ramus bone graft to a Division B–w ridge. The ridge is now converted to Division A. (B) Root form implant may now be inserted without compromise to implant position or existing width of bone.


• **Fig. 16.23** Division B Summary; (1) Osteoplasty may compromise crown-height space, (2) Small diameter implant may be biomechanically non-ideal, (3) Augmentation is the most ideal treatment as it restores implant to pre-existing conditions.

• **BOX 16.5   Division C Bone**

- Width (C–w bone): 0 to 2.5 mm
- Height (C–h bone):
- Angulation of occlusal load (C–a bone): >30 degrees
- CHS: >15 mm
- Prosthesis:
  - Fixed: most likely FP-2 or FP-3
  - Removable: ideally RP-5 because of increased CHS
• **Fig. 16.24** Bone resorbs from Division A to Division B rapidly and from Division C–w to C–h to Division D slowly. There exists a long plateau from Division B to Division D. This is why it is important to prevent bone loss immediately after an extraction to resorb.

The doctor must appreciate that the C–w bone will resorb to a C–h ridge as fast as the A resorbs to B and faster than B resorbs to C–w. In addition, without implant or bone graft intervention, the C–h available bone will eventually evolve into Division D (severe atrophy). Many completely edentulous patients are treated with implants in the mandible and conventional dentures in the maxilla, primarily because the mandibular C–h arch is more often the cause of patient complaint (Fig. 16.25). However, the patient should be educated about the future maxillary bone loss that will render maxillary implant treatment almost impossible without advanced bone graft procedures before placement.

The Division C edentulous ridge does not offer as many elements for predictable endosteal implant survival or prosthodontic management compared with Divisions A or B. Anatomic landmarks to determine implant angulations or positions in relation to
● **Fig. 16.25** Division C Premaxilla: Significant ridge resorption leading to a C-w and then a C-h ridge.

the incisal edge are usually not present; therefore greater surgical skill is required. The doctor and patient should realize that Division C ridge implant-supported prostheses are more complex and have slightly more complications in healing, prosthetic design, or long-term maintenance. On the other hand, the patients usually have greater need for increased prosthodontic support. In spite of the reduced bone volume, altered treatment plans that decrease stress can provide predictable, long-term treatment.

There is one uncommon subcategory of Division C, namely, C–a. In this category, available bone is adequate in height and width, but angulation is greater than 30 degrees regardless of implant placement (Fig. 16.26). When present, this condition is most often found in the anterior mandible; other less-observed regions include the maxilla with severe facial undercut regions or the mandibular second molar with a severe lingual undercut. Root form implants placed in this bone category may be positioned within the floor of the mouth and compromise prosthetic reconstruction, speech, and comfort (Fig. 16.27).

Implant treatment planning for the completely edentulous C–h arch is more complex than in Division A or B. There are seven implant treatment options for Division C bone (Box 16.6); all of these options require greater clinician skill than similar treatment modalities in Division A or B.

Treatment Options

A C–w ridge may be treated by osteoplasty, which most likely will change the ridge to a C–h, not Division A (i.e., because of the lack of height after osteoplasty). This most often occurs in the mandibular anterior region to allow for root form implants. On occasion the C–w osteoplasty may convert the ridge to Division D, especially in the posterior mandible or maxilla. Care should be taken not to let this occur, because bone grafting procedures will be contraindicated or more challenging after the height has been reduced.

Another treatment option is to alter the Division C by grafting. After the ridge is augmented, it is treated with the options available in the acquired bone division. The patient who desires a fixed prosthesis often requires an autogenous graft before implant placement to acquire proper lip support and ideal crown height.

• BOX 16.6	Division C Treatment Options

- Osteoplasty (C–w)
- Root form implants (C–h)
- Augmentation procedures before implant insertion
- Subperiosteal implant (C–h, C–a partial, or completely edentulous mandible)
- Disk Implants

Augmentation of C–w is most often used when prosthetic guidelines require a fixed restoration or excess force factors require greater surface area implants and improved biomechanics for the prosthesis. The C–w augmentation is more difficult than for Division B bone, because the need for bone volume is greater, yet the recipient bed is more deficient. Therefore block bone grafts are usually indicated.[66-68] Soft tissue complications, such as incision line opening and lack of papilla, are more common in C–w augmentations compared with Division B.

The C–h posterior maxilla is a common and unique edentulous condition. The residual ridge resorbs in width and height after tooth loss, similar to other regions. However, because of the initial extensive ridge width dimension, a decrease of 60% in dimension still is adequate for 4-mm-diameter implants. In addition to the residual alveolar bone resorption, the maxillary sinus expands after tooth loss (pneumatization). As a result the available bone height is decreased from both the crestal and apical regions. Sinus grafts, which elevate the maxillary sinus floor membrane and then graft the previous sinus floor region, were developed by Tatum[65] in the mid-1970s. This area is the most predictable intraoral region to augment in excess of 10 mm of vertical bone. Therefore sinus grafting (either lateral wall or transcrestal) is often prescribed before placing endosteal implants in the C–h posterior maxilla (Fig. 16.28).

Various implant approaches are used in the Division C–h available bone. Shorter endosteal implants are the most common options.[52,53] A C–h root form implant is usually 4 mm or greater in width at the crest module and 10 mm or less in height. Many previous studies indicated implant survival is decreased once an implant is 10 mm or less in height.[35,69,70] For example, a large multicenter study of 31 different sites and 6 different implant designs observed 13% failure with 10-mm implants, 16% failure with 8-mm implants, and 25% failure with 7-mm-long implants.[35] The implant failure does not occur after surgery but rather after prosthetic delivery. However, many recent studies have shown high success rates for short implants in comparison with longer implants.

When endosteal root form implants are used in Division C–h bone with greater crown heights, additional implants should be placed to increase the overall implant-bone surface area, and the prosthesis should load the implants in an axial direction. Because the CHS is greater than 15 mm, the design of a removable prosthesis should often reduce cantilever length and incorporate a stress relief mechanism. In these cases, reduced long-term predictability
● **Fig. 16.28** Division C–w Implant Placement. (A) Cone beam computed tomography cross section showing compromised width of bone, ideally requiring bone augmentation. (B) Small-diameter implant placement showing inadequate available bone that would most likely result in crestal bone loss.
● **Fig. 16.29** Mandibular subperiosteal implant that is a custom implant placed on top of the bone, which retains an RP-4 prosthesis.

is usually expected if additional implants or less stressful prostheses are not used, because a greater moment force is transmitted to the implants. The most efficient way to reduce stress is by maintaining the overdenture prosthesis as an RP-5, not an RP-4 prosthesis. With an RP-5 prosthesis the soft tissue will absorb most of the primary force because the implants or attachments are used only for secondary support.

An alternative design to endosteal implants in the posterior mandibular edentulous Division C–h arch is subperiosteal and disk design implants (Fig. 16.29).[71-73] Subperiosteal implants are more predictable in the mandibular arch than in the maxilla; however, they have fallen out of favor recently. The limitations of anatomy for root form implants may be bone angulation, a square arch form, or inadequate bone height. When the anterior bone angulation is unfavorable, root form implants may be positioned too far lingually for prosthodontic support, speech, or hygiene. The superstructure and abutment posts for the subperiosteal implant are designed and cast before implant placement. The permucosal posts may be designed with greater latitude than endosteal implants. When anterior root forms are placed in an edentulous mandible with a square arch form, the superstructure

may not be cantilevered distally because of the poor anteroposterior distance. As a result a fixed restoration or RP-4 overdenture prosthesis is contraindicated with anterior root forms in a square arch form. A subperiosteal implant may provide anterior and posterior bone support, and the square arch form does not contraindicate an RP-4 prosthesis. Autogenous grafts or nerve repositioning may be necessary to place endosteal implants in the posterior Division C–h mandible. The increase in treatment time, surgical risks, and postoperative complications (such as paresthesia) are to be thoroughly discussed with the patient. Circumferential or unilateral subperiosteal implants permit the placement of posterior prosthodontic units without risk for paresthesia from nerve repositioning or lengthened treatment time associated with autogenous bone grafts and endosteal implants.[73]

Another alternative for the posterior mandible or premaxilla with Division C–h bone is a disk design implant that engages the lateral aspect of the cortical bone and may be used in available bone height of 3 mm or more. As a general rule, these implants are used in addition to other root form implants. Their inclusion in the treatment plan for C–h posterior sections of edentulous mandibles eliminates cantilevers in full-arch restorations.[71,74]

The prosthetic options for Division C ridges more often consist of removable prosthesis in the completely edentulous maxillary arch. A maxillary overdenture in a Division C ridge allows for support of the upper lip without hygiene compromise. In a Division C mandible the greater CHS often mandates an overdenture design with soft tissue support (RP-5). A fixed restoration in the Division C mandible often requires both anterior and posterior implant support. The fixed prosthesis in Division C bone with greater than 15 mm CHS is most often a hybrid prosthesis, with denture teeth attached to a precious metal substructure with acrylic resin. In this way the complications and costs of a porcelain-metal fixed restoration may be reduced.

In general, Division C–h presents less favorable biomechanical factors to the implant support. Therefore additional implants or teeth, cross-arch stabilization, soft tissue support, or an opposing removable prosthesis often need to be considered in the prosthetic design to improve the long-term prognosis. Treating the Division C ridge requires greater experience, caution, and training than does the previous two bone divisions; however, excellent results may be achieved.

The completely edentulous patient who does not have implant treatment should be well educated that the bone resorption process will continue, with significantly increased risk for the conventional removable restoration. Waiting to treat the patient until irreparable problems develop is a poor treatment alternative that results in the need for more advanced procedures such as iliac crest grafts and significant risk for associated complications.

In conclusion, as in all other bone divisions, the final prosthesis determines the treatment option. For mandibular RP-4 restorations, five root forms in the anterior mandible may be used (if the other dental criteria permit). However, the greater CHS or a square arch form may mandate an RP-5 prosthesis with anterior root form implants. The combination of anterior root forms and posterior subperiosteal implants (or disk implants) is an uncommon treatment option for RP-4 or fixed prosthesis in the mandibular arch. These types of treatment options require an advanced skill set not only surgically, but also prosthetically. Augmentation is often required for a fixed prosthesis in either of the Division C complete edentulous arches if stress factors are high and cannot be reduced.

• **Fig. 16.30** The left posterior mandible is Division A, with abundant bone in height and width (left). The residual ridge on the right is a Division D with a dehiscent mandibular canal.
• **Fig. 16.31** Division D mandible with mainly basal bone in the anterior mandible and dehiscence nerves in the posterior.

Division D (Deficient Bone)

Long-term bone resorption may result in the complete loss of the residual ridge, accompanied by basal bone atrophy (Fig. 16.30). Severe atrophy describes the clinical condition of the Division D ridge. At one time, it was believed that only the alveolar process would resorb after tooth loss and the basal bone would remain. However, bone loss may continue beyond the previous roots of teeth and even include the bone over the inferior mandibular nerve or the nasal spine of the maxilla. Basal bone loss eventually results in a completely flat maxilla. In the mandible the superior genial tubercles become the most superior aspect of the ridge. The mentalis muscle will lose much of its attachment, even though the superior portion of the muscle attaches near the crest of the resorbed ridge. The buccinator muscle may approach the mylohyoid muscle and form an aponeurosis above the body of the mandible. The mandibular arch also presents with mental foramina and portions of the mandibular canal dehiscent. Therefore it is not infrequent that these patients report neurosensory deficits of the lower lip, especially during mastication. The CHS is greater than 20 mm, which is a significant force multiplier and can rarely be reduced enough to render long-term success (Fig. 16.31 and Box 16.7).

- >20-mm crown height prosthesis
  - Fixed: FP-3
  - Removable: ideally RP-5 because of increased CHS
• **Fig. 16.32** Division D mandible with extensive atrophy leading to possible pathologic fracture of mandible.

The prosthetic result for Division D without augmentation is the poorest treatment outcome of all the divisions of bone. Fixed restorations are nearly always contraindicated, because the CHS is so significant. Completely implant-supported overdentures are indicated whenever possible to decrease the soft tissue and nerve complications, but require anterior and posterior implant support, which almost always requires bone augmentation before implant placement. Bone augmentation for Division D is difficult to improve the CHS enough to warrant a fixed restoration unless there are favorable force factors. An RP-5 restoration is not suggested, because bone loss will continue in the soft tissue–supported region of the overdenture, and usually the buccal shelf (primary stress bearing area) is not present.

The completely edentulous Division D patient is the most difficult to treat in implant dentistry. Benefits must be carefully weighed against the risks and complications. Although the practitioner and patient often regard this condition as the most desperate, these patients do not usually understand the possible chronic complications that may result (e.g., oral antral fistulae, deviated facial). If implant failure occurs, the patient may become a dental cripple—unable to wear any prosthesis and worse off than before treatment (Fig. 16.32).

Autogenous iliac crest bone grafts to improve the Division D are strongly recommended before any implant treatment is attempted.[74] After autogenous grafts are in place and allowed to heal for 5 or more months, the bone division is usually Division C–h or Division A, and endosteal implants may be inserted (Figs. 16.33 and 16.34).

Autogenous bone grafts should always be indicated for the placement of implants, never to increase support for a denture. The autogenous bone grafts are not intended for improved denture support. If soft tissue–borne prostheses are fabricated on autogenous grafts, studies have shown 90% of the grafted bone resorbs within
● **Fig. 16.33** Autogenous Iliac Crest Graft: An autologous iliac crest bone graft in situ. The block is fixated with screws to the host bone.

● **Fig. 16.34** Post–Graft Implant Placement.

● **Fig. 16.35** Division D premaxilla revealing no host bone present.

● **Fig. 16.36** Division D posterior maxilla showing bone posterior to the edenulous area, however insufficient bone where implants are indicated.

● **Fig. 16.37** Preoperative cone beam computed tomography cross section showing no bone present.

5 years as a result of accelerated resorption.[75] Additional augmentation to compensate for this resorption is not indicated. Repeated relines, highly mobile tissue, sore spots, and patient frustration are all postoperative consequences. On the other hand, autogenous bone grafts are maintained long term in conjunction with implant placement because of the stress to the bone. Another option with a low success rate is the addition of dense hydroxyapatite to improve denture support. Migration of the graft at the time of surgery or in the future after soft tissue loading is a frequent sequel.

The partially or completely edentulous patient with a posterior Division D maxilla may undergo sinus graft procedures with a combination of autograft and allograft regenerative materials.[65] The CHS may be insufficient for onlay grafts in the posterior maxilla, despite a lack of available bone height, because the sinus expands faster than the crest of the ridge resorbs. Endosteal implants of adequate height can rarely be positioned without a sinus graft. After the Division D posterior maxilla is restored to Division A or C–h, root form implants may be inserted for posterior prosthodontic support. In most cases, greater surface area is required in the form of increasing implant number or implant diameter (Figs. 16.35 to 16.39).

Endosteal root form implants without autogenous grafts may be used on rare occasions in the anterior Division D mandible when the remaining bone is dense and the opposing arch is edentulous. Care must be taken during placement, because mandibular fracture at insertion or during postoperative healing is a possible complication.[76,77] Under these conditions the CHS is very great, and the number of implants often four or fewer. Implant failure
• **Fig. 16.38** Lateral wall sinus augmentation window preparation.
• **Fig. 16.39** Cone beam computed tomography cross sections depicting post–sinus graft.

• **Fig. 16.40** Axial View of Post–Sinus Augmentation.

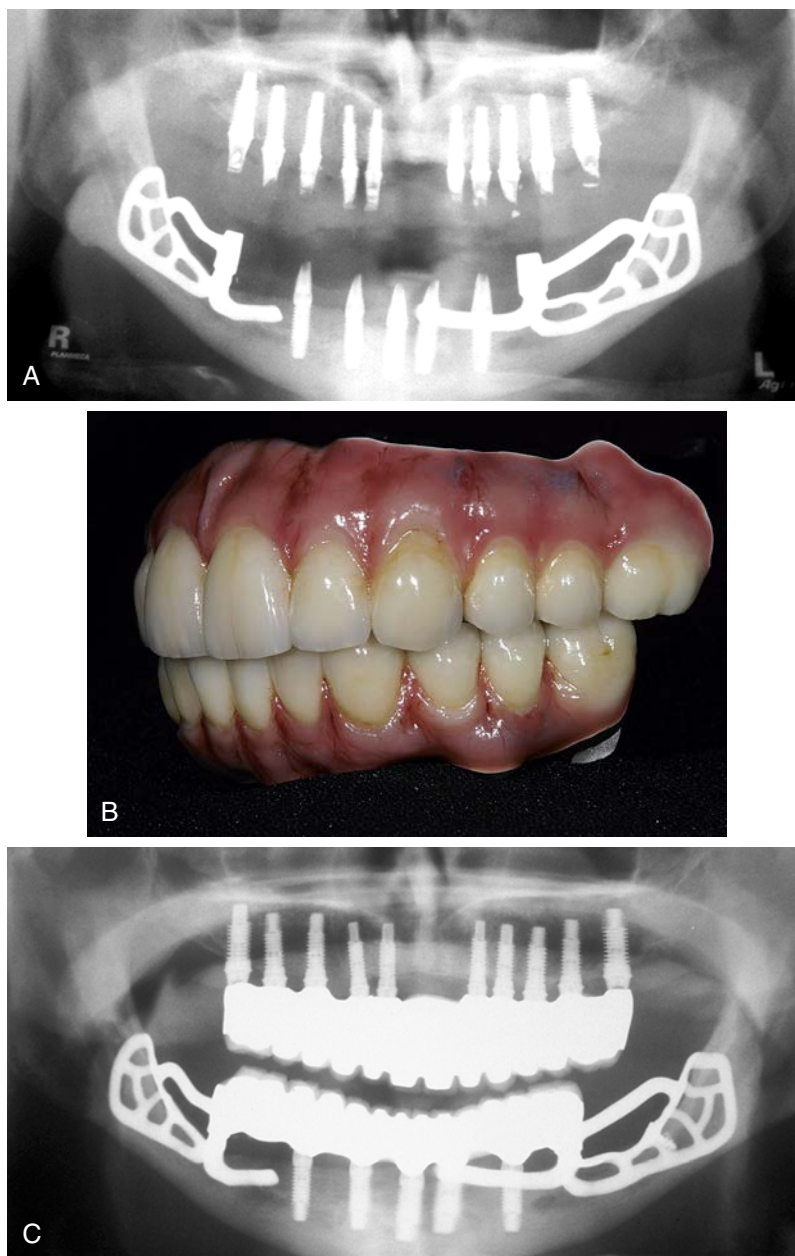
• **Fig. 16.41** Anterior root form implants were placed in a Division D mandible. As a result of the failure of one implant, the mandible has fractured and has a continuity defect.

after loading is a greater risk. Implant failure results with circumferential bone loss, which may be associated with mandibular fracture through the implant site. An RP-5 removable restoration is usually indicated for Division D with only anterior implants. However, the RP-5 restoration allows for continued bone resorption and atrophy to continue in the posterior regions. Therefore the prudent therapy is to educate the patient as to the risks of his or her current condition and offer an autologous bone graft and implants to support an RP-4 restoration. The choice to render treatment is the doctor's, not the patient's. The implant support should not be compromised when implant failure may result in significantly greater risks.

The Division D arch requires greater doctor training and results in more frequent complications related to grafting, early implant failure, and soft tissue management; therefore treatment options include a more guarded prognosis. It should be the goal of every implant clinician to educate and treat the patient before a Division D bone condition develops. In contrast, the profession treats periodontal diseases before pain in the region occurs, and carious lesions are removed before abscess formation. The profession monitors bone loss around teeth in fractions of a millimeter and offers continued care to reduce the risks for future tooth and bone loss. Likewise the prudent practitioner should monitor bone loss in edentulous sites, and offer education and treatment before deleterious effects (Figs. 16.40 to 16.42).

Summary

In implant dentistry the prosthesis is designed at the onset of treatment to satisfy the patient's needs and desires, and obtain optimal results. This may range from a completely fixed prosthesis to one with primarily soft tissue support. After the final prosthesis type has been established, the key implant positions, patient force factors, bone density in the implant sites, and implant number, size, and design are determined. The primary criterion for proper implant support is the amount of available bone. Four divisions of available bone, based on the width, height, length, angulation, and CHS in the edentulous site, have been presented. Consistent implant treatment plan procedures elaborated for each category of bone may be followed.

The Division A edentulous ridge offers abundant bone in all dimensions. Division A root form implants are optimally used and most often as independent support for the prosthesis. Division B bone may provide adequate width for narrower, small-diameter root from endosteal implants. The decreased width and surface area usually require additional implants to be included in the final prosthesis design. Division B may be changed in condition to a Division A by augmentation or osteoplasty. The treatment options may be selected in light of the area to be treated. For example, in the anterior maxilla, augmentation is most often selected because of esthetics. In the anterior mandible,


● **Fig. 16.42** (A) A panoramic radiograph of 10 implants inserted into an edentulous maxilla after bilateral sinus grafting. The mandible has five endosteal implants in a C–h anterior mandible. The posterior mandible has bilateral subperiosteal implants inserted for posterior prosthetic support. (B) The maxillary and mandibular FP-3 restoration. (C) A panoramic radiograph of the FP-3 prostheses in situ. *(From Misch DE. Available bone and dental implant treatment plans. In: Misch CE, ed.* Dental Implant Prosthetics. *2nd ed. St. Louis, MO: Mosby; 2015.)*

osteoplasty is common because of the available bone height and low esthetic concerns. In the posterior mandible, multiple Division B implants may be used, because the bone density is good, the available bone height is limited, and esthetics are not a primary factor. When stress factors are greater, bone augmentation precedes Division A root form implants, regardless of the anatomic location.

The Division C edentulous ridge exhibits moderate resorption and presents more limiting factors for predictable endosteal implants. The decision to restore with endosteal implants or to upgrade the bone division by augmentation before implant placement is influenced by the prosthesis, patient force factors, and

patient's desires. The Division D edentulous ridge corresponds to basal bone loss and severe atrophy, resulting in dehiscent mandibular canals or a completely flat maxilla. The patient often requires augmentation with autogenous bone before implant and prosthodontic reconstruction.

If the existing conditions do not qualify for a predictable end result, the patient's mind or mouth must be modified. For example, the expectations of the patient must be reduced so the prosthesis may be changed from FP-1 to RP-4, or the bone must be augmented to improve the height and width and to change the division so that long-term implant support and prosthetic design will be compatible.

Prosthetic Options in Implant Dentistry

RANDOLPH R. RESNIK AND CARL E. MISCH

Implant dentistry is similar to all aspects of medicine in that treatment begins with a diagnosis of the patient's condition. Most treatment options are derived from the obtained diagnostic information. Traditional dentistry provides limited treatment options for the edentulous patient. Because the dentist cannot add abutments, the restoration design is directly related to the existing oral condition. In contrast, implant dentistry can provide a range of additional abutment locations, thus allowing for a wide spectrum of treatment options. Bone augmentation may further modify the existing edentulous condition in both the partial and total edentulous arch, and therefore also affects the final prosthetic design. As a result, a number of treatment options are available to most partially and completely edentulous patients. Therefore once the diagnosis is complete, the implant treatment plan of choice at a particular moment is patient and problem based. Not all patients should be treated with the same restoration type or design.

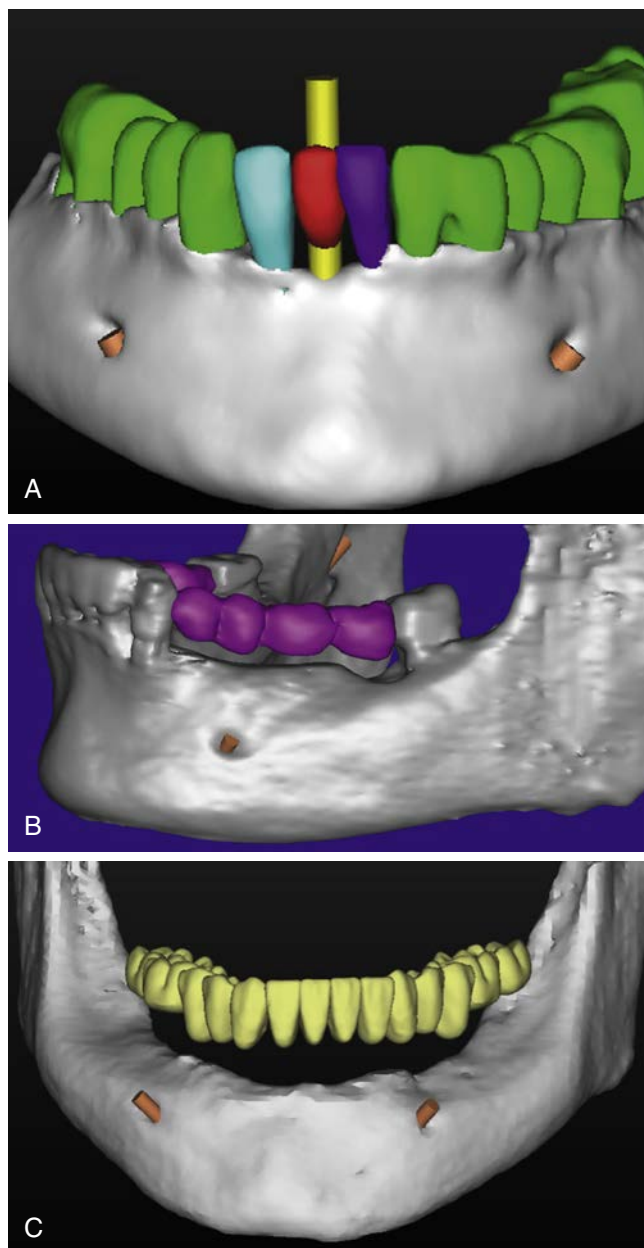
Almost all human-made creations, whether art, buildings, or prostheses, require the end result to be visualized and precisely planned for optimal results. Blueprints indicate the finest details for buildings. The final structure should be clearly identified before the project begins, yet implant dentists often forget this simple but fundamental axiom. Historically in implant dentistry, bone available for implant insertion dictated the number and locations of dental implants. The prosthesis then was often determined after the position and number of implants were selected. The goals of implant dentistry are to replace a patient's missing teeth to normal contour, comfort, function, esthetics, speech, and health, regardless of the previous atrophy, disease, or injury of the stomatognathic system. It is the final prosthesis, not the implants, that accomplishes these goals. In other words, patients are missing teeth, not implants. The prosthesis should be designed first, to satisfy predictably a patient's needs and desires. In the stress treatment theorem[1] the final restoration is planned first, similar to the architect designing a building before making the foundation. Only after this is accomplished can the abutments necessary to support the specific predetermined prosthesis be designed (Fig. 17.1).

Completely Edentulous Prosthesis Design

The completely edentulous patient is too often treated as though cost was the primary factor in establishing a treatment plan. However, the clinician and staff should specifically ask about the patient's desires. Some patients have a strong psychological need to have a fixed prosthesis (FP) as similar to natural teeth as possible. In contrast, some patients do not express serious concerns whether the restoration is fixed or removable as long as specific problems are addressed. In general a patient with existing teeth that are to be extracted are more likely to have interest in a fixed-implant prosthesis. However, a patient with a removable prosthesis (RPs) is most commonly interested in an overdenture prosthesis. The existing anatomy is evaluated after it has been determined whether a fixed or removable restoration is desired, to assess the ideal final prosthetic design.

An axiom of implant treatment is to provide the most *predictable*, most *cost-effective* treatment that will satisfy the patient's anatomic needs and personal desires. In the completely edentulous patient a removable implant-supported prosthesis offers several advantages over a fixed-implant restoration (Box 17.1). However, some completely edentulous patients require a fixed restoration because of personal choice or because their oral condition makes the fabrication of teeth difficult if a removable prosthesis is planned. For example, when the patient has abundant bone and implants have already been placed, the lack of crown height space may not permit an RP.[2]

Too often treatment plans for completely edentulous patients consist of a maxillary denture and a mandibular overdenture with two implants. However, in the long term, this treatment option may prove a disservice to the patient. The arches will continue to lose bone, and the bone loss may even be accelerated in the premaxilla.[3,4] Once this dimension is lost, the patient will have much more difficulty with retention and stability of the restoration. In addition, the lack of posterior implant support in the mandible will allow posterior bone loss to continue.[5] Facial changes and reduced posterior occlusion with the maxillary prosthesis is to be expected. The clinician should diagnose the amount of bone loss and its consequences on facial esthetics, function, and psychological and overall health. Patients should be made aware of future compromises in bone loss and the associated problems with minimal treatment options, which do not address the continued loss of bone in regions where implants are not inserted.

It is even more important to visualize the final prosthesis at the onset with a fixed-implant restoration. After this first important step, the individual areas of ideal or key abutment support are determined to assess whether it is possible to place the implants to support the intended prosthesis. The patient's force factors and


• **Fig. 17.1** When evaluating edentulous sites for implant treatment plans, CBCT images should be used to determine the most ideal prosthesis. (A) 3D CBCT image of implant placed in the missing # 25 area. The position of the implant to the adjacent teeth can easily be determined along with the crown height space. The final prosthesis will most likely be a FP-2. (B) CBCT image showing the osseous contour in relation to the clinical crown of the prosthesis. Note the vertical defect on the second molar which will most likely change the prosthesis type, (c) 3D CBCT image of an edentulous arch depicting the discrepancy between the bone level and prosthesis. In this situation, the prosthesis will most likely be a FP-3.

bone density in the region of implant support are evaluated. The additional implants to support the expected forces on the prosthesis designed may then be determined, with implant size and design selected to match force and area conditions. Only then is the available bone evaluated to assess whether it is possible to place the implants to support the intended prosthesis. In inadequate natural or implant abutment situations, the existing oral conditions or the needs and desires of the patient must be altered. In

- Facial esthetics can be enhanced with labial flanges and denture teeth compared with customized metal or porcelain teeth. The labial contours of the removable restoration can replace lost bone width and height, and support the labial soft tissues without hygienic compromise.
- The prosthesis can be removed at night to manage nocturnal parafunction.
- Fewer implants may be required.
- Less bone augmentation may be necessary before implant insertion.
- Shorter treatment if no bone augmentation is required.
- The treatment may be less expensive for the patient.
- Long-term treatment of complications is facilitated.
- Daily home care is easier.
- Repairs are much easier than with a fixed prosthesis.

other words, either the mouth must be modified by augmentation to place implants in the correct anatomic positions, or the mind of the patient must be modified to accept a different prosthesis type and its limitations. A fixed-implant restoration may be indicated for either the partially or the completely edentulous patient. The psychological advantage of fixed teeth is a major benefit, and edentulous patients often feel the implant teeth are better than their own. The improvement over their removable restoration is significant.

The completely implant-supported overdenture (RP-4) usually will require the same number of implants as a fixed-implant restoration. Thus the cost of implant surgery may be similar for fixed or removable prostheses. FPs often last longer than overdentures, because attachments are not present which require replacement, and acrylic denture teeth wear faster than porcelain to metal or zirconia.[6] The chance of food entrapment under a removable overdenture is often greater than for a fixed restoration, because soft tissue extensions and support are often required in the latter. The laboratory fees for a FP may be similar to a bar, coping attachments, and overdenture. Because the denture or partial denture fees are much less than FPs, many clinicians charge the patient a much lower fee for removable overdentures on implants. However, chair time and laboratory fees are often similar for fixed or removable restorations that are completely implant supported. Therefore, implant overdentrues (e.g. RP-4) should often parallel the cost of a fixed prosthesis. or clinicians to undercharge for overdenture implant-supported prostheses.

Partially Edentulous Prosthesis Design

A common axiom in traditional prosthodontics for partial edentulism is to provide a fixed partial denture whenever applicable.[7,8] The fewer natural teeth missing, the better the indication for a fixed partial denture. This axiom also applies to implant prostheses in the partially edentulous patient. Ideally the fixed partial denture is completely implant supported rather than joining implants to teeth. This concept leads to the use of more implants in the treatment plan. Although this may be a cost disadvantage, it is outweighed by significant intraoral health benefits. The added implants in the edentulous site result in fewer pontics, more retentive units in the restoration, and less stress to the supporting bone. As a result, complications are minimized, and implant and prosthesis longevity are increased (Box 17.2).

- Greater masticatory force
- Greater patient satisfaction
- Psychological (feels more like natural teeth)
- Less food entrapment
- Less maintenance (no attachments to change or adjust)
- Longevity (less prosthesis failure)
- Possible overhead cost as completely implant-supported overdentures

TABLE 17.1	**Prosthodontic Classification**
Type	**Definition**
FP-1	Fixed prosthesis; replaces only the clinical crown; looks like a natural tooth.
FP-2	Fixed prosthesis; replaces the crown and a portion of the root; crown contour appears normal in the occlusal half but is elongated or hypercontoured in the gingival half.
FP-3	Fixed prosthesis; replaces missing crowns and gingival color and portion of the edentulous site; prosthesis most often uses denture teeth and acrylic gingiva, but may be porcelain to metal, or zirconia.
RP-4	Removable prosthesis; overdenture that is completely implant supported, no soft tissue support.
RP-5	Removable prosthesis; overdenture supported by both soft tissue (primary) and implant (secondary). The primary stress bearing areas are maintained in the prosthesis (maxilla—residual ridge and horizontal palate; mandible—the line should not begin with a dash. Please move the elements on the last two lines to ensure this doesn't happen. buccal shelf).

From Misch CE. Bone classification training keys. *Dent Today.* 1989;8:39-44.

Prosthetic Options

In 1989, Misch[9,10] proposed five prosthetic options for implant dentistry (Table 17.1). The first three options are FPs (FP-1, FP-2, and FP3). These three options may replace partial (one tooth or several) or total dentitions and may be cemented or screw retained. They are used to communicate the appearance of the final prosthesis to all of the implant team members and the patient. These options depend on the amount of hard and soft tissue structures replaced and the aspects of the prosthesis in the esthetic zone. Common to all fixed options is the inability of the patient to remove the prosthesis. Two types of final removable implant restorations are RPs (RP-4 and RP-5); they depend on the amount of implant and soft tissue support, not the appearance of the prosthesis.

Fixed Prostheses

FP-1

An FP-1 is a fixed restoration and appears to the patient to replace only the anatomic crowns of the missing natural teeth. There must be minimal loss of hard and soft tissues to fabricate this prosthesis type. The volume and position of the residual bone must permit *ideal placement* of the implant in a location similar to the root of a natural tooth.

The final restoration appears similar in size and contour to most traditional FPs used to restore or replace natural crowns of teeth (Fig. 17.2).

The FP-1 prosthesis is most often desired in the maxillary anterior region, especially in the esthetic zone during smiling or speaking and patients with a high smile line. The final FP-1 prosthesis appears to the patient to be similar to a crown on a natural tooth. However, the implant abutment can rarely be treated exactly as a natural tooth prepared for a full crown. For example, the cervical diameter of a maxillary central incisor is ~6.5 mm with an oval to triangular cross-section. However, the implant abutment is usually 4 mm in diameter and round in cross-section. Therefore inherent discrepancies are present between natural teeth and implants.

In addition, the placement of the implant rarely corresponds exactly to the crown-root position of the original tooth. The thin labial bone lying over the facial aspect of a maxillary anterior root remodels after tooth loss and the crest width shifts to the palate, decreasing up to 40% within the first 2 years.[11] The occlusal table is also usually modified in unesthetic regions to conform to the implant size and position, and to direct vertical forces to the implant body. For example, posterior mandibular implant-supported prostheses have narrower occlusal tables at the expense of the buccal contour, because the implant is smaller in diameter and placed in the central fossa region of the tooth.[12]

Because the width or height of the crestal bone is frequently lacking after the loss of multiple adjacent natural teeth, bone augmentation is often required before implant placement to achieve natural-looking crowns in the cervical region (Fig. 17.3). There are rarely interdental papillae in edentulous ridges; therefore soft tissue augmentation also is often required to improve the interproximal gingival contour. Ignoring this step in the process causes open "black" triangular spaces (i.e., where papillae should usually be present) when the patient smiles. FP-1 prostheses are especially difficult to achieve when more than two adjacent teeth are missing. The bone loss and lack of interdental soft tissue complicate the final esthetic result, especially in the cervical region of the crowns (Fig. 17.4). The restorative material of choice for an FP-1 prosthesis is zirconia or lithium disilicate.

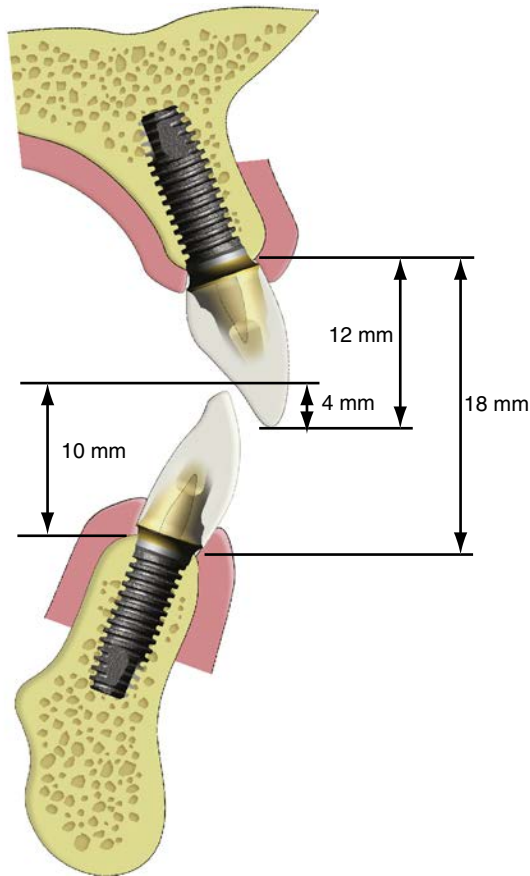
FP-2

FP-2 appears to restore the anatomic crown and a portion of the root of the natural tooth. The volume and topography of the available bone is more apical compared with the ideal bone position of a natural root (1 to 2 mm below the cement-enamel junction) and dictate a more apical implant placement compared with the FP-1 prosthesis. As a result, although the incisal edge is in the correct position, the gingival third of the crown is overextended or hypercontoured, usually apical and lingual to the position of the original tooth. These restorations are similar to teeth exhibiting periodontal bone loss and gingival recession (Fig. 17.5).

The patient and the clinician should be aware from the onset of treatment that the final prosthetic teeth will appear longer than healthy natural teeth (without bone loss). The esthetic zone of a patient is established during smiling in the maxillary arch and during speech of sibilant sounds for the mandibular arch (Figs. 17.6 and 17.7). If the high lip line during smiling or the low lip line during speech do not display the cervical regions, the longer teeth are usually of no esthetic consequence, provided that the patient has been informed before treatment.

As the patient becomes older, the maxillary esthetic zone is altered. Only 10% of younger patients do not show any soft tissue during smiling, whereas 30% of 60-year-olds and 50% of 80-year-olds do not display gingival regions during smiling (Fig. 17.8). The low lip position during speech is not affected as much as the high smile line. Only 10% of older patients show the mandibular soft tissue during speech.[13,14]

• **Fig. 17.2** (A) An implant is positioned in the maxillary right canine position. The hard and soft tissue conditions are ideal for a crown of normal contour and size. (B) The maxillary right canine implant crown in position. The soft tissue drape is similar to a natural tooth, and the crown contour is similar to the clinical crown contour of a natural tooth. This is the goal of an FP-1 prosthesis.
• **Fig. 17.3** FP-1 (A) congenitally missing left lateral incisor, (B) large osseous defect resulting in inadequate amount of bone for implant placement, (C) autogenous block graft, and (D) final FP-1 zirconia restoration.

A multiple-unit FP-2 restoration does not require as specific an implant position in the mesial or distal position because the cervical contour is not displayed during function. The implant position may be chosen in relation to ideal bone width, angulation, or hygienic considerations rather than purely esthetic


• **Fig. 17.4** The hard and soft tissue must be ideal in volume and position to obtain an FP-1 appearance for the final restoration. When multiple teeth are replaced, bone and tissue augmentation is usually required to obtain an FP-1 prosthesis.

demands (compared with the FP-1 prosthesis). On occasion the implant may even be placed in an embrasure between two teeth. This often occurs for mandibular anterior teeth for full-arch fixed restorations. If this occurs, the most esthetic area usually requires the incisal two-thirds of the two crowns to be ideal in width, as though the implant were not present. Only the cervical region is compromised. Although the implant is not positioned in an ideal mesiodistal position, it should be placed in the correct facial-lingual position to ensure that contour, hygiene, and direction of forces are not compromised. The material of choice for an FP-2 prosthesis is zirconia or lithium disilicate.

FP-3

The FP-3 fixed restoration appears to replace the natural teeth crowns and has pink-colored restorative materials to replace a portion of the soft tissue. As with the FP-2 prosthesis, the original available bone height has decreased by natural resorption or osteoplasty at the time of implant placement. To place the incisal edge of the teeth in proper position for esthetics, function, lip support, and speech, the excessive vertical dimension to be restored requires teeth that are unnatural in length. However, unlike the FP-2 prosthesis, the patient may have a normal-to-high maxillary lip line during smiling or a low mandibular lip line during speech. The ideal high smile line displays the interdental papilla of the maxillary anterior teeth but not the soft tissue above the midcervical regions. Approximately 7% of males and 14% of females have a high smile, or "gummy" smile, and display more than 2 mm of gingival above the free gingival margin of the teeth[13] (Fig. 17.9).

The patient may also have greater esthetic demands even when the teeth are out of the esthetic smile and speech zones. Patients report that the display of longer teeth appears unnatural even though they must lift or move their lips in unnatural positions to see the covered regions of the teeth. As a result of the restored gingival color of the FP-3, the teeth have a more natural appearance in size and shape, and the pink restorative material mimics the interdental papillae and cervical emergence region. The addition of gingival-tone acrylic, porcelain, or zirconia for a more natural FP appearance is often indicated with multiple implant abutments because bone loss is common with these conditions, There are basically three approaches for an FP-3 prosthesis: (1) a hybrid restoration of denture teeth and acrylic and metal

• **Fig. 17.5** (A) FP-2 prosthesis resulting from implant placement too far apically. Ideally the implant neck should be 2 to 3 mm below the free gingival margin of the adjacent teeth. (B) Because the FP-2 prosthesis is hypercontoured, it is often not esthetically pleasant. However, in this example, because of the bone and tissue loss of the adjacent teeth, the FP-2 prosthesis blends in very well.

Number of teeth displayed in a smile
● **Fig. 17.6** The number of teeth observed during a high smile line is variable. Almost 50% of patients display the teeth up to a first premolar. Only 3.7% of patients display the maxillary teeth to the first molar. (*Adapted from Tjan AHL, Miller GD. Some esthetic factors in a smile.* J Prosthet Dent. *1984;51:24-28.*)

Appearance of mandibular teeth in facial positions among women
● **Fig. 17.7** The mandibular teeth in the esthetic zone are observed during sibilant sounds, because more teeth show during speech than at rest or smiling. (*Adapted from Cade RE. The role of the mandibular anterior teeth in complete denture esthetics.* J Prosthet Dent. *1979;42:368-370.*)

Height of a smile line
● **Fig. 17.8** A smile that shows interdental papillae but no cervical tissue is ideal and found in 70% of patients. A low smile line shows no soft tissue during smiling and is seen in 20% of patients (more men than women). A high smile line displays interdental papillae and the cervical regions above the teeth, and is observed in 11% of patients (more women than men). (*Adapted from Tjan AHL, Miller GD. Some esthetic factors in a smile.* J Prosthet Dent. *1984;51:24-28.*)

• **Fig. 17.9** (A) A full-arch FP-3 maxillary implant prosthesis. Note the maxillary placement of implants in embrasure areas and irregular tissue level. (B) The high smile line of the same patient. The low lip position during smiling permitted the fabrication of an FP-2 prosthesis.

• **Fig. 17.10** FP-3 Restorative Materials. (A) The hybrid FP-3 consisting of acrylic and denture teeth on a metal substructure; (B) porcelain fused to metal FP-3 consisting of a metal substructure and porcelain; and (C) monolithic zirconia, which is fabricated from a solid block of zirconia and stained to the teeth and tissue colors.

substructure,[15] (2) a porcelain-metal restoration, or (3) a monolithic zirconia prosthesis. The most important factor involved in selecting the prosthetic material is esthetics, longevity, and durability. Today the material that is advantageous and fulfills these requirements is monolithic zirconia (Figs. 17.10 and 17.11; Table 17.2).

Another factor that determines the restoration material is the amount of crown height space.[2,16] An excessive crown height space means a traditional porcelain-metal restoration will have a large amount of metal in the substructure, so the porcelain thickness will not be greater than 2 mm. Otherwise there is an increase in porcelain fracture. Precious metals are indicated for implant restorations to decrease the risk for corrosion and improve the accuracy of the casting, because nonprecious metals shrink more during the casing process. However, the large amount of metal in the substructure acts as a heat sink and complicates the application of porcelain during the fabrication of the prosthesis. In addition, as the metal cools after casting, the thinner regions of metal cool first and create porosities in the structure. This may lead to fracture of the framework after loading. Furthermore, when the casting is reinserted into the oven to bake the porcelain, the heat is maintained within the casting at different rates; thus the porcelain cool-down rate is variable, which increases the risk for porcelain fracture. In addition, the amount of precious metal in the casting adds to the weight and cost of the restoration. An FP-3 porcelain-to-metal restoration is more difficult to fabricate for the laboratory technician than an FP-2 prosthesis. The pink porcelain is more difficult to make appear as soft tissue and usually requires more baking cycles. This increases the risk for porosity or porcelain fracture (Figs. 17.12 and 17.13).

An alternative to the traditional porcelain-metal FP is a hybrid prosthesis (see Table 17.2). This restoration design uses a smaller metal framework, with denture teeth and acrylic to join these elements together. This prosthesis is less expensive to fabricate and is highly esthetic because of the premade denture teeth and acrylic pink soft tissue replacements. In addition, the intermediary acrylic between the denture teeth and framework may reduce the impact force of dynamic occlusal loads. The hybrid prosthesis is easier to repair in comparison to porcelain, because the denture tooth may be replaced with less risk than adding porcelain to a traditional porcelain-metal restoration. However, the fatigue of acrylic is greater than the traditional prosthesis; therefore repair of the restoration is more commonly needed.

Monolithic zirconia has been able to curtail all of the complications from the hybrid and porcelain fused to metal restorations. Monolithic zirconia has been shown to have a high flexural and compressive strength, which approximates 1465 MPa. Because of its monolithic nature, minimal interocclusal space (~8 mm) is needed for the fabrication of the prosthesis and can be fabricated with ~0.5-mm interocclusal space. A high 5-year success rate has

• **Fig. 17.11** Complications of FP-3 Hybrid Prostheses. (A) Attrition and wear of the denture teeth, especially if opposing natural teeth or porcelain; (B) delamination is common, which is usually caused by excess force on the prosthesis; and (C) the acrylic and denture teeth tend to harbor bacteria, leading to difficulty in hygiene and often causing peri-implant disease.

TABLE 17.2   Comparison of Porcelain-to-Metal Versus Hybrid Prostheses Versus Zirconia (FP-3)

Consideration	Porcelain	Hybrid	Monolithic Zirconia-Metal
Occlusal vertical	>12 mm	≥15 mm	≥10 mm
Technique	Same	Same	Same
Retention	Cement or screw	Cement or screw	Cement or screw
Precision of fit	Fair	Fair/Good	Good
Esthetics	Same	Same	Same
Soft tissue	Difficult	Easier	Easier
Time/appointments	Same	Less	Same
Weight	More	Less	More
Cost	More	Less	More
Impact forces	More	Less	Excellent
Volume (bulk)	Same	Same	Same
Long term	Same	Same	Excellent
Occlusion	Stable	Variable	Stable
Speech	Same	Same	Same
Biofilm accumulation	Medium	High	Low
Hygiene	Same	Same	Same
Complications	Medium	High	Low
Aging of materials	Less	More	Less
